Stickler syndrome (hereditary arthroophthalmopathy)

Stickler and Pugh and Stickler et al (45,46), in 1967–68, described the classic form, now called *Stickler syndrome type 1* and constituting about 75% of cases. It is characterized by flat midface, cleft palate, high myopia with retinal detachment and cataracts, hearing loss, arthropathy with generally mild spondyloepiphyseal dysplasia, and either diminished height or Marfan-like build in some cases. The binary combination of eye changes and cleft palate was described both earlier (10,19) and later by a large number of authors (8,9,11,13,17,18). We believe that Walden syndrome (51) is the same as Stickler syndrome. Excellent reviews are those of Temple (47) and Snead and Yates (39).

Stickler syndrome type 2, representing the other 25%, is characterized by midface hypoplasia, anteverted nares, small mandible, sensorineural (40%) or mixed (30%) hearing loss, and joint pain (50%). Height is not reduced. There is mild myopia (5,14,27,41). Phenotypically, Stickler syndrome type 2 is similar to *Marshall syndrome* (35), the latter probably having in-frame deletion near the 3′ end of the gene.

Inheritance for both types is autosomal dominant with considerable variable expression, especially interfamilial but also intrafamilial (57). About 70% of cases of Stickler syndrome are due to mutations in the COL2A1 gene (Type 1 Stickler syndrome) that maps to 12q13.11–q13.2 (1,2,5,6,12,14,21,30,32,40,50,52,54,55). Virtually all mutations involve premature stop codons (1,32,55) predicting a truncated protein. An unusual exception is the family reported by Ballo et al (3).

Table 9–4. Stickler syndrome and related syndromes[a]

Inheritance	AD	AD	AD	AR

[a] From T Pihlajamaa et al, Am J Med Genet 80:115, 1998.
[b] Heterozygous OSMED: non-ocular "Stickler" syndrome or Weissenbacher-Zweymüller phenotype; homozygous OSMED: Insley-Astley syndrome.

Type XI collagen, a heterotrimer composed of α1(XI), α2 (XI), and α1 (II) chains copolymerizes with Type II collagen and probably regulates fibril thickness. Mutations of the COL11A1 gene that maps to 1p21 lead to Type 2 Stickler syndrome and/or Marshall syndrome (15,31, 36–39).

Non-ocular "Stickler" syndromes were mapped at 6p21 near the COL11A2 gene (7). These have been collectively called OSMED (otospondylo-megepiphyseal dysplasia), a condition that may be dominant (heterozygous; also called Weissenbacher-Zweymüller phenotype) or recessive (homozygous; also called Insley-Astley syndrome). The symptoms resemble Stickler syndrome, but midface hypoplasia is more expressed, and patients are small, have large epiphyses, and lack eye involvement (Table 9–4). It is caused by mutations in the COL11A2 gene on chromosome 6p21 (31,38,48,49). The original patient of Weissenbacher and Zweymüller (53) has been found to have a dominant heterozygous COL11A2 mutation (28). There is still further genetic heterogeneity (27,50,52,54).

Facies. The craniofacial spectrum ranges from an essentially normal face (15%–25%) to midfacial flattening due to short maxilla, prominent eyes, epicanthic folds, depressed nasal bridge, anteverted nares, long philtrum, and small chin (Fig. 9–51A–C). The facies becomes less distinctive with age. Cleft palate, submucous cleft palate, bifid uvula, or abnormal palatal mobility has been reported in 20% of type 1 cases, less often in type 2 cases (16) (Fig. 9–51D). About 30% of infants with Robin sequence have Stickler syndrome (22,33).

Eye. In type 1, myopia, 8–18 diopters, is found in 75%–80% of patients, usually earlier than 6 years of age. It is possibly congenital and stable. Before the twentieth year, paravascular pigmented lattice degeneration or retinal detachment is observed in 70%, often bilaterally. If untreated, this leads to blindness. Associated eye findings are astigmatism (60%), wedge- and fleck-type curved cortical cataracts (45%), strabismus (30%), and open-angle glaucoma (10%). Detachment occurs in 60%. Eye findings have been extensively discussed (4,6,20,25,34,56).

In Type 2 families, one sees severe early-onset myopia and retinal degeneration, but the vitreous changes are not membranous as in type 1 (31,40,54). There are sparse and irregularly thickened (beaded) bundles of fibers throughout the vitreous cavity. Detachment occurs in less than 50% (39).

Ears. Progressive sensorineural high-tone hearing loss has been noted in 60% of type 1 patients (17,26,29,42,45,47,57). In type 2, sensorineural loss occurs in 90%. Conductive hearing loss has rarely been noted (43,47).

H

Fig. 9–51. *Stickler syndrome.* (A,B) Some patients have body habitus resembling Marfan syndrome. (C) Round face with midface hypoplasia. (D) Cleft palate. (E,F) Enlargement of elbows and kness. (G,H) Flattening of the ends of metacarpals and radii, and degenerative changes at hip. (A,B from GB Stickler and DG Pugh, Mayo Clin Proc 42:495, 1967. C from J Hall, Birth Defects 10(8):157, 1974.)

Musculoskeletal findings. Some patients have Marfanoid body habitus (Fig. 9–51A,B), but at least 25% are below the 3rd centile in height. In childhood, joint hypermobility is common (23) but decreases with age. The joints may be enlarged, often hyperextensible (35%) and sometimes painful and warm with use, becoming stiff with rest (Fig. 9–51E–G). Talipes equinovarus may occur (17).

In infancy, there is rhizomelic shortening of limbs, metaphyseal widening, and vertebral coronal clefts. During childhood, mild spondyloepiphyseal dysplasia (multiple epiphyseal ossification disturbances, moderate flattening of vertebral bodies) and diminution of the width of the shaft of tubular bones are noted. Scoliosis has been evident in 10%. The pelvic bones are hypoplastic, the femoral necks being poorly modeled and plump (Fig. 9–51H). There is progressive early joint degeneration in 30%, beginning in the third or fourth decades (23). The skeletal features observed radiographically and the clinical joint involvement are not always present in Stickler syndrome (17,29,43). Short cranial base and hypoplastic midface have been borne out by cephalometric study (33).

Other findings. Mitral valve prolapse has been found in almost 50% in some studies (24) but not in others (39).

Differential diagnosis. All patients with *Robin sequence*, especially with an autosomal dominant history, should be examined periodically for severe myopia to prevent ocular complications of Stickler syndrome. Other disorders with some degree of overlap include *Kniest dysplasia, SED congenita, Wagner syndrome, Marshall syndrome*, and SPONASTRIME *dysplasia*. SPONASTRIME dysplasia exhibits midfacial hypoplasia but does not manifest myopia, generalized epiphyseal dysplasia, or sensorineural hearing loss. The so-called Weissenbacher-Zweymüller syndrome is not, in fact, a syndrome but a phenotype common to Kniest syndrome, OSMED, and Stickler syndrome. *Knobloch syndrome*, a recessive disorder, is characterized by severe myopia and exencephaloceles, most often in the occipital area.

Short stature, low nasal bridge, cleft palate, and sensorineural hearing loss (OSMED, megepiphyseal dysplasia, non-ocular Stickler syndrome)

Several authors (1–7,9,11,14) have described a syndrome characterized by midface hypoplasia, generalized epiphyseal dysplasia, and sensorineural hearing loss. Giedion et al (3) and Gorlin et al (4) used the terms *oto-spondylo-megaepiphyseal dysplasia (OSMED)* and *megepiphyseal dwarfism*, respectively, to apply to this disorder. The same syndrome was described by Insley and Astley (5) and Nance and Sweeney (11). About 20 cases have been reported. We are uncertain about the diagnosis of two cases (8,13).

Both homozygous and heterozygous forms have been described. Autosomal recessive inheritance is indicated by multiple affected sibs and parental consanguinity (5,10,14,16). Homozygosity for a missense mutation in the COL11A2 gene on 6p21.3 has been demonstrated (9a,16,17). The original patient with *Weissenbacher-Zweymüller syndrome* has been shown to have heterozygous OSMED (nonocular Stickler) syndrome (2,13,17) (Table 9–4).

Feeding difficulties are noted during the neonatal period, and infancy is characterized by enteritis and respiratory problems (bronchitis, pneumonia, etc.) that recur throughout life.

Stature is significantly reduced in most cases.

The nose is very small with anteverted nostrils and the nasal bridge is severely depressed (Fig. 9–52A–D). High myopia is not seen because the mutated α2 (XI) chain is not expressed in the vitreous (15). The midface is hypoplastic and the mandible small. Cleft palate has been observed in about 65%. Moderate to severe nonprogressive sensorineural or rarely mixed hearing loss has been documented in most cases.

The limbs are short. The hands are short with stubby fingers. The metacarpophalangeal joints are enlarged and have reduced mobility, and the fifth metacarpals are often shortened. In later life, the joints become enlarged and painful, and there is progressive lumbar lordosis. Radiographically, at birth, the leg bones are relatively short and broad (dumbbell form) with mild metaphyseal flaring and absent to small capital femoral epiphyses. The epiphyses are enlarged (Fig. 9–52E–G). Coronal clefts of the spine are seen in infancy. During childhood, platyspondyly with anterior wedging becomes evident with squared iliac wings. Wide flat epiphyses, metaphyseal flaring, mild vertebral dysplasia, large fused carpal bones (50%), and short metacarpals are seen in adults. The tarsal bones are large in 50%. Osteoarthritis is manifest in early adulthood.

Histologic study of cartilage shows severe osteoarthritis. Ultrastructurally, collagen fibrils are increased in diameter and exhibit aggregation (16). This reflects the size-limiting function of type XI collagen.

The homozygous recessive syndrome should be distinguished from types 1 and 2 *Stickler syndrome* and from the dominantly inherited nonocular form of Stickler syndrome due to a COL11A2 splice site mutation (2,17). Both OSMED and Stickler syndrome exhibit midface hypoplasia, epiphyseal dysplasia, and hearing loss that are more marked in OSMED. Myopia and vitreoretinal degeneration are not seen in OSMED. This can be explained by the absence of the α2-chain of type XI collagen in the human vitreous.

Weissenbacher-Zweymüller phenotype

The Weissenbacher-Zweymüller phenotype, a congenital neonatal rhizomelic dwarfism with metaphyseal widening of long bones and vertebral coronal clefts, first described in 1964 (10), has been considered to be the neonatal form of Stickler syndrome (4,8,11), but may also be seen in *OSMED* and in *Kniest syndrome*. Chemke et al (1), in 1992, presented a critical analysis of reported cases and demonstrated autosomal recessive inheritance. This is supported by two affected sibs in an inbred kindred. We believe that they had OSMED. Pihlajamaa et al (6) demonstrated that the original patient had heterozygous OSMED caused by a mutation in COL11A2 (Table 9–4).

There is short length at birth. The limbs are abbreviated. The face is flat, the nose small. The mandible is hypoplastic and the palate cleft (Robin sequence). There may be nasal root depression and mild sensorineural hearing loss (1–3,5,8,9). There is no eye involvement.

The long bones exhibit rhizomelic shortness with widened metaphyses, especially the distal femur. Further, there is a characteristic coronal clefting of lumbar vertebrae. These changes disappear with time, and there is catch-up growth after 3 years of age (1–3,5).

The identical twins reported by Ramer et al (7) with occipital encephalocele and meningocele and hearing loss, respectively, are difficult to classify. The children described by Kelly et al (4) and Winter et al (11) appear to have *Stickler syndrome*.

SPONASTRIME dysplasia

Fanconi et al (4) and other authors (2,3a,3,5–10) have described a condition that resembles Stickler syndrome, but appears to have autosomal recessive inheritance because of occurrence in sibs and parental consanguinity (Fig. 9–53). Several authors named the entity SPONASTRIME dysplasia because of the *SPO*ndylar-*NA*sal anomalies and *STRI*ated *ME*taphyses, although the term was not thought very useful (6).

The disorder should be differentiated from *otospondylomegaepiphyseal dysplasia* (*OSMED*) (Table 9–4), in which the epiphyses are large and the joints are more markedly restricted in mobility, especially in the hands, and which is caused by mutations in the COL112A gene on chromosome 6p21. Differentiation of the *Weissenbach-Zweymüller* phenotype can be difficult (20).

Verloes et al (10) suggested division of SPONASTRIME dysplasia into two types, one with normal intelligence and normocephaly (4–8), and one with severe mental impairment, microcephaly, and a somewhat different facial appearance (2,10). Although splitting into two groups seems justified, the use of the terminology SPONASTRIME dysplasia for the patients of Camera et al (2,3) and Verloes et al (10) has been rightfully disputed (6).

Feeding difficulties have been noted during the neonatal period, and infancy has been characterized by recurrent infectious respiratory problems and enteritis. Developmental milestones are normal. The limbs are short. Prenatal and postnatal growth are below the 5th centile (−3.4 to −4.6 SD). The tallest adult male was 154 cm, the tallest female 145 cm (6). The elbows and metacarpophalangeal joints may have somewhat reduced mobility, but usually joints are hypermobile. Progressive kyphoscoliosis and lumbar lordosis have been noted. The abdomen is prominent.

The head appears large. The forehead is prominent, and the midface is hypoplastic. The nose is very small with anteverted nostrils and the nasal bridge is severely depressed (Fig. 9–53). Epicanthic folds are prominent. Intelligence is normal. Two patients had avascular necrosis of the hip, and one a subglottic stenosis and tracheomalacia (6).

Radiographically, the long bones, especially of the legs, are relatively short and broad with mild metaphyseal flaring and dense longitudinal metaphyseal striations around elbows and knees, especially after the fifth year. Metacarpals are short. Kyphoscoliosis and lumbar hyperlordosis are evident with defects of the upper anterior angles of the vertebral bodies at the thoracolumbar junction. Vertical striation of long bones can be present, too. Langer et al (6) carefully described the change in lumbar vertebral characteristics with time.

One patient had biochemically a growth hormone deficiency, but supplementation did not result in catch-up growth (6). Two other sibs had chemical hypothyroidism, again without change in growth pattern after treatment (6).

The EVE syndrome, an acronym for *E*piphyseal, *V*ertebral, and *E*ar dysplasia, is somewhat similar to SPONASTRIME dysplasia (1). It, too, is autosomal recessive. Another condition, *CODAS syndrome*, appears to be sporadic.

Winchester syndrome

Winchester et al (13), in 1969, reported two sibs from Puerto Rico with a connective tissue disorder of short stature, joint contractures with claw hands, peripheral corneal opacities, osteoporosis, carpal-tarsal osteolysis, stiff joints with severe rheumatoid-like joint destruction, skin lesions, and coarse facies (Figs. 9–54 to 9–57). Mentation was normal. Brown and Kuwabara (1) described the same sibs. Other patients have been recorded by several authors [2,3(Case 2),4–9,12]. Because of three sets of affected sibs and parental consanguinity (5,7,13), inheritance is autosomal recessive. Winchester et al (13) suggested their cases to have a mucopolysaccharidosis. Dunger et al (3) noted excessive collagen turnover in skin and gingival biopsies and identified an abnormal oligosaccharide in the urine of two patients of which the first one probably had infantile systemic hyalinosis (14). Repeat analysis did not confirm the findings (14). Hollister et al (5) suggested a collagen synthesis disturbance as they found focal areas of fibroblastic proliferation replacing normal collagen bundles in the skin. The condition is well reviewed by Winter (14).

Painful joints and limited mobility in the hands and sometimes wrists, knees, and spine arise in the first year of life or shortly thereafter. With time, clawing of the hands, and flexion contractures of other joints arise. Walking can be difficult. Height growth falls below the third centile. The face may be normal at birth, but later coarsens. There are prominent forehead, large and fleshy nose, and thick lips. Gingival enlargement is common. Most cases developed peripheral corneal opacities between the second and fifth year. Liver and spleen are not enlarged. The skin can be normal (1,13), or thickened, hyperpigmented and leathery (2,5,6), and may show patches of soft hair on limbs or trunk (3).

Radiologically, the main symptoms are generalized osteoporosis and progressive carpal and tarsal osteolysis. The long bones show widened metaphyses, somewhat irregular epiphyses, and a thin cortex. Destructive and erosive changes are clear on the articular margins of the metacarpals and metatarsals. Ankylosis may be present. The vertebral column can

show compression of vertebral bodies, instability of first cervical vertebrae, and kyphoscoliosis.

Winchester syndrome resembles Farber disease and *Scheie disease*, and infantile systemic hyalinosis, and, in the first years, confusion with juvenile rheumatoid arthritis may arise. Torg et al (11) described three sibs with osteolytic changes of hands and feet, generalized osteoporosis, and skin symptoms (tender subcutaneous nodules, hyperpigmentation, erythema), which resembles Winchester syndrome strongly.

Shinohara et al (10) reported a single girl with generalized osteoporosis, osteolysis of hands and feet, corneal opacities, normal skin, and in addition pulmonary stenosis and nephropathy (proteinuria and focal glomerulosclerosis).

Mesomelic short stature, acral synostosis, unusual facies, umbilical anomalies, and agenesis of soft palate (Verloes-David syndrome)

Verloes and David (3) described a father and two children with mesomelic shortness of stature with severe alterations in the ankle, knee, and elbow. Other possible examples are those of Leroy et al (1) and Pfeiffer et al (2).

The facies was unusual with downslanting palpebral fissures, hypertelorism, ptosis, beaked nose, microretrognathia, and agenesis of the soft palate (Fig. 9–58A,B).

Skeletal anomalies included brachymetacarpy and brachymetatarsy of rays 3–5, partial fusion of proximal row of carpal bones, tarsometatarsal

fusion, and deformation of the radius and ulna somewhat resembling Langer-type mesomelic dysplasia (Figs. 9–58C and 9–59).

The umbilical cord near the body is covered with skin.

Inheritance is autosomal dominant.

Metaphyseal acroscyphodysplasia

The combination of alopecia and a metaphyseal bone dysplasia has been reported by Bellini and Bardare (1) in 1966 (Fig. 9–60A). Other cases were subsequently noted (2–6).

Height is reduced, largely due to abbreviation of the lower limbs (1,4). The metaphyses are widely splayed and the epiphyses are extremely wedge-shaped, especially at the knees. Cone-shaped epiphyses involve both long and short bones. Bone maturation is accelerated. The posterior clinoid processes are elongated. The vertebral bodies are biconcave, and the odontoid is hypoplastic (Fig. 9–60B–D).

There was absence of hair, eyebrows, and eyelashes in two reports (1,5).

Miscellaneous findings include hypospadias and cryptorchidism (1,5) and bilateral vesicoureteral reflux (1), craniosynostosis (4), and mental retardation (2,3).

Inheritance is autosomal recessive.

A similar bone dysplasia but with more severe brachydactyly and without alopecia was delineated by Verloes et al (7).

Micromelic dysplasia with dislocated radius

Four patients (2 sets of sibs), the children of an inbred Arabic Muslim kindred, presented at birth with severe short-limbed dwarfism. Borochowitz et al (1) suggests that, in addition to these children, patients 4 and 5 of Maroteaux et al (2), alleged to have omodysplasia, really had this same constellation of anomalies.

The humeri were short with distal deficiency and a twisted appearance, lateral eversion of the humeral condyle, and dislocated radial head. The proximal radii and ulnae were widely separated. The femora were short with distal deficiency.

The face was round with a median frontal port wine stain. The nose was short with a depressed bridge. The philtrum was protruded with a prominent vermilion.

Viljoen et al (3) reported a similar patient.

Oto-facio-osseous-gonadal syndrome

da-Silva (1), in 1997, described two male sibs and possibly a female sib, the product of a consanguineous union, with short stature, brachycephaly with prominent forehead, flat midface, downslanting palpebral fissures, low nasal root, hypoplastic alae and round nasal tip, prominent low-set pinnae, sensorineural hearing loss, narrow thorax, genu valgum, inguinal hernia, and cryptorchidism.

Radiographs showed wormian bones, fusion of carpal bones, and delayed bone age.

There was some resemblance to *otopalatodigital syndrome.*

Reference (Oto-facio-osseous-gonadal syndrome)

1. da-Silva EO et al: Oto-facio-osseous-gonadal syndrome: A new form of syndromic deafness. Clin Genet 52:51–55, 1997.

Pointer syndrome

Mahbubul Huq et al (1) described a complex syndrome of facial anomalies, skeletal abnormalities, and camptodactyly. The term "Pointer" is derived from the camptodactyly involving all except the index fingers that point. There are neonatal respiratory problems and feeding problems owing to absent or poor suck. The face is characterized by microretrognathia, a box-shaped nasal bridge with prominent nasal tip and anteverted nares, hypertelorism, downslanting palpebral fissures, hypoplastic and low-appearing supraorbital ridges, and microretrognathia. Camptodactyly of the 2nd, 3rd, and 4th fingers with pointing appearance of index fingers is already present at birth. There is progressive bowing of the limbs, especially the legs, and pathologic fractures.

Radiologic findings include camptodactyly with phalangeal dislocations, lateral and anterior bowing of the tibiae, metaphyseal widening of long bones, rounded vertebral bodies, generalized osteoporosis, and mild shortness of long bones with pathologic fractures as noted above.

An affected brother and sister, the offspring of first cousins once removed, suggests that autosomal recessive inheritance is involved.

Reference (Pointer syndrome)

Schimke immuno-osseous dysplasia

Initially believing that he was dealing with a mucopolysaccharidurıa, Schimke et al (13), in 1971, first described the combination of short stature due to spondyloepiphyseal dysplasia, progressive renal failure, episodic lymphopenia with recurrent infections, cerebral ischemia, and unusual facies. Additional examples were provided by Schimke et al (14) and others (1–5,7–12,15–17). About 25 cases have been reported to date. Hashimoto et al (6) reported a similar condition with late onset.

Intrauterine growth retardation has been noted in about 50%. Postnatal growth is disproportionate with short neck and trunk, exaggerated lumbar lordosis, and protruding abdomen in almost all patients (Fig. 9–61A,B).

Facial changes, seen in 80%, include low broad nasal bridge with bulbous tip and elongation of philtrum (Fig. 9–61C). Corneal opacities have been seen in 25%. The neck, as noted above, is almost always short. About 35% have microdontia. Dentinogenesis imperfecta has been noted but needs confirmation (2a).

Skeletal alterations include lordosis with flattened and anteriorly rounded vertebral bodies, small capital femoral epiphyses with lateral subluxation, and slanted acetabular roofs. The pelvis is hypoplastic (Fig. 9–61D,E).

Intellectual and/or motor delay is found in 20% (1,1a,17).

Focal glomerular sclerosis and nephrotic syndrome with proteinuria and progressive renal failure is an almost constant feature. About 95% exhibit hypertension. Hypercholesterolemia is probably also seen in most cases. About 50% exhibit transient ischemic attacks leading occasionally to infarction (1,1a). Autoimmune enteropathy has also been noted (7). TSH is elevated in 50% (1a).

Hematologic changes include episodic leukopenia/lymphopenia (90%), neutropenia and thrombocytopenia (40%), anemia (65%), and defective cellular immunity (absent mitogenic response). About 50% have recurrent infections. Abnormal immunoglobulin levels have been seen in 60%.

Multiple lentigines of the skin have been seen in 80%. The hair may be fine or thin in 65% (1,15).

Affected sibs were reported by Spranger et al (16), Lama et al (8), and Boerkoel et al (1). Inheritance appears to be autosomal recessive.

While various combinations may be found in a number of disorders, the phenotype of this syndrome appears distinctive.

Elevated TSH has been noted in 50% (1).

Spondylocarpotarsal synostosis syndrome

Spondylocarpotarsal synostosis syndrome was probably first described in 1975 by Langer and Moe (5), who reported a type of congenital scoliosis in sibs. At least 18 cases have been reported (1–4,6–10). Langer et al (6) suggested the name *spondylocarpotarsal synostosis syndrome (with or without unilateral unsegmented bar).*

Inheritance is clearly autosomal recessive (1,2,5,6).

Height is usually at the third centile. The trunk is disproportionately short (5). Scoliosis, usually recognized before the age of 6, increases in severity in time, often resulting in restricted vital capacity (Fig. 9–62A,B). The spine shows asymmetric segmentation, i.e., multiple symmetrical block vertebrae. There may be subluxation of C_2 on C_3 (7). Other abnormalities in the thoracic spine include small vertebral bodies slightly smaller on the concave side of the curve. The discs between them are narrowed. There is often a unilateral unsegmented bar on the concave side of the curve. Most of the ribs in the region of the bar are fused to the vertebral bodies (Fig. 9–62C–E). Lordosis is also common.

In addition to scoliosis, the carpal bones are abnormally formed; the first multangular is often abnormally shaped. There may be two bones in place of the second multangular, and there is fusion of the capitate-hamate and lunate-triquetrum. The navicular may be smaller than normal (Fig. 9–62F,G). The fifth fingers may have clinodactyly. The feet show calcaneonavicular synostosis, and often there is pes planus. Often there is limitation of pronation and supination at the elbows (6).

Cleft palate and sensorineural or mixed hearing loss are variable manifestations (2,6). Cataracts, rarefication of retinal pigmentations, and narrowing of retinal vessels have also been noted (8).

Unusual facies, rhizomelic bone dysplasia with club-like femora (omodysplasia)

The term *omodysplasia* was coined by Maroteaux et al (7) in 1989. It consists of rhizomelic shortening, especially of the upper limbs. Two of their patients (Cases 4 and 5) have *omodysplasia.* An earlier example is that of Barrow and Fitzsimmons (2). Several other examples have been documented (1–6,8,9).

Facial anomalies include posterior sloping of forehead, frontal and/or glabellar and facial hemangiomata, epicanthic folds, narrow palpebral fissures, small nose, depressed nasal bridge, broad nasal base, long philtrum, thin vermilion, micrognathia, and short neck (Fig. 9–63A). Small pterygia may be present in the axillary and popliteal regions.

Extension and flexion at the knees and elbows are limited. Skeletal changes involve short humeri with defective growth at distal ends, proximal hypoplasia of radius, distal hypoplasia of ulna, hypoplastic everted condyle, upper radioulnar diastasis, anterior dislocation of radial head, and ulnar subluxation. The femora have a clubbed shape proximally (Fig. 9–63B,C).

Some examples of congenital heart anomalies have been found (2,7). Undescended testes have been noted (2,5).

Inheritance is autosomal recessive (1,3,4,8,9).

Differential diagnosis would include *atelosteogenesis III.*

Chapter 10
Proportionate Short Stature Syndromes

Aarskog syndrome (facial-digital-genital syndrome)

Credit is usually given to Aarskog (1) for describing the disorder in 1970. However, earlier reports had been made (4,28,57). The condition is characterized by unusual facies, short stature, abnormalities of hands and feet, and genital anomalies. In most families, inheritance is compatible with an X-linked recessive pattern, female heterozygotes frequently exhibiting minor stigmata (43). Bawle et al (9) and Tyrkus et al (52) reported women with full expression of the syndrome, each of whom had an affected son. Porteous et al (43) localized the gene to Xp11.21, which was later confirmed (46) and called FGD1 (44). Pasteris et al (40), using positional cloning methods, identified a mutation in a gene that showed strong homology to RAS-like RHO/RAC guanine nucleotide exchange factors. The Rho family plays important roles in the regulation of actin cytoskeleton organization and cell growth. Mutations probably result in a disturbance of signal transduction and, hence, developmental growth anomalies (58). A mouse model has become available (41).

Several pedigrees demonstrating male-to-male transmission have been reported (14,25,29,55,57). Genetic heterogeneity is likely. About 150 male cases have been published. Several reviews (3,43,51) and surveys (20,43) are available. A summary of the major clinical features can be found in Table 10–1.

Facies. The forehead is broad with prominent ridging of the metopic suture (10,12,16), and the face is usually round. There is a widows' peak in approximately 70% (10,12,16,17,22,24,43,51). Scalp defects (22) and macrocephaly may be encountered (34). The corneal diameter may be enlarged (3,32). Hypertelorism in 90%, ptosis of upper eyelids in 50% (12,23,28), and short, broad, stubby nose with anteverted nostrils in 70% characterize the face. Various other eye anomalies include tortuosity of retinal vessels (42), strabismus (32), and ophthalmoplegia (23,28,36,48). The philtrum is usually long (16,17,22,25). A variety of malformations of the external ear has been described, most commonly thickened or fleshy earlobes (3,43,51). The maxilla is often hypoplastic (25,36,48). A linear curved depression below the lower lip is common (10,12,33) (Fig. 10–1).

Musculoskeletal system. Although birth size has been normal in most reports, growth retardation usually becomes evident during the first few years of life. Most patients are below the 3rd centile in height, and many patients exhibit prolonged pubertal growth spurt, although adults rarely exceed 160 cm (25). Hands and feet are short as are the fifth fingers (16,53), and there is mild soft tissue webbing between the fingers in over 70% (6,12,25,28,30,43,51). Hyperextension of the proximal interphalangeal joints and flexion of the distal interphalangeal joints are found in 80% (10,20,23–25,39,48) (Fig. 10–2). In approximately 80%, there is fifth finger clinodactyly (25,43,51). The feet are small, broad, and flat with splayed bulbous toes (12,30,35). Occasionally, there is metatarsus adductus (10,23,31,47). In approximately 45%, pectus excavatum is noted (43). Inguinal hernia has been seen in over 60% (25,30,43). The umbilicus is prominent with a protruding buttonlike central area surrounded by a deep ovoid depression (11,19,24,52).

Radiographically, striking changes are generally limited to the cervical spine and hands (10,34,48). Spina bifida occulta or cervical vertebral defects have been found in over 50% (24). Scott (see 46) described hypoplasia of the first cervical vertebra with an unfused posterior arch; on extension, the vertebra entered the foramen magnum. Odontoid hypoplasia has also been described (7). With flexion, there was subluxation of the first and second cervical vertebrae. Spinal cord compression at C1–C2 has required occipito-cervical fusion (47). RJ Gorlin has observed a patient with fusion of the second and third cervical vertebrae. Supernumerary ribs have been noted (16). The terminal phalanges of the fingers and the middle phalanx of the fifth finger are hypoplastic in over 80% (25,43,51). Camptodactyly is rare (37). Hanley et al (28) noted osteochondritis dissecans. Bone age is often retarded (25).

Genital anomalies. The scrotum appears bifid, with the scrotal fold extended ventrally around the base of the penis, somewhat resembling a shawl about the neck (Fig. 10–3). Presumably this genital anomaly results from failure of caudal shift of the fused labioscrotal folds. With age, shawl scrotum disappears (20,43). Commonly, one or both testes are undescended (25). Hypospadias (16) and macroorchidism (20) are rare findings. No characteristic genital anomaly is described in girls, although one female was noted to have clitoral hypertrophy (35).

Other findings. Bilateral single palmar creases (8,12,25,30) and a single crease in the fifth fingers are frequent (10,12,30,46,56); distally displaced axial triradii have also been noted (11,25,30,39). Most patients are of normal or low normal intelligence (17), but mild to moderate mental retardation has been reported (20,22,34,36,48). Growth hormone was deficient in two patients (3,33), but normal in several others (1,22,39,46). Lymphedema (37), dolichomegasigmoid (21), cardiac defects including pulmonary stenosis, aortic coarctation, aortic stenosis, and atrial and ventricular septal defects (1,18,54), and anomalous cerebral venous drainage (54) have been described.

Table 10–1. *Aarskog syndrome*—clinical features in 130 male patients

Clinical feature	%
Craniofacial	
Widow's peak	70
Hypertelorism	90
Ptosis	52
Downward slanted palpebral fissures	55
Short nose	70
Wide philtrum	85
Maxillary hypoplasia	85
Crease below lower lip	82
Abnormal auricles	80
Skeletal	
Short stature	85
Short/broad hands	82
Clinodactyly fifth finger	80
Mild interdigital webbing	70
Joint laxity	70
Broad feet, bulbous toes	70
Genital	
Shawl scrotum	80
Cryptorchidism	65

A B

Fig. 10–1. *Aarskog syndrome*. (A) Facies is characterized by broad forehead, hypertelorism, bilateral ptosis of upper eyelids, and low-set ears. (B) Similar facies in patient from a different family. Note unilateral ptosis. [From CI Scott Jr, Birth Defects 7(6):240, 1971.]

Oral manifestations. Enamel hypoplasia and a "col" deformity of the anterior mandible have also been noted in one patient (36). Halse et al (27), in examining 10 patients in three families, found delayed dental eruption in 3 of 4 patients aged 7–11. Congenitally missing teeth and short roots were found in the family originally reported by Aarskog (1,2), and Dayal et al (13) described taurodontism. Upper central incisors were found to be large in adults (20). Cleft lip and palate have been described in a few affected males (15,26,30,35,48,56); a carrier female (30) had cleft lip.

Differential diagnosis. *Noonan syndrome* and *LEOPARD syndrome* share features with this disorder such as short stature, hypertelorism, ptosis of upper eyelids, and hypogonadism. Seaver and Cassidy (45) reported a mother and son who had features of Aarskog and Noonan syndrome. *Robinow syndrome* also resembles the Aarskog syndrome, as does *pseudohypoparathyroidism*.

Teebi et al (49,50) reported a newly recognized autosomal recessive disorder, the *facio-digito-genital syndrome*, with some similarities to Aarskog syndrome, including short stature, hypertelorism, short stubby nose, anteverted nostrils, ear anomalies, small broad hands, and shawl scrotum. However, the eyes did not downslant nor was there ptosis. The hair was sometimes coarse, dry, and hypopigmented. Sixteen patients, both male and female, are known, all born to consanguineous parents. Naguib (38) reported 3 sibs with an Aarskog-like entity, consisting of large upward slanted palpebral fissures, telecanthi, ptosis, proptosis, hypospadias, shawl scrotum, and polysyndactyly. The parents were first cousins.

Fig. 10–2. *Aarskog syndrome*. The hands are short and wide with frequent webbing of the fingers, hypermobility, and subluxation of the proximal interphalangeal joints. (Courtesy of P Berman, Montreal, Canada.)

Bloom syndrome

Bloom syndrome consists of intrauterine growth retardation, sunlight sensitivity leading to telangiectatic erythema (Figs. 10–4 and 10–5), a tendency to chromosomal breakage with dicentrics, tetraradial figures, and high frequency of sister chromatid exchanges (Figs. 10–6 and 10–7), immunologic deficiency, hypogonadism and infertility in males, and an increased risk of neoplasia. The condition was first recognized by Bloom (5–7), a genetically oriented dermatologist, in 1954. Another case was reported by Torre and Cramer (56) as a case of discoid lupus erythematosis with primordial dwarfism. German (18) first recognized chromosomal breakage and emphasized the predilection for neoplasia. The Bloom Syndrome Registry currently has 168 patients on record (22,25,26,54).

The reader is referred to the following sources for detailed coverage: extensive reviews (13,18,19,21,44,58), neoplastic aspects (8,9,22), tumor surveillance (21,25,26,28), chromosomal breakage and sister chromatid exchange (3,10,13,20–24,27,30,38,51), immunologic deficiency (50,58,61), endocrine aspects (1,34,37,42,58), dermatologic aspects (18), growth (18,58), and genetic aspects (14,29,32).

Genetics. The syndrome has autosomal recessive inheritance. Both sexes are affected, although a slight female deficit remains unexplained. Heterozygous carriers are normal, the only unusual finding to date being a tendency for low levels of blood immunoglobulins. The gene occurs with high frequency among Ashkenazi Jews who orginated from Eastern Europe and in non-Jews of Spanish ancestry (16). More than 1 in 120 is a heterozygous carrier among Israeli Ashkenazi (28). In 1998, 52 of the 168 registered persons were of Askenazi descent (54). The gene probably expanded to high frequency through the founder effect and random genetic drift in a relatively isolated population. German et al (29) suggested genetic heterogeneity.

Parental consanguinity is not increased in affected Jewish families. The gene does occur with very low frequency in other populations and, in contrast, parental consanguinity in non-Jewish families is very high (28,41,44), for example, in the Japanese population (23).

A maternal uniparental disomy for chromosome 15 was reported to be associated with the syndrome (64). Bloom syndrome was later mapped at 15q26.1 (53). The gene product was shown to have homologies with Rec Q helicase, one of the DNA helicases that can unwind DNA in

A B

Fig. 10–4. *Bloom syndrome*. (A) Telangiectatic erythema of face. (B) Extensive facial telangiectasia in 14-year-old male. (From J German, Am J Hum Genet 21:196, 1969.)

the 3′ to 5′ direction along the bound strand (14,15,45). Unrestrained recombination probably leads to disturbed cell death (17) The helicase gene is closely linked to the proto-oncogenes (FES) (21). A rapid method to detect the 6 base pair deletion–base pair insertion that is commonly found in Ashkenazi Jews has been developed (54).

Cytogenetics. Chromosomal breakage and sister chromatid exchanges are characteristic (24). The unusually high rate of approximately 60–120 sister chromatid exchanges per cell, representing a 5- to 10-fold increase, is pathognomonic (3,10,13). Chromosome changes in leukemic clones are nonrandom (52). No increased chromosomal breakage has been detected in heterozygous carriers (38). Phenotypic dysmorphism occurs in patients with cells that are normal and cells that have a 10-fold increase in sister chromatid exchanges (27,58). Retarded DNA chain growth has also been documented, possibly resulting from a slow rate of replication fork movement. It has further been suggested that mitotic activity is low in fibroblast cultures (31). Vijayalaxmi et al (60) indicated that approximately eight times the normal number of 6-thioguanine-resistant lymphocytes were detected in blood, the basis for the increase being unknown, with genomic instability from chromosomal aberrations as one possible explanation. Willis and Lindahl (63) and Chan et al (12) reported DNA ligase I deficiency in lymphoid cells.

Fig. 10–5. *Bloom syndrome*. Four-year-old boy far below third percentile in height, with telangiectatic erythema of face. (From J Keutel et al, Z Kinderheilkd 101:165, 1967.)

Growth. Growth deficiency of prenatal onset is a prominent clinical feature, birth weight rarely exceeding 2300 g at term. Mean birth length is 44 cm. Final height attainment rarely exceeds 145 cm in males and 130 cm females (18,36). Body habitus is normal except for its fragile appearance. Affected infants and children eat much less than normal and subcutaneous fat is sparse during infancy and childhood, although vigor and strength are generally normal. There is disproportionate microcephaly, accentuated by delicacy and narrowness of the face. The head is dolichocephalic. Some patients have prominent nose and ears, with slightly receding mandible (Figs. 10–4 and 10–5) (7,9,33,36,39,55).

Performance. Intelligence is usually normal, although mild mental deficiency has been observed in some patients (8,18,19,36,55). Psychological problems are common and may result from short stature and unsightly facial lesions; interference with school progress may occur and simulate low intelligence. A squeaky, high-pitched strident voice is characteristic and occurs in both sexes (7,33,36).

Skin. Light sensitivity is noticed early in infancy and leads to development of telangiectatic erythema, which may appear anytime between early infancy and 2 years of age. Erythema involves light-exposed areas of the face; superficially it resembles lupus erythematosus because of the butterfly distribution across the nose. Severe lesions also may occur on the lower eyelids, lips, ears, and neck. A chronic fissure or ulcer of the lower lip is a bothersome complication and chronic cheilitis is a prominent feature. The eyelashes may be lost. The forearms and dorsa of the hands may become involved, but rarely does the erythema extend to the trunk. Exposure to sunlight may cause bullae and vesicles. Milia may be seen in scarred areas (5,7,8,33,39,49,55). German (18) noted that skin lesions appeared to be less severe in females than in males. Heavily pigmented individuals, such as Mexicans (48) and Japanese (2,35), exhibit less telangiectasia and sun sensitivity than lightly pigmented individuals.

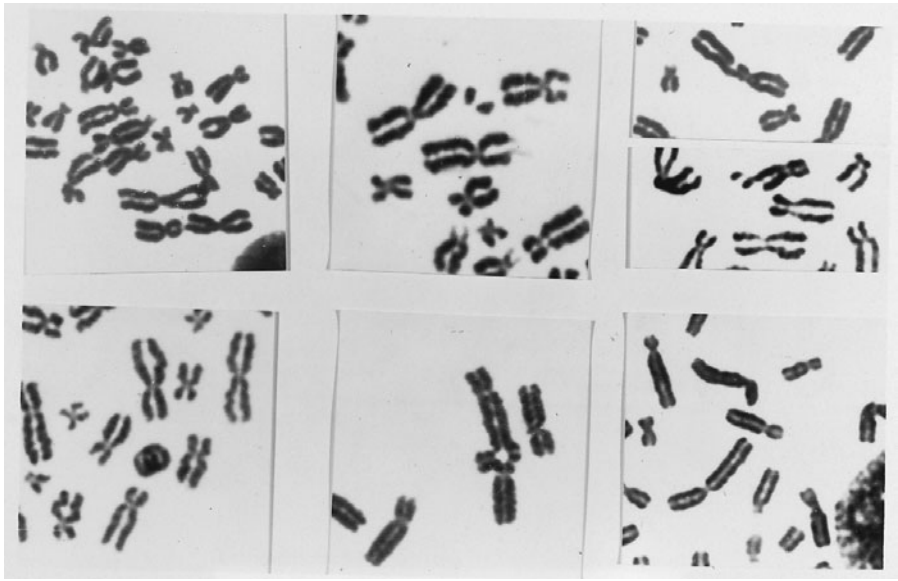

Fig. 10–6. *Bloom syndrome*. Various chromosome changes including dicentrics, acentric fragments, ring, breaks, and tetraradial figure. (Courtesy of J German, New York, New York.)

Hyperpigmented areas, irregular in outline and shape and varying from one to many centimeters in greatest dimension, are found mainly on the trunk, but also on various parts of the extremities. The spots are café-au-lait in color, although in affected black patients they are dark brown, almost black. Less often observed are hypopigmented areas that are irregular in outline and smaller in size. In some instances, both hyper- and hypopigmented spots may be observed in the same patient. Keratosis follicularis is found in approximately 20%. Acanthosis nigricans was noted in one patient who developed diabetes mellitus during puberty (7,18).

Immunologic features. Decreased immunoglobulin levels are characteristic and manifest as reduced IgA, IgG, or IgM. Although the immunologic disturbance has variable expression, a specific deficiency is similar in affected members of the same family (18,33,36,39,50,59–61). A single complementation defines patients of diverse ethnic background (62).

Endocrine findings. Hypogonadism of moderate degree and infertility are characteristic of affected males. Involvement of the tubular elements of the testes explains the occurrence of sterility and, although the Leydig cells also appear to be affected, patients have normal secondary sexual characteristics except for testicular development. Testes are small to diminutive in size, and cryptorchidism is common. Adult males seem to have no sperm (19). Menstruation occurs in postpubertal females, but periods may be irregular and infrequent in some (18,34,58).

Normal growth hormone response has been observed following pituitary stimulation in two instances, although deficient release of growth hormone was documented in another patient (1,58). Growth velocity was noted to increase during administration of exogenous human growth hormone in one instance (58). Insulin-dependent diabetes appearing from ages 11–40 years has been reported (19,37,42).

Fig. 10–7. *Bloom syndrome*. Note markedly increased number of sister chromatid exchanges (partial mitosis). (Courtesy of J Cervenka, Minneapolis, Minnesota.)

Neoplasia. Commonly observed malignancies include leukemia, lymphoma, adenocarcinoma, and squamous cell carcinoma (4,8,9,20,21, 25,26,28,43,44,55) (Table 10–2). Wilms tumor has been recorded three times (11). Recently, a cerebellar medulloblastoma was described (46). The mean age of detection has been 24.8 years, the earliest occurring at 4 years of age and the latest at age 44. Four patients have each had two malignancies: adenocarcinoma of the sigmoid at age 37 and adenocarcinoma of the gastroesophageal junction at age 44 in one patient; adenocarcinoma of the sigmoid and squamous cell carcinoma of the esophagus, both detected at age 39, in another patient; disseminated lymphoma and squamous cell carcinoma of the epiglottis, both detected at age 30, in still another patient, and Hodgkin lymphoma, and subsequently leukemia at age 21 (25,26,28,44). Takemiya et al (55) described multiple tumors of the skin, lung, and colon.

There is an overall risk of at least 44% for developing a neoplasm ($n = 132$). This must be considered a minimal estimate because other malignancies will probably be detected in this same population with time.

Other findings. Conjunctivitis and telangiectasia of the conjunctival vessels may be observed (48). Colloid body–like spots in Bruch's membrane have been noted (40,55). A variety of low-frequency abnormalities have been recorded, including congenital heart defect, unequal leg lengths, absent toe, syndactyly, supernumerary digits, clinodactyly, hip dislocation, pes equinus, hypodontia, large protruding ears, single palmar crease, sacral dimple, and urethral or meatal narrowing (7,18,33,39,44).

Differential diagnosis. Bloom syndrome has been grouped with *ataxia telangiectasia, Cockayne syndrome, Rothmund-Thomson syndrome, Werner syndrome, dyskeratosis congenita*, Fanconi anemia, and *xeroderma pigmentosum* (18,39). Nearly all these disorders are characterized by growth retardation, increased neoplasia (both lymphoreticular and carcinomatous), immunologic deficiency, late-onset diabetes, and premature senility of the skin and conjunctiva.

Table 10–2. *Bloom syndrome*—the first 100 neoplasms recorded in the Bloom syndrome registry

Type of neoplasm	No. cases identified
Leukemia	
Acute lymphyocytic	7
Acute myelogenous	6
Other	9
Malignant lymphoma	
Non-Hodgkin	20
Hodgkin	2
Carcinoma	
Skin	8

Sunlight sensitivity is also a feature of *Cockayne syndrome, Rothmund-Thomson syndrome, and xeroderma pigmentosum*. Pigmentary skin changes are seen in sun-exposed areas of patients with *ataxia telangiectasia, Werner syndrome, dyskeratosis congenita*, and Fanconi anemia. Increased chromosomal breaks have been reported in Fanconi anemia, *Cockayne syndrome, ataxia-telangiectasia,* and *dyskeratosis congenita* (18,39). However, they are unlike the changes found in Bloom syndrome (51), and in no other disorder investigated to date are sister chromatid exchanges as strikingly increased in frequency as in Bloom syndrome (30).

Laboratory aids. A characteristically increased number of chromosome breaks and sister chromatid exchanges is demonstrable in blood lymphocytes, freshly aspirated bone marrow cells, skin fibroblasts and long-term culture, and some lymphoblastoid cell lines (18,33,36,39,50,59,60). Serum IgA, IgG, and IgM are reduced and there is in vitro impaired response to pokeweed mitogen (59,61). Prenatal diagnosis may be possible using serial sonographic estimates of fetal size and growth rate to detect severe growth retardation (14), and should also be possible molecularly. Increased numbers of micronuclei are found in exfoliated cells in patients with Bloom syndrome (47).

de Lange syndrome (Brachmann-de Lange syndrome)

The syndrome of primordial growth deficiency, severe mental retardation, anomalies of the extremities, and characteristic facial appearance (Figs. 10–8 to 10–13), was independently described by Brachmann (14) in 1916 and by de Lange (24) in 1933. The condition has been known as de Lange syndrome (1,4,9,11–13,27,30,38,60), de Lange Amsterdam dwarf syndrome (31), Cornelia de Lange syndrome (2,7,10,34,35,42, 43,51,53,54,55,59,71,74,85), Brachmann-de Lange syndrome, and typus degenerativus Amstelodamensis (24,80,93). The reader is referred to the following sources for special coverage: extensive surveys (13,39, 45,74), references (67), numerical taxonomy (73,92), epidemiology (9), history (23,66,67), chromosomal findings (9,16,97), genetic studies, familial cases, and twins (7,12,19,27,28,33,51,61,65,69,76,89), evolution of phenotype (42,71), phenotypic overriding of racial characteristics (40), radiographic findings (14,38,52), neurological, psychometric, and behavioral aspects (2,5,11,31,34,35,46,49,78,79,84), limb anomalies (70), cardiac defects (13,30,37,45,62,75,91), gastrointestinal abnormalities (17,53), dermatoglyphics (13,87), and pregnancy (28,64).

Over 400 cases are known (1,10,42,45). Epidemiologic estimates vary. Beck and coworkers (8,10) reported a population prevalence of 0.6/100,000 in Denmark. Opitz (67) suggested a birth prevalence of 1/10,000 in the United States.

A B

Fig. 10–8. *de Lange syndrome*. (A) Typical craniofacies and oligodactyly of upper limbs. Hirsutism of thighs. (B) Characteristic cranio-facial appearance with microcephaly, small hands and feet, small external genitalia. (A courtesy of RW Smithells, Leeds, England. B courtesy of M Silverman, Atlanta, Georgia.)

Most cases are sporadic. Affected sibs have been reported on a number of occasions (12,16,33,45,50,69,73). Several families with vertical transmission have been observed (3,7,20,22,28,45,50,55,61,76). Pregnancy in a woman with de Lange syndrome has been described; a clinically normal female infant was delivered (64). Instances of consanguinity (10,71,73), concordant monozygotic twins (65,67,94), discordant monozygotic twins (19), and discordant dizygotic twins (45,89) have also been noted. Chromosomal studies have been normal in most instances, although occasional, inconsistent chromosomal anomalies have been recorded (10,13, 16). Recurrence risk has been estimated to be 1.5% or less (45). The phenotypic overlap between de Lange syndrome and duplication 3q syndrome has been suggestive for a locus on 3q26.3 (27,40,54,57,97). Ireland et al (43) have described a genuine patient with a de novo translocation between 3q26.3 and 17q23.1. A patient with a partial duplication of 3q26 but without de Lange features has been reported (57). Searches for uniparental disomy in patients with de Lange syndrome have been negative (26,83). Multiple mitochondrial DNA deletions were found once (63).

Clinical variability and diagnosis. Lower birth weights are correlated with more severe phenotypic features (39), including more severe upper limb anomalies and greater psychomotor retardation (35). A significant excess of females is also found in the lower-birth-weight group (5,39). Variability is marked. We believe that many with mild phenotypic changes are being missed (1,22,36,42,82).

Using the technique of numerical taxonomy, Preus and Rex (73) constructed a diagnostic index of 30 characters that could discriminate de Lange from non-de Lange syndrome in 99% of the cases, leaving a 1% zone of doubt. The possibility of mildly affected individuals with minimal mental deficiency or borderline IQ, normal head circumference, normal height, and/or normal limbs has been discussed by Opitz (67) and others (4,6,22,81,83,92). Findings in de Lange syndrome are summarized in Table 10–3.

Growth. Birth weight is 2500 g or less in approximately 70% in spite of normal duration of pregnancy (48). Postnatal growth retardation is severe in 96%, both height and weight usually remaining far below the third centile for age (48). Bone age is delayed, and, not uncommonly, the sequence of development of various centers of ossification may be disturbed (12). Recurrent respiratory infections and an early demise before 6 years of age are common (9,13).

A B

Fig. 10–13. *de Lange syndrome*. (A,B) Hirsutism of back, with whorling. (From O Noe, Clin Pediatr 3:541, 1964.)

Central nervous system. Microbrachycephaly is usual, reported frequencies varying from 50% to 90% (8,13,16,48). Mental deficiency (75%–100%) (11,16), abnormal speech development (75%–100%) (16), behavioral problems (57%) (39,79), vermis hypoplasia (68), seizures (14%–20%) (5,39), hypertonia (less than 25%) (16), and, rarely, hypotonia (16) have been reported.

The cry is usually low pitched and growling (13). Patients frequently do not exhibit facial expression of emotion and commonly display stereotypic movements (13a). Vestibular stimulation or vigorous movement tends to elicit pleasurable responses (46,79). Younger patients are dysphonic, with a frequency below normal pitch register, and older subjects are hoarse (31). In the studies of Hawley et al (39), Sarimski (79), and Berney et al (13a), behavior problems included regurgitation, projectile vomiting, chewing and swallowing difficulties, lack of interest in food, and excessive screaming, biting, and hitting as well as frequent temper tantrums. Self-mutilation has been discussed by Shear et al (84). Andrasik et al (2) reported therapeutic strategies. Early intervention appears to play a major role in the level of developmental (49). Hearing loss occurs in 24% (39). IQ scores range from 4 to 101 (5,34,76,78,93); however 80% of the patients reported by Barr et al (5) were severely or profoundly retarded. Berney et al (13a) noted that 18% were borderline or mild while 43% were profoundly retarded.

Craniofacial features. Patients resemble one another to a remarkable degree (Fig. 10–9) and Huang et al (41) noted that the facial phenotype overrides racial characteristics. The typical facial appearance may not be evident during the first year of life (69), and Passarge et al (71),

Short neck	66
Cryptorchidism	73
Cardiac anomalies	14
Small umbilicus	53

Adapted from L Jackson et al, Am J Med Genet 47:940, 1993.

Ireland and Burn (42), and Allanson et al (1) have discussed and illustrated evolution of the facial phenotype with age.

The skull is microbrachycephalic. The temporal and scalp veins may be conspicuous. The eyebrows are confluent (synophrys), the eyelashes long and curly, and the hairline is low. Myopia, ptosis, and nystagmus are common (56). The nose is small with a flat nasal bridge. The nostrils are anteverted and the philtrum is long. A bluish hue is often observed about the eyes, nose, and mouth. The ears may be malformed, small, apparently low-set, and hirsute (13) (Fig. 10–10). The neck is short and thick. Craniometric studies are available (1,86).

Micrognathia is common and prominent mental spur may be seen (14). The lips are thin, with the corners of the mouth downturned. Cleft palate occurs in approximately 20% (12,13,27,30,60,69,74,93). Patients with cleft palate have a high chance of having hearing loss (45). Delayed tooth eruption and microdontia have been noted (12,60). Late eruption and widely spaced teeth were found in 93% of 64 patients reported by Hawley et al (39). A broad acellular zone with gracile fibers around blood vessels has been observed in the gingiva (77).

Limbs. Generally, the hands and feet are small. The fingers are often short and tapering, with clinodactylous fifth digits that have only a single flexion crease. The thumbs are proximally placed in approximately 70% and the thenar muscles are hypoplastic. Flexion contractures of the elbow are present in approximately 65%. Soft tissue syndactyly of the second and third toes is common. Approximately 25% exhibit severely malformed upper limbs, varying from oligodactyly to more severe phocomelia. Limb involvement may be unilateral or bilateral and, when bilateral, is not necessarily identical or even closely similar (Figs. 10–8, 10–11, and 10–12) (13,45,70).

Radiographically, the humerus, radius, and ulna are shortened. Hypoplasia and dorsal dislocation of the radial head are observed in 80%. Often the neck of the humerus is elongated. The semilunar notch of the ulna is shallow. In some cases, the forearm bones are absent. The first metacarpal and middle phalanx of the index and fifth fingers are often hypoplastic, as are the third, fourth, or fifth metatarsals (29). The acetabular angle is low, especially when the child is less than 1 year of age. Coxa valga is a constant feature. The sternum is short with a reduced number of ossification centers, and the ribs are rather thin (13,14,24,52). The available metacarpophalangeal profile analysis showed a characteristic pattern, especially in shortening of the first metacarpal and fourth middle phalanx (14,18,38).

Dermatoglyphic findings include hypoplastic ridge patterns, single palmar creases, and increased atd angle. There is also an increase in radial loops on the third and fourth fingertips (87) and c–d interdigital triradius (13).

Skin. Hirsutism is often generalized, with hair whorls over the shoulders, lower back, and extremities (Fig. 10–13). The nipples and umbilicus are frequently hypoplastic. Cutis marmorata is present in 60% (13,45,85). Pigmented nevi are relatively common.

Genitourinary system. The kidneys are often hypoplastic, dysplastic, or cystic (30). Cryptorchidism and/or hypospadias occur in 73% (45) to 94% (39). Females commonly have bicornuate or septate uterus and long narrow ovaries (93).

Gastrointestinal abnormalities. A variety of gastrointestinal abnormalities have been reported, including malrotation, annular pancreas, pyloric stenosis and/or duodenal obstruction, hiatus hernia, inguinal hernia, umbilical hernia, colon duplication, Meckel's diverticulum, and gastric ulcer perforation (17,39,53,96). Extensive reflux may lead to the Sandifer complex (88). A congenital diaphragmatic hernia has been described several times (20).

Cardiovascular system. Approximately 15%–20% of all patients have a congenital heart defect (13,37,45,62,91). Recorded defects have included VSD, ASD, tetralogy of Fallot, endocardial cushion defect, PDA, hypoplasia of leaflets of aortic valve, tricuspid stenosis, pulmonic stenosis, rudimentary left ventricle, anomalous venous drainage, overriding aorta, and ventricular fibroelastosis (31,62,69,91).

Other findings. A variety of miscellaneous anomalies have been discussed by Berg et al (13) and others (45,59,96). Endocrinological aspects have been discussed elsewhere (13,81). Laboratory studies have not revealed any consistent abnormalities (13). Melegh et al (63) reported mitochondrial DNA deletions, and Froster and Gortner (32) described thrombocytopenia.

Differential diagnosis. There is considerable phenotypic overlap with *dup(3q) syndrome* that we feel is nevertheless distinct. Clinical features of *fetal alcohol syndrome, Coffin-Siris syndrome*, and *KBG syndrome* may occasionally be confused with de Lange syndrome. The case described by Ponder et al (72) had *Peters plus syndrome*. Children with *Gorlin-Chaudhry-Moss syndrome* can exhibit facial resemblance to de Lange syndrome. Stratton et al (90) described a patient with pre- and postnatal growth retardation, bilateral severe upper limb defects including ulnar agenesis, ASD, VSD, and facial dysmorphisms distinctive from de Lange syndrome. It should also be noted that de Lange (25), in 1934, described another syndrome with congenital muscular hypertrophy, hypertonia, and developmental retardation. This condition, too, has sometimes been called de Lange syndrome, but it has nothing to do with the syndrome discussed here.

Laboratory aids. Pregnancy-associated plasma protein A has been suggested as a marker in prenatal diagnosis (95). Prenatal diagnosis by sonography, using especially the ulnar limb defects and diaphragmatic hernia as parameters, has been accomplished (47,58).

Dubowitz syndrome

In 1965, Dubowitz (5) reported sibs with intrauterine growth retardation, primordial short stature, microcephaly, mental retardation, high-pitched voice, and characteristic facial appearance (Figs. 10–14 and 10–15). He assumed that the children had Bloom syndrome. In 1971, Grosse et al (8) suggested that the disorder was a distinct entity. Approximately 150 cases have been published to date (25). We cannot accept the case described by Lerman-Sagie et al (13) who may well have had deletion of 22q11.2. Autosomal recessive inheritance has been demonstrated because of multiple sib involvement (5,8,10,12,18,21,24,25,27,29–31) and parental consanguinity (18,31). It has also been documented in identical twins (30) and in one of dizygotic twins (25). The cause remains unknown. There is resemblance with mildly expressed Smith-Lemli-Opitz syndrome, and indeed a moderately lowered cholesterol level has been published in a single case (1). We have not confirmed this among several patients.

Moller and Gorlin (16), Belohradsky et al (2), Ilyina and Lurie (10), and Tsukahara and Opitz (25) surveyed the disorder. Evolution of the phenotype has been demonstrated (6,9,14,16). The major clinical features are summarized in Table 10–4.

Growth. Birth weight is approximately 2.4 kg (males) to 2.2 kg (females), and birth length is approximately 45 cm. Prenatal growth failure has been evident in approximately 70%. Postnatal growth is retarded in 90%. Head circumference at birth averages 31 cm. Delayed bone age has been reported in 72%.

Facies. In nearly all cases there is microcephaly, the degree of which does not correlate with mental retardation. The small head circumference seen at birth remains small. High sloping forehead with sparse frontal hair and flat supraorbital ridges are seen in approximately 90%. Facial asymmetry has been noted occasionally. A broad-based nose and nasal tip are seen in over 50%, especially at a younger age. Telecanthus is very frequent, and ptosis with or without blepharophimosis, often asymmetric, is seen in 65%. Low-set and somewhat dysmorphic pinnae have been noted in about 75%. Approximately 75% have microretrognathia (10). The face elongates with age (Figs. 10–14 and 10–15). Both premature aging (6,14) and an appearance younger than chronologic age (9) have been described. Ocular symptoms have included strabismus, microphthalmia (10), tortuous retinal vessels (10,15,18), hypopigmentation

Fig. 10–14. *Dubowitz syndrome*. Primordial shortness of stature, blepharophimosis, ptosis of eyelids, and micrognathia. (From F Grosse et al, Z Kinderheilkd 110:175, 1971.)

A B C

Fig. 10–15. *Dubowitz syndrome*. (A) Note high forehead with flat supraorbital ridges, widely spaced eyes, blepharophimosis, and small mandible. (B) Sister of patient shown in A. Note similar facies. (C) 30-year-old (originally described by Dubowitz in 1965). Note triangular face, laterally sparse eyebrows, asymmetric ptosis, prominent nasal bridge, and narrow chin. (C from KE Hansen et al, Am J Med Genet 55:161, 1995.)

(10,17,18,25), coloboma of iris (23,25), fibrous strands in anterior chamber (19), tapetoretinal degeneration (10), and other anomalies (10,25).

Skin. An eczematous skin eruption, especially of the face and extremities, has been noted in approximately 60%, usually from birth (25). The site of involvement has varied from a limited area to the entire body. It often clears by age 2 to 4 years, but it may last until adulthood. Variable minor soft-tissue syndactyly of the second and third toes has been documented in 25%.

Central nervous system. Motor milestones are reached at normal times. Moderate or severe mental retardation has been evident in 15% and 10%, respectively. Most children have been estimated to be in the dull normal range. However, normal intelligence has been noted (26). Hyperactivity has been manifested by approximately 70% (10,20). Speech is delayed in 60%.

Table 10–4. *Dubowitz syndrome*—clinical findings ($n = 141$)

Feature	Reported cases	%
Prenatal growth retardation	83	(63)
Postnatal growth retardation	119	(86)
Psychomotor retardation	90	(72)
Hyperactivity	50	(36)
Microcephaly	112	(79)
High, sloping forehead	43	(30)
Sparse, thin hair	58	(41)
Blepharophimosis	60	(42)
Ptosis	53	(38)
Broad nasal bridge	31	(22)
Broad nasal tip	20	(14)
High, narrow palate	30	(21)
Cleft palate	22	(16)
High-pitched voice	38	(27)
Micrognathia	81	(57)
Low-set ears	24	(17)
Eczema	59	(42)
Clinodactyly of fifth fingers	48	(34)
Cutaneous syndactyly	22	(16)
Retarded bone maturation	37	(26)
Cryptorchidism	26	(18)

Adapted from M Tsukahara and JM Opitz, Am J Med Genet 63:277, 1996.

Other findings. High-pitched voice has been noted in 50%. Approximately 65% exhibit poor feeding, frequent vomiting, and chronic diarrhea during infancy. The vomiting is usually related to gastroesophageal reflux (25). Approximately 50% of affected males manifest hypospadias or cryptorchidism. Rarely, congenital cardiac defects have been reported (11,12,14,22,25).

Of considerable interest are reports that have noted an association with leukemia (7), lymphoma (2,21), neuroblastoma (21), and aplastic anemia (3,10,28). Although there have been some suggestions that these patients have an immune defect, its precise nature has not been defined (8,15,18,21). Sauer and Spelger (21) noted hypogammaglobulinemia in one sib and IgA deficiency in the other. Both children had malignancies. Thuret et al (24) noted IgA deficiency. Recurrent infections are common in Dubowitz syndrome.

Oral manifestations. Cleft palate, bifid uvula, or submucous cleft palate have been found in approximately 30% (2,4,8,10,18,25,30). Various dental anomalies were described, including oligodontia, microdontia, crowded teeth, macrodontia, and malocclusion (10,25).

Differential diagnosis. Dubowitz syndrome may be confused with *Bloom syndrome, fetal alcohol syndrome*, or Fanconi anemia, and resembles mildly expressed *Smith-Lemli-Opitz syndrome*.

Hallermann-Streiff syndrome

Hallermann-Streiff syndrome is characterized by dyscephaly, hypotrichosis, microphthalmia, congenital cataracts, beaked nose, micrognathia, and proportionate short stature. The condition was probably first described by Aubry (2) in 1893, although he did not report the complete syndrome. Another early report is that of Bergmeister (5). Hallermann (27), in 1948, and especially Streiff (56), in 1950, separated the syndrome from progeria and mandibulofacial dysostosis. An important early paper is that of François (18), who, in 1958, presented two cases, reviewed 22 cases from the literature, and further delineated the syndrome. The condition has also been called François syndrome (3,4,9,19) and oculomandibulodyscephaly (53). Over 180 cases have been recorded to date. Several extensive reviews and surveys are available (3,6,8,12,19,58). A portrait by a contemporary Mexican artist has been documented (44).

Virtually all cases have been sporadic. There is no sex predilection. The syndrome has been described as concordant in monozygotic twins (61) and has been seen in one of dizygotic twins (1). Affected females have had normal children (28,43). We cannot accept any of the familial cases reported to date. For example, Guyard et al (24) described an affected father and daughter and Koliopoulos and Palimeris (35) reported what they called "atypical Hallermann-Streiff-François syndrome" in three successive generations. Neither of these papers describes Hallermann-Streiff syndrome. François (18,19) cited several familial cases as personal communication that have never been published. He further cited two affected sibs reported by Hall et al (26) as examples, although Hall et al (26) specifically recognized the condition they reported as an entity different from Hallermann-Streiff syndrome; they named their disorder pseudoprogeria/Hallermann-Streiff (PHS) syndrome (vide infra).

Table 10–5. *Hallermann-Streiff syndrome*—principal features ($n = 150$)

Abnormality	%
Dyscephaly	98–99
Cataract	81–90
Microphthalmia	78–83
Dental abnormalities	80–85
Hypotrichosis	80–82
Skin atrophy	68–70
Proportionate short stature	45–68

From D Barrucand et al, Rev Oto-Neuro-Ophthalmol 50:305, 1978 and B Carles Mermet, Thesis, Lyon, 1979.

The affected cousins reported by Schanzlin et al (49) do not represent familial examples either. Although a second cousin clearly had Hallermann-Streiff syndrome, the proband had dup(10q) with buphthalmos, sclerocornea, total aniridia, nasal abnormality, micrognathia, and bifid halluces. Chromosomal studies have been normal in almost all instances (3,4,17,21,33,37), with few exceptions (29,34).

The sporadic cases reported by Scoppetta et al (52) and Steel et al (55) are not examples of the syndrome. Consanguinity was reported by Berbich et al (4), but in their sibship of eight children, only one was affected. François (19) cited a number of other instances of consanguinity. However, families that can be verified had only one affected individual per family.

Natural history. Clinical findings are summarized in Table 10–5. Narrow upper air passages may make feeding difficult during infancy (13a,29,46). Pneumonia and/or severe feeding difficulties have led to the demise of affected infants in several instances. Anesthetic risks have been discussed by Ravindran and Stoops (45) and Sataloff and Roberts (48). Sleep apnea has also been noted (13a,20).

Birth weight is normal in about 65%, prematurity and/or low birth weight occurring in the other 35% (58). Short stature is seen in 45%–68% (19). Growth is diminished proportionately, being at least 2–5 SD below the mean. Final height attainment for females is approximately 152.4 cm, with males being 2.5–5.0 cm taller.

Craniofacial features. The face is small, with a long, thin, tapering, "pinched" nose, and receding chin (51). An odd-shaped, bulging skull with brachycephaly is often accompanied by frontal or parietal bossing (Fig. 10–16). Mild microcephaly and malar bone hypoplasia also occur but are not constant features (19,37). Gaping or dehiscence of sutures, as well as delayed closure of fontanels, has been described by nearly all authors. Increased wormian bones have been reported (11). The nose is thin, pointed, and often curved and may have a tendency to septal deviation (7,43). Hypotrichosis, especially of the scalp, brows, and lashes, occurs in approximately 80% (3,8,21,22,58). Scanning electron microscopy has shown absent or abnormal cuticle development in the hair shafts (21). Alopecia is most prominent about the frontal and occipital areas, but is especially marked along suture lines (57). Cutaneous atrophy and/or atrophic alopecia, present in approximately 70% (3,8,22), is largely limited to the scalp and nose. Scalp skin is thin and taut, and scalp veins are prominent. Similar changes may be observed on the nose.

Previously undiagnosed patients tend to visit ophthalmologists because of visual impairment from congenital cataract. Microphthalmia of variable severity (78%–83%) and bilateral congenital cataracts (81%–90%) occur with high frequency (3,8,58). Cataracts consist of milky white liquefied lens masses that resorb spontaneously in approximately 10% (19,54,64). Blue sclerae have been described in approximately 22%–31%, nystagmus in 32%–45%, strabismus in 33%–37%, glaucoma in 7%–11%, pupillary membrane persistence in 5%, and down-slanting palpebral fissures in 12%–13% (3,8,30,37,57–59,61). Donders (16) published a histopathologic study of the eye from an autopsy case. Anomalies of the fundus, conjunctiva,

Table 10–7. *Hallermann-Streiff syndrome*—other abnormalities ($n = 150$)

Abnormalities	%
Mental deficiency	15
Neurological manifestations	Infrequent
Skeletal defects	10–50
Genital anomalies	10–12
Cardiac defects	2–9
Ear anomalies	9
Hematopoietic abnormalities	7
Pulmonary anomalies	3
Digestive system abnormalities	3
Muscular hypotrophy	3
Hepatic anomalies	2
Renal anomalies	1–2

From D Barrucand et al, Rev Oto-Neuro-Ophthalmol 50:305, 1978; B Carles-Merment, Thesis, Lyon, 1979; L Crevits et al, J Neurol 215:225, 1977; and Y Suzuki et al, Dev Med Child Neurol 12:496, 1970.

and cornea as well as miscellaneous ocular findings (Table 10–6) are well documented in several accounts (3,7,8,17–19,23,27,37,39,41,57, 60,61,63,64).

The mandible is hypoplastic with double chin and central clefting or dimpling (7,18,23,27,56). The ascending ramus is usually short, and the condyle may be missing or the fossa hypoplastic (18,34,36). Radiographic examination reveals a characteristic temporomandibular joint displacement of approximately 2 cm forward from its normal position that is located just in front of the external auditory meatus (61). The midface is hypoplastic with a prominent nasal bone. The palate is high and narrow and the paranasal sinuses are diminished in size (17). Microstomia is present in approximately 10% (34,61). The gonial angle is straight. Cephalometric and anthropometric studies have been carried out (20,25,62).

Dental anomalies are common (80%–85%) and may include absence of teeth, persistence of deciduous teeth, malocclusion and open bite, malformed teeth, severe and premature caries, supernumerary teeth, and especially natal teeth (2,3,7,8,17–19,27,29,31,39,40–42,47,50,56). A well-documented histopathologic study of dentoalveolar abnormalities observed at autopsy is available (53).

Central nervous system. Mental deficiency has been noted in approximately 15% (34,58); and although an estimate as high as 31% has been indicated elsewhere (3,8,19), Crevits et al (13) has warned that the psychometric aspects of the syndrome have been treated very subjectively, with only rare instances of psychometric testing. Hyperactivity, choreoathetosis, and generalized tonic-clonic seizures have been noted occasionally (13,17,34).

Other findings. A wide variety of miscellaneous findings has been reported (Table 10–7). Hypogenitalism has been reported in 10%–12% (3,8,29). Also documented have been cryptorchidism, hypospadias, clitoral enlargement, breast asymmetry, and breast atrophy (3,19). Axillary and pubic hair may be scant (17,18).

Various cardiac anomalies including pulmonic stenosis, ASD, VSD, PDA, and tetralogy of Fallot have been reported in approximately 5% (15,32,65).

Chandra et al (10) reported a case with deficiency of humoral immunity and hypoparathyroidism. Although immunodeficiency, hypoparathyroidism, and cardiac anomalies have now been observed in Hallermann-Streiff syndrome, true DiGeorge sequence has not occurred. The patient reported by Chandra et al (10) had normal cell-mediated immunity with reduced serum IgG and plasma opsonic function.

A great many other abnormalities have been observed, including occipital bossing, hydrocephaly, calcification of falx cerebri (3,19,38,65), osteoporosis (41), syndactyly (61), lordosis and/or scoliosis (39,50), spina bifida, winging of scapula (34,43,58,61), pectus carinatum or excavatum (19,61) and thin gracile bones (11). Vitiligo and livedo have also been noted (18,37,65).

Differential diagnosis. *Progeria* differs from the Hallermann-Streiff syndrome by having premature arteriosclerosis, nail dystrophy, acromicria, and chronic deforming arthritis. In addition, the eyes are normal. *Wiedemann-Rautenstrauch syndrome* should also be excluded.

Mandibulofacial dysostosis shares in common with the Hallermann-Streiff syndrome micrognathia, high palatal vault, and malar hypoplasia, but usually has lower eyelid colobomas and associated ear anomalies.

The autosomal recessive pseudoprogeria/Hallermann-Streiff (PHS syndrome) (26) has similarities to the Hallermann-Streiff syndrome but has, in addition, severe spastic quadriplegia. Furthermore, appearance at birth is normal except for absence of eyebrows and eyelashes. The disorder is progressive, with limb spasticity and psychomotor delay evident by 6 months of age. Dennis et al (14) described a lethal recessive disorder characterized by slender long bones, underossified skull, and congenital cataracts.

Rubinstein-Taybi syndrome

In 1963, Rubinstein and Taybi (93) observed a combination of broad thumbs and halluces, characteristic facial dysmorphism, growth retardation, and mental deficiency (Figs. 10–17 to 10–19). However, the syndrome had been described as early as 1957 in the French literature by Michail et al (74). Rubinstein (92) reviewed 571 patients in 1989. The syndrome has been observed in whites, blacks, and Orientals (47,92). The reader is referred to the following sources for detailed coverage: extensive review (92), genetic aspects (47), growth (106), craniofacial features (4), natural history (2,43,48,105), neoplasias (75), oral characteristics (44), cardiac aspects (104), psychological investigations (50), and bibliography (42).

The prevalence in the general population has been estimated to range from 1/300,000 to 1/720,000 (101). As several of the patients used in this study proved to have a different diagnosis on careful follow-up (81), these figures are no longer usable. Hennekam et al (47) estimated a birth prevalence of 1/125,000 in the Netherlands. This figure has proved to be correct for the Netherlands in the period 1988–1998 (RCM Hennekam, unpublished data, 2000).

Genetics. The overwhelming majority of reported cases are sporadic. Fourteen MZ concordant, one MZ discordant, and four discordant DZ twins have been recorded (6,33,47,48,53,54,59,64,83,85,97). Affected sibs were noted by Johnson (57). Apparent dominant transmission has been described (31,45,70). In several other reports (23,35,41,108), familial recurrence was unconvincing or the diagnosis unlikely (47). The

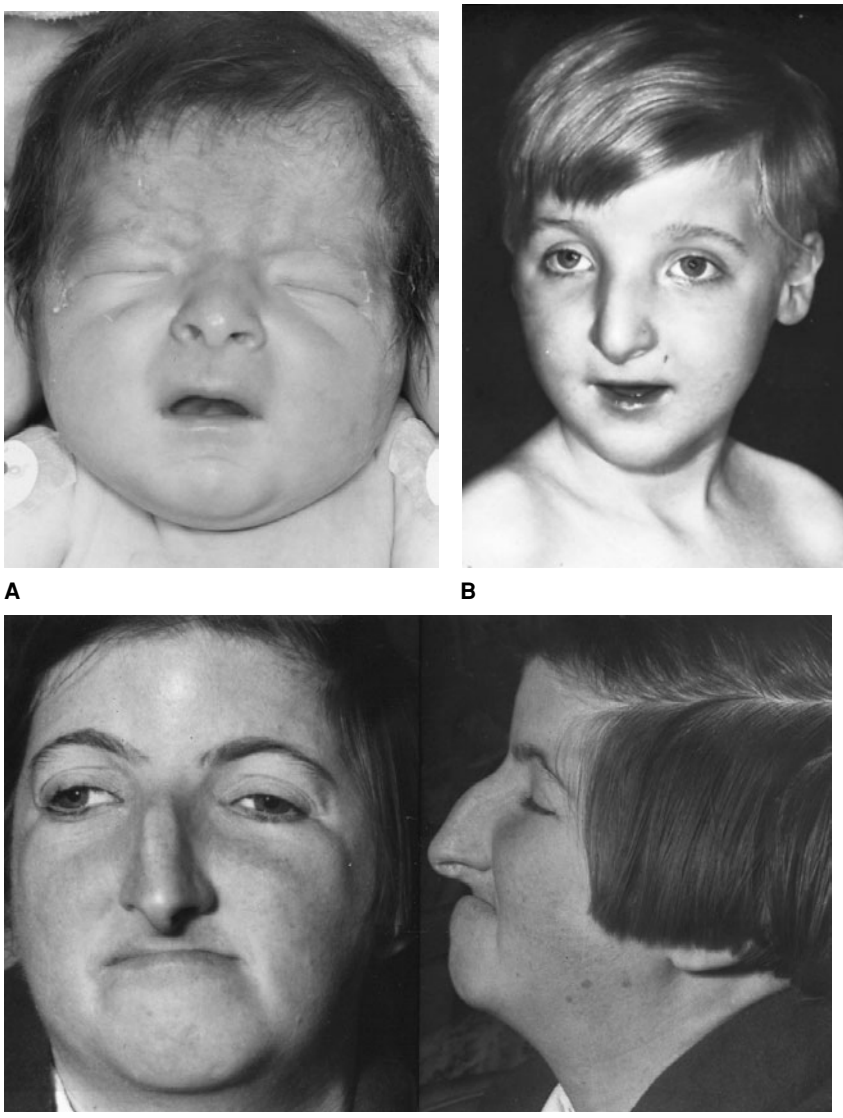

Fig. 10–17. *Rubinstein-Taybi syndrome*. (A–E) Characteristic facial appearance at different ages. Note septum extending below nasal alae. (B,C from R Weiland, Arch Kinderheilkd 179:78, 1969. D,E from JM Berg et al, J Ment Defic Res 10:204, 1966.)

parents in ten families (47) were consanguineous. Several family histories are noteworthy because of the presence of broad thumbs in relatives (47,92).

Hennekam et al (47) reviewed the cytogenetic findings in 306 patients in 1990: 295 had normal karyotype and nine had (inconsistent) chromosome anomaly. Imaizumi et al (55) and, later on, Tommerup (112), Lacombe (65), and Hennekam (unpublished observation) described translocations or inversions involving locus 16p13.3. This allowed for the detection of submicroscopie deletions by fluorescence in situ hybridization (17,51).

Several series of patients have been investigated for microdeletions at 16p13.3 (17,51,71,73,107,116), in which deletions could be demonstrated in approximately 15% of the cases, depending on the reliability of the clinical diagnosis. For an analysis of specific mutations, see Blough et al (12a). No major differences were found in patients with and without deletion, with the possible exception that more frequent microcephaly and angulated halluces were noted in those with the deletion (51,107). The empiric recurrence risk for sibs was calculated to be 0.1% (47).

Eventually, Petrij et al (82) described mutations in two patients in the transcription cofactor CBP (CREB binding protein), making the Rubinstein-Taybi syndrome a haplo-insufficiency disorder. The mechanism by which decreased CBP levels affect pattern formation is unclear. In Drosophila, CBP was shown to be a cofactor in the hedgehog signaling pathway (1), which may explain in part the pleiotropic effects of CBP. Five cosmids may be used for detection of microdeletion (82a).

Systemic manifestations. Natural history has been well documented (48,105). Various findings are listed in Table 10–8. Polyhydramnios has been reported in 30%. Two patients have been described with both an aged appearance and a meningioma (11,48).

Growth. Length, weight, and head circumference at birth are between the 25th and 50th centiles. Average birth length is 49 cm, with a range of 43.9–53.3 cm. Average birth weight is 31 kg, with a range of 2.05–4.28 kg. Mean head circumference is 34.2 cm (males) and 32.2 cm (females), with a range of 29–38 cm (106). Often there is poor weight gain during infancy (106). Males are often overweight for height during childhood, while females are overweight during adolescence.

Values for final height attainment for males are 153.1 cm and for females 146.7 cm (106). Mean head circumference at adulthood is 54.7 cm (males) and 52.4 cm (females)(3).

Performance and central nervous system. Global mental deficiency is characteristic with the most severe delay in expressive speech (50). The average IQ has been reported to be 51 (range 33–72) (n = 37) (48) or 36 (range 25–79) (n = 40) (50). Affected individuals tend to be loving and friendly, although maladaptive behavior has also

Based on CA Stevens et al, Am J Med Genet 72:188, 1997; RCM Hennekam and JM Van Doorne, Am J Med Genet Suppl 6:42, 1990; and RCM Hennekam et al, Am J Med Genet 6:17, 1990.

been noted. Persistence is low. A specific behavioral phenotype has been described (50). Despite their limited verbal abilities, the communicative level is good.

Electroencephalographic abnormalities, seizures, absence of corpus callosum, and hyperactive deep-tendon reflexes have been noted (39,48,87,93,105). Rarely, other abnormalities such as Dandy-Walker anomaly (7,14) and myelinization defects (84) are found.

Craniofacial features. The facial appearance is striking, with microcephaly, prominent forehead, down-slanting palpebral fissures, epicanthal folds, strabismus, broad nasal bridge, beaked nose with the nasal septum extending below the alae, highly arched palate, and mild micrognathia (Fig. 10–17). The features are recognizable in the newborn. Facial changes with time have been studied by Allanson (2) and Hennekam (43,48). Grimacing or unusual smile has been observed frequently. Other findings may include long eyelashes, nasolacrimal duct obstruction, ptosis of eyelids, congenital or juvenile glaucoma, refractive error, and minor abnormalities in shape, position, and degree of rotation of ears (9,12,14, 16,18,26,29,39,48,62,67,69,78,92,93,114). Van Genderen et al (114) described an abnormal waveform of Visual Evoked Potentials, and cone or cone–rod dysfunction on electroretinography. Low-frequency abnormalities have included bifid uvula, submucous palatal cleft, bifid tongue, macroglossia, short lingual frenum, natal teeth, and thin upper lip (44,92, 95,105). Talon cusps (markedly enlarged cingulum on maxillary incisor teeth) have been observed in over 90% (32,44,62) (Fig. 10–20), necessitating specific dental care (20,44). Talon cusps are found in 1% of the normal population. Cephalometric studies (49) and objective evaluation of craniofacial structures (4) are available.

Hands and feet. Broad thumbs and great toes have been present in almost all reported cases. In most instances, the terminal phalanges of the fingers are also broad. Persistent fetal pads are common. Clinodactyly of fifth fingers and overlapping of toes are present in over half the cases. Angulation deformities of the thumbs and halluces, together with abnormally shaped proximal phalanges, occur in approximately 35% (48,92, 105,118). Abnormally shaped first metatarsals and duplication of the proximal or distal phalanx of the halluces have also been reported. Rarely, postaxial polydactyly of the feet, partial cutaneous syndactyly involving the toes, and absence of the distal phalanx of the hallux have been noted (18,26,48,92,93,105,110) (Figs. 10–18 and 10–19). There is no description of a proven case with preaxial polydactyly. The metacarpophalangeal pattern profile may be specific (46).

Alterations in the frequency of various fingerprint patterns have been observed, but findings have been inconsistent (5,26,36,53,87,92,93).

Skeletal system. Growth retardation and delayed bone age are common. Large anterior fontanel or delay in closure, large foramen magnum, and parietal foramens have been reported in some cases. Other skeletal anomalies have included pectus excavatum, other sternal abnormalities, rib defects, scoliosis, kyphosis, lordosis, spina bifida, flat acetabular angles, slipped capital femoral epiphysis (15), flaring of ilia, and notched ischia (48,92). Various other low-frequency anomalies have been discussed by Rubinstein (92), Robson (88), and Hennekam (48).

The gait is commonly stiff. Hypotonia, lax ligaments, increased fracture frequency, and hyperextensible joints have also been noted (92). Patellar dislocation can be bothersome (48,76,103). Several pubertal patients have severe aseptic hip joint inflammations (RCM Hennekam, personal observation). A tethered cord has been described (90).

Fig. 10–20. *Rubinstein-Taybi syndrome*. Talon cusps of four maxillary permanent incisors, marked distal marginal ridge on left lateral incisor. (From DG Gardner and SS Girgis, Oral Surg 47:519, 1979.)

Genitourinary system. Probably all male patients have incomplete or delayed descent of the testes. Anomalies of the urinary tract, including duplication of the kidney and ureter, renal agenesis, nephrotic syndrome, and other abnormalities, have been recorded in a number of cases (34,48,108,115). Urinary tract infections occur in approximately 20%–25% (48,105). Rarely, angulated penis and hypospadias have been noted (48,92).

Other findings. A variety of congenital heart defects have been found in approximately 35% (104). Abnormal lung lobulation, supernumerary nipples, nevus flammeus of the forehead, nape, or back (60%), hirsutism (75%), and other abnormalities have been described (18,20,48,57,92,105). Supernumerary nipples are found in 15% (19). Precocious puberty has also been noted (54a). Multiple pilomatrixomas have been reported (19,72,75). Herranz et al (52) reported a patient with piebaldism. An increased tumor risk (75), such as nasopharyngeal rhabdomyosarcoma (102), intraspinal neurilemoma (94), neuroblastoma (54a,75), pheochromocytoma (13), angioblastic meningioma (11,48,RCM Hennekam, unpublished observation), and acute leukemia (58), has been recognized (75). Keloids or hypertrophic scarring has been described in 5%–20% (37,48,89,98,105). Gastroesophageal reflux (38) and megacolon (39,48) are rarely found. Other rare complications are thymus hypoplasia (61), IgA deficiency and other immunologic disorders (48,115a), bifid uterus and menstruation problems (66), migraine (48,105), branchial arch anomalies (48), and ankyloblepharon filiforme adnatum (48,108).

Obstructive sleep apnea may cause considerable problems (24,48,119). In a single report, cardiac arrhythmias due to neuromuscular blocking agents (succinylcholine) were described (105). Another anaesthetic problem may be difficulties in intubation due to easy collapsibility of the laryngeal walls (22,48). Fryns et al (28) observed that maternal serum screening tests may be positive in pregnancies with the entity.

Differential diagnosis. Although many components of the syndrome may occur as isolated findings or as features of various other syndromes, the overall pattern of anomalies is sufficiently distinctive to permit diagnosis in most instances. The authors have seen numerous patients who have exhibited only some of the stigmata of the Rubinstein-Taybi syndrome (47,92). Some may represent incomplete forms. Differential diagnosis can be a problem in the newborn period. Occasionally, some cases have been confused with de *Lange syndrome* (64), *Saethre-Chotzen syndrome* (68), or with *trisomy 13* (117). Broad thumbs may be observed in *Apert syndrome* and *Pfeiffer syndrome*, and short thumbs and fingers are seen in Type D brachydactyly. Cotsirilos et al (21) reported a mother and two sibs affected with a Rubinstein-Taybi–like disorder. Six other relatives of the mother were reported to have broad thumbs and halluces. The family with broad thumbs and mental deficiency reported by Robinow (86) probably represents a separate entity. Prieto syndrome has a similar facies but X-linked inheritance (86).

Seckel syndrome and other microcephalic primordial dwarfisms

Seckel syndrome. Seckel syndrome is characterized by marked intrauterine and postnatal growth retardation, microcephaly, mental retardation, and typical facial appearance with a beaklike protruding nose (Figs. 10–21 and 10–22). In the past, the condition has been overdiagnosed (41,81). Of Seckel's two original patients (68), only case 1 fits the proper diagnostic criteria. Seckel syndrome is compared to the other major forms of microcephalic primordial dwarfism in Table 10–9.

Fig. 10–21. *Seckel syndrome*. Proportionate short stature, microcephaly, curved nose, and small mandible in two affected sibs. (From B Boscherini et al, Eur J Pediatr 137:237, 1981.)

Fig. 10–22. *Seckel syndrome*. Characteristic facies, with small head circumference and micrognathia, lending prominence to the midface. (Courtesy of JJ Sauk, Baltimore, Maryland.)

Table 10–9. Major manifestations of Seckel syndrome compared to those in osteodysplastic primordial dwarfism

	Seckel Syndrome	OPD I	OPD II
Prenatal growth retardation	+++	21/21	17/17
Postnatal growth retardation	+++	11/11	17/17
Moderate/severe MR	+++	10/10	15/16
Microcephaly	+++	21/21	16/17
Sparse/absent scalp hair	−	14/15	5/14
Small anterior fontanel	++	18/18	4/9
Receding forehead	+++	14/15	7/12
Prominent eyes	++	21/21	6/14
Blepharophimosis	++	0/10	3/11
Prominent nose	+++	16/17	15/16
Teeth anomalies	++	2/2	2/8
Micrognathia	+++	16/18	16/17
Dysplastic, low-set ears	+++	12/13	9/13
Short neck	−	14/15	4/11
Relatively large hands/feet	−	7/10	0/12
Short fingers	+	14/14	6/8
Hyperkeratosis	−	10/12	0/9
Dislocations	++	9/11	1/14
Contractures	+	7/12	1/13
Delayed osseous maturation	+++	19/19	16/16
Disproportionate short long bones	−	13/14	15/17
Bowed long bones	−	9/13	2/13
Brachymesophalangy	−	5/8	12/14
Brachymetacarpy I	−	5/7	4/9
Pelvis anomalies	+/−	17/17	9/14

Key: +++, 75–100; ++ 50–75; + 25–50; +/− 25 or less; −, absent.

Adapted from RCM Hennekam and K De Geest, Dysmorphol Clin Genet 3:39, 1989; S Sigaudy et al, Am J Med Genet 80:16, 1998; and F Majewski and T Goecke, Am J Med Genet 80:25, 1998.

From the literature, only 30 cases qualify as examples of Seckel syndrome [2 (case 1),3,7 (case 1–2),9,12,13,17,27,28,35,37 (case 2),44, 50,59 (case 2),63 65,68 (case 1),69,75,77,78,82 (case 1–3)]. The male-to-female sex ratio is equal, and both sexes are equally severely affected. All parents have been normal. Consanguinity has been described in two Yemeni Arab families (36,69). Affected sibs have been reported by eight authors (3,7,13,27,36,63,69,82). The syndrome has autosomal recessive inheritance. Courtens et al (16) reported a boy with a Seckel-like phenotype and interstitial deletion of 2q33.3q34. Another family maps to 3q22.1–q24 (24). A great many cases from the literature do not qualify as examples of Seckel syndrome [6,7 (case 3),10,14,20,21–24,29,40,42,53,57,59 (case 1,3),60,61,66,68 (case 2–4,6–15),72,73,82 (case 4,5),84,92].

Growth and development. Striking features of Seckel syndrome are listed in Table 10–9. Mean birth weight of affected newborns at term is approximately 1540 g (range 1000–2055 g). Postnatal growth deficiency is, on average, 7.1 SD below the mean, with a range of −5.1 to −13.5 SD. Head circumference is as retarded as height in half the cases; in the remaining instances, head circumference is the singularly most retarded parameter. All patients are mentally retarded, with half having an IQ below 50. Moderate mental deficiency has been observed in some instances (44).

In addition to delayed osseous maturation, the phalanges exhibit ivory epiphyses and cone-shaped epiphysis in the proximal phalanges. The carpal bones are relatively small, and disharmony occurs in maturation between the carpals and phalanges (62).

Craniofacial features. Craniofacial features are striking, with severe microcephaly, receding forehead, relatively large eyes, and micrognathia, lending prominence to the midface and curved nose (Fig. 10–22). Synostosis of cranial sutures occurs in approximately 50%. Other craniofacial features may include facial asymmetry, down-slanting palpebral fissures, lobeless ears, highly arched or cleft palate, enamel hypoplasia, crowded teeth, and class II malocclusion (27,44,82). Bilateral optic atrophy and tapetoretinal degeneration and mild nerve deafness have been reported (36).

Other findings. Limb anomalies include clinodactyly of fifth finger, abnormal finger flexion creases, dislocation of radial head, and hip dysplasia. Other findings may include cryptorchidism, clitoromegaly, hypospadias, and hirsutism (44,69). Case 1 of Sugio et al (76) had hydronephrosis. Butler et al (12) reported pancytopenia in one patient and chromosome instability in two; other reported hematologic anomalies were increased sister chromatid exchange (13) and acute myeloid leukemia (28). Woods et al (90) reported a patient with Seckel-like features, who showed an increased mitomycin C sensitivity. Central nervous system anomalies included agenesis of the callosal body, hypoplasia of the cerebellar vermis or complete cerebellum, pachygyria, large basal ganglia, and arachnoidal cysts (36,69,76).

Findings not previously emphasized have been discussed by Thompson and Pembrey (82).

Osteodysplastic primordial dwarfism. In a series of papers, Majewski and coworkers suggested a subdivision of the other forms of microcephalic primordial dwarfism in three types (44–48). Later, it appeared that types I and III were, in fact, identical (25,43,89). Majewski (43) proposed to reclassify type III, and to designate the form of dwarfism present in Caroline Crachami (8), two German sibs, and possibly several patients from the ancient literature (43) as such.

Osteodysplastic primordial dwarfism (OPD) type I (formerly termed types I and III, and also called Taybi-Linder syndrome) has been described in approximately 30 cases (4,5,21,25,35,47,48,51,54,55,71,80, 81,87a,89); we are uncertain about the diagnosis in one case [2 (case 1)] due to insufficiency of data.

The disorder was comprehensively reviewed by Sigaudy et al (71). The major characteristics that separate type I osteodysplastic primordial

D

Fig. 10–23. *Microcephalic primordial dwarfism (osteodysplastic type I).* (A) Microcephaly, hypotrichosis, prominent eyes, large fleshy nose, small dysplastic ears, and micrognathia. (B) Radiograph showing microcephaly, steep skull base. (C) Radiograph showing shortened humeri, bilateral dislocation at elbows, short metacarpals, absence of secondary ossification centers in humeral heads, carpals, and capitellum. (D) Hypoplasia of lower ilia, widened iliac angle, lateral bending of femoras, absent epiphyses at knees. [A courtesy of F Majewski and J Spranger, Mainz, Germany. B courtesy of HN Bass and RS Sparkes, Los Angeles, California. C,D from HN Bass, Syndrome Ident 3(2):12, 1975.]

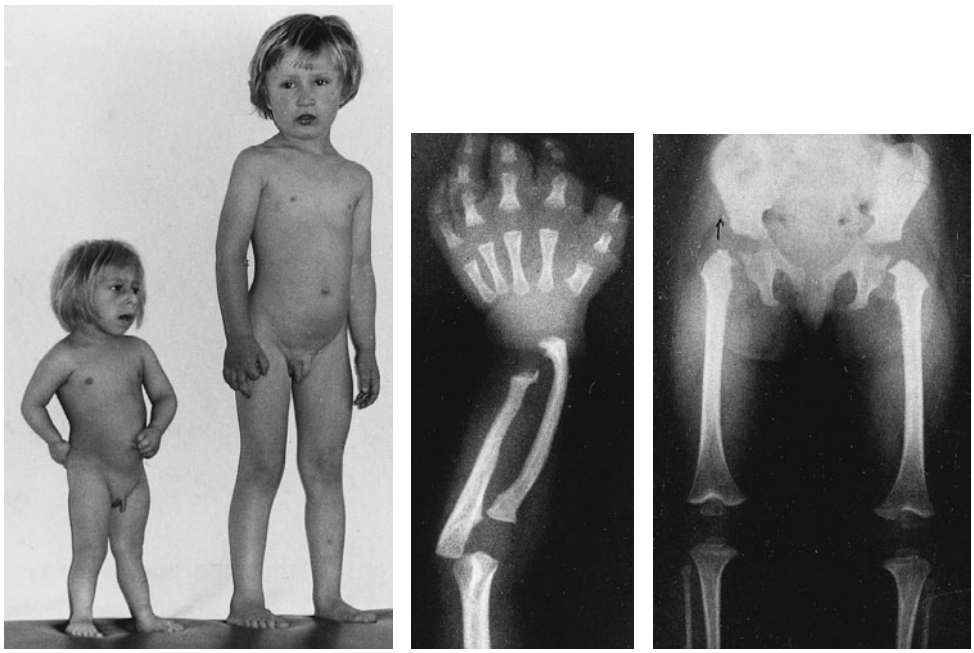
dwarfism from Seckel syndrome are the sparse or absent scalp hair, low-set ears, short neck, relatively large hands and feet, and hyperkeratosis (Fig. 10–23 and Table 10–9). Malformations of the central nervous system have included brain dysgenesis, pachygyria, heterotopias, agenesis of corpus callosum or cerebellar vermis, and hypoplastic frontal lobes (25,38,54,55,71,80,81,89), which are similar to the brain findings in Seckel syndrome. Other anomalies have included neonatal cholestasis (5), tetralogy of Fallot (46), atrial septal defect and coarctation of aorta (71), and renal tubular leakage (21), focal medullary hypoplasia (5), renal cysts (71), or renal hypoplasia (71).

Radiographic features have included delayed osseous maturation, generalized shortening of long bones that are often bowed and show enlarged metaphyses, and pelvic anomalies (hypoplasia of iliac wings and acetabulae; horizontal acetabular fossae). The clavicles may be elongated, and some platyspondyly has been described (48,89). One patient had multiple fractures (5), at least in part due to renal problems. Type I has autosomal recessive inheritance (71). Prenatal diagnosis has been accomplished (71).

Type II has been reported 18 times [1,2 (case 2),10,26,31,44,45,47,48, 52,70,74,87,88]. Masuno et al (52) and Majewski and Goecke (45) provided an overview. Besides pre- and postnatal failure, microcephaly, moderate developmental delay, except in one case (26), and facial features, type II has been characterized by somewhat sparse scalp hair (but less expressed compared to type I), disproportionately short forearms and legs that were generally not bowed, brachymesophalangy, brachymetacarpy I, metacarpal pseudoepiphyses, V-shaped flaring of distal femoral metaphyses, and high, narrow pelvis, proximal femoral epiphysiolysis and coxa vara (Fig. 10–24). Internal malformations are uncommon, and have included hypospadias (74) and partial callosal body agenesis (74). Consanguinity in 6 of 10 parents (1,45,70,87,88), affected sibs (87), and equal number of affected males and females, all point to autosomal recessive inheritance.

Several other patients with microcephalic osteodysplastic dwarfism have been described that we are unable to classify further (11,15,21,29, 31,32,41,44,49,64,83,91).

Differential diagnosis. The craniofacial features of Seckel syndrome allow differentiation from other syndromes of growth deficiency with microcephaly such as *Dubowitz syndrome, fetal alcohol syndrome, trisomy 18, de Lange syndrome, Bloom syndrome, Nijmegen breakage syndrome*, and Fanconi syndrome. The sibs with microcephaly, cataracts, spasticity, kyphoscoliosis, and severe mental retardation described by Scott-Emuakpor et al (67) and later called CAM(F)AK syndrome (79) probably had early-onset *Cockayne syndrome* (75). Mutchinick (58)



A B C

Fig. 10–24. *Microcephalic primordial dwarfism (osteodysplastic type II).* (A) Patient next to age-matched control child. In addition to mental retardation, marked growth retardation, microcephaly, small forehead, moderately prominent nose, and micrognathia. (B) Note disproportionate shortness of forearms, brachymesophalangy, brachmetacarpy I. (C) Observe V-shaped flare of distal femoral metaphyses, triangular distal femoral epiphyses, proximal femoral epiphysiolysis, and coxa vara. (From F Majewski et al, Am J Med Genet 12:23, 1982.)

described two sisters with microcephaly, postnatal growth retardation, mental retardation, speech delay, and facial dysmorphia. The entity was later confirmed in three brothers (19), one of whom had, in addition, internal hydrocephaly, atrial septal defect, situs abdominalis inversus, and biliary duct agenesis. It has been called Mutchinick syndrome.

Silver-Russell syndrome

The syndrome of short stature of prenatal onset, triangular facies, body asymmetry, variation in pattern of sexual development, café-au-lait pigmentation, and clinodactyly of fifth fingers (Figs. 10–25 to 10–27) was independently described by Silver (59) in 1953 and by Russell (53) in 1954. Most authors regard the Silver-Russell syndrome as a single entity (22,27,38,51,63), although some have argued that it is not clearly separable from low-birth-weight infants (63). Donnai et al (16) described a more severe form. A survey of 368 cases is that of Wollmann et al (67).

The etiology is unknown and is probably heterogeneous. Syndrome heterogeneity has been discussed by several authors (43,54,61). More than 500 cases, in all racial groups, have been reported (18,35,38,

Fig. 10–25. *Silver-Russell syndrome*. (A–C) Proportionate short stature. Note leg asymmetry and similar facies. (A from G Schumacher and H Niederhoff, Helv Paediatr Acta 22:404, 1967. B,C from RH Haslam et al, Pediatrics 51:216, 1973.)

Fig. 10–26. *Silver-Russell syndrome*. Normal-sized cranium with disproportionately small facial bones. Note downturned angles of mouth. (Courtesy of A Russell, London, England.)

44,51,67). Most have been sporadic, but familial occurrence has been noted (18). In several instances, the mother was stated to be short or showed other minimal signs (10,22,35,43). Autosomal dominant inheritance with most cases representing fresh mutations is possible (2,18). However, approximately 7%–16% exhibit maternal uniparental disomy for chromosome 7q31-qter (6,20,28,29,34,45–47,68); uniparental disomy for chromosomes 2,7,8,11,14,16, and 20 was not found (4,20). Insulinlike growth factor 1 receptor (TGF1R) was thought to be a likely candidate gene on chromosome 7, but in 33 patients biallelic expression was found (1,24,62). Miyoshi et al (37) suggested that one of the maternally expressed genes (MEG1) is apparently identical to growth factor receptor-bound protein 10 (GRB10), which is homologous to human chromosome 7p11.2 (37a,64a). GRB10 binds to the insulin receptor and to IGF1R, and inhibits its growth-promoting activities. Eggerman et al (21) found a paternally inherited deletion of the chorionic somatomammotrophin hormone 1 (CSH1) gene, which maps to 17q22–24, in one patient with Silver-Russell syndrome. Although deletions of GSH1 without phenotypic consequences have been described, the role of a heterozygous deletion in the entity was considered possible.

Concordant monozygotic twins (50) and dizygotic twins (58) have been documented as well as discordant monozygotic twins (5,40,55). Autosomal recessive inheritance has been suggested in a Yemenite Arab family (64). The sibs described by Fuleihan et al (25) probably had 3-M syndrome, and the sibs reported by Schwingshackl et al (56) appears to have had Bloom syndrome. Our collective experience suggests that the diagnosis is overused.

More than 10 cases with a chromosomal anomaly involving mosaicism for trisomy 18 (12,29,31), del (18p) syndrome (13), diploid-triploid mosaicism, ring chromosome 15 (9,24,32,51,62,66), and two apparently balanced translocations involving 17q25 (36,48) and a Silver-Russell–like phenotype have been reported.

Fig. 10–27. *Silver-Russell syndrome*. Clinodactyly of fifth fingers. (Courtesy of A Russell, London, England.)

Growth. Mean birth weight is 1940 ± 353 g in males and 1897 ± 325 g in females at full term, and birth length is approximately 43.1 ± 3.7 cm (67). The placenta is small. Short stature is maintained throughout childhood, height usually being below the third centile. Adult height averages 151.2 cm in males and 140 cm in females, or approximately −4.3 SD (15,27,44,50,63,67). Females seem to gain some subcutaneous fat after puberty (15).

Facies. The facies is characterized by pseudohydrocephaly due to relative smallness of the face (Figs. 10–25 and 10–26). The calvaria, while appearing large, is really somewhat smaller than normal (23,33). The forehead is prominent or bossed and the face triangular, with the chin small and pointed in approximately 65% (22). The sclerae may be bluish in infancy (35). The eyes seem large (44). In one case, marked asymmetry of the optic nerve was found (57).The mouth appears wide and the corners are often turned downward. The upper lip vermilion is thin. The pinnae may protrude. Appearance becomes markedly less striking with age.

Musculoskeletal system. Congenital asymmetry has been noted in 65%–80% (22) (Fig. 10–25). Although occasionally total, it may involve only the head, trunk, or limbs. Rarely, asymmetry becomes evident only with growth (58). Poor muscular development and delay in early gross motor performance are common.

Delayed closure of the anterior fontanel is found in 20% (22,27). Occasionally, there is hip or elbow dislocation. The fifth fingers are abbreviated and exhibit clinodactyly in over 75% (53,63) (Fig. 10–27).

Radiographically, bone age is retarded in relation to both sexual development and chronological age until puberty in 50% (27,30,63). The long bones tend to be slender. The humerus is somewhat shortened in 20% (22). Hypoplasia of the middle phalanges of the fifth fingers is evident in 80%. Pseudoepiphyses are found more often at the base of the second metacarpal than in the normal population (63), and frequently there are distal phalangeal ivory epiphyses (30). Soft-tissue syndactyly between the second and third toes is seen in approximately 20% (22). The total and posterior cranial base are reduced in length (33).

Urogenital anomalies. Variation is sexual development has been found in over 30% (58), but there is usually normal puberty (63). Cryptorchidism and/or hypospadias are present in over 35% of males (16,35,48,52,58,65). Females have exhibited premature estrogenation of the urethral or vaginal mucosa in approximately 25% (22). Ambiguous genitalia have also been reported (26,28,35). Renal and/or ureteral anomalies such as hydronephrosis, ureteropelvic obstruction, pyelonephritis with reflux, renal tubular acidosis, and enlarged kidneys have been found (3,29,60).

Other findings. Café-au-lait spots have been noted in approximately 25% (22). Hyperhidrosis and tachypnea are frequent findings in the neonatal period due to hypoglycemia (23,27,43). Dermatoglyphics are not specific (7). Mild developmental delay or mental retardation has been reported in approximately 35% (22,64). Testicular cancer, hepatocellular carcinoma, testicular seminoma, and craniopharyngioma have been reported (8,13,17,65).

Oral manifestations. Downturned corners of the mouth have been noted in over 60% (58). The maxilla and mandible are small, the palate is high and narrow, and the teeth are crowded and may show enamel defects (33).

Differential diagnosis. Silver-Russell syndrome is one of a large group of conditions categorized as "intrauterine growth retardation" or "low-birth-weight dwarfism." Differential diagnosis includes a plethora of conditions with short stature and precocious sexual development (58). To be excluded are *mulibrey nanism*, an autosomal recessive disorder associated with pericardial constriction and characteristic eye findings, and *3-M syndrome*, another autosomal recessive condition. An X-linked disorder of short stature with skin pigmentation has also been described (43). The authors suggested that other examples may be of this type (10,22,25).

Café-au-lait pigmentation and/or body asymmetry may be seen with *neurofibromatosis, hemihyperplasia (hemihypertrophy), McCune-Albright syndrome, Klippel-Trenaunay syndrome, Proteus syndrome*, and several chromosome anomalies.

Laboratory findings. Urinary gonadotropin levels have been elevated in approximately 10% (14,58,60). Hypoglycemia following short periods of fasting has been described (22,27,28), and growth hormone deficiency has been reported in a few cases (17,19,28,39,41). Cassidy et al (11) and Okabe and Ueda (42) have discussed hypopituitarism in the syndrome.

3-M syndrome

Although first described by Fuhrmann et al (5) in 1972, Miller et al (11), in 1975, rediscovered this distinct type of low-birth-weight proportionate dwarfism and named the syndrome after the initials of the first three authors of the paper. Spranger et al (15) independently observed the same condition. Additional cases have been reported (3,6–8,12–14,16,17). Hennekam et al (8) reported three affected sibs and reviewed the findings in previously recorded cases. To date there have been approximately 30 examples noted.

Inheritance is autosomal recessive. Presumably heterozygotes have thinner bones and a prominent talus (7) and may show some facial characteristics (8). A preliminary report mentioned a decreased production of collagen type III (9).

Low birth weight at full term and proportionate small size characterize the disorder. Dolichocephaly and triangular facies are evident (Figs. 10–28 to 10–30). The malar region is flat, the ears outstanding, the lips patulous, and the chin pointed and prominent. The dental arch is V-shaped with malocclusion and anterior crowding. Frontal bossing and short broad neck with prominent trapezius muscles are evident. The shoulders are square and high, and the thorax short. Pectus carinatum or

Fig. 10–28. *3-M syndrome*. Low-birth-weight proportionate dwarfism in 4- and 15-year-old sibs. Note triangular face, outstanding pinnae, patulous lips, pointed outstanding chin. (From J Spranger, Eur J Pediatr 123:115, 1976.)

Fig. 10–29. *3-M syndrome*. Note flattened malar region, upturned nares, long philtrum and full lips. (From RCM Hennekam et al, Am J Med Genet 28:195, 1987).

excavatum is common and there may be transverse grooves above the costal margins. The scapulae are winged, the joints are hyperextensible, and the fifth fingers are short. Recurrent dislocations and fractures have been described (8), as were gonadal fusion and hypospadias (17). In a single case, intracerebral aneurysms have been present (12), but these were not found in others (9).

Radiographically, the bones are slender, especially the diaphyses. This becomes more prominent with age. The vertebral bodies are tall (3,13). The pubic and ischial bones are small, the iliac wings flared, the femoral neck short, and the talus prominent (Figs. 10–31 to 10–33). Bone age is slightly delayed.

Fig. 10–30. *3-M syndrome*. Marked dolichocephaly. (From RM Winter et al, J Med Genet 21:124, 1984.)

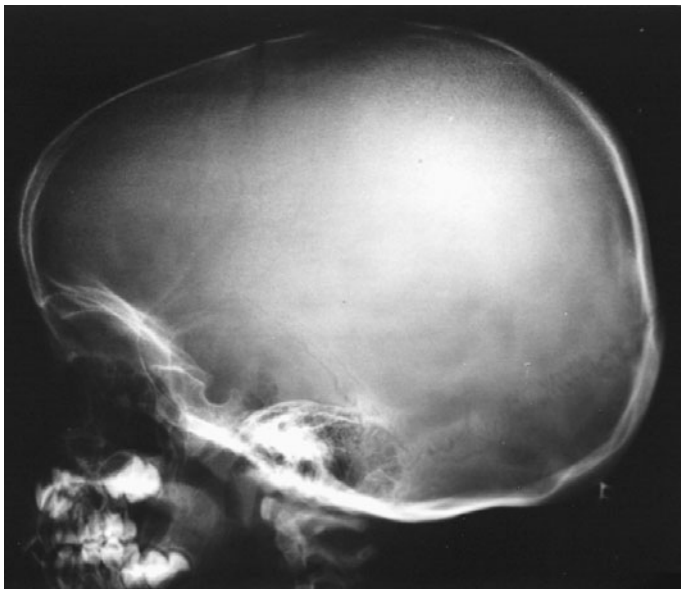

Fig. 10–31. *3-M syndrome*. Narrow long bones with overconstriction of diaphyses and metaphyseal flaring. (From RM Winter et al, J Med Genet 21:124, 1984.)

Several patients with 3M-syndrome have been erroneously labeled as having *Silver-Russell syndrome* (6). Body asymmetry is not seen in 3-M syndrome. Furthermore, there is no altered pattern of sexual development, craniofacial disproportion (pseudohydrocephaly), or delayed closure of the anterior fontanel. Height is shorter than in those with Silver-Russell syndrome (14). The facies somewhat resembles that seen in *Bloom syndrome*, and the two conditions have been confused (13). Gracile bones are frequently found in any abnormality in which fetal hypokinesia is found. Le Merrer et al (10) delineated an autosomal recessive syndrome, similar to 3-M syndrome, which can be differentiated by a round face

Fig. 10–32. *3-M syndrome*. Tall vertebral bodies. (From RM Winter et al, J Med Genet 21:124, 1984.)

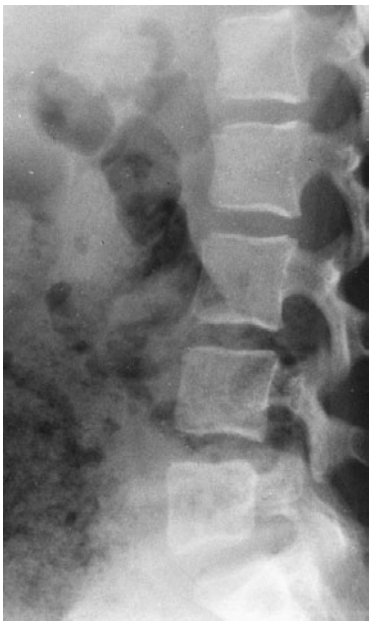

Fig. 10–33. *3-M syndrome*. Vertical talus with prominent calcaneus. (From RM Winter et al, J Med Genet 21:124, 1984.)

and full lips ("gloomy face") and absence of any radiologic abnormality. Several cases described as having the 3-M syndrome [4,16 (3rd case),17 (4th case)] have been said to have dwarfism with *gloomy face*. Cameron et al (2) described a still-different entity in two sisters, who have a somewhat different face, no square shoulders or prominent heels, and with short, broad long bones, square iliac bones, short femoral necks, and narrowing of the interpedicular distance inferiorly. We cannot identify the disorder described by Callaghan (1). Also to be excluded is *mulibrey nanism*.

Prenatal diagnosis of 3-M has been noted (10a).

Fig. 10–34. *Mulibrey nanism.* (A–C) Three unrelated adolescent patients exhibiting similar facies. (From J Perheentupa et al, Lancet 2:351, 1973.)

Mulibrey nanism

Perheentupa et al (11), in 1973, described a form of prenatal growth retardation associated with anomalies of *MU*scle, *LI*ver, *BR*ain, and *EY*e, employing the mnemonic "mulibrey" (Figs. 10–34 to 10–36).

More than 40 patients have been described, most stemming from Finland (8,12) but also from Argentina, Canada, Egypt, France, Mexico, the Netherlands, Spain, and the United States (5,6). It should be considered as part of the differential diagnosis in children with short stature (17). The disorder has autosomal recessive inheritance. There is an increased risk for miscarriages (3). The gene for mulibrey nanism has been assigned to 17q22–q23 (1,10). The gene is a zinc finger transcription factor (1a). An exhaustive review is provided by Lapunzina et al (6).

Weight and length at birth are usually 1.5 to 2 SD below the mean. With time, growth becomes progressively retarded. Adult males vary from 136 to 161 cm; adult females range from 126 to 151 cm. Some have shown a good response on growth hormone supplementation (5,7). Patients may die in childhood from cardiac involvement or pulmonary infections, but most survive to adulthood without incapacity. A humeral immunodeficiency has been described (5).

Facies. The face is triangular and the forehead is prominent and high. The size relationship between skull and face resembles those seen normally in young infants. The nasal bridge is deep and broad (Fig. 10–34).

Fig. 10–35. *Mulibrey nanism*. Fluorescein angiogram of fundus showing conglomerate of dots and severe hypoplasia of choroid. (From J Perheentupa et al, Lancet 2:351, 1973.)

B

Fig. 10–36. *Mulibrey nanism.* (A) Typical skull radiograph at 1.4 years exhibiting abnormal cranial form, J-shaped sella, and increased basilar angle. (B) Fibrous dysplasia lesions of the tibia have been found in about 30%. (From J Perheentupa et al, Lancet 2:351, 1973).

Eyes. There is mild hypertelorism. Aggregation and dispersion of pigment in the midperiphery and more peripheral areas of the fundus, with yellow dots are characteristic (Fig. 10–35). Other findings are hypoplasia of the choroid (4), colobomata (8), and corneal dystrophy (13,16). The optic discs, maculae, and the ERG are normal.

Heart. Thickened and adherent pericardium results in cardiac constriction in 35%, visible in prominent jugular veins, enlarged liver (6,11,18–20), and, in some cases, ascites with congestive heart failure (2,20). Radiographically, this gives the heart a globular shape.

The myocardium is usually normal, although myocardial fibrosis has been described (4,19).

Liver. The liver is enlarged, especially in the neonatal period, probably due to passive venous congestion, secondary to the constrictive pericarditis.

Central nervous system. Intelligence is normal. Some patients have dysarthria (9). Abnormal large ventricles can also be found (11).

Skin. Naevi flammei, found in half of the patients, are mostly located on the limbs (3).

Musculoskeletal system. The extremities are thin and short. About 70% are mildly hypotonic. Radiographically, bone age is normal. There are frequent absent or small frontal and sphenoidal sinuses (9) and J-shaped sella turcica. Fibrous dysplastic lesions of the tibia have been found in approximately 30% (4,19) (Fig. 10–36).

Miscellaneous findings. Wilms tumor has been reported in about 4% of patients (1a,14,15).

Oral manifestations. Dental malocclusion has been noted in approximately 40% and hypodontia in approximately 20% (3,9). The tongue appears small (9). The voice is usually weak and high-pitched (3,4,9). In 30%, the paranasal sinuses are small.

Differential diagnosis. There is considerable overlap with *Silver-Russell syndrome*.

Chapter 11
Overgrowth Syndromes and Postnatal Onset Obesity Syndromes

Beckwith-Wiedemann syndrome [EMG (exomphalos-macroglossia-gigantism) syndrome]

In 1963, Beckwith (2) reported three cases of a newly recognized syndrome consisting of macroglossia, omphalocele, cytomegaly of adrenal cortex, hyperplasia of gonadal interstitial cells, renal medullary dysplasia, and hyperplastic visceromegaly (Figs. 11–1 to 11–5). Subsequently, Beckwith (3) enlarged his series of patients, noting postnatal somatic gigantism, mild microcephaly, and severe hypoglycemia. In 1964, Wiedemann (107) independently reported the syndrome in three sibs and observed a further component—a dome-shaped defect of the diaphragm. Other important contributions have been made by many investigators (5,6,8,9,13,18,30,35,38–48,54,55,66–70,73,76,81,88,90,101,108–110,113,115). Over 500 cases have been reported. The frequency has been estimated at 1 per 12,000 births (31,112). Exhaustive reviews have been published (14,15,28,29,31,33,44,73,79). The most recent update is that of Cohen (17). Early diagnosis of this striking condition alerts the clinician to the dual threat of hypoglycemia and possible neoplasia. Clinical and laboratory findings are listed in Table 11–1.

Etiology. The molecular aspects of the Beckwith-Wiedemann syndrome have been extensively studied by Weksberg and colleagues (56,57,105). The syndrome is caused by alterations in chromosome region 11p15, which is subject to imprinting (80,96). Particularly implicated are mutations in (CDKNIC) $p57^{KIP2}$ (approximately 5%) and biallelic expression of IGF2 (approximately 50%) (51). Other genes are also found in the 11p15 region: KVLQT1, HASH2, INS, and H19. It is possible that Beckwith-Wiedemann syndrome, with its pronounced variability in clinical expression, is caused by imbalance of growth-promoting and growth-inhibiting genes in the 11p15 region (16,17,40,52,56,57, 104,105). The proportion of cells with paternal uniparental disomy correlates with organ size (44a). Unbalanced translocation involving the area has been reported (32a).

Cases of Beckwith-Wiedemann syndrome can be classified on the basis of family history, karyotype, and molecular testing. Findings do not have to be mutually exclusive. Autosomal dominant pedigrees account for about 15% of cases and expression is almost always found in individuals born to female carriers (5,6,9,47,61,71,73,82). Paternal imprinting is involved (100). Karyotypes are normal in about 98% of patients. Paternally derived duplications and maternally derived translocations and inversions account for the other 2% of cases (65,95). Uniparental paternal disomy is present in about 10%–20% of patients (43). Female monozygotic twins have occurred with high frequency. Most have been discordant for the syndrome (12,53,60,74). Overexpression of IGF2 has been implicated in several subsets of Beckwith-Wiedemann patients: (*a*) those with paternal uniparental disomy; (*b*) those with somatic mosaicism for partial paternal isodisomy, which can explain some instances of hemihyperplasia; and (*c*) those with disruption of maternal imprinting with both paternal and maternal alleles active, which can explain patients with and without hemihyperplasia and even patients with crossed hemihyperplasia (87). There is anthropometric evidence of heterogeneity (70a). Embryonal tumors reported in Beckwith-Wiedemann syndrome (Wilms tumor, adrenal cortical carcinoma, hepatoblastoma, and rhabomyosarcoma) retain paternal alleles but lose heterozygosity, specifically maternal alleles (56,57,105).

Pathogenesis. Growth hormone production has been normal in patients with the Beckwith-Wiedemann syndrome (91). Because of endocrine cytomegaly, Beckwith (3) suggested that the fetal adrenal cortex is either overactive or underactive, with excess stimulation caused by a feedback mechanism similar to that found in adrenogenital syndrome. He further noted that the abnormalities observed in the hypophysis, gonads, islets of Langerhans, and paraganglia should be considered in evaluating the abnormal growth present in the syndrome and that altered placental endocrine physiology could conceivably play a role in producing many of the features found during the neonatal period.

The visceromegaly of the syndrome may possibly result in omphalocele and diaphragmatic eventration. Against this view is Beckwith's observation (personal communication, 1969) in affected premature cadavers that profound visceromegaly is absent as well as the absence of abdominal and diaphragmatic defects in other conditions with early, increased abdominal pressure, such as infantile polycystic disease, universal nephroblastomatosis, and low intestinal atresia.

Infant mortality. The infant death rate is approximately 20%, usually resulting from either congestive heart failure or severe malformations associated with the syndrome (79).

Growth. Polyhydramnios is frequent and the placenta tends to be about twice normal weight (106). This has led to the diagnosis of the syndrome using FISH technique (25). Average length for males at birth is above the 95th centile and growth throughout adolescence parallels the normal growth curve at or above the 95th centile. Average birth length for females is at the 75th centile and length increases to the 95th centile by 18 months. Female height then remains at or above the 95th centile throughout adolescence, again paralleling the normal growth curve (79,106). Gigantism is not always present at birth. Growth may even be subnormal for a few months, although somatic gigantism eventually results in most cases (3,33). Advanced bone age is usually present and there may be widening of the metaphyses and cortical thickening of long bones. Hemihyperplasia (hemihypertrophy) has been a feature in approximately 20% of cases (3,28,29,33,44,90,110).

Sippell et al (85) studied the growth of seven patients longitudinally. They found that growth velocity remained above the 90th centile up to 4–6 years of age. After puberty it was +2.5 SD, or about 13.2 cm greater than their parents' height. Bone age was markedly advanced, especially during the first 4 years. Weight was above the 90th–97th centile during infancy and early childhood and remained there, usually being appropriate or slightly subnormal for height, until adulthood. Three girls, however, reached and maintained the 50th centile during or after puberty. Spontaneous pubertal development occurred within normal limits.

Performance and central nervous system. Intelligence is usually normal (33), although mild to moderate retardation was a regular feature in Beckwith's series (3). Mild microcephaly has been an associated feature in some cases (3,18). In other cases, mental deficiency may be due, in part, to undetected hypoglycemic episodes during infancy. Seizures have been a feature in some instances.

Fig. 11–1. *Beckwith-Wiedemann syndrome.* Note large tongue and omphalocele. (From MW Moncrieff et al, Postgrad Med J 46:162, 1970.)

Craniofacial features. Macroglossia (Figs. 11–1 and 11–2) is very common at birth (70) but is not an obligatory feature of the syndrome, and it may not present until the first few months of life (11). Chronic alveolar hypoventilation has been reported secondary to macroglossia on occasion (88). Tongue biopsies have been normal. In some cases, macroglossia tends to regress, with gradual accommodation of the tongue to the oral cavity. At present, it is not known whether this is caused by enlargement of the oral cavity relative to the tongue, shrinkage of the tongue relative to the oral cavity, or a combination of both processes. Persistent macroglossia, seen in almost 100%, leads to anterior open-bite, and requires surgical intervention (34). Patients with the syndrome have also been observed to be prognathic. Is macroglossia directly responsible for the prognathic mandible? Some authors have noted cessation of prognathic growth following partial glossectomy. However, careful long-term studies of many patients are needed. It is conceivable that prognathism may reflect the generalized somatic gigantism that occurs in the syndrome. Further, is the prognathism a true mandibular prognathism, or is it relative to hypoplastic changes in the midface?

Facial nevus flammeus (Fig. 11–2A), a feature seen in 60%, tends to become less prominent during the first year of life. Ear lobe grooves (Fig. 11–3A) are very distinctive, consisting of slitlike linear indentations. Indented ear lesions on the posterior rim of the helix or concha (Fig. 11–3B) have been observed in 75% (47). Because of the rarity of these anomalies in the general population (1), they serve as valuable diagnostic signs of the Beckwith-Wiedemann syndrome when they are present. Mild microcephaly has been a feature of some cases (3,18). Cleft palate or submucous cleft palate has been noted in 3% (23,93). Various other low-frequency anomalies of the head and neck are listed under *Other abnormalities*.

Visceromegaly. Omphalocele (Fig. 11–1) or umbilical hernia or diastasis recti are noted in 75%. Omphalocele is especially frequent with CDKNIC mutations (51). Malrotation anomalies may be a feature. In considering the visceromegaly noted in the syndrome, hepatomegaly and nephromegaly occur in about 60%, but cardiomegaly is found in no more than 15%. Pancreatomegaly has been a feature of autopsied

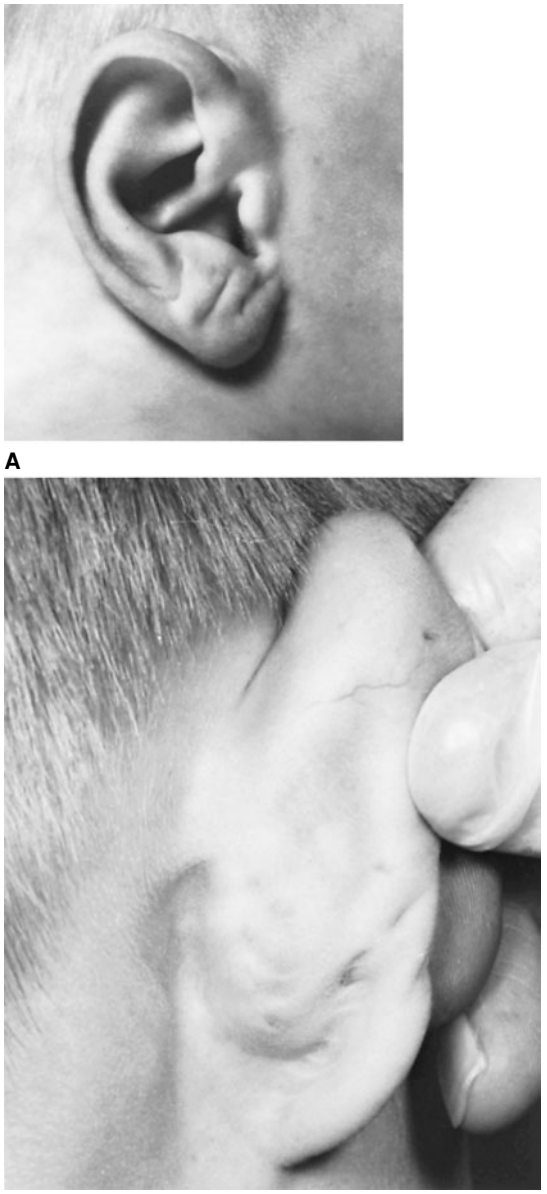

Fig. 11–3. *Beckwith-Wiedemann syndrome.* (A) Linear grooves on earlobe. (B) Punched-out depressions of posterior pinna. (A from H-R Wiedemann, Z Kinderheilkd 106:171, 1969.)

cases. Medullary sponge kidney has been observed on occasion (4). Genital overgrowth has been noted in some instances. Hyperplastic bladder, uterus, and thymus have also been reported (3,44,69,101,107). A dome-shaped defect of the diaphragm (Fig. 11–4) has been seen in a number of cases. In this defect, the posterior part of the diaphragmatic leaf is elevated.

Histopathology. The histopathologic features of the syndrome reflect the visceromegaly observed grossly. In the pancreas, hyperplastic changes are evident in the acini, islets, and ducts. In the kidney, the lobular arrangement is disordered. Each lobule is capped by a wide, persistent nephrogenic activity zone. Medullary dysplasia is evident with most pyramids showing an increased amount of stroma. Cytomegaly of the fetal adrenal cortex (Fig. 11–5) is prominent, the cells containing sudanophilic droplets. The adrenal cortex is cystic and the medulla is hyperplastic. In the pituitary gland, cells resembling amphophiles are increased in number. Gonadal interstitial cells are hyperplastic. The paraganglia are

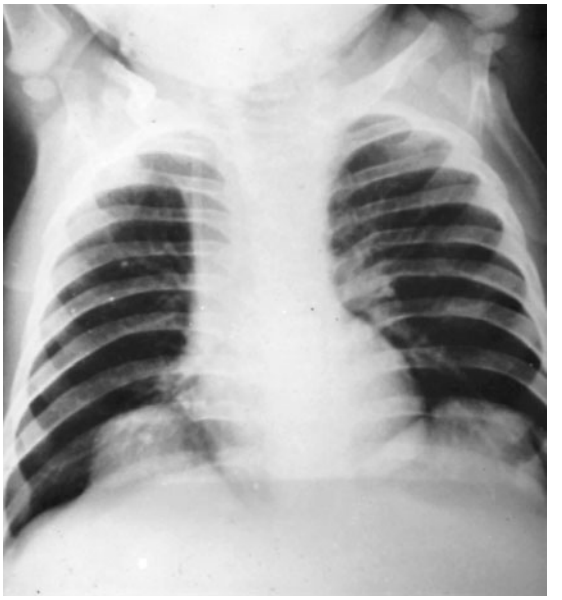

Fig. 11–4. *Beckwith-Wiedemann syndrome.* Bilateral diaphragmatic eventration (From I Irving, J Pediatr Surg 2:499, 1967.)

also hyperplastic (3). In some cases, both macroglossia and omphalocele are absent, but the visceral histologic lesions are florid (114).

Cardiovascular anomalies. Greenwood and associates (38) reported cardiovascular abnormalities in 12 of 13 patients. Seven had congenital heart defects, including ASD, VSD, PDA, hypoplastic left heart, and tetralogy of Fallot; the other five had idiopathic cardiomegaly.

Fig. 11–5. *Beckwith-Wiedemann syndrome.* Adrenocytomegaly. (From K Bech, Acta Pathol Microbiol Scand 79A:279, 1971.)

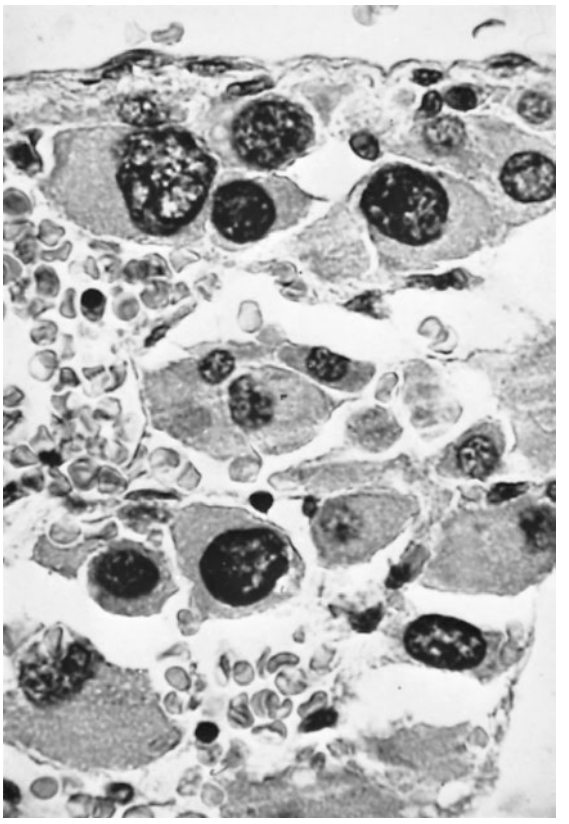

Table 11–1. *Beckwith-Wiedemann syndrome*[a]. Estimated frequencies of clinical and laboratory findings

[a]Frequencies estimated from 174 cases from the literature tabulated by C Sotelo-Avila et al, J Pediatr 96:47, 1980. See MJ Pettenati et al, Hum Genet 74:143, 1986 for different percentages. There is an obvious ascertainment bias in the frequencies of various findings from reported cases. On the one hand, the more severe cases are most likely to be reported. On the other hand, the presence or absence of various findings may be omitted from some reports.

[b]Includes maxillary hypoplasia, prominent occiput, flat nasal bridge, highly arched palate, frontal ridge, downslanting palpebral fissures, etc.

VSD was observed in three patients by Kosseff et al (48) and in five patients by Niikawa et al (73). ASD has been noted (73,81), as has coarctation of the aorta (6,45). Pulmonary artery stenosis was reported by Raine et al (81).

Other abnormalities. Polyhydramnios has been found in about 50% (106). Various low-frequency anomalies have been reported, including, among others, persistent anterior fontanel, prominent metopic ridge, meningomyelocele, malformed cerebellum, preauricular pits, cleft palate, conductive hearing loss from fixation of the stapes, accessory nipples, pectus excavatum, pectus carinatum, congenital hip dislocation, clinodactyly, postaxial polydactyly, pyloric stenosis, ileal stenosis, atresia of colon, imperforate anus, pyelocalyceal diverticula, other renal and ureteral malformations, prune belly, inguinal hernia, hypospadias, cryptorchidism, unicornuate uterus, and bicornuate uterus (6,7,18,21,44,45, 48,73,75,89,94). Wales et al (102) reported a premature Beckwith-Wiedemann infant who developed bronze baby syndrome when exposed to phototherapy.

Neoplasms. Wiedemann (110,112) noted that of 388 reported and personally observed cases, 29 developed a total of 32 neoplasms. Of these, 26 were intra-abdominal, 5 were extra-abdominal, and 1 was a malignant lymphoma, giving a total reported tumor percent of 7.5%. It is important to emphasize that reported cases of Beckwith-Wiedemann syndrome with neoplasia have an ascertainment bias that favors the reporting of cases with tumors; the true frequency of neoplasia may be lower. Although approximately 13% of patients have hemihyperplasia (hemihypertrophy) (90,110), 40% with neoplasia have hemihyperplasia (110). Thus, Beckwith-Wiedemann patients with hemihyperplasia have an increased risk for developing tumors.

Nephroblastoma is reported most commonly followed by adrenal cortical carcinoma, followed by hepatoblastoma. Other reported neoplasms have included malignant lymphoma, neuroblastoma, glioblastoma, renal cell carcinoma, rhabdomyosarcoma, pancreatoblastoma, gastric teratoma, adenoma of adrenal cortex, fibroma of the heart, umbilical myxoma, retroperitoneal ganglioneuroma, carcinoid tumor of the appendix, and fibroadenoma of the breast (10,26,30,32,59,79,81,86,90,110, 115,116). Tumors found with the syndrome are compared with tumors associated with hemihyperplasia (hemihypertrophy) and with Sotos syndrome in Table 11–2. Perhaps there is a common mechanism involving

[a]See text and references provided (From MM Cohen, Jr, Adv Hum Genet 18:181, 1989.)

[b]Not all cases of hemihypertrophy are part of the Beckwith-Wiedemann spectrum.

[c]Tumors occur with lower frequency in Sotos syndrome than with either Beckwith-Wiedemann syndrome or hemihyperplasia (hemihypertrophy).

[d]Most commonly observed neoplasms in descending order of frequency.

development of Beckwith-Wiedemann syndrome and embryonal tumors that represents somatic development of homozygosity for a mutant allele at a locus on chromosome 11 (49). Those with Wilms tumor do especially well when compared to those who have the tumor but not the syndrome (80a).

Prenatal diagnosis. Ultrasound monitoring of fetal size, organ size, and abdominal wall contour may be useful for families with a positive history of the syndrome. Weinstein and Anderson (103) noted increased amniotic fluid, bilateral cystic kidneys, and a larger-than-expected fetus at 20 weeks. Winter et al (113), using serial ultrasound monitoring, showed enlarged abdominal circumference and an omphalocele at 18 weeks. Omphalocele has also been detected by α-fetoprotein (15). Shapiro et al (84) detected a large placenta in a Beckwith-Wiedemann fetus by ultrasound.

Differential diagnosis. The facial features and large tongue may, at times, suggest a *mucopolysaccharidosis,* an *oligosaccharidosis,* or hypothyroidism. The combination of macroglossia and umbilical hernia can be seen in both *trisomy 21 syndrome* and hypothyroidism. The syndrome of macroglossia, intrauterine growth retardation, and transient neonatal diabetes mellitus has been discussed by Dacou-Voutetakis et al (20). Autosomal dominant inheritance of macroglossia has been observed (82). Omphalocele may occur alone or with a variety of associated anomalies and syndromes (14). Familial omphalocele (24,63) and familial gastroschisis and abdominal hernia (97) are also known to occur.

Perlman and others (36,37,42,58,72,77,78,82a) reported an autosomal recessive syndrome consisting of polyhydramnios, visceromegaly, macrosomia, macrocephaly, nephromegaly, hepatomegaly, renal hamartomas, nephroblastoma, and Wilms tumor in the absence of macroglossia, omphalocele, and hemihyperplasia. Wilms tumor and abnormal sexual differentiation occur in Drash syndrome (64).

In 1934, de Lange (22) described three children with a distinctive condition that bears some superficial resemblance to Beckwith-Wiedemann syndrome. Findings include congenital muscular hypertrophy, hypertrophy, hypertonia, and developmental retardation. Macroglossia and large ears were observed in two of the three patients, and overgrowth at birth was a feature in one instance. Autopsy findings in one case demonstrated polymicrogyria and a widespread porencephalic process.

Infants of diabetic mothers sometimes resemble infants with Beckwith-Wiedemann syndrome in being gigantic and hypoglycemic. Combs et al (18) have pointed out that newborn infants of diabetic mothers are overweight for their length, whereas Beckwith-Wiedemann syndrome patients are not. They further noted that the hypoglycemia seen in Beckwith-Wiedemann syndrome may persist beyond the immediate neonatal period, whereas the hypoglycemia found in infants of diabetic mothers occurs very early and is of brief duration. Infant giants represent a rarely encountered disorder in which gross macrosomia occurs without associated malformations. Overgrowth is based on prenatal hyperinsulinism that persists into postnatal life. A history of maternal diabetes is always negative and maternal glucose tolerance tests are always normal (14).

Sotelo-Avila and his coworkers (90) have noted that Beckwith-Wiedemann syndrome and hemihyperplasia (hemihypertrophy) are probably at either end of the same spectrum, intermediate forms being the connecting links. In our opinion, *hemihyperplasia* (*hemihypertrophy*) is etiologically heterogeneous and although some cases represent the Beckwith-Wiedemann spectrum, other cases do not. There have been mislabelings and overlap of patients with *Simpson-Golabi-Behmel syndrome*. This has been extensively discussed by Elliott and Maher (28), Verloes et al (98), and Coppin et al (19).

Laboratory findings. Approximately 60% of reported cases have neonatal hypoglycemia (29,90). The condition is transitory, being responsive to medical therapy with spontaneous regression usually occurring during the first 4 months of life. Polycythemia has been noted in 20% of the cases. Also reported in a few instances are hypocalcemia, hypercholesterolemia, and hyperlipidemia (90).

High-resolution chromosome banding studies should be carried out.

High maternal serum α-fetoprotein levels have been recorded in some instances (31a) and may indicate the presence of nephroblastoma (8), gigantism with visceromegaly (76), or possibly Beckwith-Wiedemann syndrome with associated hypothyroidism. On occasion, hypothyroidism (67), thyroxine-binding globulin deficiency (2), or low uptake with normal levels of protein-bound iodine have been noted. Beckwith-Wiedemann syndrome patients with low serum thyroxine levels should be further evaluated for frank hypothyroidism or simply thyroxine-binding globulin deficiency (54). Shah (83) recommends abdominal and renal ultrasound scans at 3-month intervals up to age 5, or more frequently if necessary, and then scans at 6-month intervals until adolescence. Daugbjerg and Everberg (21) recommend hearing tests at intervals from early childhood.

Hemihyperplasia (hemihypertrophy)

Hemihyperplasia (hemihypertrophy), described in 1822 by Meckel (32) and in 1839 by Wagner (49), gained widespread recognition after the studies of Gesell (12) and Lenstrup (28) during the 1920s. Comprehensive reviews carried out since 1965 include those of Ringrose et al (39), Parker and Skalko (35), Gorlin and Meskin (15), Cohen (6,8), Bell and McTigue (2), and Pollock et al (37). Contributions have been made by many authors (11,14,16,17,19,45).

Although the term *hemihypertrophy* has been used conventionally and frequently in the medical literature, it is inappropriate, as the condition so obviously refers to hemihyperplasia. The differences between common asymmetry, hemihyperplasia, hypertrophy, hemiatrophy, and preferential laterality have been discussed by Cohen (7). In hemihyperplasia, the enlarged area may vary from a single digit, a single limb, or unilateral facial enlargement to involvement of half the body (14,15,39,47,48). Hemihyperplasia may be segmental, unilateral, or crossed. About 2% are crossed (37). In some cases, the defect is limited to a single system—for example, muscular, vascular, skeletal, or nervous system—but it may frequently involve multiple systems (Figs. 11–6 to 11–9) (48).

Almost all cases are sporadic if incomplete forms of the Beckwith-Wiedemann syndrome and neurofibromatosis are excluded. Tomooka et al (47) estimated a birth prevalence of 1/86,000 livebirths. Increased birth weight has been observed (mean, 3.8 kg) (28). A 2:1 female predominance for hemihyperplasia has been noted (23).

The etiology and pathogenesis are poorly understood. A tendency toward dizygotic twinning has been observed (12). Various chromosomal mosaicisms have been occasionally found, including diploid/triploid mosaicism and trisomy 18 mosaicism. Many other theories have been advanced to explain hemihyperplasia, including anatomic and functional vascular or lymphatic abnormalities; lesions of the central nervous system, leading to altered neurotrophic action; endocrine abnormalities; asymmetric cell division and deviation of the twinning process; fusion of two eggs following fertilization, leading to unequal regulative ability in the two halves; mitochondrial damage to an overripened egg, leading to overregeneration and unilateral enlargement of the neural tube; and proliferation of neural crest cells (34,37). The range and variability of clinical abnormalities, together with the large number of sporadic cases, suggest etiologic heterogeneity. One subset of hemihyperplasia overlaps and is continuous with the Beckwith-Wiedemann syndrome.

Clinical manifestations. Asymmetry is usually evident at birth and may become accentuated with age, especially at puberty. Occasionally, asymmetry has been stated not to be present at birth, but to develop later. However, such observations are valid only when measurements are

Fig. 11–6. *Hemihyperplasia.* Note asymmetry of body, with complete left-sided hemihyperplasia. Note also syndactyly of toes.

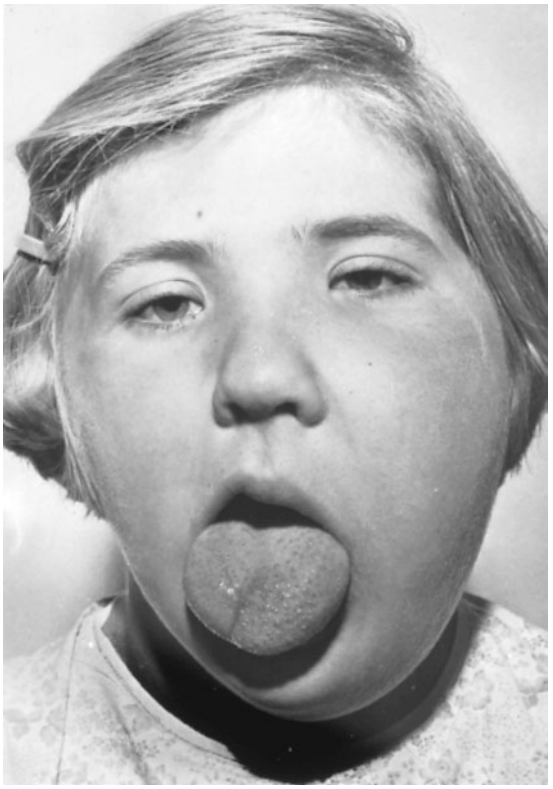

Fig. 11–7. *Hemihyperplasia.* Unilateral hyperplasia of face and tongue.

taken at birth. The bones have been found to be unilaterally enlarged with increased bone age on the affected side reported (35). A variety of nonneoplastic abnormalities have been observed to affect the limbs, teeth, skin, central nervous system, cardiovascular system, liver, kidneys, and genitalia (Figs. 11–6 to 11–9; Table 11–3).

Cutaneous anomalies include telangiectasia, nevus flammeus, and hirsutism (39). Oral and dental anomalies include enlarged hemitongue and enlarged teeth on affected side with early eruption (15,22,33). Medullary sponge kidney is a frequent finding (16,19,41,44). Many miscellaneous anomalies have also been noted. The most extensive reviews of abnormalities by system and miscellaneous anomalies are those of Ringrose et al (39), Parker and Skalko (35), Gorlin and Meskin (15), Bell and McTigue (2), and Cohen (8).

Neoplasms. Various neoplasms have been reported in association with hemihyperplasia, including, most commonly, Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma, in that order. Other tumors have also been noted: neuroblastoma, pheochromocytoma, testicular carcinoma, undifferentiated sarcoma of the lung, cyst of liver, and adrenal adenoma (11,15,20,23,29,31,35,36,38,42,43,46). Hoyme et al (21) reported a tumor incidence of 5.9%. A 1.36:1 right-sided predominance and a 1.88:1 female-to-male sex ratio were found in 168 patients. Tumors occurred ipsilateral and sometimes contralateral to the hemihyperplastic side (23).

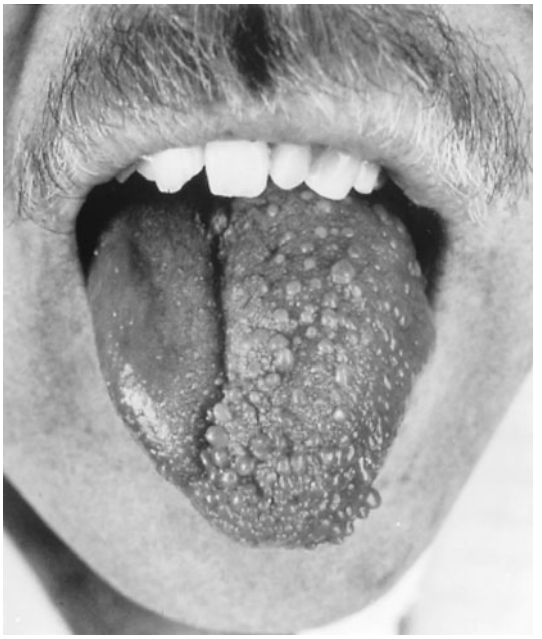

Fig. 11–8. *Hemihyperplasia.* Marked hemihyperplasia of tongue with enlargement of fungiform papillae. Note sharp demarcation at midline. (Courtesy of BB Horswell, Farmington, Connecticut.)

Differential diagnosis. So-called familial instances of hemihyperplasia are frequently incompletely documented and may represent other disorders, particularly *neurofibromatosis.* There is no question that the spectrum of the *Beckwith-Wiedemann syndrome* shades into hemihyperplasia. However, not all cases of hemihyperplasia represent the Beckwith-Wiedemann syndrome, particularly those sporadically occurring cases with no other signs and symptoms of the latter (6). Hemihyperplasia may also be observed with the *linear verrucous epidermal nevus syndrome* (13,33) and with the syndrome of hemihypesthesia, hemiareflexia, and scoliosis (1). The HIPO syndrome consists of hemihyperplasia, intestinal webs, preauricular tags, and cloudy cornea (18). There may be an autosomal dominant form of facial hemihyperplasia (5). Hennekam et al (19a) and Biesecker et al (4) described a somewhat Proteus-like disorder with arteriovenous and lymphatic malformations, linear verrucous epidermal nevus, and mild overgrowth. K. Jones and R. Gorlin have seen such a child but a unique PTEN mutation was found.

Table 11–3. Hemihyperplasia (hemihypertrophy)—miscellaneous findings

Skin	*Central nervous system*
Nevi (39)	Hemimegalencephaly (12,39)
Pigmentation (30,39)	Cerebral hemiatrophy
Cutis marmorata (39)	Macrocephaly (43)
Telangiectasis (39,48)	Cyst of septum pellucidum (35)
Nevus flammeus (12,39,43)	Mental deficiency (48)
Coarse skin on affected side (39)	Seizures (35,43,48)
Ichthyosis on affected side (9)	*Cardiovascular*
Hirsutism (39)	Congenital heart defects (39, 48)
Hypertrichosis (24)	*Liver*
Thicker hair on affected side (39)	Cyst (38)
Excessive secretions of sebaceous and sweat glands	Focal nodular hyperplasia
Increased skin temperature on affected side (39)	*Kidney*
Limb	Medullary sponge kidney (16,19,41,44,47)
Macrodactyly (16,39)	Unilateral nephromegaly
Polydactyly (39)	Abnormal collecting system (35)
Syndactyly (39)	Polycystic kidneys (40)
Clubfoot (39)	*Genitalia*
Skeletal	Hypospadias (35,39)
Increased bone age on affected side (12)	Cryptorchidism (35,39)
Compensatory scoliosis (39)	Macropenis (39)
Hip dysplasia (39)	Enlarged testis on affected side (35)
Dental, oral	Clitoromegaly (39)
Enlarged teeth on affected side (15)	*Other*
Early eruption of teeth on affected side (15)	Strabismus (39)
Abnormal tooth roots	Tracheoesophageal fistula (35)
Enlarged alveolar ridge on affected side (15)	Supernumerary nipples (39)
Enlarged tongue on affected side (15)	Umbilical hernia (39)
	Inguinal hernia (34,39)
	Short stature (39)

Asymmetry may also occur with arteriovenous aneurysm, congenital lymphedema, *Silver-Russell syndrome, McCune-Albright syndrome, Klippel-Trenaunay syndrome, Proteus syndrome,* multiple exostoses, Ollier syndrome, *Maffucci syndrome, Langer-Giedion syndrome*, hemihyperplasia/lipomatosis syndrome, and facial tumors of childhood (4). Hemiatrophy may occur secondarily to early central nervous system insult and may also occur in *Romberg syndrome, Sturge-Weber syndrome*, and unilateral ichthyosiform erythroderma (9). *Bencze syndrome* (3,26) is an autosomal dominantly inherited form of facial asymmetry associated with esotropia, amblyopia, and submucous cleft palate.

Laboratory aids. Patients with isolated, nonsyndromic hemihyperplasia should be screened with ultrasound for tumors, especially Wilms tumor, every 6 months for the first 4 years of life and probably less frequently thereafter until age 7. Chromosome studies may, on occasion, reveal mosaicism of various types.

Sotos syndrome

Sotos syndrome (cerebral gigantism), described by Sotos et al (31) in 1965, is an overgrowth syndrome characterized by increased birth length, increased birth weight, excessive growth during the first four years of life, advanced bone age, and distinctive facial features including macrodolichocephaly, ocular hypertelorism, and prominent mandible. Opitz et al (25) critically reviewed the syndrome. An extensive update is that of Cohen (9). Over 300 cases are found in the literature. Sotos syndrome is relatively common among overgrowth syndromes and appears to occur ten times more frequently than Weaver syndrome. Most cases are sporadic, and increased paternal age has been noted (11). Identical twins have been discordant for the syndrome (3). Several reported families have been consistent with autosomal dominant inheritance (25,28,37). Schrander-Stumpel et al (30) found a balanced translocation: t(3;6)(p21;p21). Breakpoint mapping has been carried out on this patient (19a). This is in part supported by the observation of Cole et al (13) that there is loss of heterozygosity at 3p21 in small cell lung carcinoma that has been found in Sotos syndrome.

Most patients can be diagnosed by craniofacial gestalt accompanied by significant overgrowth (1). Occasional patients have been confused as having Weaver syndrome. Still other patients cannot be confidently diagnosed as having either syndrome. Opitz et al (25) suggested that the many similarities between Sotos syndrome and Weaver syndrome may possibly indicate allelic rather than locus heterogeneity. Boys with fragile X may overlap phenotypically with those having Sotos syndrome (2,33). Clinical findings are listed in Table 11–4.

Table 11–4. Clinical findings in Sotos syndrome[a]

	Total number of patients	Percentage with finding
Growth		
Large birth weight	19	84
Excessive growth	102	97
Accelerated osseous maturation	102	79
Large hands and feet	80	83
Performance		
Developmental retardation	100	84
Lack of fine motor control	92	72
Neonatal adaptation and/or feeding difficulties	80	44
Craniofacial		
Macrocrania	20	90
Dolichocephaly	100	85
Receding hairline	18	94
Prominent forehead	101	96
Ocular hypertelorism	98	92
Downslanting palpebral fissures	20	65
Pointed chin	101	79
Highly arched palate	97	96
Premature eruption of teeth	80	57

[a] Based on 80 cases reviewed by Jaeken et al (18), and 22 cases reviewed by Wit et al (36). Because the findings are based on sporadic cases, there is an obvious ascertainment bias toward the severe end of the phenotypic spectrum.

Growth and skeletal findings. Overgrowth is commonly evident in the newborn, birth weight averaging 4200 g in males and 4000 g in females. Birth length, birth weight, and head circumference are, respectively, 3.2, 1.0, and 1.8 standard deviations above the mean (12). Excessive growth is particularly pronounced during the first four years of life. Bone age is advanced and gradually increases until the fifth year, after which the difference between bone age and chronological age stabilizes (35). From four years onward, growth curves usually remain above the 97th centile. Midparental height of affected individuals is similar to the normal mean midparental height. A small percentage of affected individuals have more extreme final height attainment (35). Early feeding problems are seen in 35% (11).

The hands and feet are large (6). Dysharmonic maturation and abnormal sequences in the appearance of carpal bones occur in some affected individuals (8). A characteristic metacarpophalangeal pattern has been reported (4,5,14). Joint laxity is frequent with pes planus especially common. Rarely, there is significant scoliosis (16a).

Performance and CNS abnormalities. Most patients have nonprogressive neurologic dysfunction manifested by unusual clumsiness which improves with age. Cole and Hughes (12) reported a mean DQ/IQ of 78 with a range of 40–129 (n = 23), but indicated that their figures probably underestimated ability in Sotos syndrome because some children from regular schools could not be formally assessed. Delay in expressive language and motor development during infancy is particularly common and in some instances may be followed by attainment of normal or near normal intelligence. Cole and Hughes (12) have observed that patients with Sotos syndrome tend to improve as they get older. Delay in walking until after 15 months of age and speech delay until after two and one half years are usual. Autism has been seen (21). Seizures and respiratory and feeding problems have been noted in about 20%. Often drooling is observed. Attention deficit may also be a component in some instances. Occasionally, other neurological signs have been reported, including nystagmus, strabismus, increased deep tendon reflexes, hypotonia, and muscle weakness (8,9).

Dilatation of the cerebral ventricles is seen in 70%–100% (20a,26,36). Other abnormalities include absent corpus callosum, prominent cortical sulci, cavum septum pellucidum, and cavum velum interpositi (20a,29). Schaefer et al (29) in a neuroimaging study of 40 patients, found prominence of the trigone in 90%, prominence of the occipital horns in 75%, and ventriculomegaly in 63%.

Craniofacial features. Dolichocephaly and marked frontal bossing are accentuated by frontoparietal balding (Fig. 11–10). The head circumference is usually well above the 97th centile. Narrow temples make the eyes appear wide-set, but true ocular hypertelorism is not found. Strabismus is noted in 40%. The cheeks are full. Although the mandible is long and narrow inferiorly, squared, or pointed, true prognathism is rare. The palate is highly arched, and prematurely erupted deciduous teeth are observed in more than 50% of cases (8,9). Cephalometric analyses are available (22,34).

Other findings. Congenital heart defects have been discussed by Keneko et al (19), Cole and Hughes (12), Noreau et al (24), and Tsukahara et al (32). Many low-frequency abnormalities have been reported, including, among others, juvenile macular degeneration, optic disc pallor, glaucoma, bones in the anterior fontanelle, vertebra plana, kyphoscoliosis, brittle nails, syndactyly, functional megacolon, and autonomic failure with persistent fever (8,9,17a,37).

Neoplasms. Cohen (10) critically reviewed neoplasms reported to occur with Sotos syndrome. Retrospective literature review suggests a

A B

Fig. 11–10. *Sotos syndrome.* (A) Eighteen-month-old male showing typical facies. Note receding hairline and small nose. (B) Six-month-old female with characteristic facies. (A courtesy of MM Steiner, Chicago, Illinois.)

tumor frequency of about 3.9% (7,9,17,23). Tumors have included Wilms tumor, hepatocellular carcinoma, neuroblastoma, vaginal epidermoid carcinoma, small cell carcinoma of lung, sacrococcygeal teratoma, giant cell granuloma of the mandible, and acute lymphatic leukemia (10,17,19b).

Laboratory findings. A 14% frequency of glucose intolerance has been demonstrated in Sotos syndrome by numerous investigators (8,18).

Differential diagnosis. Enlarged head circumference may be seen in several other conditions: hydrocephalus, *neurofibromatosis, achondroplasia,* autosomal dominant macrocephaly, and so on. Although some syndromes occur with overgrowth and others are associated with macrocephaly, Sotos syndrome is a distinctive condition. Several syndromes have been confused with Sotos syndrome (7,11). Cole and Hughes (12), evaluating 79 patients, found that 50% were misdiagnosed. Cole and Hughes (11a) and others (23a,31a) proposed that autosomal dominant macrocephaly, obesity, unusual facies, delayed bone age, mental retardation and autism is a distinct entity. This has come to be known as Cole-Hughes macrocephaly syndrome. *Nevo syndrome* (8), in addition to Sotosoid features, has generalized edema at birth, severe muscular hypotonia, contractures of the feet, wrist drop, and clinodactyly. The condition has autosomal recessive inheritance. *Weaver syndrome* has a distinctive facial appearance, widened distal long bones, and more accelerated osseous maturation. The *Bannayan-Riley-Ruvalcaba syndrome* (8,9) has some Sotosoid features but has distinctive pigmentary spotting of the penis and intestinal polyposis, especially of the colon. Inheritance is autosomal dominant. Some patients clinically suspected of having Sotos syndrome have also been reported with *fragile X syndrome* (2,33). Goldstein et al (16) observed two patients with overgrowth, congenital hypotonia, nystagmus, strabismus, and mental deficiency; they were thought to bear some resemblance to those with Sotos syndrome. The patient reported by Evans (15) probably had *pseudohypoparathyroidism* or *acrodysostosis.* Although there is stated to be resemblance to the autosomal dominant Siena-type overgrowth syndrome, we do not think there is overlap (20). We are not able to identify the Sotosoid syndrome with redundant skin folds and vesicoureteris reflux (27).

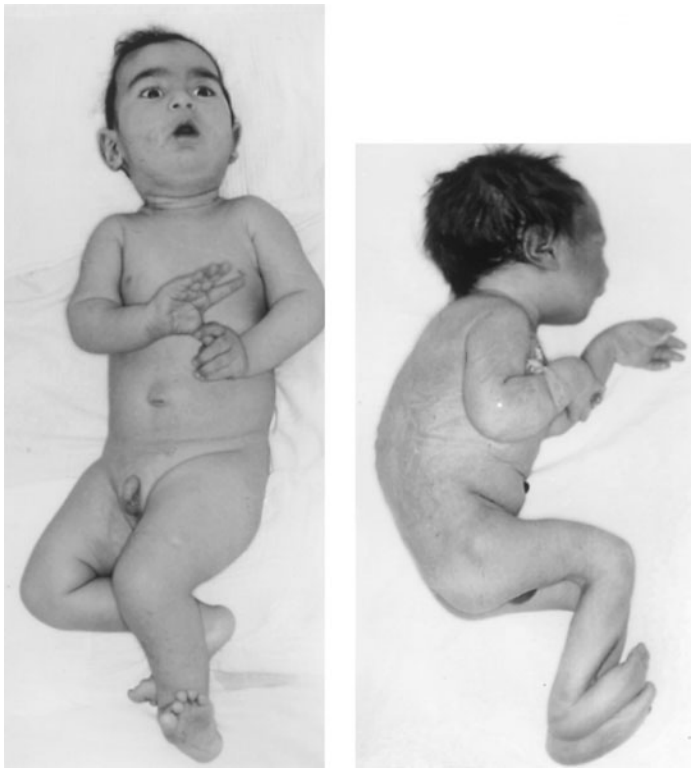
Nevo syndrome

The syndrome was observed by Nevo et al (6) in 1974 in three sibs among a large inbred family from Israel. Whereas Nevo and coworkers (6) described their patients as having cerebral gigantism, Cohen pointed out that the condition was clearly at variance with cerebral gigantism (2) and named the condition Nevo syndrome (3).

Al-Gazali et al (1) reported two further children from two unrelated families. Hilderink and Brunner (5) observed a patient from a consanguineous Dutch family. Another patient was noted by Dumić (4). To date, seven children have been reported from five families; three of these families are Arabic. Autosomal recessive inheritance is established.



A B

Fig. 11–11. *Nevo syndrome.* (A) Large infant. (B) Second affected infant. Note contractures and puffy hands. (From S Nevo et al, J Med Genet 11:158, 1974.)

Features of Nevo syndrome similar to those found in *Sotos syndrome* include intrauterine overgrowth, accelerated osseous maturation, dolichocephaly, large extremities, clumsiness, and retarded motor and speech development. Nevo syndrome has, in addition, generalized edema at birth, severe muscular hypotonia, contractures of the feet, wrist drop, and clinodactyly (Fig. 11–11). Large, low-set, malformed ears and cryptorchidism were observed in some patients (6).

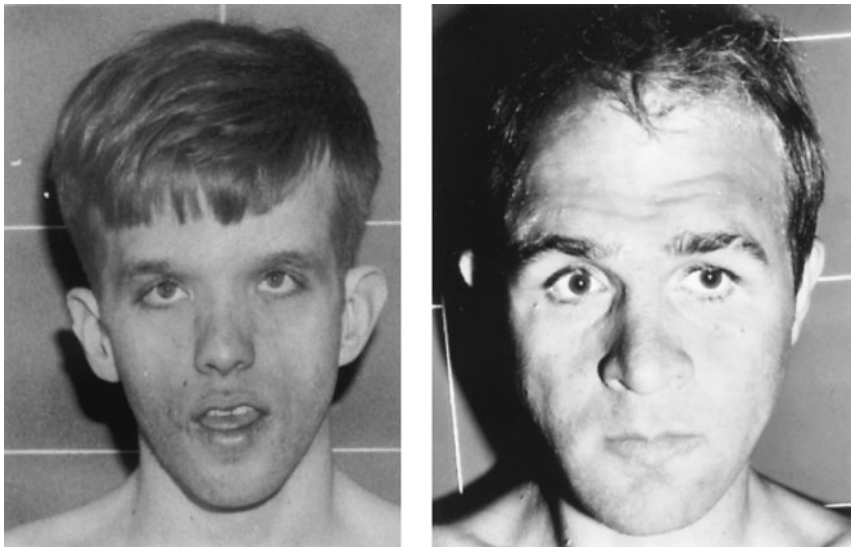
Bannayan-Riley-Ruvalcaba syndrome (Bannayan-Zonana syndrome, Ruvalcaba-Myhre syndrome, Riley-Smith syndrome)

Riley and Smith (30) in 1960, observed the association of macrocephaly, pseudopapilledema, and multiple hemangiomas. Bannayan (2), in 1971, and Zonana et al (41), in 1976, described macrocephaly with multiple subcutaneous and visceral lipomas and hemangiomas. Ruvalcaba et al (31), in 1980, reported patients with macrocephaly, intestinal polyposis, and pigmented spotting of the penis. Gorlin et al (14) extended the



A B

syndrome to include Hashimoto thyroiditis and suggested a relationship to juvenile polyposis of infancy. At least 45 cases have been described (1–40). Cohen (5) proposed the syndrome be named for the first authors of the three original reports. Of interest to the reader are the editorial comments of Cohen and MacLean (6).

Inheritance is autosomal dominant. More males than females have been reported (10,29). The syndrome, mapping to 10q23, is due to mutations in a tumor suppressor gene, PTEN, a dual specificity phosphatase. Bannayan-Riley-Ruvalcaba syndrome is allelic to Cowden syndrome. Phenotypic and molecular overlap have been recorded (28b). Germline mutations have been found in almost 60% of cases, none within the PTPase core motif as yet (1a,24,25). In fact, there are examples of overlapping phenotypes (1a,12,42), and families in which the two phenotypes exist (3). Translocation causing the syndrome has been noted (1). The PTEN gene is expressed in the embryo in areas other than those affected by the syndrome (13a).

Birth weight is usually in excess of 4000 g, with birth length above the 97th centile. Postnatal growth decelerates, older children and adults both being well within the normal range (9,10,31).

Hypotonia, gross motor delay, mild-to-severe mental deficiency, and cognitive speech delay have been reported in approximately 70% (9,17,22,26,27,29,34). About 25% exhibit seizures (9,29). DiLiberti and Budden (8) and Powell et al (29) reported asymmetric motor development. These minor motor asymmetries were transient and improved with age. Deep tendon reflexes are diminished.

Craniofacial features. Head circumference is at least 4.5 SD above the mean in nearly all affected. A few patients have exhibited delayed closure of the anterior fontanel. Ocular hypertelorism has been noted in some instances (Fig. 11–12). Downslanting palpebral fissures and strabismus or amblyopia are frequently noted. Examination of the eyes under slit lamp has demonstrated prominent Schwalbe lines and clearly visible corneal nerves in approximately 35% of patients (9,15). Pseudopapilledema has been found in some cases (11,30).

Skin. Pigmented macules are found on the penile gland and shaft in 25% of affected males (7,14) (Fig. 11–13). This spotting is often subtle and may be missed if not specifically looked for. The macules may not appear until mid-childhood or later.

Cutaneous angiolipomas with a vascular component that vary in number, size, and location have been observed in over half the patients (9). About 25% have a small number of café-au-lait spots on the trunk and lower limbs (29). One patient had acanthosis nigricans-like lesions of the face. Another patient had accessory nipples (31).

Hashimoto thyroiditis. Hashimoto thyroiditis, an autoimmune disorder of delayed hypersensitivity, is characterized by euthyroid or mildly hypothyroid goiter. It occurs predominantly in middle-age females, although it may be seen in adolescent or preadolescent females. Gorlin et al (14) expanded the syndrome to include Hashimoto thyroiditis.

Goiter or fullness in the throat with mild dysphagia is usually present. Onset is insidious. The gland is 2–5 times normal size, firm to rubbery in consistency, and painless. Asymmetric enlargement is noted in about 35%.

Microscopically there is diffuse involvement of the entire gland marked by a dense infiltration of lymphocytes throughout the parenchyma and in focal collections with true germinal centers. Fibrous connective tissue is not significantly increased. The acinar lining cells are swollen with granular, eosinophilic (oncocytic) cytoplasm and large hypochromatic nuclei. The acini are small with slitlike lumina containing almost no colloid (14).

Gastrointestinal system. Hamartomatous (juvenile) polyps, usually multiple and limited to the distal ileum and colon, may be associated with intussusception and/or rectal bleeding. Polyps have been found in 45% of all patients. Polyps other than juvenile type have been found (23a).

Fig. 11–13. *Bannayan-Rily-Ruvalcaba syndrome*. (A,B) Pigmented macules on penile shaft. (A form J DiLiberti, Am J Med Genet 15:491, 1983. B from R Ruvalcaba et al, Clin Genet 18:413, 1980.)

A B

While some become manifested in childhood, others have not become evident until middle age (9,13). Protein-losing enteropathy has been observed (14,22,23,32,33,35–38).

Musculoskeletal system. At least 60% of patients had a myopathic process in the proximal muscles (4,10) which manifests as delayed motor development. There is exercise intolerance. Muscle biopsy has shown intracellular lipid accumulation, predominantly in enlarged type I muscle fibers (7,29), Type II fibers are smaller than normal and contain less fat (10). Metacarpophalangeal profile patterns show accelerated growth of the first metacarpal and first and second middle phalanges (16). Joint hyperextensibility, pectus excavatum, and scoliosis have been reported in about 50% (9,18).

Neoplasms. Mesodermal hamartomatous masses are usually discrete lipomas (75%). Capillary or venous malformations (10%) and lymphatic malformations (10%) are seen. In 20% of patients, the vascular malformations are of the combined type (21). Most of the hamartomas are subcutaneous, but may be intracranial (20%) or osseous (10%). Some lipomas may be aggressive and can cause serious complications (26). The puzzling patient of Okumura et al (28) had manifestations of Bannayan-Riley-Ruvalcaba syndrome, Klippel-Trenaunay syndrome, and Proteus syndrome. A Proteus-like syndrome was noted by Zhou et al (40a). Hamartomatous polyposis has already been discussed in the section on the gastrointestinal system.

Malignant tumors have been noted in some patients. One adult male had a thyroid tumor and two other affected males had thyroidectomies at a young age. One affected female has had rapid onset of bilateral invasive breast cancer at age 34 (DiLiberti, personal communication, 1986).

Other abnormalities. Adult males had enlarged testes (9,13). A patient seen by one of us (RJG) had a painful testis due to fatty infiltration. We have also noted hemihyperplasia in a few patients.

Differential diagnosis. An exhaustive discussion of conditions associated with macrocephaly is that of Gorlin et al (14). The most common cause is autosomal dominant macrocephaly. Other syndromes are those of *Sotos, Weaver, Marshall-Smith*, and *macrocephaly-cutis marmorata*. Lipomas, hemangiomas, and lymphangiomas may also occur in *Proteus syndrome.* The combination of macrocephaly, angiomatosis, and limb asymmetry in sporadic cases has been discussed by Stephan et al (39). Hashimoto thyroiditis has been reported in association with familial adenomatous polyposis and with generalized hypertrophic myopathy and chorioretinal dystrophy (14).

Familial juvenile polyposis, an autosomal dominant disorder which maps to 18q21.1, placed the affected at increased risk for gastrointestinal adenocarcinoma (20). Hereditary mixed polyposis maps to 6q (40). There has been considerable argument whether the gene for some patients with juvenile polyposis is the PTEN gene (20).

Laboratory aids. Electromyography, muscle biopsy, and mutational analysis should be performed on all infants with macrocephaly, normal CT scans, and hypotonia. Patients with Bannayan-Riley-Ruvalcaba syndrome should be monitored for gastrointestinal polyposis and thyroid neoplasms. Muscle-free carnitine levels have been reduced (29).

Weaver syndrome

In 1974, Weaver et al (38) reported a syndrome of persistent overgrowth of prenatal onset, accelerated osseous maturation, distinctive craniofacial appearance, developmental delay, widened distal long bones, and camptodactyly (Table 11–5). Most cases are sporadic. Parent-to-child transmission has been recorded on several occasions (10,16,28). Fitch (12,13) and Ardinger et al (2) reported cases and reviewed the literature. Recent critical reviews are those of Opitz et al (28) and Cole et al (8). A recent update is that of Cohen (7). Many cases have been reported (1,2,4–21, 23,27–29,32,38–40). There is a 3:1 male-to-female ratio (2,5,28), and females have been noted to be more mildly affected (2,7,28,35).

Table 11–5. Features of Weaver syndrome

Findings	Frequencies
Growth	
Prenatal growth excess	16/20
Postnatal growth excess	19/20
Accelerated osseous maturation	19/19
Performance	
Hypertonia	10/18
Hypotonia	5/18
Developmental delay	19/19
Hoarse, low-pitched cry	14/17
Craniofacial	
Broad forehead	18/19
Flat occiput	6/11
Large ears	15/17
Ocular hypertelorism	19/19
Prominent or long philtrum	10/14
Relative micrognathia	17/19
Limbs	
Camptodactyly	11/16
Prominent fingerpads	6/9
Thin, deeply set nails	9/10
Broad thumbs	4/6
Clinodactyly, toes	4/5
Limited elbow or knee extension	10/13
Widened distal long bones	16/18
Foot deformities[a]	7/10
Other	
Excess loose skin	11/12
Umbilical hernia or diastasis recti	12/17
Inguinal hernia	4/14
Inverted nipples	3/4

[a] Talipes equinovarus, talipes calcaneovalgus, metatarsus adductus.

Growth and skeletal findings. Mean birth weight is 4785 g in males and 3883 g in females. Birth length is 56 cm in males and 53 cm in females. Head circumference at birth is 36.6 cm in males and 35.2 cm in females. Adult head circumference is 61 cm in males and 59.5 cm in females (28). Final height attainment is 194.2 cm in males and 176.3 cm in females. Adult weight is 102.2 kg in males and 87.6 kg in females.

Performance and central nervous system. Mild hypertonia (75%) or hypotonia is common, and motor development is mildly to moderately retarded. The cry is low-pitched and hoarse (100%). Although the appetite is voracious, hypothalamic dysregulation has not been demonstrated. Difficulty in swallowing or breathing has been noted in several cases. Other findings have included cysts of the septum pellucidum, pachygyria, dilation of the ventricles, basal cisterns, sylvian cistern, and interhemispheric fissure, consistent with nonspecific cerebral atrophy, and enlarged vessels and hypervascularization in the areas of the middle and left posterior cerebral arteries (2,7,28).

Craniofacial features. Macrocephaly (90%), broad forehead (100%), and flattened occiput are characteristic. Scalp hair is moderately thin. The ears are large (95%) and may be mildly dysmorphic or low-set (Fig. 11–14). Other features include hypertelorism, long prominent philtrum (90%), depressed nasal bridge (80%), relative micrognathia, and redundant nuchal skin folds. Low-frequency findings have been noted such as mild craniofacial asymmetry, upslanting or downslanting palpebral fissures, small palpebral fissures, ptosis, strabismus, and highly arched palate (2,5,28).

Limbs. Common findings include camptodactyly (65%), prominent finger pads, thin deeply set nails, broad thumbs, clinodactyly of toes, and limited extension at elbows and knees. Foot deformities have been noted such as talipes equinovarus, talipes calcaneovalgus, metatarsus adductus, pes adductus, and pes cavus. Deep creases may be observed on the palmar and plantar surfaces (2,7,28).

Bone age is remarkably advanced; the growth parameters of head circumference, length, and weight are two-to-three times the expected rate. Carpal maturation is accelerated over that of phalanges and metacarpals (Fig. 11–15). Other skeletal findings include abnormal cervical vertebrae, widened or splayed long bone metaphyses, especially of the femurs, and somewhat mottled epiphyses. The iliac wings may be broad and low (2,6,28).

Neoplasms. Although many overgrowth syndromes are associated with neoplasia, two neuroblastomas (17,19a), one ovarian yolk sac tumor (9), and one sacrococcygeal teratoma (22a) have been reported with Weaver syndrome.

Differential diagnosis. Weaver syndrome should be differentiated from *Sotos syndrome,* with which it is sometimes confused (28). There are Weaver-like syndromes and misdiagnosed Weaver syndrome cases from the literature (15,22,24,30,31,33,34,36,37). These have been reviewed by Cohen (7). Van Asperen et al (3) reported familial type 1 *neurofibromatosis* associated with an overgrowth syndrome resembling Weaver syndrome. Some patients cannot be diagnosed confidently as having either Sotos syndrome or Weaver syndrome (28).

Marshall-Smith syndrome

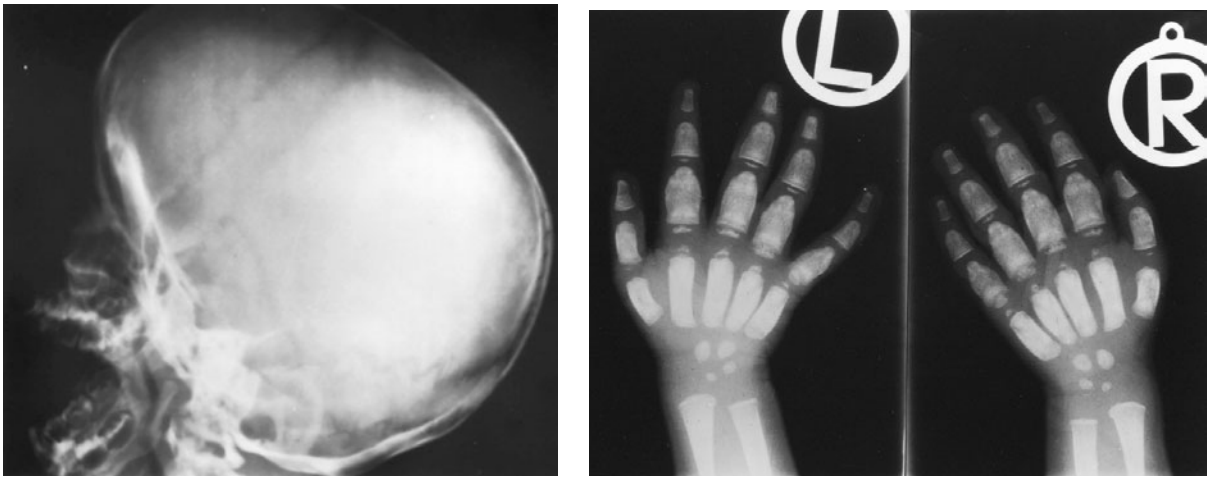
In 1971, Marshall et al (18) first reported a disorder characterized by accelerated skeletal maturation, mental and somatic retardation, failure to thrive with chronic respiratory distress and early death, characteristic facial appearance, and remarkable skeletal alterations (Figs. 11–16 to 11–18). At least 25 cases have been reported (1–9,12–23,25–31) and all have been isolated examples. Perhaps it represents a new lethal dominant mutation. Findings have been summarized by Hoyme et al (14) (Table 11–6).

Growth, performance, and natural history. Moderate to severe respiratory distress accompanied by noisy stridor may necessitate intubation. There is failure to thrive, and death due to pneumonia occurs almost always within months. However, a few children have survived for up to 7 years (14,26). The child will often lie with the head extended due to laryngeal hypoplasia (6,18,29). Speech is poor and frequently the child is hypotonic. Psychomotor delay is common. Partial growth hormone deficiency was found by Roodhooft et al (23).

Craniofacial features. The forehead is prominent with frontal ridging, while the supraorbital ridges are flattened in 85%. The eyes bulge or are proptosed in nearly all affected and there may be megalocornea (Fig. 11–17). The sclerae are blue in 60%. Optic atrophy has been found (26,30). The eyebrows are bushy with synophrys. The nose is small with a low nasal bridge and anteverted nostrils in essentially all patients. Unilateral or bilateral choanal stenosis or atresia has been reported (12,15,22,28,29). The helices of the pinnae are often folded with hypoplastic cartilages (8), and the ears may be low-set. The mandible is

A B

Fig. 11–17. *Marshall-Smith syndrome.* (A,B) Bulging eyes, coarse eyebrows, low nasal bridge, micrognathia. (A,B from JCS Perrin et al, Birth Defects 12(5):209, 1976.)



A B

Fig. 11–18. *Marshall-Smith syndrome.* Radiographs. (A) Prominent calvaria, small facial bones, and hypoplastic mandibular rami. (B) Radiograph of hand at 22 days. Note enlarged bullet-shaped proximal and middle phalanges, very small distal phalanges; phalangeal epiphyses, curved first metacarpal, and advanced bone age. (A from RE Marshall et al, J Pediatr 78:95, 1971. B from M Hassan et al, Pediatr Radiol 5:53, 1976.)

small in 85%. The mouth is small and the palate may be highly arched. Stridor appears to be related both to glossoptosis (documented in 35%), rudimentary epiglottis, and hypoplastic larynx (6,12,13,16,29). Hearing loss may be part of the syndrome (14,30).

Musculoskeletal system. The hands and feet and/or digits are often stated to be long. Radiographically, carpal and tarsal bone age is markedly advanced (15,19,22,28). At birth, the phalangeal epiphyses, femoral heads, and patellae are usually ossified, suggesting a bone age of 4 years or more (17,19,20). The frontal bone is prominent and the calvaria thickened and prominent. The orbits are shallow and the facial bones small or hypoplastic. The mandibular rami are underdeveloped with absence of the angle (9,12,13,18,28) (Fig. 11–18A).

Table 11–6. Features of the Marshall-Smith syndrome[a]

Findings	Frequencies
Growth, skeletal	
Accelerated linear growth	2/18
Accelerated osseous maturation	18/18
Broad phalanges	17/17
Failure to thrive	11/13
Performance	
Neurodevelopmental abnormalities	13/13
Structural brain anomalies	7/14
Respiratory	
Respiratory tract abnormalities	15/18
Recurrent pneumonia	14/18
Pulmonary hypertension	4/18
Death in early infancy	10/18
Craniofacial	
Prominent forehead	15/18
Small face	12/18
Prominent eyes	17/18
Blue sclerae	11/18
Flat nasal bridge	17/18
Anteverted nares	15/16
Micrognathia	14/18
Glossoptosis	6/17
Choanal atresia/stenosis	3/17
Other	
Hypertrichosis	7/18
Umbilical hernia	6/18

[a] Adapted from HE Hoyme and MJ Bull; Eighth David W. Smith Workshop on Malformations and Morphogenesis, Greenville, South Carolina, August 15–19, 1987.

Long bones tend to be thin (7,13,16–31). The proximal and middle phalanges of the hands are remarkably thick. The former are rectangular; the latter are bullet-shaped. The terminal phalanges are greatly reduced in size. The metacarpals are also widened distally and are poorly modeled (Fig. 11–18B). Scoliosis has been noted in a few cases. Severe spinal stenosis and instability at the craniocervical junction have been documented (8). One of us (RCM Hennekam) has observed increased fractures.

Muscle biopsy showed hypoplasia of type IIa and IIb fibers (23).

Other abnormalities. Umbilical hernia or omphalocele is present in approximately 35% (16,18,26,29). Generalized hypertrichosis occurs in about 50% (16). Pachygyria of the occipital and temporal areas of the brain has been documented in some instances (18,28). Only a few children have had cardiovascular defects and these have included PDA, ASD, and hypertrophy of the pulmonary arteries (12).

Differential diagnosis. Comparison is sometimes made with *Weaver syndrome,* but except for accelerated osseous maturation, the phenotypes are distinct. Differences have been well reviewed by Fitch (10,11). In *Sotos syndrome,* phalangeal age is ahead of carpal age, but in Marshall-Smith syndrome the opposite occurs. The case reported by Shimura et al (24) as an example of overlap between Marshall-Smith syndrome and Weaver syndrome represents simply Weaver syndrome, in our opinion. The case of Smyth et al (25) appears to represent Marshall-Smith syndrome.

Simpson-Golabi-Behmel syndrome

The syndrome is an X-linked disorder characterized by prenatal and postnatal overgrowth, intellectual impairment, characteristic facial appearance, and a variety of other anomalies. Golabi and Rosen (4) reported the disorder in four affected males with partial manifestations in a female obligate carrier. Striking features of the syndrome consisted of macrosomia, mental deficiency, broad nose, wide mouth, cleft palate, large cystic kidneys, and musculoskeletal and limb abnormalities. Neri et al (13) noted that the precedent set by Simpson et al (20) and the contribution made by Behmel et al (1,2) necessitated a change in eponymic designation from Golabi-Rosen syndrome to Simpson-Golabi-Behmel syndrome. Neri et al (14) recently reviewed the clinical and molecular aspects of the syndrome. About 35 examples have been described (3,12). A good general discussion of gene regulation is that of Selleck (19a).

Etiology. The Simpson-Golabi-Behmel gene maps to chromosome region Xq25–q27 (17,19,24). Pilia et al (18) identified different microdeletions in three families. Mutations in a cell surface heparan sulfate proteoglycan, glypican-3 (GPC3) play an important role in controlling the growth of mesodermal and endodermal tissues. Veugelers et al (22) reported deletion of the GPC3-GPC4 gene cluster in one family. However, not all families show a deletion (12).

Simpson-Golabi-Behmel syndrome and Beckwith-Wiedemann syndrome share some clinical similarities, but there are also differences. GPC3 binds to IGF2 and it may modulate IGF2 action. It is not known whether the IGF2 receptor and GPC3 compete for IGF2 ligand or whether a trimolecular complex is formed (23). This has importance in clinical overlap of Beckwith-Wiedemann, Perlman, and Simpson-Golabi-Behmel syndromes (6,21).

Clinical findings. Many cases have been reported. Clinical findings are summarized in Table 11–7. Recently, Lin et al (11) reported cardiac abnormalities in 36% (n = 99). Simpson-Golabi-Behmel syndrome has a number of features in common with *Beckwith-Wiedemann syndrome* and clinical differentiation can be challenging, but can be resolved at the molecular level.

Growth. Overgrowth is impressive at birth and continues postnatally in almost 100%. Birth weights of 4000–5000 g have been noted (4,13).

Central nervous system. Mild to moderate mental retardation has been present in most (4,13–15), but there has been severe delay in others (5,16). Hypotonia is common. Speech is delayed in almost all patients.

Craniofacial abnormalities. Macrocephaly and coarse facies are common. The palpebral fissures tend to slant downward. The nose is

Fig. 11–19. *Simpson-Golabi-Behmel syndrome.* Note hypertelorism, broad flat nasal bridge, short upturned nose, large mouth. Weight greater than 90th percentile at birth. (From M Golabi and L Rosen, Am J Med Genet 17:345, 1984.)

broad and the mouth wide. The tongue is large and malocclusion is common. Several patients had a central groove of the lower lip. Cleft lip and/or palate have been documented (10) (Figs. 11–19 and 11–20). Odontogenic keratocysts have been described, but possibly the patient has Gorlin syndrome (9a).

Fig. 11–21. *Simpson-Golabi-Behmel syndrome.* Postaxial hexadactyly, mild soft tissue syndactyly between second and third digits. (From M Golabi and L Rosen, Am J Med Genet 17:345, 1984.)

Extremities. The hands are large and square. The thumbs and halluces are broad. Postaxial hexadactyly and 2–3 manual soft-tissue syndactyly are frequent (Fig. 11–21). The nails may be hypoplastic, especially those of the index fingers.

Musculoskeletal anomalies. Pectus excavatum, various rib and vertebral anomalies, and clefting of the xiphisternum have been noted (4,13). Umbilical/unguinal hernias have been documented in 35%. There may be advanced bone age (4,12,13).

Skin. Supernumerary nipples are seen in 40% as are coccygeal skin tags. Spotty perioral and palatal pigmentation has been described.

Embryonal neoplasia. There is a higher-than-normal occurrence of Wilms tumor, atypical embryoma, neuroblastoma, hepatoblastoma, rhabdomyoma, and hepatocellular carcinoma (5,8,10,12,18).

Fig. 11–20. *Simpson-Golabi-Behmel syndrome.* (A,B) Coarse facies, wide nasal bridge, wide mouth. (C) Note hypertelorism, short broad upturned nose, and large mouth. (A,B from A Behmel et al, Hum Genet 67:409, 1984. C from M Golabi and L Rosen, Am J Med Genet 17:345, 1984.)

A

B

C

Other findings. Various kidney findings have been noted (large kidney, lobulated kidneys, cystic kidneys, duplication of renal pelvis), and hypospadias and cryptorchidism have been seen. Congenital heart anomalies have been cited.

Visceroptosis of the liver, pectus excavatum, and neonatal respiratory distress have been documented.

Prader-Willi syndrome

Prader-Willi syndrome was initially identified in 1956 by Prader, Labhart, and Willi (104). They described 14 patients with obesity, hypogonadism, cryptorchidism, mental retardation, and hypotonia (Figs. 11–22 to 11–25). Since then, well over 1000 cases have been documented (7,8, 13,14,16,17,22,24,25,27,31,39,40,51,53,60,64,78,79,90,92–94,110,117, 124,133,134). About 1 per 10,000–15,000 individuals are diagnosed with Prader-Willi syndrome (10). Updated reviews are those of Cassidy (25,27) and Nicholls (92,93).

Fig. 11–22. *Prader-Willi syndrome.* Marked obesity, small hands, and hypoplastic genitalia. (From MM Cohen Jr and RJ Gorlin, Am J Dis Child 117:213, 1969.)

Etiology. Cytogenetic and molecular genetic issues have been addressed by numerous authors (3,4,9,12,16,18,28,37,38,41–44,47,54,55, 61, 63, 67,68,73,75,80–82,85,88,90,92–94,96,98,101,103,105–114,118, 124,126,128,132). Of three subgroups of 15q11–q13, the proximal region contains genes that are expressed from the paternally inherited chromosome only. Mosaicism has been detected using FISH technic (112). Multiple molecular genetic mechanisms lead to Prader-Willi syndrome by abrogating one or more genes in this region. Each of these imprinted genes is expressed in the brain. About 70% of patients have a recognizable deletion of 15q11.2. Most other cases involve maternal disomy (86). At least 1% have very small 20–100 kbp deletions, including virtually all families with recurrences (25). Mitotic duplication of the maternal chromosome 15 is another mechanism (42a).

A number of genes in the Prader-Willi region have been described. The promoter elements at SNRPN (small nuclear ribonucleoprotein N) likely play a key role in initiating imprint switching during spermatogenesis. Other genes include ZNF127, IPW, PAR1, and PAR5 (25,27,73, 92,93,96). Another gene, NDN (necdin-encoding gene), is expressed at high levels in the brain and may contribute to abnormal brain development (85). Triplication of the region has been noted (119a).

Ohta et al (96) identified three sporadic cases of Prader-Willi syndrome with an imprinting mutation (IM) but no detectable mutation in the imprinting center (IC). In these cases, the syndrome may arise from developmental or stochastic failure to switch the maternal-to-paternal imprint

Fig. 11–23. *Prader-Willi syndrome.* Facial obesity, narrow bifrontal diameter, almond-shaped eyes, characteristic mouth. (From MM Cohen Jr and RJ Gorlin, Am J Dis Child 117:213, 1969.)

during spermatogenesis (113a). The *P* gene in the distal region of 15q11–q13 is non-imprinted and codes for tyrosinase positive albinism, and its deletion probably causes the hypopigmentation found in Prader-Willi patients (25,116). First cousins have been reported, one with Prader-Willi syndrome, the other with Angelman syndrome (31).

Familial occurrences and recurrence risk. Familial occurrences of Prader-Willi syndrome have been recorded a number of times (30,35,41,53,55,63,84,98) and concurrence of Prader-Willi and Angelman syndromes has also been noted (50,114). Recurrence risk is less than 1 per 1,000. Kennerknecht (70) estimated an overall recurrence risk of 0.4%, but indicated that if two or more sibs were affected, the risk in the next sib would be 50%.

Genotype–phenotype correlations. Genotype–phenotype correlations have been observed. Lower birth weight has been noted in deletion

Fig. 11–24. *Prader-Willi syndrome.* Disproportionately small hands. (From MM Cohen Jr and RJ Gorlin, Am J Dis Child 117:213, 1969.)

Fig. 11–25. *Prader-Willi syndrome.* Hypoplastic genitalia with penis buried in fat. (From MM Cohen Jr and RJ Gorlin, Am J Dis Child 117:213, 1969.)

patients and shorter birth length in males has been observed in maternal disomy. Cassidy and Schwartz (27) found statistically significant differences with higher frequency in deletion patients of the typical facial appearance, unusual skill with jigsaw puzzles, skin picking, high pain threshold, hypopigmentation, and abnormalities of speech production. Allanson et al (2) found that patients with PWS due to maternal UPD have a longer face, more prominent nose, smaller mouth, and broader and more prominent mandible than those with deletion. Gillessen-Kaesbach et al (46) noted more frequent hypopigmentation and lower birth weight in those with a deletion.

Mitchell et al (90) compared the phenotypes of 43 deletion patients with 79 maternal disomy patients, finding no major clinical differences between the two groups except for more frequent hypopigmentation in the deletion group. Significant sex ratio changes were also observed. The maternal disomy group had a predominance of males (68%). Females with maternal disomy were found to be less severely affected than female deletion patients with respect to length of gavage feeding and later onset of hyperphagia.

Natural history. Individuals with Prader-Willi syndrome have a predictable life scenario. About 7% are premature and 40% are breech deliveries. They have low-normal birth weight, severe hypotonia, and severe feeding difficulties in the newborn period (53). Cryptorchidism and hypogenitalism are noted in males. Otherwise, no significant dysmorphology is found (53). The severe hypotonia requires prolonged and special feeding techniques (22,24,25,27,31,39,40,53,90,91). Hypotonia may be the only finding in infancy (89). Failure to thrive may be a problem during the first 6–12 months (22,24,25,27,58,95). Gradual improvement in muscle tone during the last half of the first year heralds an improved rate of weight gain (7,22,24,25,27,53,133,134). By 3 years, significant weight gain has occurred and delayed milestones are usually recognized (53). Unusual facial appearance, poor linear growth, and small hands and feet are noted at this time (53). Between 3 and 5 years, obesity and mild behavioral problems begin (53). Between mid-childhood and adolescence, obesity becomes more prominent, as do behavioral problems such as stubbornness, temper tantrums, and violent reactions (53,133,134). No signs or few signs of puberty exist (51). During teenage years and young adulthood, severe obesity often causes cardiorespiratory problems (51) and an increased frequency of diabetes mellitus (51,133,134). The teenager and/or adult with Prader-Willi syndrome may become unmanageable, causing much despair in the family (22–25,27,51). Diagnosis at any time, but particularly before 5 years of age, can potentially lead to effective treatment by weight reduction and control with an ameliorating effect on many problems (22,24,25,27). Wharton et al (127) reported six patients with dramatic acute gastric distention. Old age has been discussed by Carpenter (21).

Growth. Low-normal birth weight and failure to thrive are characteristic (53). Proportionate short stature by adulthood is usually in the mild to moderate range (13,51,58). Adult males have an average height

of 61 in., and adult females, 59 in. (8). No consistent hormonal basis for short stature has been identified (8,100).

A number of anthropometric studies have been carried out (13–15, 19,62). Foot length tends to be smaller than hand length, and both hand and foot lengths frequently fall within the normal range before 10 years of age. As the discrepancy between height age and chronological age increases, hand and foot lengths become proportionately smaller. No anthropometric differences have been found between chromosome 15 deletion cases and nondeletion cases.

Central nervous system and performance. Severe congenital hypotonia is a constant feature during the neonatal period and early infancy. Improvement usually begins during the latter half of the first year (53). Hypotonia is clearly associated with poor fetal activity (74%–85%), breech presentation (22%–40%), and severe feeding difficulties (7,22,24,25,53). Early delays in developmental milestones (i.e., sitting up at 1 year, walking alone at 24–30 months) are also probably related (22–25,27,51,53,104,133,134). Mean IQ is about 54 (6). Various studies, including muscle biopsies, nerve conduction times, and electromyelograms, have either been normal, inconsistent, or nonspecific, which suggests that the hypotonia is probably central in origin (8,22,24,25,27).

Sleep disorders are common: daytime somnolence (50%), snoring (45%), restless sleep (40%), cataplexy (15%) (22–25,27). Mental retardation is usually mild (63%) to moderate (31%), but in 3%–8%, intelligence appears to be normal (22–25,27,51,109). Avoidance of obesity through early diagnosis and treatment may improve ultimate intelligence. Seizures occur in 16%–20%, but are usually not a chronic problem (7,53). Febrile convulsions are not unique to Prader-Willi syndrome but can be found in any neurodevelopmentally handicapped individual (131). Speech difficulties are found in almost all children (22,87,133). Visual motor discrimination skills are better than auditory verbal processing skills (34).

It is ironic that Prader-Willi children are known for their severe behavior problems when they are frequently loving, placid, and pleasant to be around. However, it is the behavior problems that cause families the most concern. Large, out-of-control, and not particularly hypotonic adolescents and adults can be very destructive and dangerous to themselves (22,33,51,53,133,134).

Decreased pain sensitivity, particularly of the skin, may explain why ordinary cuts and bruises can be picked at constantly by Prader-Willi individuals without apparent pain (22–25,27,51,53). Chronic sores and scarred skin lesions are found in all children beyond mid-childhood. Nasal bleeding secondary to chronic picking can be a difficult problem (51). Rectal picking with bleeding has been noted (5).

Albinoidism. Some degree of oculocutaneous albinoidism is common (11,32,56,130). Misrouting of retinal-ganglion fibers at the optic chiasm, typically seen in albinos, may be responsible for the strabismus found in Prader-Willi individuals (32). The hypopigmentation is due to deletion of the *P* gene (116).

Obesity. Excessive weight is the major complicating factor in Prader-Willi syndrome (83a). Once severe hypotonia remits, the child begins to gain weight at an excessive rate (53,95). Even before clinical obesity is evident, skinfold thickness indicates excessive adipose tissue (14). Obesity is usually obvious between 3 and 5 years (53) and has a generalized distribution, sparing only the distal finger tips and upper cranium (Figs. 11–22 and 11–24). Voracious appetite or binge eating can be dramatic, but weight gain can occur even on low daily caloric intake (59). Obesity can reach gigantic proportions causing severe cardiorespiratory distress as seen in Pickwickian syndrome (53,79,95,133). Frequent nodding-off or sleeping during normal waking hours and normal activities is typical for older obese individuals with Prader-Willi syndrome (22–25,27,51,79,97). Diabetes mellitus occurs in 4.5%–19% of late-teenage and adult individuals with Prader-Willi syndrome (8,51,79) and seems to be related directly to age and degree of obesity. Insulin is required in about 66%, but with significant weight loss, the need for insulin disappears (51,53). There is some evidence that weight reduction or avoidance of obesity in young Prader-Willi children stabilizes intelligence quotients. Some theorize, and common sense dictates, that effective weight control prolongs life expectancy in individuals with Prader-Willi syndrome (51). Anesthetic risk shows an increased but surprisingly low (2.5%) complication rate considering the obese state of many affected individuals (125).

Sexual development. Cassidy et al (22–25,27) surveyed genital abnormalities and hypogonadism in 105 patients. In general, individuals with Prader-Willi syndrome have few or no signs of pubescence (51). Males have high frequencies of scrotal hypoplasia, cryptorchidism, and micropenis (Fig. 11–25) (51,53,123). When males have any signs of puberty, minimal development of axillary and pubic hair occurs with a slightly higher frequency of demonstrable but scant beard (51).

Hypogonadism, hypogonadotropism, and hypergonadotropic-hypogonadism have been ascribed as causes of faulty sexual development (7,65,66). Testicular abnormalities and oligospermia have also been documented (7,69). Females have similar problems, although usually there is some breast development, and menstrual periods, if they do occur, are usually delayed in onset, irregular, and scant (51). Occasionally, male and female patients have precocious puberty; however, it is almost always incomplete and not true precocious puberty (121). Neither males nor females are fertile (51).

Craniofacial features. Head circumference is usually normal, but the bifrontal diameter is narrow (14,53). These and other measurements have been critically documented (14,15). The eyes are almond shaped (53). Because the medial upper lid hooks sharply downward, the eyes often have a slitlike appearance and an upward slant during infancy (117). Strabismus occurs in 40%–95% (8,53). An open, inverted, V-shaped mouth is usually present in the young child (Fig. 11–23) (22–25, 27,117). Enamel hypoplasia, dental caries, and malocclusion occur with increased frequency (31,38,53,60,75,133). Reduced salivation has been reported (8,22–25,27).

Limbs. The hands and feet are stated to be small (8,13,53) (Fig. 11–24). Although microsomic hands and feet are thought to be present congenitally, they are not usually recognized as such during the first 2 years (53,62). The fingers are short and narrow, but can look wide proximally and tapered distally when obesity becomes significant (22–25, 27,38,53,78,86,104,133). Hudgins and Cassidy (62) found normal-size hands when patients tended to be of normal height.

Skeletal system. Orthopedic and/or osseous problems are common. At birth, talipes (6.4%) and congenital hip dislocation (9.4%) occur with increased frequency (53,133). Later, scoliosis, osteoporosis, and slight increase in fracture rate are often noted (22–25,27,51,53). Delayed bone age can be seen (13,53). Metacarpophalangeal pattern profiles have been used to separate Prader-Willi syndrome from obese non–Prader-Willi controls (13). Skeletal roentgenograms show abnormalities that are both subtle and consistent, but that lack enough specificity to be useful as a major diagnostic tool (75).

Hematologic findings. Three instances of leukemia have been reported (51,52) and one case has been associated with factor XI deficiency (45).

Differential diagnosis. Prader-Willi syndrome should be distinguished from other postnatal-onset obesity syndromes: *Bardet-Biedl syndrome*, *Albright hereditary osteodystrophy, Cohen syndrome,* and Urban-Rogers-Meyer syndrome (120), in which there is a Prader-Willi habitus, with osteopenia, camptodactyly, and mental retardation. The disorder has been described only in males, two of them brothers (99). An X-linked Prader-Willi–like disorder of hypogonadism, gynecomastia, mental retardation, and obesity was reported by Vasquez et al (122). Mental deficiency may be associated with obesity and on occasion with *fragile X* and even with *Angelman syndrome.* Acquired hypothalamic injury from accidents, tumors, or surgical complications may closely mimic Prader-Willi syndrome (25). Syndromal obesity also occurs with paternal dup(7)(q24.3–q27) (115). Other postnatal-onset obesity syndromes have been discussed by Camera et al (20).

Laboratory aids. FISH with probes for 15q11–q13 and a centromeric control probe is the method of choice to detect large deletions or unbalanced translocations in suspected Prader-Willi patients (36,119). Polymorphic marker analysis, using DNA samples from an affected child and a parent, can be used to identify maternal disomy. Differential DNA methylation of maternal and paternal alleles include several genes and DNA markers in 15q11–q13: ZNF127,NDM,PW71, and SNRPN. The most reliable methylation probe is at SNRPN; the maternal allele is completely methylated and the paternal allele is completely unmethylated in all cases. Thus, methylation at SNRPN is the best single diagnostic tool for both Prader-Willi syndrome and Angelman syndrome (3,71,72,92,126).

Pregnancies with diminished fetal activity are candidates for molecular diagnosis by CVS. Other candidates are fetuses in which trisomy 15 or mosaic trisomy 15 have been detected by CVS (28,54,105).

Cohen syndrome

Cohen syndrome was first reported by Cohen et al (5) in 1973 as an obesity/hypotonia syndrome associated with mental retardation, narrow hands and feet, and characteristic facial appearance consisting of down-slanting palpebral fissures, short philtrum, open mouth, prominent upper central incisors, maxillary hypoplasia, and mild micrognathia (Figs. 11–26 to 11–28). The original report identified male and female sibs and one sporadic instance. To date, well over 100 cases have been recorded (2,3,6–14,16–23,25,27–36,38–43). Some cases have been reported as Cohen-like or resembling Cohen syndrome (1,13,15). In some series, individual cases are suspect, particularly among the sporadically occurring examples (4,10,14,25,27,35). Goecke et al (14) recognized the difficulty in diagnosing sporadic cases because of the wide variability of features among reported patients. Morris et al (24) attempted to divide Cohen syndrome into two separate groups: one with chorioretinal dystrophy, leukopenia, and lack of obesity, the other with classic Cohen syndrome. Norio and Raitta (25) saw no need for such a division and using the criteria of Morris et al (24), case 3 of Cohen et al (5) could not be classified in either category.

The inheritance of Cohen syndrome is autosomal recessive. Affected sibs have been documented frequently (4,5,8–10,13,14,20,24,27,31,35,36), and consanguinity has been noted in a number of instances (20,26,35). Identical female twins were reported by North et al (28). The gene (COH1) has been mapped to 8q22–q23 (18,19,38).

Growth. Newborns have low-normal birth weights, averaging between the 10th and 25th centiles (13,26,35). About 60%–70% ultimately have short stature (26,27), although tall stature has also been documented in a few cases (27,35).

Truncal obesity usually becomes evident between 5 and 12 years of age (Fig. 11–26) (4,5,13). Severe obesity or weight above the 97th centile does not occur, as a rule, and not all patients develop truncal obesity (10,35).

Delayed puberty was first noted by Carey and Hall (4) in 1978. Delayed or absent signs of puberty occur in approximately 80% (27). Precocious puberty was found in the twins reported by North et al (28). About 30% of males are cryptorchid (35).

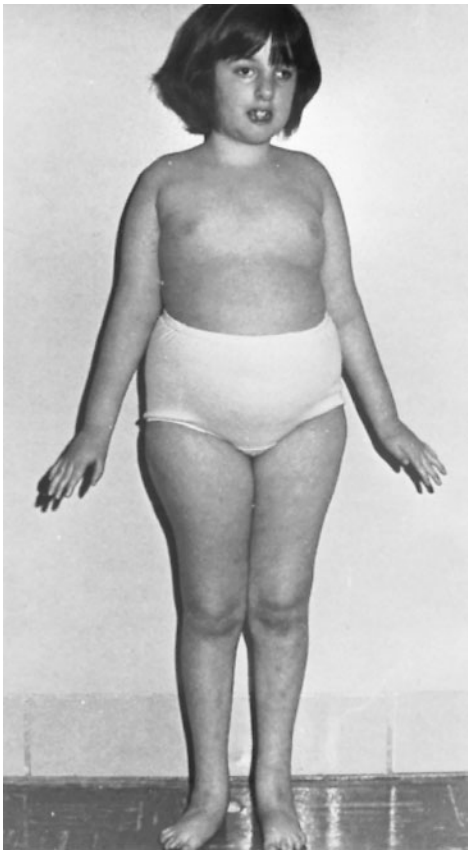

Fig. 11–26. *Cohen syndrome.* Obesity of mid-childhood onset, tapering hands and feet. (From MM Cohen Jr et al, J Pediatr 83:280, 1973.)

Central nervous system and performance. Hypotonia may be present at birth (13). It is usually noticeable in infancy (92%) and may persist into late childhood or early adolescence (4,27). The hypotonia may explain the high frequency of kyphosis and kyphoscoliosis (54%) (35).

Microcephaly is present in 50%–60% (26,27), usually of mild to moderate degree, and may be prenatal or postnatal in onset (14,26). Macrocephaly has been recorded in some patients (10,28). The corpus

Fig. 11–27. *Cohen syndrome.* (A,B) Characteristic facial appearance with mild microcephaly, downslanting palpebral fissures, short philtrum, and open mouth. (From MM Cohen Jr et al, J Pediatr 83:280, 1973.)

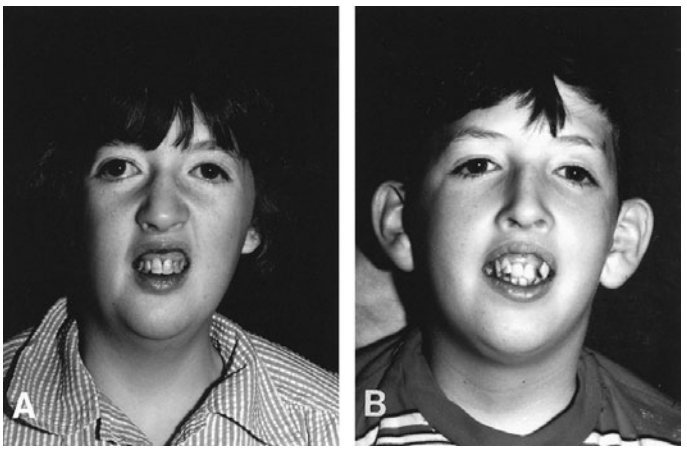

Fig. 11–28. *Cohen syndrome.* Narrow hands and fingers. (From MM Cohen Jr et al, J Pediatr 83:280, 1973.)

callosum is enlarged (17). Autistic behavior may be present up to the age of two years (13). Mental retardation is almost constant, with intelligence quotients ranging from 30 to 80 (26,35). About 6% have minor, nonchronic seizures (27). The demeanor has been noted to be happy, pleasant, and affectionate (5).

Facial features. Open mouth, exposed upper gingiva, and prominent upper central incisors are characteristic (5). The philtrum is short; the upper lip is arched and everted (5,26). Maxillary hypoplasia and mild micrognathia combined with high nasal bridge give the upper two-thirds of the midface a narrow prominence (Fig. 11–27) (5,26,35). The palate is usually high and narrow (97%) (26). The helical rims may be hypoplastic in some cases (26).

Eyes. The palpebral fissures are commonly downslanted (4,5,26,35). Occasionally, iris and/or retinal colobomas may occur with or without microphthalmia (4,5,27). Myopia (46%) and strabismus (52%) are frequent eye findings (27). In one series, 90% had myopia (K. Chandler, personal communication, 2000). Retinal pigmentary abnormalities (or chorioretinopathy) are seen in 80% (4–7,10,27,34,35,39, K. Chandler, personal communication, 2000). ERG is isoelectric and there is peripheral visual loss with some night blindness. The eye findings should never be confused with retinitis pigmentosa; blindness per se has never been noted in Cohen syndrome (26).

Limbs. Cubitus valgus and hyperextensible joints are found in about 50%. Mild syndactyly of the fingers, sometimes of the second and third fingers, occurs in 30%–35% (26,27). Hands are narrow and fingers are thin and long (Fig. 11–28) (4,5,26,27,35). Feet and toes are similarly affected, but less dramatically. Arms and legs are slender, probably secondary to decreased muscle mass (26).

Cardiovascular system. Heart defects have been noted in 10% (35) and may include floppy mitral valve, mitral valve prolapse, pseudotruncus with VSD, and isolated VSD (23,34,35). Norio et al (26) noted significant systolic murmurs in five of six of their cases.

Laboratory findings. Nonsymptomatic congenital neutropenia has been documented in many cases (13,17a,20,26,37). Olivieri et al (30) reported greatly increased neutrophil adhesive capability. Kivitie-Kallio et al (17a) studied 26 patients and found mild-to-moderate granulocytopenia beginning at early age. Massa et al (22) reported a patient with isolated growth hormone deficiency. Okamoto et al (29) found remarkably high levels of urinary hyaluronic acid in three patients and suggested that Cohen syndrome involves a metabolic abnormality in the extracellular matrix. Méhes et al (23) suggested that Cohen syndrome might be a connective tissue disorder. Higgins et al (16) demonstrated pyridoxine responsive hyper-β-alaninemia in one patient. ERG is isoelectric (26).

Differential diagnosis. Cohen syndrome is very distinctive; it is usually easy to separate from other postnatal-onset obesity syndromes. Most cases are not correctly diagnosed until mid-childhood to early adolescence (35). It is important to note that open mouth and prominent upper central incisors often occur in mouth-breathing (or adenoid) facies independently of Cohen syndrome. Furthermore, upper central incisors are prominent in all children from mid-childhood to the onset of adolescence because of the naturally occurring contrast between permanent and deciduous teeth in the mixed dentition. Every patient with mouth-breathing facies and either mental retardation or obesity does not have Cohen syndrome per se, nor does every child with obesity and mental retardation who cannot be diagnosed as having one of the other well-delineated postnatal-onset obesity syndromes.

Cohen syndrome has also been called Pepper syndrome (26) and Mirhosseini-Holmes-Watson syndrome (37); two sibs in the latter category had tapetoretinal degeneration. Norio and Raitta (25) indicated that Mirhosseini-Holmes-Watson syndrome is the same as Cohen syndrome or at least an allelic disorder. Some cases of Cohen syndrome have been misdiagnosed as *Prader-Willi syndrome, Marfan syndrome, Sotos syndrome,* hypothyroidism, minimal brain dysfunction, and most frequently as mental retardation of unknown cause (26). Hyperhyaluronicaciduria is a characteristic finding in *Werner syndrome*.

Camera-Marugo-Cohen syndrome

A syndrome of neonatal hypotonia, mental retardation, short stature, truncal obesity, gynecomastia, hypogonadism, camptodactyly, clinodactyly, and valgus deformity was first reported in 1979 by Urban et al (3) and Vasquez et al (4). Other examples are those of Camera et al (1) and Lambert et al (2).

The facies is characterized by narrow forehead, hypertelorism, and blepharoptosis.

Börjeson-Forssman-Lehmann syndrome

Börjeson et al (3), in 1962, reported a syndrome of characteristic facies (Fig. 11–29), mental retardation, obesity, hypotonia, and hypogonadism.

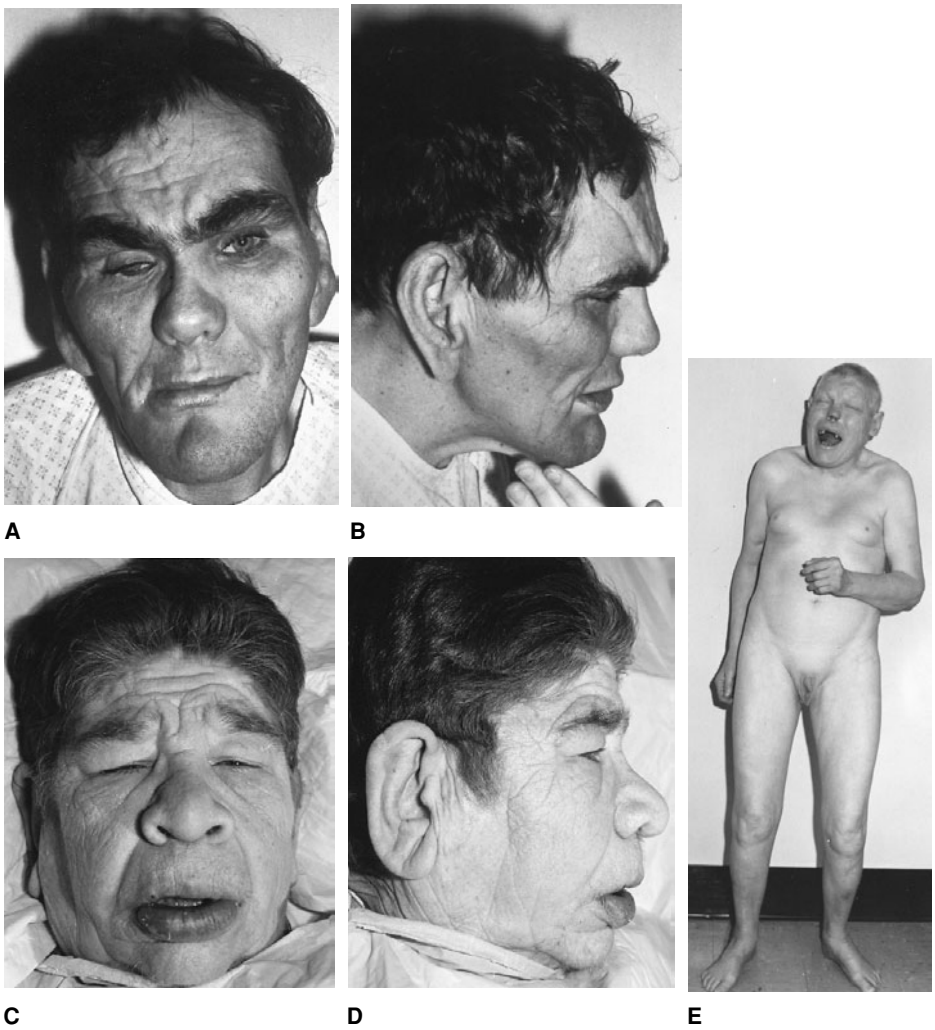

Fig. 11–29. *Börjeson-Forssman-Lehmann syndrome.* (A–D) Characteristic coarse facial appearance with microcephaly, prominent supraorbital ridges, deeply set eyes, nystagmus, ptosis, and large ears. (E) Characteristic facies, gynecomastia, lack of secondary sexual development. (A,B from HH Ardinger, Am J Med Genet 19:653, 1984.)

The syndrome is X-linked with variable expression in female heterozygotes (1,5,7,12,16). The gene map locus is Xq26–q27 (8–11,13). More than 35 cases have been reported (1,3–13,16). Over 80% of affected males are short and at least 60% are obese. These findings may be secondary to hypogonadism.

All affected males have a coarse facial appearance characterized by microcephaly, prominent supraorbital ridges, deep-set eyes, nystagmus, ptosis, and large ears (1,3,12,16) (Fig. 11–29A–D).

Radiographic studies have shown thickened calvaria, narrow cervical spinal canal, Scheuermann-like vertebral changes, mild epiphyseal dysplasia, delayed closure of radial and ulnar epiphyses, and short distal phalanges (1).

Hemizygotes have moderate to severe mental retardation. About 50% exhibit seizures and all have hypotonia. Electroencephalographic study has shown a paucity of alpha rhythms (1). CT scans show mildly dilated lateral ventricles. Female heterozygotes may have somewhat dull intelligence.

Hemizygotes have small atrophic or nonpalpable testes that descend late, small penis, and hypoplastic prostate. Secondary sexual development is poor and puberty is delayed until late in the second decade (1,12). Gynecomastia is frequent (Fig. 11–29E). Robinson et al (12) noted twin female heterozygotes with ovarian dysfunction.

Dermatoglyphic patterns of an affected male included bilateral I4 whorls, double loop hypothenar patterns, Sydney lines, and fibular arch pattern (7).

One case has been insufficiently documented (2) and another case has been erroneously identified (14). Differential diagnosis includes *Prader-Willi syndrome, Coffin-Lowry syndrome,* and *Biedel-Bardet syndrome*. In spite of the severity of their cases, we believe that the patients reported by Verloes et al (15) have Börjeson-Forssman-Lehmann syndrome.

Chapter 12
Hamartoneoplastic Syndromes

Acanthosis nigricans

Although Pollitzer (62) and Janovsky (44) described acanthosis nigricans (AN) in 1890, it was Pollitzer (63), in 1909, who made the first extensive study of cases previously reported and who emphasized the relationship of the skin disease to abdominal malignancy. During the next 85 years, over 1200 cases have been reported. Several excellent surveys (11,76) have been carried out, probably the greatest contributions being those of Curth and coworkers (19–23).

Acanthosis nigricans is not rare, being seen in at least 7% of children and more often noted in African-American children (13%) (81).

Throughout the years, AN has been classified in various ways, with all classifications being based on the clinical presentation and the association of AN with other conditions. The traditional classification divides AN into benign and malignant forms. It should be emphasized that this division is improper because the skin changes in both the so-called benign and malignant forms are histologically identical, with no cellular evidence of malignancy. The division was established to stress the association of AN with internal malignancy, especially gastrointestinal adenocarcinoma. Presently there is a tendency to divide AN into only two groups, the first associated with an internal malignant neoplasm and the second group composed of several entities that have in common their association with insulin resistance (30,39).

We believe that a division of AN according to clinical presentation can aid in the proper identification of the underlying associated conditions. In reviewing the literature, the following associations of AN have been identified:

A. Neoplastic association
B. Nonneoplastic association
   (1) Insulin-resistant types
      a. Type A syndrome (insulin receptor; includes leprechaunism) (HAIR-AN syndrome)
      b. Type B syndrome (antibodies)
      c. Type C syndrome (postreceptor level)
      d. Obesity
      e. Other endocrinopathies (includes Prader-Willi syndrome)
   (2) Congenital syndromes (Crouzono-dermo-skeletal dysplasia syndrome, Beare-Stevenson syndrome, thanatophoric dysplasia, SADDAN syndrome)
   (3) Autosomal dominant type
   (4) Drug-induced type
   (5) Miscellaneous types (idiopathic or isolated reports of association with other diseases or syndromes)

The nonneoplastic association types occur with greater frequency than the neoplastic association form. The discussion that follows will present, first, the clinical characteristics of AN and then a summary of each of the associated conditions.

Skin. The typical findings are dark-brown, smooth, hyperkeratotic papules, ranging from slight discoloration to cases in which the entire skin can be affected. In approximate order of frequency of pigmentation and papillomatous changes are the axillae, nape and sides of neck, genitalia, groin and inner thighs, umbilicus, perianal area, antecubital and popliteal surfaces, periorbital areas, and areolas (3,55). In addition to these changes, there is exaggeration of normal skin markings. The axillae or neck usually become pigmented before other areas are involved (Fig. 12–1).

The palms may be rugose (tripe palms) (6,16,17,49,65). In binary combination the phenomenon is especially associated with pulmonary carcinoma. When seen in binary combination with gastric carcinoma, acanthosis nigricans is usually present (34,59).

Clinical manifestations also include florid cutaneous papillomatosis and the sign of Leser-Trélat (multiple, rapidly growing seborrheic keratoses) (92). These manifestations may occur individually or in association with each other (2,27,75).

The major histologic changes observed are marked deposition of surface keratin with abnormal stratum corneum. The name acanthosis nigricans is not well chosen, as thickening of the epidermis is variable. In fact, atrophy is not uncommonly seen. The dark color is not related to increased melanocytes but to the proliferation of keratinocytes (30,55,68,73).

Most patients with acanthosis nigricans exhibit insulin resistance (28a,70). This may be due to a defect of the insulin receptor or in the number of receptors (56). This stimulates pancreatic islet B cells to produce excess insulin to compensate for the defect. The insulin binds to insulin receptors or insulinlike growth factor receptors which have tyrosine kinase activity. This induces cellular activity. Both fibroblasts and keratinocytes have insulin receptors and IGF receptors. There is resultant increased glycosaminoglycan deposition in the dermis and focal acanthosis of the epithelium. This results in papillomatosis and hyperkeratosis.

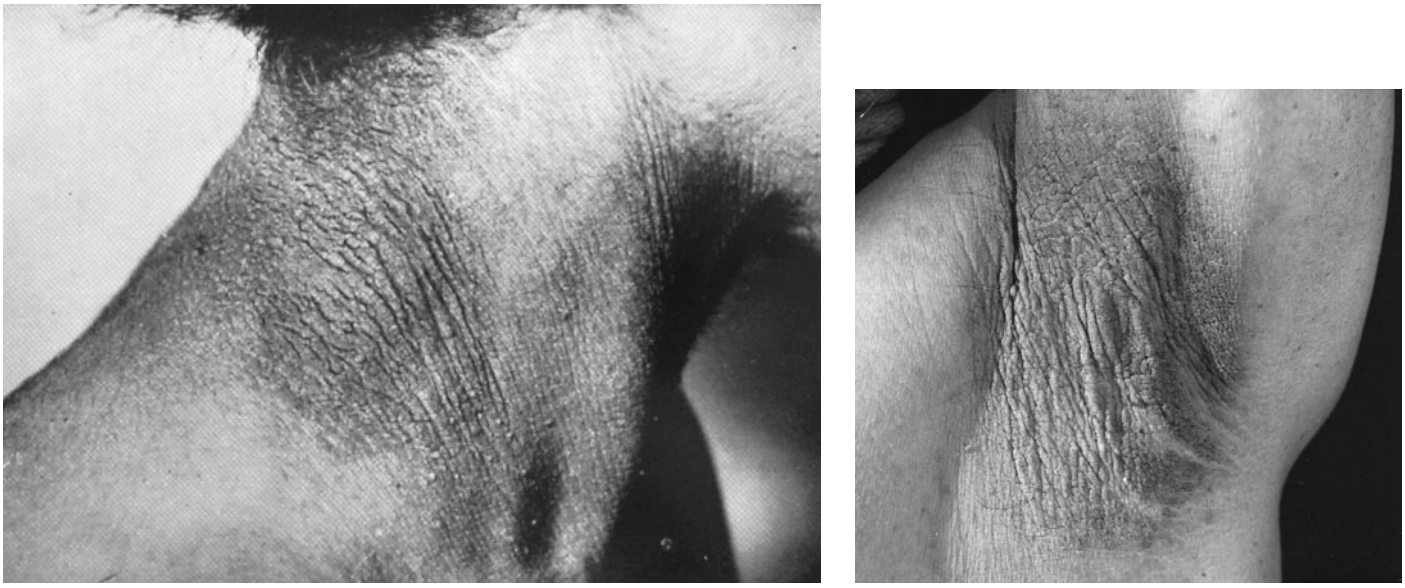
Pathogenesis in the case of malignant tumors is less clear, but it is assumed that growth factors or receptors (EGFR, TGFα) produced by the adenocarcinomas stimulate proliferation and increase resistance to apoptosis in keratinocytes and fibroblasts. These have insulinlike activity at the cell receptor level that effects the same end (4,25,54,76).

Nicotinic acid produces insulin resistance by activity at the cell receptor level (79).

Insulin receptors are found in ovarian stroma. In these cells, insulin is synergistic with luteinizing hormone. It is assumed that during puberty, elevated levels of insulin cause hyperandrogenemia. The more obese these patients, the higher the androgen levels. Hypothyroidism and its association with AN is probably effected through the attendant obesity (60).

Oral manifestations. Possibly the earliest description of oral lesions in AN was made by Pollitzer (63) in 1909. Masson and Montgomery (52) and Fladung and Heite (28) suggested that at least 50% of patients with the neoplastic association form have oral lesions. On the other hand, Sedano and Gorlin (77), on the basis of a survey of over 200 cases of the neoplastic association form, think that a truer value is about 30%–40%. A similar figure was reported by Brown and Winkelmann (11). Unfortunately, the oral mucosa is seldom thoroughly inspected in the course of a general examination.

Of all oral tissues, the tongue and lips are involved most frequently and to the greatest degree (58,85). The dorsum of the tongue, or at times the lateral border, exhibits hypertrophy and elongation of papillae. These give the tongue, marked by deep fissures or furrows, a shaggy or prickly appearance. In addition, one may see papillomatous growths studding its surface (52,63). In contrast to the skin lesions, the growths are rarely pigmented (11).



A B

Fig. 12–1. *Acanthosis nigricans*. (A) Pigmentations and papillomatosis of cervical region associated with gastric adenocarcinoma. (B) Pigmentation and papillomatosis of axillary area associated with gastric adenocarcinoma. (A from HO Curth, New York, New York.)

The lips, especially the upper, may be markedly enlarged and covered by filiform or papillomatous growths. These are especially marked at the angles of the mouth (19,52,63) (Fig. 12–2).

The buccal mucosa is usually less severely involved (2,55,86). There is generally a diffuse unevenness of its surface and a velvety white appearance. Occasionally, single fungiform growths are observed (19,52). The palate may be similarly affected (63). The gingiva, especially the interdental papillae, may become so much enlarged as almost to cover the teeth, resembling idiopathic fibromatosis (2,55,86). The connective tissue in these areas is well vascularized and with elongated papillae. Oral lesions are more deeply pigmented than the normal mucosa.

There is insufficient evidence to suggest the frequency of oral involvement in the nonneoplastic associations of the disease, but it would not appear to be great (11,48,84), Fladung and Heite (28) estimating 15%.

Malignant neoplasia. Curth and coworkers (19,22) and Rigel and Jacobs (71) presented impressive evidence that about 75% of the associated tumors are abdominal adenocarcinomas, of which almost 60% arise in the stomach. Other adenocarcinomas, such as those of uterus (3), pancreas, intestines (86), and, in a smaller percent, bile duct (67), bladder, lung (71), and breast (56), can be associated with AN. These carcinomas have a high degree of malignancy and prognosis is very poor.

Although most patients in this group are middle-aged or older, younger patients have been described (76). The extent of cutaneous and mucosal involvement is greater than in other associations.

The mortality rate is 100%, the average survival period after discovery being less than 2 years. Brown and Winkelmann (11) and Ackerman and Lantis (1) and others (43) argue that, although adenocarcinomas predominate, other tumors such as lymphomas may be part of the neoplasia-associated form (57). Garrott (33) suggested that when AN is associated with osteosarcoma, the distribution of skin lesions is different (extensor surfaces) and it affects young individuals.

Involvement of the skin may precede, accompany, or follow the detection of the cancer. In about 20%, AN precedes the appearance of the malignancy by up to 16 years. It parallels the cancer in proportion to the degree of spread; it may regress with radiation therapy or surgical removal of the tumor and may reflourish with recurrence of the adenocarcinoma (19,22,46). Generalized skin hyperpigmentation and pruritus occur in about 40% of neoplastic-associated type cases (11,38,55,76).

Other mucosae, such as vaginal, esophageal, conjunctival, laryngeal, and pharyngeal, can also be involved with papillary lesions (76,86).

Insulin-resistant types. This group is composed of conditions associated with AN and characterized by tissue resistance to the action of insulin (5). Patients with insulin resistance have been classified into *type* A (HAIR-AN syndrome). *H*yper*A*ndrogenism, *I*nsulin *R*esistance, and AN characterize this condition, observed mostly in adolescent or young females (5). Virilization, polycystic ovaries, and accelerated early growth with coarse features are part of the clinical findings. Five percent of female patients with hyperandrogenism assessed for hyperinsulinemia when fasting and after oral glucose administration have been found to present this syndrome (31). This variety is due to genetic defects in insulin receptor pathway (30). The vulva is most often (55%) affected by AN in this group, less often the axillae (35%) or neck (30%) (37). Leprechaunism also falls into this type. *Type B* is observed in older females with autoimmune disorders in which insulin resistance is due to circulating autoantibodies directed against the insulin receptor. Recently, a third variety has been described, *type C*. The clinical findings are similar to those found in type A, but in type C the insulin resistance seems to be located at postreceptor levels. The latter has been occasionally observed in men (32). Furthermore, Ritchie et al (72) have reported the association of AN, insulin resistance, hypogonadotrophic hypogonadism, hyperprolactinemia, and multiple organ-specific antibodies in a brother and sister. An excellent review is that of Rendon et al (69).

Seemanová et al (78) reported a 5-year-old boy with protruding eyes, puffy eyelids, ptosis, divergent strabismus, downslanting palpebral fissures, large ears, retrognathia, macrostomia, prominent everted lips, hypotonia, macrosomia, and acromegaloid signs with big hands, feet, ears, and penis. The child also had fasting hypoglycemia, dry and curly scalp hair, and marked AN of skin, neck, axillae, inguinal area and abdomen. Fibroblast cultures showed insulin binding in the normal range but a decreased number of insulin binding sites.

Obesity. This variety is almost always observed in young female patients where receptor and postreceptor mechanisms are responsible for the insulin-resistant state (31,50,51). Hud et al (42) found that 75% of an adult obese population had AN, correlating with the severity of the obesity, especially in African-Americans.

(C) Thickening of labial mucosa and papillomatosis. Pigmentation of oral mucosa is characteristically absent. (A,B courtesy of K Wolff, Vienna, Austria. C courtesy of A Proppe, Kiel, Germany.)

Other endocrinopathies. AN occasionally associated with a variety of other endocrinopathies may reflect the insulin resistance frequently observed in those disorders. The endocrinopathies have included *lipodystrophic diabetes* (13), adrenogenital syndrome (87), Cushing syndrome, acromegaly, Addison disease, Alström syndrome (36), Edmonds syndrome (36), Stein-Leventhal syndrome, *Prader-Willi syndrome* (69), ovarian hyperthecosis, and hyper- or hypothyroidism (11,12,21,30,69). Diabetic patients with insulin resistance may also present AN (7,14).

Mendenhall (53) described two sisters and a brother derived from first-cousin parents. They had unusual facies with marked prognathism, premature aging, precocious eruption of both primary and secondary dentitions with dysplastic teeth, thickened nails, hirsutism, AN, abdominal protuberance, insulin resistance, diabetes mellitus, and phallic enlargement in the male. Pineal hyperplasia was found at necropsy (66). West et al (88,89) reported similar findings in a brother and sister. This is called *Robson-Mendenhall syndrome*. Brown and Winkelmann (11) described two patients with malignant pinealoma and AN.

Congenital syndromes. AN has been observed in patients with *Bloom syndrome, Crouzono-dermo-skeletal dysplasia, thanatophoric dysplasia, and SADDAN syndrome*, among others (20,21,69).

Association of AN and Crouzon-like syndrome was first briefly pointed out by Curth (20) in a dermatology congress without actual case presentation. At least two dozen cases have been published in which this association is fully documented (9,35,41,47,68,82). Meyers et al (54), in 1995, reported that Crouzon-like syndrome and acanthosis nigricans is due to a mutation in the fibroblast growth factor receptor 3 (FGFR3) transmembrane domain mutation, Ala391Glu. The same finding was reported by Wilkes et al (90) in 1996. This is now called *Crouzonodermoskeletal syndrome*.

Beare-Stevenson syndrome is characterized by AN with cutis gyrata, craniosynostosis, cleft palate, hypodontia, and other defects (6,8,80). Przylepa et al (64), in 1996, reported two different mutations in fibroblast growth factor receptor 2 (FGFR2) in patients with the Beare-Stevenson syndrome. In three sporadic cases, a novel missense mutation was found causing an amino acid to be replaced by a cysteine. Two had the identical Tyr375Cys in the transmembrane domain and one had a Ser372Cys mutation in the carboxyl-terminal end of the linker region between the immunoglobulin III-like (Iglll) and transmembrane domains.

Baker et al (4), in 1997, reported an Arg248Cys mutation in the extracellular region of FGFR3 in two long-term-survival patients with

thanatophoric dysplasia type 1 and acanthosis nigricans. The reader is also referred to *SADDAN syndrome*.

Autosomal dominant type. Genetic studies have revealed that in some families a nonneoplastic type of AN exhibits irregular autosomal dominant inheritance (24,28,45,83). This variety manifests as a genodermatosis resembling ichthyosis hystrix, which may be present at birth or may begin later, either in childhood or, more often, at puberty, at which time it becomes more active.

Drug-induced type. The ingestion of diethylstilbestrol or nicotinic acid, or even topical application of nicotinic acid, may occasionally induce the development of AN (26,61,76). About 25% of those on nicotinic acid therapy for hypercholesterolemia for over six years will develop AN (79). AN can appear following corticosteroid therapy (59) or heroin use (79). AN has been seen at the site of insulin injections (29).

Miscellaneous types. A variety of conditions have been sporadically reported associated with AN, such as lupoid hepatitis, pemphigus vulgaris (18), and *hyperphosphatasemia (juvenile Paget's disease of bone)* (74).

Differential diagnosis. Regarding endogenous pigmentation, one should consider Addison's disease, arsenic poisoning, and hemochromatosis, but in none of these conditions is there an associated papillomatosis. Ichthyosis hystrix, *Cowden syndrome*, bromoderma, pemphigus vegetans, *hyalinosis cutis et mucosae*, condyloma acuminatum, and hairy tongue must all be excluded. In Afro-Americans, dermatosis papulosa nigra should be ruled out. Hirschowitz et al (40) described AN in a syndrome of nerve deafness, absent gastric motility, small intestine diverticulitis, and progressive sensory neuropathy. Autosomal recessive inheritance appeared likely. A generalized cutaneous papillomatosis similar to AN, including oral mucosa and palmoplantar surfaces, with no associated internal malignancy and starting at age 63, has been described in an Italian male (93).

Laboratory aids. Abundant deposits of glycosaminoglycans (GAGs) consisting mainly of hyaluronic acid have been found in the papillary dermis of lesions of AN patients with polycystic ovaries and insulin resistance (10). Normal amounts of GAGs were found in nonaffected skin of the same patient (91).

Cowden syndrome (multiple hamartoma and carcinoma syndrome, Lhermitte-Duclos disease)

The syndrome of multiple hamartomas, first described in detail by Lloyd and Dennis (48) in 1963, has its name derived from an affected individual. However, Costello (19), in 1941, reported the skin lesions in a patient who Brownstein et al (12) later documented with the disorder. Another early example is that of Witten and Kopf (89) in 1957. At least 200 cases of the syndrome have been published, emphasizing its hamartomatous character and delineating its principal involvement of the skin, gastrointestinal tract, breasts, and thyroid (Figs. 12–3 to 12–5). There are several excellent reviews (7,23,24,27,38,48,49,53,66,71,75). The frequencies of various abnormalities found in Cowden syndrome are listed in Table 12–1.

Inheritance is autosomal dominant with complete penetrance and variable expressivity (29,65,75). There is an excess of affected females (39). Anticipation was demonstrated with greater severity and earlier onset in each succeeding generation (39). Nelen et al (59) mapped the gene for Cowden syndrome to 10q23.3. Padberg et al (62), in 1991 and Sutphen et al (76), in 1999, showed that Lhermitte-Duclos disease is a component of Cowden syndrome. Liaw et al (46) and Marsh et al (54), in 1997, demonstrated that Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome were allelic, both being due to mutations in PTEN, a tumor suppressor gene (55). One sometimes sees examples of both conditions in one family (64a,92). The PTEN gene is responsible in embryonic development for organizing the relationship among different cell types (46,50,51,60,64). The gene encodes a dual specificity phosphatase that plays a broad role in sporadic human malignancy as well (23). The mutations, although scattered over the entire length of the gene, often involve exon 5 (55), in which a hot spot has been noted (73), but there is no clear cut genotype-phenotype correlation (60a). Diagnostic criteria have been discussed by Eng (23a) (Table 12–2).

Facies. Although head circumference is increased in 45% (39,75), the face is most remarkable for the large number of skin (mostly trichilemmomas) and oral (fibrous hyperplasia) hamartomata (vide infra). Adenoid facies has been present in some patients (20,48).

Skin. Mucocutaneous abnormalities are present in 99% of the cases (23,49,75). Age of onset of the dermatologic lesions is not well documented; however, they are usually noted by the patient at the end of the second or third decade (71). Typical lesions seen in 85% are trichilemmomas. They are lichenoid or papillomatous papules and small

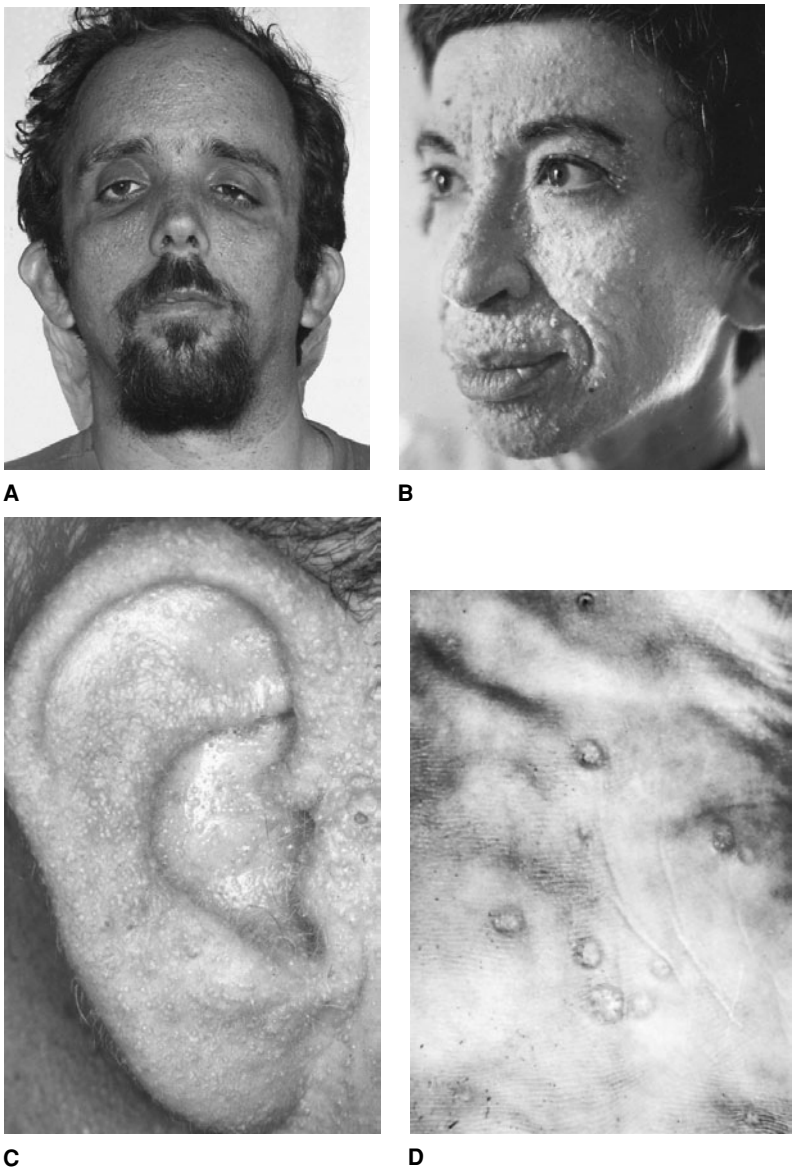

Fig. 12–3. *Cowden syndrome*. (A,B) Flesh-colored keratotic papules, particularly around eyes, nose, and mouth. Compare facies. (C) Ear involvement. (D) Punctate hyperkeratoses of palms. (B courtesy of M Wortzel, Camden, New Jersey. C from WC Gentry et al, Birth Defects 11(4):137, 1975. D from M Rosenbluth, Periodontics 1:81, 1963.)

nodules, located primarily on and around the eyelids, alae nasi, nasolabial folds, mouth, pinnas, lateral neck, glabella (85%), and the dorsa of hands and forearms (70%) (8,29,33,41,48,87) (Fig. 12–3A–C). They are numerous, some individuals having 50 or more. Punctate keratoses are present on the palms and soles (50%) (9,29,33,71) (Fig. 12–3D).

The microscopic features of the skin lesions have been reported in detail by several authors (12,72–74). Hair follicle hamartomas, with most lesions showing the pattern of trichilemmomas, are composed of large, pale glycogen-rich epithelial cells centrally surrounded by a single layer of smaller palisaded cells. A few display features intermediate between those of trichilemmomas and inverted follicular keratoses, whereas others have characteristics intermediate between trichilemmoma and tumor of the follicular infundibulum. Some specimens show nonspecific verrucous acanthomas or were not diagnostic. Any patient with two or more trichilemmomas should be considered to have Cowden syndrome (64). Trichilemmomal carcinoma has been described in one case (61). Dermal fibromas (acrochordons) are also found, characterized by interwoven collagen bundles with a laminated or tortuous appearance, embedded in abundant mucin (75).

Subcutaneous lipomas (9,11,29,40,68,70,71,85) have been noted in 25% and cutaneous hemangiomas (3,6,40,68,71,84,85) in 35%.

Squamous cell carcinoma of the skin of the nose (9) and basal cell carcinomas of the skin of the face (5) and perianal skin (15) have been reported.

Breasts. About 75% of females have fibrocystic disease or fibroadenomas, while another 25% have breast cancer, bilateral in about 35% (6,13,32,39,80). Specific references include: fibroadenomas (13), virginal hypertrophy (48,71), fibrocystic disease (4,48,70,71), ductal papillomas (71) and intraductal adenocarcinomas (6,13,29,48,52,65,71,77, 84,85,88). About 65% have nodal metastases. Adenocarcinoma of breast in males has been reported (28,55). Both carried germline PTEN mutations. Gynecomastia and fibrocystic disease have been noted in males.

Brain. Macrocephaly, ataxia, seizures, tremors, increased intracranial pressure, diadochokinesia, and dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease), a rare disorder of the cerebellum, is characterized by global hypertrophy of the folds, thickening of the molecular layer, enlargement of the Purkinje cells, and granular layers with astrogliosis (61,70,81). A number of examples have clearly been associated with Cowden syndrome (1,42,47,57,80,82,87). Padberg et al (58), Albrecht et al (1), Eng et al (26), and Wells et al (87) demonstrated that Lhermitte-Duclos disease was part of Cowden syndrome. See Albright et al (1) for survey of cases. There may be massive enlargement of the cerebellum and displacement and compression of the brainstem anteriorly resulting in hydrocephalus.

Meningiomas have been reported (22,33,47,52,76,85) as has astrocytoma (82) and medulloblastoma (6).

Mental retardation was documented in 10% (39).

Fig. 12–4. *Cowden syndrome*. Note thyroid enlargement. (From KM Lloyd and M Dennis, Ann Intern Med 58:136, 1963.)

Thyroid. Benign thyroid gland abnormalities, noted in about 60%–65% (39,71), include "goiter" (13,21,65,70,71,85,86) and adenoma (4,15,31,33,35,48,52,56,66,68,70,73). Follicular adenocarcinoma (13,39,85) is found in about 7% (Fig. 12–4). Hashimoto thyroiditis (85) and myasthenia gravis (90) have also been reported. Thyroid tumors have been noted in both males and females (28,55).

Gastrointestinal tract. The frequency of gastrointestinal neoplasms is not known, since all reported patients have not received complete gastrointestinal examinations. However, Carlson et al (16) and Chen et al (17) noted that 70% of those who had undergone lower gastrointestinal examinations had hamartomatous colonic polyposis. Hanssen et al (39) suggested that 40% have benign neoplasms, while 3% have colon cancer, a figure no different from that of the normal population. Chen et al (17) reported involvement of the entire alimentary tract. Polyps are found in descending order in the colon, stomach, small intestine, and esophagus. Polyps have been reported as early as 5 years of age (85) and have been found in all parts of the intestinal tract: esophagus (33,40,41,45,68,71,85,86), stomach (31,37,86), small intestine (31,37,86), and large intestine (31,32,74,86). On microscopic examination, polyps may be ganglioneuromatous (45), hyperplastic (32,40), benign lymphoid (40,71), hamartomatous (13,16,32,44,80), lipomatous (40,44), leiomyomatous (16), juvenile (40), and adenomatous (45,85). Esophageal polyps have been diagnosed on microscopic examination as exhibiting glycogenic acanthosis (40,45).

Gorensek et al (32) reported one patient with many hyperplastic polyps and adenocarcinoma of the descending colon. Burnett et al (13) reported adenocarcinoma of the cecum and Walton et al (84) described metastatic colon carcinoma; neither report noted preceding polyposis. We do not believe that malignant degeneration of colonic polyps is characteristic of the syndrome (69,79).

Other neoplasms. Many other neoplasms have been noted: cerebral gangliocytoma (71), meningioma (33,52,86), medulloblastoma (6), dural arteriovenous malformation (71), hemangioma (9,11,40,68, 71,84,85), parotid hamartomas (79), neurofibroma (21), granular cell tumor (71), xanthoma (10), salivary gland carcinoma (68), neuroma of Auerbach's plexus (13), lipomas (13,16,29,39,67,68,70,71,85), cystic hygroma (87), angiolipoma (29,86), angiomyomas of the extremities (29), liposarcoma (11,71), acute myelogenous leukemia (20), non-Hodgkin

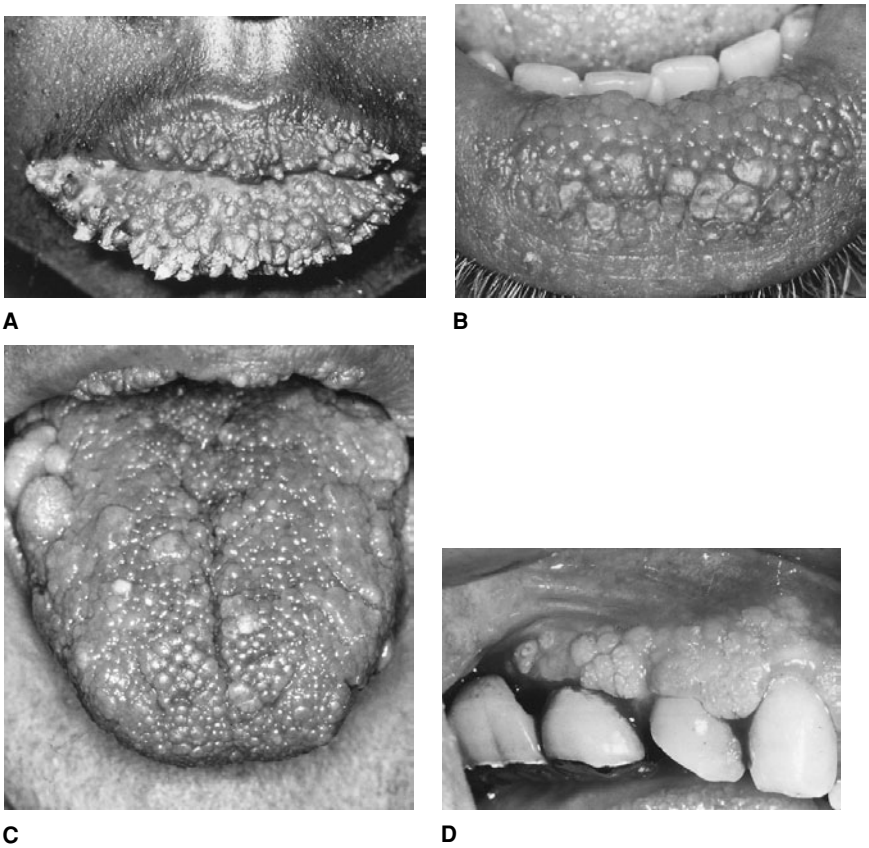

Fig. 12–5. *Cowden syndrome*. Oral involvement. (A,B) Papillomatous lesions of lips. (B) Close-up of lower lip involvement. (C) Papillomatous tongue. (D) Gingival involvement. (A from BS Allen et al, J Am Acad Dermatol 2:303, 1980. C from P Fritsch et al, Hautarzt 32:285, 1981.)

Table 12–1. Abnormalities associated with Cowden syndrome (n = 100; M = 37; F = 63)

Abnormalities	Percent
Mucocutaneous	
Multiple facial papules	85
Acral keratoses	73
Palmoplantar keratoses	54
Multiple oral papillomas	85
Dermal fibromas	24
Multiple skin tags	16
Oral fibromas	86
Scrotal tongue	20
Lipomas	31
Vascular malformations	18
Cutaneous and oral malignancies	8
Thyroid gland	
Goiter, adenoma	68
Hyperthyroidism	2
Hypothyroidism	3
Thyroiditis	3
Thyroglossal duct cyst	2
Follicular adenocarcinoma	3
Female breast	
Fibrocystic disease	52
Anatomic abnormalities	8
Virginal hypertrophy	6
Ductal adenocarcinoma	28
Ductal papilloma	14
Male breast	
Benign gynecomastia	7
Female genitourinary system	
Menstrual irregularities	20
Ovarian abnormalities (mainly cysts)	19
Leiomyomas	5
Vaginal and vulvar cysts	6
Adenocarcinoma of uterus	6
Carcinoma of uterine cervix	3
Carcinoma of ovary	2
Transitional cell carcinoma of renal pelvis	2
Male genitourinary system	
Hydrocele, varicocele	3
Transitional cell carcinoma of bladder	3
Gastrointestinal tract	
Polyps of upper GI tract	22
Polyps of colon and rectosigmoid	29
Diverticula of colon and sigmoid	2
Ganglioneuromas and neuromas	4
Epithelioid leiomyoma of rectosigmoid	1
Hepatic hamartoma	1
Adenocarcinoma of cecum	2
Adenocarcinoma of colon	1
Facial dysmorphism and skeletal abnormalities	
High head circumference	21
Adenoid facies	8
Highly arched palate	14
Kyphosis, kyphoscoliosis	14
Hand and foot abnormalities	6
Pectus excavatum	6
Bone cysts	4
Nervous system	
Neuromas of cutaneous nerves	5
Neurofibroma	3
Meningioma	3
Hearing loss	2
Eye	
Cataracts	3
Angioid streaks	2
Congenital blood vessel anomaly	1
Myopia	3

Table 12–2. *Cowden syndrome*—diagnostic criteria

Major criteria	
Cutaneous facial papules	
Oral mucosal papillomatosis	
Minor criteria	
Acral keratoses	
Palmoplantar keratoses	
Diagnostic requirements	
two major criteria or	
one major and one minor criterion or	
one major and family history or	
two minor and family history.	

From OS Salem and WD Steck. J Am Acad Dermatol 8:686, 1983.

lymphoma (20), melanoma (16,34,43,67,80), endometrial carcinoma (5), transitional cell carcinoma of bladder (40,46,55), renal cell carcinoma (36), and Merkel cell carcinoma of skin (36).

Skeletal abnormalities. Large head circumference was found in 80% by Starink et al (74). Lordosis (9), kyphosis (71), scoliosis (13,20), kyphoscoliosis (48), pectus (20), and bone cyst (28,48) have been documented.

Genitourinary abnormalities. About 50% of female patients have genitourinary anomalies. Menstrual irregularities (20%) and ovarian cysts (20%) have been documented (11,13,83,84). Other tumors have included: transitional cell carcinoma of the bladder, renal cell carcinoma, uterine cervical cancer, and uterine leiomyomas (36). These may be aleatory. There is increased incidence of miscarriage (11,85).

Other findings. Angioid streaks of the retina have been reported (2,3). Laryngeal polyps that interfere with phonation have also been noted (32,85,86). Pulmonary changes have been discussed by Solli et al (70a).

Oral manifestations. Papular and verrucous lesions of the lips, tongue, gingivae, alveolar ridges, buccal mucosa, palate, and tonsils have been seen in 85% (2,6,9,14,18,21,29,30,33,35,46,77) (Fig. 12–5). These lesions may coalesce and produce a cobblestone appearance (35, 65,78). The light microscopic appearance of oral lesions is consistent with the diagnosis of fibroma according to some investigators (11–13, 30,37,85). Others have described epithelial hyperplasia and papillomatosis (48,72,77). Squamous cell carcinoma of the tongue has been reported (15). We suspect that this association was fortuitous.

Differential diagnosis. A patient reported by Byars and Jurkiewicz (14) exhibited giant fibroadenomas of the breast, secondary kyphosis, hypertrichosis, and gingival fibromatosis. This condition (Byars-Jurkiewicz syndrome) may represent a disorder distinct from Cowden syndrome.

On clinical examination, cutaneous lesions in Cowden syndrome resemble those of warts, acrokeratosis, epidermodysplasia verruciformis, Darier disease, Torre-Muir syndrome, *lipoid proteinosis*, and *tuberous sclerosis*. However, the microscopic features and associated abnormalities serve to distinguish among these disorders. The intraoral lesions of focal epithelial hyperplasia and *multiple endocrine neoplasia syndrome, type 2B* are somewhat similar to those of Cowden syndrome, but differ on microscopic examination. The lesions at the oral commissures simulate those of *acanthosis nigricans* and oral lesions resemble those of Heck disease.

Polyps of the colon are found in a number of disorders (for discussion, see *Gardner syndrome)*. Ganglioneuromatous proliferation of the bowel may also be associated with *multiple endocrine neoplasia type 2b syndrome, neurofibromatosis*, and with juvenile polyposis of the colon (64) that does not exhibit PTEN mutations (25).

A Proteus-like syndrome has been shown to be due to PTEN mutations (91).

Laboratory aids. Biopsy of cutaneous and mucosal lesions should aid in differential diagnosis. T lymphocyte deficiency (37) has been reported but the significance is moot.

Germline mutation testing for PTEN can establish the diagnosis of Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome (9a,25,55).

Gardner syndrome

During 1950–1953, Gardner and coworkers (48,49) recognized and reported a syndrome of multiple adenomatous polyposis of the large intestines, multiple osteomas of facial bones, cutaneous epidermoid cysts, and desmoid tumors and fibrous hyperplasia of the skin and mesentery. Similar cases had been documented earlier (18,38,46,47), but Gardner was the first to recognize the hereditary pattern.

Gardner syndrome (GS) was initially thought to be an entity separate from familial adenomatous polyposis (FAP). However, with accumulation of data, many investigators have demonstrated that it represents one tail of the spectrum of that disorder (36,131,132). Cohen (28) found that about 50% of those with FAP had no extracolonic manifestations.

Inheritance is autosomal dominant with complete penetrance, and markedly variable expressivity (11,17,48,116). The FAP-GS gene has been mapped to 5q21–q22, but there is probable genetic heterogeneity (13,105,114,138,147,149). The syndrome has been found in individuals with interstitial deletion of 5q22.1–q31.1 (85,97). Linked DNA markers or direct detection can be used for presymptomatic diagnosis (40,115,147). The severity of the disease depends upon which codon is mutated (35,41). GS has been reported in 28-year-old monozygous

twins (51). One had complete expression of the disorder; the other had only osteomas of the jaws. The frequency of FAP-GS has been estimated to be between 1 in 12,000 (11,156) and 1 in 1400 (116). New mutations account for about 25% (98). The mutation rate of 5×10^{-6} mutations per gene per generation is on the same order of magnitude as other human mutations (11).

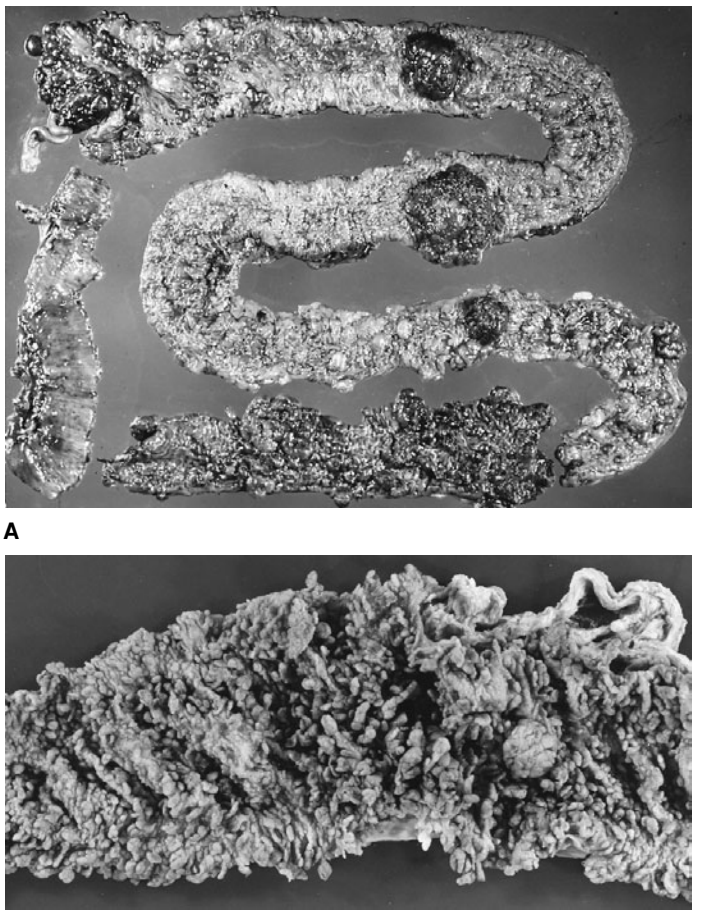
Osteomas. The osteomas associated with FAP, and particularly those associated with GS, are of various sizes and have limited growth potential. The radiopacity and microscopy are similar to those of mature compact bone and they have well-developed Haversian systems (5,72). The osteomas can be found in any bone, but most often are seen throughout the calvaria, frontal and ethmoidal sinuses, maxilla, and mandible (Fig. 12–6) (25,78,122). The tooth-bearing areas of the mandible and even of the maxilla are commonly involved (72). Those in the mandible often become confluent and enlarge (5,72,143,154). In a Japanese study, 50% had skeletal involvement (153), and 46% had three or more osteomas of the jaws (72), whereas 81%–93% had one or more (72,153,154). The osteomas may protrude (exostoses), but in most cases they appear as enostoses without palpable swelling (25,72,154). Bülow et al (14) studied individuals at risk for FAP and found that 76% had mandibular densities, contrasting sharply with 4% in the normal population. Long tubular bones, most often the radius, ulna, and metacarpals, may be sites of small osteomas, but involvement—in contrast to that of the facial skeleton—is minimal, and usually manifests as rather diffuse radiologic subperiosteal cortical thickening. In a few cases, however, these osteomas presented as small, well-defined exostoses (25,78). Osteomas may be found in members of families with FAP who do not have manifest polyposis (52) and may precede the appearance of intestinal symptoms (51,122). Woods et al (161), however, found significant bone lesions in only 15%.

Epidermoid cysts. Cysts of the skin occur in about 50%–60% of all cases of GS, but have been present in some families in nearly all of those affected (91,158). In one study of 74 patients with the syndrome, over 50% had cysts and all those with cysts had or subsequently developed colonic polyposis (91). The number of cysts has ranged from 1 to 20, with an average of 4 per patient. They occur most often on the legs, face, scalp, and arms, the trunk being seldomly affected (Fig. 12–7A) (91). Although the cysts may appear at any time from birth to 35 years, they most often become manifest around puberty, prior to the appearance of colorectal polyposis (48,52,91,93). New cysts appear periodically (52,158). The early appearance of the cysts can be used as a guide to indicate which members of a family are at risk for developing polyposis (30,39).

The histologic picture of the cyst shows the characteristic features of epidermoid cysts (Fig. 12–7B) (91), although they are often referred to as sebaceous cysts. It has been pointed out that about 50% of the cysts have shadow cells, resembling pilomatrixoma (31,93,120,127).

Gastrointestinal system. Multiple intestinal polyposis of the colon and rectum with a marked tendency to malignant degeneration is characteristic (Fig. 12–8A,B). Although the polyps may appear before puberty (30,39,116), the chance for malignant transformation at this age is less than 5%. The mean age for diagnosis of the polyps is 23–31 years (92). The mean age for diagnosis of the intestinal cancer is 37 years (116). By 30 years, about 50% of the patients exhibit malignant degeneration,

Fig. 12–8. *Gardner syndrome*. (A) Multiple polyps of colon undergoing malignant transformation to adenocarcinoma. (B) Close-up of multiple colonic polyps. (B from K Ooya et al, J Oral Pathol 5:305, 1976.)



A

B

but the frequency of malignancy with advanced age is probably near 100%. The origin of the polyps is multiclonal (70). The age of presentation and the degree of malignancy depend on the specific mutation (23,24).

Polyposis of the stomach and small intestines has rarely been reported (52,59,66,82,155,163), and malignant degeneration of small bowel polyps appears to be relatively low (2%–3%) (16). The reader is referred to a good summary of these and other cases (131).

The association of periampullary adenocarcinoma (carcinoma of the ampulla of Vater, duodenum, or pancreas) has been established (18,79). It may develop in the absence of other extracolonic adenomatous polyps. The frequency has been estimated as high as 12% among patients with FAP but in only 2%–3% among patients with GS (12). Lymphoid hyperplasia of the terminal ileum has also been noted (131).

Desmoid tumors. Both abdominal and extraabdominal desmoids exhibiting diffuse fibrous infiltration have been seen in 15%–30% of patients with GS (22,26a,42,78), but in only 6% of those with FAP (84,136) (Fig. 12–9). The tumors usually arise 1–3 years following abdominal surgery. Their removal may be followed by further desmoid formation, although desmoids, fibromas, and fibrosarcomas of the skin have been noted without prior surgery (108,136). It should be noted that among patients who exhibit both FAP and desmoids, about half will show other stigmata of GS (101,134). Desmoid tumor development depends upon which codons are mutated (23,24). Mesenteric and retroperitoneal fibromatosis has been reported in patients with no stigmata other than FAP (52,101,124,134). Occasionally, the fibroblastic tumors may precede the discovery of the colonic polyposis (101,131).

Other neoplasms. There appears to be a distinct proclivity for those with FAP to develop a variety of neoplasms. The extracolonic neoplasms may be diagnosed a long time prior to the symptoms of intestinal polyposis (10,46,109). Various tumors of the central nervous system (glioma, medulloblastoma) have been reported (4,19,20,28,33,94,113,136,162). This has created confusion with Turcot syndrome, which has been confused with GS (see *Differential diagnosis*). Papillary carcinoma of the thyroid been found in at least 35 cases and is 100 times more frequent in the syndrome than in the normal population (102). See Delamarrre (37) for tabulation of cases. Other examples are offered (4,8,28,29,82,137). At least 90% of these patients are female. Many of these patients also had medulloblastoma.

A wide variety of other neoplasms has been reported: adrenal adenoma (38,106), adrenal adenocarcinoma (99), hepatocellular carcinoma (164), hepatoblastoma (50,55,71,83,88,96,142), retroperitoneal leiomyoma (28,55,108), neurofibroma (12), rhabdomyosarcoma (6), osteosarcoma (65,157), osteochondroma (56), chondrosarcoma (54), lipoma

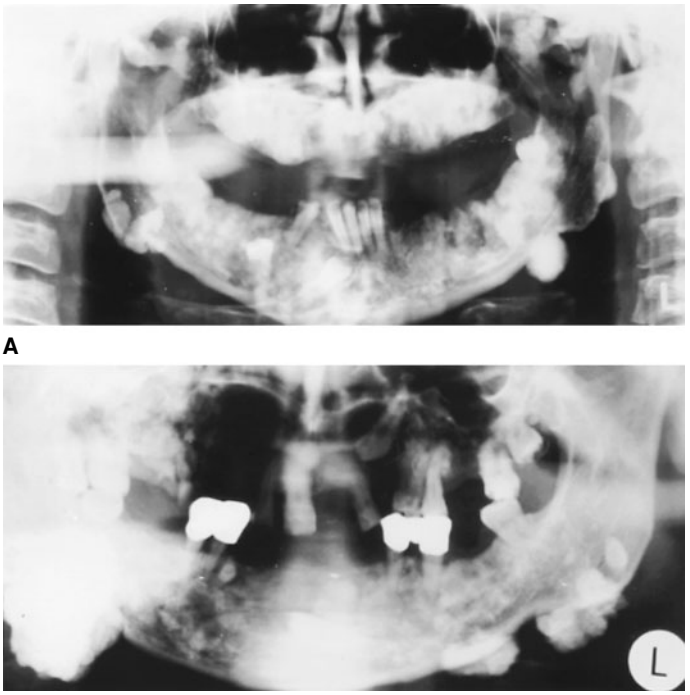

Fig. 12–10. *Gardner syndrome*. (A,B) Panorex of jaws showing osteomas and odontomas. (A from J Wolf et al, Br J Oral Maxillofac Surg 24:410, 1986. B From F Sitzman and H Bruning, Dtsch Zahnarztl Z 32:781, 1977.)

(28,89), fibroma of the breast (56,134), basal cell carcinoma (28,95,103), and a host of other tumors (28,63,131,132,157).

Eye findings. Over 60% of patients with GS have one oral patch of congenital hypertrophic retinal pigment epithelium (CHRPE) (Fig. 12–9). The ocular fundal lesions are bilateral in over 75% (64,88, 104,117,140,150,151). However, Shields et al (133) found no such correlation and Houlston et al (68) cautioned using its presence as a marker. It has been demonstrated that whether CHRPE is present depends upon which codons are mutated (19,23,24,110).

Skin. Increased skin pigmentation has been noted (159).

Oral manifestations. Fitzgerald (46) appears to be the first to have described multiple odontomas in the syndrome—he did so in 1943. In 1962, Fader et al (45) added supernumerary teeth (Fig. 12–10). These findings have been supported by many other investigators (25,78,123, 135).

In 97 patients with FAP, 17% had dental abnormalities; 11% had supernumerary teeth and/or osteomas, and 9% had impacted permanent teeth (139). Utsunomiya and Nakamura (154) found impacted teeth in about 35% of patients with intestinal polyposis. Söndergaard et al (139) noted supernumerary teeth in 10% and impacted teeth in 9%. Ida et al (72), in a study of 52 patients with polyposis coli, reported embedded teeth (27%), supernumerary teeth (21%), and compound odontomas (11%). One or more osteomas of the jaws were found in over 80%. Occult radiopaque lesions of the jaws are common (21,109,112,143,160). Thakker et al (144), using a weighted scoring system, found almost 70% to have significant bony changes.

Various incidental findings have included hypercementosis (165), root resorption, ankylosis (5), and persistent primary teeth (2).

Differential diagnosis. Multiple polyps of the intestine have been described in a number of disorders (Table 12–3). The reader is referred to several excellent reviews (17,36,57,61,126).

Juvenile polyposis of the colon. Juvenile polyps of the colon may have autosomal dominant inheritance (141). The polyps are hamartomatous and not precancerous. They are composed of an excess of lamina propria in which epithelium-lined tubules are embedded with or without cystic dilatation and secondary inflammation.

Turcot syndrome. In 1959, Turcot et al (152) reported sibs with multiple intestinal polyposis and brain tumors. Several authors (7,74, 81,86,103,107,146,152) subsequently reported sibs with glioblastoma multiforme and multiple polyposis. Astrocytoma, spongioblastoma, and glioma have also been reported (75,146). Multiple café-au-lait spots and axillary freckling, similar to that seen in neurofibromatosis, may be seen (44,75,145). Parental consanguinity and sib involvement clearly indicate autosomal recessive inheritance (7,32,44,76,103, 107,121,146,152). Tops et al (148) have shown that Turcot syndrome is not allelic to FAP. However, there have been both numerous examples of nonfamilial occurrence of brain tumors with colonic polyposis and several examples of brain tumors in typical FAP (GS) that have dominant inheritance. These cases have been reviewed elsewhere (74,75,87, 96,121,146). The brain tumors in these cases are far more often medulloblastoma (60,100,104). Colonic polyps in Turcot syndrome are presumably smaller in number, larger in size, and earlier to undergo malignant degeneration than those in FAP.

Peutz-Jeghers syndrome. This autosomal dominant syndrome, characterized by generalized gastrointestinal hamartomatous polyps and macular pigmentation of the face, lips, and oral mucosa, is described in detail later in this chapter. The typical polyp contains muscularis mucosa. The epithelial element is related to the smooth muscle in the same manner as in normal mucous membrane.

Cronkhite-Canada syndrome. Generalized gastrointestinal polyposis in middle-aged to elderly individuals may be associated with edema, malabsorption, diarrhea, protein-losing enteropathy, generalized alopecia, and nail dystrophy. Brownish skin pigmentation may be diffuse over the face, neck, and hands, including palmar creases (34,77,80). The disorder is not hereditary. Most cases have been reported from Japan.

Muir-Torre syndrome. This autosomal dominant syndrome includes multiple sebaceous neoplasms (generally benign), keratoacanthomas, and adenocarcinomas, most often of the colon, endometrium, and ovary (1,27,58,62). Over 135 cases have been published (62). It has been shown to be due to an underlying DNA mismatch-repair defect and to be allelic to dominant nonpolyposis colorectal cancer (88).

Perifollicular fibromas and intestinal polyposis (Birt-Hogg-Dubé syndrome, Hornstein-Knickenberg syndrome). Hornstein (67) reported autosomal dominant perifollicular fibromas and skin tags of the face, neck, and trunk associated with adenomatous colorectal polyposis as an entity separate from Gardner syndrome. The association of skin tags and intestinal polyps has been discussed by several authors (2,26,125,130). Ishii et al (73) reported sibs with congenital atrichia, pigmented and papular cutaneous lesions in the 20s, and gastrointestinal polyposis in the 30s.

Other multiple intestinal syndromes. Polyps of the large intestine may be seen in *Cowden syndrome*. There are several inherited examples of associated polyposis of stomach and colon, familial polyposis of the entire gastrointestinal tract, and several cases of solitary polyps of the colon and rectum apparently inherited as an autosomal dominant trait (66). However, it is possible that these are merely examples of the variability of familial colonic polyposis (17,36).

Howel-Evans syndrome refers to the occurrence of gastrointestinal adenocarcinoma and punctate keratosis of the palms and soles (9).

Bannayan-Riley-Ruvalcaba syndrome consists of macrocephaly, intestinal polyposis, and pigmentary spotting of the genitalia; inheritance is autosomal dominant. *Infantile Cronkhite-Canada syndrome* consists

Table 12–3. Syndromes with polyposis

Syndrome	Characteristics	References
Cowden syndrome	Facial papules, acral keratoses, oral papillomas, thyroid adenoma, fibrocystic disease of the breast, menstrual irregularities, gastrointestinal polyposis, ductal adenocarcinoma of the breast, autosomal dominant	See pages 432–437.

Torre-Muir syndrome	Multiple sebaceous tumors; keratoacanthomas; adenocarcinomas of colon, endometrium, and ovary; sporadic occurrence	(27,58,62)
Perifollicular fibromas and intestinal polyposis	Perifollicular fibromas; skin tags of the face, neck, and trunk; adenomatous colorectal polyposis; autosomal dominant	(3,26,67,125,130)
Bannayan-Riley-Ruvalcaba syndrome	Macrocephaly, intestinal polyposis of distal ileum and colon, pigmentary spotting of the penis, hypotonia, mild to moderate mental deficiency, infantile overgrowth	See pages 410–413.

of diffuse gastrointestinal polyposis, macrocephaly, alopecia, nail dystrophy, clubbing of fingers and toes, hypotonia, hepatosplenomegaly, anemia, and protein-losing enteropathy (90,128,129). Most examples undoubtedly represent *Bannayan-Riley-Ruvalcaba syndrome*.

Juvenile polyposis has been associated with arteriovenous malformations and hypertrophic osteoarthropathy [see Gorlin et al (53) for review of earlier cases]. Additional examples have been described by Prieto et al (119) and Erkul et al (43). Germline mutations in SMAD4 that map to 18q21.1 account for some cases of juvenile polyposis (68). Some germline PTEN mutations have been found as well (111).

Diagnosis. The presence of multiple epidermoid inclusion cysts, desmoids, or bony growths, especially of the facial skeleton, should lead to a complete search for the intestinal component. Recording of these incidental findings should be just as mandatory as radiographic search for additional intestinal polyps if a single rectal polyp is detected. The discovery of multiple polyps, or of any other component, also places the onus of responsibility upon the investigator to search other relatives thoroughly for stigmata. Since a negative report does not mean that polyps or other components will not appear in future years, periodic reexamination of all persons with a parent or sib who had one or more signs is necessary.

Prenatal or presymptomatic diagnosis can be carried out by the use of closely linked DNA markers (40).

Laboratory aids. Radiographic survey, especially of the facial skeleton, and barium studies of the large and small intestines are mandatory. Prenatal and postnatal diagnosis can be carried out by molecular methods (98,115,118,147).

Gorlin (nevoid basal cell carcinoma) syndrome

Nevoid basal cell carcinoma syndrome (NBCCS) is characterized by numerous basal cell cancers and epidermal cysts of the skin, odontogenic keratocysts of the jaws, palmar and plantar pits, calcified dural folds, various neoplasms or hamartomas (ovarian fibromas, medulloblastoma, lymphomesenteric cysts, fetal rhabdomyomas, etc.), and various stigmata of maldevelopment (rib and vertebral abnormalities, cleft lip and/or palate, cortical defects of bones, etc.) (Figs. 12–11 to 12–15).

The condition, first described independently by Jarisch (95) and White (211) in 1894, probably existed during dynastic Egyptian times (175). It has been variously known as basal cell nevus syndrome, Gorlin-Goltz syndrome, Gorlin syndrome, and nevoid basal cell carcinoma syndrome. Admittedly, none is satisfactory, as selection of only one facet (and in blacks a relatively uncommon one) is highly biasing. The term *nevus* does not project the truly cancerous nature of the skin lesions—although only a small number of basal cell carcinomas become aggressive. Eponyms imply priority of description (and are often wrong, frequently chauvinistic, and say nothing about the disorder). They serve to plague residents who are required to memorize them.

Early American reports are those of Binkley and Johnson (18), Howell and Caro (91), and Gorlin and Goltz (70). Comprehensive systematic surveys (52,67,68,106,125,181) and historic reviews (67,90) of the syndrome are available.

The frequency of NBCCS has been variously estimated. Maddox (128) found the syndrome in about 0.4% of all cases of basal cell carcinomas. Rahbari and Mehregan (158) calculated that 2% of those younger than 45 years of age with basal cell carcinomas have NBCCS, in contrast to 22% of those younger than 19 years. Evans et al (50) suggested that the minimal prevalence was 1 per 57,000. A similar prevalence can be calculated from the data of Pratt and Jackson (157). Chevenix-Trench et al (29) found a minimal prevalence of 1 per 164,000.

NBCCS has autosomal dominant inheritance with complete penetrance and quite variable expressivity. There is no sex predilection. About 35%–50% represent new mutations (132). The gene has been mapped to chromosome 9q22.3 (29,34,53,54,58,165,203,212). It consists of 23 exons with 12 transmembrane spanning domains and two large extracellular loops (117). There have been a few examples of deletion of this area of chromosome 9 in patients with the syndrome (7,17,184). These patients have been mentally retarded. Widespread developmental anomalies as well as other neoplasms and overgrowth and loss of heterozygosity at this site suggested mutation of a tumor suppressor gene (37,58). Tumor suppressor genes are recessive oncogenes (anti-oncogenes), homozygous inactivation being a requisite for their carcinogenic expression (37,119). The gene *PTCH*, which modifies the Hedgehog signaling pathway, is mutated not only in the syndrome but in ordinary basal cell carcinomas (3,30,45,57,59,75,100,149,186,202,205a,217). *Patched*, a transmembrane gene in the absence of its ligand, sonic hedgehog, acts as a cell cycle regulator, normally inhibiting expression of downstream genes (*smoothened*, among others) which control cell fates, patterning, and growth (185). In accordance with the Knudson two-hit hypothesis, the gene of one homolog results from inherited point (germline) mutation with loss of the second homolog by mitotic nondisjunction, deletion, or mitotic recombination, i.e., random somatic events (119). In NBCCS, tumors (basal cell carcinomas, keratocysts, meningiomas, ovarian fibromas, odontogenic keratocysts) exhibit loss of heterozygosity (116,177).

Note differences in size and pigmentation. (D) Photomicrograph of nevoid basal cell carcinoma. Note ectopic calcification (100×, H and E). (E) Palmar pits. Pits are usually a few millimeters deep, more evident in those performing manual labor; relatively rare in children. (F) Photomicrograph of palmar pit. Note mild acantholysis of epithelium at bottom of pit. (A from JB Howell and MR Caro, Arch Dermatol 79:67, 1959. B,F courtesy of JB Howell, Dallas, Texas. C courtesy of RA Cawson, London, England.)

Various physical anomalies (bifid rib, macrocephaly, cleft lip, etc.) apparently need but one-hit. The reader is referred to several excellent reviews of the molecular aspects of NBCCS (8,20,146,184). There is no genotype–phenotype correlation (117,213). Two patients have been reported with associated Turner syndrome (1a,107a). It is interesting that the gene for Ferguson-Smith syndrome (multiple self-healing squamous cell carcinomas or keratoacanthomas) maps to the same site on chromosome 9q22.3, possibly representing different mutations within the same gene (71,167). There is a second *Patched* gene at 1p32–p34 that may play a similar role (33,186,187). Farther down the hedgehog pathway, Gli2 overexpressed causes basal cell carcinoma in mice (71a).

Craniofacial features. The head appears large (>60 cm in adults). Relative macrocephaly (occipitofrontal circumference greater than 95th centile for height) is found in 50% (106). Although one-third of probands have an occipitofrontal circumference less than the 50th centile for height, i.e., when head size is adjusted for height, most do not have true macrocephaly (8). Only rarely is hydrocephalus reported (126). Frontal bossing, noted in 25%, may cause the eyes to appear sunken. Mild true hypertelorism is seen in only about 5%. The eyebrows are highly arched in about 40% (181). Median age of onset is 25 years. In about 35% in both whites (67) and blacks (65), mild mandibular prognathism, noted as "pouting lower lip," is seen. Facial milia are scattered among the basal cell carcinomas in at least 50%–60%, especially around the eyes, eyelids, nose, malar region and upper lip (vide infra). The palate tends to be high (Fig. 12–11).

Eyes. Various ocular problems occur with a frequency (10%–25%) far greater than in the normal population. These include congenital cataract (5%), microphthalmia, orbital cyst, coloboma of iris, choroid and optic nerve, strabismus (15%), and nystagmus (52,67,130,176,200). Small keratin-filled cysts (milia) are found intermixed with basal cell carcinomas in 30%–50% (29) on the palpebral conjunctiva, where they are transitory.

Skin. Basal cell carcinomas, which may appear as early as 2 years of age, especially on the nape, most often proliferate between puberty and 35 years (181). Median age of onset is 25 years. Of those over 30 years, only about 10% have none (164). There appears to be a relationship to increased sun exposure, because only about 40% of blacks with the syndrome manifest basal cell cancers, and then usually have only a few lesions in contrast to the numerous basal cell carcinomas evident in whites (ca. 90%) (65,109). It should be emphasized that the melanotic skin pigmentation does not protect against ionizing radiation (109).

The basal cell cancers, which vary in number from a few to literally thousands, range in size from 1–10 mm in diameter. They are pearly to flesh colored to pale brown and may be mistaken for skin tags, nevi, hemangioma, or molluscum contagiosum. Most often the basal cell carcinomas involve the face, back, and chest (Fig. 12–12). Only rarely is one found below the waist or on the extremities. New lesions appear from time to time, but most remain static in growth. It is only after puberty that the basal cell carcinomas can become aggressive and invade locally. It must be emphasized that only a small fraction of the lesions become

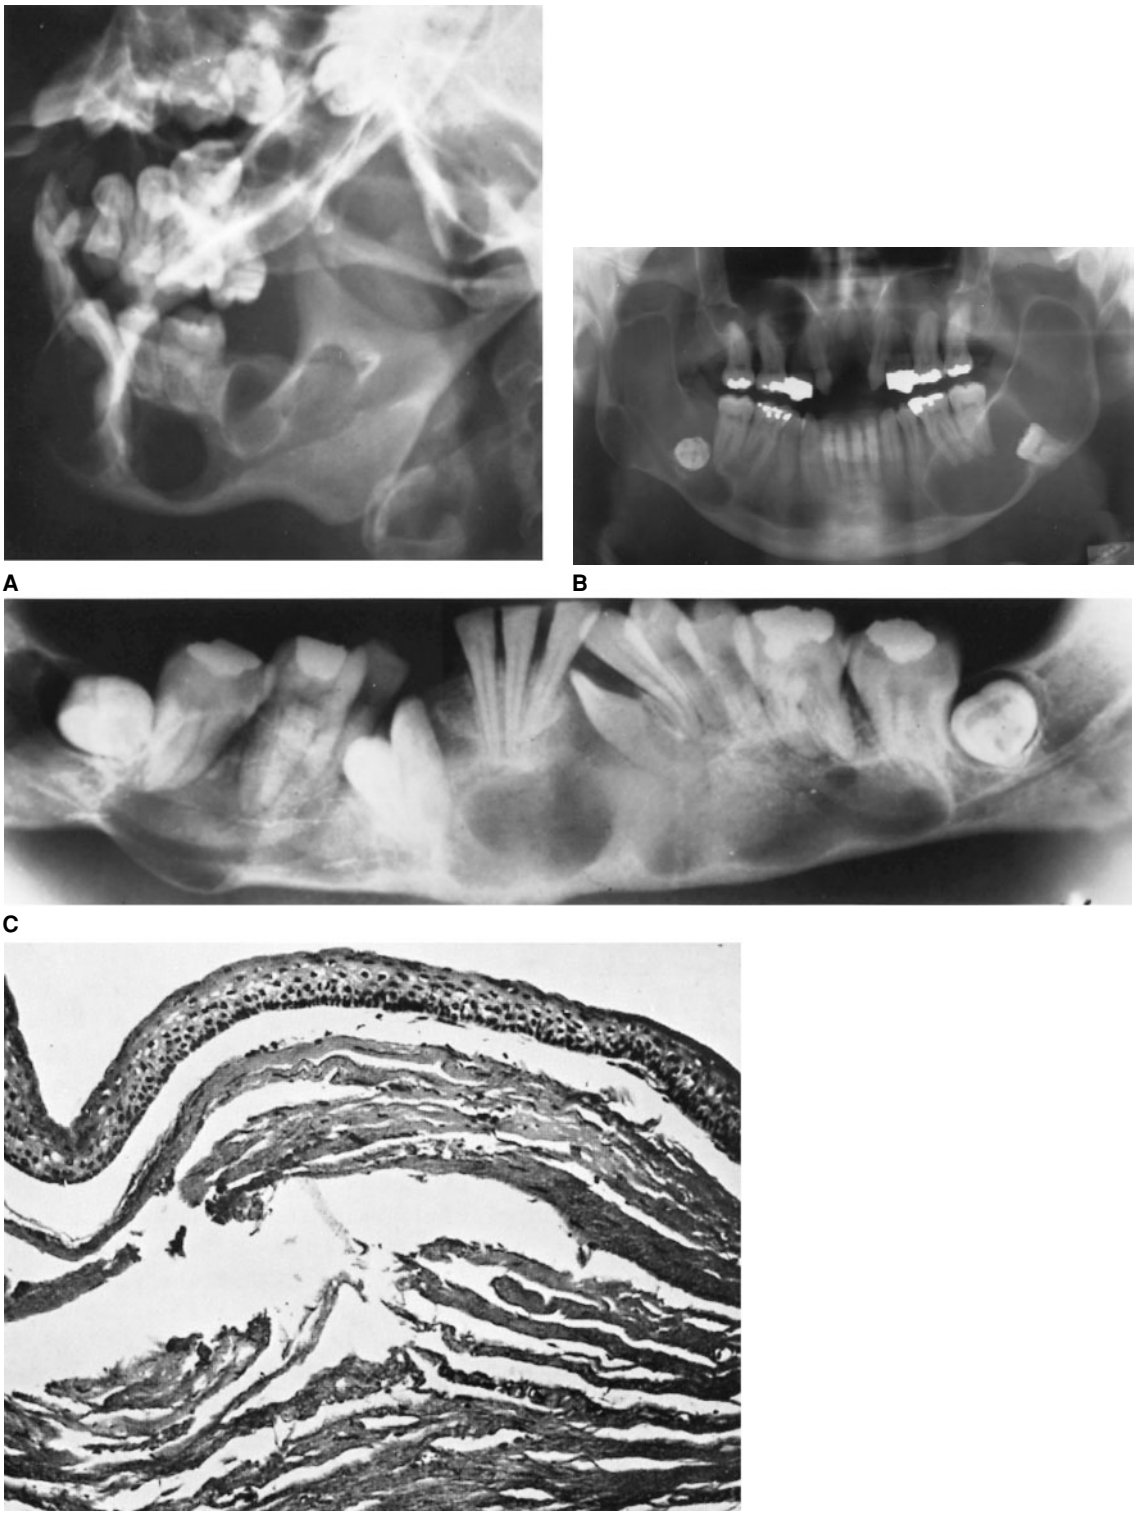

Fig. 12–13. *Gorlin syndrome*. (A) Multiple cysts scattered throughout both jaws. (B) Panorex showing multiple odontogenic keratocysts. Note displaced molars. (C) Extensive involvement of mandible with multiple cysts. (D) Photomicrograph of odontogenic keratocysts from 40-year-old female. (A from RJ Gorlin et al, Cancer 18:89, 1965. invasive. Increase in size, ulceration, bleeding, or crusting indicates invasion. Radiation therapy causes proliferation of basal cell carcinomas and invasion several years later (67,208). Death has resulted in the very rare instance from invasion of the brain or lung. Even less often has metastasis been documented (10,14,63,140,215).

Several examples of unilateral or even quadrant involvement with basal cell carcinomas likely represent postzygotic somatic mutation (25,26,74,89,183,216,222).

Multiple basaloid follicular hamartomata have been noted by Gartmann et al (61) in a family with the syndrome. The relationship of

Table 12–4. *Nevoid basal cell carcinoma syndrome*—diagnostic findings in adults

50% or greater frequency
Enlarged occipitofrontal circumference (macrocephaly, frontoparietal bossing)
Multiple basal cell carcinomas
Odontogenic keratocysts of jaws
Epidermal cysts of skin
High-arched palate
Palmar and/or plantar pits
Rib anomalies (splayed, fused, partially missing, bifid, etc.)
Spina bifida occulta of cervical or thoracic vertebrae
Calcified falx cerebri
Calcified diaphragma sellae (bridged sella, fused clinoids)
Hyperpneumatization of paranasal sinuses
15%–49% frequency
Brain ventricle asymmetry
Calcification of tentorium cerebelli and petroclinoid ligament
Calcified ovarian fibromas
Short fourth metacarpals
Kyphoscoliosis or other vertebral anomalies
Lumbarization of sacrum
Narrow sloping shoulders
Prognathism
Pectus excavatum or carinatum
Pseudocystic lytic lesion of bones (hamartomas)
Strabismus (exotropia)
Syndactyly
Synophrys
14% or less but not random
Medulloblastoma
True ocular hypertelorism
Meningioma
Lymphomesenteric cysts
Cardiac fibromas
Fetal rhabdomyoma
Ovarian fibrosarcoma
Marfanoid build
Anosmia
Agenesis of corpus callosum
Cyst of septum pellucidum
Cleft lip and/or palate
Low-pitched female voice
Polydactyly, postaxial—hands or feet
Sprengel deformity of scapula
Vertebral body fusion
Congenital cataract, glaucoma, coloboma of iris, retina, optic nerve, medullated retinal nerve fibers
Subcutaneous calcifications of skin (possibly underestimated frequency)
Minor kidney malformations
Hypogonadism in males
Mental retardation

Modified from RJ Gorlin et al, Dermatol Clin 13:113, 1995.

multiple basaloid follicular hamartomata to nevoid basal cell carcinomas has been hotly debated (98,207).

Barr et al (11) suggested that these were analogous to the odontogenic keratocysts (vide infra). Larger, often multiple, epidermal cysts arise on the limbs and trunk in about 50% of whites (12,29,143,181). About 35% of blacks have these cysts (65). Transitory multiple cysts located on the palpebral conjunctiva (120) have been noted in 40%.

Palmar and, somewhat less often, plantar pits (1–2 mm) are asymmetrically present in 65%–80% (29,52,181). Palmar pits are as frequent in blacks as in whites (65). They are better visualized if the patient wets the hands in warm water for 10 minutes before examination. Individuals whose occupations involve manual labor may have more obvious pits because of ingrained dirt or grease. They may be present in children, but a careful age-related study is lacking. Rarely, basal cell carcinomas have arisen in these pits (198). Such cases have been cited by Gorlin (67). An additional example is that of Golitz et al (66) (Tables 12–4 and 12–5).

Table 12–5. *Nevoid basal cell carcinoma syndrome*—diagnostic criteria (diagnosis based on two major or one major and two minor criteria)

Major criteria
1. More than 2 BCCs or one under age of 20 yr
2. Odontogenic keratocyst
3. Three or more palmar pits
4. Bilamellar calcification of falx cerebri
5. Bifid, fused, or splayed ribs
6. First-degree relative with NBCCS
Minor criteria
1. Macrocephaly adjusted for height
2. Fontal bossing, cleft lip/palate, hypertelorism
3. Sprengel deformity, pectus, syndactyly of digits
4. Bridging of sella turcica, hemivertebrae, flame-shaped radiolucencies
5. Ovarian fibroma
6. Medulloblastoma

Adapted from VE Kimonis et al, Am J Med Genet 69:299–308, 1997.

Odontogenic keratocysts. Characteristically, multiple (average: 6; range: 1–30) cysts of both the upper and lower jaws appear after the seventh year of life. Median age of appearance is about 15 years. Mandibular cysts are three times as common as maxillary examples (Fig. 12–13). Evans et al (52), in a population-based study, found odontogenic keratocysts in 90% of those over 40 years and in 80% of those over 20 years, with an overall frequency of over 65%. They peak during the second and third decades but continue to appear during the life of the patient (29,182). In one patient they did not present until the sixth decade (164). There is no racial predilection (65). The cysts may be extremely large but rarely cause symptoms. They effect marked tooth displacement but only rarely cause fracture (190). About one-third do not produce significant symptoms. Approximately 50% present with swelling, 25% with mild pain, and 15% with unusual taste following rupture of a cyst (29). Rarely they perforate the cortex and extend into soft tissues. In the maxilla, the sinuses may be invaded; in the mandible, the cysts may extend throughout the molar–ramus area to the coronoid process. They may cross the midline (67).

There is marked tendency (over 60%) for these cysts to recur following surgery (47). This appears to result from several causes: incomplete removal, retention of epithelial islands and/or satellite microcysts which occur with great frequency in the connective tissue capsule, and from proliferation of the basal layer of the epithelium (39,45,103,219).

There have been very few reports of ameloblastoma arising in the odontogenic keratocysts (28,31,76,96,129,178). The brief article of Jensen (97), in spite of its title, suggests only odontogenic rests. Squamous cell carcinoma has arisen from a cyst wall in a few examples (79,138,159).

Odontogenic keratocysts present as multilocular or invaginated cysts (along with microdaughter cysts or epithelial rests in 25%–50% of the cases), with parakeratinized or, rarely, orthokeratinized (4%), stratified squamous epithelium consisting of five to eight rows of cells having a regularly oriented, well-defined basal epithelial cell layer, palisaded nuclei, but no rete ridges (67). Some of the larger keratocysts expand in size to include tooth follicles.

In some cases, the epithelial rests proliferate to produce a picture like that of squamous odontogenic tumor. The mitotic index is comparable to that of the dental lamina. Budding of the epithelium into the connective tissue and suprabasilar splitting are noted in at least 50%. Inflammatory cells rarely are found in the underlying connective tissue. The cyst capsule is thin (103). Some cysts exhibit foci of calcification in the walls (35).

Woolgar et al (219) and Dominiguez et al (46) found significant differences between syndrome keratocysts and single keratocysts. Syndrome keratocysts were found to have a markedly increased number of satellite cysts, solid islands of epithelial proliferation, odontogenic rests within the capsule, and mitotic figures in the epithelial lining of the main cavity. There are immunochemical differences between syndromal and solitary keratocysts (121). Woolgar et al (219) noted that syndrome keratocysts tend to occur at a much earlier age than single keratocysts. Most authors believe that odontogenic keratocysts arise from the dental lamina (13,181).

Cleft lip and/or palate have been found in 3%–8% (41,52,67,106,114, 171,181,189,196).

Musculoskeletal and radiographic findings. Mean height in males is 183 cm, 174 cm in females (8). About 15% of patients are extremely tall (190,191). The calvaria tends to be large (80%) with frontal and biparietal bossing, but this appears to be correlated with height (8). The interorbital distance is only mildly increased (39) (Fig. 12–14).

Lamellar calcification of the falx cerebri is found in 55%–95% (normal: 5%) (29,163). Calcification of the tentorium cerebelli has been noted in 20%–40%, the petroclinoid ligament in 20%, and the diaphragma sellae in 60%–80%. Radiographically this appears as if the sella turcica is bridged—i.e., as if there were fusion of the anterior and posterior clinoid processes (29,48). Agenesis of the corpus callosum with or without lipoma has been noted as well as empty sella syndrome (196a).

Fused, splayed, hypoplastic, or bifid ribs have been documented in 45%–60% (162). Kyphoscoliosis with or without pectus is found in 25%–40% with spina bifida occulta of the cervical or thoracic vertebrae in 60% (162). The latter was noted in only 20% of a series by Kimonis et al (106). Sprengel deformity and/or unusual narrow sloping shoulders has been described in 10%–40% (29,106,157,164). Other anomalies seen in about 40% include cervical or upper thoracic vertebral fusion, hemivertebra, and lumbarization of the sacrum. Pectus occurs in about 15%–25% (106).

Various other bony anomalies have been reported in about 5%: pre- or postaxial polydactyly of hands or feet, hallux valgus, syndactyly of fingers 2–3. These examples have been cited by Gorlin (67). Shanley et al (181) found syndactyly in 3% and polydactyly in 4%. Although the fourth metacarpal has been alleged to be short, this is a "poor sign" because about 10% of the normal populations has a positive sign (29,67).

Small pseudocystic bone lesions (flame-shaped lucencies) have been identified in the phalanges, metapodial bones, carpal and tarsal bones, long bones, pelvis, and calvaria in 30% (19,42,48,106,145). Calvarial involvement may give the impression that medulloblastoma has spread to bone (80). Histologically, the flamelike lesions are hamartomas consisting of fibrous connective tissue, nerves, and blood vessels (136). Subcutaneous calcification of fingers and scalp has also been reported (140). Sclerotic bone lesions have been reported occasionally (19,83,220). A radiolucency of the upper humerus has been documented (40).

Kidney anomalies. Minor kidney anomalies, found in roughly 5%, have included horseshoe kidney, L-shaped kidney, unilateral renal agenesis, renal cysts, and duplication of renal pelvis and ureters (32,67,173). Because most of these findings have been diagnosed on laparoscopy or at autopsy, their frequency is probably higher.

Hypogonadism in males. Perhaps 5%–10% of males exhibit such signs of hypogonadotrophic hypogonadism as anosmia, cryptorchidism, female pubic escutcheon, gynecomastia, and/or scanty facial or body hair (67,206). Gorlin (67) cited numerous examples. Shanley et al (181), in their survey, noted 10% with anosmia.

Medulloblastoma, other brain tumors, and seizures. The association of NBCCS with medulloblastoma was first pointed out by Herzberg and Wiskemann (85) in 1963. The tumor characteristically presents during the first 2 years of life in NBCCS, as opposed to 7–8 years in the general population. Cases reported prior to 1986 can be found tabulated in the 1987 summary of Gorlin (67). The incidence of medulloblastoma in NBCCS was determined by Evans et al (50) to be 1%–2% in 173 consecutive cases of the tumor. Conversely, a population study of NBCCS determined 3%–5% had medulloblastoma. There appears to be male sex predilection: male to female, 3:1 (112). Because medulloblastoma presents early (mean 2.5 years) in patients with NBCCS, children who present with the tumor especially those less than 5 years, should be carefully examined for signs of the syndrome (106). An especially malignant medulloblastoma was reported by Albrecht et al (1).

Radiation therapy of medulloblastoma results in profuse numbers of invasive basal cell carcinomas appearing in the radiation field (from nape to base of spine) (51,67,208). Clinically, a "rash" appears from 6 months to 3 years after radiation therapy. The rash represents activated basal cell carcinomas, which often become markedly invasive in another 10 years. It should be pointed out that numerous small radiolucencies of bone that are really hamartoses may be confused with intracalvarial spread of medulloblastoma (67).

Other brain tumors are infrequent. The next most common appears to be meningioma (67,139,197) (Fig. 12–15A), but other tumors have included: astrocytoma (27,52,84), craniopharyngioma (197), and oligodendroglioma (107). These tumors may well be secondary to radiation therapy (106,148).

Cysts of the brain have been reported: colloid cyst of the third ventricle (188), "median ventricular cyst" (38); arachnoid cyst (152,196a); intraparenchymal cyst (199; Chevenix-Trench, personal communication, 1992), cysts of the septum pellucidum (38,115,123). Empty sella syndrome has been found (196a).

Seizures have been occasionally noted (64,141,142) unassociated with brain tumors, possibly due to focal neuronal heterotopia (87).

Cardiac fibroma. Cardiac fibromas occur in NBCCS with far higher frequency than that of chance. In general, primary cardiac tumors are rare in infancy and childhood, estimates ranging from 0.03%–0.08%, with cardiac fibromas being the second most frequently found, most often in the anterior left ventricular wall (36). They are discrete, well circumscribed, non-encapsulated, firm, gray-white, 3–4 cm in diameter and may upon occasion exhibit central calcification. When they project into the chamber, the hemodynamics of the left ventricle is impeded. Conduction defects (arrhythmias) can eventuate from involvement of the intraventricular septum (88). About 5% of those with cardiac fibromas have NBCCS (Fig. 12–15B).

Approximately 20 examples of cardiac fibroma have been reported in NBCCS (4,23,24,32,36,41,49,52,55,67,78,82,86,94,113,122,124,150, 166,196a). Evans et al (52), in a population-based study, estimated that the frequency of cardiac fibroma in the syndrome is about 3%. The tumor is composed of fibroblasts embedded in dense matrix of collagen and elastic fibers. Because of the variability of microscopic appearance, the same tumor has been stated to be a cardiac fibroma in one report (94) and a fibrous histiocytoma in a second report (101). A possible case is that of Grubben et al (72).

Cardiac fibromas in NBCCS have been quite similar to those occurring as solitary examples. Most have arisen in the left ventricle. Presentation time has varied from birth to 60 years (HA Heggtveit, Hamilton, Ontario, Canada: Personal communication, 1992), but some have been recognized due to cardiomegaly. Most, having caused no symptoms, have been found incidentally.

Mesenteric cysts. Single or multiple chylous (lymphatic) mesenteric cysts have been documented. As most of these examples have not produced symptoms, the majority have been found at laparotomy and hence are underestimated. Gorlin (67) cited at least 10 examples.

The cysts are thin-walled and measure 2–14 cm in diameter. The contents are chylous but may contain hemorrhagic turbid fluid. Microscopically, the wall is composed of hyaline fibrous connective tissue and smooth muscle. Islands of lymphocytic cells may be located beneath the endothelial lining.

A true enterogenous cyst was reported by MacSweeney et al (127).

Ovarian fibromas and fibrosarcomas. Ovarian fibromas are rare, accounting for only 4% of all ovarian tumors. Less than 10% are found in women less than 30 years, and their occurrence in prepubertal females is truly unusual (99). It is difficult to know the true frequency of ovarian fibromas in NBCCS, as they do not present unless they become large and calcified and twist on their pedicles. A population-based study carried out in 1992 suggested that a figure of 25% might be reliable (52). Shanley et al (181) and Kimonis et al (106) found ovarian fibromas on ultrasound in 15%. Ovarian fibromas associated with NBCCS are most often bilateral (75%), often overlapping medially. A number of such cases have been erroneously diagnosed as calcified uterine

leiomyomas. In contrast, the ovarian fibroma not associated with the syndrome is unilateral and calcified only 10% of the time (180). Cases reported prior to 1986 are cited by Gorlin (67). Additional examples have been noted (21,56,191,221). The tumor may rarely be virilizing (92) or renin-secreting (56,221).

Histopathologically, they are composed of mature fibroblasts separated by collagenic connective tissue in which extensive calcified foci may be seen.

Ovarian fibrosarcoma has also been described (93,110,123,169, 172,194) as well as other ovarian tumors (15,169,193).

Fetal rhabdomyoma. Schweisguth et al (179), in 1968, was the first to report fetal rhabdomyoma in a newborn with NBCCS. Originally thought to be an intercostal rhabdomyosarcoma, immunochemical reexamination in April 1986 (67) showed its true nature. Dahl et al (39) described examples on the thigh and chest wall in a newborn child with NBCCS. In 1975, R. Gorlin (unpublished, 1975) had occasion to see an adult male with NBCCS who had a fetal rhabdomyoma of intercostal muscles. Klijanienko et al (108) reported a presternal example in a 1-year-old. Subsequently, additional fetal rhabdomyomas appeared at the angle of the mandible at 6 years and in the cervical area at 26 years. DiSanto et al (44) reported a 6-year-old female child with fetal rhabdomyoma of the posterior mediastinum and retroperitoneum. Hardisson et al (77) described a retroperitoneal example in a 15-year-old male.

Miscellaneous other tumors. There appears to be an increased incidence of several other neoplasms or hamartomas: leiomyomas of the bowel and mesentery (81,102,199), leiomyosarcoma (60), lymphangiomyoma (170), melanoma (9,104,195), mesenchymoma (176,218), Hodgkin's disease (142,156,224), rhabdomyosarcoma (13), nasal dermoid (154), seminoma (223), paratesticular pseudotumor (209), schwannoma (108), pleomorphic adenoma of parotid (81), adrenal cortical adenoma (199), and a host of other neoplasms cited by Gundlach and Kiehn (73), Gorlin (67), and Stieler et al (193). Cyst of the lung was noted by Totten (201).

Chromosome instability and cellular radiation sensitivity. Carefully controlled studies by Sarto et al (174) and Bale et al (5) have not supported chromosomal instability or increased rates of sister chromatid exchange. Studies of cellular radiation sensitivity have also resulted in conflicting results [for complete discussion, see (68)]. Dezawa et al (43) found an increased number of nucleoli in fibroblasts of patients with the syndrome.

Differential diagnosis. Basaloid follicular hamartomas have been reported with alopecia and myasthenia gravis on several occasions (22,111,131,133,137,168,192,210). Bazex syndrome consists of basal cell carcinomas (especially of the face) (40%), follicular atrophoderma (especially of hands, feet, and elbows) (85%), hypotrichosis (85%), milia (65%), and generalized hypohidrosis or anhidrosis of face and head (25%), (62,105,147,155,160,204). [The reader should note that there is another Bazex syndrome (acrokeratosis paraneoplastica), a quite unrelated disorder.] It has X-linked dominant inheritance (111), the gene mapping to Xq24–q27 (205). Follicular atrophoderma also occurs in *chondrodysplasia punctata*. Rombo syndrome, named after a family, resembles Bazex syndrome, but there is neither follicular atrophoderma nor sweating abnormality, and it has autosomal dominant inheritance (2,135). Rasmussen syndrome consists of trichoepitheliomas, milia, and cylindromas (161). The binary combination of congenital hypotrichosis and milia has been documented in a few instances (151,160). Mehregan and Hardin (134) described tricholemmal cysts, palmar pits, and cicatricial alopecia. The sebaceous nevus has been found to have deletions in PTCH (219a).

Laboratory diagnosis. Prenatal, presymptomatic and possible preimplantation diagnosis has been accomplished in at-risk infants by ultrasonography and molecular techniques (6,16,88,153).

Klippel-Trenaunay syndrome, Parkes Weber syndrome, and Sturge-Weber syndrome

This section considers Klippel-Trenaunay syndrome, Parkes Weber syndrome, and Sturge-Weber syndrome together because all three have various types of vascular malformations. However, it is shown that they

should be considered separate clinical entities that almost always occur sporadically. In this connection, it is essential to discuss vascular tumors vs. vascular malformations and also the Kasabach-Merritt phenomenon. The analysis here is based on Cohen (11).

Klippel-Trenaunay syndrome. Klippel-Trenaunay syndrome consists of (a) combined vascular malformations of the capillary, venous, and lymphatic types, (b) varicosities of unusual distribution, in particular the lateral venous anomaly (vide infra), observed during infancy or childhood, and (c) limb enlargement. Males and females are equally affected. The lower limb is involved in almost 95% of patients, the upper limb accounting for almost 5% of patients. Approximately 15% have combined upper and lower limb involvement. Uncommonly, patients may have trunk involvement only (29,46,49,58).

The original paper of Klippel and Trenaunay (24) shows that "Trenaunay" and not "Trénaunay" is correct; there is no accented *e* although many articles have added the accent (see 17 for review). Well over 1500 cases have been recorded (29,36,46,49,58). Servelle (49) alone documented 768 operated patients.

Conventional wisdom about Klippel-Trenaunay syndrome includes the following: (a) addition of arteriovenous fistulas and renaming the disorder Klippel-Trenaunay-Weber syndrome (3,19,22,25–27,39,48); (b) overlap with Sturge-Weber syndrome (6,15,18,21,44,52); (c) the presence of a bleeding diathesis of the Kasabach-Merritt type (46); and (d) familial aggregation (1,8,12,25,28,29,38) with various genetic interpretations. This conventional thinking can be seriously challenged.

Etiologic considerations. Koch (25) cited a number of familial cases from the literature. Relatives of probands had isolated varicosities or birth marks of the posterior neck. Some examples of neurofibromatosis were also included.

Lian and Alhomme (28) reported congenital varicose veins in three generations of a family in which the propositus had Klippel-Trenaunay syndrome. Norwood and Everett (38) noted an affected propositus whose brother and mother had macular stains scattered over the face and trunk. Lindenauer (29) observed a brother and sister with well-documented Klippel-Trenaunay syndrome. Craven and Wright (12) described a patient with Klippel-Trenaunay syndrome whose grandmother was also said to be affected. Ceballos-Quintal et al (8) observed a 3-year-old girl with Klippel-Trenaunay syndrome; the mother had a capillary malformation on her back and developed varicose veins in both legs. The maternal grandmother also had varicosities but no vascular malformation.

Aelvoet et al (1) sent a questionnaire to 114 patients with Klippel-Trenaunay syndrome; results were based on 91 respondents. Klippel-Trenaunay syndrome patients were said to have been found in both a propositus and a second-degree relative in two different families. "Naevi flammei" and "angiomatous naevi" were noted in some relatives of Klippel-Trenaunay syndrome patients. Varicosities were also found in some families. Aelvoet et al (1) indicated that familial occurrence of Klippel-Trenaunay syndrome was found once in 880 cases. There appears to be increased parental age and increased number of pregnancies (29a).

Happle (20), in reviewing the data provided by Aelvoet et al (1), suggested that paradominant inheritance could be an explanation of (a) why Klippel-Trenaunay syndrome occurs sporadically, (b) why the lesions of Klippel-Trenaunay syndrome are arranged in mosaic fashion, (c) why relatives with Klippel-Trenaunay syndrome are so rare, and, when recorded, do not exhibit Mendelian inheritance, and (d) why "naevi flammei" show an increased incidence in relatives of Klippel-Trenaunay syndrome patients.

Assuming paradominant inheritance, Klippel-Trenaunay syndrome would be caused by a single gene defect. Heterozygous individuals would almost always be normal and thus the allele would be transmitted imperceptibly. The trait would only become expressed if a somatic mutation occurred early during embryonic life. The resultant loss of heterozygosity would result in either homozygosity or hemizygosity for the Klippel-Trenaunay syndrome mutation (20).

Whelan et al (55) reported a case of Klippel-Trenaunay syndrome associated with a 5:11 balanced translocation. Wexler et al (54) noted a case with chromosomal mosaicism for a 1:20 translocation.

Careful scrutiny of published "familial cases" indicates one or more of the following problems: (a) inadequate documentation of cases; (b) overinterpretation of minor manifestations in relatives, including "nevus flammeus," hemangiomas, and varicosities,[1] all of which occur commonly in the general population; and (c) defining Klippel-Trenaunay syndrome as a capillary malformation *with or without* "hemihypertrophy" with no mention of lymphatic malformations, lateral venous anomaly, lymphatic vesicles or venous flares within the capillary malformation, or macrodactyly; thus, it is uncertain whether these cases represent Klippel-Trenaunay syndrome. Only the affected brother and sister described by Lindenauer (29) are *well-documented* examples of Klippel-Trenaunay syndrome within a family.

It is possible that when the basic molecular defect becomes known, it may be the same or similar to those of Parkes Weber syndrome and Sturge-Weber syndrome. It is only claimed here that it is useful to distinguish them because their clinical implications are so different. Also, it is not claimed that there is no genetic basis, only that future documentation of families must be much more thorough to prove this.

Capillary malformations. Capillary malformations of the skin are bluish to purplish in color. No large surgical series of Klippel-Trenaunay syndrome patients includes patients with capillary malformations involving the face (29,36,46,58). Capillary malformations may be studded with lymphatic vesicles and venous flares (vide infra) (Fig. 12–16).

Varicosities. Varicosities in Klippel-Trenaunay syndrome differ from commonly occurring varicose veins in two ways. The distribution is different, being more extensive, and the age of onset is different, first being manifest during infancy or childhood. The classic lesion is the lateral venous anomaly, which occurs in about 80% of patients. The malformation begins as a plexus of veins on the dorsum and lateral side of the foot and extends superiorly for various distances (Fig. 12–17). Termination occurs in the popliteal vein in 11% of patients, superficial femoral vein in 17%, deep femoral vein in 19%, and external iliac vein in 6%; full leg-length distribution is found in 33% of patients (46,58).

Veins may have valves or may be valveless. Ectatic veins may appear as studded venous flares in capillary malformations of the skin. These result from reflex of venous blood secondary to hypertension in the main venous anomaly (58). Intermittent episodes of thrombophlebitis in the affected limb have been reported in about 50% of children ($n = 47$), often associated with pain. Phleboliths result from past thromboses. Pulmonary embolism is found in about 10% of children ($n = 47$) (46) and may be higher in adults (5). The risk is particularly increased postoperatively.

Abnormalities of the deep veins are common in some series but not in others. Defects may include agenesis, atresia, hypoplasia, valvular incompetence, or aneurysmal dilatation (5,29,46,58). Resection of varicosities in patients with Klippel-Trenaunay syndrome is controversial. Severe vascular reflux and the presence of deep venous anomalies in some cases probably contraindicate excision. Graded elastic compression should be the first line of treatment, with surgical resection being reserved for significant incapacitating problems (46).

Significant arteriovenous communications of the type found in Parkes Weber syndrome are never found in Klippel-Trenaunay syndrome; in many large surgical series (29,46,49,58), clinically significant arteriovenous malformations are *not* reported (see Parkes Weber syndrome below). In Klippel-Trenaunay syndrome, there are *physiologic arteriovenous connections that are always trivial and never clinically important* (5,57).

Lymphatic malformations. Lymphatic abnormalities are very common and are found in more than 70% of patients with Klippel-Trenaunay syndrome (23,58). Cutaneous capillary malformations may be studded with lymphatic vesicles that leak lymph. Lymphedema of the lower limb is particularly common (Fig. 12–17). When the trunk is involved, lymphatic malformation of the intestine may be associated with a

[1] Varicosities in Klippel-Trenaunay syndrome have early onset in infancy or childhood, with more extensive distribution than classic varicose veins in the general population.

A B

Fig. 12–16. *Klippel-Trenaunay syndrome*. (A,B) Extreme enlargement of hands, disparity in size of arms, fixation of left elbow joint. (From E Nöh and R Steckenmesser, Z Orthopad 112:243, 1974.)

protein-losing enteropathy. Micro- and macrocystic lymphatic malformations often involve the groin, genitalia, and retroperitoneum.

Limb enlargement. Lower limb enlargement is found in almost all cases. The affected limb may be thicker and longer. Thickness results from soft-tissue enlargement and is especially pronounced with lymphatic involvement. Increased adiposity is found in some patients. When the long bones are involved, the affected limb is increased in length and bone thickness is also increased. With leg-length discrepancy, compensatory scoliosis may result.

Macrodactyly may involve toes on the affected foot but may be present on both feet. Other abnormalities are associated with some cases. Cutaneous syndactyly rarely involves more than two toes. Miscellaneous defects may include polydactyly, clinodactyly, talipes equinovarus, talipes calcaneovarus, and metatarsus varus (33).

Secondary cutaneous manifestations. These may include eczema, hyperhidrosis, atrophy, ulceration, and cellulitis (16).

Other. Cerebral hemihyperplasia has been found in 18% (52a).

Parkes Weber syndrome. Parkes Weber syndrome, considered a separate entity here, is commonly designated with a hyphen—Parkes-Weber syndrome. In Parkes Weber's own papers (41–43), no hyphen is used. He described patients with enlarged arteries and veins, capillary or venous malformations, and enlargement of a limb. Although Parkes

Note increased girth and axial overgrowth. The cutaneous capillary malformation is studded with lymphatic vesicles. (Courtesy of JB Mulliken, Boston, Massachusetts.)

Table 12–6. Comparison between Klippel-Trenaunay syndrome and Parkes Weber syndrome

	Klippel-Trenaunay syndrome	Parkes Weber syndrome
Color of cutaneous vascular malformation	Tends to be bluish to purplish	Usually pink and more diffuse
Arteriovenous fistulas	Insignificant	Significant
Lateral venous anomaly	Very common	—
Limb affected		
Upper	5%	23%
Lower	95%	77%
Limb enlargement	Usually disproportionate, involving soft tissue and bone; macrodactyly, particularly of toes, common	Arm- or leg-length discrepancy
Prognosis	Usually good; pulmonary embolism encountered occasionally	More problematic, particularly in those that develop bradycardia, which may lead to cardiac enlargement or limb amputation

Data from AE Young, Hemangiomas and malformations. In: Vascular Birthmarks, JB Mulliken and AE Young (eds), W.B. Saunders Company, Philadelphia, 1988, and DJ Robertson, Ann R Coll Surg Engl 18:73, 1956.

Weber syndrome and Klippel-Trenaunay syndrome are similar, slow-flow venous malformations are predominant in Klippel-Trenaunay syndrome, but arteriovenous (AV) fistulas are always found in Parkes Weber syndrome. Large series of patients are those of Robertson (45) and Young (58). All cases have been sporadic.

The involved limb is warm. The color of the cutaneous vascular malformation is usually more diffuse and pinker than that observed in Klippel-Trenaunay syndrome. Lymphatic malformations do not occur and no lymphatic vesicles are found in the discolored skin. The prognosis in Parkes Weber syndrome is more problematic; cardiac failure may lead to cardiac enlargement and cutaneous ischemia, requiring limb amputation (45,58). Klippel-Trenaunay syndrome and Parkes Weber syndrome are contrasted in Table 12–6.

Sturge-Weber syndrome. Sturge-Weber syndrome, a sporadically occurring disorder, is defined as a capillary malformation of the leptomeninges with or without choroid and facial V1 or V1–V2 involvement (Table 12–7). The syndrome can be explained by an embryonic defect with secondary consequences. During the sixth week of development, a vascular plexus forms around the cephalic portion of the neural tube and beneath the ectoderm destined to become facial skin. Normally, this vascular plexus regresses during the ninth week, but in Sturge-Weber syndrome, it persists, resulting in a capillary malformation of the leptomeninges overlying the cerebral cortex together with a facial "port-wine" stain on the ipsilateral side. Variation in the persistence or regression of the vascular plexus accounts for cases with unilateral or bilateral involvement and also for cases with capillary malformation of the leptomeninges with absence of facial involvement (2,10,51) (Figs. 12–18 and 12–19).

Capillary malformations of the skin may extend below the head and neck and appear anywhere on the body, including the upper and lower limbs. Limb involvement is different from that found in Klippel-Trenaunay syndrome. The latter has lymphatic malformations, lateral venous anomaly, lymphatic vesicles and venous flares within the capillary malformation, limb enlargement, and macrodactyly—*which do not occur in Sturge-Weber syndrome*. Only capillary malformations are found in Sturge-Weber syndrome. Hemiparesis, present in some patients, may result in a *hypotrophic limb*.

Table 12–7. *Sturge-Weber syndrome*—manifestations (n = 52)

Manifestation	%
Craniofacial capillary malformation	98
Unilateral	46
Bilateral	54
V_1	100
V_2	76
V_3	60
Extracephalic capillary malformation	52
Seizures	83
Neurologic deficits	65
Headaches	62
Glaucoma	60
Lower-limb hemihypoplasia	48

Data from E Sujansky and S Conradi, Am J Med Genet 57:35, 1995.

Overgrowth may occur in Sturge-Weber syndrome, but it tends to be minor and is always secondary to the vascular anomaly. Overgrowth of the bony maxilla is common. When the capillary malformation involves the ear, its length may be greater than that of the contralateral ear. Rarely, a digit may be enlarged. In contrast, overgrowth in Klippel-Trenaunay syndrome is striking and macrodactyly may occur in the "uninvolved" limb.

Fig. 12–18. *Sturge-Weber syndrome*. (A) Note facial distribution of angiomatosis. (B) Note bilateral involvement. (C) Same patient as observed in B. Note angiomatosis on body and enlargement of left arm and hand. This patient represents an example of Sturge-Weber syndrome as part of Klippel-Trenaunay syndrome). (B,C from MM Cohen Jr, Dysmorphic syndromes with craniofacial manifestations. In: Orofacial Genetics, Stewart RE, Prescott GH (eds), Mosby, St. Louis, 1976.)

Fig. 12–19. *Sturge-Weber syndrome*. Gingival enlargement and angiomatosis. Eruption of teeth on affected side is more advanced than on unaffected side.

Seizures occur in about 83% of the cases (Table 12–7). These can begin during infancy; seizures are contralateral to the leptomeningeal capillary malformation. Most often seizures are local, but generalized seizures may also occur. Hemiparesis is less frequent (2,51).

CT and MRI may demonstrate subtle early leptomeningeal abnormalities. Using SPECT with xenon-133 to evaluate cerebral blood flow, 75% of infants studied prior to the onset of seizures had *increased* cerebral blood flow in the involved cortex. Patients who had already developed seizures had *hypoperfusion* of the damaged hemisphere. Thus, rapid cerebral impairment follows seizures in patients with Sturge-Weber syndrome (4,9,13).

Seizures and cognitive disability. An alteration in the vascular dynamics of leptomeningeal malformation results in precipitation of calcium deposits in the cerebral cortex underlying the vascular malformation (Fig. 12–20), producing the double contoured ("railroad track") phenomenon. Seizures and mental deficiency may be secondary to this process. Several other possibilities have been suggested. First, documented microgyria might account for intractable seizures and cognitive deterioration. Second, arterial or venous thrombosis might also explain neurological and neuropsychological deterioration. Third, high seizure rates of discharge from the involved hemisphere might interfere with the function of the normal hemisphere or with its vascular control. Focal hyperperfusion for voluntary and cognitive acts might then be impaired. Fourth, abnormal venous circulation with reduced capacity for venous return might result in venous hypertension and chronic progressive ischemia. Failure to increase cerebral blood flow during seizures might then compromise an already ischemic cortex, resulting in further deficit and more seizures (2,4,30–32,40,50,53).

Vascular tumors and vascular malformations. Mulliken and Glowacki (37) and Mulliken (34) made a distinction between hemangiomas and vascular malformations based on cellular kinetics and clinical behavior. Hemangiomas have endothelial hyperplasia with rapid postnatal growth followed by slow involution. In contrast, vascular malformations are characterized by flat endothelium, growth of the lesion being commensurate with growth of the child. In vascular malformations, a single type of channel anomaly may predominate, or combined channel anomalies of various types may occur (Table 12–8).

Mulliken (34) noted that the "standard" terminology used for vascular lesions had led to confusion, improper diagnosis, illogical treatment, and misdirected research efforts. The Mulliken classification, which is based on research and clinical behavior of vascular lesions, is now considered state-of-the-art in plastic surgery. Significant inroads are also being made in dermatology and pathology.

Adapted from JB Mulliken, Semin Vasc Surg 6:204, 1993.

Burns et al (7) indicated that by clinical and cellular criteria, vascular birthmarks can be classified as hemangiomas, malformations, or macular stains. Because hemangiomas occur in 10%–12% of normal infants by one year of age and macular stains are found in about 40% of normal newborns, the authors queried whether either of these are *pathogenetically related* in the syndromes in which they have been described. True hemangiomas occur only rarely in malformation syndromes, but vascular malformations are common. Clinical conditions of concern in this chapter—Klippel-Trenaunay syndrome, Parkes Weber syndrome, and Sturge-Weber syndrome—have vascular malformations, not hemangiomas.

Kasabach-Merritt phenomenon. "Kasabach-Merritt syndrome" is better designated "Kasabach-Merritt phenomenon" because it is likely to be pathogenetically variable, as thrombocytopenia occurs in various types of vascular neoplasms and has variable therapeutic response (47).

Understanding the Kasabach-Merritt phenomenon is important for understanding Klippel-Trenaunay syndrome, in which it does *not* occur. The term "Kasabach-Merritt syndrome" is frequently applied incorrectly to patients with extensive venous or lymphaticovenous malformations who develop a localized intravascular coagulopathy (chronic consumptive coagulopathy) in which the platelet count is minimally depressed, varying from 50,000 to 150,000/mm^3. In contrast, with true Kasabach-Merritt phenomenon, thrombocytopenia is profound, varying from 3,000 to 60,000 mm^3 with an average of less than 25,000/mm^3 (47). The distinction has important treatment implications. For example, heparinization might be indicated in consumptive coagulopathy, particularly with thrombotic complications, but would be contraindicated with Kasabach-Merritt thrombocytopenia (47).

It has been demonstrated that the Kasabach-Merritt phenomenon occurs only with Kaposiform hemangioendothelioma and tufted angioma, *not* with common hemangioma (47). The differences between Kaposiform hemangioendothelioma and hemangioma are contrasted in Table 12–9. Tufted angioma is composed of discrete vascular tufts in the dermis and hypodermis together with peripheral crescentlike slits (13,14,56). Neither Kaposiform hemangioendothelioma nor tufted angioma occurs with Klippel-Trenaunay syndrome, and therefore the Kasabach-Merritt phenomenon does not occur with Klippel-Trenaunay syndrome either; Klippel-Trenaunay syndrome is associated with vascular malformations. Klippel-Trenaunay syndrome patients with extensive lymphaticovenous malformations may develop chronic consumptive coagulopathy, in which the platelet count is minimally depressed (50,000–150,000/mm^3).

Diagnosis. Klippel-Trenaunay syndrome should be separated clinically from Parkes Weber syndrome, because the prognosis is much more problematic in the latter disorder with its associated AV communications (Table 12–10). Although geneticists, dermatologists, and many other clinicians have merged the two conditions as "Klippel-Trenaunay-Weber syndrome," surgeons who deal with *large numbers* of Klippel-Trenaunay syndrome patients *all* separate the two disorders (29,36,46,49,58).

Presumed cases of merged Klippel-Trenaunay syndrome and Sturge-Weber syndrome simply represent Sturge-Weber syndrome with capillary malformations below the head and neck (Table 12–10). None of these presumed "combined cases" have essential manifestations of Klippel-Trenaunay syndrome such as lymphatic malformations, lateral venous anomaly, lymphatic vesicles and venous flares within the cutaneous capillary malformation, limb enlargement, or macrodactyly.

Table 12–9. Hemangioma and kaposiform hemangioendothelioma—a comparison.

	Hemangioma	Kaposiform hemangioendothelioma
Female:male ratio	3:1 (higher in some series)	~1:1
Time of appearance	Nascent at birth or appears within first 2 weeks; if deep or visceral, as late as 2–3 months	Present at birth, neonatal period, or later during infancy (2–12 months)
Location	~66% cervicofacial; ~20% multifocal (particularly intrahepatic); rare on trunk or retroperitoneum	Predilection for trunk, extremities, or retroperitoneum; never multifocal
Clinical appearance	If superficial: soft, red, raised; if deeper: bluish and slightly raised; if very deep or visceral: normal skin	Red to purple; centrifugally, advancing rim of ecchymosis with poorly defined margins; warm and indurated (edematous) on palpation; after widespread petechiae of thrombocytes < 10,000/mm^3
	Hemangioma	Kaposiform hemangioendothelioma
Histopathology	Proliferative phase: rapidly dividing endothelial cells. Early involuting phase: mast cells macrophages, fibroblasts. Involuted phase: fibrous tissue	Infiltrative growth pattern; spindle-shaped endothelial cells; microthrombi; hemosiderin
Kasabach-Merritt phenomenon	No	Yes
Complications	~20% (e.g., major ulcerations, destruction, distortion of involved tissue or obstruction of vital structures); ~1% life-threatening complications	12%–24% mortality rate (hemorrhage, sepsis, and/or inversion of vital structures)

Derived from JB Mulliken, Semin Vasc Surg 6:204, 1993 and M Sarkar et al, Plast Reconstr Surg 100:1377, 1997. Table from MM Cohen Jr, Am J Med Genet 93:171, 2000.

Differential diagnosis. Vascular malformations may also occur in *Maffucci syndrome*, *Bannayan-Riley-Ruvalcaba syndrome*, *Proteus syndrome*, and *macrocephaly–cutis marmorata syndrome*. Increased limb girth and macrodactyly may be found in *hemihyperplasia*.

Table 12–10. Criteria for distinctions between Klippel-Trenaunay, Parkes Weber, and Sturge-Weber syndromes

Klippel-Trenaunay syndrome	Slow flow, combined vascular (capillary, lymphatic, and venous) involving limb(s) and/or trunk
Parkes Weber syndrome	Fast flow, combined vascular (capillary, arterial, and venous) involving upper/lower limbs
Sturge-Weber syndrome	Capillary malformation of leptomeninges with or without choroid and facial V_1 or V_1–V_2 involvement. Capillary malformations can occur elsewhere on body.

Adapted from MM Cohen, Jr, Am J Med Genet 93:171, 2000.

Laboratory aids. Documenting the manifestations of Klippel-Trenaunay syndrome more thoroughly is essential in the future. Included should be an MRI with gadolinium to distinguish lymphatic from venous malformations. When this is done, perhaps all or most patients with true Klippel-Trenaunay syndrome will be found to have a lymphatic component. Careful study (magnetic resonance venogram or phlebography/venography) should also document the lateral venous anomaly and any abnormalities that may be present in the deep veins of the leg.

MRI is the most informative modality for studying various vascular malformations and can demonstrate flow characteristics and the extent of involvement within tissue planes. MRI can demonstrate the arteriovenous malformations of Parkes Weber syndrome. Cranial CT and MRI with contrast enhancement can demonstrate early leptomeningeal abnormalities in Sturge-Weber syndrome. Additional single-photon emission CT (SPECT) with xenon-133 to evaluate cerebral blood flow is a highly reliable method for diagnosing the CNS abnormalities in Sturge-Weber syndrome. In various conditions, CT may be used to demonstrate intraosseous vascular malformations and also secondary bone changes (13,34,35).

Maffucci syndrome (enchondromatosis and vascular malformations)

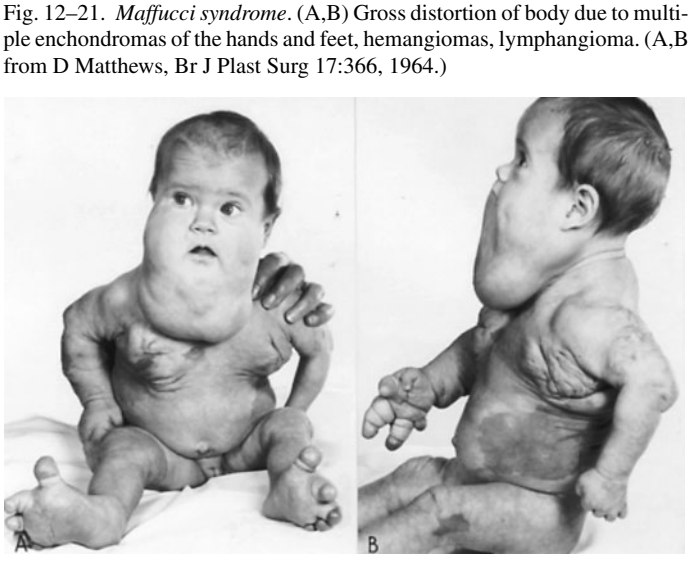
This syndrome is characterized by enchondromatosis, bone abnormalities, vascular malformations, and phlebolithiasis. The condition was described by Maffucci (40) in 1881 and by Kast and von Recklinghausen (32) in 1889. There are a number of excellent reviews (2,8,9,13,31,36). About 225 cases have been described, about 40% of these during the past 25 years. The etiology is unknown. All reported cases have been sporadic and there is neither racial nor sex predilection (2,36).

Skeletal system. Enchondromas are usually diagnosed between 1 and 5 years of age (38,44). These cartilaginous tumors are most numerous in the phalanges of the hands and feet, but may involve any bone preformed in cartilage (12,14,36,43,49). They have been unilateral in approximately 40% (2), but are frequently bilateral, although asymmetric. Skeletal abnormalities may become so severe as to produce gross bone deformity (Figs. 12–21 and 12–22) (10,14,27,36,43,49). Limb-length discrepancy (2,4,15,16,30,34,41), scoliosis (4,9,30,34,35,52), and bowing of limbs (4,28,34,38,41) may also occur. Short stature is not uncommon (30,34,44). Fractures have been reported (4,9,12,24,25,27,34,41,49,52).

Vascular abnormalities. Vascular malformations are often venous, but capillary malformations have also been recorded (1,2,11,12,14,16, 18,36,39,45,46,49). They occur most commonly on the skin, and the hand is frequently involved. Internal sites have also been noted, including the meninges (18), pharynx (37,38,52), tonsil (55), esophagus, ileum, and anal mucosa (25,27,35a,46). Phlebectasia has been reported in approximately 25% (2,46) and phlebolithiasis is common (6,7,10,28,34,36,41,44,50). Lymphatic malformations also occur (4,34,37,41,51).

Neoplasms. Chondrosarcomas may develop in enchondromas (7,16,18,24,26,36,49,50,54). The incidence of malignant transformation has been estimated as 17.8% and also as 30% (2,8,17,24,36). These figures are clearly inflated because of reporting bias. A variety of other tumors have been noted, including carotid body tumor (3), angiosarcoma (8,19,33), pancreatic carcinoma (50), hepatic adenocarcinoma (50), ovarian teratoma (34), ovarian cystadenocarcinoma (38), malignant ovarian tumor of mesenchymal origin, otherwise unspecified (36), glioma (13,18), astrocytoma (18), pituitary adenoma (42, also see 47), and unspecified brain tumor (50).

Fig. 12–21. *Maffucci syndrome*. (A,B) Gross distortion of body due to multiple enchondromas of the hands and feet, hemangiomas, lymphangioma. (A,B from D Matthews, Br J Plast Surg 17:366, 1964.)



Oral manifestations. Vascular malformations, seen in 5%–10%, have been frequently noted on the tongue (34,35,35a,37,39,41), although the buccal mucosa (5,34,37), lips (56), gingiva (56), and palate (39,46,49,53) have been documented sites.

Differential diagnosis. The syndrome should not be confused with Ollier disease (enchondromatosis without vascular malformations). Occasionally, difficulty may be encountered in distinguishing Maffucci syndrome from blue rubber bleb nevus syndrome, in which capillary malformations are found on the skin but multiple enchondromas are not present. Gallione et al (22) suggested that familial venous malformation syndrome that maps to 9p is identical to blue rubber bleb nevus syndrome. Sakurane et al (46) described a patient with Maffucci syndrome and the blue rubber bleb nevus syndrome who probably really had Maffucci syndrome. Schnall and Genuth (47) reported a patient with enchondromas, vascular malformations, pituitary adenoma, parathyroid adenoma, and neurilemoma of the nerve roots at the level of the sixth thoracic vertebra, which may represent a disorder different from Maffucci syndrome. Patients with the *Klippel-Trenaunay syndrome* and blue rubber bleb syndrome (23) also have cutaneous capillary malformations but lack enchondromatosis. *Proteus syndrome* should be excluded. Various other forms of enchondromatosis have been discussed elsewhere (20,21,24,29,48).

Laboratory aids. Use of CT scans has been advocated to distinguish enchondromas from chondrosarcomas (54).

Multiple endocrine neoplasia, type 2B (multiple mucosal neuroma syndrome, MEN type 3)

Initially described in part by Wagenmann (90) and by Froboese (36) in 1922–1923, the syndrome of multiple mucosal neuromas, pheochromocytoma, medullary carcinoma of the thyroid, and asthenic body build with muscle wasting of the extremities (marfanoid habitus) was delineated in considerable detail by a number of authors (16–23,37,40–42,46,53,59,94). About 150 patients have been described.

The syndrome has autosomal dominant inheritance with high penetrance and variable expression. About 50% represent new mutations (20). The gene maps to 10q11.2 (67). The syndrome can be explained by hyperplasia and/or neoplasia of neural crest derivatives (6,86,93,94). MEN 2B is due to two different missense mutations in the receptor tyrosine kinase of the RET protooncogene (9,15,32,49). Over 95% are caused by a single methionine to threonine (M918T) substitution in the intracellular tyrosine kinase domain (32,65). The mutation is of paternal origin (14). The other 4% are due to an A883F mutation.

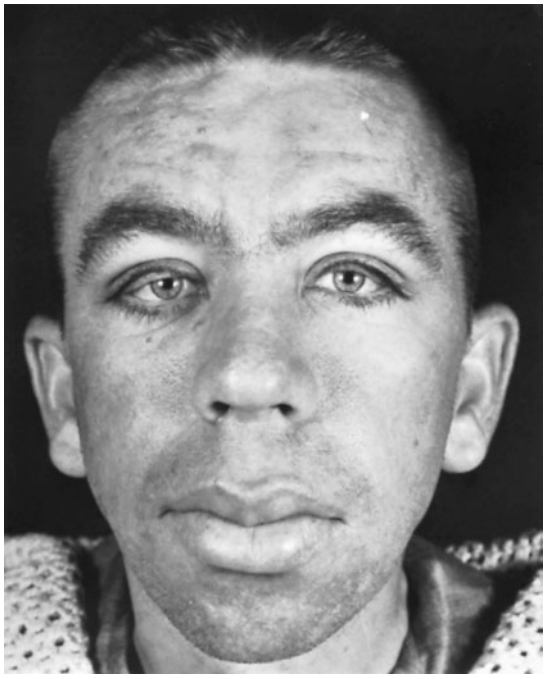

Fig. 12–23. *Multiple endocrine neoplasia, type 2B*. Facies is characterized by coarse features, large nodular lips, eversion of upper eyelids. (From RN Schimke et al, N Engl J Med 279:1, 1968.)

Facies. In infancy, there is often a history of profound difficulty in feeding with failure to thrive. The distinct facies is elongated and characterized by a wide-eyed expression, broad-based nose, and large nodular lips with submucosal nodules on the vermilion border. The tarsal plates are visibly thickened resulting in eversion of the upper eyelids. Surgical reduction of the lips reveals enormous enlargement of the diameter of the peripheral nerves (69). The lower face appears long (Fig. 12–23). The characteristic facies is not always present (77). Circumoral and/or midfacial lentiginosis has been occasionally seen (6,12,26).

Ophthalmologic manifestations. The upper eyelid margins are thickened and often everted (10,24,43,53,62). Pedunculated neuromas are present on the palpebral conjunctiva, eyelid margins, or, rarely, the cornea in about 60%.

The cornea is the site of thickened prominent white medullated nerve fibers (5,10,36,53,64,79,82) that can easily be seen under slit lamp examination. They extend into the pupillary area, where they anastomose (Fig. 12–24).

It is the personal experience of one of us (RJG) that there are insufficient tears in about 40%. This has rarely been noted (66).

Otolaryngologic manifestations. Nasal, laryngeal, and bronchial mucosa may also be the site of neuromas (5,10,41,53,54,64,79). Perinasal skin may rarely be affected (77,85). Hyperplasia of neurenteric ganglion cells has been found in the bronchi.

Thyroid gland. Medullary carcinoma of the thyroid has been found in more than 90% (53,70). With predictive testing, most patients have been about 10 years of age at time of initial diagnosis of the thyroid cancer but about 75% have metastasis at the time of diagnosis. However, patients

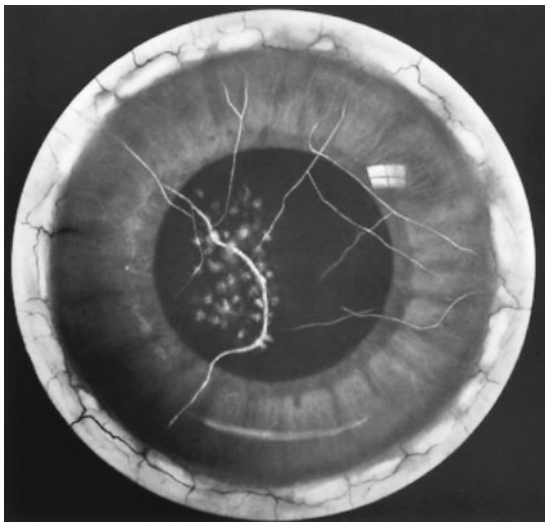

Fig. 12–24. *Multiple endocrine neoplasia, type 2B*. White medullated corneal nerve fibers which anastomose in pupillary area. [From DL Knox, Birth Defects 7(3):161, 1971.]

in the first decade of life, including one as young as 6 months (83,84), have been reported to have already developed this neoplasm (53,64,70). Prophylactic thyroidectomy should be done as soon as diagnosis is made. Prospective surveillance should begin at birth and continue to the age of about 40 years. The carcinoma occurs with equal frequency in both sexes and may be present without symptoms or palpable nodules in the thyroid gland (35,83). Several tumors often develop multifocally within the same or within different lobes of the thyroid gland (35,61,64). In over 90% this neoplasm spreads through lymphatic vessels to cervical lymph nodes and mediastinum. Metastasis to regional lymph nodes is frequently found at initial thyroid surgery (Fig. 12–25A) (24,25,41,52,70,79). The average age at death from this neoplasm is 21 years (75).

Medullary carcinoma of the thyroid arises from parafollicular cells (C cells) that have their origin in the embryonic ultimobranchial body, which in turn is derived at least in part from the neural crest (41,48,58,95). It is the only thyroid tumor that contains amyloid (Fig. 12–25B), which is seen interspersed among the cells and fibrous septa. The amyloid frequently calcifies. The C cells on electron microscopy exhibit characteristic secretory granules (Fig. 12–25C). C-cell hyperplasia is frequently found adjacent to areas of carcinoma; occasionally, in young patients, only C-cell hyperplasia is present, indicating that it is a precursor of medullary carcinoma (27,88). In addition to elaborating calcitonin, medullary thyroid carcinoma may also produce amyloid, serotonin, cytokeratin, chromogranin, bombesin, carcinoembryonic antigen, 5-hydroxyindole acetic acid, histaminase, bradykinin, various prostaglandins, DOPA decarboxylase, somatostatin, and an ACTH-like peptide (11,41,79).

Adrenal gland. Pheochromocytoma has been diagnosed in about 50%. It increases in frequency with age, probably being present in 90% of older patients. It most often presents during the second and third decades of life, especially when provoked during investigation of the thyroid neoplasm. About 10% of patients die from a cardiovascular crisis just before or after surgery; the average age at death in those with pheochromocytoma is 21 years (75). Although rare, extra-adrenal lesions have been reported (63). The presence of pheochromocytomas due to catecholamine secretion is often heralded by paroxysmal weakness, flushing, pounding headache, nausea, hypertension, dyspnea, palpitation, flatulence, paresthesia, blanching of the extremities, profuse sweating, and intractable diarrhea. Abdominal discomfort or cramping is frequently experienced.

Pheochromocytomas arise from cells derived from the neural crest. The tumors are multiple and bilateral in 70% when associated with medullary carcinoma of the thyroid (Fig. 12–26) (5,60,63,79,92,94,96). When bilateral, one of the tumors may precede the other by decades. They range in size from a few millimeters to several centimeters in diameter. Malignant change is uncommon before the tumor exceeds 4 cm in diameter (80). Adrenal medullary hyperplasia is a precursor to pheochromocytoma (20,92).

Gastrointestinal tract. Gastrointestinal abnormalities may be present shortly after birth. Abdominal distension is common. At least 30% have some intestinal complaint: megacolon (Fig. 12–27A), diverticulosis, and chronic constipation alternating with watery diarrhea (16,19,28,29,61,64). Achalasia has also been reported (26). These abnormalities are in part related to a vasoactive intestinal peptide (90) and in response to the secretory products of the medullary carcinoma of the thyroid (61). Histopathologic study has revealed diffuse intestinal ganglioneuromatosis (Fig. 12–27B), which may involve the entire gut as well as the liver, gallbladder, and pancreas (16,19,94,96). Esophageal dysmotility has also been shown (28). Rectal carcinoid (30) and adenomatous polyposis coli have been found (72).

Musculoskeletal alterations. At least 60% have an asthenic or Marfanoid habitus with severe muscular wasting (56). Weakness especially of the proximal muscles of the extremities seen in 15% simulates a myopathic state (Fig. 12–28) (10,20,23,25,29,41,62,64,69,79). Various skeletal alterations include: pectus excavatum, talipes equinovarus, pes cavus (25%), slipped femoral epiphysis (10%), aseptic necrosis of lumbar spine, kyphoscoliosis (25%), lordosis, and increased joint laxity (12%). These findings have been extensively reviewed elsewhere (34,41,69).

Other findings. Melanotic skin pigmentation has been reported, possibly reflecting elaboration of an MSH-like peptide by the medullary carcinoma of the thyroid (25). Hypertrophy of peripheral nerves has been found (51,68,97). Dyck et al (31) found involvement of autonomic nerves as well as of somatic motor and sensory neurons; these investigators postulated that neurologic symptoms in this disease could be attributed to neuroma formation. The cutaneous nerves are enlarged (22). Pubertal delay has been reported (59,93).

Oral manifestations. Oral and labial involvement is the first component of the syndrome to bring attention to the disorder, almost always in the first decade of life (51). In possibly 50%, these lesions are congenital or noticed in early infancy (16,19,41–43,51,64). The oral lesions consist of mucosal neuromas that principally involve the lips and tongue, although the buccal mucosa, gingiva, and palatal mucosa may be affected (20,41–43) (Fig. 12–29A,B). Both lips are extensively enlarged and nodular and have been described as blubbery. The lingual lesions are most commonly found on the anterior dorsal surface of the tongue and appear as pink pedunculated nodules; they have also been reported on the ventral tongue surface (56).

On light and electron microscopy, the mucosal nodules are plexiform neuromas (18,24,42,97)—that is, unencapsulated masses of convoluted myelinated and unmyelinated nerves surrounded by a thickened perineurium (Fig. 12–29C) which elaborate calcitonin (79). Histochemical investigation demonstrates absence of both specific and nonspecific cholinesterase activity, in contrast to neurofibroma, which rarely contains axons but is cholinesterase positive (42). Mucosal neuromas are epithelial membrane antigen positive and S-100 negative (13).

Cephalometric studies report high palatal vault, posterior crossbite, steep mandibular plane, and mandibular retrognathism (73). The mandibular canal and mental foramen are widened (Fig. 12–29D) (2). Mandibular prognathism has been noted in several patients (29,53).

Differential diagnosis. Pheochromocytoma may occur as an isolated tumor or as an autosomal dominant trait (87). It is also found in about 1% of cases of neurofibromatosis. Pheochromocytoma may also be seen with von Hippel–Lindau syndrome (4) and with brain tumors, including cerebellar hemangioblastoma, ependymoma, astrocytoma, meningioma, and spongioblastoma. Medullary carcinoma of the thyroid has been reported to occur without other abnormalities or as an autosomal dominant

trait (45). Pheochromocytoma-medullary thyroid carcinoma-parathyroid adenoma (MEN 2A, Sipple syndrome), an autosomal dominant disorder also mapping to 10q11.2, results from missense mutations, i.e., replacement of one of several cysteine residues in the *extracellular* domain of the RET proto-oncogene molecule. As indicated earlier, patients with MEN 2B have a mutation in the intracellular catalytic domain of the molecule (32). MEN 2A is about six times as common as MEN 2B. Importantly and in contradistinction to MEN 2B patients, most of those with MEN 2A have hyperparathyroidism secondary to hyperplasia or adenomas of the parathyroids due to excess calcitonin (88). The corneal nerves may be somewhat enlarged in MEN 2A (55). Hyperparathyroidism may rarely have autosomal dominant inheritance or exhibit central giant cell granulomas or fibro-osseous lesions of the jaws (74,91). Carney et al (21) reported three families in which pancreatic islet cell tumors and pheochromocytomas had autosomal dominant inheritance. Griffiths et al (45) described the association of pheochromocytoma, neurofibromatosis, and duodenal carcinoid. Other overlapping syndromes have been reviewed by Schimke (76). Ganglioneuromatous polyps and juvenile or adenomatous polyposis of the large bowel have been reported. Intestinal ganglioneuromatosis as an isolated finding may have autosomal dominant inheritance (3). In a small series of apparently isolated intestinal ganglioneuromatosis cases, occult germline RET M918T mutations were found. Ultimately they were found to have MEN2B (33). Multiple systematized neuromas of the skin and mucosa have been reported in the absence of the syndrome (1).

Laboratory aids. It should be emphasized that DNA analysis permits the unambiguous identification of MEN 2B carriers (60,81). Germline RET testing should be done from cord blood or during the neonatal period. As indicated earlier, 95% have the M918T mutation, the other 4% being due to an A883F mutation (68). Before molecular technology was available, elevated calcitonin levels were expected if medullary carcinoma of the thyroid was present (7) even if the tumor was not clinically apparent. Screening was begun at birth and continued at regular

intervals until age 35 (38). Several measurements were used in detection of recurrence, metastases, or growth of residual tumor using both serum and urinary assays (7). The pentagastrin stimulation test with or without calcium infusion was employed for producing maximum calcitonin secretion (21,79,88). Intradermal injection of 1:1000 histamine produces a wheal but no flare in patients with medullary carcinoma of the thyroid, a finding that is probably related to calcitonin gene-related peptide (5,41,71). It appears to be a type of dysautonomia and is probably related to the deficient tears seen in 40% of patients. Irregular calcification of the tumor metastases to lungs, liver, and bone (50) may be demonstrated in about 10% (30) by radionuclide scanning with technetium 99m (50,69). Fine needle aspiration biopsy has been used effectively in patients with palpable tumor (79). Fluorescamine can be employed for cytology on smears pretreated with formaldehyde gas (79).

Increased vanilmandelic acid and altered epinephrine/norepinephrine ratios demonstrate pheochromocytoma (47,89). Radiographically, the kidney may be displaced downward or eggshell calcification of the upper pole may be found (44). Preferred methods of imaging are CT and ultrasound. Scintigraphy may aid in diagnosis of pheochromocytoma or its metastases (8,35,57). Intestinal ganglioneuromatosis has a characteristic appearance on barium enema, such as alternating areas of spasm and dilatation (30).

Multiple odontoma-esophageal stenosis syndrome

Herrmann (3) reported a young male with huge tumors of the maxilla and mandible containing 1200 and 900 teeth, respectively, in various stages of development, including geminated and invaginated teeth. In 1973, Schmidseder and Hausamen (5) studied the same patient, noting that his two sons (one dying from pneumonia soon after birth) also manifested multiple odontomas of both jaws in infancy. The surviving infant was found to have a liver disorder and pulmonary stenosis. Subsequently, a daughter was born who again manifested odontomas. The boy experienced recurrences of odontomas that exhibited a higher degree of differentiation. He also suffered esophageal stenosis, as did his father (7).

Bader (1) reported multiple odontomas of both jaws in a female infant with calcified aortic stenosis, congenital cylindric bronchiectasis, leiomyomatosis of the esophagus with stenosis, hyperplasia of the myenteric plexus, and chronic interstitial cirrhosis of the liver. GL Barnes (personal communication, 1974) observed sibs with odontomas in four quadrants, malrotation and stenosis of the bowel, and iris colobomas.

Multiple odontomas were documented in male sibs by Schmitz and Witzel (6), but associated anomalies were not mentioned. Beisser (2) and Malik and Khalid (4) also reported multiple bilateral odontomas in both jaws.

In view of the occurrence of what appears to be a syndrome of multiple odontomas, chronic interstitial cirrhosis of the liver, and esophageal stenosis in two generations, it must be assumed that the disorder is inherited as an autosomal dominant trait. In case of Schmitz and Witzel (6), the parents of the male sibs were normal.

The neurofibromatoses (NF1 Recklinghausen type, NF2 acoustic type, other types)

In 1849, Robert Smith (160), the First Professor of Surgery at Dublin Medical School, reported the clinical and necropsy findings in two cases of neurofibromatosis and cited 75 references from the earlier medical literature. He did not recognize that the tumors contain neural elements, however, and it was von Recklinghausen's (175) publication in 1882 that convinced the medical world that neurofibromatosis (NF) was a distinct entity. A recent survey is that edited by Viskochil (174).

The reader is referred to the following sources for more detailed coverage: general aspects (30,33,39,81,111a,123,130,131,133,178), NF1 Recklinghausen type (8,15,31,39,79,81,106,131), NF2 acoustic type (17,48–50,79,110,112,131,142,154), tumors and neoplasms (27,44,64, 75,96,104,121,177,181), cutaneous manifestations (15,38,39,83,88,111, 183,187,191), skeletal findings (73,74,78,87,95,156), central nervous system manifestations (41,110,139), ophthalmologic features (54,56,60, 104,128,192), endocrine findings (148), pediatric aspects (23,36,37,46, 73,148,187), and animal models (68,149, see 131).

Types of neurofibromatosis. These have been classified by Cohen (32).

Neurofibromatosis, type 1 (NF1). This classic form of neurofibromatosis accounts for about 90% of all cases. The mutation rate has been calculated to be 1×10^{-4} mutations per gamete per generation (39), the highest in humans. Clementi et al (29) found a mutation rate of 6.5×10^{-5}. Major features include six or more café-au-lait spots, cutaneous neurofibromas, and Lisch nodules. Axillary freckling develops in approximately 66% of all patients. Inheritance is autosomal dominant with about 50% of cases representing new mutations.

Neurofibromatosis, type 2 (NF2). The hallmark consists of bilateral acoustic neuromas. Symptoms are usually caused by pressure on the vestibulocochlear and facial nerve complex, the first symptom usually being hearing loss that often begins during the teenage years or early twenties, but occasionally may occur as early as the first or as late as the seventh decade of life. Café-au-lait spots and cutaneous neurofibromas are also present, but occur less commonly than in NF1. Neurofibromas are easy to overlook; they are generally less than 2 cm in diameter, minimally raised, and often have a roughened surface that may have more prominent hairs than the surrounding skin. Axillary freckling is uncommon. On occasion, deep plexiform neurofibromas may result in palpable masses. Tumors of the central nervous system are especially common, Schwann cell tumors occurring most frequently. However, multiple tumors of meningeal or glial origin may also occur. Other Schwann cell tumors may develop along the cranial nerves or spinal roots (110). Some patients with NF2 have multiple schwannomas in the absence of acoutic tumors, meningiomas, or ocular pathology (86). Purcell and Dixon (127) reported schwannomatosis with meningiomas, gliomas, and astrocytomas. Presenile lens opacities or subcapsular cataracts occur in about 50%. Lisch nodules are uncommon. NF2 has autosomal dominant inheritance with penetrance of over 95%. Because NF1 and NF2 may both have central and peripheral manifestations, the previously used terms "peripheral neurofibromatosis" for NF1 and "central neurofibromatosis" for NF2 have been discarded as misleading and confusing (110).

Neurofibromatosis, type 3, Riccardi type. This type of neurofibromatosis has features of NF1 and NF2. Café-au-lait spots are usually pale, few in number, and may be large. Cutaneous neurofibromas are especially common on the palms. A multiplicity of brain tumors occurs, including acoustic neuromas, meningiomas, and spinal/paraspinal neurofibromas. Optic gliomas do not occur. Lisch nodules are absent. Brain tumors are usually of early onset with a rapid course that precludes procreation. To date, all cases have been sporadic (131).

Neurofibromatosis, type 3, intestinal type. In this form, neurofibromatous involvement is limited to the gastrointestinal tract. Onset of symptoms is delayed until adulthood and some carriers are asymptomatic until their middle or late adult years. Increased risk of intestinal problems include those of bleeding, intussusception, and obstruction (65,105). Inheritance is dominant and most likely autosomal, although no male-to-male transmission has been recorded as of this writing (65). Reciprocal translocation between chromosomes 12 and 14 has been described in one family and may be due to chance, or to linkage of the gene for intestinal neurofibromatosis to one of the breakpoints in chromosome bands 12q13 and 14q13 (172).

Neurofibromatosis, type 4. This is a residual category of variant phenotypes for patients who do not fit neatly into any other known type (131) (NF1, NF2, or NF3, Riccardi type).

Neurofibromatosis, type 5, segmental neurofibromatosis. Neurofibromas and café-au-lait spots restricted to one area of the body have been recorded frequently (39,59,84,89,91,115,117,120,131, 137,141,143,147,167a). Evidence is consistent with somatic mosaicism for NF1 mutations. Combemale et al (35) reviewed 88 cases. Wolkenstein et al (189) found that segmented NF is about 30 times less common than classic NF1.

Familial spinal neurofibromatosis. Although spinal neurofibromatosis is a serious complication in 1%–2% of NF1 patients and occurs more commonly in NF2, several families have only spinal neurofibromatosis (9,32).

Duodenal carcinoid syndrome. In this triad, duodenal carcinoid tumor and pheochromocytoma occur together with neurofibromatosis (32).

Etiology. Genetic aspects, chromosome map location, and the molecular biology of NF1 and NF2 have been discussed by many authors (8,14,15,22,23,32,43,47,53,58,70,79,81,82,86,94,107,109,116,129,131, 132,134,142,144,150,154,157,158,169,172). Inheritance is autosomal dominant. It has been reported in monozygotic twins (171).

NF1 is caused by mutations in a tumor suppressor gene that maps to chromosome region 17q11.2. The first hit is a germline mutation, with second hits occurring in developing tumors. The mRMA encoded is 11–13 kb with at least 59 exons. Four alternatively spliced transcripts have been identified (157). There are at least eleven NF1-related sequences, nine of which are located near centromere sequences of seven different chromosomes (129,151). Approximately 82% of the germline mutations that have been characterized to date severely truncate neurofibromin, the encoded protein (157,170). Hoffmeyer et al (70) reported the skipping of exons containing premature-termination codons. Klose et al (94) noted two independent mutations in the same family.

NF2 is caused by mutations in a tumor suppressor gene that maps to chromosome region 22q12.2. This has been ascertained after a high rate of acoustic neuromas has been found in those with chromosome abnormalities (168). Mutations have been identified in approximately two-thirds of affected individuals. The gene produces a protein called merlin or schwannomin. Merlin is absent in nearly all schwannomas (153). Increased expression of merlin impairs cell motility, adhesion, and spreading (58). A first-hit germline mutation is followed by second hits in developing tumors (107,155). Evans et al (47) found that somatic mosaicism is likely to be a common cause of NF2 in sporadic cases.

Biljsma et al (17) noted a G→A transition at the donor splice site of exon 5 in both affected and those at risk in the NF2 family.

Phenotypic/molecular correlations. In NF1, large deletions occur with greater frequency in patients with mental retardation, severe learning disorder, minor anomalies, and many cutaneous or plexiform neurofibromas of early onset (103,190). However, large NF1 deletions cannot be predicted solely on the basis of the clinical phenotypes (169).

In NF2, with missense and splice site variants, a milder phenotype has been demonstrated. In protein-truncating mutations, the phenotype is more severe (48,144).

Unusual aspects of neurofibromatosis. Whether the neurofibromatosis-Noonan syndrome (2,4,5,28,92,113,124,146,167) represents a true syndrome or variable expression of NF1 has been debated. A discrete entity may occur in a minority of reported patients who lack Lisch nodules, have few neurofibromas of the skin, and lack internal neurofibromas: The condition breeds true in affected families. Café-au-lait spots are also known to be a feature of classic Noonan syndrome. In most cases of neurofibromatosis-Noonan syndrome, Noonanoid features represent variable expression of NF1. One family has been reported in which Noonan syndrome and NF1 segregated separately (14,21). Watson syndrome, a combination of pulmonic stenosis, café-au-lait spots, and mental deficiency (3,98,167,179) has mild signs of both NF1 and Noonan syndrome. Allanson et al (6) showed linkage to the NF1 gene.

Asperen et al (10) reported a mother and son with NF1 and overgrowth with a Weaver syndrome–like phenotype. The proband had more than six café-au-lait spots, Lisch nodules, axillary freckling, and numerous neurofibromas. NF1 was confirmed at the molecular level.

Legius et al (102) reported a 2-year-old boy with NF1 and encephalocraniocutaneous lipomatosis. Findings included more than five café-au-lait spots and increased T2-weighted signals in the basal ganglia on MRI scan. An NF1 mutation was confirmed. The patient also had hemimegalencephaly, regional alopecia, lipomas of the occipital region, and seizures.

Neurofibromatosis, type 1. The classic form of neurofibromatosis, as described by von Recklinghausen (175), appears with a frequency of one case per 2500 to 3000 births and occurs approximately once in 200 individuals with mental deficiency (39). About 80,000 people in the United States are affected (131). Inheritance is autosomal dominant with almost 100% penetrance (131). Although it has been suggested that 25% of all cases represent new mutations (116), an earlier study (39) and a recent, large study (131) show that 50% represent new mutations, and an increase in paternal age at the time of conception has been found as an associated feature (134). Some authors (116) have suggested that maternal neurofibromatosis increases the overall severity of the disorder in affected offspring of the mothers, but in a large, well-controlled study (132), no significant differences in overall severity were found between maternal affected, paternal affected, and sporadically occurring cases.

Many of the features such as café-au-lait spots, neurofibromas, sphenoid bone dysplasia, and pheochromocytoma are of neural crest origin (131,133,178). Other findings, such as cerebral cortical heterotopias and optic gliomas, appear to be derived from the neural tube itself. Still other findings, such as pseudoarthrosis, coarctation of aorta, renal artery stenosis, rhabdomyosarcoma, and leukemia, appear to be of mesodermal origin (131,133).

Natural history. Natural history has been discussed by a number of authors (13,131,161). Over 40% of patients have some manifestations at birth, and over 60% by the second year of life (52). Café-au-lait spots usually develop first, with multiple lesions present within the first year of life. In about 50%, axillary freckling appears later. Cutaneous neurofibromas appear around the onset of puberty and increase in number throughout life. An increased number appear during pregnancy (45). Lisch nodules, best observed in slit lamp examination, begin to appear in early childhood and have been observed in almost all affected adults (79). Average height is reduced and 16% are below the third centile (131).

About 33% of all patients develop one or more complications. Plexiform neurofibromas occur in 30%. About 6% of those over 18 develop some form of malignancy. Other important complications include neurological problems in 10% (including epilepsy, aqueductal stenosis, and spinal neurofibromas), scoliosis in 5%, pseudoarthrosis in 3%, gastrointestinal neurofibromas in 2%, endocrine neoplasms in 2%, and renal artery stenosis in 2% (79). Approximately 8%–9% have mental retardation, but learning disabilities of various kinds affect 25% (131).

Growth. Clementi et al (30) studied growth in 528 NF1 patients. Impaired height affected only a subset of subjects and did not seem to be related to disease severity. Although endocrinopathies can also affect growth, only 3.8% of patients were so affected. Slight overweight was found in NF1 adults, particularly males.

Macrocephaly was a feature in most subjects and was not related to hydrocephalus found in 2.3% of patients. OFC velocity in NF1 girls was the same as that of normal girls, but in NF1 boys, the OFC pubertal growth spurt was much more pronounced and delayed than in normal boys. A disproportion between OFC and height in boys was evident and appeared to be related to disease severity. In children less than 6 years of age, macrocephaly was found in 50%, short stature in 25%, hypertelorism in 64%, and thoracic abnormalities in 37% (31).

Neoplasia. The most distinctive and common skin neoplasm is the neurofibroma, especially the plexiform variety (63). Fialkow et al (51) analyzed neurofibromas from glucose-6-phosphate dehydrogenase A–B heterozygotes and concluded that each tumor had multiple cell origin, with tumorogenesis minimally involving 150 cells.

Neoplasms may be present at birth or appear during childhood or even later. They vary greatly in size with localized enlargement of many nerve trunks in larger neurofibromas. They are most striking on the skin, with some patients manifesting few, hundreds, or even thousands of individual neurofibromas and others having large unilateral pendulous masses (Fig. 12–30). Many organs may be involved, including stomach, intestines, kidney, bladder, larynx, and heart (19,23,24,42,69,138). In the head and neck region, the most commonly affected sites are the scalp, cheek, neck, and oral cavity (57,97,108). Neurofibrosarcomatous transformation has been reported in 3%–12% (52,67,74, 79,96). Schwannomas, meningiomas, astrocytomas (especially optic gliomas), ependymomas, and rarely medulloblastomas have been observed (41,75,83,131,139).

A variety of other tumors and neoplasms have been recorded, including cutaneous angiomas in 53% (181), subungual glomus tumors (93a,123a), subcutaneous leiomyomas (52), carcinoid tumor (52,77), xanthogranulomas with excessive frequency in young patients (121,131), subcutaneous neurofibromas in and about the cervical spinal cord in about 2%–5% (131), pheochromocytoma in about 1% or less (75,131), neuroblastoma (75), rhabdomyosarcoma (75), Wilms tumor (75,177), leukemia with a striking excess of nonlymphocytic forms, especially juvenile chronic myelogenous leukemia (27,75,131), adenocarcinoma of pancreas (131), lipoma (52), liposarcoma (44), and virilizing adrenal carcinoma (52).

Skin. In addition to nodular tumors of the skin, café-au-lait spots are found in over 99%. The smooth-edged pigmented macules are usually present at birth, but may take months, or even a year, to appear (Fig. 12–31). They increase in size during the first decade and vary in size from 1 to 2 mm to over 15 cm. Their distribution is random over the body except for a disproportionately small number on the face (130). The color varies from yellowish to chocolate-brown. The presence of six or more café-au-lait spots greater than 1.5 cm in diameter has come to represent the criterion for diagnosing neurofibromatosis, although fewer are present in some instances (38,39,130,140,187). Axillary freckling is present in approximately 50% (145) and, if present, is a significant diagnostic clue. Inguinal freckling may also be found (30). Giant pigment granules are found in café-au-lait spots (119). Pigmented hairy nevi may also be noted (63,163). Cutaneous blue-red and pseudoatrophic macules and palmar melanotic macules have been reported as additional

Fig. 12–30. *Neurofibromatosis*. Various craniofacial features of neurofibromatosis. (A) Unilateral exophthalmos due to bony defect of the posterosuperior orbital wall. Facial asymmetry. (C) Severe involvement with unilateral neurofibromatosis. (C from J Coblin and B Reil, J Maxillofac Surg 3:23, 1975.)

cutaneous signs (183,191). Dermatoglyphic findings include an excess of digital central pocket patterns (176). Stein et al (163) reported a case of NF1 that presented as epidermal nevus syndrome.

Central nervous system. Mental deficiency with an IQ under 70 occurs in about 8%–9%. Learning disabilities, present in 25%, include easy distractibility, impulsiveness, deficient visual-motor coordination, excessive scatter of scores from one set of test items to another, and language and vocabulary deficits (131). Seizures are seen in about 5% (131), and frank hydrocephaly with aqueductal stenosis (76) as well as asymptomatic ventricular dilation (76,131) have been recorded. Distortion of cortical architecture from glial proliferation and neuronal heterotopias deep in the cerebral white matter have been described (41,63,139). Rosman and Pearce (139) suggested that neuronal heterotopias, best explained by cortical neuron migration arrest during brain development, might be linked to mental retardation. Ventriculomegaly with Chiari type 1 malformations has been observed in NF5 (3). Riviello et al (136) reported two cases of aqueductal stenosis and reviewed 25 cases in the literature, estimating a frequency of about 1%.

Eyes. Any part of the eye may be involved. Neurofibromas of the eyelids have been occasionally observed. Intraorbital lesions may produce proptosis and muscle palsies. Sphenoid bone dysplasia may produce pulsating exophthalmos. Phakoma, congenital glaucoma, corneal opacity, detached retina, optic atrophy, and congenital ptosis of eyelids have also been reported (54,56,60,108,128). Lisch nodules of various sizes may be found anywhere in the iris (80) and are an almost constant feature (Fig. 12–32). These lesions are melanocytic hamartomas and are seen only in NF patients. Lisch nodules have a direct relationship to increasing patient's age and severity of skin lesions (192).

Skeletal system. Bony abnormalities have been particularly well discussed by Crawford (36) and Crawford and Bagamery (37). Scoliosis, the most common skeletal defect observed in NF (37), ranges from mild to severe curvature; the etiology is thought to be secondary to a localized neurofibroma eroding and infiltrating bone. Other spinal defects include kyphosis, cervical spine abnormalities, and spondylolisthesis. Commonly observed are subperiosteal erosive changes caused by pressure from proliferating neurofibromatous tissue in the periosteum and overlying soft parts. Central "cystic" lesions of bone result from expansive growth of neurofibromas within the medullary cavity in some patients. Still others (152) have shown fibrous connective tissue. In other cases, no cause for central lesions can be found (87).

Pseudoarthroses (commonly with bowing of the tibia and fibula, occasionally the radius) are also common (72,90). Bony defects of the skull, especially of the posterosuperior orbital wall, overgrowth of cranial bones, and craniofacial asymmetry have been reported. Macrocephaly is a well-known association (131,136). Hypertelorism has been found in 24% in the series reported by Westerhof et al (184). A variety of other anomalies may be observed, including hemihyperplasia of a limb or digit, spina bifida, absent patella, elevated scapulas, congenital dislocations (especially of the hip, radius, and ulna), clubfoot, syndactyly, and complete or partial absence of limb bones (37,39,63,74,78,87,122,135). Postaxial polydactyly was noted in one affected family by Merlob et al (114).

Endocrine system. Findings have been well reviewed by Saxena (148). In childhood, the most common endocrine abnormality is sexual precocity (99). Other findings have included hypopituitarism, hypogonadism, gigantism, acromegaly, delayed sexual development, obesity, hypoglycemia, diabetes insipidus, goiter, myxedema, and hyperparathyroidism.

Cardiovascular system. Cardiovascular anomalies are low-frequency findings: pulmonic valvular stenosis, supravalvular aortic stenosis, coarctation of aorta, ASD, congenital heart block, stenotic renal arteries, and other defects (7,42,61,63,93,138,159). Vascular malformations of the parotid gland have been reported (49).

Oral manifestations. The frequency of oral lesions in the past was stated to be 4%–7%, but recent studies of a large series of patients by Shapiro et al (156) ascertained by clinical and complete radiographic studies suggest a higher frequency. D'Ambrosio et al (40) reported an excellent study of jaw and skull changes, noting intraoral manifestations in 66% and skeletal involvement of the maxilla and mandible in 58%. Their overall sample had involvement of some kind in 92%. Although the age range was 6–66 years, we assume that children made up a small percentage of the sample. Most common are oral neurofibromas, enlarged fungiform papillae, intrabony lesions, wide inferior alveolar canals, and enlarged mandibular foramina (12,156). Tumors may involve any oral soft tissue, although there is some predilection for the

tongue (11,62,85,100,162,166,180,186,188). Tongue lesions, consisting mostly of macroglossia and/or single or multiple tumors, have a sex ratio of almost 2M:1F (12) (Fig. 12–33). Lesions of the bony maxilla and mandible are uncommon (135,173,188), but with marked involvement of the face there may be combined maxillo-zygomatico-temporomandibular

hypoplasia not from pressure atrophy but from maldevelopment of these bones (95). Hyperplasia of the soft oral tissues has been described associated with underlying bony hypoplasia (185). Teeth are consequently in malposition, with total or partial retention. No enamel or dentin defects have been reported (185). Lee et al (101) found increased bone density, enlarged mandibular foramen, lateral bowing of ramus, increased dimensions of coronoid notch, and decrease in mandibular angle. Ruggieri et al (143a) and Ardekian et al (8a) reported a unique case of giant cell granulomas of the mandible and femora in a patient with typical NF1. (A similar case was described by S. Hersh, Cleveland, 2000).

Other findings. Fibrosing alveolitis has been an associated finding (126,178). Velopharyngeal insufficiency with no cause identified after extensive workup was recorded in seven patients (125). The reader is referred to several sources for other low-frequency abnormalities (23,39,46,131).

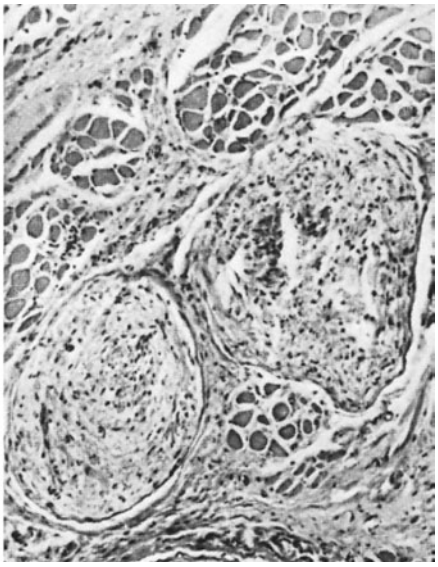
Differential diagnosis. Neurofibromatosis should be distinguished from *multiple mucosal neuroma syndrome* (*multiple endocrine neoplasia, type 2B*), *Klippel-Trenaunay syndrome*, *multiple lipomatosis*, hemihyperplasia/multiple lipoma syndrome, *LEOPARD syndrome*, and *hemihyperplasia* (*hemihypertrophy*). The café-au-lait spots of *McCune-Albright syndrome* tend to be more markedly scalloped (coast of Maine appearance) in contrast to the smooth-edged lesions (coast of California appearance) of neurofibromatosis (140,187). Stephan et al (165) described isolated cases of cutaneous angiomatosis and macrocephaly in association with the Klippel-Trenaunay syndrome. The *Bannayan-Riley-Ruvalcaba syndrome* (192), characterized by macrocephaly, multiple lipomas, and hemangiomas with dominant inheritance should be excluded, as should *Proteus syndrome* (32,33).

Café-au-lait macules have been associated with disseminated nonossifying fibromas of the long bones and jaw under the name of Jaffe-Campanacci syndrome (20,118,163). The jaw lesions resemble giant cell granulomas. Café-au-lait spots may, by themselves, be an autosomal dominant trait. The gene does not map to the NF1 site (18,25). However, Abeliovich et al (1) found linkage with NF1.

In *Noonan-like/multiple giant cell lesion syndrome*, a severe Noonanoid phenotype occurs together with giant cell lesions of bones, joints, and/or soft tissue; pulmonic stenosis is found in some cases (34).

Gorlin and Koutlas (55) reported an autosomal dominant syndrome of multiple cutaneous schwannomas, multiple melanotic nevi and multiple leiomyomas of the vagina.

A



B

Fig. 12–33. *Neurofibromatosis*. Oral involvement. (A) Neurofibromatosis tumor of tongue. (B) Photomicrograph of plexiform neurofibroma of tongue seen in A.

Johnson-McMillan syndrome is characterized by alopecia, hyposmia, conductive hearing loss, microtia, and hypogonadism. A mother and son with the syndrome also have multiple café-au-lait spots and mild retardation (66,88a,88b).

It should be carefully noted that single or even multiple neurofibromas or schwannomas without neurofibromatosis are frequently observed by surgeons and pathologists. Familial glioblastoma multiforme was reported without neurofibromatosis by Chemke et al (26).

Laboratory aids. Biopsy of individual lesions is useful for establishing the diagnosis in questionable cases. The café-au-lait macules of NF1 tend to have more large pigmented granules than those in McCune-Albright syndrome (16). Johnson and Chorneco (88) reported more dopa-positive melanocytes/mm^2 in the café-au-lait macules of neurofibromatosis than in those of normal individuals. The density of melanin macroglobules is significantly higher in biopsies of café-au-lait macules of patients with NF1 than in patients with NF2 or normal controls (111). Soft-tissue neurofibromas have been found to take up 99mTc DTPA. The localization of this radioisotope in soft-tissue benign neoplasms of NF facilitates their identification by scintigraphy (86). In questionable cases, NF1 mutations may be identified. MRI has been used to diagnose NF2 presymptomatically (50).

Peutz-Jeghers syndrome

The syndrome of mucocutaneous melanotic pigmentation associated with hamartomatous intestinal polyposis was probably first described in 1896 by Sir Jonathan Hutchinson (39), although he was not aware of the presence of polyposis at the time. Follow-up by Parkes Weber (58) of one of his patients revealed the cause of death to be intussusception. Credit for pointing out the relationship between these ostensibly unrelated conditions goes to Peutz (60), a Dutch physician who, in 1921, described the syndrome in three generations. This family was reexamined in 1999 (83). Knowledge of the disorder, however, did not become widespread until Jeghers et al (41), in 1949, published a comprehensive account of 10 cases. Dozois et al (22) were the first to point out the increased rate of ovarian tumors in female patients. Dormandy (20) Klostermann (43,44) and Tomlinson and Houlston (73) provided excellent summaries of the clinical features of the syndrome. Giardiello et al (31) showed that the overall risk of cancer is considerably higher than previously supposed. An excellent review is that of Westerman et al (83a).

The syndrome has autosomal dominant inheritance with high penetrance (20,41,44,78). Almost 35% of cases represent new mutations (7). The gene has been mapped to 19p13.3 (1,35,55) and represents germline mutations in a novel serine threonine kinase, *STK11/LKB1*, a tumor suppressor gene (36,42,54,82,83). The mutations cause truncation of the encoded protein inactivating it. Loss of heterozygosity has been demonstrated (36). Not all patients with Peutz-Jeghers syndrome can be linked to this gene (53,56). A second locus at 19q13.4 has been found (9a,53,54), but this needs confirmation.

Gastrointestinal system. Polyposis of the gastrointestinal tract is the clinically most important component of the syndrome. The polyps are hamartomatous in origin (6,7,21). Bartholomew et al (7) suggested the following frequencies: jejunum, 65%; ileum, 55%; large intestine and rectum, 36% each; stomach, 23%; duodenum, 15%. A higher frequency of gastric and colonic polyps was found by Utsunomiya et al (78). Bartholomew et al (7) indicated, in their survey of 117 cases, that 43% had a family history of both polyps and pigmentation and 13% of pigmentation alone.

Thus, polyps may be found anywhere in the mucus-secreting portion of the gastrointestinal tract and may make themselves apparent by producing obstruction or intussusception. The number per patient is variable, but far less than in familial adenomatous polyposis. Usually the intussusception is self-resolving, but it may lead to serious small bowel obstruction and death. The age of onset of symptoms varies from a few weeks to 82 years (average, 29 years), and may present somewhat earlier in males (26). However, about 70% experience some type of gastrointestinal symptoms prior to diagnosis: intermittent colicky pain (85%) and melena or rectal bleeding (35%) (7). Rectal prolapse occurs in 7%–30% (27,74,83). In the majority of patients, the period before diagnosis is about 5 years. Hypochromic anemia due to bleeding from polyps has been found in 15%–35% (83).

The polyps are usually described as benign hamartomas, varying in size from 0.5 to 7.0 cm in diameter (26,82). Dormandy (20) suggested that these growths arise from primitive adenomatous vesicles embedded in the intestinal wall (Fig. 12–34). This view has been supported by other investigators (6,7,65,82) and adenomatous epithelium may be found in the hamartomas. Protein-losing enteropathy has been noted (39a).

Malignancy has been discussed by a number of authors (14,28,38, 39a,48,62,65,78,83). It is generally believed that malignant tumors develop in 10%–20%, a 20-fold increase over the general population. In a review of cases with malignant transformation, Dozois et al (21) found no parallelism between location of the malignant tumor and the site of polyps—that is, the most common locations for the adenocarcinomas (stomach and colon) are the least likely to be sites of polyps. In the extensive long-term study of Giardiello et al (31), cancer developed in 48%. A similar figure was determined by Spigelman et al (71). There was an increased risk for neoplasms to develop at both gastrointestinal and nongastrointestinal sites (31). The mean interval between diagnosis of the syndrome and diagnosis of cancer was 25 ± 20 years (range: 1–64 years). Neoplasms occurred in 8 of 13 families and, in a few pedigrees, were not clustered. Nongastrointestinal cancers included a 100-fold excess of pancreatic carcinoma and others such as ductal carcinoma of breast, adenocarcinoma of lung, and multiple myeloma in addition to colonic malignancy and ovarian tumors. Within the gastrointestinal tract, only adenomatous polyps became malignant, never hamartomatous polyps. Reasons for the lower malignancy rates found by other investigators (21,48,78) were well analyzed by Giardiello et al (31).

Microscopically, gastrointestinal hamartomas represent focal overgrowths in improper proportions of tissues indigenous to that part of the gastrointestinal tract (64). A branching-tree or frondlike arrangement with a core of smooth muscle and stromal tissue may be seen scattered

throughout the growths (Fig. 12–35). Frequent mitotic figures are characteristic. The growths may extend to the serosal surface.

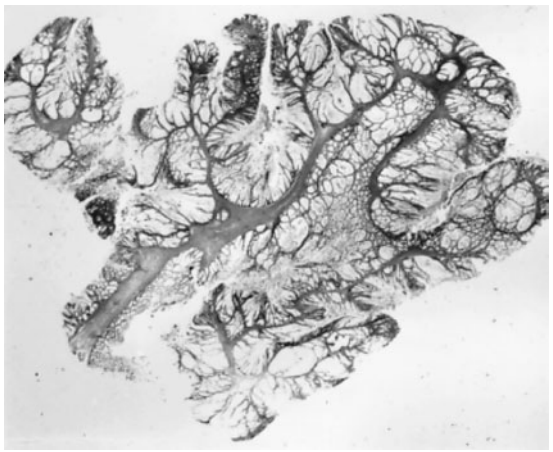
Enteritis cystica profunda characterized by mucosal glands and mucinous cysts that penetrate the tunica muscularis of the small and large bowel has been documented (2,46). The condition, in our opinion, represents extreme hamartomatosis or pseudoinvasion.

Polyps of other organs include the nose (19,20,33,40,44,60,83,89), mouth (49), choanae and antrum (40,49), uterus (44,62,89), ureter and bladder (20,33,56,60,69), gallbladder (29), bile duct (67), and esophagus (3,57). Bronchial adenosis has also been noted (20,33,60).

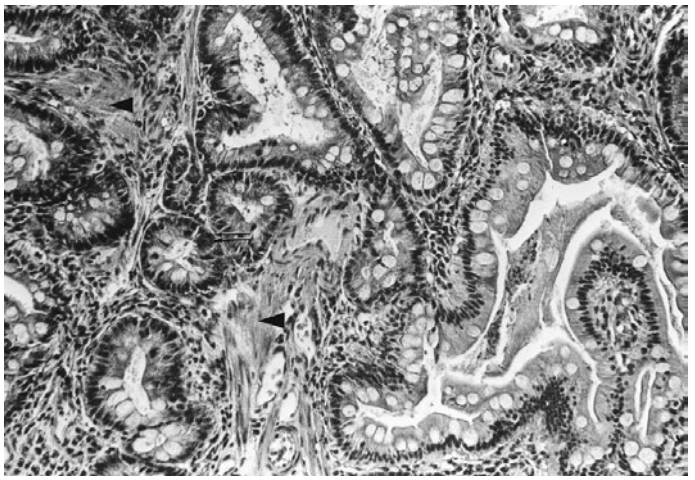
Skin. In about 50%, numerous, usually discrete, brown to bluish-black macules are present on the skin, especially about the body orifices—perioral, periorbital, perianal, and perigenital (75) (Figs. 12–34A and 36). Though some patients exhibit only a few pigmented macules, others are markedly pigmented. Pigmented spots occur on the extremities in about 65% (7,52,72,78), fingers, toes, (85,89), sometimes on the palms or soles, or, occasionally, in other areas, such as the umbilicus, axilla, or shoulder (30,89). Pigmentation of the nails has also been described (45,79) and of psoriatic plaques (5,52). The mucocutaneous pigmentation appears in about 75% during the first or second year of life, before the onset of abdominal symptoms, and seems to fade somewhat at puberty. It may, however, appear as late as the eighth decade.

Ovarian cysts and tumors and uterine adenocarcinoma. Ovarian tumors occur in about 10%–14% of female patients (16,21). They may be found even in very young children (21). Granulosa cell tumors (8,15,17,21,22,33,41,62) have been associated with precocious puberty (17,68). Brenner tumor, dysgerminoma, (22,77) and cystadenoma (22) have also been noted. Cervical adenocarcinoma has been found in at least 20 cases (2,50,51,61,86).

Scully (66) suggests that a distinctive ovarian neoplasm, which he called "sex cord tumor with annular tubules" (SCTAT), may be part of the syndrome. The tumors tend to be bilateral, often of microscopic size, frequently calcified, and nonmalignant. The neoplasm, probably derived from granulosa cells, produces endometrial hyperplasia. Christian (17) reviewed the literature and reported 15 patients with ovarian tumors among 125 female patients with the syndrome and questioned whether SCTAT is a tumor or a hamartoma. Hart et al (34) classified SCTAT as a distinctive annular and membranous variant of the granulosa cell tumor in view of the morphologic similarities and clinical behavior. In a review of 74 cases of SCTAT, Young et al (86) found that 27 patients



A



B

Fig. 12–35. *Peutz-Jeghers syndrome*. (A) Low-power view of polyp from large intestine. Note arborization of nonstriated muscle. (B) Photomicrograph of adenomatous polyp. (A from JD Reid, Cancer 18:970, 1965. B from KJ Walecki et al, Pediatr Radiol 14:62, 1984.)

had the syndrome and four of these also had cervical adenomas. Young et al (87) found three different gynecologic neoplasms: SCTAT, well-differentiated mucinous adenocarcinoma of the cervix, and a distinctive sex cord–stromal tumor.

Testicular tumors. Cantú et al (16) reported a 6-year-old boy with feminizing sex-cord tumor, and Dubois et al (24) and Coen et al (18) reported SCTAT in young boys (3–5 years). A number of authors (23,37,84,88) have found bilateral large cell Sertoli cell tumors, gynecomastia, rapid growth, and advanced bone age.

Other neoplasms. Breast carcinoma (9,32,47,63,76), pancreatic adenocarcinoma (12,31), and bile duct carcinoma (11) have also been reported.

Oral manifestations. On the lips, especially the lower, and on the oral mucosa, round, oval, or irregular, rarely confluent macules of bluish-gray pigment of variable intensity may be seen (90). They vary in size from 1 to 12 mm and are usually somewhat larger than those on the skin. About 98% of 117 patients had pigmentation of the lips, and 88% had involvement of the buccal mucosa (7). Less frequently pigmented are the palate and gingiva. Only rarely are the tongue and the oral floor involved (44,60,72). There does not appear to be any relationship between the

Fig. 12–36. *Peutz-Jeghers syndrome*. (A,B) Melanotic pigmentation of the lips. (A from LG Bartholomew et al, Gastroenterology 32:434, 1957. B from M Zingsheim, Hautarzt 17:85, 1966.)

amount of oral pigmentation and the degree or distribution of the visceral polyposis (Fig. 12–36).

Several investigators have pointed out that labial pigment also tends to fade at puberty, and that the pigment on the buccal mucosa fades to a lesser degree (41,44,78,83), thus being helpful in diagnosis (6,7). Rarely, pigmentation may be present without polyposis (20,41,89).

Pigmentation of other mucosal surfaces, viz. conjunctival (4,76), nasal (20,49), and anal (59), may also be seen. Pigmented oral papillomatosis (49) has been reported.

Differential diagnosis. Oral mucosal pigmentation may be seen normally in over 90% of blacks or members of other dark-skinned races and in 5% of whites (25,90). Solitary melanotic macule of the oral mucosa or lip (usually of vermilion border of lower lip of females) must be excluded (13,70). Laugier-Huntziker syndrome is characterized by acquired melanotic pigmentation of the lips, oral mucosa, longitudinal nail beds, and, occasionally, genitalia (10,80). In Addison's disease, the cutaneous pigmentation is generalized and often increased along body folds and scars. The distribution of freckles does not ordinarily occur perioorally or labially, and intraorally is more generalized. Lentiginosis profusa (*LEOPARD syndrome*) is generalized over the skin but does not involve mucosal surfaces. Lentiginosis also occurs in *Carney syndrome*. Oral pigmentation may rarely occur in *McCune-Albright syndrome*. Polyposis and pigmentation have been described in association with alopecia and nail dystrophy, that is, Cronkhite-Canada syndrome (see *Gardner syndrome*). Still other causes of oral pigmentation have been discussed (52).

Other forms of polyposis of the intestinal tract are usually limited to the colon. These include familial polyposis coli, *Gardner syndrome*, juvenile polyposis, and disseminated polyposis of the colon and rectum. These and other types are discussed in the section on Gardner syndrome.

Sex cord tumor of the ovary may occur in women without Peutz-Jeghers syndrome. In contrast to those with the syndrome, the tumors tend to be unilateral, large, rarely calcified, and mixed with Sertoli and/or granulosa cells; they are malignant in about 15%.

Laboratory aids. The presence of labial and/or oral pigmentation should suggest a thorough history and examination of the gastrointestinal

tract by proctoscopic and radiographic means. Diagnosis of early intussusception may be possible by ultrasonography (81).

Proteus syndrome (and encephalocraniocutaneous lipomatosis)

Proteus syndrome is a complex and variable disorder consisting of overgrowth of hands and/or feet, asymmetry of limbs, connective tissue nevi, epidermal nevi, vascular and lymphatic malformations, and cranial hyperostoses. The syndrome was first delineated by Cohen and Hayden (18), who reported a newly recognized disorder in two similar patients. They further distinguished the condition from neurofibromatosis and Klippel-Trenaunay syndrome. Four years later, Wiedemann et al (56) reported four patients and named the condition after the Greek god Proteus, who could change his shape to avoid capture. Well over 120 cases have been reported, and many other unreported patients are being followed in medical clinics (3,11,18).

Table 12–11. Clinical features of Proteus syndrome

Features	Previously reported cases	Joseph Merrick
Growth		
Asymmetry of limbs	38/38	+
Partial gigantism of hands and/or feet	31/38	+
Skeletal		
Bone hypertrophy	31/38	+
Scoliosis/kyphosis/ abnormal vertebrae	20/38	+
Joint limitation/angulation	17/38	+
Skull hyperostoses	20/38	+
Skin		
Verrucous epidermal nevi	26/38	+[a]
Thickening of skin and subcutaneous tissue	23/38	+
Lipomas[b]	26/38	+
Vascular anomalies[c]	20/38	–
Dilated veins	15/38	–
Unspecified subcutaneous masses	31/38	+
Craniofacial		
Macrocephaly and/or frontal bossing	7/38	+
Epibulbar tumor	5/38	–
Enlarged eye	6/38	–
Strabismus	9/38	–
Prognathism	3/11	–
Performance		
Mental deficiency[d]	11/37	–
Motor delay	6/38	–
Seizures	2/13	–

[a] Treves writes of "papillomatous" skin, which in one area merges into "a mere roughening of the skin." The latter may represent a verrucous epidermal nevus.
[b] Pelvic lipomatosis has been found in three instances, thus increasing the total number of patients affected with lipomas.
[c] Vascular anomalies include hemangiomas, lymphangiomas, "venous dilation," "purplish discoloration," and varicosities.
[d] Mental deficiency is a variable feature, so Merrick's normal mentation is fully compatible with Proteus syndrome.
From MM Cohen Jr, Proc Greenwood Genet Ctr 6:187, 1986.

There has been long-standing confusion in attempts to distinguish between Proteus syndrome and neurofibromatosis (NF1). Connective tissue nevi found in Proteus syndrome are distinct from lesions found in neurofibromatosis (12). Cohen (8–10) provided evidence that Joseph Carey Merrick, pejoratively known as the "Elephant Man," had Proteus syndrome and not, as previously thought, neurofibromatosis (Table 12–11).

Somatic mosaicism lethal in the nonmosaic state, an etiologic hypothesis for Proteus syndrome, was postulated by Happle (23,26). Mosaicism may arise either from a genetic half chromatid mutation or from early somatic mutation. Characteristics of such a disorder include sporadic occurrence, 1:1 sex ratio, mosaic distribution of lesions, and variable extent of involvement, but never diffuse involvement of the entire body or an entire organ system (23). Two known instances of monozygotic twins discordant for Proteus syndrome (17,33,51) lend support to the hypothesis of somatic mosaicism. DNA fingerprinting has shown single band differences in one of these pairs of monozygotic twins discordant for Proteus syndrome. Differences have also been found in the normal and affected areas of another Proteus patient (51).

Purported instances of transmission from parent to child (52) are not convincing. Happle (25,26) discussed the possibility of "paradominant inheritance," should a rare example of familial Proteus syndrome be recorded in the future. According to this hypothesis (25), heterozygosity for a paradominant mutation would confer phenotypic normality and the

allele could be transmitted unperceived for generations. The gene carrier would exhibit Proteus syndrome when a somatic mutation occurred during embryogenesis, giving rise to a cell line that would be either hemizygous, from allelic loss, or homozygous, from a point mutation. On rare occasions, more than one relative might be affected. Because the trait is neither simply mendelian nor entirely non-mendelian but sometimes tends to imitate dominant transmission, Happle (25) proposed the term "paradominance."

Mosaic distribution of lesions and variable extent of involvement implies that criteria for the diagnosis of Proteus syndrome should be loose rather than overly rigid (11,53). Encephalocraniocutaneous lipomatosis (ECCL) possibly represents a significantly more localized form of Proteus syndrome. Comparison of individual cases of ECCL (1,22,42,49) demonstrates a continuum, not two distinct entities that share some common manifestations. For example, in ECCL, cutaneous, craniofacial, and meningeal lipomas, usually unilateral, occur, but cutaneous lipomas below the head and neck and visceral involvement have been found in some cases. Other patients have had mental deficiency, seizures, malformations of the central nervous system, epibulbar dermoids, connective tissue nevi, and focal alopecia. In some instances, hyperostoses of the calvaria have been noted. All of these defects, except possibly focal alopecia, have been seen in Proteus syndrome. Happle (28,30) believes that Proteus syndrome and ECCL are separate entities. The association of ECCL with an NF1 mutation, reported by Legius et al (38), is likely coincidental.

Natural history. Although birth weight may be increased in Proteus syndrome, with some newborns weighing 4000 g or more, normal birth weight and even small-for-gestational-age infants have been observed. At birth, patients with Proteus syndrome are usually normal or show mild to moderate alterations, hyperplasias, or hamartoses. Vascular malformations may be present. Patients with highly significant hyperplastic overgrowth of limbs at birth are very unlikely to have Proteus syndrome. Most often they have Klippel-Trenaunay syndrome or hemihyperplasia/multiple lipomas syndrome. The most remarkable postnatal growth in Proteus syndrome occurs during the first few years of life. However, a few patients may even be short during childhood. The syndrome is characterized by disproportionate overgrowth of bone and soft tissue. Somatic growth during adolescence and final height attainment are apparently normal. Bone and soft-tissue overgrowth tend to plateau after adolescence (3,4,7,11,21), although there are some exceptions and an occasional neoplasm has been noted from age 20 to 30 or older. Some patients have died of unusual causes, including suffocation, cerebellar abscess secondary to otitis media, laryngospasm, pulmonary embolism following a surgical procedure under general anesthesia, invasive metastatic mesothelioma, and invasive papillary adenocarcinoma of the testis (9,11,21,41).

Facial phenotype with mental deficiency. Cohen (11) described a facial phenotype in Proteus syndrome patients with mental deficiency and, in some cases, seizures and/or brain malformations. Manifestations include dolichocephaly, long face, minor downslanting of palpebral fissures and/or minor ptosis, low nasal bridge, wide or anteverted nares, and open mouth at rest. These facial manifestations may even override the severe craniofacial distortion produced by bony overgrowth in some cases (Figs. 12–37 and 12–38).

Connective tissue nevi. Connective tissue nevi are common, and are facultative, not obligatory, i.e., they may or may not be present. They have been recorded most frequently on the plantar surface of the feet, but can also be found on the hands, abdomen, and nose (11). When present, a connective tissue nevus is almost pathognomonic for Proteus syndrome (Fig. 12–39). Histologically, connective tissue nevi are characterized by highly collagenized connective tissue (33). MRI characteristics have been documented (53a).

Epidermal nevi and other skin lesions. Epidermal nevi are etiologically and pathogenetically heterogeneous (24). In Proteus syndrome, nevi are evident in early life and may be found on the neck, trunk, or extremities. Lesions may be linear, whorled, or verrucous, and, in some cases, may exhibit abrupt midline margins (3,4,7,17–19,54,55). Infrequently, a single café-au-lait spot may be observed. Areas of patchy dermal hypoplasia and of hypopigmentation have also been noted (9,18, 29,31,50,54,55,57). Coexistence of lesions can be found in some cases.

Fig. 12–37. *Proteus syndrome*. Unusual craniofacial appearance, kyphoscoliosis, and protuberant abdomen. (From JT Fay and SR Schow, J Oral Surg 26:739, 1968.)

Vascular malformations. Vascular malformations may be of the capillary, venous, or lymphatic type, or may occur as combined channel anomalies—for example, capillary and venous channel or capillary, venous, and lymphatic channels. They are developmental anomalies lined by flat endothelium exhibiting a normal, slow rate of turnover. They grow proportionately with the patient; they never regress, but they can expand. So-called combined tumors such as "angiolipomas" probably do not occur; they probably represent lipomas with a vascular stroma. So-called "lymphohemangioma" is a misnomer for combined lymphatic-capillary malformation. Varicose veins have been reported in the hypogastric and inguinal region and on the legs (3,4,9,13,18,20,37,43,44,56).

Lipomas and dysregulation of adipose tissue. Lipomas in Proteus syndrome are composed principally of mature adipocytes. Decreased and increased fat can be found in the same patient at different sites in the body, indicating dysregulation of adipose tissue (7,11,27,29,36,52). Lipomas may be confined or infiltrative. Although histopathologic examination always shows benign adipose-tissue cells, the location of lesions is of great importance. Superficial lesions tend to be confined and may be self-limited in growth, although this is not always the case. On the other hand, intraabdominal and intrathoracic lipomas have increased potential for invasive behavior, despite benign histologic appearance (19). Infiltration of the spinal canal has been reported (35,52).

Unusual tumors. Cohen (11,16) and Gordon et al (21) showed that several unusual types of tumors are occasionally associated with Proteus syndrome: ovarian cystadenoma (most commonly unilateral; two cases bilateral), various types of testicular tumors, central nervous system tumors (particularly meningiomas), and monomorphic adenoma of the parotid gland (39). Bilateral cystadenomas of the ovary are rare in children and adolescents and therefore of diagnostic value in Proteus syndrome. In adults, bilateral ovarian involvement is found in a significant percentage of cystadenocarcinomas (21). Monomorphic adenoma of the parotid gland is very uncommon, occurring most frequently in elderly

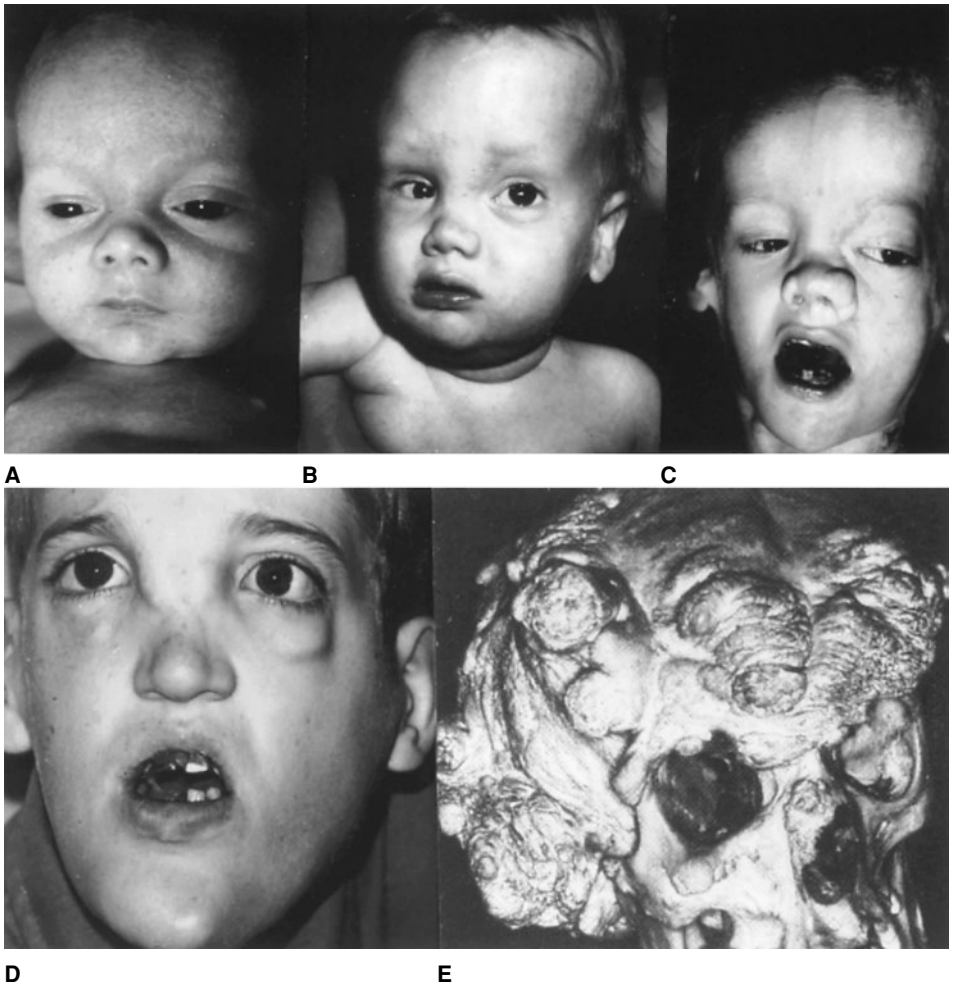

Fig. 12–38. *Proteus syndrome*. Craniofacial features. (A–C) Evolution of features. (A) Patient at 1 month. (B) Same patient at 5 months. (C) Same patient at 5.5 years. (D) Boy developing hyperostoses of nasal bridge, left infraorbital region and mandible. (E) Hyperostoses in Joseph Merrick's skull. [A–C from JAR Tibbles and MM Cohen Jr, Br Med J 293:683, 1986. D from MM Cohen Jr and PW Hayden, Birth Defects 15(5B):291, 1979. E from M Howell and P Ford, The True History of the Elephant Man, Allison and Busby, London, 1980.]

men. The presence of this tumor in two adolescent girls with Proteus syndrome (11,18,21) is highly significant. Multiple tumors are found in some cases (11,17,21).

Skeletal abnormalities. Disproportionate overgrowth, commonly asymmetric in nature, can involve the arms, legs, hands, feet, and digits (3,4,9). Scoliosis and kyphoscoliosis are common (7,9,20,34,41,46, 54,56). Genua valga has also been observed (7,19,34,46), and heel valgus has been noted in a number of instances (7,9,18,34). Megaspondylodysplasia is also common; cervical, thoracic, or lumbar vertebrae may be affected (2,4,45,57). When the cervical vertebrae are involved, the neck can appear elongated (20,37,52); the appearance of the neck can be exaggerated by dysregulation of adipose tissue with decreased neck fat. Overgrowth may affect other bones, such as the metatarsals (3) and the ribs (7,45). Bony protuberances of the hands and feet (3,9) have been observed (7,18,54,55,56), and, on occasion, the long bones of the legs and arms may be involved.

Hyperostoses are bony overgrowths that are not true tumors. Cohen (9,11) used the term hyperostoses in preference to exostoses and osteomas; the latter two terms should be avoided, because both have somewhat different patterns of osseous organization. Hyperostoses may occur in calvarial, facial, nasal, alveolar, and mandibular bone (5,20a). They may be small or they may grow to be large in size, producing striking asymmetry (47). They are most common in the calvaria and least common in nasal and alveolar bone. Hyperostosis of the external auditory canal is uncommon in Proteus syndrome (9,18).

Spleen and thymus. Although limb overgrowth is most common in Proteus syndrome, perhaps any organ may be involved. An uncommon manifestation, found in four patients, is pronounced splenomegaly; one instance was associated with a history of reduced platelet counts. Another uncommon manifestation is enlargement of the thymus (3,4,6).

Central nervous system. Intelligence may be normal, although some degree of mental deficiency has been evident in about 20% of cases and seizures have been documented in approximately 13%. However, a number of patients have had various brain malformations (9,11,18,39,48). Meningiomas have been discussed above (20a).

Pulmonary abnormalities. Hotmisligil (35) estimated that about 16% of patients had pulmonary abnormalities (n = 55). Cystic anomalies were reported in two patients by Wiedemann et al (56). One patient had progressive dyspnea at rest and frequent superinfection. About 12%–13% of patients have had such cystic lung changes. Serious and potentially lethal lung involvement has been emphasized by Newman et al (45).

Renal abnormalities. A variety of renal abnormalities have been recorded, including nephrogenic diabetes insipidus, kidney cysts, vascular malformations of the bladder and kidney, ureterectasis, heminephromegaly, duplicated renal collecting system, and hydronephrosis (11,35,36).

Other abnormalities. Epibulbar dermoids, retinal dysplasia, and a host of other anomalies have been reported in some cases (17,19a,20a,53). Rare findings include rectal polyposis, muscular atrophy, mixed mesenchymal bronchial hamartoma (19), and vocal cord nodule (50).

Differential diagnosis. The two disorders most commonly confused with Proteus syndrome are *Klippel-Trenaunay syndrome* and

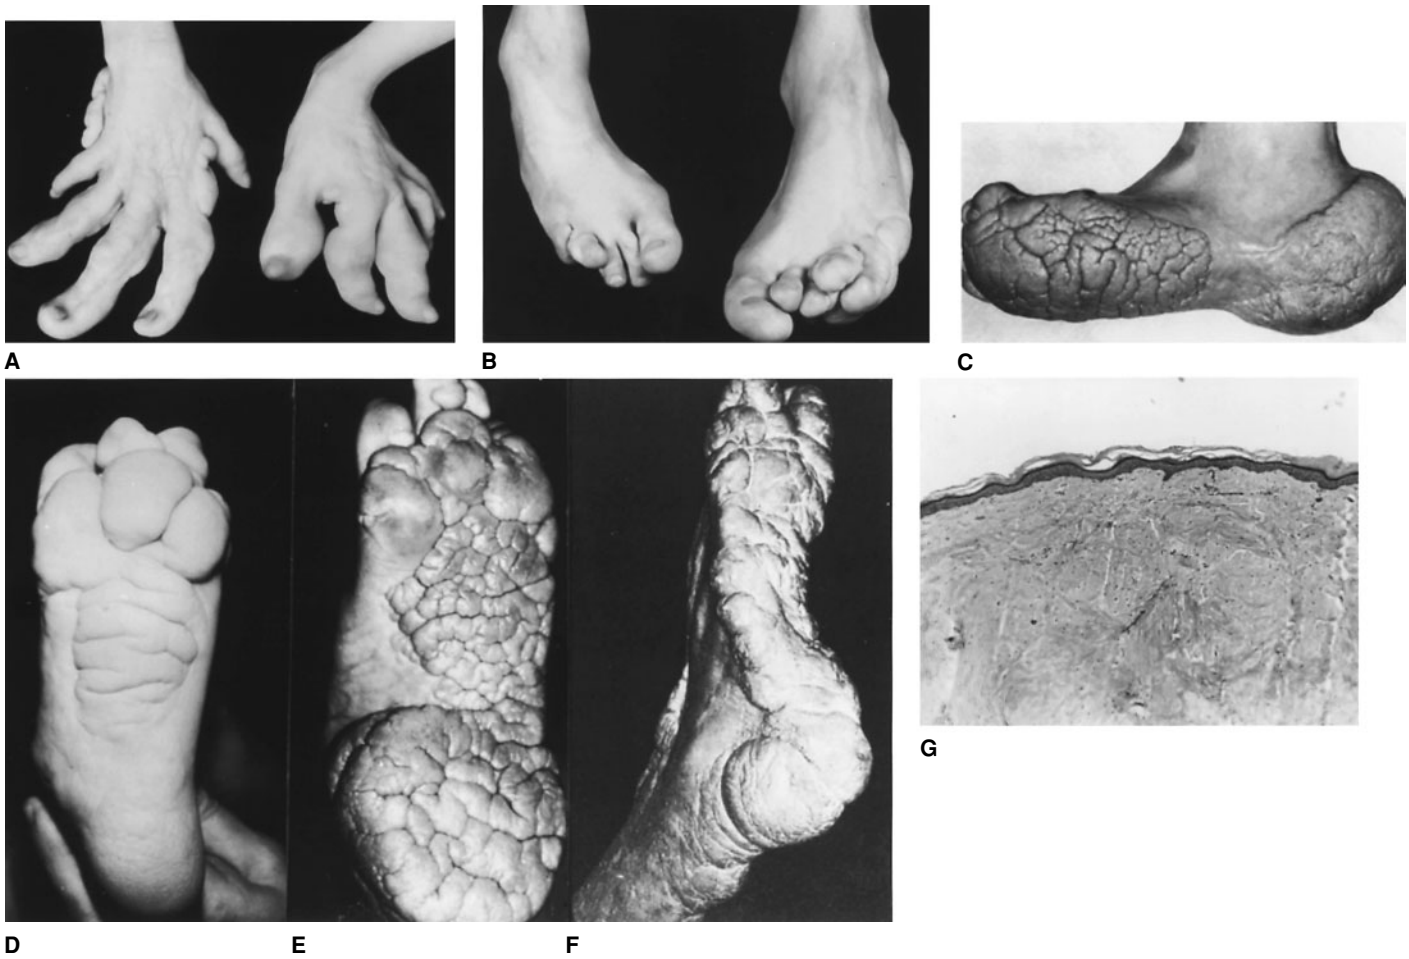

Fig. 12–39. *Proteus syndrome*. (A–F) Enlargement of hands and/or feet associated with gigantic fingers and/or toes, sometimes with fibrous overgrowth. Note "moccasin" lesion in C. (D–F) Evolution of "moccasin" lesion typical of Proteus syndrome. (D) Patient at 5.5 years. (E) Second patient at 13 years. (F) Third patient at 29 years (plaster cast of the Elephant Man's foot). (G) Photomicrograph of fibrous lesion from foot. Note highly collagenized fibrous connective tissue and no evidence of neurofibroma. (A,B courtesy of N O'Doherty, Dublin, Ireland.) F from M Howell and P Ford, The True History of the Elephant Man, Allison and Busby, London, 1980.]

hemihyperplasia/lipomatosis syndrome (3,4,17). Hemihyperplasia with multiple lipomas is a distinct subset of *hemihyperplasia*. Cutaneous capillary malformation may occur in some instances. Mild-to-moderate signs are present at birth. Progressive overgrowth does not occur. Rather, it tends to be commensurate with growth of the child (3,13). Hemifacial hyperplasia with meningeal involvement is still a different disorder (32). Lipomas may occur in *Gardner syndrome* in association with osteomas of the frontal bone, maxilla, or mandible. In *Maffucci syndrome*, the vascular anomalies are commonly venous and occur together with enchondromas. These tumors have not been found in Proteus syndrome (14,43,44). Some patients with striking hyperostoses of the skull and facial bones have been diagnosed as having "Thanos syndrome," a condition that does not exist (15). Isolated plantar cerebriform collagenomas is still debatable (4,40).

A Proteus-like condition has been noted (3,32a), some examples having PTEN mutations (57).

Schimmelpenning syndrome (formerly "epidermal nevus syndrome")

Schimmelpenning syndrome is characterized by sebaceous nevi, together with cerebral, ocular, and skeletal abnormalities (Table 12–12). The epidermal nevus is nonspecific, and Happle (26,27) has shown that there are

Table 12–12. Features of the Schimmelpenning syndrome

Findings	Percent (n = 60)
Cutaneous	100
Epidermal nevi	
Nevus unius lateris	(60)
Ichthyosis hystrix	(20)
Linear nevus sebaceus	(10)
Localized acanthosis nigricans	(20)
Other verrucous or mixed lesions	(33)
Hemangiomas	37
Dermatomegaly	15
Hypopigmentation	10
Café-au-lait spots	10
Many melanocytic nevi	10
Skeletal	70
Kyphosis/scoliosis	28
Ankle and foot deformities	15
Genua valga	5
Hemihypertrophy (hemihyperplasia)[a]	15
Short limbs	10
Finger and toe deformities	10
Cranial and facial bone deformities	15
Bone cysts	3
Vitamin D–resistant rickets	2
Neurologic	50
Mental deficiency	40
Seizures	33
Hemiparesis	14
Cranial nerve involvement[b]	8
Ocular	33
Extension of nevus to lid	19
Lipodermoid	15
Nystagmus	2
Coloboma and cortical blindness	2

[a] Or localized gigantism in some instances. Involves both bone and soft tissue.
[b] VI, VII, and VIII.

A B

Fig. 12–40. *Schimmelpenning syndrome*. (A) Involvement of hair, face, neck, back, buttocks, and legs of a 4.5-year-old child. (B) Hand lesion of patient shown in A. (A,B from B Lieber, Monatsschr Kinderheilkd 137:585, 1979.)

several well-defined conditions with epidermal nevus: Schimmelpenning syndrome, nevus comedonicus, pigmented hairy epidermal nevus, Proteus syndrome, and CHILD syndrome. Nomenclature in the past has been very confusing (1,38,43,63,66) and has been reviewed elsewhere (24). A good early history has been compiled by Hornstein and Knickenberg (29).

The syndrome has been described by Schimmelpenning (57) in 1957, Feuerstein and Mims (19) in 1962, and many others (4,45,50). Over 100 cases have been recorded (14,18,62,72), and both general and specific reviews have been published (10,14,16,22,30,38,40,44,46,48,62,63,66,68). Less certain are patients with incomplete documentation (24,35,37).

All cases are sporadic. The sex ratio is 1:1. The syndrome is likely to be caused by the action of an autosomal dominant lethal mutation that survives by mosaicism (26,27). Supporting the concept of somatic mosaicism are two reports of discordant monozygotic twins (15,58). There is also one affected dizygotic twin (39). Most observed instances of affected or partially affected family members are suspect and are unlikely to represent Schimmelpenning syndrome (4,7,47,62). Deletion of the PTCH gene has been demonstrated in 8 of 20 sebaceous nevi (71).

Cutaneous manifestations. The sebaceous nevus is the hallmark of the syndrome. When the scalp is involved, broad patches may be present. Some cases may be associated with partial alopecia (21,28). Elsewhere, sebaceous nevi always follow the lines of Blaschko (28). Lesions may be of any size (26,27). Histopathologic examination shows hyperplastic sebaceous glands. However, before puberty, organoid differentiation may be minimal or absent in scalp lesions and at any age when the trunk or extremities are involved (26,27) (Figs. 12–40 and 12–41).

Central nervous system. Defects of the central nervous system have been well documented (6,14,17,20,25,31,32,36,43,46,49,56) and the subject has recently been reviewed by Gurecki et al (25). Seizures and moderate to severe developmental delay are common. Other reported findings have included hemimegalencephaly, hemiatrophy, migrational defects, and vascular anomalies. Also noted have been agenesis of the corpus callosum (6,17), central precocious puberty (31,70), and Dandy-Walker malformation (17).

Ocular defects. The most common ocular manifestation is extension of the epidermal nevus to involve the eyelid, eyelid margin, and conjunctiva (Fig. 12–41C). Other abnormalities have included coloboma of the lid and/or iris and retina, epibulbar lipodermoid, corneal opacity and pannus formation, oculomotor dysfunction, nystagmus, optic nerve hypoplasia, and cortical blindness (19,30,32,34,45,49,52,59,64,65,68).

Skeletal abnormalities. Asymmetry of the skull, hypoplastic nasal and orbital bones, and frontal bossing have been observed (50,52,64). Other defects have included incomplete development of various bones, vertebral defects, incomplete formation of the talus, camptodactyly, clinodactyly, brachydactyly, ischial and pubic hypoplasia, incomplete rib formation, abnormal clavicles, shortening of limb bones, kyphoscoliosis, posterior luxation of the ankle, pes equinovarus, and genua valga (39,40,42,52,55,62,63). Vitamin D–resistant rickets has been recorded in a number of patients (2,5,12,23,31,51,60,64,72). Cystic bone changes (giant cell granulomas) have been recorded rarely (8,70) and are problematic (see *Differential diagnosis*).

Oral manifestations. The most extensive review is that of Murakami et al (53). Features may include hemihyperplastic tongue, papillomatous lesions, ameloblastoma, oligodontia, hypoplastic teeth, malformed teeth and odontodysplasia (3a,7,9,11,41,44,45,50,54,61,67,72) (Fig.12–42). Cleft palate (4) and bifid uvula (32) are probably coincidental.

Other findings. A number of other findings have been noted, including coarctation of the aorta, unusual origin of the subclavian artery, PDA, myocardiopathy, horseshoe kidney, chondroblastoma, and intrahepatic cystic biliary adenomas (6,13,45,49,50,62).

Differential diagnosis. Happle (26,27) has shown that epidermal nevi are of various types, which may be found in CHILD syndrome, nevus comedonicus, pigmented hairy epidermal nevus, and *Proteus syndrome* as well as Schimmelpenning syndrome. Happle (26) has also discussed less-well-delineated conditions with epidermal nevi. *Encephalocraniocutaneous lipomatosis* is subsumed under the rubric of Proteus syndrome. In our opinion, much of the early literature has retrospectively merged several entities (62,63). Neoplasms recorded in the syndromes (3,16,38,44,47,48) are also suspect and may have been recorded within a spectrum of overlapping conditions. These neoplasms have been reviewed elsewhere (24).

Cystic lesions of bone reported in Schimmelpenning syndrome are rare and may be coincidental (33). Unilateral polyostotic fibrous dysplasia in

Fig. 12–41. *Schimmelpenning syndrome*. (A) Involvement of face and scalp. (B) Similar involvement in another patient. Corneal vascularization with clouding and blindness. (C) Linear nevus extending from forehead to tip of nose in mentally retarded female with hydrocephaly and seizures, epibulbar dermoid. (D) Similar alterations in other children. (E,F) Ten-year-old male with linear distribution, focal alopecia, hyperpigmented areas. Patient was blind and had epileptiform seizures. (A courtesy of B Pattberg, Berlin, Germany. B from B Leiber, Monatsschr Kinderheilkd 127:585, 1979. C from PM Marden and HD Venters, Am J Dis Child 112:79, 1966. D courtesy of G Sugarman and W Reed, Los Angeles, California. E,F from JE Kelley et al, Oral Surg 34:774, 1972.)

one case (70) is not well documented. Bitter (8) reported a true giant cell tumor of jaw bones, but the histology shows giant cell granuloma. Kaplan et al (33) also noted giant cell granuloma.

Fryburg and Greer (21) noted epidermal nevus with cutis aplasia congenita.

Tuberous sclerosis

In tuberous sclerosis, the classic triad consists of seizures, mental deficiency, and angiofibromas. Bourneville (9,9a), in 1880, gave the first detailed description of the neurologic symptoms and cerebral pathology in three patients and coined the term "tuberous sclerosis." Another paper, coauthored with Brissaud, was published in 1900 (10). However, as early as 1862, Von Recklinghausen (114) described an infant with cardiac myomas and sclerotic lesions of the brain. In 1890, Pringle (84) reported a 25-year-old mildly retarded woman with facial lesions that he called "adenoma sebaceum," a term coined earlier by Balzer and Ménétrier (4). Historical aspects of the disorder have been especially well reviewed by Gomez (33) and Morgan and Wolfort (72). Tuberous sclerosis is also known as Bourneville-Pringle syndrome, epiloia, and adenoma sebaceum syndrome. The last term, so long used, should be abandoned because facial lesions are angiofibromas, not sebaceous adenomas. Several important reviews are available (14,33,46,57,82,87). We especially recommend the comprehensive 1991 review (33) and a discussion of diagnostic criteria (49a,83).

Tuberous sclerosis is characterized by a potential for hamartomatous growth in multiple organs and has a broad range of expression (Table 12–13). The classic triad of seizures, mental retardation, and angiofibromas (Fig. 12–43) represents one end of the spectrum of severity; mild cases can be difficult to detect. Autosomal dominant inheritance with very variable expressivity has been demonstrated (14,31,33,53). About two-thirds of the cases are sporadic (50,77,96). Gonadal mosaicism has been found in 6% (92,93,113,121). Lack of penetrance exists but appears to be relatively uncommon (5,114). There is reduced biologic fitness. Mutations in one of two genes, TSC1 at 9q34 and TSC2 at 16p13.3, cause tuberous sclerosis (3,13,18,24,28,52,83,111,122). Although linkage study suggests that the two forms are of equal frequency (43,52,98), mutational analysis indicates that TSC1 mutations are in the minority and may represent only 15% (1,19a). TSC2 mutations are more severe (4a).

Table 12–13. Diagnostic criteria for tuberous sclerosis

Primary criteria (only one required for diagnosis)	Secondary criteria (two required for diagnosis)
Facial angiofibromas	Infantile spasms
Ungual fibromas	Hypopigmented macules
Cortical tuber (at necropsy)	Shagreen patch
Subependymal hamartomas (at necropsy or on CT)	Single retinal hamartoma
	Bilateral renal angiomyolipomas or cysts
Multiple retinal hamartomas	Cardiac rhabdomyoma
Fibrous plaque on forehead	First-degree relative with a primary diagnosis of tuberous sclerosis

Adapted from MR Gomez, Tuberous Sclerosis, Raven Press, New York, 1979.

C

Fig. 12–43. *Tuberous sclerosis*. (A–C) Characteristic distribution of facial angiofibromas. Compare severity of lesions. Note gingival hyperplasia secondary to diphenylhydantoin therapy in A. Note large fibromatous mass on forehead in C. [A from BE Medley et al, Semin Roentgenol 11:35, 1976. B from R Goodman and RJ Gorlin, The Face in Genetic Disease, Mosby, St. Louis, 1970. C from MM Cohen Jr in Orofacial Genetics, Stewart RE, Prescott GH (eds), Mosby, St. Louis, 1976.]

Mosaicism is a potential cause of failure of molecular diagnosis (56,113). Loss of heterozygosity has been demonstrated in hamartomas from both TSC1- and TSC2-related patients, indicating that they are both tumor suppressor genes (35,36,42,104). There is no solid evidence that the phenotype is significantly different in TSC1 and TSC2 patients (83) (vide infra). Hamartin is the product of the TSC1 gene (50), while tuberin is the product of the TSC2 gene (43,111). The TSC2 gene has a small region of homology to the GTPase activating protein GAP3.

Jones et al (50) and Young et al (122), however, suggested that mutations are less common among sporadic cases and mental retardation less frequent in TSC1 cases. Kwiatkowska et al (55) noted that mutations are found in only 15%–20% of spontaneous TSC1 examples. In both TSC1 and TSC2 cases, the mutations lead to premature truncation of the respective proteins. There is no genotype–phenotype correlation in TSC1 cases (112).

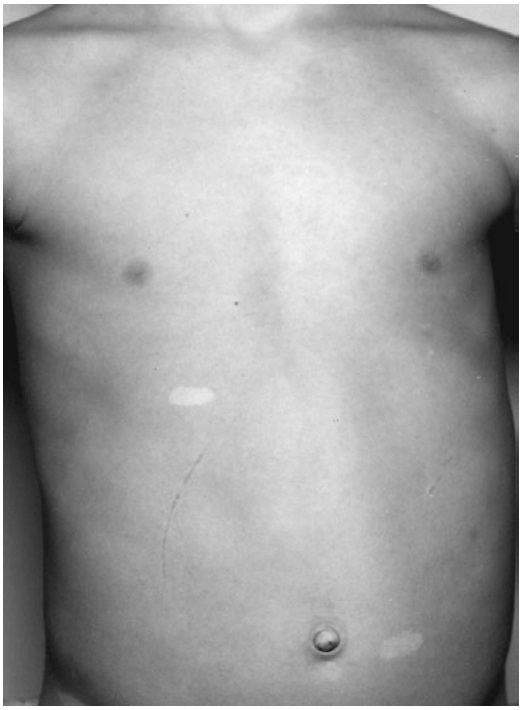

Fig. 12–44. *Tuberous sclerosis*. Note hypomelanotic macules. (Courtesy of MR Gomez, Rochester, Minnesota.)

Incidence is 1 in 6000 births (47,77,96). Published estimates of the prevalence of clinically ascertained tuberous sclerosis in institutions for the mentally retarded range from 0.32% to 1.1% (33). Surveys of autopsy data indicate a frequency of approximately 2.5%–2.8% (33).

The studies of Cassidy et al (14) and Gomez (33) clearly show that minimal diagnostic criteria for tuberous sclerosis can be used only if family members at risk are thoroughly evaluated. Detailed skin examination was the most sensitive diagnostic test (96%). However, as skin findings may not be present in infancy and early childhood, other tests can be useful, including cranial CT (67%), funduscopic examination through dilated pupils (33%), and renal ultrasound (50%–70%) (14). Using such criteria, Gomez (33) has listed the findings for primary and secondary diagnosis of tuberous sclerosis (Table 12–7). All manifestations are, however, age dependent. The reader is also referred to official diagnostic criteria (83).

Skin. Hypomelanotic macules are the earliest and one of the more commonly (65%) observed skin lesions (Fig. 12–44). They are often present at birth, but sometimes they can be observed only with a Wood's lamp. Most hypomelanotic muscles are leaf-shaped or round on one end and tapered on the other. Forty percent have 5 or more lesions (118). In about 20%, depigmented hair patches are found. They may be the first sign of the disorder (65). Confetti-like hypopigmentation of the lower legs (10%–20%) and multiple acrochordons of the neck were noted in a family that did not map to TSC1 (120).

Symmetric facial angiofibromas occur in 70%–85%. They are pink or reddish with a smooth glistening surface. They tend to be limited to the nasolabial folds, cheeks (butterfly distribution), perioral area, and, less often, the forehead and scalp. The upper lip, except for the area beneath the nose, is usually spared. They are rarely present at birth but typically appear during ages 5–10 years and progress during adolescence, and may occur as late as 25 years (73). Rarely, the facial angiofibromas are segmental, presumably representing postzygotic mutation (2,64).

Other findings include raised leathery plaques in the lumbosacral area or rarely on the chest wall (shagreen patches) (6) (35%–55%), periungual or subungual fibromas (Fig. 12–45), usually appearing at

Fig. 12–45. *Tuberous sclerosis*. Subungual fibromas. (Courtesy of A Lodin, Stockholm, Sweden.)

puberty; and pedunculated cutaneous nodules or skin tags (molluscum fibrosum pendulum) (14%) (26,33,49,91,118). The subungual fibromata increase in frequency with age. They are seen in almost 90% of those older than 30 years. Fryer et al (29) has discussed forehead plaque as a presenting sign in tuberous sclerosis. When present, they are smooth patches of slightly raised skin with a reddish or yellowish discoloration.

Performance and central nervous system. Brain MRI is most sensitive for tubers, but brain CT is better for ascertaining calcium-containing subependymal giant cell astrocytomas. Hamartomatous calcification, if not present at birth, may develop as early as 5 months of age and progress throughout infancy and childhood. Hamartomatous foci consist of subependymal nodules and cerebral or, far less often, cerebellar cortical tubers (Fig. 12–46A). Olfactory nodules can also be seen (23).

Seizures occur in about 80%–90%. Approximately 30% have focal seizures, and 15% have both generalized and partial seizures. The frequency of various types of seizures are as follows: tonic–clonic seizures (41%), infantile spasms (30%), myoclonic seizures (16%), atypical absence (7%), tonic seizures (6%), and akinetic seizures (4%). Partial seizures break down as follows: motor seizures (16%), complex symptoms (10%), and unknown types (2%) (32,46,69,78,117).

Approximately 40% have mental deficiency (117). A close correlation has been established between seizures and mental retardation, 89% of all individuals having seizures being mentally subnormal. In addition, the age of seizure onset and the severity of mental subnormality are directly related (32). Fryer et al (30) reported an affected family through five generations with no history of seizures or mental retardation.

Approximately 56% have intracranial calcifications (Fig. 12–47A,B) (69). Most occur in the cerebrum, 63% of lesions being bilateral, the remaining 37% being unilateral. Cerebellar calcifications occur in approximately 12%. The calcification is progressive: in children below 1 year 15%, below 5 years 35%, but by 14 years 50%–60% (69).

Increased intracranial pressure caused by tumor obstruction of cerebral spinal fluid circulation occurs infrequently, and less than 4% of patients have separated cranial sutures. Midventricular dilatation occurs in about 50% (69,80). Space occupying lesions, usually subependymal giant cell astrocytomas, cause obstruction of the foramen of Monro in 10%–20% (69). Convincing examples of other types of central nervous system tumors are extremely rare (12,85).

Childhood autism (25%–40%) may be related to temporal lobe tubers. Dementia in adults is almost always associated with the presence of seizures or growth of a tumor, which frequently causes obstruction with increased intracranial pressure (32,48).

Skeletal system. Approximately 65% have cystlike areas in the phalanges and irregular periosteal new bone formation along the shafts of the metacarpals and metatarsals (Fig. 12–47C). Less frequently, the long bones are involved (86,101). Gigantism of a single digit of the hand has been reported on several occasions (16,54,59,76,90a,105,108a).

Ocular findings. Retinal hamartomas are found in approximately 50%. Two basic types of retinal lesions occur. The most common type is smooth, semitransparent, relatively flat, circular, or oval-shaped with distinct boundaries, being grayish or yellowish in color and being found in 55% of patients with retinal lesions. The opaque and nodular type occurs in approximately 45% of patients with retinal hamartomas. The lesions are elevated and multinodular, resembling the grains of tapioca, salmon eggs, or mulberries. They frequently occur along the disc margin or halfway toward the periphery of the retina. Some patients have retinal hamartomas with the morphologic characteristics of both types. This accounts for 15% of patients with hamartomas (90).

Renal abnormalities. Renal abnormalities, seen in 60%, are angiomyolipomas (Fig. 12–46B) (19,89) and, less commonly, polycystic kidneys (89,119). The multiple renal cysts, seen in 2%–3%, apparently represent a contiguous gene syndrome on 16p13.3 that involves the PKD1 gene. These lead to renal failure (100). Approximately 50%–65% of autopsied cases have angiomyolipomas (19,110). These are multiple (90%), bilateral (85%), and appear earlier in life than the isolated tumor (19). Their prevalence increases with age (75). They are seldom troublesome, although exceptions have been noted (25,33,39,63,70a,71,89). Renal angiomyolipoma by itself is a major diagnostic criterion for tuberous sclerosis (110). Renal cell carcinoma has been documented in 2% of patients (7,19). They can be multiple and bilateral, but more commonly are unilateral, and have been reported in TSC1 cases (99).

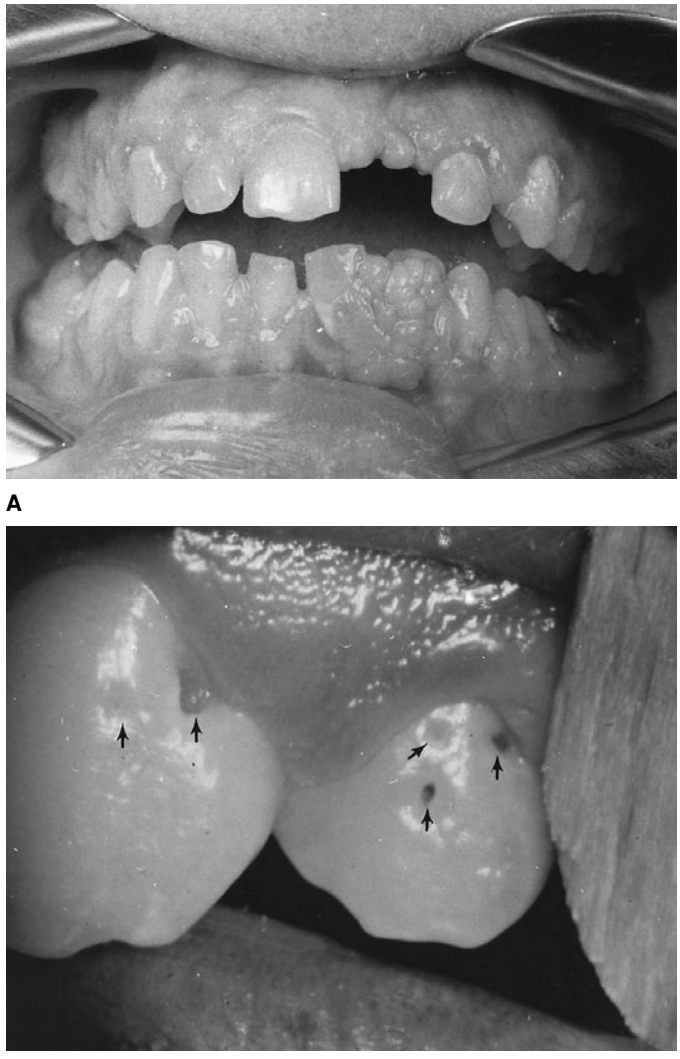
Histologically disturbing changes occur in the spindled smooth muscle cells that form disorganized sheets, sinuous bands, or small clusters between the fat cells and frequently spread centrifugally from vessel walls. The frequent findings of hyperchromatic nuclei, pleomorphism, and occasional mitotic activity are atypical histologic features, but should not be taken as evidence of malignancy (43,89). An instance of Wilms tumor has been recorded (36).

Cardiac manifestations. Approximately 30% have cardiac rhabdomyomas, and about 50% of patients with cardiac rhabdomyomas have tuberous sclerosis (40,116). Most rhabdomyomas occur intramurally, and only a small percentage represent intracavitary tumors. Cardiac signs and symptoms occur on the basis of obstruction of blood flow, myocardial involvement with secondary deterioration of ventricular function, or disturbance of cardiac rhythm. Wolff-Parkinson-White syndrome was found in 20% (8,70,74). Most lesions are multiple rather than single, and their most frequent occurrence in infants suggests that the entity is a hamartoma rather than a neoplasm (20,33,62). They tend to regress with age (106).

Other findings. Cystic disease of the lungs, pulmonary lymphangiomyomatosis (honeycomb lung), occurs almost exclusively in females (11F:1M), presenting in the third decade (58,69). There is good evidence that this is caused by novel TSC2 mutations (107,123). Conversely, about 5% of women with tuberous sclerosis exhibit pulmonary lymphangioleiomyomatosis (2a). Hemangiomas of the spleen and angiomyolipomas of the liver occur in 50%, usually as small (1–2 cm) lesions. Hamartomas have also been noted in the thyroid, pancreas, and testes (17,22,33). Rectal polyposis has been found in 1 of 15 patients (34). Various endocrinopathies have been recorded (101), including precocious puberty.

Oral manifestations. The oral mucosa may be the site of nodular fibrous growths (Fig. 12–48A). Approximately 35%–45% of patients have such lesions (118). Most frequently they occur on the anterior gingiva but may be found on the oral cheek or lingual mucosa (61,79,104). Enamel pits (Fig. 12–48B) have been observed (44,110). In some series, the frequency has been very high—from 50% (27,60,97) to 100% (68). The deciduous teeth are similarly involved (95). Calcifying epithelial odontogenic fibroma (94) and, especially, intraosseous fibrous lesions of the jaws have been documented (21,67,108,119).

Differential diagnosis. Most frequently mistaken for facial angiofibromas are multiple trichoepitheliomas, syringocystadenomas, colloid milia, atypical xanthomas, or, occasionally, intradermal nevi.



A

B

Fig. 12–48. *Tuberous sclerosis*. Oral lesions. (A) Gingival fibromas. (B) Pit-shaped enamel defects. (B from Vikilzadeh and R Happle, Hautarzt 31:336, 1980.)

Radiographic differential diagnosis of the skull should include *Sturge-Weber angiomatosis*, calcifying subdural hematoma and calcifying neoplasms, cytomegalic inclusion disease, toxoplasmosis, rubella, HTLV III intrauterine infections, and *hyalinosis cutis et mucosae*. Long-bone changes in tuberous sclerosis should be differentiated from those of *neurofibromatosis*, fibrous dysplasia, enchondromatosis, gout, sarcoid, and hypertrophic arthritis. Shagreen patches may also be seen in association with osteopoikilosis and *Proteus syndrome*. Rarely, *Klippel-Trenaunay* syndrome has been observed with tuberous sclerosis (33,109).

Laboratory aids. Laboratory aids include Wood's lamp examination of the skin, cranial CT and MRI, renal ultrasound, and radiographs of the hands, feet, and skull (69,102). Cardiac ultrasound is sensitive in children less than 2 years but is not helpful in adults. Imaging studies are positive in over 90%, CT being more useful for detection of subependymal nodules and MRI being more accurate for the number and location of cortical subcortical lesions (11,66). Funduscopic examination through dilated pupils, preferably with fluorescein angiography, is essential. Disclosing solution can be used to demonstrate enamel pits. All parents of patients with tuberous sclerosis should be thoroughly examined before recurrence risk counseling is given.

Prenatal diagnosis has been accomplished through detection of cardiac rhabdomyoma by ultrasound and echocardiography (3a,15,51,81).

Mutational testing is difficult, expensive, and not commercially available. There are over 400 mutations in TSC1 and TSC2 genes found to date, with a wide spectrum of types throughout both genes.

Chapter 13
Syndromes Affecting the Skin and Mucosa

Aplasia cutis congenita

Aplasia cutis congenita is the localized or widespread absence of skin at birth. First described by Cordon in 1767 (17), the defect became more widely known with Campbell's report (14), in 1826, of two sibs with involvement of the scalp vertex. Over 550 cases have been reported to date. Clinical associations, classification, and etiology have been discussed in several noteworthy reviews (21,22,27,31,33,65,104,105,108).

Lesions are commonly present as ulcerated or membranous defects of variable size near the midline of the scalp vertex (Figs. 13–1 and 13–2). Small lesions are usually located at or in proximity to the parietal hair whorl (109). Absent hair is a constant feature. The defect is single in most cases (75%), but double, triple, or multiple vertex defects may occur (23). Although most single defects (66%) are oval-shaped and small (0.5–3 cm), more extensive defects over 10 cm in diameter have been reported (21). Defects may involve the epidermis only or may extend to full skin thickness. Osseous involvement of the calvaria, found in 20%–30%, is detected radiographically by demonstrating an area of bone deficiency underlying the cutaneous defect (21).

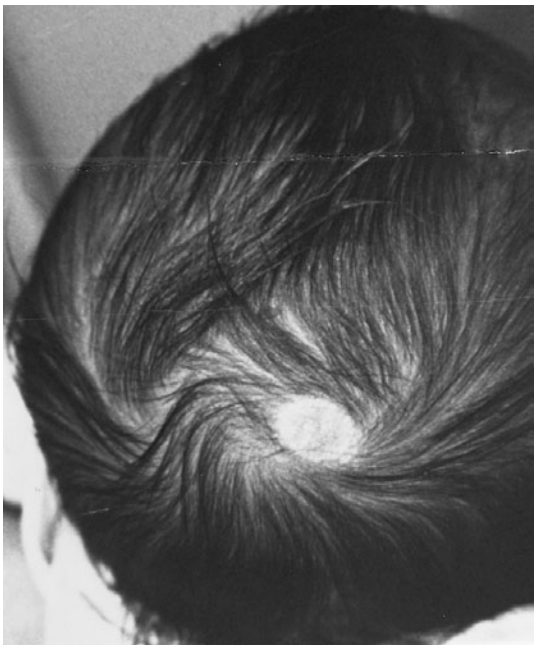
Small, superficial midline defects tend to heal gradually without complications during the initial week after birth, leaving a residual atrophic or hypertrophic scar with alopecia. Healing of a calvarial defect is generally complete during the first year of life (21). Extensive scalp defects, which may extend to involve the dura (21,65), pose a significant risk for infection, potential meningitis, venous thrombosis (67), and sagittal sinus hemorrhage (9,14,21,39,97).

A male newborn has been reported with congenital symmetrical abdominal skin defects and alopecia of the scalp in a spiral pattern. The distribution of both skin anomalies was reminiscent of the lines of Blaschko, suggesting somatic mosaicism as a possible cause for the defects (46).

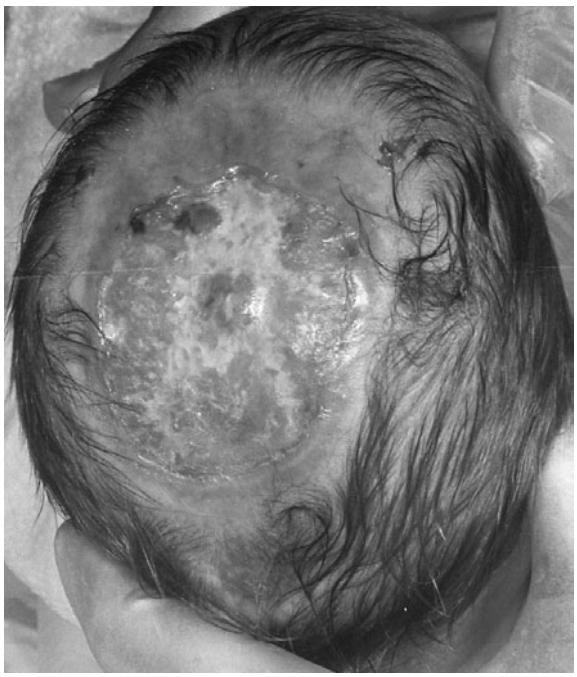
Although most cases are sporadic, many familial instances have been recorded. Autosomal dominant inheritance with incomplete penetrance and variable expressivity occurs most frequently (35,79,93,108,122), but autosomal recessive inheritance is implicated occasionally, usually in offspring of consanguineous parents (41,79). Concordant monozygotic (50) and discordant monozygotic (124) twins have been documented. Aplasia cutis congenita involving the trunk and/or limbs is etiologically heterogeneous, and familial examples have been noted in some instances (32,94) (Fig. 13–2).

Aplasia cutis congenita is a feature of many syndromes and also occurs on a disruptive (71,73,104), infectious (3,103,107,109), and teratogenic basis. Association with many isolated malformations has been documented as well (27). Der Kaloustian et al (23) have reported on 2 families having members affected with the Poland sequence and the aplasia cutis congenita of Adams-Oliver syndrome. Conditions associated with aplasia cutis congenita are summarized in Table 13–1. Those not involving the head, neck, or scalp are excluded from this table (27).

Fig. 13–1. *Aplasia cutis congenita*. (A) Healed oval lesion of aplasia cutis congenita at site of parietal hair whorl. (B) Extensive ulcerative lesion in trisomy 13 syndrome. (A from MJ Stephan et al, J Pediatr 101: 850, 1982.)



A



B

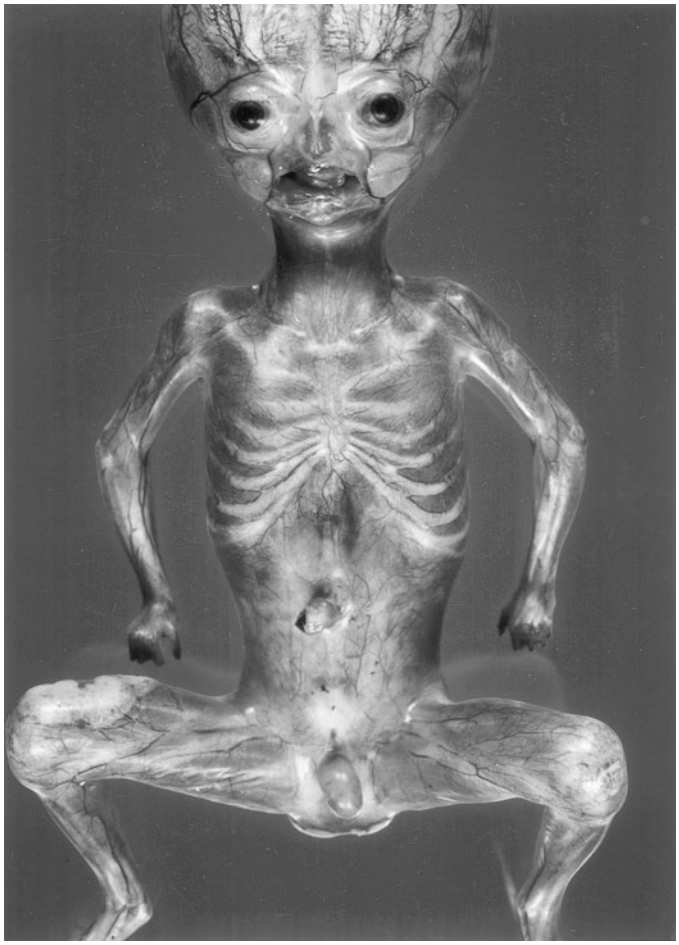


Fig. 13–2. *Aplasia cutis congenita*. Extensive form. (From MS Park et al, J Med Genet 35:609, 1998.)

Differential diagnosis. Congenital scalp defects should be considered separately from aplasia cutis congenita involving the trunk and extremities. Differential diagnosis includes localized scalp infection, congenital dermoid cyst, small meningocele, heterotopic brain or glial tissue (54,83), and traumatic lesions secondary to fetal scalp monitoring (11). As the child grows and scarring of the cutis aplasia lesions occurs, sebaceous nevus, and alopecia of pseudopelade type may be confused with it. Particular care must be taken to distinguish linear or stellate lesions of aplasia cutis congenita from linear alopecia seen in "en coup de sabre" morphea.

Isolation of herpes simplex type 2 virus has been reported from a newborn with three occipitoparietal ulcerated scalp defects, with serologic confirmation of elevated antiherpes complex IgM (109). These lesions healed spontaneously with local scarring.

For extensive aplasia cutis congenita involving the trunk and extremities, it is important to exclude various types of *epidermolysis bullosa* (5,6,33,123). Clinically helpful clues of epidermolysis bullosa include frequent oral mucosal involvement and development of further lesions after birth. If doubt remains, ultrastructural examination of a skin biopsy from the margin of a lesion will distinguish epidermolysis bullosa and define the genetic type. We have kept in our classification the condition described by Jones et al (58) since epidermolysis bullosa is only one manifestation of a syndrome comprising aplasia cutis congenita, cleft palate, and ectrodactyly. Nonfamilial truncal and extremity aplasia cutis congenita have sometimes been attributed to thromboplastic emboli derived from a fetus papyraceous resulting from death of a co-twin early in the second trimester of pregnancy (76,78). In other cases, when no fetus papyraceous is discovered, the emboli may originate from the placenta itself (73). *Restrictive dermopathy* should also be excluded.

There is insufficient evidence either to establish or eliminate a direct causal relationship between fetal aplasia cutis congenita and the use of methimazole in cases of pregnancies complicated by maternal hyperthyroidism (118). However, since propylthiouracil is an equally effective antithyroid agent and has not been associated with aplasia cutis congenita, it should be the preferred thioamide for the treatment of hyperthyroidism during pregnancy (75).

Laboratory aids. Histologic sections from a skin biopsy will confirm the diagnosis in uncertain cases. The defective area is devoid of elastic fibers, dermal papillae, and normal blood vessels. No well-demarcated border between normal skin and aplasia cutis congenita is observed; rather, there exists an intermediate zone of skin within which dermal appendages such as hair papillae, sebaceous glands, and sweat glands are found to be small to rudimentary and to decrease in size and number centripetally with gradual transition from normal skin to the ulcer of aplasia cutis (120). Aplasia cutis congenita may also be a rare cause of elevated amniotic fluid alpha-fetoprotein levels, and a distinct acetylcholinesterase electrophoretic band (24,37).

Delleman syndrome (oculo-cerebro-cutaneous syndrome)	20
Ectodermal dysplasias (various types of tricho-odonto-onychial subgroup)	88,112,113
Ectrodactyly, ectodermal dysplasia, cleft lip/palate, scalp defects	59
Schimmelpenning syndrome	34,68
Extensive aplasia cutis congenita	86
Facial dysplasia, myopia, delayed dentition, short stature	106
High myopia and cone–rod dysfunction	38
Hypoplastic midface, broad nasal bridge, prefrontal lipoma, epicanthus, ectodermal dysplasia	36,67,70
Limb anomalies and tetralogy of Fallot	74
Megalocornea, scoliosis, short stature	92
Multiple hamartomas, giant pigmented nevocellular nevus, and central nervous system malformation	81
Oculo-ectodermal syndrome	26,36,111
Ridged metopic sutures, depressed nasal bridge, upward-slanting eyes, cleft lip and palate, low-set ears, short neck, dextrocardia, hydrocele, talipes equinovarus	100
Sakati syndrome	16
Spear-Mickle syndrome	16,102
Vertebral and eye anomalies, short stature (VECS)	90
II. Systemic distribution of associated findings	
A. Central nervous system	
Congenital midline porencephaly	125
Craniospinal rachischisis	42
Early telencephalic defects	30
Holoprosencephaly	65–67
Hydranencephaly	30
Hydrocephaly	14,53
Leptomeningeal angiomatosis and aneurysm of distal posterior cerebral artery	91
Meningocele	53
Occult spinal dysraphism	48
Spastic paralysis and mental retardation	95
Tethered cord	87
B. Cardiovascular system	
Arteriovenous malformation	101,116
Coarctation of the aorta	18
Congenital heart defects	19
Patent ductus arteriosus	19
Valvular heart disease	82
Ventricular septal defect/ pulmonary stenosis	85
C. Gastrointestinal system	
Cleft lip–palate	53,65
Intestinal lymphangiectasia	9
Omphalocele	117
Tracheoesophageal fistula	19
D. Ophthalmological system	
Atrophic alopecia, ocular defects and scarring tendency of skin	72
High myopia and cone–rod dysfunction	38
Knobloch-Layer syndrome	63,98,99
Oculo-ectodermal syndrome	26,36,111
E. Miscellaneous	
Closure defects of ventral body wall and/or neural tube	51
Cutis marmorata	119
Extensive aplasia cutis congenita	86
Piebaldism	12

Aplasia cutis congenita, ear malformations, facial paresis, and dermal sinuses (Scalp-Ear-Nipple syndrome, Finlay-Marks syndrome)

In 1979, Anderson et al (2) reported a Mexican-American family in which four generations were affected with aplasia cutis congenita of the scalp, ear defects (uni- or bilateral lop ear, conductive and possibly mixed hearing loss), dermal sinuses (both pretragal and parasternal), and unilateral facial palsy. Hypoplastic facial canals were verified by tomography in those with facial palsy. Finlay and Marks (4) and other authors (1,3–9) reported somewhat similarly involved families with the SEN syndrome, an autosomal dominant disorder of *S*calp defects (aplasia cutis congenita), *E*ar abnormalities (small or rudimentary tragus, antitragus, and lobule), and rudimentary or absent *N*ipples (Fig. 13–3). Turnpenny (personal communication, 2000) suggested anticipation.

Differential diagnosis would include *branchio-oto-renal syndrome*. Approximately 30 cases have been described. Aplasia cutis congenita of the scalp has been an almost constant feature as has dysplastic pinnae. Hypoplasia of the nipples was noted in about 60%. Scanty hair has been reported in 35% and hypohidrosis in about 50% of those tested. Nail dysplasia is seen in 40% and variable tooth anomalies in 75%. Cutaneous syndactyly and/or campotdactyly have been observed in 75%.

Aplasia cutis congenita with epibulbar dermoids (oculo-ectodermal syndrome)

In 1993, Toriello et al (9) reported two unrelated boys with aplasia cutis congenita, epibulbar dermoids, and cutaneous hyperpigmentation (Figs. 13–4 and 13–5). Later, Gardner and Viljoen (5) and Evers et al (3) described similar cases in girls. Strabismus and epicanthal folds may also be part of this condition, but hyperpigmentation of the skin has not been described in the last two reports. The genetic basis of the condition is uncertain.

Differential diagnosis includes *oculocerebrocutaneous (Delleman) syndrome*, which presents with orbital cysts, cerebral malformations, dermal defects, skin appendages, skeletal defects and mental retardation (1). Another condition to consider is mild *Proteus syndrome*, which includes areas of scalp alopecia, ocular choristomas, seizures, lipomas, connective tissue nevi, mental retardation, and cerebral malformations (8). Finally Chaurasia and Goswami (2) in 1971, Frieden (4) in 1986, Lering et al (7) in 1988, and Lees et al (6) in 2000, described patients with scalp, skin, and eye anomalies that are distinct from the presentation of aplasia cutis congenita with epibulbar dermoids (9).

Aplasia cutis congenita, high myopia, and cone-rod dysfunction

In 1996, Gershoni-Baruch and Leibo (1) reported a brother and sister, born to consanguineous parents with congenital nystagmus, cone–rod dysfunction, high myopia, and aplasia cutis congenita on the midline of the scalp vertex.

This condition is distinct from other forms of cone and rod dysfunction (2). Leung et al (3), in 1988, described two sibs with aplasia cutis congenita of the scalp associated with ocular defects such as myopia, keratoconus, nystagmus, atrophic irides, and atrophic pigment epithelium. The critical difference from the condition described by Gershoni-Baruch and Leibo (1) is their particular tendency to develop permanent atrophic linear or macular scars following minor trauma to the forearms, hands, and lower legs.

Vertebral and eye anomalies, cutis aplasia congenita, and short stature (VECS)

Prasad et al (1), in 1998, described a six-year-old female with short stature, prominent eyes due to megalocorneae, pointed chin, cutis aplasia of the scalp, nasal lacrimal duct obstruction, sagittal craniosynostosis, and kyphoscoliosis with multiple segmentation defects of the thoracic vertebrae, and eleven pair of ribs.

Ascher syndrome

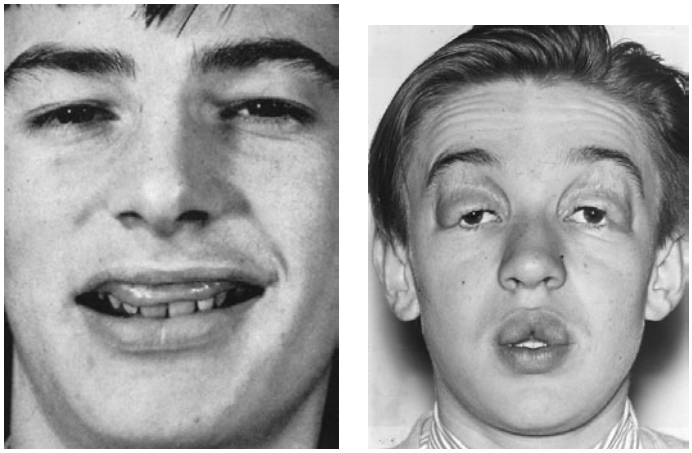
In 1920 and 1922, Ascher (1,2) brought to the attention of ophthalmologists the syndrome of blepharochalasis, double lip, and nontoxic thyroid enlargement, although the combination of blepharochalasis and double lip was described in 1909 by Laffer (17). Subsequently, additional examples of the complete syndrome were reported (8,9,13–15,20,22). Examination of other reports (3–7,10–12,18–21,23–31) indicates that blepharochalasis may occur as an isolated abnormality, as may double lip. Blepharochalasis was described as an isolated finding as early as the nineteenth century (12). In Ascher syndrome, autosomal dominant transmission has been suggested (3,11,21,27), many sporadic cases apparently representing fresh mutations. We are aware of blepharochalasis and double lip that was shown to be Ehlers-Danlos syndrome type VII.

Eyes. Sagging eyelids are striking. The upper lids and less commonly the lower lids are characterized by relaxation of the tarsal fold, which allows the tissue between the eyebrow and the edge of the lid to hang slack over the palpebral fissure. The lid skin is markedly thin and atrophic. Atrophy and drooping of the lid often follow repeated angioneurotic edema-like episodes. In several cases, swelling of the lids has appeared during the first 8 years of life. In others, its occurrence was noted at about the time of puberty (16,25). The swelling of the lids and the enlargement of the lips may occur simultaneously (8,22) (Figs. 13–6 to 13–8). Double lip has been reported in association with cheilitis glandularis (6).

Gross surgical examination of tissue removed from the relaxed skin of the lid has shown prolapsed orbital fat or, more frequently, hyperplastic lacrimal gland tissue. The lids, on microscopic examination, have exhibited an increased number of blood vessels, but no unanimity of opinion exists about changes in the elastic fibers (20).

Lips. The lip, almost always the upper, is the site of a horizontally running duplication located between the inner (pars villosa) and outer (pars glabrosa) parts of the lip (20). The fold cannot be seen when the lips are closed, but only when the patient is smiling or talking. The enlargement of the lip may exist from childhood (3,5,11). Rarely, the lower lip is also enlarged (7,11) (Figs. 13–6 to 13–8).

Microscopic examination of the excessive labial tissue usually reveals loose areolar tissue and hyperplastic mucous glands, numerous blood-filled capillaries, and infiltration with plasma cells and lymphocytes (3,5,7,10,15).



A B

Fig. 13–6. *Ascher syndrome*. (A) Note transverse crease with "doubling" of upper lip and sagging of lateral portion of upper eyelids. (B) Patient with appearance similar to that of patient in A. (A from MC Oldfield, Br J Surg 47:58, 1959. B from K Stehr, Dtsch Med Wochenschr 87:1148, 1962.)

Thyroid. Thyroid gland enlargement is variable and not usually associated with toxic symptoms. Barnett et al (3), however, reported a patient with hypothyroidism and myxedema. Enlargement may appear several years after eyelid involvement (2), but usually appears during the second decade. It may be evident only on scanning with radioactive iodine (22).

Differential diagnosis. Blepharochalasis and double lip may each occur as isolated anomalies. Most instances of so-called double lower lip are actually lip sinuses of the transverse furrow type (23). Floppy eyelid syndrome, the combination of blepharochalasis and chronic papillary conjunctivitis, has been discussed by Goldberg et al (12). The *Melkersson-Rosenthal syndrome* (cheilitis glandularis, facial paralysis, and fissured tongue) and vascular neoplasms (hemangioma, lymphangioma) should be considered. The syndrome of *acromegaloid features and thickened oral mucosa* should be excluded as well as *dermatosparaxis* (EDS VIIC).

Acromegaloid features and thickened oral mucosa (Hughes syndrome)

Hughes et al (4) described a four-generation kindred in which 13 individuals were affected with a progressively coarse acromegaloid facial appearance and thickening of the lips and oral mucosa. Inheritance is autosomal dominant.

The most striking features are thickened lips without true doubling, overgrowth of the oral mucosa resulting in exaggerated rugae and frenula, and thickened upper eyelids leading to narrow palpebral fissures. Both facial appearance and large doughy hands remind the observer of acromegaly (3) (Figs. 13–9 and 13–10).

In 1992, Dallapiccola et al (1) reported a family with the same disorder affecting a mother and 4 children. Another example was described by DaSilva et al (2).

In differential diagnosis *pachydermoperiostosis, Ascher syndrome*, and *multiple mucosal neuroma syndrome* should be excluded. In Hughes syndrome, the skin was not furrowed. The nose becomes rather significantly bulbous, far more than that seen in pachydermoperiostosis. Although the oral mucosa becomes thickened in Ascher syndrome, it is not to the degree found in Hughes syndrome and, although the hand joints are hyperextensible (Fig. 13–10), there is no clubbing as there is in pachydermoperiostosis.

A

B

Fig. 13–8. *Ascher syndrome*. (A,B) Compare similar alterations in older patients (A courtesy of AF Morgan, Seattle, Washington.)

It is important not to confuse this condition with another Hughes syndrome [thrombosis, thrombocytopenia, and recurrent spontaneous abortions associated with antiphospholipid antibodies (3)].

Cutis laxa syndromes

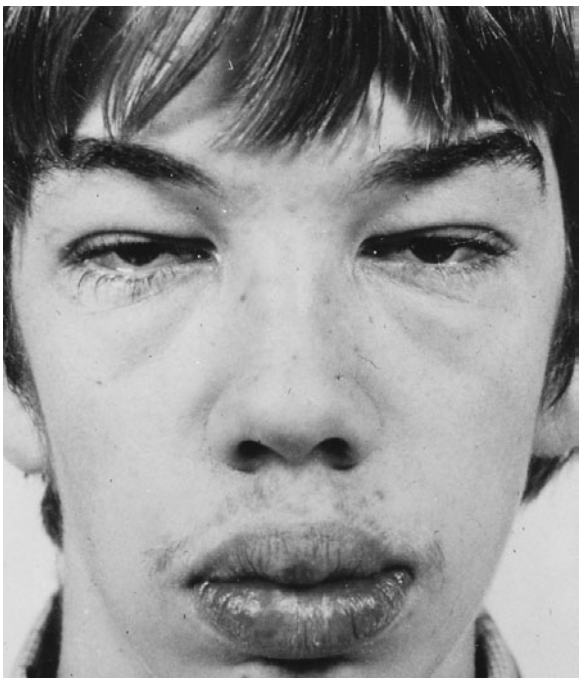
Cutis laxa (CL) is characterized by skin that hangs in loose folds. There are many forms, some genetic and others acquired. Confusion existed in the early literature, since the various Ehlers-Danlos syndromes (EDS) also had that designation. Although the term *cutis laxa* was used as early as 1833 by Alibert (2), the generalized form was probably first described by Graf (36) in 1836.

The term *cutis laxa* indicates loose, lax, droopy skin. It may be present at birth or may appear at different stages of growth and development. This physical finding is associated with a heterogeneous group of conditions. Thus, we have divided the conditions in which the skin is the most striking and important finding into groups according to the three patterns of inheritance: autosomal recessive, autosomal dominant, and X-linked. In doing this, we have discussed separately several well-defined syndromes (e.g., *De Barsy, Costello, SCARF, gerodermia osteodysplasticum, Bamatter, Ehlers-Danlos*), where other findings are as or more striking than the associated cutis laxa. The acquired forms of *cutis laxa* are mentioned under "Differential diagnosis."

Autosomal recessive form. In the most common of these forms, birth weight is normal but often there is mild postnatal growth deficiency. Most of these children die by the third year of life. Affected sibs (35,71,72,97,107) and parental consanguinity (1,25,50,61,72,96,112)

Fig. 13–9. *Acromegaloid features and thickened oral mucosa*. (A) Thickened lips, fullness of upper eyelids leading to narrowed palpebral fissures. (B) Similar coarse features and bulbous nose. (A courtesy of HE Hughes, Cardiff, Wales. B from HE Hughes et al, J Med Genet 22:119, 1985.)

A



B

indicate autosomal recessive inheritance. The defect appears to be in lysyl oxidase which maps to 5q23.3–q31.2 (40,55). We believe that the syndrome reported by Dallaire et al (18) does not represent a separate disorder as they suggest.

Facies and skin. Due to accentuation of skin folds, the infant appears aged. The upper lip is long and the columella is short. Blepharochalasis and, at times, ectropion add to the aged appearance (35,38,94). The skin of the entire body appears too large. There is no hyperelasticity, fragility, or difficulty in healing (Fig. 13–11).

Cardiorespiratory. Tachypnea, pneumonitis, and airway obstruction associated with emphysema are common features. This results in severe hypoxemia, respiratory failure, cor pulmonale, and right ventricular

Fig. 13–11. *Cutis laxa, recessive type*. Affected sibs look much older than their chronologic ages of 5 and 6 years. (Courtesy of FA Balboni, Garden City, New York.)

Fig. 13–12. *Cutis laxa, recessive type*. Multiple herniae of bladder.

enlargement. These findings, together with diaphragmatic hernia, lead to early demise (35,38,94,97). The emphysema results from generalized elastolysis. Bundle branch block (35), pulmonary artery stenosis (72,112), and dilated and tortuous carotid, vertebral, and pulmonary arteries, and dilated aortic root (35,109,112) have been noted.

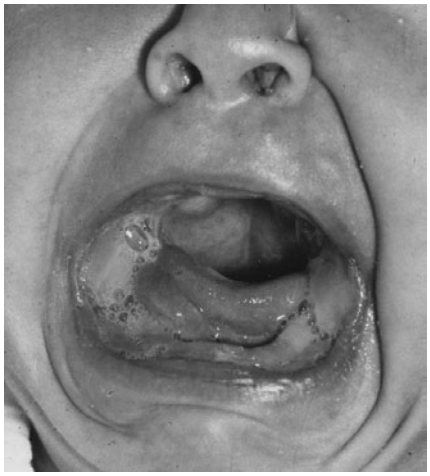
Musculoskeletal. Hernia is common, including inguinal (1,14,35,71, 94,97), diaphragmatic (1,16,35,96), and ventral and/or umbilical (35,97) types. Loose joints are rarely noted (1).

Gastrointestinal. Diverticula of the gastrointestinal tract involving the pharynx (50), esophagus (35,94), and rectum (35,71,72,97) have been documented.

Genitourinary. Bladder diverticula have been described by several authors (1,34,35,50,94,97) (Fig. 13–12). Vaginal prolapse has also been noted.

Oral. The voice is deep and resonant in quality due to laxity of the vocal cords (6,35,114). There is also looseness of the oral and pharyngeal mucosa (35) (Fig. 13–13).

Fig. 13–13. *Cutis laxa, recessive type*. Oral mucosa hangs loosely. (Courtesy of AH Mehregan, Monroe, Michigan.)



Cutis laxa, with late closure of fontanels, intrauterine growth retardation, and hyperlaxity of joints was possibly described first by Debré et al in 1937 (23). Several other authors have reported examples of this condition (1,3,8,27,28,33,47,48,52–54,56,75,78,81,84,86,90,101,108). It should be noted that the patient reported by Theopold and Wildhack (101) is a cousin of the patients reported by Fittke (27). Possibly the patient described by Schirren et al (93) had this condition. Inheritance is probably autosomal recessive, but most patients are female (53,78,86,90). The rate of parental consanguinity is high. Genevieve et al (32a) described 3 of 7 affected with cutis laxa, cleft palate, and mental retardation.

Birth weight and length are under the 10th centile. Delayed postnatal growth, mild gross motor retardation, poor feeding, mild mental retardation, frontal bossing, sagging jowls, reversed V-shaped eyebrows, epicanthic folds, sunken nasal bridge, and apparent mild hypertelorism are common. In addition to congenital cutis laxa, which is especially severe over the abdomen, hands, and feet, there is late closure of the fontanels, especially the anterior one. The skull sutures are markedly separated. The hips, either one or more often both, are congenitally dislocated in 85%. All joints, especially those of the hands, exhibit generalized laxity, which leads to unusual positioning. All appear to have fifth finger clinodactyly. Talipes equinovarus has been noted in a few cases. The subcutaneous veins of the abdomen are markedly dilated and the abdominal musculature is lax. Large inguinal hernias have been noted. Less constant findings include downslanting palpebral fissures, macular coloboma, myopia, iris hypoplasia, single transverse palmar crease, and hydronephrosis (3,93). Cleft lip has been reported (78).

Fig. 13–14. *Cutis laxa*. Autosomal dominant type of cutis laxa in 15-year-old girl who looks older than her middle-aged mother. (From P Beighton, Br J Plast Surg 23:285, 1970.)

Autosomal dominant form. This form is less common than the autosomal recessive type and runs a quite benign course (5,6,11, 17,19,45,83,94,96,99,102,109,113). Perhaps the earliest published example is that of Rossbach (88) in 1884. Onset is usually somewhat later than that in the recessive forms. Drooping of eyelids and sagging facial skin, together with accentuation of the nasolabial and other facial folds, produce an aged appearance. The nose is often hooked, the nostrils everted, and the philtrum long. An affected pubertal child will often look older than the unaffected parent (Fig. 13–14). Complications are few and lifespan is normal.

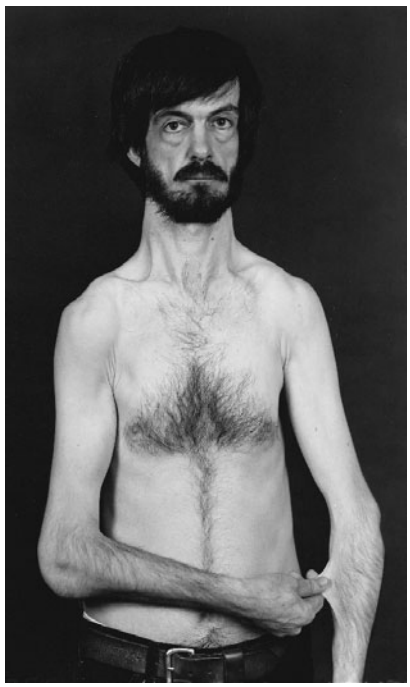
Rarely associated abnormalities have included hoarseness (5,11,45), pulmonary artery stenosis (45,109), mitral valve prolapse (11), hernia (96), bronchiectasis (6), joint dislocations (11), tortuosity and dilatation of carotid arteries and aorta (24,45), dilation of sinuses of Valsalva (11), and coarctation of the aorta (5,102).

In 1998, an elastin gene mutation was reported producing abnormal tropoelastin and abnormal elastic fibers in autosomal dominant cutis laxa (26,100). The elastin gene maps to 7q11.2 (26). Mutations occur in exons 30 and 32.

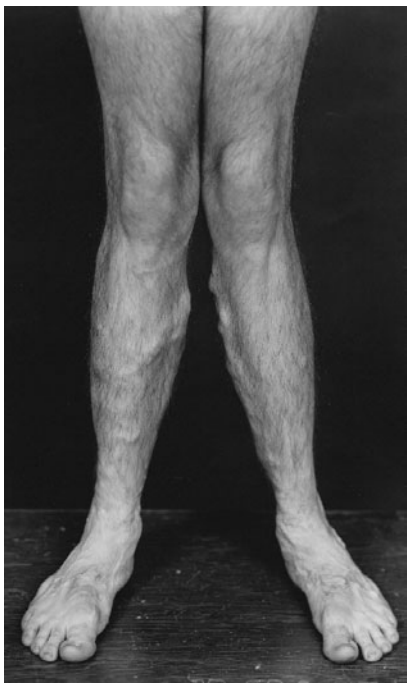
X-linked form or occipital horn syndrome (formerly Ehlers-Danlos syndrome type IX). First reported by Lazoff et al (62) in 1975, the occipital horn syndrome is characterized by occipital exostoses, soft and easily bruisable skin, hyperextensible joints, and widening and bowing of multiple long bones (9,12,13,59,67,81a,91,105,110). At least 20 cases have been reported (105).

The syndrome is clearly X-linked. Female heterozygotes may exhibit mild signs (46). No affected male has reproduced. The disorder maps to Xq13.3 in the Menkes disease gene (51,64,73a), known as *ATP7A* (37).

The face, neck, and trunk are long and thin (9,13) (Fig. 13–15A). The hyperelastic, soft, and bruisable skin with resultant atrophic scars and the hyperelastic joints are not as marked as in EDS type I or as mild as EDS type II. Varicose veins have been frequently noted (91) (Fig. 13–15B).



A



B

Fig. 13–15. *Occipital horn syndrome*. (A) Patient showing long neck, narrow sloping shoulders, long thorax, hyperelasticity of skin. (B) Genua valga, varicosities, pes planus. (Courtesy of DD Weaver, Indianapolis, Indiana.)

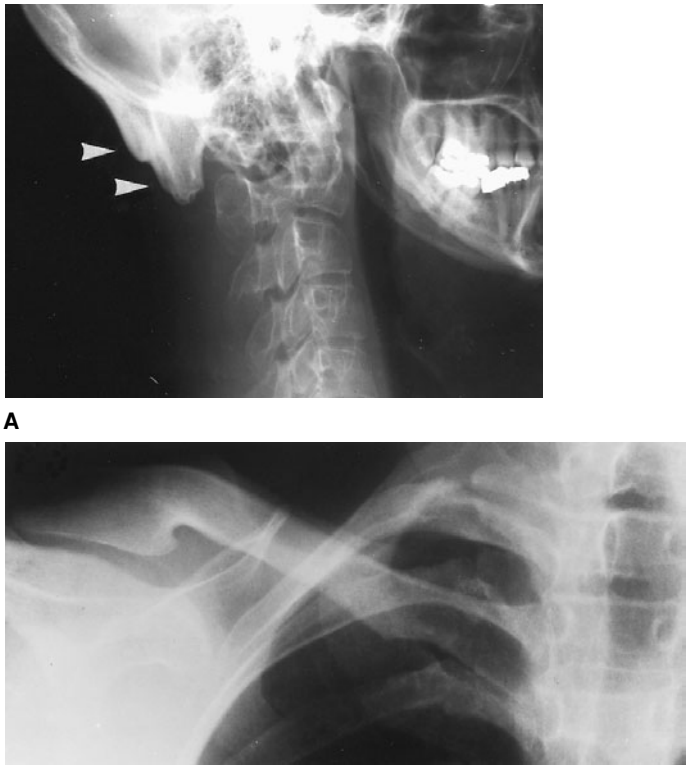


Fig. 13–16. *Occipital horn syndrome*. (A) Arrows point to occipital exostoses. Note long neck. (B) Club-shaped distal clavicles. (A,B from DJ Sartoris, Radiology 152:665, 1984.)

Patients exhibit limited extension of the narrow shoulders, elbows and knees, hypermobility of finger joints, pes planus, and genu valga in 75% (Fig. 13–15A). Pectus excavatum or carinatum has been found in 40%. Various hernias (hiatal, femoral, inguinal) have been described in about 35%. Bladder diverticula with bladder neck obstruction were found in 60%–70%. Chronic diarrhea of unknown cause has been noted in 40% (9,12,59,62,91). Borderline IQ has been documented in 40% and mental retardation has been reported (105,110).

Radiologic findings include occipital exostoses (horns) symmetrically located on each side of the foramen magnum (Fig. 13–16A). These may be palpated, are a constant feature, and may become large with age. The horns may represent ectopic bone formation within the trapezius and sternocleidomastoid aponeuroses. The clavicles are very short, with a widened medullary cavity and hammer-shaped distal extremities (Fig. 13–16B), the femora exhibit focal hyperostosis at sites of tendon and ligament insertion (Fig. 13–17A). Carpal fusion involving capitate-hamate and trapezium-trapezoid coalescence has been noted in over 50% (91) (Fig. 13–17B). Less specific are deformations of the humerus, radius, ulna, tibia, and fibula (90%), osteoporosis (70%), narrowing of rib cage (65%), dislocation of radial head (40%), mild platyspondyly, coxa valga, and flattening of the acetabular roofs. Dilated and tortuous arteries have been noted (46).

The disorder, exhibiting low serum copper and ceruloplasmin levels, is due to a defect in copper metabolism leading to lysyl oxidase deficiency and abnormal collagen (13). Allelism with *Menkes syndrome* (80) at the *MNK* gene locus was demonstrated in a definitive way by Das et al in 1995 (20). Mutations in the *MNK* gene cause defective uptake of copper and secondary deficiency of lysyl oxidase, a copper-dependent enzyme. This, in turn, results in abnormal cross-links in collagen molecules. Ronce et al (87) reported a C2055T transition in exon 8 of the *ATP7A* gene, associated with exon skipping in an occipital horn syndrome family.

Differential diagnosis. Acquired cutis laxa may follow nonspecific cutaneous inflammation, persistent urticaria, or nephrotic syndrome

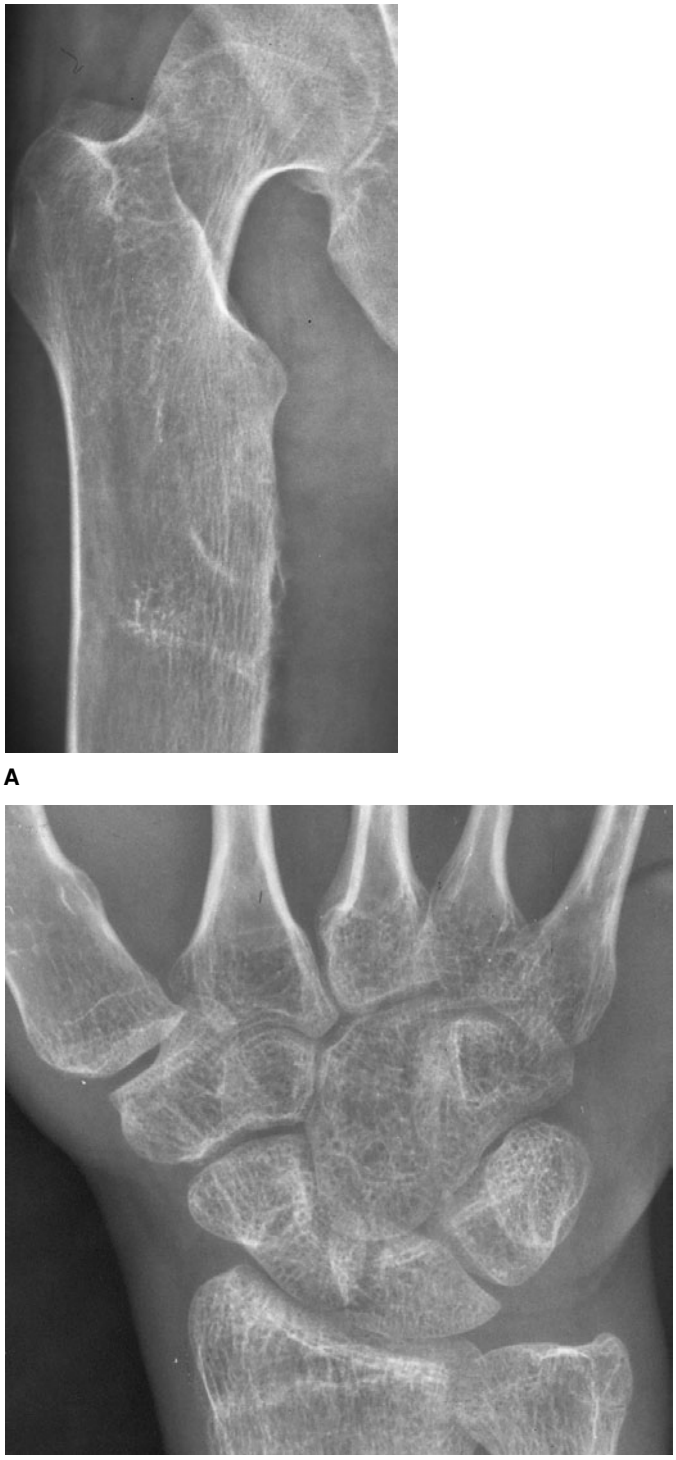

Fig. 13–17. *Occipital horn syndrome*. (A) Femur shows focal hyperostosis at site of tendon insertion. (B) Capitate-hamate and trapezium-trapezoid coalescence. (A,B from DJ Sartoris. Radiology 152:665, 1984.)

(103). Occasionally there is no history of prior skin disorder (7). Some patients have only cutaneous involvement, whereas others have internal manifestations: pulmonary emphysema with cardiovascular complications, femoral, inguinal, ventral, or diaphragmatic hernias, diverticula of intestinal tract, cystocele, rectocele, and uterine prolapse (7,49,50,60). Ruptured patellar tendons and associated multiple myeloma have been reported (15,70,95). It may also be associated with a plasma cell dyscrasia,

with immunoglobulins deposited on dermal elastic fibers (74). The reader is referred to several reviews of acquired cutis laxa (41,69,82,111,114).

Braun-Falco et al (10) were dealing with a case of prune belly. Tracheobronchiomegaly (Mounier-Kuhn syndrome) is characterized by dilatation and diverticulas of the trachea and bronchi (31). The "wrinkly" skin syndrome, a recessively inherited disorder characterized by congenital wrinkling of the skin of the chest, abdomen, and dorsa of the hands and feet, must be excluded. The palms and soles have increased numbers of wrinkles. There is generalized hypotonia with winging of the scapulae (32).

Cutis laxa of the facial skin has also been found in association with a dominantly inherited syndrome of systemic amyloidosis with corneal lattice dystrophy, cranial nerve palsy, hair loss, nephropathy, and, occasionally, cardiopathy (Meretoja syndrome) (39,73,85). It has also been seen with severe osteoporosis (89) as well as in *gerodermia osteodysplastica, De Barsy syndrome, Lenz-Majewski syndrome, Costello syndrome* (22), and *ablepharon-macrostomia syndrome* (79). A congenital generalized cutis laxa may result from chronic maternal penicillamine therapy during pregnancy. These infants may have severe pulmonary complications (66,98,111). Tsukahara et al (104) described a disorder intermediate between cutis laxa and *Ehlers-Danlos syndrome* in a mother and child. *SCARF syndrome* is a possibly X-linked recessive disorder of cutis laxa, skeletal abnormalities, craniosynostosis, psychomotor retardation, and unusual facies (58).

Bladder diverticula may also be seen in *Menkes syndrome*, prune belly sequence, *Ehlers-Danlos syndromes*, and *Williams syndrome*.

Acquired cutis laxa was described in dermatitis herpetiformis and sarcoidosis (65).

Pathology. With orcein or Weigert elastic fiber stain, absence or marked diminution of elastic fibers has been observed, especially in the papillary layer of the dermis. Degenerative changes are marked by fragmentation of elastic fibers. Some fibers are short and thin. Abnormalities of fibrillin have been reported in acquired cutis laxa (63).

Ultrastructural changes include deficiency of elastin and uneven distribution of dense, amorphous, or granular substances that produce dense bundles (42,68,74,92). The various types of cutis laxa cannot be differentiated by light or electron microscopic study.

Laboratory aids. The mechanism by which there is insufficient elastin is not known.

Olsen et al (76) found no qualitative difference between control and cutis laxa elastic mRNAs. However, quantitation of the elastin mRNA by slot blot hybridization showed markedly reduced levels. In some cases, enhanced degradation of elastin has been demonstrated (4,106). Kitano et al (57) found diminution of elastic fibers throughout the dermis, globular and unstained elastin, and relatively large amounts of the microfibrillar components of elastic fibers.

While low serum copper and increased elastase and/or decreased antielastase levels (35,38,42) have been reported, others have found normal or even elevated values (42,45). Recent evidence indicates that cutis laxa fibroblasts that express little or no elastin have normal transcriptional activity but abnormal rates of elastin mRNA degradation. This defect is substantially reversed by TGF-β through mRNA stabilization (21,115).

Khakoo et al (55) described autosomal recessive cutis laxa in boys from 2 separate families who showed deficiency of lysyl oxidase. Neither had occipital osseous projections or abnormality of copper metabolism that are characteristic of the X-linked form. In one case, the mother showed partial deficiency of lysyl oxidase; in the second case, the parents were first cousins.

Collagenase mRNA levels are increased in fibroblasts derived from patients with cutis laxa. This is due to the upregulation at the transcriptional level by endogenous activation of DNA binding of AP-1 in cutis laxa fibroblasts.

Hatamochi et al (43,44) showed that the levels of type VI collagen mRNA were increased in cutis laxa fibroblasts and the levels of α-1 (VI) and α-3 (VI) chain mRNAs increased in parallel. Increases in type VI collagen mRNAs correlated well with production levels of the corresponding proteins and suggest that this may be related to the skin changes in cutis laxa.

Acquired cutis laxa is associated with normal enzyme levels (45). Moreover, ultrastructural and biochemical observations confirmed a dramatic reduction in dermal elastin, whereas collagen content was normal (29). In generalized acquired cutis laxa associated with celiac disease, there may be evidence of immunoglobulin A deposits on the dermal elastic fibers (30).

Cutis laxa may also be associated with 7p trisomy (77).

Cutis laxa, craniosynostosis, mental retardation, unusual facies, skeletal anomalies, and ambiguous genitalia (SCARF syndrome)

Koppe et al (1), in 1989, used the acronym SCARF for a syndrome exhibiting *S*keletal abnormalities, *C*utis laxa/craniosynostosis, *A*mbiguous genitalia, *R*etardation, and *F*acial abnormalities.

Two affected male children connected through their mother suggest X-linked recessive inheritance.

The face was characterized by multiple hair whorls, high broad nasal root, and small chin. One of the boys had ptosis, epicanthic folds, and low-set posteriorly rotated pinnae. The enamel was dysplastic (Fig. 13–18).

Cutis laxa was generalized and associated with excess nuchal skin, which evolved into neck webs. The nipples were widely spaced.

Musculoskeletal findings included synostosis of the lambdoidal and coronal sutures, short sternum, pectus carinatum, abnormally shaped vertebrae, abnormal modeling of long bone, and diastasis recti/umbilical hernia.

There was mild to moderate mental retardation. Micropenis and perineal hypospadias were present in both brothers.

Although reference was made regarding overlap with *Lenz-Majewski syndrome*, we do not see the resemblance.

Fig. 13–18. *SCARF syndrome*. (A) Note lax skin, pectus carinatum, umbilical hernia, ambiguous genitalia. (B,C) Child at 5 1/2 years. Note low hairline, high nasal bridge, low-set posteriorly angulated pinnae, downslanting palpebral fissures, ptosis, strabismus, and webbed neck. (Courtesy of P Kaplan, Philadelphia, Pennsylvania, and from R Koppe et al, Am J Med Genet 34:305, 1989.)

A B C

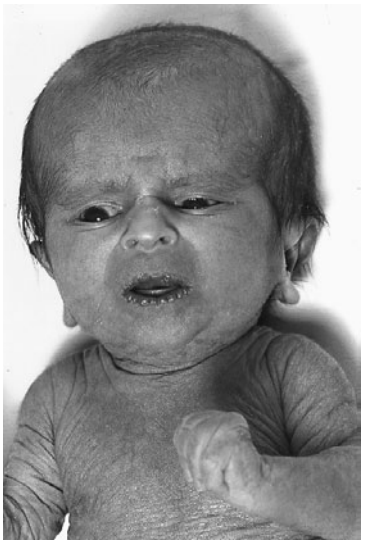

Fig. 13–19. *De Barsy syndrome*. Wizened face of 10-day-old. Note loose wrinkled skin. (From BF Pontz et al, Eur J Pediatr 145:428, 1986.)

Reference [Cutis laxa, craniosynostosis, mental retardation, unusual facies, skeletal anomalies, and ambiguous genitalia (SCARF syndrome)]

De Barsy syndrome

De Barsy et al (3) and others (2,4–11) described a syndrome of intrauterine growth retardation, wrinkled atrophic skin, open fontanels and sutures, corneal clouding, somatic and mental retardation, brisk deep tendon reflexes, athetoid posturing, hypermobility of small joints, and muscular hypotonia. The facies is characterized by frontal bossing in early childhood, but postnatal changes include microcephaly, prematurely aged appearance, corneal clouding, large dysplastic ears, hypertelorism, and thin lips (Figs. 13–19 to 13–23). Some patients have cataracts (10). About a dozen examples have been published (6). We are not convinced that the child noted by Bartsocas (1) has the syndrome. Inheritance is autosomal recessive (7,9,10). Possibly the child reported by Wiedemann (12) in 1969 has De Barsy syndrome or *gerodermia osteodysplastica*.

Elastic fibers are frayed and reduced in number. There appears to be defective elastin synthesis (5,6). Chemotactic migration of cultured fibroblasts is reduced, and there is impaired granulocyte function (5,6).

Fig. 13–21. *De Barsy syndrome*. Progeroid aspect, microcephaly, reduced subcutaneous fat, pectus excavatum, and growth retardation. (From J Kunze et al, Eur J Pediatr 144:348, 1985.)

Fig. 13–20. *De Barsy syndrome*. Microcephaly, large pinnae with poor modeling, downslanting palpebral fissures, strabismus, and right-sided cataract. (From J Kunze et al, Eur J Pediatr 144:348, 1985.)

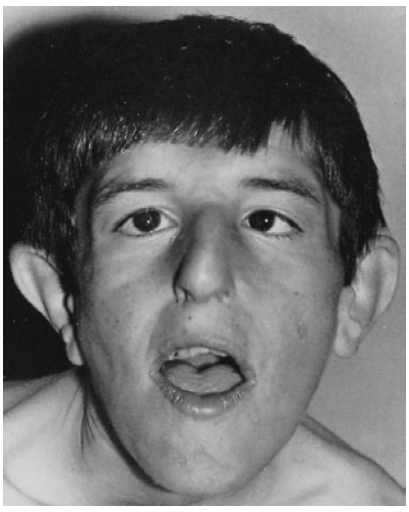

Fig. 13–22. *De Barsy syndrome*. Lax skin of abdomen. (Courtesy of F Majewski, Düsseldorf, West Germany.)

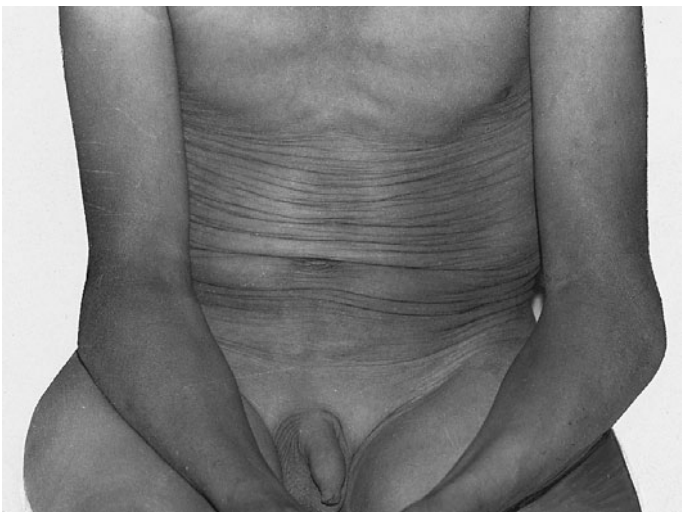

Fig. 13–23. *De Barsy syndrome*. Lax thin skin of hand. (Courtesy of F Majewski, Düsseldorf, West Germany.)

The disorder must be differentiated from *cutis laxa syndromes* and those of premature aging (acrogeria, metageria, *gerodermia osteodysplastica, Wiedemann-Rautenstrauch syndrome*).

Gerodermia osteodysplastica (Bamatter syndrome)

The family first reported by Bamatter et al (2), in 1949, was reviewed by the same group of investigators over a 20-year period (3,4,6–8,13,17). The disorder manifests a characteristic facies, hyperlaxity of the skin and joints, and growth retardation. Other families have been reported (1,4,5,11,12,15,16,20). Others are probable examples (18). In the interest of linguistic purity, we have changed the name from geroderma osteodysplastica to gerodermia osteodysplastica (21). About 25 examples have been reported.

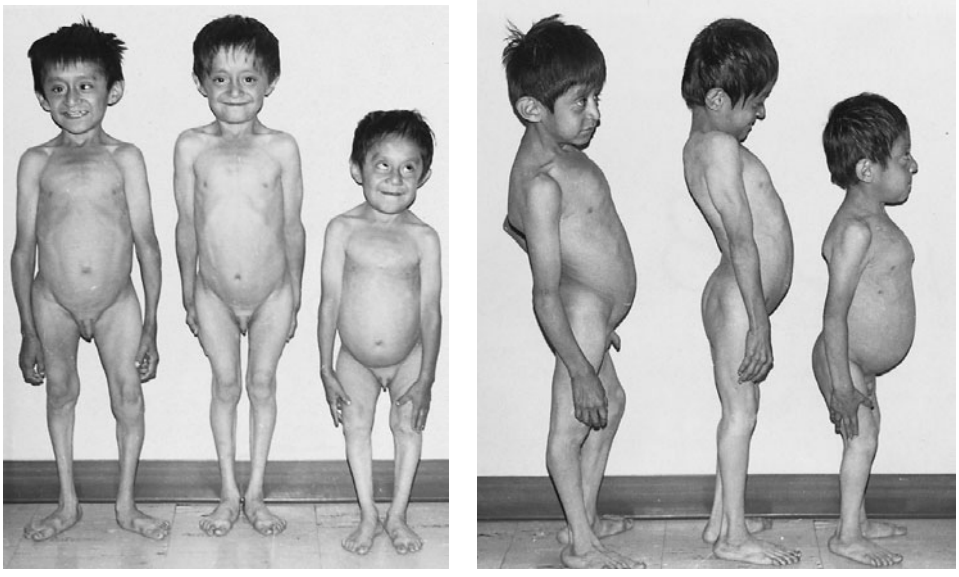
There is autosomal recessive inheritance (1,12,14,15). The disorder is undoubtedly underreported (11).

Growth retardation is below the third centile in perhaps a third of the children. Frequently, span is greater than height. There is delayed onset in walking.

Facies. Due to looseness of the skin, a sad senile appearance is imparted. The eyeballs appear sunken. The eyelids and cheeks droop. The head tends to be brachycephalic. The forehead is prominent. The nose is often jutting and fleshy. The lower lip is downturned and the midface is frequently mildly hypoplastic with relative mandibular prognathism. About half the patients exhibit malar flush (Figs. 13–24 and 13–25).

Skin. The skin is thin and creased with recoil. The subcutaneous veins are prominent. The skin is especially without turgor over the hands and feet and is easily wrinkled.

Microscopically, there is fragmentation of elastic fibers.



A B

Fig. 13–24. *Gerodermia osteodysplastica*. (A,B) Six-, seven-, and eight-year-old sibs with saggy cheeks, premature wrinkling of skin of face, abdomen, dorsum of hands and feet, stooped posture, winged scapulae, and flatfeet. (From R Lisker et al, Am J Med Genet 3:389, 1979.)

Fig. 13–25. *Gerodermia osteodysplastica*. Facies showing premature aging. (Courtesy of D Klein, Geneva, Switzerland.)

Musculoskeletal. Constant features are marked muscular hypotonia and hyperlaxity of joints (hands, feet, knees, hips), with associated hernias, flatfeet, and dislocated hips. Inguinal hernia has been found in approximately 35%. Virtually constant features are osteoporosis with resultant platyspondyly, anterior wedging, and occasionally biconcave vertebral bodies (1,7). Compression fractures may be observed within the first few years of life. Long bones tend to fracture with minimal trauma. Mild scoliosis and sternal anomalies are present in about 65%. Radiographic changes include multiple Wormian bones in the lambdoidal suture and evanescent metaphyseal pegs indenting the epiphyses of long bones, especially at the knees (9).

Oral manifestations. At least 70% have downturned lower lip. Almost constant features are malocclusion and highly arched palate. The alveolar bone is decreased in amount.

Radiographically, the mandibular lingula is funnel-shaped and molar roots extend below the inferior dental canal. Hypercementosis of maxillary incisors and mandibular molars surrounded by a radiolucent halo has been documented (15).

Differential diagnosis. Gerodermia osteodysplastica is most likely to be confused with the *cutis laxa syndromes*. Acrogeria is characterized by wrinkled and aged-appearing skin, most marked over the dorsa of the hands and feet; flatfeet; and dislocated hips. Many of these cases of acrogeria represent EDS IV. However, in gerodermia osteodysplastica, the skin is not atrophic and the superficial veins are not highly visible. Commonly associated with acrogeria are wide cranial sutures, blue sclerae, diaphyseal narrowing of long bones, and nail dysplasia. Furthermore, individuals who have acrogeria are not jowly and do not exhibit the joint hyperextensibility and the osteoporotic bony changes seen here.

The syndrome should be differentiated from *wrinkly skin syndrome* reported by Gazit et al (10). This autosomal recessively inherited disorder is characterized by wrinkled skin of the anterior chest and/or dorsal surfaces of the hands, hypotonia, kyphosis, winged scapulas, and prominent cutaneous venous pattern. There are also microcephaly, severe myopia, and chorioretinitis.

The *De Barsy syndrome*, characterized by congenital athetosis, mental retardation, severe growth retardation, and laxity of skin and ligaments, must also be excluded. *Lenz-Majewski syndrome* and *Patterson syndrome* (*pseudoleprechaunism*) have wrinkly skin as one of their components, but the phenotypes of those disorders are so distinct that discussion is not relevant.

Wrinkly skin syndrome

Gazit et al (3), in 1973, described 3 sibs born to consanguineous Iraqi-Jewish parents. An additional 10 patients have been described (1,2,4–6). Zlotogora (8) suggested that this condition is the same as *cutis laxa with growth and developmental delay*.

Typical manifestations include low birth weight; delayed growth and development; wrinkled inelastic skin over the hands, feet, and abdomen, with an aged appearance; prominent subcutaneous truncal veins; craniofacial anomalies; microcephaly; and bilateral hip dislocation.

Nearly all of the patients have been of either Moslem (2,6) origin or Sephardic Jewish descent (3–5). In nearly all cases, there was parental consanguinity. Three patients of European origin had del(2q32) (7). The disorder in these cases went from mother to two children.

Differential diagnosis includes *pseudoxanthoma elasticum*, the *cutis laxa syndromes*, and the *Ehlers-Danlos syndromes*. In contrast to cutis laxa, the skin in wrinkly skin syndrome is hypoelastic, and there are no loose folds of skin over the face. The classic beaked nose, short columella, and long upper lip are absent in wrinkly skin syndrome.

It differs from the Ehlers-Danlos syndromes in that there are no easy bruisability, hemorrhages, ecchymoses, poor scar formation, abnormal wound healing, or hyperelasticity of the skin and joint hypermobility.

Ehlers-Danlos syndromes

The Ehlers-Danlos syndromes (EDS) constitute a heterogeneous group of generalized connective tissue disorders. The five cardinal elements of EDS include hyperextensible doughy skin, atrophic scars, joint hypermobility, connective tissue fragility, and bruising (36). The earliest-recognized description was of a young Spaniard, George Albes, who was exhibited to the Academy of Leyden in Holland in 1657 by Van Meek'ren (2,32). The first scientific description was by Tschernogobow, a Russian dermatologist, who presented an affected 17-year-old boy to the Moscow Venereology and Dermatology Society meeting in 1892. He attributed the multisystem features to a generalized defect in formation of connective tissue (14,36).

Ehlers (17), in 1901, reported the association of hyperelastic skin, skin hemorrhages, and loose-jointedness. Danlos (13), in 1908, added cutaneous pseudotumours and fragility, and Weber and Aitken (51) included subcutaneous spherules. Terminology became especially complex during the early part of the twentieth century. The eponym Ehlers-Danlos syndrome finally emerged as the name used most commonly.

Comprehensive surveys are those of Steinmann et al (43), Beighton (3), and Pope and Burrows (36). The following aspects also have detailed coverage in different publications: molecular defects and connective tissue metabolism (7,8,10,20,24–26,29,30,37,38,40,47,48,52), ultrastructural studies of the skin (6,19,22,23), histologic and mechanical studies of the skin (21,34,44), collagen studies (1,7,12,15,18,28,30,33, 39,41,46,47,49,50), cardiovascular abnormalities (11,16,27,31), and complications of pregnancy (35,42,45).

Based on recent advances in the elucidation of the molecular mechanisms, many EDS subtypes are now well understood. The alteration of certain molecular components disrupts collagen fibril assembly, with particular anatomical distributions. Thus, the molecular composition of the skin, ligaments, tendons, cartilage, vasculature (arteries, veins, capillaries), eyes (cornea and vitreous), pleuroperitoneum, and intestinal walls may be severely weakened and disorganized (36).

Genetic, biochemical and molecular studies have defined more than 10 types of Ehlers-Danlos syndrome. Their clinical features, inheritance, and biochemical or molecular defects are summarized in Table 13–2. Whenever possible, it is essential to establish the specific type of Ehlers-Danlos syndrome because additional clinical investigations, follow-ups, and precautionary measures may be crucial for optimum care. Approximately 80% of affected individuals have type I or type II, around 10% have type III, 4% type IV, and about 6% have various other types (4). In 1998, Beighton et al (5) proposed a new, simplified classification of EDS into six major types and a seventh group comprising all the others. This classification was intended to make diagnostic efforts easier and more useful to the "generalist." For each type, major and minor criteria were defined. These may be used as a diagnostic starting point. However, for most, a more detailed approach may be necessary, based on the continuous development of molecular tests.

Before we address the specific forms of Ehlers-Danlos syndrome, let us briefly consider collagen structure (8–10).

Collagen structure and biosynthesis. Collagens, which have important structural properties, are the most abundant family of proteins in the body. Collagens are composed of molecules containing three chains (heterotrimers or homotrimers), with a triple-helical domain characterized by the repeating amino acid sequence $(Gly\text{-}X\text{-}Y)^n$. There are more than 28 genes coding for the chains that form more than 16 different types of collagen molecules. The loci of these genes are dispersed on at least 12 chromosomes (Fig. 13–26A).

Collagens are of five different types: (a) fibrillar (collagens 1,2,3,5 and 11), (b) basement-membrane, (c) fibril-associated with interrupted triple helixes, (d) network-forming, and (e) long-chain collagen of anchoring fibrils with interrupted triple helix.

Mutations of fibrillar collagen are responsible for the production of certain types of EDS. These collagens are distributed in skin, bone, tendon, arteries, cartilage, vitreous humor, placenta, chorion, and uterus. This distribution explains the pathogenesis of the clinical manifestations due to the mutations of the genes coding for these specific types of collagen (8).

The individual precursor chains of the triple helix of the collagen molecule are synthesized on membrane-bound polyribosomes. While the growing chain is being transferred into the lumen of the rough endoplasmic reticulum, certain prolyl and lysyl residues in the triple-helical domain are hydroxylated and some hydroxylysyl residues are glycosylated (Fig. 13–26B). The assembly of the three proα chains occurs through structures in the C-terminal propeptide domain of each chain. The folding of the triple-helix also occurs from the C-terminal end of the molecule. After the procollagen triple helix is secreted, N- and C-terminal propeptide extensions are cleaved by a limited proteolysis by procollagen N-proteinase and procollagen C-proteinase, which are endopeptidases and are collagen type specific (8) (Fig. 13–26C).

Table 13–2. Clinical features, modes of inheritance, and biochemical defects in Ehlers-Danlos syndromes

Type	Synonym	Inheritance	Clinical features	Histology and electron microscopy	Basic biochemical or molecular defect
EDS I	Gravis type	AD	Soft, velvety, hyperextensible skin, easy bruising, "cigarette paper" scars, hypermobile joints, varicose veins, molluscoid pseudotumors	Cauliflower fibrils	COL5A1-linked in some families. Mutations include exon skips, translocation and cystein substitution
EDS II	Mitis type	AD	Similar to Ehlers-Danlos Type I, but less severe	Cauliflower fibrils	Probably allelic to EDS I
EDS III	Hypermobile type	AD	Marked large and small joint hypermobility. No cutaneous scars	Non-specific	Unknown
EDS IV	Vascular type IV A acrogeric IV B acrogeric IV C ecchymotic IV D	 AD AR AD AR	Thin, translucent skin with visible veins, marked bruising. Skin and joints have normal extensibility. Risk of arterial, intestinal, uterine rupture highest in acrogeric subtypes	Collagen depletion (Type III), variation in fiber size	COL3A1 mutations. Numerous point mutations and exon skips, rarely deletions
EDS V	X-linked type	XL	Resembles EDS II. Very rare.		Not lysyl oxidase deficient
EDS VI	Ocular type	AR	Soft, velvety, hyperextensible skin; hypermobile joints; premature scoliosis; arterial rupture in 30%; ocular fragility and keratoconus		Lysyl hydroxylase point mutations or exon skips. VIA: decreased lysyl hydroxylase levels. VIB: normal levels
EDS VII A	Arthrochalasis multiplex congenita	AD	Congenital hip dislocation, joint hypermobility, mild facial cutis laxa: Some have skin fragility and mandibular hyperplasia.	Fibrils are angular in A and B, and hieroglyphic in C	Types A and B specific exon 6 skips or deletions of COL1A1. Type C procollagen peptidase deficiency
B,C	Dermatosparaxis	AR	Severe cutis laxa		
EDS VIII	Periodontitis type	AD	Generalized periodontitis, skin similar to EDS		
EDS IX	Vacant—formerly, "Occipital horn" syndrome, now classified as X-linked type of cutis laxa				
EDS X	Fibronectin abnormality	AR/AD	Similar to EDS II. Faulty platelet aggregation		Association with fibronectin may be coincidental
Others	Progeroid form EDS type unspecified EDS type unspecified	 AD AR

Ehlers-Danlos syndrome type I (severe form, EDS I) and type II (mild form, EDS II)

The clinical findings in EDS types I and II may be dramatic, with markedly soft, velvety, hyperextensible skin, impressive joint hypermobility, easy bruising, and thin, atrophic, "cigarette-paper" scars. Varicose veins are common. Birth prevalence of these two disorders is estimated to be approximately 1/10,000–20,000 (5,39). The clinical phenotypes of EDS I and II overlap substantially. They represent allelic autosomal dominant mutations with variable penetrance. Compound heterozygosity is also possible. A good general review is that of Brinckmann et al (13).

Inheritance is autosomal dominant. Mutations in the COL5A1 gene of collagen type α1(V) chains are responsible for EDS I and EDS II (16,40,47). The collagen is disorganized and forms so-called cauliflower fibrils (47) (Fig. 13–27). Several groups have reported linkage of human COL5A1 which maps to 9q34.2–q34.3 markers in families with EDS I or EDS II (50a,56). The mutations of these two conditions are therefore considered to be allelic (16,37). Several COL5A1 mutations have been reported with either EDS I or II phenotypes. In one, the COL5A1 gene is interrupted by a translocation at intron 24 (53). In the second, an exon 65 skip is found in the affected members of a three-generation family (55). In the third, there is a mutation in COL5A1, the gene encoding the proα1(V) collagen chain, segregating with EDS I in a four-generation family. The mutation causes the substitution of the most 5′ cysteine residues by a serine within a highly conserved sequence of the proα1(V) C-propeptide domain, resulting in reduction of collagen V by preventing incorporation of the mutant proα1(V) chains in the collagen V trimers (18,19). Moreover, splicing defects in COL5A1 gene were detected in a patient with EDS I and in a family with EDS II (16,49).

Mutations of the COL5A2 gene which encodes the α2(V) chain of type V collagen have also been identified in patients with EDS I (40). These mutations consist of a 7bp deletion that results in skipping of exon 27 or a single nucleotide substitution that results in skipping of exon 28 (40).

Nuytinck et al (42a) described typical EDS type 1 patients with mutations in type I collagen.

It also seems that collagen type V controls type I collagen fibril packing (11,12,14,36,41). This may explain the striking fibrillar disorganization that typifies EDS I and II. It also implies that the disorganization is a direct effect of the mutant type V collagen.

It is thought that collagen type XI regulates the thickness of collagen type II fibrils and collagen V and XI coassociate in vitreous humor. Corneal shape depends also on collagen V. This may explain why corneal or vitreous abnormalities and high myopia cosegregate with premature osteoarthritis in some EDS families (47).

Moreover, arterial fragility may be caused by COL5A2 mutations (42). This suggests that α2(V) chains and collagen type III interact analogously to α1(V) chains and type I collagen chains (47).

COL5A1 homozygotes are either exceptionally rare or are genetic lethals.

A tenascin defect has been postulated (15,22).

General features. Prematurity, due to early rupture of fetal membranes, is observed in as many as 50% of type I cases (2,52) and to a lesser degree in type II cases. In addition, there may be postpartum hemorrhage following episiotomy or lacerations, and uterine or bladder prolapse (52).

Children with types I or II EDS are often thought to have joint hypermobility as newborns, but may not come to medical attention until about one year when they are noted to be slow to walk because of poor joint stability. Susceptibility to skin tearing, forming of scars, and easy bruising become apparent. Referral for evaluation for child abuse is consequently not uncommon (43). Evidence of mitral valve prolapse by clinical criteria or by echocardiography may be present in childhood and certainly by adolescence. Early onset of joint symptoms may also occur, apparently resulting in premature osteoarthritis from mechanical stress on joints produced by excessive mobility and mild joint instability.

There is often concern that routine surgery is hazardous, but although tissue is slightly more friable than normal, careful attention to detail during surgical procedures makes the likelihood of complications minimal. Sutures are generally left in place two or three times longer than usual to ensure adequate healing. Pregnancy-related maternal and fetal morbidity may be prevented by specific measures (23,46). Life expectancy for individuals with type I or type II Ehlers-Danlos syndrome is normal (5,31,32). However, a case of acute lymphoblastic leukemia was reported in a patient with EDS II (1). Anxiety, depression, anger, and interpersonal concerns are significantly elevated in patients with EDS (38).

Skin. The skin has a velvety feel and is hyperelastic, especially over the major joints. It is thinner than normal, brittle, and fragile (27). Minimal trauma may produce gaping wounds. Healing results in pigmented, papyraceous scars. These scars are usually detected over the forehead, chin, knees, shins, and/or elbows (Figs. 13–28 and 13–29). Bruising is variable in degree. Secondary skin creases may be found over the palms (25).

Molluscoid pseudotumors may be present over the heels and major joints. Often the skin is redundant on the hands and feet (10,33). Calcified, cystlike structures, 2–10 mm in diameter, may be found subcutaneously, especially over bony prominences of the forearms and shins in about 30% (8). Varicose veins are common and acrocyanosis is frequent.

Evaluation of the mechanical properties of skin in EDS I and EDS II revealed prominent increases in the skin extensibility and elasticity (29).

Musculoskeletal system. Hyperextensibility of the joints, a weak hand clasp, and pes planus are usually present (7,20,54) (Fig. 13–30). Genu recurvatum has been noted in about 25%, and there may be recurrent joint dislocations. Talipes has been found in approximately 5%. The ulnar styloid process may be elongated. Kyphoscoliosis and thoracic asymmetry are observed in 15%–20% but usually are not severe (8,20).

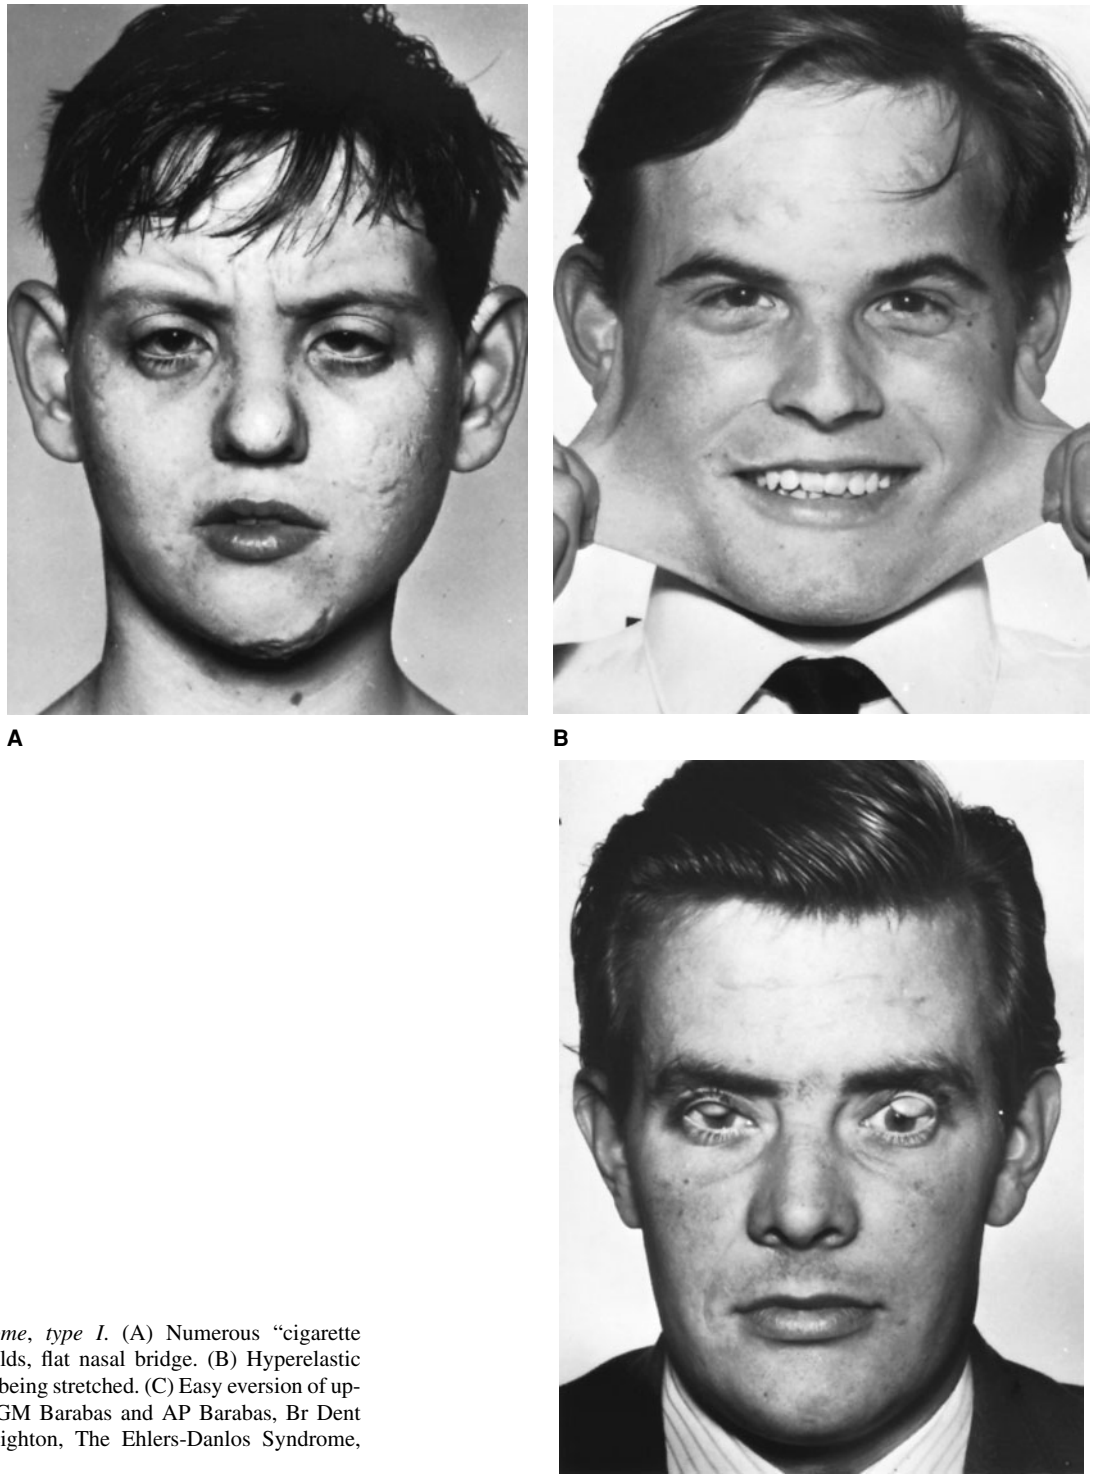

Fig. 13–28. *Ehlers-Danlos syndrome*, *type I*. (A) Numerous "cigarette paper" scars of face, epicanthal folds, flat nasal bridge. (B) Hyperelastic skin returns to normal position after being stretched. (C) Easy eversion of upper lids (Méténier sign). (A from GM Barabas and AP Barabas, Br Dent J 123:473, 1967. B,C from P Beighton, The Ehlers-Danlos Syndrome, Heinemann, London, 1970.)

Lumbar platyspondyly has been described (34). Inguinal or umbilical hernia has been found in 10%–20% (9). Soft tissue contractures have been noted (28).

Cardiovascular defects. Leier et al (35) studied 16 patients with type I EDS. Most patients had mitral valve prolapse and six had tricuspid valve prolapse. Dilatation of the aortic root or ectasia of the sinuses of Valsalva, or both, also occurred in six. However, arterial fragility is virtually unknown. Congenital heart defects included two cases of bicuspid aortic valve, one instance of pulmonic valvular stenosis, two VSDs, and one ASD.

Craniofacial features. Epicanthic folds are seen in about 25% (6,10,33). Blue sclerae are noted in less than 10% (10,20,33). Myopia and strabismus have been observed with far greater frequency than blue sclerae. Microcornea, retinal detachment, keratoconus, and angioid streaks have also been noted (44). Hyperextensibility of the skin allows the easy eversion of the upper eyelids (Méténier's sign) (5) (Fig. 13–28C). The pinnae may project outward (21).

Approximately 50% of patients can touch the nose with the tip of the tongue, an ability found in only 8%–10% of the general population (Gorlin sign) (Fig. 13–31C). The oral mucosa is fragile and easily bruised. Oral healing may be slightly retarded, since the edges of a wound draw apart, but there is no evidence of abnormal healing or excessive scar

Fig. 13–29. *Ehlers-Danlos syndrome, type I.* Papyraceous scars of knees with pseudotumor below left knee. (From GM Barabas and AP Barabas, Br Dent J 123:473, 1967.)

formation in the mouth (4). The gingiva are more liable to injury, and periodontal disease has been reported at an earlier age (10,33). Recurrent subluxation of the temporomandibular joint has also been reported (7,24,39,50). The inferior labial and lingual frenula are missing.

Barabas and Barabas (4) found that premolar and molar teeth had high cusps and deep occlusal fissures. Radiographically, teeth may have stunted and deformed roots and large pulp stones in the coronal part of the pulp chamber (3,4,26,30,45,48,51) (Fig. 13–31A,B). Barabas (3) found hypoplastic areas in enamel, irregularities of amelodentinal and cementodentinal junctions, and formation of pathologic dentin, more frequently in the root than in the crown containing vascular inclusions, abnormal dentinal tubules, and many denticles. Carr and Green (17) found multiple odontogenic keratocysts in EDS II.

Ehlers-Danlos syndrome type III (familial hypermobility)

Ehlers-Danlos syndrome type III (familial hypermobility) is characterized by joint laxity and soft velvety hyperextensible skin. In the newborn, joint laxity is often striking, although dislocation is rare at this time. Infants may be slow to walk because of joint looseness. In the adult, the shoulder, patella, and temporomandibular joints are frequently dislocated (1–3). Major complications include joint pain, and early-onset degenerative joint disease (16). Pregnancy and delivery are usually uncomplicated (17).

Approximately 10% of Ehlers-Danlos syndrome patients have type III. EDS III has autosomal dominant inheritance. In 1994, Narcisi et al (15) identified a Gly637Ser mutation in the *COL3A1* gene in a family in which multiple members had a connective tissue disorder resembling either EDS III or familial joint instability syndrome.

Formerly, type III was known as the *benign* hypermobile variety of Ehlers-Danlos syndrome (8,9). However, there appears to be an increased risk of mitral valve prolapse as an associated complication (5,13). Mechanical properties of the skin are essentially within normal limits (7). Certain patients with clinical manifestations of EDS III may have peripheral neuropathy with brachial plexus palsy and lumbosacral plexopathy (6). Multiple supernumerary teeth have been reported (14).

Differential diagnosis includes: *Ehlers-Danlos syndrome type VII*, an autosomal dominant joint instability syndrome characterized by dislocation of the hip, patella, and elbows (10), and normal variant hypermobility found in approximately 4%–7% of the general population (4,11,12).

Ehlers-Danlos syndrome type IV (ecchymotic, arterial, or Sack-Barabas type)

EDS type IV, also known as the ecchymotic, arterial, or Sack-Barabas variety of Ehlers-Danlos syndrome, has the most ominous prognosis because of predilection for catastrophic bleeding from major arteries and spontaneous perforation of the gastrointestinal tract. There are low birthweight and prematurity (36). Joint hypermobility is usually limited to the digits and is evident in 30%. Skin hyperextensibility may be minimal or absent in adults, but congenitally dislocated hips are not uncommon. The skin is characteristically thin and translucent with an easily observed prominent venous network, especially apparent over the chest and abdomen. Minor trauma leads to extensive ecchymosis, resulting in scarring over bony prominences. In childhood, "battering" may be suspected (42). Other than tendon and muscle rupture, musculoskeletal and orthopedic problems do not occur in type IV. Prevalence estimates range from 1/100,000 to less than one in a million (2,3).

Heredity. Both autosomal dominant (1–3,9,35,54) and autosomal recessive (1,33,34,49) forms have been observed. Consanguinity was recorded in a family of two affected sibs reported by Sulh et al (49).

In 1979, Byers et al (5) proposed a preliminary classification of type IV with subtypes A,B,C, and D. Subtype IV A has autosomal dominant inheritance and a life expectancy of 30–50 years. Gilchrist et al (13) reported a long lived kindred. The gene maps to 2q31. Tsipouras et al (57) demonstrated further heterogeneity with different mutations affecting the stability and secretion of proα 1(III) chains of type III procollagen in two separate families, both having autosomal dominant transmission. Subtype IV B has autosomal recessive inheritance (1,33) and a life expectancy of 15–30 years. Subtype IV C is represented by a sporadic case in one family. Extreme dilatation of rough endoplasmic reticulum of dermal fibroblasts was noted (5). Subtype IV D, now thought to have autosomal recessive inheritance (49), is associated with collagen fibrils that are small in diameter but vary in size. As Byers et al (5) recognized in 1979, this classification is heuristic.

Biochemical and molecular pathology. Biochemical heterogeneity has been demonstrated and most likely results from different mutations in the same gene for type III procollagen rather than in different genes (6,39,48).

There is strong clinical, histological, biochemical, and molecular evidence that faulty collagen III causes dermal atrophy and vascular and gastrointestinal fragility (17,26,31,58). Collagen III predominates in skin, blood vessels and ligaments. It is a homotrimer of a1(III). Its deficiency causes EDS IV but may, less specifically, cause EDS III (31).

There are two general patterns of mutations. The first (group 1) exhibits poorly secreted and overhydroxylated collagen III. These are caused by either helical glycine substitutions or exon skips. Patients with such severe biochemical deficiencies have severely abnormal clinical phenotypes (31). Mutations have been found that (a) interfere with secretion of assembled molecules, (b) alter expression of one allele, or (c) lead to increased intracellular degradation of type III collagen molecules. Superti-Furga et al (50,51) described multiple exon deletion resulting in heterozygosity at the *COL3A1* locus. Various skin changes have been observed, depending on the nature of the mutation. Small collagen fibrils and a mixed population of fibril sizes may be present. In patients with defects in secretion, marked dilatation of the rough endoplasmic reticulum is found in fibroblasts (33,35,48,54).

Generally, 3′ mutations are acrogeric, whereas the phenotypes of 5′ or middle helical exon skips are harder to recognize. Unfortunately, even the latter are at risk for arterial rupture which is nevertheless much more frequent in mutations at the 3′ end (31).

The second abnormal pattern includes null alleles. In this group, there is reduced collagen type III without intracellular retention or overmodification. The residual collagen III molecules are normal and the clinical phenotype is milder (31).

Pope et al (1996) (38) summarized 23 *COL3A1* mutations that they have analyzed. Most cause premature arterial fragility and thin skin, with EDS IV features. There are 14 glycine substitutions, eight exon skips and one small inframe deletion. Each mutation is private for the affected family. Other mutations are referred to in other studies (7,16,18,21–23,25,27,37,40,41,45,55,56).

Radioimmunoassay has revealed low levels of procollagen type III aminopropeptide in a subgroup of patients with EDS type IV (47). This is a peptide released during conversion of type III procollagen to collagen and is abnormally low in many patients with EDS IV.

Skin. The skin is thin, inextensible, and translucent (30%), showing a venous pattern over the trunk, abdomen, and extremities, and early aging. Bruising is marked, and extensive ecchymoses may follow even minor trauma in 65%. Bony prominences are covered with thin, darkly pigmented scars which differ from those observed in types I and II (Fig. 13–32C).

The facies is characterized by large-appearing prominent eyes, loss of subcutaneous connective tissue, a somewhat pinched or sharp nose, and thin lips, producing the so-called "acrogeric facies" (54) (Fig. 13–32A). The skin over the face has a parchmentlike appearance. Large varicose veins may be present (Fig. 13–32B) and the shins appear ecchymotic (Fig. 13–32C). Skin histology shows striking dermal thinning (from one-third to two-thirds of normal), collagen depletion, and elastin proliferation. Transmission electron microscopy reveals collagen fibril disorganization with irregularity and bimodal size distribution. Collagen III/I ratios seem to influence collagen fibril diameter and interactions and, if mutated or diminished, seriously impair the long-term strength and stability of arteries (31). In some cases, cells in the dermis have extremely dilated rough endoplasmic reticulum, the dermis is thin, and there is a reduced proportion of collagen although the proportion of elastic fibers appears increased. Certain mutations in *COL3A1* gene have effects on secretion, fibrillogenesis and skin architecture.

Vascular complications. Patients are at greatly increased risk for arterial aneurysm or dissection (80%), arteriovenous fistulas (20%), spontaneous rupture of colon (10%), and rupture of gravid uterus (2,3,8,9,19,43,46,52). There is early onset of varicose veins. Recurrent abdominal pain without major findings is common and may result from mural hemorrhage in the small bowel. The location of arterial hemorrhage determines the presenting symptoms in some patients (stroke, abdominal bleeding, arteriovenous, carotid-cavernous sinuses fistula, limb compartmental syndrome), whereas bowel rupture (flank pain) is the first complication in others. Removal of the distal two-thirds of the colon, the most common site of rupture, may decrease the likelihood of recurrence. Over 40% die prior to surgery. Surgical attempts at vascular repair and angiographic studies have been especially risky due to the friability of vessel walls and other tissues.

A B C

Fig. 13–32. *Ehlers-Danlos syndrome, type IV*. (A) Note prominent eyes and outstanding ears. (B) Varicosity of veins. (C) Ecchymotic type showing severe bruising following minor trauma over knees and shins. Elbows also commonly involved. Skin and joint hyperextensibility are less marked than in severe type (see Table 13–2). (A,B from HMB Sulh et al, Clin Genet 25:278, 1984; C from P Beighton, The Ehlers-Danlos Syndrome, Heinemann, London, 1970.)

Other problems. Intracranial aneurysms (44), cardiac involvement and vascular aneurysms with spontaneous coronary artery rupture and cardiac tamponade (10,12), cavitary pulmonary lesions and spontaneous pneumothoraces (11,15), ocular complications (30), atlantoaxial subluxation (14), and gingival recession may be associated with EDS IV. Life span is generally shortened. Death has been reported from 12 to 60 years, most commonly during the 20s and 30s. Causes of death include exsanguination from major artery rupture, sepsis from bowel rupture, and shock from uterine rupture (2,3). Lewkonia and Pope (19) described joint contractures and acroosteolysis.

The complications of pregnancy, in addition to vascular rupture and uterine rupture, include tearing of vaginal tissues during delivery (1,28,29,43,53). Life-threatening complications may occur in 15%–20%.

Prenatal diagnosis. Prenatal diagnosis is available for most families with EDS IV. This requires a combination of histology, electron microscopy, and type III collagen protein or *COL3A1* gene analysis. Prenatal diagnosis by amniocentesis, chorionic villus biopsy, or termination of pregnancy is potentially hazardous in affected females owing to the inherent fragility of cervical, uterine, or abdominal blood vessels (31,32,43).

Ehlers-Danlos syndrome type V (X-linked)

In 1968, Beighton (1) first reported this entity in two English families. Skin hyperextensibility was striking, but joint hypermobility, most evident in the fingers, was mild. Cutaneous fragility, bruising, and scarring tended to be moderate. Both spheroid and molluscoid pseudotumors were found. There was generalized musculoskeletal weakness (dorsal kyphosis, hernia, pes planus, genu valga). Intestinal obstruction and brain abscess were noted in two male sibs. Clinical features were generally similar to those affected with type II (1–9). Life span is probably normal and female carriers are asymptomatic (2). The condition is extremely rare (9).

Inheritance is X-linked recessive. In 1985, Beighton and Curtis (4) conducted a follow-up of the two families studied by Beighton (1) in 1968. In family 1, a sister of 3 affected males had an affected son.

Biochemical studies have failed to identify any abnormality. According to Steinmann et al (9), X-linked inheritance is questionable and, thus, the existence of this disorder as a distinct entity remains to be proven.

Ehlers-Danlos syndrome VI (ocular-scoliotic type)

Pinnell et al (27), in 1972, described a form of EDS characterized by a deficiency of lysyl hydroxylase, an enzyme that modifies collagen.

Inheritance is autosomal recessive. Intermediate values of lysyl hydroxylase have been found in heterozygotes. Prenatal diagnosis is possible (9). The gene for lysyl hydroxylase has been mapped to 1p36.3, and has been cloned and sequenced (15). EDS VI may be caused by either a low level or a low activity of the enzyme (14,39). The hydroxylysine content of defective tissues varies between 5% and 50%, being

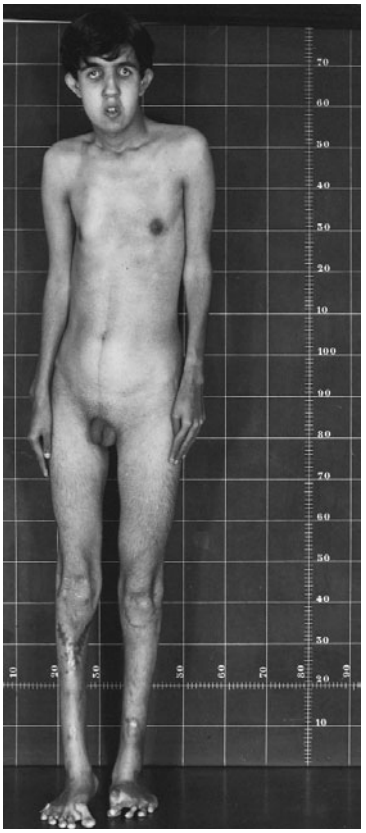

Fig. 13–33. *Ehlers-Danlos syndrome, type VI.* Note scoliosis, arachnodactyly, scarred skin, splayed feet. (From B Steinmann et al, Helv Paediatr Acta 30:255, 1975.)

lowest in skin, bone, and tendon. Mutations include partial duplications (16,17,28), homozygous or compound heterozygous exon skips (14,17), or a homozygous stop codon (19).

Many manifestations of EDS VI are similar to those of EDS I, namely moderately severe articular hypermobility, skin hyperextensibility, and connective tissue fragility. In addition, there are spinal malalignments and ocular complications. In a few persons with EDS VI, vascular and gastrointestinal catastrophes have been documented (5,32). Height is originally normal, but scoliosis develops during adolescence and is progressive. Often there is also delay in motor development (38) (Figs. 13–33 to 13–36).

EDS VI is very heterogeneous since, in a few individuals, normal lysyl hydroxylase activity has been documented (21). The latter form of the condition is designated EDS VIB to distinguish it from the classical form, EDS VIA, in which the enzyme is abnormal. Ihme et al (20) suggested three forms of EDS VI: (a) severe form, with absent hydroxylysine in skin collagen and low lysyl hydroxylase activity in skin, (b) clinically similar form but with normal skin hydroxylysine and low activity of lysyl hydroxylase in skin fibroblasts, and (c) predominantly ocular form with normal biochemical findings (40).

Both type A (9,11,22,23,27,34,36,38) and type B (21,28,30,33) patients exhibit very severe hypotonia in the newborn period, generalized loose-jointedness with dislocation, excessively stretchable soft velvety bruisable and fragile skin, and scoliosis at birth which is progressive (35,39). Ambulation may be lost in the second or third decades. Some patients may exhibit arterial rupture (39) (Figs. 13–37 to 13–41).

Epicanthic folds, blue sclerae, keratoconus, keratoglobus (Fig. 13–36A), and angioid streaks are common (8). Glaucoma (36) manifests in the third decade, with retinal detachment in the fourth. The cornea or globes may rupture following minimal trauma. Corneal diameter may be somewhat reduced (33). Moderate myopia is common, as is hearing loss.

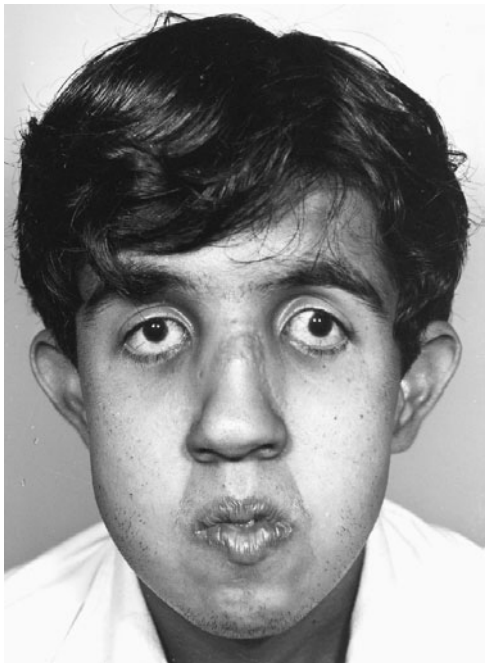

Fig. 13–34. *Ehlers-Danlos syndrome, type VI.* Microcorneae, ectropion, downward-slanting palpebral fissures, puckered mouth. (From B Steinmann et al, Helv Paediatr Acta 30:255, 1975.)

Differential diagnosis. Neonatal *Marfan syndrome, osteogenesis imperfecta, Larsen syndrome*, pseudoachondroplasia, and *cartilage-hair hypoplasia* may present with joint laxity. The autosomal recessive syndrome of pseudogliomatous blindness, osteoporosis, and mental retardation may also have retinal detachment and ligamentous laxity (25).

Brittle cornea, blue sclera, keratoglobus, keratocornea, and microcornea in various combinations have autosomal recessive inheritance with or without joint laxity, fractures, macrocephaly, hearing loss, and mild mental retardation (1–7,10,12,13,18,24,32,37) (Fig. 13–41A). Robertson (30) discovered that 50% of his patients with keratoconus had joint hypermobility (Fig. 13–41B).

Stein et al (33) and Hyams et al (18) reported Tunisian patients with red hair and suggested that this finding may be part of the syndrome. Zlotogora et al (41) noted two groups of patients with "brittle cornea syndrome." The first group was composed of 5 families of Tunisian Jewish origin. The second group consisted of 9 families that came from various ethnic backgrounds. These persons had a normal distribution of hair color. Zlotogora et al (41) suggested that the locus for the gene may be closely linked to the locus for a gene responsible for hair color, with linkage disequilibrium in Tunisian Jews. Royce et al (31) described the syndrome of brittle cornea and blue sclerae in a Syrian girl with consanguineous parents. She had red hair and joint hyperextensibility but with normal collagen lysyl hydroxylation.

Laboratory findings. Diagnosis is made by measuring total urinary hydroxylysyl and lysyl pyridinoline cross-links after hydrolysis (26). Dermal hydroxylysine estimation can also be carried out (36).

Ehlers-Danlos syndrome type VII [autosomal dominant (arthrochalasia type congenita) (EDS VIIA and B) and autosomal recessive (dermatosparaxis type) (EDS VIIC)]

In 1973, Lichtenstein et al (18) identified a distinct type of EDS in three isolated patients who presented with severe hypermobility of joints with multiple dislocations, especially of the hips, and scoliosis which in large part accounted for the short stature (Fig. 13–37). The skin was soft, but only mild hyperelasticity and fragility of the skin were observed. The facies was characterized by epicanthic folds, depressed nasal bridge, and micrognathia. Similarly affected isolated examples had been described earlier by Hass and Hass (12). Several affected sibs in a large consanguineous kindred have also been documented (2). Later, other clinical presentations were reported (19,26,30,38) and anomalies of collagen I structure and metabolism were discovered (25). The so-called Viljoen type is a variant of EDS VIIB.

Classification. There are two distinctive phenotypes of EDS VII, one overlapping with EDS I/II and the other with congenital cutis laxa (3,25). The former is mild, affecting mostly the joints. It exhibits autosomal dominant inheritance. The latter is severe, affects primarily the skin, and is autosomal recessive.

The autosomal dominant group is further divided into EDS VIIA and EDS VIIB. This subdivision is based on abnormal type I procollagen maturation, that is failure to remove the amino-terminal propeptide. In type VIIA the proα(1) (COL1A1) chain is affected, and in type B it is the proα2(1) (COL1A2) chain (7,9,10,27,31). Type VIIC is caused by mutations in procollagen 1 N-proteinase (8). Hood et al (16) demonstrated markedly variable clinical expression in individuals with the same structural mutation. Collagen fibril morphology is only marginally abnormal. The fibers are angular in transverse section rather than forming cauliflowers (25).

The autosomal recessive form is termed EDS VIIC. Its clinical manifestations (Fig. 13–38) (11,21,28,30,38) include late closure of anterior fontanel, hypertrichosis, large-appearing eyes, blue sclerae, thickened eyelids, prolapsed upper lip mucosa, easy bruising, predisposition to fractures, soft velvety hyperextensible skin which sags, suggesting *cutis laxa*, large fontanels with wide sagittal and metopic sutures, micrognathia, and umbilical hernia (22,30,38). It is caused by deficiency of procollagen N-peptidase (19) due to homozygosity or compound heterozygosity of mutant alleles. Electron microscopic examination of the skin shows collagen sheets rather than fibrils, and characteristic distortions resembling hieroglyphics (30,38). The basement membrane is defective with an apparent paucity or focal absence of type IV collagen and laminin (23,28).

Biochemical and molecular pathology. EDS VII thus results from two distinct but related mechanisms of faulty collagen type I metabolism. Either there is a structural abnormality at the protease cleavage site [proα1(I)-EDS VIIA or proα2(I) EDS VIIB, respectively] or a defect in the protease (EDS VIIC) (15,19,25,30).

Collagen type I is a heterotrimer with two α1(I) and one α2(I) chains and loss of either the pNa1 or pNa2 peptidase cleavage sites may cause EDS VIIA or EDS VIIB, respectively (5,9,24,26).

The faulty conversion of procollagen to collagen in EDS VII was described by Lichtenstein et al (18), Steinmann et al (31), and Cole et al (6,7). Until the end of 1997 (1), the total number of individuals reported with this condition has been 16. All of them, except one, have mutations in the splice-junction sequences of the COL1A1 gene (three individuals) or the COL1A2 gene (12 individuals). These affect the splice donor site of COL1A2 (14,17,20,32–38), the last nucleotide of the exon in the COL1A2 gene (37), the splice-acceptor site of the COL1A2 gene (4), or the last nucleotide of exon 6 in the COL1A1 gene (8,35).

Differential diagnosis. EDS VII and *osteogenesis imperfecta* (OI) overlap clinically and biochemically (13,29). In EDS VII, cutaneous fragility and ligamentous laxity predominate, while in OI, the bone fragility is the most striking finding (25). EDS VIIC resembles *Ascher syndrome*.

Ehlers-Danlos syndrome type VIII (periodontal type)

In 1972, McKusick (13) first identified a form of EDS characterized by periodontal disease, scarring of pretibial skin unaccompanied by joint hypermobility, and hyperextensibility of skin. Stewart et al (21), in 1977, and later others (2,3,5,9,15), reported kindreds with marfanoid habitus, unusual facies, severe skin fragility and bruisability, and evidence of visceral involvement (duodenal rupture), moderate or marked skin stretchability, or normal facies and body habitus with only slight joint hypermobility. Other examples are less certain (1,4,8,12,17). Hartsfield et al (6,7) questioned the existence of this type since they found periodontitis in type IV, and Lapière and Nusgens (10) found reduced type III collagen in type VIII. The case of Müsebeck et al (14) is not documented and may be type IV. However, a large comprehensive study is needed.

The onset of skin fragility is noted in childhood. Ecchymoses following slight trauma resolve except for the pretibial areas. These heal with tender yellow-brown atrophic wrinkled scars as necrobiosis lipoidica diabeticorum or venous stasis (Fig. 13–39A). DDAVP may be used to treat hemorrhagic symptoms (22).

Histology of the skin lesions shows a granulomatous collagen degeneration resembling necrobiosis lipoidica diabeticorum (11).

The periodontal disease appears after puberty and the permanent teeth are usually lost by the third decade (Fig. 13–39B). There is collagen degradation as judged by gingival resorption and cutaneous inflammation (16,18,19). Leukodystrophy may also be associated with EDS VIII (20).

Inheritance is autosomal dominant.

Ehlers-Danlos syndrome type X (fibronectin defect)

Arneson et al (2), in 1980, described four sibs affected with joint hyperextensibility, easy bruising, thin hyperextensible skin, and with "fish-mouth scarring," but with normal texture. The parents were unaffected. The clinical presentation of these patients resembles that of EDS II and III. Narrow pelvis (4) and mitral valve prolapse (2,4) were also noted.

A platelet aggregation deficit resulted in petechiae. The common link to joint hypermobility and platelet malfunction was thought to be defective fibronectin and the addition of affinity-purified normal human fibronectin restored aggregation.

Only one family with this phenotype has been reported. A variety of clotting abnormalities (1,7) as well as defective platelet size and function (3,5,6) have been described in other EDS families.

Other types of Ehlers-Danlos syndrome

Since Ehlers-Danlos syndrome (EDS) is a very heterogeneous condition, some patients cannot be included in the present general classification. However, they must be mentioned for additional information, and to encourage further reports and better delineation.

Hernández et al (5) described a variant of EDS, the progeroid form, in two unrelated males where, in addition to joint and skin hyperextensibility, increased bruisability, hernia, and papyraceous scars, the patients had mental retardation, wrinkled facies, short stature, fine curly hair, scant eyebrows and lashes, telecanthus, prominent pinnae, periodontitis, winged scapulae, cryptorchidism, multiple nevi, and varicose veins. In both patients, paternal age was increased, suggesting de novo dominant mutation. A third case was described in 1981 (6), stressing the progeroid facial appearance and mental retardation; and two more patients were reported in 1986, with histopathologic ultrastructural studies (7).

Kresse et al (9), in 1987, reported a 4-year-9-month-old boy with features of both Ehlers-Danlos syndrome and progeria. The child had delayed mental development, short stature, osteopenia, defective deciduous teeth, loose but elastic skin, delayed wound healing with thin, atrophic scars, scanty scalp hair, hypotonic muscles and hypermobile joints. Quentin et al (10) demonstrated that fibroblasts from this patient had a deficiency in galactosyltransferase that catalyzes the second glycosyl transfer reaction in the assembly of the dermatan sulfate chain. There was an unsubstituted xylose residue in the glycosaminoglycan-free core protein secreted by the patient's fibroblasts.

In 1982, Friedman and Harrod (3) described a seemingly dominant condition in mother and son. They presented with large hernias, positional foot deformities, severe scoliosis, mild joint hypermobility, periodontitis, aortic rupture, and allergy problems (eczematoid dermatitis and asthma). Both had facial asymmetry, prominent nasal bridge, and small jaw. The mother had "cigarette paper" scars over her legs.

Conditions suggesting autosomal recessive inheritance have also been reported. In 1979, Beasley and Cohen (1) described two sibs with a "new" and presumably autosomal recessive form of EDS. The parents were consanguineous. The patients had hyperelasticity of the skin of the hands, very mild scarring, generalized hyperextensibility of the joints, dislocation of the hips, and decreased muscle mass (Fig. 13–40).

Shohet et al (11), in 1987, reported two unrelated patients with minor signs of EDS but with severe aortic change. One of the patients had a similarly affected sister and brother.

Hamada et al (4) reported four unrelated patients with soft-tissue contractures and moderate joint hypermobility, skin hyperelasticity, and skin fragility.

Carter and Sweetnam (2) reported dominant inheritance in several families that suffered from recurrent dislocation of joints. Horton et al (8) described a large family in which many members had joint laxity, most also having congenital hip dislocation. It was the recommendation of a workshop convened in Berlin in 1986 by Beighton that the Ehlers-Danlos designation be used for joint hypermobility with skin changes, leaving this as a separate category. Thus, familial isolated generalized articular hypermobility (Fig. 13–41) should not be confused with Ehlers-Danlos syndrome.

Dyskeratosis congenita (Zinsser-Engman-Cole syndrome, Scoggins type, autosomal recessive type)

Dyskeratosis congenita (DC) is characterized by reticular skin hyperpigmentation, nail dystrophy, lacrimal duct obstruction, leukoplakia of mucous membranes, bone marrow hypofunction, and predisposition to malignancy. It was first described by Zinsser in 1906 (66). The second report was in 1926 by Engman (22), who was not aware of Zinsser's earlier publication. Cole et al (9), in 1930, further delineated the condition and brought it to the attention of dermatologists. The syndrome has been seen in all races (55). Excellent reviews have been published by Sirinavin and Trowbridge (55), Womer et al (62), and Rodermund et al (53).

Dyskeratosis congenita is a heterogeneous condition, but most cases (90% are males) are compatible with X-linked recessive inheritance (Zinsser-Engman-Cole syndrome) (7,11,12,14,20,30,53,55,56,63). The gene has been assigned to Xq28 (3,12,36). It has been reported in monozygotic twins (8).

Scoggins et al (54), in 1971, described a black family with autosomal dominant inheritance (dyskeratosis congenita, Scoggins type). Three generations were affected with male-to-male transmission. Tchou and Kohn (59), in 1982, also suggested the existence of an autosomal dominant form.

Juneja et al (32) and others (7,21,41,57) described an autosomal recessive form in a brother and sister.

In 1995, Drachtman and Alter (20) analyzed the clinical manifestations of dyskeratosis congenita according to mode of inheritance. They classified all sporadic male cases and families with multiple male cases as X-linked recessive and families with affected male and female members in consecutive generations as autosomal dominant. All sporadic female cases, including those where both male and female sibs were affected and those with parental consanguinity in only one generation, were classified

(Based on C Sirinavin and AA Trowbridge, J Med Genet 12:339, 1975.)

as autosomal recessive. They noted variation in the clinical phenotype with the mode of inheritance. The X-linked recessive and autosomal recessive cases had a higher incidence of nail dystrophy, cutaneous manifestations, and leukoplakia, with a median age of diagnosis of around 15 years. Autosomal dominant cases had milder clinical manifestations, with a median age at diagnosis of 28 years and the median survival of more than 50 years. However, it is not yet clear whether the autosomal recessive and dominant forms represent separate genetic loci. Moreover, the sporadic female cases categorized in the autosomal recessive group may be carriers of the X-linked recessive form.

In 1998, Heiss et al (31) described a novel gene in Xq28, *DKC1*, which is responsible for X-linked dyskeratosis congenita. They identified six different mutations. Dyskerin, the protein coded for by *DKC1*, is multifunctional and possibly involved in rRNA biosynthesis, ribosomal subunit assembly, and/or centromere/microtubule binding (38,42). Hoyeraal-Hreidarsson syndrome is allelic (64).

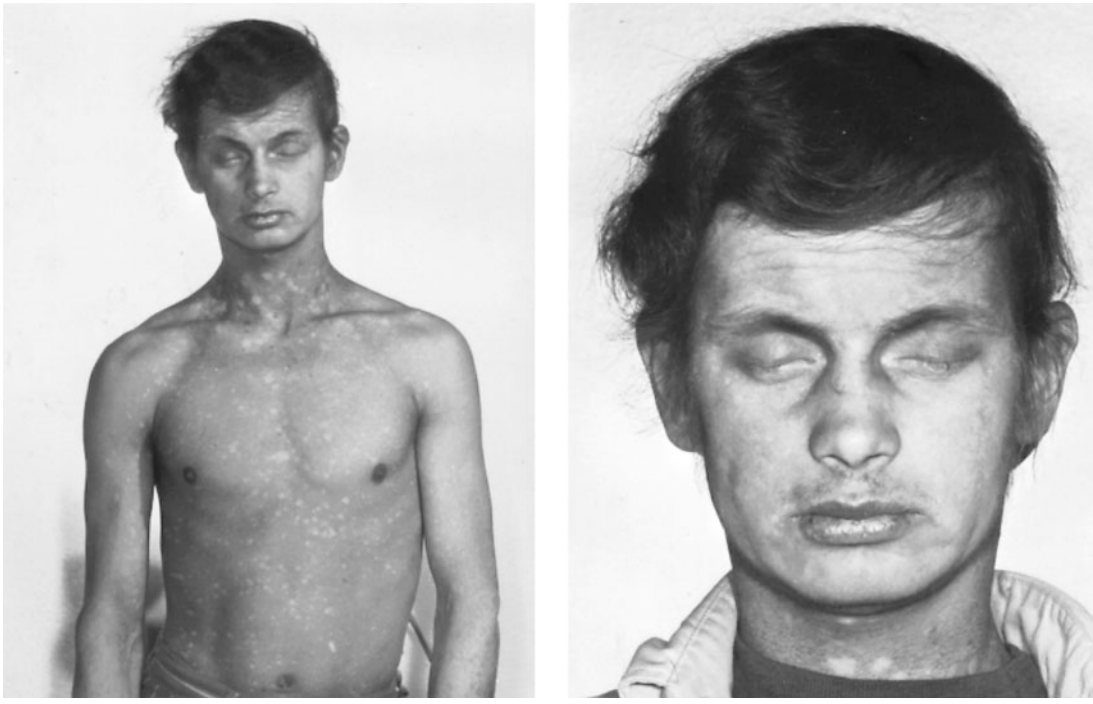
Highly skewed X inactivation was observed in white blood cells, cultured skin fibroblasts, and buccal mucosa from female carriers of DC (16). The skewed X inactivation was reported by other investigators as well (23,60). Ferraris et al (23) hypothesized that, at least in some DC families, the selective pressure in the cells of carriers may be strong enough to result in negative selection of cells expressing the mutant alleles, resulting in extreme skewing of X-chromosome inactivation in cells of hematopoietic descent.

General aspects. Dyskeratosis congenita is a misnomer, since the syndrome is neither dyskeratotic nor congenital. Oral lesions are characterized by a decreased number of keratinosomes associated with decreased epithelial turnover. As a rule, cutaneous manifestations of the disorder are not present during infancy.

The clinical features are summarized in Table 13–3. Findings in hemizygous males are usually manifest at 5–10 years. Skin, nail, and mucosal changes appear during the first decade. Patients are usually frail and have generalized growth retardation. Hematopoietic manifestations appear in about 50% and develop during the second and third decades. Neoplasms may evolve over the third, fourth, or fifth decades. Mean age at death is about 25 years, usually from infections (50%), gastrointestinal bleeding (20%), or malignancy (30%).

Skin and its appendages. The most prominent skin changes closely resemble those found in poikiloderma vasculare atrophicans, involving especially the face, neck, upper arms, and chest and appearing around 8–9 years of age. A prominent reticulated hyperpigmentation of the skin is present, usually described as gunmetal in color (Fig. 13–42). Microscopy

Fig. 13–42. *Dyskeratosis congenita*. (A) Whitish, irregular atrophic areas, increased pigmentation, and telangiectasia, producing appearance that resembles poikiloderma vasculare atrophicans. (B) Sparse scalp hair, blepharitis due to absence of lacrimal puncta.



A **B**

A B

Fig. 13–43. *Dyskeratosis congenita.* (A,B) Note shriveled, shrunken appearance of nails.

reveals atrophy of the epidermis and subcutaneous tissues, accompanied by capillary hyperplasia. Melanin pigment is heavily deposited in macrophages, especially near blood vessels. Characteristically, no inflammatory exudate is evident (10,13,26–29,50,55). Cutaneous macular amyloidosis has been noted in one instance (41), a Blaschko line pattern in another (4).

Hyperhidrosis of the palms and soles, but with generalized hypohidrosis elsewhere, has been described in about 90%, and palmar and plantar keratoses have occurred in approximately 70%. Cutaneous bullae are noted in 25%. Acrocyanosis of the hands and feet has been reported in about 55% (10,13,22,25–29,50,55,62).

Nail dystrophy, initially longitudinal ridging and splitting (Fig. 13–43), found in 98%, is not of the same degree in all digits, and fingernails tend to be more severely affected than toenails (55). Nail changes are usually seen by 10 years of age. They become progressively dystrophic and are often lost.

The hair is thin and lusterless in 50%. Sparse body hair in some cases is related to hypogonadism. Eyelashes and eyebrows may be absent (50,55).

Dokal et al (19) found that skin fibroblasts in primary cultures were abnormal both in morphology (polygonal cell shape, ballooning, and dendritelike projections) and in rate of growth (with a doubling time around twice that of normal). No significant difference from the normal was found in fibroblast survival after using 4 clastogens and gamma radiation.

Mucosal manifestations. Leukoplakia, a feature in 87%, can occur on any mucosa, but most commonly affects the oral mucosa prior to puberty (44).

Crops of vesicles and bullae appear on the oral mucosa. They are recurrent and essentially painless. Because of moisture and maceration, they rupture early, leaving ulcerated areas, with epithelial tags along the margin. After several attacks, the mucosa becomes atrophic and the tongue loses its papillae and appears smooth. Under ultraviolet light, the normal orange fluorescence of the tongue is absent. Eventually, the mucosa becomes thickened, fissured, and white (Fig. 13–44). Mucosal atrophy or stenosis has been described in the mouth, esophagus, anus, urethra, and vagina (7,26,27,33,46,55,58,64,65).

Eyes and ears. Chronic blepharitis, ectropion (9,13,22,27,47,50) and profuse tearing due to keratinization with obstruction of the lacrimal points (80%) (27,46,49) around puberty have been described. Rare ophthalmologic findings, such as congenital cataracts, are reviewed by Womer et al (62). Thinning of the eardrum, malformation of the middle ear, and sensorineural hearing deficit have been reported (11,13).

Gastrointestinal features. Although not often emphasized, many patients have gastrointestinal problems. Abdominal pain, vomiting and dysphagia, occurring in about 60%, may result from esophageal strictures or diverticula (60%). Severe diarrhea, sometimes bloody because of mucosal ulcerations, has been noted. Liver disease is relatively common, and hepatic cirrhosis has been recorded (5,7,13,27,57,62).

Hematologic manifestations. Two serious complications of dyskeratosis congenita are anemia and cancer (44). With progressive pancytopenia, the age of onset and the rapidity of progression are variable, but the mean age of onset is about 15 years. A decline in the platelet count usually occurs first, followed by progressive anemia and, later, granulocytopenia. (7,9,17,27,32,55,56,62).

Bone marrow failure has been reported in approximately 50% of cases of dyskeratosis congenita (6,18,39,40) and is the principal cause of early mortality (36). It increases to more than 80% by age 30 years (37). In some patients, symptoms related to aplastic anemia may precede the diagnosis of DC (24). Friedland et al (25) considered the disorder to be a stem cell defect. Following in vitro clonogenic assays, as well as long-term bone marrow culture studies, Marsh et al (43) suggested also that the symptoms of aplastic anemia in DC may be due to a defect at the level of the hematopoietic stem cell.

In 1997, Vulliamy et al (60) found that in families with X-linked DC, the hematopoiesis of heterozygous female cells expressing the normal DC allele had a growth advantage over the cells that express the mutant allele.

It has also been noted that splenomegaly occurs in 45% and hepatomegaly in 15% of patients, although they are not sites of extramedullary hematopoiesis.

Reichel et al (51) found reports of 15 cases of elevated fetal hemoglobin in association with dyskeratosis congenita and added another case.

Fig. 13–44. *Dyskeratosis congenita.* Thick white plaques of labial and lingual mucosa.

Immunologic manifestations. A wide range of immunoglobulin abnormalities may occur, including decreased IgG and IgM with normal IgA, normal IgG and IgA with slightly decreased IgM, and increased IgG. Abnormalities of cell-mediated immunity have also been noted (28,59). Autopsies have revealed a number of findings, including lymphoid depletion with absence of the primary germinal follicles and occasionally fibrosis of lymph nodes. The high frequency of opportunistic infections is further evidence of abnormal immune function (48,55,62).

Neoplasia. Malignancy occurs in about 17%, the mean age being about 30 years. Carcinoma of the oral mucosa has been recorded at least six times. Other tumors have included carcinomas of the nasopharynx, esophagus, rectum, cervix, and vagina (34). Squamous cell carcinoma of the hand, adenocarcinoma of pancreas, and Hodgkin's disease have also been reported (8–10,12,13,26,50,55,62). Tchou and Kohn (59) noted an increased rate of cancer in unaffected sibs. It has been suggested that p53 expression is a good marker to predict premalignant change in skin keratoses (46).

Central nervous system. Mental deficiency occurs in about 40% and is mild to moderate in degree. Schizophrenia has also been reported (13,27,55).

Other findings. Small testes and small penis have been observed in about 40% of males. Rarely, hypopituitarism, enlarged thyroid, and secondary hypogonadism have been recorded (55).

A variety of skeletal anomalies have been documented including joint deformities, incomplete closure of vertebral arches, and other minor skeletal anomalies (56). Radiolucencies in the shafts of long bones with coarse trabeculation in the metaphyses have been reported (55,62). Osteoporosis, bone fragility, and aseptic necrosis of the hip have been encountered, usually but not always attributable to steroid therapy (62). Intracranial calcifications were reported by several authors.

The teeth are subject to early decay (50,55), periodontal disease (13,65), and malformation and malposition (13,50). These changes, with rare exception, have never been well documented and merit further investigation.

Differential diagnosis. Differential diagnosis includes Fanconi syndrome, *Rothmund-Thomson syndrome, Bloom syndrome, xeroderma pigmentosum* and *focal dermal hypoplasia*. Similarities and differences between dyskeratosis congenita and Fanconi syndrome have been discussed by a number of authors (55,57). An allelic variant called Hoyeraal-Hreidarsson syndrome consists of infant lethality, intrauterine growth retardation, mental retardation, cerebellar hypoplasia, pancytopenia, and oral mucosal lesions (64).

Laboratory findings. Chromosomal breakage has been reported by several authors (7,30,35,48). These findings have been questioned and most karyotypes have been normal (11,62). Pai et al (49) showed that fibroblasts, peripheral blood lymphocytes, and transformed lymphoblasts of six DC patients and an obligate DC heterozygote showed more chromatid breaks than controls exposed to bleomycin during the G2 phase of the cell cycle. Unsynchronized DC fibroblasts also showed decreased survival following bleomycin treatment. Lymphocytes from DC patients, when treated with bleomycin for the final 24 hours of culture showed more chromatid and chromosome damage than normal. Ning et al (45) found that the mean number of chromosome breaks per cell in bleomycin-treated lymphocytes was higher in patients with DC and in obligatory heterozygotes than in normals. However, unequivocal heterozygote detection was not possible because of overlapping values.

De Bauche et al (15) reported increased frequency of chromatid breaks and chromatid gaps after X-radiation during the G-2 phase of the cell cycle. Bone marrow metaphases and fibroblasts from some patients showed numerous unbalanced chromosomal rearrangements (dicentrics, tricentrics, and translocations) in the absence of any clastogenic agents. A higher rate of chromosomal rearrangements was found in the older patients (19).

Dyskeratosis benigna intraepithelialis mucosae et cutis hereditaria

In 1977, From et al (1) described a father and son with a hereditary syndrome that affected the skin, oral mucosa, and bulbar conjunctiva.

Fig. 13–45. *Dyskeratosis benigna intraepithelialis mucosae et cutis hereditaria*. Skins showing brownish papules with keratotic plugs. (From E From et al, J Cutan Pathol 5:105, 1978.)

The disorder was characterized by recurrent nonseasonal conjunctivitis, epiphora, and photophobia. Suppurating, red or brown, papular eruptions with central keratotic plugs (not greater than 10 mm in diameter) were found on the scrotum, buttocks, and body, the majority being on the lower limbs (Figs. 13–45 and 13–46).

Trauma-provoked papular lesions and Koebner phenomenon were also noted. Verrucalike lesions were described on palmar and plantar surfaces of the hands. Leukoplakic lesions were seen on the buccal mucosa. Total tooth loss (both primary and permanent) at an early age due to edematous hypertrophic gingivitis was noted (Fig. 13–47).

Pathologic findings in mucous membrane epithelium and epidermis included moderate to severe simple hyperplasia, acantholysis (with no "corps ronds"), moderate hyperortho- and/or hyperparakeratosis, and benign dyskeratosis characterized by pronounced single cell keratinization. No true dysplasia was found (Fig. 13–48). Gingival biopsy showed focal intraepithelial microabscesses and spongiform edema.

The syndrome is distinguished from *Papillon-Lefèvre syndrome* and *dyskeratosis congenita*.

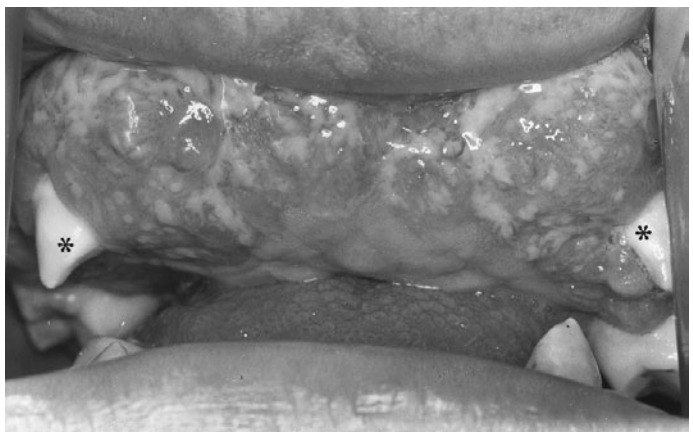
Pachyonychia congenita (Jadassohn-Lewandowsky syndrome, Jackson-Lawler syndrome)

Although sketchy earlier reports exist (31), Jadassohn and Lewandowsky (29), in 1910, described a patient with a syndrome of dystrophic fingernails and toenails, palmoplantar keratosis and hyperhidrosis, follicular keratosis, and oral leukokeratosis. In 1951–1952, Jackson and

Fig. 13–46. *Dyskeratosis benigna intraepithelialis mucosae et cutis hereditaria*. Hyperkeratotic papules of scrotum. (From E From et al, J Cutan Pathol 5:105, 1978.)

Lawler (28) reported a family with pachyonychia congenita, palmoplantar hyperkeratosis, hyperhidrosis, and follicular keratosis. However, oral leukokeratosis was not observed. In addition, their patients had cutaneous cysts and natal teeth. Corneal dystrophy was found to be an exclusive feature of this type. Some had recurrent flexural infections. Kindreds with characteristics shared by both syndromes have been reported (4,50), suggesting that the differences originally observed represented variability of expression. The opposite point of view, that of separating the disorder into four subtypes, was expressed by Feinstein et al (19) in 1988. Since the publication of all of these reports, mutations at different keratin loci have been identified for the variants described by Jadassohn and Lewandowsky (type 1) (29) and Jackson and Lawler (type 2) (28). However, because

Fig. 13–47. *Dyskeratosis benigna intraepithelialis mucosae et cutis hereditaria*. Marked hypertrophic gingivitis at 2.5 years. (From E From et al, J Cutan Pathol 5:105, 1978.)



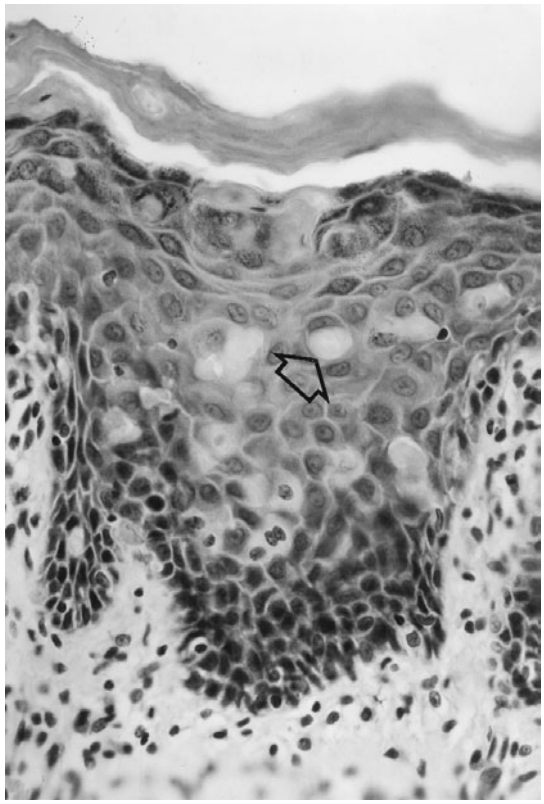


Fig. 13–48. *Dyskeratosis benigna intraepithelialis mucosae et cutis hereditaria*. Photomicrograph of buccal white lesion showing hyperparakeratosis and numerous dyskeratotic cells (arrow). (From E From et al, J Cutan Pathol 5:105, 1978.)

of the significant overlap in the clinical manifestations, the two disorders will be presented together.

Pachyonychia congenita has a frequency of about 0.7/100,000 population (20), with a 9:5 male predilection (38). At least 350 cases have been reported. An excellent statistical study is that of Kansky et al (31).

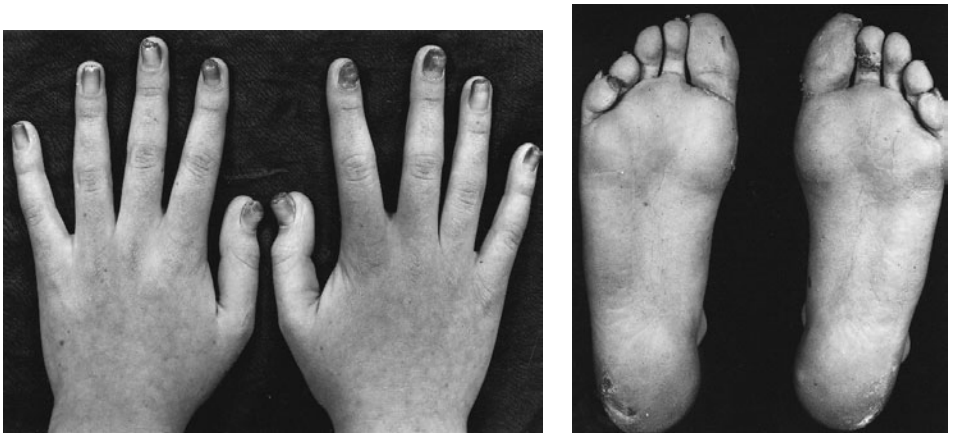
Heredity and molecular genetics. Pachyonychia congenita of both types 1 and 2 has autosomal dominant inheritance. An autosomal recessive form was suggested but has not been definitively confirmed (11,24, 47).

Mutations associated with pachyonychia congenita were identified in different keratin genes. Those involving the *KRT6A* gene at 12q13 and the *KRT16* gene at 17q12–q21 were found to cause pachyonychia congenita type 1 (3,7,21,37,52). Mutations of the *KRT17* gene at 17q12–q21 were associated with pachyonychia congenita type 2 (21,37,41,48). We have no information on gene localization for types 3 and 4 which, in addition to nail changes, include cheilitis, corneal dystrophy, and cataracts. Type 4 exhibits hearing loss and mental retardation (33a).

KRT16 and *KRT17* gene mutations may also produce phenotypes with little or no nail changes. *KRT16* mutations may present as focal non-epidermolytic palmoplantar keratoderma and *KRT17* mutations can result in a phenotype resembling steatocystoma multiplex (15).

Skin and skin appendages. At birth (14,23,53) or soon after (54), fingernails and toenails become thickened, tubular, and hard (Fig. 13–49A). Their undersurfaces fill with a horny, yellow-brown material that causes the nail to project upward from the nail bed at the free edge. Pachyonychia congenita has also been reported in the absence of other syndrome abnormalities (10).

Hyperhidrosis of the palms and soles nearly always occurs, but the rest of the skin is dry and may be described as ichthyotic. Palmar and plantar hyperkeratoses are noted in 40%–65% during the first few years of life.



A B

Fig. 13–49. *Pachyonychia congenita*. (A) Note thickening and elevation of fingernails at free edge in 13-year-old female. (B) Note ruptured blisters of toes and heels. Often there is severe hyperkeratosis of soles. (From ADM Jackson and SD Lawler, Ann Eugen 16:141, 1951.)

During warm weather, bullae appear on the feet, especially on the plantar surfaces of the toes and heels and along the sides (2,51). They burst, may become infected, are very painful, and often make walking difficult (3,33,45,53) (Fig. 13–49B). Diffuse hyperkeratosis of the perineum has also been described (8,14).

During the first few years of life, pinhead-sized follicular papules appear over the elbows, knees, popliteal areas, and buttocks (2,51). In the center of each papule, a horny plug is seen. Verrucous lesions may also occur in the same areas. The skin is thickened because of acanthosis and parakeratosis, especially about the pilosebaceous apparatus. Follicles and sweat pores are dilated and plugged with imperfectly cornified and partly degenerated horny material (2). The hair may be dry (10) and twisted (59), and alopecia has been reported (32,38). Cornoid lamellae have been described in a patient in whom oral leukokeratosis was not well documented (44,58).

Electron microscopic studies of involved skin from the knee (52) show increased number and thickness of tonofibrils, an increased number of desmosomes throughout the epidermis, intracellular and extracellular edema, and large, abnormal keratohyaline granules. These findings are consistent with a defect in keratinization. Similar findings were reported by Thormann and Kobayasi (54). Ultrastructural findings have also been described by Thomas et al (53). Eruptive villus cysts, especially of the head, neck, and upper chest, appear around puberty (5,6, 16,18,22,28,33,38,39,46,56,57,60) (Fig. 13–50). Most reports do not adequately describe the histology of the skin cysts. However, Hodes and Norins (26) and Velasquez and Bustamante (56) determined that their patients had steatocystomas, whereas Clementi et al (13), Chapman (10), and Soderquist and Reed (49) determined that the cysts in their patients were epidermal inclusion cysts.

Laryngologic and esophageal abnormalities. Hoarse voice and thickening of the posterior commissure of the larynx have been noted (1,13,14,28,33,38,62). Patients may have multiple, white exophytic lesions involving the ventricles, true cords, subglottis, and interarytenoid area (13,23). Hagemann and Vogel (25) reported dysphagia due to esophageal involvement.

Oral manifestations. White patches are observed on the dorsum and lateral borders of the tongue (3,17,23,32,35,50,55,61). The buccal mucosa at the interdental line, the gingiva, and palate can also be involved (10,17,23,35,61,63) (Fig. 13–51). These lesions may be present as early as the first decade.

On microscopic examination, the oral mucosa is characterized by hyperparakeratosis, acanthosis, and generalized intracellular vacuolization of the epithelial cells (4,63).

Natal teeth are frequently present (4,5,8,26,28,42,45,49,56).

Differential diagnosis. Late onset of the nail disease has been described by several authors and designated as pachyonychia congenita tarda (9,27,34,40,43).

Haber and Rose (24) reported two male sibs with bullae on hands and feet, oral leukokeratosis, leukonychia of fingernails, onycholysis of fingernails and toenails with slight elevation by subungual debris, keratoderma of palms and soles, and hyperkeratotic papules on dorsa of fingers and toes. There were no skin cysts, and natal teeth were not mentioned. Parents were normal but consanguineous. Although this disorder might be autosomal recessive, X-linked inheritance cannot be excluded.

Chong-Hai and Rajagopolan (11) reported a child born to consanguineous parents and presenting with the nail abnormalities of pachyonychia congenita, palmar and plantar hyperhidrosis, blistering of feet, follicular keratoses, epidermal cysts, and oral leukokeratosis. Autosomal recessive inheritance was suggested, but a new dominant mutation cannot be excluded.

Tidman et al (55) have also described a variant with cutaneous amyloidosis and hyperpigmentation. This dominant form is associated with diffuse rippled pigmentation of the neck, axillae, waist, buttocks, and

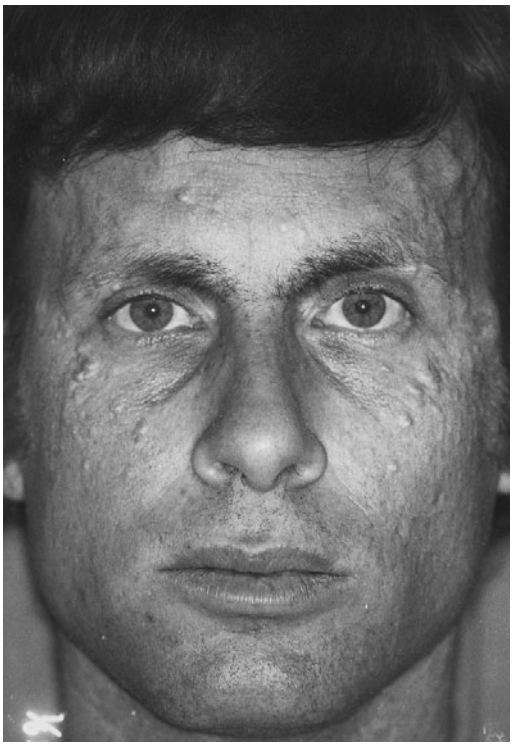

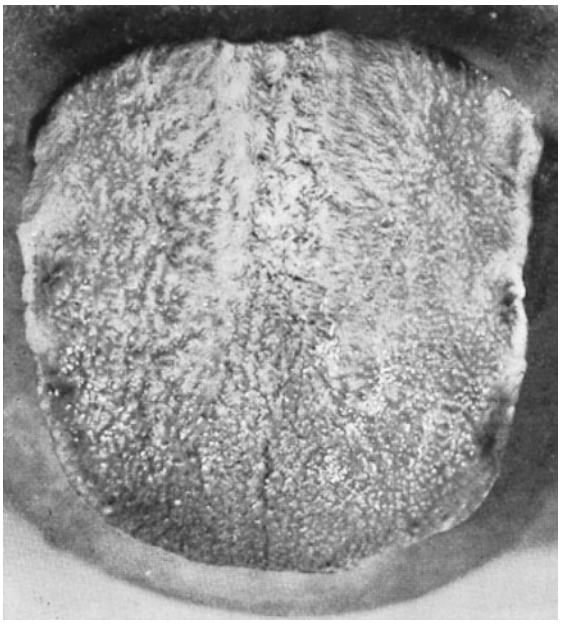

Fig. 13–51. *Pachyonychia congenita*. Thickening of oral mucosa, especially that of tongue and buccal mucosa.

thighs that fades with age. Histologic and ultrastructural examination of the hyperpigmented skin has revealed pigmentary incontinence and deposition of amyloid within the papillary dermis.

In pachyonychia congenita, the nail changes are distinctive. However, the oral leukokeratosis is nonspecific and is also seen in *dyskeratosis congenita, hereditary benign intraepithelial dyskeratosis*, white sponge nevus (30), and *leukoplakia, tylosis and esophageal carcinoma*. Other clinical findings serve to distinguish these disorders from pachyonychia congenita. Patients with *endocrine-candidiasis syndrome* also have diffuse white lesions of the oral mucous membranes.

The frequency of natal teeth unassociated with other abnormalities has been estimated to range from 1:700 to 1:30,000 (average 1 per 3000) white newborns (12,33). However, natal teeth occur in 1 in 28 Native Americans of Athabascan origin (44). Natal teeth may also be found in *Ellis–van Creveld syndrome, Hallermann-Streiff syndrome*, and *Wiedemann-Rautenstrauch syndrome*. McDonald and Reed (36) reported a kindred in which natal teeth and steatocystoma multiplex were inherited as a dominant condition.

Hereditary benign intraepithelial dyskeratosis (Witkop-Von Sallmann syndrome)

Hereditary benign intraepithelial dyskeratosis (HBID) was described in a North Carolina triracial isolate (white-black-Indian) in 1960 by Witkop et al (9) and by Von Sallmann and Paton (6). The patients reported by Yanoff (10) had already been included in the study by Witkop et al (9). The chief components are plaques of the bulbar conjunctiva and oral mucosal thickenings clinically similar to white folded hypertrophy.

The syndrome has autosomal dominant inheritance with complete penetrance (9). The gene maps to 4q35 where there is a duplicated region (1,1a).

Eyes. About the limbus, both nasally and temporally, there are foamy gelatinous plaques, more superficial than pterygia, on a hyperemic bulbar conjunctiva (Fig. 13–52). The eye lesion is usually noted within the first year of life (5,6). There is vernal exacerbation with shedding in the summer or fall.

The dyskeratotic process may involve the cornea, producing blindness from shedding and resultant vascularization of this structure (3). Photophobia and itching of the eyes, especially in children, is common.

Oral manifestations. The oral mucosal thickenings are asymptomatic. They appear as soft white folds and plaques, resembling white sponge nevus (11,12). Though the thickenings appear at birth, they are

Fig. 13–52. *Hereditary benign intraepithelial dyskeratosis*. Superficial gelatinous plaques on hyperemic bulbar conjunctiva involving limbus and cornea. (Courtesy of CJ Witkop Jr, Minneapolis, Minnesota.)

mild, increasing in severity to about 15 years of age. There is no tendency for the plaques to undergo malignant degeneration (Fig. 13–53).

Differential diagnosis. White sponge nevus and oral lesions of pachyonychia congenita bear a distinct clinical resemblance to those of HBID.

Laboratory aids. Tissue sections of buccal or conjunctival scrapings treated with Giemsa stain are characteristic (Fig. 13–54). Acanthosis, vacuolization of the stratum spinosum, and intraepithelial dyskeratosis characterized by waxy eosinophilic cells called "tobacco cells" and "cell-within-a-cell" pattern are noted. These latter changes are especially evident in Papanicolaou-stained smears (2,6) (Fig. 13–55).

Witkop and Gorlin (8) found similarities in oral smears from HBID and keratosis follicularis (Darier-White disease). The grains of the latter

Fig. 13–53. *Hereditary benign intraepithelial dyskeratosis*. Leukokeratosis of buccal mucosa. (Courtesy of CJ Witkop Jr, Minneapolis, Minnesota.)

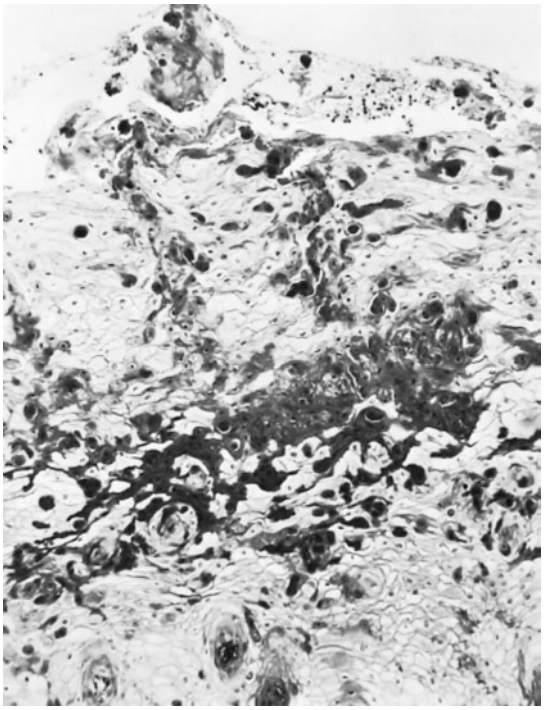

Fig. 13–54. *Hereditary benign intraepithelial dyskeratosis*. Section of buccal mucosa demonstrating dyskeratotic eosinophilic cells in acanthotic epithelium (Giemsa stain). (Courtesy of CJ Witkop Jr, Minneapolis, Minnesota.)

resemble the "tobacco cells" of the former, and the corps ronds of the latter resemble the "cell-within-a-cell" body seen in the syndrome under discussion. However, the "cell within a cell" is far more common in oral smears of HBID, and, in addition, one rarely sees the small blue parabasilar cells so often noted in keratosis follicularis. Witkop (7) pointed out that patients receiving methotrexate and 5-fluorouracil also exhibit the "cell-within-a-cell" phenomenon in exfoliated buccal cells.

Ultrastructural studies have revealed numerous vesicular bodies in immature dyskeratotic cells, and the disappearance of cellular interdigitations and desmosomes in mature dyskeratotic cells (4).

Leukoplakia, tylosis, and esophageal carcinoma (Clarke–Howel-Evans syndrome)

In 1954 Clarke and McConnell (1) and, later, Clarke et al (2,3) and Howel-Evans et al (7) reported the association of hyperkeratosis of palms and soles (tylosis) and carcinoma of esophagus in two families. Subsequently, Tyldesley and Hughes (21) and Tyldesley (20) reexamined members of these two kindreds and found, in addition, oral leukoplakia. Several other kindreds with this constellation of abnormalities have been reported (4,5,10–14,17,18).

Inheritance is autosomal dominant. The gene has been mapped to 17q24 (6,9,12,19). Ruhrberg et al (15) proposed that the chromosomal localization of the human envoplakin gene (*EVPL*) to the region of the tylosis-esophageal cancer gene at 17q25 raises the possibility that loss of envoplakin function could be responsible for this condition. Envoplakin is a membrane-associated precursor of the epidermal cornified envelope. It is considered to link desmosomes and keratin filaments to the cornified envelope.

Skin. The age of onset of palmar and plantar hyperkeratosis is usually during the second decade of life (7), although onset between 1 and 5 years of age has been suggested (5) (Fig. 13–56). The tylosis is diffuse, may be yellow, and is sometimes associated with hyperhidrosis. In some women, the feet alone have been reported to be affected (5,7). Ritter and Petersen (14) and others (4) also described hyperkeratotic nodules on the distal and proximal interphalangeal joints and hyperpigmentation and hyperkeratosis on the upper parts of the arms.

Gastrointestinal tract. Squamous cell carcinoma of the esophagus develops in 95% of individuals by age 65. The age of onset may be as early as the fourth decade (7). Although the lower third of the esophagus is the most common site, the lesion may originate in the middle or upper third (7) (Fig. 13–57).

Oral manifestations. Clinical leukoplakia develops on the buccal mucosa (12,17) (Fig. 13–58) as early as 4 years of age as a diffuse gray-white lesion. On microscopic examination, parakeratosis, spongiosis of the superficial layer of the epithelium, and acanthosis are noted; no atypia

A B

Fig. 13–56. *Leukoplakia, tylosis, and esophageal carcinoma*. (A) Palmar hyperkeratosis. (B) Plantar hyperkeratosis. (A,B from W Howel-Evans et al, Q J Med 27:413, 1958.)

is seen. In older patients, lesions are smaller and more discrete; however, more diffuse regions may also be found. Ultrastructural studies demonstrate intranuclear electron-dense particles, similar to those found in nuclei of epithelium from the esophageal carcinomas (22).

Differential diagnosis. Many syndromes have associated hyperkeratosis of palms and soles. These include *hyperkeratosis palmoplantaris and periodontoclasia in childhood (Papillon-Lefèvre syndrome)* and *hyperkeratosis palmoplantaris and attached gingival hyperkeratosis*. Yesudian et al (23) reported a large kindred in which tylosis was present at birth. Inheritance was autosomal dominant. The tylosis was not associated with hyperhidrosis. Three members developed squamous cell carcinoma of the tylotic skin in the third decade of life; one of these three also developed squamous carcinoma of the lower end of the esophagus at age 40. The oral cavity was not described. The *Schöpf syndrome*, in addition to palmoplantar keratosis, has small cysts of marginal eyelids, hypotrichosis, and onychodystrophy; hypodontia was reported but not well documented. Shine and Allison (17) reported a family with onset of hyperkeratosis of the palms and soles at adolescence; there was no associated hyperhidrosis. Dysphagia had been noted since infancy. The proband developed esophageal carcinoma at the site of an esophageal stricture. Inheritance was autosomal dominant. Tylosis has been associated with bronchogenic carcinoma (16).

White lesions of the oral mucous membranes, similar to those seen in this syndrome, are also found in white sponge nevus (8), *hereditary benign intraepithelial dyskeratosis, pachyonychia congenita*, and *dyskeratosis congenita*.

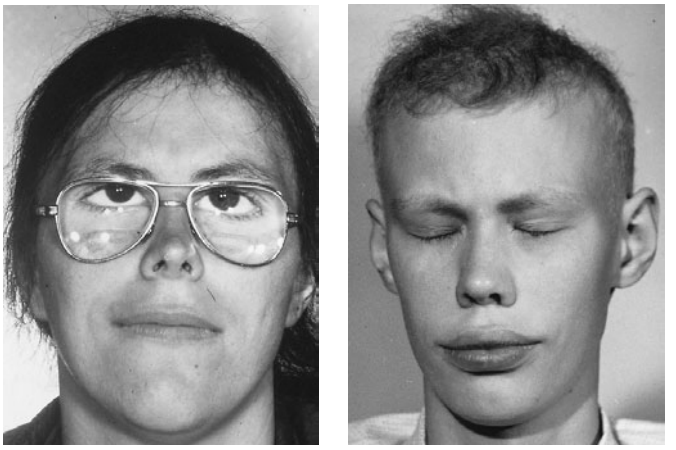
Mucoepithelial dysplasia syndrome (Witkop syndrome)

Witkop et al (4,6–9), from 1978 to 1982, described an autosomal dominantly inherited syndrome that involved the skin and various mucous membranes, eyes, and lungs.

Other families have also been reported (1–3,5), and RJ Gorlin has seen another kindred.

The disorder is heralded in infancy by severe tearing and photophobia. Corneal vascularization, development of a pannus, nystagmus, and cataracts first appear at 4–6 years of age, leading to blindness before puberty (Fig. 13–59). The oral, nasal, vaginal, urethral, anal, and bladder mucosae are fiery red (Fig. 13–60). Red erosive or granular periorificial mucosal lesions, noted by the end of the first year, tend to persist. The skin of the trunk and extremities (but not the hands and feet) is rough (follicular keratosis), and the scalp hair is scant (nonscarring alopecia). Patients often complain of easy burning on sun exposure.



A B

Fig. 13–59. *Mucoepithelial dysplasia syndrome*. (A,B) Sparse scalp hair, strabismus, photophobia, and cataracts. (Courtesy of CJ Witkop Jr, Minneapolis, Minnesota.)

Chronic rhinorrhea, upper respiratory tract infections, pneumonia, diarrhea, bladder infections with pyuria, and/or hematuria are common findings. Spontaneous pneumothorax is frequent in males, eventuating in terminal fibrocystic-type lung disease, cor pulmonale, and death in the third and fourth decades.

Mucosal biopsies show dyshesion, lack of keratinization, and dyskeratosis. Mucosal PAP smears principally exhibit numerous basal and parabasal cells (lack of epithelial maturation), nuclear atypia, and cytoplasmic vacuolization (Fig. 13–61). Ultrastructural changes suggest desmosomal and gap junction defects.

Hypohidrotic ectodermal dysplasia

The syndrome is characterized chiefly by hypohidrosis, hypotrichosis, and hypodontia. Charles Darwin (23) cited Wedderburn as having found the disorder in an Indian from the subcontinent. Thurnam (109), in 1848, also described the condition. According to Perabo et al (79), it may have been recorded as early as 1792 by Danz. Christ (13), in 1913, further defined it as a "congenital ectodermal defect," and Weech (119), in 1929, impressed by the depression of sweat gland function, coined the term "anhidrotic ectodermal dysplasia." We believe that "hypohidrotic" is more accurate a term. The frequency of occurrence is between 1/10,000 and 1/100,000 births (15,20). A most comprehensive survey is that of Airenne (2). A good discussion of classification is that of Pinheiro and Freire-Maia (83).

The syndrome usually (vide infra) has X-linked inheritance (17,41). The *EDA1* gene has been mapped to Xq12–q13.1 (31,122,123). There are apparently 12 exons. The gene isolated by positional cloning (53) codes ectodysplasia A, a transmembrane protein, with deletion mutations in collagenous repeats (8,46,53). Only a small percent of affected males can be detected by direct mutational analysis (31). A new splice form of the *EDA1* gene now permits diagnosis of nearly all cases (69). Males have full expression of the disorder. About one-third of female carriers exhibit no clinical changes (12a). Another one-third have minor expression, such as hypodontia, and the other one-third express the condition to a less severe degree than males. The teeth of carrier females may be deficient in number and/or have conical crown form. They may have reduction in body and scalp hair, and eczema. Sweating occurs in a patchy distribution, consistent with lyonization (17,80,82,84). About 80% of carriers have difficulty in nursing. Sofaer (99,100) suggested that 1 in 500 females with hypodontia in the permanent dentition and 1 in 50 with hypodontia in the deciduous dentition may be carriers for hypohidrotic ectodermal dysplasia. A remarkable report describes the disorder in monozygotic quadruplets (26).

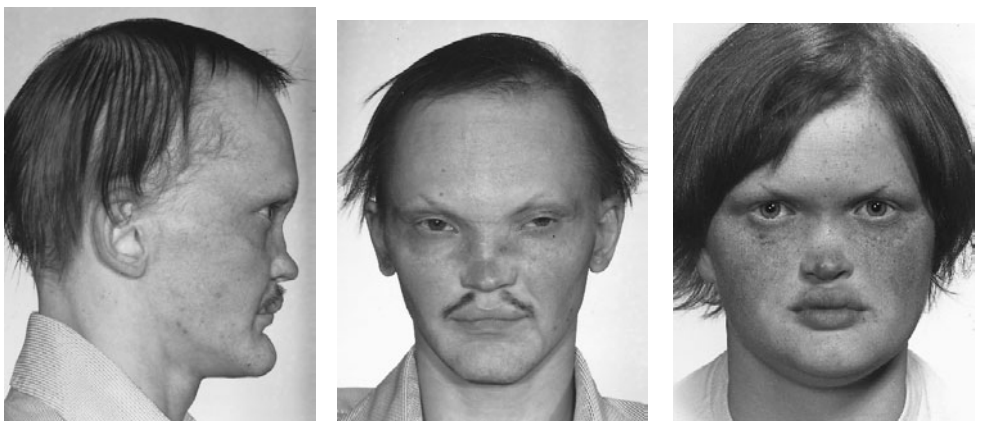
There have been a number of females with full expression of the syndrome. Some of these had balanced X/autosomal translocations, the break point being in the Xq12–Xq13.1 region (58,62,86). Other female examples clearly represent genetic heterogeneity. Passarge et al (77,78) reported a large consanguineous kindred with affected males and females. Gorlin et al (41), in 1970, reviewed all published examples of affected females and suggested the existence of an autosomal recessive form that could not be distinguished on clinical grounds from the X-linked form. For examples published prior to 1970, the reader is referred to Gorlin et al (41). Many additional autosomal recessive examples have been documented (3,7,22,28,49,51,54,56,68,72a,76,78,88,104,107,108,110,117); however, the first definitive molecular proof of an autosomal recessive form was not presented until 1997 by Munoz et al (71). The autosomal recessive and dominant forms map to 2q11–q13 (6,47,51,70,71).

Hypohidrotic ectodermal dysplasia has also been seen in Holstein-Friesian cattle (95).

Facies. Frontal bossing, usually marked, and depressed nasal bridge give added emphasis to the small size of the face. There are often fine linear wrinkles and pigmentation about the eyes (98). Due to absence of teeth, and resulting reduced vertical height, the lips are protuberant. The pinnae are often outstanding (79) (Fig. 13–62).

Cephalometric and anthropometric studies of hemizygotes and heterozygotes have shown a small lower facial height and depth, small palatal and cranial base widths, small malar bones, small calvarial height, prominent forehead, depressed nasal bridge, and high-set orbits (10).

Skin and skin appendages. A hallmark of this disorder is hypohidrosis. Because other physical features of this syndrome are not so apparent in the first year, the child may present with a "fever of unknown origin." Inability to sweat, because eccrine sweat glands are severely



A B C

Fig. 13–62. *Hypohidrotic ectodermal dysplasia*. (A,B) X-linked recessive form. Face is characterized by frontal bossing, depressed nasal bridge, thin hair, and periorbital increased pigmentation. (C) Female with autosomal recessive form. Note sparse hair and fine linear wrinkling around eyes. (From EC Passarge et al, Humangenetik 3:181, 1966.)

reduced in number, results in intolerance to heat, with severe incapacitation and hyperpyrexia after only mild exertion. The disorder is hypohidrotic rather than anhidrotic. Bizarre heat loss has been documented (89). The skin has been somewhat scaly or eczematous.

The skin is soft and thin. Dryness is often severe, because sebaceous glands are absent (52). Eczema is seen in 65%, especially during the early years of life (17). The body is usually devoid of lanugo hair. After puberty, the mustache and beard are described as normal, although axillary and pubic hair are frequently scant (65). Scalp hair is often blond, fine, stiff, and short. The eyelashes and, especially, the eyebrows are scanty or often missing. Female heterozygotes often exhibit sparse scalp hair, spotty sweating, random reduction in sweat pores, and a mosaic, patchy distribution of body hair (80). Happle and Frosch (43) noted that the hypohidrosis in heterozygotes follows Blaschko lines.

Nails are usually normal, but rarely may be spoon-shaped (119). Mammary glands may occasionally be aplastic or hypoplastic (65,75,112), and nipples may be rudimentary (65,75). Congenital absence of nipples in a putative heterozygote has been reported (12). There has been a report of sebaceous gland hyperplasia (74). Dermatoglyphic alterations have been described (87,116).

Eyes. Lacrimal gland function has been reported diminished in a few cases (60,67) and increased in others (81). There are no meibomian glands and, frequently, punctate epithelial keratopathy has been found (27). Congenital glaucoma has been noted in some patients (48,93); this association may have been coincidental or the patients may have had a syndrome different from hypohidrotic ectodermal dysplasia.

Otolaryngologic manifestations. Mucous glands in portions of the respiratory tract have been described as absent by some investigators (25). Pharyngeal and laryngeal mucosa may be atrophic, resulting in dysphonia (27,79,98). On laryngologic examination, breathy voice quality has been noted. Vocal folds appeared to close completely, although they are dry. Abnormal voice quality on spectrographic analysis has also been documented (19). Atrophy of the nasal mucosa associated with severe crusting and a fetid secretion (ozena) is frequent (27,60,79). These crusts may obstruct the nasal passages and make feeding difficult. Scintigraphic studies (63) have suggested an inflammatory process in the parotid glands.

Other findings. Several reports have noted that about 65% exhibit allergic disorders, especially eczema and asthma (17,98,113). Although rare, death may occur in infancy due to respiratory infection or hyperpyrexia (25). The latter may be accompanied by seizures. Pinheiro and Freire-Maia (81) noted deviation of some of the terminal phalanges of the hands and feet.

Oral manifestations. In hemizygotes, the most striking oral abnormality is absence of most deciduous and permanent teeth. Maxillary central incisors and canines usually have a conical crown form (Fig. 13–63). Frequently one or more molars may be present. More rarely, one or both jaws may be edentulous (94). Female heterozygotes exhibit reduction in numbers of teeth and smaller crown size than hemizygous males (20,63). Taurodontism is frequent (20). Because so many teeth are congenitally missing in hemizygous males, vertical dimension is reduced, and the lips are protuberant. The vermilion border is indistinct and pseudorhagades may be present (20,112).

The alveolar processes do not develop in the absence of teeth and, hence, are missing in those areas (30,94). Cephalometric studies have been limited in number (59,72,94) but have indicated that apart from defective alveolar growth, jaw and facial development is essentially normal. However, Ward and Bixler (118), employing cephalometric analysis in 16 affected individuals, found pronounced size reduction, compared to controls, in anteroposterior dimensions of the lower two-thirds of the face, in facial height, and in the size of the ears, nose, and mouth.

A few investigators have stated that the oral mucosa appears dry or that salivary secretion is diminished (30,37,98). Aplasia of intraoral mucous glands has been noted on microscopic examination (30).

B

Fig. 13–63. *Hypohidrotic ectodermal dysplasia*. (A) Hypodontia and conical crown tooth form in 14-year-old female. No other stigmata present; possible carrier of trait. (B) Dental radiographs showing hypodontia and conical form of tooth crowns.

Differential diagnosis. Freire-Maia and Pinheiro (33) have provided a comprehensive discussion of differential diagnosis. Although the physiognomy in hypohidrotic ectodermal dysplasia is distinctive, several features resemble those of other disorders. The nasal deformity and linear perioral scarring may suggest congenital syphilis. Conical or tapered teeth, as well as congenitally missing teeth, may be found in individuals who have no other abnormalities (isolated hypodontia, oligodontia); in many cases, this condition may be familial (29,32,36,98,106). Hypodontia or oligodontia with dominant inheritance has been mapped to 4p16 (114) and to 14q12–q13 (103) and recessive hypodontia to 16q12.1 (1). Absence of all permanent teeth may be inherited as an autosomal recessive trait (42). Conical teeth are also found in *acrodental dysostosis* (21). Congenital absence of numerous teeth as well as conical teeth may be seen in *Ellis-van Creveld syndrome, Hay-Wells syndrome, Rieger syndrome, Witkop tooth-nail syndrome*, Fried tooth and nail syndrome, and *incontinentia pigmenti*; however, other abnormalities should serve to distinguish these disorders from hypohidrotic ectodermal dysplasia.

A complex ectodermal dysplasia with autosomal recessive inheritance consists of melanoleukoderma with hypodontia, hypotrichosis, retarded growth, and mental retardation (8).

In the trichodental syndrome (92), an autosomal dominant disorder, patients have fine scalp hair that grows slowly, and sparse eyebrows distally; males have a high anterior hairline. Several teeth are congenitally absent, although not as many as in hypohidrotic ectodermal dysplasia. The nails are presumably normal, and no abnormalities in sweating have been described. Pinheiro et al (83) reported a mother and two children with sparse, thin, and brittle scalp hair from birth, scanty axillary and pubic hair, sparse eyebrows and eyelashes, mild palmoplantar keratosis,

multiple congenitally absent deciduous and permanent teeth, conically shaped maxillary central incisors, café-au-lait spots, and mildly dystrophic toenails. M Pierpont and R Gorlin (personal communication, 1998) have seen such a family. Two kindreds with autosomal dominant hypohidrotic ectodermal dysplasia have been described (5,49). Autosomal recessive hypotrichosis, pili torti, hypoplasia of teeth, and cutaneous syndactyly of hands and feet was reported by Wiedemann et al (120). The parents were consanguineous.

Aswegan et al (5) reported a six-generation family of 38 individuals with autosomal dominant hypohidrotic ectodermal dysplasia. The disorder maps to 2q11–q13 (5). The skin was smooth, dry, and thin. Scalp and body hair were thin and slow-growing. Eyebrows and eyelashes were sparse and sweating was decreased. Some deciduous and permanent teeth did not develop or erupted late or had conical crown form. Nails tended to be slow growing and split. The facies was not abnormal. It is possible that the family reported by Jorgenson et al (49) had still a different condition.

The reader is also referred to a paper by Solomon and Keuer (101) for a discussion of the ectodermal dysplasias.

Cole et al (18) reported sisters with alopecia, small conical teeth, hypoplastic nails, hypohidrosis, mottled skin, lamellar cataracts, and mental retardation. Freire-Maia and Pinheiro (33) called the disorder tricho-odonto-onycho-hypohidrotic ectodermal dysplasia and suggested autosomal dominant inheritance. *ANOTHER syndrome* consists of hypohidrotic ectodermal dysplasia, freckling, enteropathy, onychodystrophy, atopy, and hypothyroidism. There is pulmonary and upper respiratory infection due to a ciliary defect. However, normal facies and dentition are noted. Zadik et al (121) reported the combination of hypothyroidism, sparse hair, unusual facies, hypohidrosis, oligodontia, and dermoid cysts. One should exclude the recessive syndrome of *cleft palate, congenital hypothyroidism, and spiked hair*. Tuffli and Laxova (111) reported a mother and son with hypohidrosis, scalp defect at the vertex, hypoplastic nipples, onychodysplasia, and possible abnormalities of dentition; in addition, the mother was unable to lactate.

Teeth often do not erupt in *cleidocranial dysplasia* and never in *GAPO syndrome*. Shokeir (97) described a family in which failure of most permanent teeth to erupt was inherited as an autosomal dominant disorder.

Autosomal dominant hidrotic ectodermal dysplasia (*Clouston syndrome*) is characterized by normal sweat and sebaceous gland function, sparse hair, severe nail dystrophy, palmar and plantar hyperkeratosis, skin hyperpigmentation, especially over the joints, and normal teeth. Another dominantly inherited hidrotic ectodermal dysplasia is characterized by sensorineural hearing impairment, polydactyly, syndactyly, nail dystrophy, and teeth that have conical crowns (61,90). The patients described by Mannkopf and Hanney (66) as having ectodermal dysplasia were of several types. Their case 7 had *focal dermal hypoplasia*. Patients possibly similarly involved are those described by Šalamon and Milicevic (91) and Friederich and Seitz (35).

An apparently hidrotic form has been described with breast aplasia (29a). A patient that defies classification was seen by RJG. She had extremely sparse body and scalp hair, including eyelashes and eyebrows. Nails and breasts were deficient and enamel was missing from the teeth.

Anhidrosis and middle-life-onset-neurolabyrinthitis has been described as an autosomal dominant disorder (45). Isolated anhidrosis may have autosomal recessive inheritance (64). Dominantly inherited hypohidrosis and hyperpigmentation with hyperkeratosis (*Naegli syndrome*) is a recognized disorder (102). Isolated amastia may be inherited as a dominant trait (40). A number of patients with so-called autosomal recessive HED undoubtedly represent still other disorders (18,56).

Laboratory aids. The dental radiograph is invaluable in determining whether teeth are congenitally absent, or whether they are present but unerupted.

Decreased sweating may be demonstrated by the starch-iodine method (Minor test) (16,30), by pilocarpine iontophoresis (80), by the use of agar plates containing silver nitrate and potassium chromate (39), by altered electrical resistance of the skin (56), or by the use of *o*-phthalaldialdehyde in xylene (116) (Fig. 13–64). Sweat pore counting may be carried out by direct observation or by use of silicone rubber (Fig. 13–65) or cellulose acetate (44,50,57,73,80,115,116). Happle and Frosch (43) suggested that the entire back be tested using the starch-iodine method, the areas of hypohidrosis following Blaschko lines.

Fig. 13–64. *Hypohidrotic ectodermal dysplasia*. Sweating demonstrated by use of *o*-phthalaldialdehyde. (From J Verbov, Br J Dermatol 83:341, 1970.)

Frias and Smith (34) advocated counting sweat pores per linear centimeter, the normal number decreasing from about 40 in infancy to 20 in old age. Carrier mothers had fewer sweat pores, a finding confirmed by Verbov (116) and Settineri et al (96). Although few sweat pores or intradermal eccrine glands or ducts are found in male hemizygotes with the X-linked form, it has been stated that a significantly decreased number are noted in both affected males and females with the autosomal recessive type (77). Heterozygotes with the autosomal recessive form have somewhat reduced pore counts (55,77). Identification of functioning sweat pores in carriers can be done by thermography (14).

Davis and Solomon (24) described some degree of cellular immunodeficiency in hypohidrotic ectodermal dysplasia. IgA has been normal in serum and saliva (98).

Hypohidrotic ectodermal dysplasia has been diagnosed prenatally by biopsy on fetoscopy (4,11,38) and by molecular means using flanking genes (105).

Hypohidrotic ectodermal dysplasia and central nervous system malformations

Soekarman and Fryns (2), in 1993, described a male with hypohidrotic ectodermal dysplasia, internal hydrocephalus, partial hypoplasia of the cerebellum, cleft palate, and severe mental retardation. The anterior fontanelle was widely patent. Fryns et al (1), in 1989, reported a somewhat similar condition (vide infra).

Hypohidrotic ectodermal dysplasia, hypothyroidism, and agenesis of corpus callosum

Fryns et al (2), in 1989, described a male with unusual facies, hypohidrotic ectodermal dysplasia, hypothyroidism, frequent respiratory and eye infections, and agenesis of the corpus callosum. Severe mental retardation and enlarged head were evident. An ectopic thyroid was found at the foramen cecum. In 1993, Soekarman and Fryns (4) reported another male with similar findings. In addition, he had cleft palate, cerebellar hypoplasia, and dacryocystitis and suffered from recurrent respiratory infections. Devriendt et al (1), in 1996, noted another male with severe mental retardation, macrocephaly, agenesis of corpus callosum, cerebellar hypoplasia, and similar face. The mother was mildly affected. The facies was characterized by relative macrocephaly, frontal bossing, low nasal bridge, hypertelorism, downslanting palpebral fissures, sparse scalp hair, and eyebrows and lashes. The teeth were small and sometimes with conical crowns. The anterior fontanel is late in closing. One patient had trichorrhexis nodosa (3).

Inheritance may be X-linked or, possibly, autosomal dominant. All but one are males, and a mother was mildly affected in one case (1).

Hypohidrotic ectodermal dysplasia, hypothyroidism, and ciliary dyskinesia (ANOTHER syndrome)

Pabst et al (3), Morris et al (2), and Pike et al (4) reported sibs with hypohidrotic ectodermal dysplasia, hypothyroidism developing in childhood, enteropathy, nail dystrophy, freckling (urticaria-like skin pigmentation), and atopy. The hair, wispy at birth, became lost. Pulmonary and upper respiratory infection due to a ciliary defect was found (3). Eyelashes and teeth were normal. This combination was called ANOTHER syndrome (*A*lopecia, *N*ail dysplasia, *O*phthalmic complication, *T*hyroid dysfunction, *H*ypohidrosis, *E*yelids and *E*nteropathy, and *R*espiratory tract infections) (4).

Inheritance appears to be autosomal recessive.

One must exclude *cleft palate, congenital hypothyroidism, and spiky hair* (1). This autosomal recessive disorder was also seen with choanal atresia and bifid epiglottis. Probably unrelated is the syndrome of congenital hypothyroidism, cleft palate, subpalpebral dermoid cysts, dacryostenosis, and oligodontia (5). Probably also unrelated is the recessive syndrome of *hypohidrotic ectodermal dysplasia, hypothyroidism, and agenesis of the corpus callosum*.

Hypohidrotic ectodermal dysplasia, unusual facies, cataracts, and mental and motor retardation

Freire-Maia et al (1), in 1975, reported a girl with trichodysplasia (dry brittle hair, absent eyebrows and lashes, hypohidrosis, and absent body hair), frontal bossing, depressed nasal bridge, normal teeth, follicular keratosis of skin, hyper- and hypochromic skin pigmentation, and nuclear cataracts. Psychomotor retardation and growth retardation were evident.

Ectodermal dysplasia and cleft lip/palate (Margarita Island syndrome)

Abramovitz-Ackerman et al (1) described a disorder seen in 27 patients from seven families from Margarita Island off the coast of Venezuela.

Hair is sparse, short, and brittle. Eyebrows and lower eyelashes are scant. There is complete alopecia by adulthood (2).

Over 90% had corkscrew hair and follicular plugging of the scalp. Seventy-five percent had keratosis pilaris, xerosis, and eczema. Palmoplantar keratoderma (100%), cutaneous syndactyly (65%), and nail dysplasia (60%) were seen. Sweating was normal.

Malar hypoplasia, anteverted pinnae, cleft lip/palate (65%) with broad or flat philtrum and dental abnormalities were also frequent.

Inheritance is autosomal recessive. The frequency on the island is 1 per 2,000. The gene has been mapped to 11p23 (3).

There is distinct resemblance to *Zlotogora-Oğur syndrome*. They are allelic (4).

"Pure" hair-nail-type ectodermal dysplasias

"Pure" ectodermal dysplasias are developmental disorders affecting only tissues of ectodermal origin. Three different pure ectodermal dysplasias involving only hair and nails have been described to date (1,3,7,8).

The first of these three pure ectodermal dysplasias is known as "pili torti and onychodysplasia," an autosomal recessive disorder (3). This condition presents with congenital onychodystrophy and severe hypotrichosis, nearly resulting in atrichia universalis. The hair is brittle. On scanning electron microscopy, it shows twisting.

The second pure ectodermal dysplasia affecting nails and hair is an autosomal dominant condition described as "hair-nail dysplasia" (7). This condition is characterized by varying degrees of hypotrichosis with thin, fragile, slow-growing, sparse hair and nail dystrophy with short, fragile, spoon-shaped nail plates. Hypotrichosis involves the whole body. The scanning electron microscopy reveals "stretched monilethrix hairs."

The third type has congenital nail dystrophy, hypotrichosis in frontotemporal regions of the scalp, associated with folliculitis decalvans of the nape of the neck. It has been reported in a woman and her son, suggesting autosomal dominant inheritance (1). In this condition, irregular scleroatrophic patches lacking hair and follicles are present at the vertex of the scalp and nape. These are associated with follicular pustules at the periphery. The nail abnormalities are observed on all the digits. They exhibit micronychia, onychorrhexis, and a triangular shape of the nail plate resulting in a hypoplastic and dystrophic appearance. The main finding in the toenails is micronychia and onychorrhexis (1). Scanning electron microscopy of hairs demonstrated abnormal hair shafts with longitudinal grooves and constrictions, resulting in a "branch of dry wood" appearance. Twisting along the longitudinal axis of the shaft was observed, and hair casts were noted. There was also an abnormally increased density in cuticular cells.

The differential diagnosis comprises the "onychotrichodysplasia and chronic neutropenia" syndrome, an autosomal recessive ectodermal dysplasia with congenital hypotrichosis, trichorrhexis nodosa, and nail dystrophy (6,9). Other previously described disorders should also be considered (2,4,5).

Ectodermal dysplasia and cerebellar ataxia

Klingmüller and Kirchhof (3) reported four males affected with what appears to be typical hypohidrotic ectodermal dysplasia, but, in addition, they exhibited cerebellar ataxia, probably independently inherited.

Georgmaneanu et al (2) described a female with progressive spinocerebellar ataxia, curly thin short dense hair exhibiting monilethrix and a somewhat unusual facies (hypertelorism, flattened nose with wide base, prominent nostrils, large mouth, thick lips, and small, widely spaced teeth). Rushton and Genel (4) described male and female sibs with ataxia due to olivopontocerebellar degeneration, mental retardation, hearing loss, hypogonadotrophic hypogonadism, short stature, and widely spaced teeth with conical crown form. Baraitser et al (1) reported two brothers with cerebellar ataxia and an ectodermal dysplasia characterized by sparse thin hair, deep-set eyes, triangular face, pes cavus, dysarthria, normal intelligence, inguinal hernia, and oligodontia.

Although grouped and compared by Baraitser et al (1), we see little resemblance among these families.

Ectodermal dysplasia and arthrogryposis

Coté et al (2), in a brief note, described a syndrome of arthrogryposis and ectodermal dysplasia. Several additional examples (1,3,5) have been added. We suspect that the case described by Parker et al (4) has the same disorder.

A B

Fig. 13–66. *Ectodermal dysplasia and arthrogryposis*. (A,B) Note thin sparse hair which exhibits pili torti. (Courtesy of ID Young, Nottingham, England.)

Stature has been below the 3rd centile. Generalized arthrogryposis has been a nearly consistent feature. Kyphoscoliosis has also been noted (1,5). Dilated cardiomyopathy was documented once (4).

The skin is thin and bruises easily (2,5). Some patients have hypohidrosis (3,5). The nails break longitudinally (2,5). The hair may be thin and sparse with pili torti (1–3) (Fig. 13–66). The teeth may be reduced in number (5) and have amelogenesis imperfecta (2,5).

Inheritance is autosomal recessive, there being affected sibs and parental consanguinity (5).

Ectodermal dysplasia, syndactyly, and mental retardation

Ilyina et al (1) noted a female with mild mental retardation, aplasia cutis congenita of scalp, large palpebral fissures, broad nasal bridge, open mouth, dysmorphic pinnae, syndactyly of fingers 3–4/toes 2–3, and severe onychogryposis. The hair was short and stiff with sparse eyebrows. There was some resemblance to *Margarita Island syndrome*.

Ectodermal dysplasia, lipoatrophic diabetes, and acrorenal field defect (AREDYLD syndrome)

Pinheiro et al (2), in 1983, employed a best-forgotten acronym, AREDYLD, to report a syndrome of lipoatrophic diabetes, ectodermal dysplasia (generalized hypotrichosis, natal teeth, dysplastic deciduous teeth, absent permanent dentition, aplasia/hypoplasia of breasts, and mild hypoplasia of renal calyx) in a female. The fifth metacarpal was markedly short in one hand. Other anomalies included hepatosplenomegaly, hypoplasia of labia minora, enlarged clitoris, bowing of tibia, and mild scoliosis. Breslau-Siderius (1) reported a female with ectodermal dysplasia, lipoatrophy, diabetes mellitus, and amastia. Mesiodens and oligodontia were also found. There was also decreased sweating.

Parental consanguinity was found in one case (2), but both were isolated female patients.

Hidrotic ectodermal dysplasia (Clouston syndrome)

Jacobsen (9), in 1928, first reported a family with atrophic nails, sparse, absent, or downy hair, and rough scaly skin. Clouston (2), in 1929, found that the patient belonged to a large French Canadian kindred. There are many subsequent reports of this and other families (3–5,7, 10,12,14,17,19–21). Rajagopalan and Tay (17) described a large Chinese kindred. See Fraser and Der Kaloustian (3a) for history.

Inheritance is autosomal dominant. Expression is variable, dysplastic nails being the most common feature. The gene has been mapped to 13q11–q12.1 (11,11a,16).

Body hair, in general, is fine, brittle, or sparse, and scalp, axillary, and pubic hair is often absent. Females are often completely bald, while males are more variable, hair loss ranging from focal alopecia to total balding (Fig. 13–67). Palmoplantar hyperkeratosis (keratoderma) is often present. The extensor surface of the finger joints may occasionally be hyperpigmented. Sweating is normal. The nails are thick, discolored, and hyperconvex with onycholysis (Fig. 13–68). The fingers may be clubbed. Ultrastructural studies of hair showed disorganizations of hair fibrils with loss of cuticular cortex (3). The teeth are normal (7).

Halal et al (6) reported autosomal recessive inheritance of similarly affected individuals who also had mental retardation. Turnpenny et al (18) described autosomal dominant inheritance of hidrotic ectodermal dysplasia affecting the skin and hair. However, oligodontia, natal teeth, and acanthosis nigricans were also present. Nail dystrophy was mild.

Christianson and Fourie (1) reported an autosomal dominant syndrome resembling Clouston syndrome, but there was absence of hyperkeratosis of the palms and soles and no skin abnormalities. Hazen et al (8) reported a hidrotic ectodermal dysplasia in which there were premature cortical cataracts and angular cheilitis. We suspect an *endocrine candidosis syndrome*. Pinheiro and Freire-Maia (15) described an autosomal dominant hidrotic ectodermal dysplasia characterized by hypotrichosis but mildly dystrophic nails. Mégarbané et al (13) reported a large kindred with autosomal recessively inherited hidrotic ectodermal dysplasia characterized by marked oligodontia, fine hair, and dystrophic nails.

CHILD syndrome

Zellweger and Uehlinger (25) appear to be the first to describe an "osteochondromatosis with nevus ichthyosiformis" that was unilateral. Happle et al (12) coined the term CHILD syndrome to represent *C*ongenital *H*emidysplasia, *I*chthyosiform erythroderma, and *L*imb *D*efects.

About 35 examples have been described (1–25), all but two (16,25) being females. Happle et al (10,14,164) postulated that the disorder is X-linked dominant, lethal in the male, and that survival depends on the child being a mosaic (9). Mother-to-child transmission has been noted (14). Affected sibs have been reported (6). Grange et al (7) have shown a deficiency of 3β-hydroxysteroid-$\triangle^8$,$\triangle^7$-isomerase in patients with CHILD syndrome. This makes CHILD syndrome and X-linked chondrodysplasia punctata to be allelic. Mutations in NSDHL, the gene that encodes the X-linked component of sterol-4-demethylase complex, have been demonstrated (19). Happle et al (16a) believe that diagnosis in the case of Grange et al (8) was incorrect and that there is only the NSDHL gene involved.

Skin. Erythematous scaly plaques are present at birth unilaterally and sharply demarcated by the midline. The plaques may extend with age. The plaques follow the lines of Blaschko (Fig. 13–69). The ichthyosiform nevus has a predilection for body folds. The lesions may also disappear with age.

Nails. There is suprabasal staining of basal layer keratin (AE1) (4,17,18). Presumably, the basal cells fail to switch to produce a more differential keratin. Involucrin-positive cells are greatly increased.

Extremities. There is ipsilateral shortening of one or both limbs. Hypoplasia of long bones is most common, but one can also find syndactyly, polydactyly, scoliosis, contractures, and hypoplasia/aplasia of hand or foot (3,21).

Punctate epiphyseal calcification may be found in the involved limbs.

Other findings. Malformed kidney has been described (3,22).

Diagnosis. Moss and Burn (20) suggested that CHILD syndrome was the same as ILVEN syndrome. This was vigorously denied by Happle (12), who, we believe, convincingly argued that they are a distinctly different form of nevus (*I*nflammatory *L*inear *V*errucous *E*pidermal *N*evus).

Hair-nail-skin-teeth dysplasias (dermo-odonto-dysplasia, pilo-dento-ungular dysplasia, odonto-onycho-dermal dysplasia, odonto-onychial dysplasia, tricho-dermo-dysplasia with dental alterations)

There are an inordinately large number of rare disorders involving dysplasia of hair, nails, skin appendages, and teeth in binary, ternary, or quaternary combination (1,2,4–10). These have been dealt with exhaustively by Freire-Maia and Pinheiro (3). Only a few can be briefly described here (2,5–10).

A B

Fig. 13–70. *Tricho-dermo-dysplasia with dental alterations*. (A) Hypotrichosis of scalp, sparse lateral eyebrows. (B) Severe oligodontia in daughter of woman seen in A. (From M Pinheiro et al, Clin Genet 29:332, 1986.)

Pinheiro et al (6) reported sibs with hair loss ranging from almost total alopecia involving scalp, eyebrows, lashes, and axillary and pubic hair to less severe involvement: finger and toenail dystrophy, palmoplantar hyperkeratosis, supernumerary nipples, and enamel hypoplasia (Fig. 13–70). All had short stature, and two sibs had a frontoparietal skull defect. Autosomal recessive inheritance was suggested. The disorder was termed *tricho-dermo dysplasia with dental alterations*.

We are not entirely convinced that the disorder is different from *odonto-onycho-dysplasia* with alopecia also reported by Pinheiro et al (7), except for greater severity in the latter. They described sisters with probably consanguineous parents. At birth, both sibs had sparse scalp hair that soon fell out. The sparse body hair distribution was similar to that noted in *tricho-odonto-onychial dysplasia*. Hypodontia, microdontia, and enamel hypoplasia were found (Fig. 13–71).

Pinheiro et al (8) described an autosomal dominant disorder with trichodysplasia, hypodontia, onychodysplasia, and bilateral inward deflection of the fourth toes. The disorder was termed *tricho-dermo-dysplasia*. A four-component disorder was titled *tricho-odonto-onycho-dermal syndrome* (5).

Pinheiro and Freire-Maia (4) reported a four-generation autosomal dominantly inherited syndrome termed *dermo-odonto-dysplasia*. Thin, fragile, or brittle finger and toe nails, palmoplantar xeroderma, oligodontia, and/or microdontia with persistence of deciduous teeth were found (Fig. 13–72A,B). The hair was dry and the beard and axillary and pubic hair were slow growing. There was variable expressivity. Differentiation must be made from the *Witkop tooth-nail syndrome*.

Fadhil et al (2) described two families with a syndrome of hyperkeratosis of palms and soles with hyperhidrosis in these areas; somewhat scaly dry skin, erythema, and telangiectasia over the nose and malar areas; and peg-shaped maxillary central incisors. The term chosen was *odonto-onycho-dermal dysplasia*. Inheritance appears to be autosomal recessive (Fig. 13–72C–F).

Incontinentia pigmenti (Bloch-Sulzberger syndrome)

Incontinentia pigmenti (IP) is a disturbance of skin pigmentation sometimes associated with malformation of the eye, teeth, skeleton and other systems. Although it may have been first noticed by Garrod (17) in 1906, credit is usually given to Bardach (2), Bloch (5), and Sulzberger (63) for clearly defining it in the 1920s. Major features include vesicular, verrucous, and pigmented macular lesions of the skin. At least 900 cases have been reported. There are several good surveys (10,33).

A sporadic pigmentary disorder associated with X/autosome translocation involving Xp11.21 has been termed IP1 (4,18,20,26,29). Linkage studies suggest that the classic disorder (IP2) maps to Xq28 (54,55,58). There are some large pedigrees (13,60,72). Frequency has been estimated to be 1:40,000 females (9). Sybert (63) stated that IP1 is not incontinentia pigmenti, but is an "X-autosome translocation associated with pigmentary abnormality."

The syndrome is X-linked dominant and essentially lethal in males (10,32,35,45). In a personal communication, RI Kelley (Jan. 2000) indicated that familial and nonfamilial forms have different forms of sterol defects: familial-sterol demethylase deficiency; sporadic-sterol isomerase deficiency). The gene for IP2 is called *NEMO*. It encodes the gamma subunit of the IKK complex in the NF-kB pathway. Male patients with *NEMO* mutations present with osteopetrosis, lymphedema, hypohidrotic ectodermal dysplasia, and immune deficiency (37,58a). Two to three percent of IP patients are males (7,9,37,42,68,77) with phenotypes identical to those of affected females (3). A number of authors (16,42,44,46,47,70) reported males with IP and XXY Klinefelter syndrome, and Scheurle (53), in a 1999 survey of 49 affected males, found that 5 had Klinefelter syndrome. To explain affected males with normal male karyotype, it has been suggested that only part of the male cells carries the mutated X. This form of mosaicism can result from a genetic error (half chromatid mutation) during gametogenesis (35). Others have disputed this (24,25). A half-chromatid back-mutation is an alternative hypothesis to explain the occurrence of affected males (34). Early somatic mutation in embryogenesis is another possibility, as is unstable premutation (69). There have been a few examples of male-to-female transmission (14,59).

Kirchman et al (32) reported 2 paternally related half sisters with incontinentia pigmenti. The father was clinically normal, with a 46,XY normal karyotype. Following confirmation of paternity, X-inactivation studies indicated that the paternal X chromosome was preferentially inactivated in each girl, implying that the father was a gonadal mosaic for the IP mutation.

Harris et al (23) reported evidence of extensive skewed X inactivation in blood from 35% of IP patients. This frequency of skewed inactivation was seen in both familial and sporadic cases. Wieacker et al (71) demonstrated that inactivation of the X chromosome carrying the IP gene has a proliferative advantage in the cell population. Migeon et al (40) found that cells that express the mutated allele are eliminated from skin fibroblast cultures and, to varying degrees, from hematopoietic tissues. Harris et al (23) presented arguments against cell selection during early embryogenesis as the explanation for the observed skewed inactivation. Parrish et al (43) reported completely skewed patterns of X-inactivation in the peripheral blood leukocytes of 98% of affected females. They also reported that new mutations were twice as common in paternal X chromosomes as in those of maternal origin.

Skin. Cutaneous abnormalities serve as a basis for the four clinical stages of the condition. However, all stages need not necessarily occur, and several stages may overlap. The first stage present at or soon after birth is characterized by linear or grouped vesicles on the extremities or trunk, sparing the face. By the end of the first month, the vesicles may disappear, recur, or be replaced by irregularly distributed violaceous papules and inflammatory lesions. The first stage clears by four months. This is accompanied by massive infiltration of eosinophils into the epidermis and marked peripheral leukocytosis with up to 65% eosinophils. The second

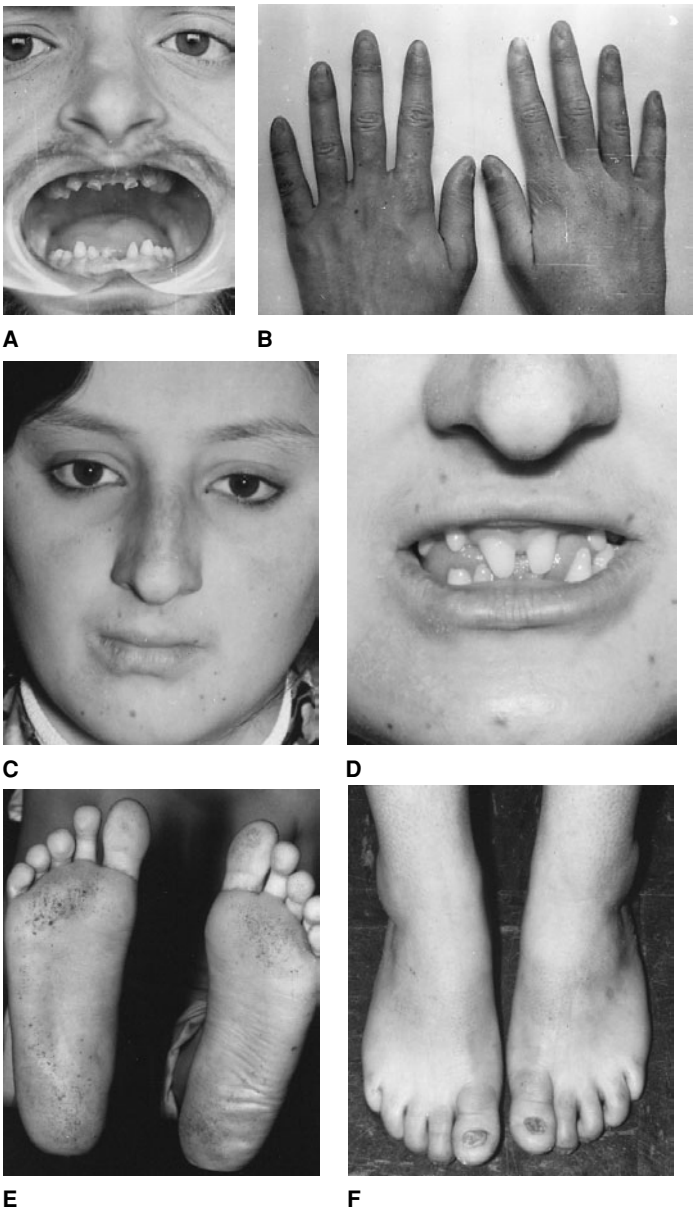

Fig. 13–72. *Dermo-odonto-dysplasia*. (A) Oligodontia and/or microdontia with persistence of deciduous teeth. (B) Hypoplastic thin, fragile fingernails. Odonto-onycho-dermal dysplasia. (C) Patient showing mild telangiectasia of nose and malar areas. (D) Peg-shaped anterior teeth. (E,F) Dystrophic nails and hyperkeratosis of soles. (A,B from M Pinheiro and N Freire-Maia, Clin Genet 24:58, 1983; C-F from M Fahdil et al, Am J Med Genet 14:335, 1983.)

stage is characterized by hyperkeratotic, warty lesions on the dorsal surface of the digits, knuckles, joints, and limbs. Although usually manifest at about 1 month of age, they may be present at birth. Resolution is usually spontaneous, with clearing being complete by 6 months in 80%, but rarely recurrent throughout childhood (41).

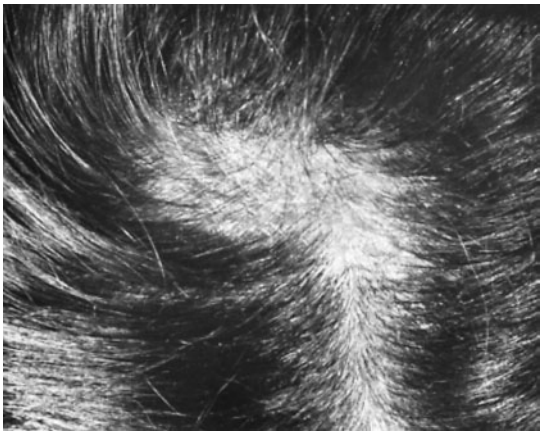
The third stage usually has onset between the third and sixth months of life, although it, too, may be present at birth. It is characterized by brownish-gray macules arranged in a reticulated pattern or in streaks, whorls, or patches more often on the trunk (especially the axillae and groin), although these lesions may occur in sites previously involved by vesicular or verrucous lesions, areas not significantly involved in either of the first two stages. The pigmentation tends to follow Blaschko lines (22). Lenz et al (36) reported unilateral involvement. Pigmentation, beginning to fade at about 2 years, usually disappears by the end of the second decade. It may resolve so completely as to be unnoticeable, although

Fig. 13–73. *Incontinentia pigmenti*. Ten-month-old female manifesting bullae, verrucae, and whorled and linear distribution of pigment. Also note area of crusting and scarring on thigh.

some residuum is often present for life (74) (Fig. 13–73). The fourth stage is "burnt out" incontinentia pigmenti characterized by pale, hairless depigmented lesions of the posterior calves (73,76).

Alopecia of the atrophic, scarring (pseudopelade) type is seen near the apex of the crown in about 40% (Fig. 13–74). Occasionally, wiry and coarse patches of hair are noted. In about 35%, the fingernails are mildly dystrophic (ridging or splitting) and breasts are asymmetric. Painful subungual tumors have been reported (36,56,57). There may be underlying bony resorption (56). Rott (50) reported partial or complete lack of sweat pores on the palms and fingers of 5 female probands, consistent with lyonization of the X chromosome.

Fig. 13–74. *Incontinentia pigmenti*. Alopecia of pseudopelade type located at crown of head.



On light microscopic examination, the vesicular stage is characterized by intraepithelial vesicles containing eosinophils; spongiosis and individual dyskeratotic epithelial cells are also noted. Eosinophils are found in the connective tissue. The second stage is manifested by hyperkeratosis, acanthosis, papillomatosis and epithelial dyskeratosis. Basal cells are vacuolated and their pigment granules are decreased in number. A mild chronic inflammatory cell infiltrate is seen in the connective tissue as well as in the epithelium. In the third stage, extensive melanin deposits are found with melanophages in the upper dermis, usually associated with a decrease in basal cell pigmentation. Ultrastructural changes in the skin have been described (8,21,52,76).

Eyes. Ophthalmologic abnormalities are noted in 25%–35% (15,39,45,49). The most common alterations include strabismus (35%), congenital cataract (5%), optic atrophy, retrolental mass (2%) (described as persistent hyperplastic primary vitreous, pseudoglioma, or retrolental fibroplasia), retinal detachment, microphthalmos (3%), retinal telangiectasia, and irregular hyperpigmentation of the conjunctiva, iris, and retina (10%) (15).

Central nervous system. Central nervous system involvement occurs in 35%–40%. Mental retardation (15%), microcephaly (5%), cerebral infarction, hydrocephalus, paresis of eye muscles, and convulsive episodes (15%) have been reported (30). CT scans have demonstrated brain atrophy (1). Those with neonatal seizures appear to have a higher rate of mental retardation (41).

Oral manifestations. Oral changes limited to the teeth have been noted in 90% (9). Pegged or conically crowned teeth (30%), congenitally missing teeth (40%), and delayed eruption are characteristic (19,36) (Fig. 13–75). Both primary and permanent dentitions are affected. Congenitally missing and malformed teeth create diastemas. Cleft lip/palate has been reported (6,51,75), but may be due to chance.

Other abnormalities. Breast hypoplasia, displaced breast, and supernumerary nipples are increased in frequency.

Various tumors have been described: retinoblastoma, Wilms tumor, acute myelocytic leukemia, paratesticular rhabdomyosarcoma (47). Several reports have described IP patients who develop many unusual and recurrent infections, suggesting that immunodeficiency may be characteristic. See p. 551, *NEMO* gene discussion. Abnormalities of one or more serum immunoglobulins have been found in some patients (11), as have defects in neutrophil chemotaxis (11,28) and lymphocyte transformation (28). An increased number of chromosomal breaks has been described by some investigators (31) but not by others (24).

Differential diagnosis. Skin changes present in early infancy must be distinguished from those of congenital syphilis, *epidermolysis bullosa*, bullous impetigo, contact dermatitis, *dermatitis herpetiformis*, and verrucous nevus. Incontinentia pigmenti should be differentiated from hypomelanosis of Ito (incontinentia pigmenti achromians) and *Naegeli syndrome*, a dominant disorder (27,61).

Hypomelanosis of Ito (48,62,65) is a neurocutaneous syndrome characterized by development of linear areas of cutaneous hypopigmentation within the first year of life, as well as neurologic, ophthalmologic, and musculoskeletal anomalies. No preceding bullous, verrucous, or hyperpigmented lesions are noted. Consistent dental abnormalities have not been reported to be associated with this disorder. There is mounting evidence that hypomelanosis of Ito represents a nonspecific sign of somatic mosaicism (66).

Dental anomalies in IP resemble those of other ectodermal dysplasias, such as *Ellis–van Creveld syndrome, Witkop tooth-nail syndrome*, and *hypohidrotic ectodermal dysplasia.* In congenital syphilis, the primary dentition is rarely involved (except possibly a deciduous molar) because of the inability of the spirochetes to pass the placental barrier until at least the eighteenth week of pregnancy. The incisors in congenital syphilis are never conical; rather, the incisal edge is narrower than the cervical portion of the crown. In hypohidrotic ectodermal dysplasia, many more teeth are congenitally missing and those present are more severely malformed than in IP. In Ellis–van Creveld syndrome other oral anomalies not present in IP are found: fusion of the lip with the adjacent alveolar ridges and notching of the mandibular alveolar process. Witkop tooth-nail syndrome is autosomal dominant.

Laboratory aids. Blood eosinophilia during the vesicular stage or even later may be marked, in some cases reaching 65% (11,67).

Prenatal diagnosis can be accomplished for those with IP2 (12).

Naegeli syndrome

Naegeli syndrome (2,5), a rare disorder, is characterized by reticular pigmentation of the skin that develops at about 2 years of life and is not preceded by an inflammatory stage. Heat intolerance and moderate hyperkeratosis of the palms and soles are also noted. Inheritance is autosomal dominant, and the gene has been mapped to 17q11.2–q21 (7). Sparrow et al (6) reported a family with what might also be Naegeli syndrome. Affected individuals had diffuse or patchy, mottled hyperpigmentation of the skin that developed in childhood. There was also thickening of the fingernails, onycholysis and subungual keratosis, decreased sweating, punctate keratoses on the palms and soles, and hypoplastic or absent dermatoglyphic patterns (1,3,4). A few patients had blistering of the heels during the first week of life. Male-to-male transmission was described.

LEOPARD syndrome (multiple lentigines syndrome, progressive cardiomyopathic lentiginosis)

LEOPARD is an acronym coined by Gorlin et al (23), in 1969, to serve as a mnemonic. The syndrome as originally described consisted of multiple *L*entigines, *E*lectrocardiographic conduction abnormalities, *O*cular hypertelorism, *P*ulmonic stenosis, *A*bnormal genitalia, *R*etardation of growth, and sensorineural *D*eafness (23). It is also known as progressive cardiomyopathic lentiginosis, Moynahan syndrome, cardio-cutaneous syndrome, and lentiginosis profusa. Several reviews have been published (12,16,18,23–25,50,59,61,74). Several incompletely documented cases have been reported (20,29,31,35,36,38,39,49,57,73,77). A neural crest defect has been suggested to explain the clinical abnormalities (51,59). Over 100 cases have been tabulated by us.

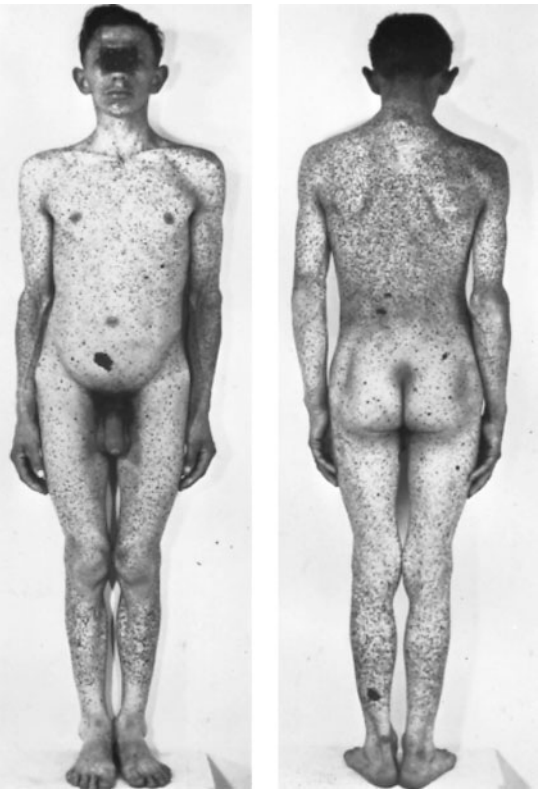
Autosomal dominant inheritance with high penetrance and marked variation in expression has been demonstrated (6,15,23,25,40,48,59,67). The condition does not map to the neurofibromatosis 1 locus (19) in spite of a suggestion that it does (84).

Facies. The face is usually triangular with biparietal bossing, hypertelorism, ptosis, epicanthal folds, and low-set ears (Figs. 13–76 to 13–78). Strabismus is seen in 20% and mild mandibular prognathism in 10%. In our experience, mild pterygium colli is frequent. Cataracts were reported by Peter and Kemp (54) and Howard (32).

Skin. Many pinpoint black-brown macules may be found anywhere on the skin, including the scalp, face, neck, upper trunk, axillae, palms, soles, and genitalia, sparing only the oral mucosa (51,83). They may number in the thousands (40,59) and are usually a few millimeters in diameter (23,24,40,51,65) (Figs. 13–76 to 13–78). Although striking when present, pigmented macules are not found in all patients (23). They may be congenital (17,81) or appear soon after birth (42,51) and increase in number until puberty (43,48,51,59,65,70). On microscopic examination, the pigmented skin lesions are lentigines (14a,23,37,43,59,66,68,80,83). Intracellular giant pigment granules similar to those in neurofibromatosis have

Fig. 13–76. *LEOPARD syndrome*. Ocular hypertelorism, numerous lentigines. (From PE Polani and EF Moynahan, Q J Med 41:205, 1972.)

Fig. 13–77. *LEOPARD syndrome*. (A,B) Twenty-seven-year-old with thousands of lentigines widely scattered over body. Lentigines first appeared at 4 years of age. Also note larger "café-noir" spots. (From JJ Herzberg, Z Kinderchir 2:187, 1965.)



A B

Fig. 13–78. *LEOPARD syndrome*. Numerous lentigines of hands. (From PE Polani and EF Moynahan, Q J Med 41:205, 1972.)

been noted (10,55,64,83). Large numbers of melanosomes accumulate in Langerhans cells (22). Features of compound nevi have also been found (63). Granular cell schwannomas of the skin of the limbs and thorax have been described (5,7,8,34,38,46,52,65,72,78). Café-au-lait spots are noted in about 20% (80). One commonly finds a few large (1–5 cm) dark *café-noir* spots scattered over the trunk (Fig. 13–77).

Cardiovascular system. Cardiac defects have been extensively reviewed (23,24,59,62,69,70,80). Valvular pulmonary stenosis, usually mild, appears to be the most common cardiac abnormality, occurring in 40% (35,80). In others, there is an unusual alteration in the pulmonary valve that has been termed "pulmonary valvular dysplasia" (35). The pulmonary valve reveals three distinct cusps but no commissural fusion. The obstruction is based on thickening of the pulmonary valvular leaflets by disorganized myxomatous tissue that renders the valve leaflets immobile. Clinically, patients with this type of valvular anomaly have a pulmonary systolic ejection murmur but no ejection click. Similar changes have been seen much less commonly in the aortic valves. About 20% have hypertrophic cardiomyopathy, involving primarily the interventricular septum, which results in both subaortic and subpulmonic stenosis (59,70). In other reports, associated atrial septal defect, infundibular or supravalvular pulmonary stenosis, or muscular subaortic stenosis has been described (35,41).

There is a unique and frequently present electrocardiographic anomaly that tends to characterize this syndrome regardless of the type of cardiac malformation. This feature is a superiorly oriented mean QRS axis in the frontal plane, generally located between −60 degrees and −120 degrees (S1,S2,S3 pattern) (48,67,69). This may not be demonstrable in every patient, but it may be present in others with the syndrome in whom no structural abnormality of the heart has been demonstrated. Electrocardiograms in some patients have revealed left axis deviation, first-degree AV block, posterior rotation, complete heart block, hemiblock, or complete bundle branch block (67,69).

Genitourinary system. Hypospadias is present in 50% of males (23,24,49,59,81,82). Unilateral or bilateral cryptorchidism is frequent (49,55,59), and the penis may be small (49). More cases have been transmitted through affected females. Absence or hypoplasia of an ovary has been reported (23,59). Late menarche is a common finding.

Skeletal system. Growth retardation is frequent; 85% are below the 25th centile for height and weight (24), and 20% are below the third centile in height (37,42,55,80). Hypopituitarism has been reported but is probably aleatory (44). Pectus carinatum (37) or excavatum (39,48,51,68,83) has been noted in about 10% (80), as has winging of the scapulas (17,37,70). Scoliosis is present in about 10% (42). In old age, there is a tendency to develop thoracic kyphosis. Spina bifida occulta, absent ribs, cubitus valgus, limitation of motion at elbows, and deficiency in the outer table of the temporal bone have been described (24,59,70). Bone age may be retarded (15). Hyperflexibility of metacarpophalangeal joints of fingers and thumbs has been noted.

Central nervous system. Hearing loss has been documented as early as birth (37), 1 year (13,51), and early childhood (42,70). Although hearing loss has been described in about 25% (80) as sensorineural (13,42, 51,83), the age of onset, degree, and type have not been well documented. Some young individuals have been reported with normal hearing (66,67,80), but loss may develop with advancing age. Vestibular changes have not been present (13). Chiari I malformation has been reported in a child (1).

Mild mental retardation (24,49,51,55,59,68,71) and electroencephalographic abnormalities (10,51,59) including diffuse encephalopathy (51) have been reported in about 30% (80). In others, intelligence was normal (17,37,42,80).

Oral manifestations. Oral mucous membranes have not been involved (14,23,24,43,51,59,65,67,69,79,80). One child has been reported with nasopharyngeal rhabdomyosarcoma (29).

Differential diagnosis. Lentigines differ from freckles in having darker color, no relationship to sun exposure, arising at an earlier age, and on biopsy having an increased number of melanocytes per unit skin area and prominent rete ridges. Segmental lentiginous nevus, which exhibits numerous pigmented macules on a café-au-lait background, probably represents a mosaic form of this or another gene, such as NF1 (3,4,30, 33,47,56,58,76,85). Granular cell schwannomas may be seen with this nevus (26,60).Blue nevi have been rarely found in association (30). Happle et al (27,28) and Tadini et al (75) view association of speckled lentiginous nevus with telangiectasia or with an organoid epidermal nevus as examples of twin spotting. Twin spots are paired patches of mutant tissue that differ from each other and from the background tissue. This comes about by somatic crossing over of two different recessive mutations localized to the same chromosome. This gives rise to two homozygous daughter cells that are the stem cells for two different mutant patches. Loss of heterozygosity can also result from chromosome deletion. Various conditions associated with increased nevi have been reviewed (45).

One can see generalized lentigenosis without systemic involvement (9).

The LEOPARD syndrome shares many features with *Noonan syndrome* and *Noonan-like syndrome, cherubism, and polyarticular pigmented villonodular synovitis*. Noonan syndrome patients do not have lentigines or hearing loss. Characteristics in common include hypertelorism, ptosis, short stature, QRS axis, pulmonary stenosis without an ejection click, cryptorchidism, delayed development of secondary sexual characteristics, and pectus. We suspect that LEOPARD syndrome and Noonan syndrome are allelic (11). One of us (RJG) has noted multiple granular cell schwannomas in both conditions. This has been recently confirmed (38a,61a). Pulmonic stenosis, abnormal QRS axis, short stature, delayed puberty, and hearing loss may be observed in *rubella embryopathy*. Swanson et al (74) reported an 18-year-old male with unilateral sensorineural hearing loss, nevi and freckles on his back, chest, and face, mild hypertelorism, normal electrocardiogram, lack of sexual hair, small penis, and renal abnormalities; he likely had a form of Kallmann syndrome.

Forney et al (21) described a dominantly inherited syndrome of short stature, bilateral conductive hearing loss with onset during the first decade of life, multiple freckles on the face and shoulders, and mitral insufficiency. In addition, there were skeletal anomalies, including fusions of the cervical vertebrae and carpal and tarsal bones.

Paver and Coleman (53) reported a male with generalized multiple lentigines, facial asymmetry and other craniofacial abnormalities, patchy sparse scalp hair, cicatricial alopecia, epicanthus, ophthalmologic abnormalities, and undescended testes.

Multiple lentigines have also been seen in *Carney syndrome. Neurofibromatosis* should also be excluded. Watson (82) reported a syndrome of short stature, mild mental retardation, pulmonary valvular stenosis, and café-au-lait spots. The gene for Watson syndrome has been mapped to the NF1 gene, representing intralocus heterogeneity (2).

Laboratory aids. Electrocardiogram and cardiac catheterization may be helpful. Biopsy may be used to confirm the diagnosis of lentigo.

Macular cutaneous and mucosal pigmentation, myxomas, and endocrine neoplasia syndrome (Carney syndrome, NAME syndrome, LAMB syndrome)

The complex of myxomas (heart, skin, breast), spotty pigmentation of the face, lips, and conjunctiva (lentiginosis, blue nevi), endocrine tumors (adrenal, testis, pituitary), and schwannomas (upper gastrointestinal tract, sympathetic chain) is called Carney syndrome. Although some components may be congenital or apparent in early childhood, diagnosis is usually made in the second and third decades of life.

The condition, described in part by several earlier investigators (2–4, 24,39,43,45,46,49), was fully fleshed out by the superb studies of Carney and coworkers (6–14,62). Subsequently, at least 200 examples have been published (8,51).

Many have been sporadic cases (2,21,33,38,39,45). However, autosomal dominant inheritance with variable expression is evident (4,12,14,17, 19,31,41,43,49,50a,57,59,60). Approximately 50% represent new mutations. There appears to be genetic heterogeneity, the syndrome mapping to 2p16 (51) and to 17q22 (15,25). The gene, related to genomic stability of dividing cells (51), is the protein kinase A type 1-α regulatory subunit (30a). The mutation results in a gain of function (52). There may be further genetic heterogeneity (5,51,54).

A B

Fig. 13–79. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. (A) Macular pigmentation of face and lips. (B) Note similar facial and mucosal pigmentation. There is a small myxoma of the right lower eyelid. [A from DL Atherton et al, Br J Dermatol 103:421, 1980. B from JA Carney et al, Medicine (Baltimore) 64:270, 1985.]

Skin. Multiple dark-brown macules (lentigines) are found in about 70% in decreasing order on the face (especially periocular and perioral), lips, conjunctiva or sclera (especially lacrimal caruncle and semilunar fold), eyelids, trunk, neck, vulva (especially labia minora), arms, thighs, and backs of hands (2,12,14,16,30,39,43,47) (Fig. 13–79). Sometimes present at birth (2), with additional lesions developing thereafter (2,22,45), they range from few to myriad in number. In general, lentigines and cutaneous myxomas (vide infra) are the first lesions to appear. The lentigines measure from 0.2 mm to 2 mm in diameter (2). Microscopic changes include somewhat acanthotic epithelium with increased numbers of clear melanocytes and increased pigment in the basal cell layer (12,39,43). Ephelides (freckles) are noted in increased numbers. Junctional and compound nevi are present in 65% (51).

Blue nevi, blue to black domed lesions, probably congenital, and measuring up to 8 mm, occur on the face, trunk, and limbs, but not on the hands or feet (2,21,45). Some patients have a few blue nevi, others up to a dozen lesions. Blue nevi situated high in the dermis are characterized by spindle-shaped melanocytes with elongated dendritic processes. Approximately 10% of the affected have both lentigines and blue nevi.

Approximately 40% develop multiple sessile papules or subcutaneous myxoid nodules during the first three decades of life (2,13,29,45). Myxomas have predilection for the eyelids (25%), external ear canals (15%), and nipples (20%) (23,29). Most lesions are 1 cm or less in diameter (Fig. 13–80). The myxoma, while sharply circumscribed, is usually not encapsulated. It is composed of scattered, polygonal, spindle and stellate mesenchymal cells set in a mucinous (often basophilic) matrix composed of proteoglycan (44). Approximately 25% of dermal myxomas exhibit an epithelial component that may be cystic or consist of thin epithelial strands (13).

Cardiac myxomas. The heart is the second most frequently affected organ. The myxomas may be single or multiple and occur in any or all chambers (36). Multiple myxomas [biatrial (40%), ventricular (15%), and recurrent (20%)], found in 65%–75%, are the most serious component (2,8,36,42,43,45,49,50) (Fig. 13–81). Embolization from the cardiac myxomas (33) occurs in 20%, with refractory congestive heart failure (39,45) in another 20%. In 40%, the cardiac myxomas are familial (59). Mean age of detection is about 25 years. With decreasing frequency, distribution is as follows: left atrium, right atrium, right ventricle, and left ventricle. Among all cardiac myxomas, those in Carney syndrome constitute about 7% (36).

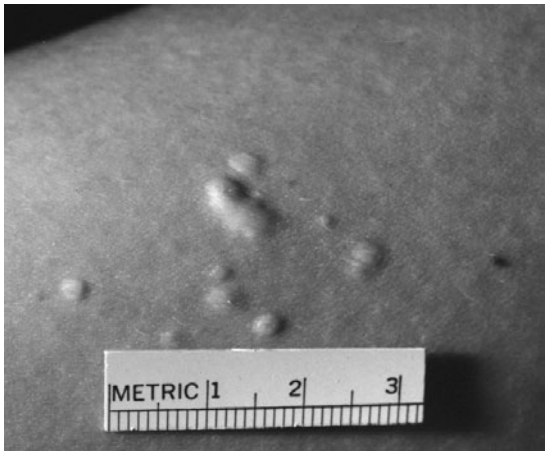

Fig. 13–80. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. Myxomas on the skin of the arm. [From JA Carney et al, Medicine (Baltimore) 64:270, 1985.]

Eyes. Macular pigmentation (lentigo) is seen on the conjunctiva, particularly the lacrimal caruncle and conjunctival semilunar area (2,12, 16,29) or sclerae (45) in 65%. Myxomas frequently occur on the eyelids and commonly recur following excision (1,12,13,20,26,29,30,49).

Genitourinary tract. Multiple black macules (lentigines) may be found on the labia minora (12,39) and labia majora (12). Cutaneous myxomas have been reported on the vulva (45) and on the perineum (12). Myxoma of the uterus (4) and atypical mesenchymal tumor of uterus (37) have been reported.

Endocrine abnormalities. Cushing syndrome due to primary pigmented nodular adrenocortical disease has been found in about 30% (2,4,12,21,28,48–50,56) (Fig. 13–82). Some of these patients have had severe osteoporosis. Discovery is usually made during late adolescence or in the 20s (11). Primary pigmented nodular adrenocortical disease appears grossly as small (usually less than 5 mm) black brown, dark green, or red nodules in the adrenals. Microscopically, it is characterized by enlarged globular cortical cells with granular, eosinophilic cytoplasm which often contains lipofuscin (56).

Fig. 13–81. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. Myxoma of heart. [From M Schweizer-Cagianut et al, Virchows Arch (A) Pathol Anat Histopathol 397:183, 1982.]

B

Fig. 13–82. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. (A) Primary pigmented nodular adrenocortical disease. Note small pigmented nodules. (B) Primary pigmented nodular adrenocortical disease. Typical pigmented nodule composed of epithelial cells, fat cells, and a few lymphocytes, situated deep in cortex. The extra nodular cortex is disorganized and lacks normal zonation. (H&E, ×64). [A from JA Carney et al, Medicine (Baltimore) 64:270, 1985. B courtesy of JA Carney, Rochester, Minnesota, unpublished, 1987.]

Approximately 10% have thyroid tumors, approximately one-half of which are malignant. Benign papillary and follicular hyperplasia of the thyroid (45) and thyroid follicular adenoma (3,12,49,53) have been reported.

Acromegaly or gigantism due to growth hormone-secreting pituitary factor has been found in 10%, onset of symptoms ranging from adolescence to the late 20s (27,32,61).

Large-cell calcifying Sertoli cell tumor of the testis causing sexual precocity has been documented in 30% of male patients (12,34,36a,41;see 49). They are bilateral in 75% cases and multicentric in each affected testis. Most patients are in their early adolescence at time of discovery. The tumors are usually hard to palpation and nontender. Microscopically, the tumors are characterized by multifocal sheets and cords of cells with abundant acidophilic cytoplasm and large areas of laminated calcification.

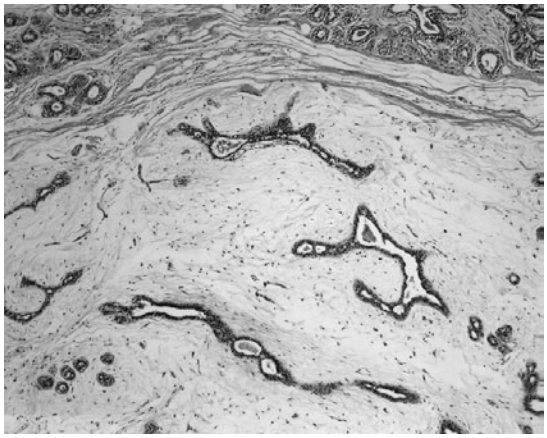

Fig. 13–83. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. Unencapsulated myxoid fibroadenoma of breast. Note elongated proliferated ducts surrounded by hypocellular stroma. [From JA Carney et al, Medicine (Baltimore) 64:270, 1985.]

Leydig cell or adrenal cortical rest tumors may also be found (40,51). Pheochromocytoma has also been noted (4,32,59).

Schwannomas. Psammomatous melanotic schwannomas involve the upper gastrointestinal tract (esophagus, stomach) and paravertebral sympathetic chain in 20% (51). A few, however, have arisen in the skin (55,58). Although usually benign, metastasis with fatal consequences has been found in 10% (7,55).

Grossly, the tumors are dark and encapsulated. They are composed of large and small polygonal epitheliumlike cells and spindle cells in organoid pattern. Melanin is noted in the cytoplasm. Laminated calcification (psammoma bodies) are scattered throughout. S-100 protein immunostaining is positive (35).

Myxoid mammary fibroadenoma and ductal adenoma. Myxoid fibroadenomas of the breast have been noted in 25% of female patients (9). These may be multiple and often bilateral (10). The lesions may be painful or tender to the touch (8,12,17,18,46). They range in size from a few millimeters to 2 centimeters in diameter. Microscopically, they are composed of abundant hypocellular very myxoid stroma and hyperplastic mammary ducts (Fig. 13–83).

Ductal adenoma of the breast with tubular features may be unilateral or bilateral. The tumor, usually located close to the areola, has been found in females 27–61 years of age (10).

Oral manifestations. Pigmented macules (lentigines) may be found on the perioral skin or vermilion border of lip mucosa in over 90%. The buccal mucosa has lentiginous spots in 5% (2,12,17,49). Approximately 3% have myxoid tumors of the hard or soft palate (2,17,43,57) (Fig. 13–84). Myxomas have also been described on the tongue (45) (Fig. 13–85).

Differential diagnosis. The syndrome should be considered in any patient under 40 years old who has cardiac myxoma in other than the left atrium or who has more than one cardiac myxoma (6). The skin and mucosal pigmentation should not be confused with that found in *Peutz-Jeghers syndrome*. The condition should also be differentiated from the *LEOPARD syndrome*. Isolated familial cardiac myxomas have been reported (49).

Laboratory aids. Cushing syndrome can be diagnosed by measurement of 24-hour urinary cortisol following a low-dose dexamethasone suppression test on initial investigation.

Plasma somatomedin C is elevated if acromegaly or gigantism is present.

The testicular tumors can be detected by ultrasonography.

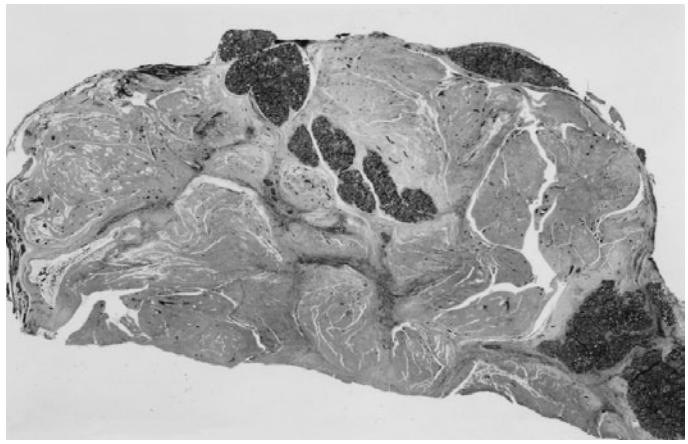

Fig. 13–84. *Macular cutaneous and mucosal pigmentation, myxoma, and endocrine neoplasia syndrome*. Palatal myxoma. Circumscribed by nonencapsulated myxoma of minor salivary glands of palate (Movat pentachrome stain, ×2). (From CA Cook et al, Oral Surg 63:175, 1987.)

Waardenburg syndrome

The syndrome described so precisely by Waardenburg in 1951 (97) was reported earlier by Mende (58), van der Hoeve (96), Klein (45), and others (70). The main features include lateral displacement of the medial canthi and lacrimal puncta with a broad nasal root, poliosis, heterochromia irides, hyperplasia of the medial portions of the eyebrows, and congenital sensorineural hearing loss. The reader is referred to several excellent comprehensive reviews (24,39,70,79,90).

During the last 15 years, a number of studies (3,34) have separated Waardenburg syndrome (WS) into several forms, based on whether dystopia canthorum is present (type I) or absent (type II), and whether upper limb defects (type III, Klein-Waardenburg syndrome) (46) or Hirschsprung disease (type IV, Waardenburg-Shah) are present (83).

It has been estimated that type II is 20 times as common as type I (5). Several series have shown that hearing loss is much more common in type II (about 77%) (51) than in type I (about 25%), and heterochromia irides is more common in WS type II (47%) than in type I. Perhaps type II is more common among blacks, but more documentation is needed to substantiate this point. Pigmentary disorders are more frequent in type II. However, it has also been shown that patients with type I and hearing loss more commonly have pigmentary disorders of the eyes, hair, and skin than those with type I who have normal hearing. Arias (4) suggested a type II that he designated "pseudo-Waardenburg syndrome" characterized by absence of dystopia canthorum but with one-sided ptosis

of the upper lid. "Waardenburg syndrome type III" is also known as the Klein-Waardenburg syndrome on the basis of a patient described by Klein (45) in 1947 with "partial albinism" blue eyes, deaf-mutism, and musculoskeletal anomalies. However, it was found that this condition is due to an allelic mutation in the PAX3 gene (whose mutations are responsible for WSI), or is a contiguous gene syndrome due to deletion of the PAX3 gene and adjacent genes. Bard (10) also suggested further heterogeneity, but we are not convinced that his patient is not an extreme example of type II.

Waardenburg syndrome types I, II, and III exhibit autosomal dominant inheritance with essentially complete penetrance and variable expressivity (50,92). Estimates of prevalence suggest that this syndrome is found in 2%–5% of all congenitally deaf persons (11,17). Between 2 and 3/100,000 in the general population are affected in the Netherlands (97). However, since most probands have been recognized because of impaired hearing, there is ascertainment bias (13,70,72). New mutations for type I have been shown to be associated with advanced paternal age. However, most Waardenburg syndrome type IV variants follow the autosomal recessive pattern of inheritance (vide infra). Germ–line mosaicism has been reported for WS1 (44). Jones et al (43) noted a paternal age effect for new mutations.

In 1989, Ishikiriyama et al (41) suggested that the locus for WS1 is located at 2q35 or 2q37.3. Farrer et al (21), in 1994, found that all families with WS1 showed linkage to the *PAX3* region of chromosome 2. Baldwin et al (9), in 1995, described 10 mutations in the *PAX3* gene in families with WS1 and, in 1996, Wildhardt et al (100) described *PAX 3* mutations in 2 additional families.

De Stefano et al (15), in 1998, tried to establish genotype–phenotype correlations in 271 individuals with WS1 from 48 families collected by the Waardenburg consortium. They grouped the 42 unique mutations in the *PAX3* gene in 5 mutation categories: (a) amino acid substitution in the paired domain, (b) amino acid substitution in the homeodomain, (c) deletion of the ser-thr-pro-rich region, (d) deletion of the homeodomain and the ser-thr-pro-rich region, and (e) deletion of the entire gene. They found that individuals with deletion of the homeodomain and the pro-ser-thr-rich region had 2.8 and 5 times greater frequency of eye pigment abnormality, white forelock, and skin hypopigmentation, respectively, than those with an amino acid substitution in the homeodomain.

Hughes et al (40), in 1994, found that WS2 is heterogeneous. They suggested that WS2 mapping to 3p12–p14.1 be named WS2A, and the unlinked form(s) be called WS2B. The reader should also see Dow et al (18).

In patients with WS2, Tassabehji et al (89), in 1994, demonstrated mutation in the gene for microphthalmia-associated transcription factor (*MITF*; Gene Map Locus 3p13). Lawani et al (50), also in 1994, mapped a WS2 gene to 1p21–p13.3. Reviewing the WS2 patients, Read and Newton (79) reported that about 15% are heterozygous for mutations in the *MITF* gene. *MITF* transactivates the gene for tyrosinase and is critically involved in melanocyte differentiation. Absence of melanocytes affects pigmentation in the skin, hair and eyes, and hearing function. Therefore, hypopigmentation and hearing loss in WS2 are likely to be the results of an anomaly of melanocyte differentiation caused by *MITF* mutation (88).

Moreover, Watanabe et al (98), in 1998, presented evidence for epistatic relationship between *MITF* and *PAX3*. They showed that *PAX3*, a transcription factor with a paired domain and a homeodomain, transactivates the *MITF* promoter and thus directly regulates *MITF* function.

PAX3 mutations were also found in WS3 (9,90). Thus, it was concluded that the mutations of WS1 and WS3 are allelic. In 1998, myelomeningocele and WS3 were reported by Nye et al (67) in patients with interstitial deletions of 2q35 and the *PAX3* gene. These patients raise the possibility of a digenic etiology of their NTDs via a genetic interaction of the deleted *PAX3* gene with a second unidentified locus. Zlotogora et al (105) presented evidence that homozygosity for a *PAX3* mutation can cause WS3, with very severe upper-limb defects (Fig. 13–86). Aymé and Philip (7) reported a probable homozygous fetus with contractures and exencephaly.

The Waardenburg-Shah (WS4) phenotype may be the result of a mutation in the endothelin-B receptor gene (*EDNRB*), in the gene for its ligand, endothelin-3 (*EDN3*), or in the *SOX10* gene (94). In 1995, van Camp (95) reported chromosome 13q deletion in patients with WS2 and Hirschsprung disease.

In 1995, Attie et al (6) described features of both Waardenburg syndrome and Hirschsprung disease in 2 girls born to consanguineous Tunisian parents. They found a homozygous missense mutation in exon 2 of the *EDNRB* gene. In 1996, Edery et al (19) demonstrated a homozygous substitution/deletion mutation of the *EDN3* gene in a patient with the Shah-Waardenburg syndrome. Independently, and also in 1996, Hofstra et al (38) identified a missense mutation in the *EDN3* gene. In 1998, Pingault et al (75) found 4 different types of *SOX10* mutations in patients with Waardenburg-Shah syndrome. These were nonsense mutations, insertions or deletions. They point to an essential role of *SOX10* in the development of two neural crest–derived human cell lineages. They further define the locus heterogeneity of the Waardenburg-Shah syndrome (37,47,87).

It seems, thus, that the Waardenburg-Shah phenotype resulting from mutations in *EDNRB* or *EDN3* is inherited as an autosomal recessive, whereas, when it is due to mutations of *SOX10*, the inheritance is autosomal dominant, probably as a result of haploinsufficiency of the *SOX10* product.

Facies. Poliosis, synophrys, heterochromia irides, broad nasal root, hypoplastic alar cartilages, and mild mandibular prognathism produce a remarkably striking appearance in those with type I syndrome (Fig. 13–87A,B).

Eyes. Although the interpupillary and outer canthal distances are normal in most affected individuals, an increased distance between the inner canthi (dystopia canthorum) is evident, resulting in blepharophimosis. This is a sine qua non in type I patients. The sclerae may be covered medially, giving a false impression of esotropia. Type II patients have a normal facies (Fig. 13–87C).

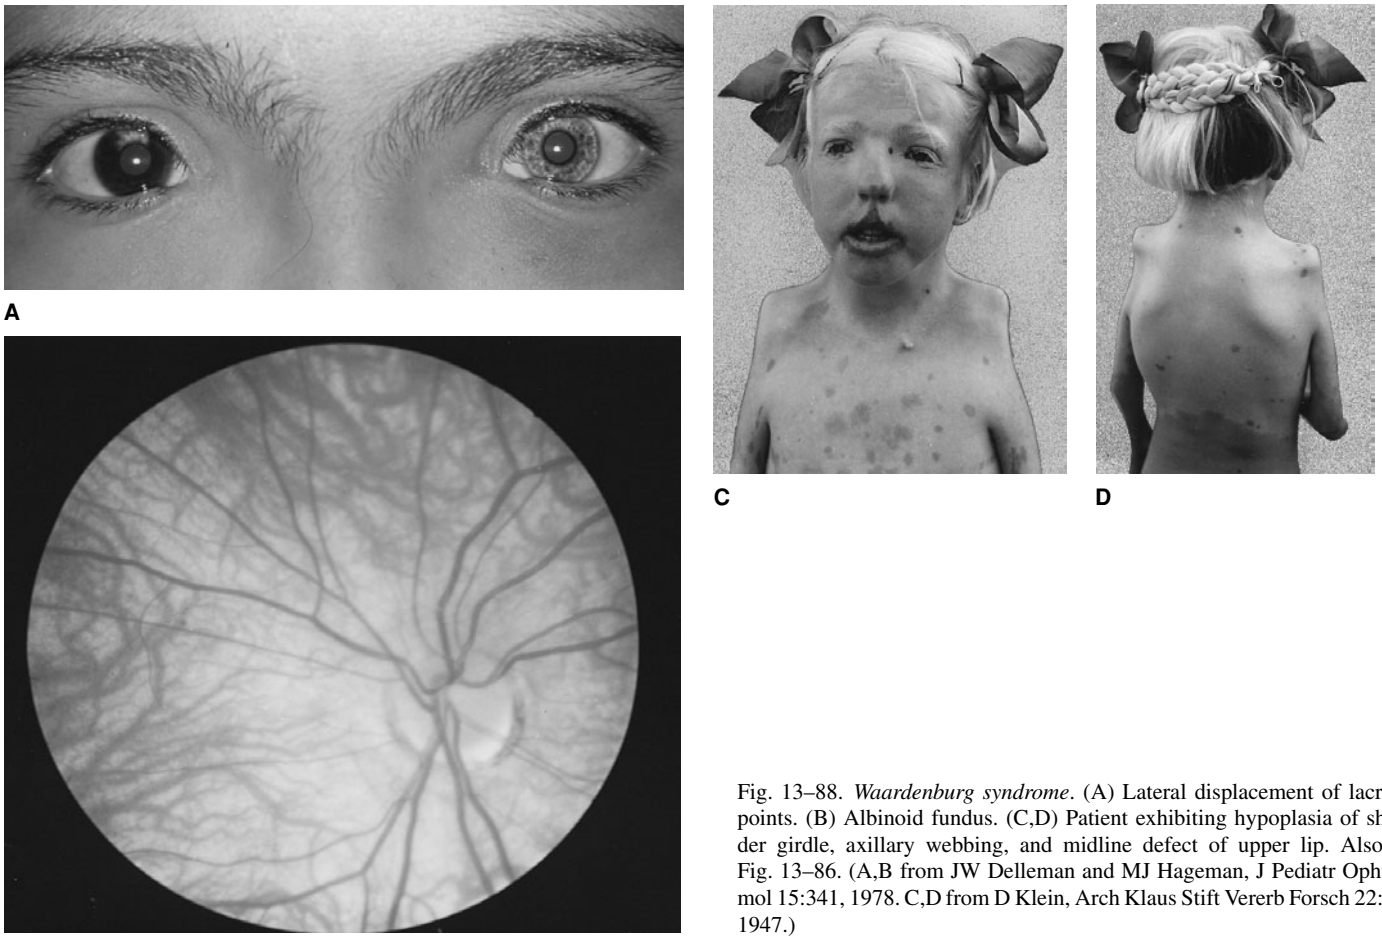
(B) White forelock, synophrys, dystopia canthorum, hypoplastic nasal alae. *Type II.* (C) Note absence of dystopia canthorum, presence of white forelock. (A from MW Partington, Can Med Assoc J 90:1008, 1964. B courtesy of M Goldberg, Chicago, Illinois.)

Arias and Mota (5) pointed out that clinical judgment regarding the presence of dystopia canthorum is not always accurate and that a W-index value should be calculated to separate type I from type II. Preus et al (76) suggested modification of the formula, and De Saxe et al (14) used a palpebral fissure index. For variability, the reader is encouraged to read Reynolds et al (80).

True ocular hypertelorism is present in about 10% (70). Normal inner canthal, outer canthal, and interpupillary values have been discussed by Pryor (77) and others (25,48,59).

The inferior lacrimal points are displaced laterally, sometimes as far as the cornea (Fig. 13–88A). There is an increased susceptibility to dacryocystitis (70). Hyperplasia of the medial portions of the eyebrows, or even confluence (synophrys), is present in 85% of type I and 25% of type II patients (34). This characteristic may be less evident in women, who often pluck these hairs (17,70). Heterochromia irides is seen in about one-third of the cases in both types. It may be partial or total, both irides ranging from a mottled to blue appearance. Hypoplastic sapphire blue irides are seen in 10%–15% of both types (34,102), although De Saxe et al (14) suggested that blacks with type II more often have clear blue eyes. Di George et al (17) and others (28) noted pigmentary mottling at the periphery of the fundi. The fundi are albinoid (16) (Fig. 13–88B). Morell et al (70) reported apparent digenic inheritance of Waardenburg



A B C D

Fig. 13–88. *Waardenburg syndrome*. (A) Lateral displacement of lacrimal points. (B) Albinoid fundus. (C,D) Patient exhibiting hypoplasia of shoulder girdle, axillary webbing, and midline defect of upper lip. Also see Fig. 13–86. (A,B from JW Delleman and MJ Hageman, J Pediatr Ophthalmol 15:341, 1978. C,D from D Klein, Arch Klaus Stift Vererb Forsch 22:336, 1947.)

syndrome type II (WS2) and autosomal recessive ocular albinism (AROA). In the family they studied, all individuals with AROA phenotype were either homozygous or heterozygous for TYR (R402A), and heterozygous for the 1 bp deletion in *MITF*. Other eye anomalies such as cataracts, microphthalmia, and ptosis have been reported in association with type I and type II patients (3,28,57,71,97,100). Convergent strabismus has been found in 20% (16).

Hair and skin. White forelock (poliosis) is present in 30%–40% of patients with either type I or type II (34). In some cases, only a few white hairs are evident. This feature may be present at birth but tends to disappear with age (14,22). In females, poliosis may not be evident because of the tendency to mask it by dyeing the hair (17). Premature (beginning in the 20s) graying of eyebrows, lashes, and hair occurs in 20%–35% of type I cases and in 5% of type II cases (34). Pigmentary anomalies, such as vitiligo, may be found in 15%–20% of affected persons of either type (70). Black forelock has also been reported in both type I syndrome (3) and in type II syndrome (14).

Ears and nose. Waardenburg syndrome accounts for over 2% of congenital deafness (61,62). Bilateral congenital sensorineural hearing loss has been observed in 20% of type I patients (34,97) and in 55% of type II patients (34). Little residual hearing is present for the lower frequencies. Approximately 15% of type I and 5% of type II have unilateral hearing loss, rarely of severe degree, in which moderate uniform loss for the lower and middle ranges occurs with improvement in the higher range—often with normal hearing for 6000–8000 cycles per second (23,34).

Hageman (33) demonstrated that where there is unilateral hearing loss, there is no correlation between the laterality of the hearing loss and the side having the blue eye in case of heterochromia irides.

The hearing loss has been shown to be due to absence of the organ of Corti and stria vascularis and a sparsity of ganglion cells (23,78).

Vestibular function was shown to be normal in 25 patients with type I syndrome (35). However, Marcus (55) noted abnormal vestibular function in type II syndrome in blacks. Tomographic findings of the inner ears of 24 type I patients were found to be normal by Nemansky and Hageman (64), but they pointed out that other investigators have discovered malformations of the semicircular canals.

The nasal root is broad, often with loss of the frontonasal angle. The alar cartilages are usually hypoplastic, resulting in narrow nostrils. The tip of the nose tends to be rounded and slightly upturned, revealing the columella (45).

Gastrointestinal system. There have been numerous reports (1,12, 20,56,68,78,83) of the association between type I Waardenburg syndrome and Hirschsprung disease, a disorder of intestinal motility characterized by absence of parasympathetic ganglion cells from the submucosal and myenteric plexuses of the gut (1,83). The association has also been documented in type II syndrome (26,54,57) and type IV syndrome (vide infra).

Waardenburg syndrome, type I, has also been reported in association with anal atresia (56,65) and with esophageal atresia (23,66), but these may well be chance findings.

The syndrome that combines features of Waardenburg syndrome and Hirschsprung disease has been referred to as the Waardenburg-Shah syndrome [Waardenburg syndrome (type IV or WS4)] (8,83). In 1981, Shah et al (83) reported studies on 7 male and 5 female babies with white forelock and white eyebrows and eyelashes, presenting with intestinal obstruction. One had isochromia irides, and in four, information was not recorded. No dystopia canthorum, broad nasal root, or white skin patches were found in 6 patients in whom the observations were recorded. None had deafness. Bonnet et al (11) reported two sisters, the offspring of consanguineous parents. Both had Hirschsprung disease, sensorineural hearing loss, hair, iris, and skin hypopigmentation, but no dystopia canthorum.

Skeletal system. Few cases have been reported in which full radiographic surveys were carried out. Among the cases reported, a variety of skeletal anomalies such as Sprengel deformity, skull anomalies, bony defects of the thorax, abnormal upper limb length, abnormal carpal bones, syndactyly, sacralization of the fifth lumbar vertebra, sacral dimple, and spina bifida have been noted (14,70,97).

Klein (45) reported a woman with Waardenburg syndrome and myo-osteoarticular defects of the upper limb and pectoral region with absence of muscles, rigidity of joints, axillary webs, and camptodactyly of all fingers (Fig. 13–88C,D). Waardenburg, on seeing this patient, investigated several Dutch institutions for the deaf and subsequently defined Waardenburg syndrome, type I. Waardenburg considered Klein's patient to have another disorder. Klein's view that his patient had Waardenburg syndrome has been subsequently vindicated by his finding of a father with essentially the same type of anomalies who has a child with full expression of Waardenburg syndrome, type I. There is a similarity to the homozygous form. Senrui (82) reported flexion contractures and limited supination of forearms. We believe that the family reported by Sommer et al (86) with flexion contractures of the hands actually had Waardenburg syndrome and does not represent a new entity. Other cases have been analyzed by Goodman et al (29). Although Goodman et al (29), Klein (46), and Sheffer and Zlotogora (84) have suggested that this represents still another type of Waardenburg syndrome (type III), we believe that the muscular and skeletal defects in the upper limb are part of the clinical manifestations of an allelic mutation at the same locus of WSI.

A patient described by Wilbrandt and Ammann (100) who also had arthromyodysplasia was noted in a family having otherwise typical Waardenburg syndrome.

Genitourinary system. A 16-day-old girl with Waardenburg syndrome type I presented with a right multicystic dysplastic kidney and hydronephrosis in the left kidney (42). Goodman et al (30) described absence of the vagina and adnexa.

Oral manifestations. The lower lip is especially full and protrudes. The mandible seems to be prognathic in most patients, although this feature has been studied cephalometrically in few instances (16,70, 94,97,100). Radiographic examination of the skull in a small series of patients has demonstrated greater lateral winging of the angle of the mandible, increasing the bigonial distance.

Facial clefting as an associated finding was pointed out by Giacoia and Klein (38) and by Gorlin et al (31). Cleft lip and/or cleft palate is about eight times as frequent in Waardenburg syndrome as in the normal population, being seen in about 1% of Waardenburg, type I populations (2,27,28,31,97). We suspect that the family reported by Pierpont et al (74) had WS type IV.

Differential diagnosis. Dystopia canthorum and hypertelorism may be seen in a variety of disorders (73). Synophrys is a feature of *de Lange syndrome* and may also occur with pilonidal cyst (81). Hypoplastic alar cartilages may be seen in *OFD I syndrome*. Poliosis, with or without piebaldism, may be inherited as an autosomal dominant trait and may be seen with *branchio-oculo-facial syndrome*. Poliosis, vitiligo, and dysacousia may be seen in combination with alopecia and uveitis in Vogt-Koyanagi syndrome (36). Heterochromia irides may be acquired, inherited as an autosomal dominant trait (23), or in association with *Romberg syndrome*. Partial albinism with deafness may occur as an X-linked dominant trait (103). Zlotogora (104) suggested that this kindred represents an X-linked dominant form of WSII. Vitiligo and congenital sensorineural hearing loss have been reported as an autosomal recessive combination (93). An autosomal dominant syndrome of white forelock, leukoderma, cerebellar ataxia, poor motor coordination, and mild mental retardation was described by Telfer et al (91).

An autosomal recessive lethal syndrome of almost total white hair (fringe of black hair at the nape), total aganglionosis, and congenital profound sensorineural hearing loss was reported in an inbred Kurdish syndrome by Gross et al (32). This cannot be mistaken for Waardenburg syndrome.

Hirschsprung disease has been reported by several authors to be associated with congenital sensorineural hearing loss (52,85,99) and with facial clefting. It should be emphasized that there is no evidence to indicate that any of these patients had Waardenburg syndrome. Various other pigmentation disorders have been reviews by Ortonne (69).

Laboratory aids. In dystopia canthorum, the inner canthal distance divided by the interpupillary is greater than 0.6 (71).

Albinism, Black locks, neural crest Cellular malmigration, and sensorineural Deafness (ABCD) syndrome

Through the courtesy of Dr. Ursula Froster, Lübeck, Germany, one of the editors (RJG) was made aware of a child with trisomy 21 with cleft lip, white scalp hair except for that in the occipital area, aganglionic megacolon, and congenital profound sensorineural hearing loss (Fig. 13–89A,B). Gross et al, in 1995, described an autosomal recessive neural crest syndrome consisting of *A*lbinism, *B*lack locks, *C*ell migration disorder of the ganglion cells of the gut, and *D*eafness, which they termed the ABCD syndrome. The syndrome occurred in a highly inbred Kurdish family in which 5 of 14 siblings were affected. All 6 patients died soon after birth. Total aganglionosis was found (Fig. 13–89C–F).

Inheritance is autosomal recessive.

Reference [Albinism, Black locks, neural crest Cellular malmigration, and sensorineural Deafness (ABCD) syndrome]

Ataxia-telangiectasia (Louis-Bar syndrome)

The syndrome of ionizing radiation sensitivity is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, recurrent sinopulmonary infections, high incidence of neoplasia, variable immunodeficiency, and chromosomal instability. Mme. Louis-Bar (49) is credited for its delineation in 1941, although earlier examples were reported by Syllaba and Henner (79). Boder and Sedgwick (11) coined the term "ataxia-telangiectasia" and clearly defined the syndrome in 1958.[1] Boder (9,10) published exhaustive reviews in 1975 and 1985. Helpful summaries are those of McKinnon (52) in 1987, Cohen and Levy (17) in 1989, Gatti et al (32) in 1991, Shiloh (72) in 1995, Gilad et al (35) in 1998, and Meyn (52a) in 1999. There have also been useful texts on the subject (12,28).

The frequency of the syndrome in white populations has been estimated to be 1 per 40,000 live births (91). Its true frequency is undoubtedly greater because heterozygote frequency may be as high as 3% (78). Even if it is 1 in 60, then the disease must be 1 in 15,000. The most common ancestral countries of origin are England and Wales, Ireland, Eastern Europe, and Germany, but Turks, Italians, and Moroccan Jews have a high frequency (72). Five different complementation groups have been

[1] We see no reason not to hyphenate the name of the syndrome.

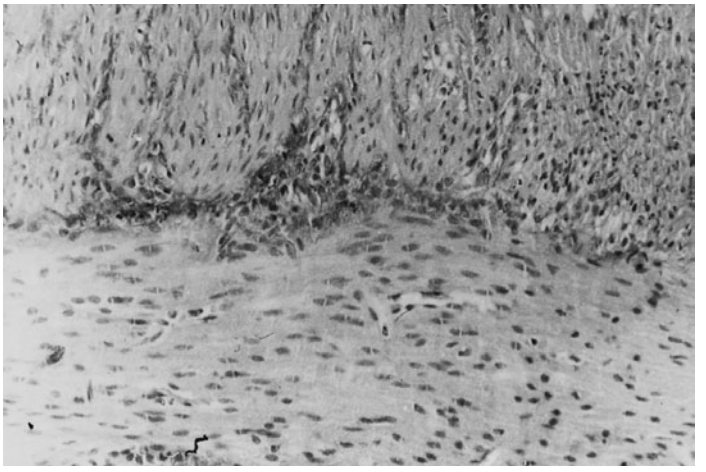
E



F

demonstrated (43,55,78), and clinical heterogeneity has been claimed by some (81) but denied by other investigators (39).

Death usually occurs during the second decade from either overwhelming pulmonary infection or cancer, the disorder possibly being more lethal in blacks (54). There is heightened sensitivity to radiation and to radiomimetic drugs (80).

Genetics. Inheritance is autosomal recessive, but the parental consanguinity rate is very low (91,92). Oxford et al (57), in 1975, described chromosomal anomalies in ataxia-telangiectasia (AT) involving mostly chromosome 14.

In 1986, Aurias et al (4) described telomere-centromere translocation followed by double duplication between chromosomes 7 and 14 in cases of AT. Gatti et al (30), in 1985, and Aurias and Dutrillaux (2,3), in 1986, reported that the sites of breaks in rearrangements (7p14, 7p35, 14q12, 14qter, 2p11, 2p12, and 22q11–q12) are those where members of the immunoglobulin superfamily are located: IGK, IGH, IGL, TCRA, TCRB, TCRG.

Gatti et al (31), in 1988, localized the AT gene to 11q22–q23 and later, in 1993 (33), pointed out that all 5 complementation groups are linked to a single region at 11q22.3. This was confirmed by McConville et al (50a). However, Hernandez et al (40), in 1993, reported a large family with no linkage to this site. Genotype-phenotype associations have been discussed by Li and Swift (48a).

In 1995, Savitsky et al (66) identified a gene that they named *ATM* (for AT mutated) which was found to be mutated in AT patients from all complementation groups. *ATM* encodes a protein that is similar to phosphatidylinositol 3′ kinases which are involved in mitogenic signal transduction, meiotic recombination, and cell cycle control (13,52a). It was speculated that the discovery of *ATM* may have broad implications in clinical medicine and basic research (46,66). More than 100 *ATM* mutations broadly distributed throughout the *ATM* gene have been documented (18,65a,95). Most AT patients are compound heterozygotes (18). More than 70% of the mutations are predicted to lead to protein truncation. The haplotypes of patients with identical mutations indicated that almost all represent common ancestry, with very few spontaneously occurring *ATM* mutations (24,83).

Rare AT patients with milder manifestations have been designated AT variants. Gilad et al (35) reported in 1998 that cell lines from these patients exhibited considerable variability in radiosensitivity, along with the typical radioresistant DNA synthesis found in AT cells. The typical AT phenotype is caused, in most cases, by null *ATM* alleles that truncate or severely destabilize the ATM protein, whereas the AT variants had 1%–17% of the normal level of ATM protein. Gilad et al (35) studied the cell line derived from a patient reported by Curry et al (21) in 1989 and found it to be devoid of the ATM protein and homozygous for a severe *ATM* mutation. They concluded that certain AT variant phenotypes, including some of those without telangiectasia, represent mutations of *ATM*. Moreover, in a patient with ataxia-telangiectasia without immunodeficiency, Toyoshima et al (85), in 1998, discovered novel point mutations within and adjacent to the phosphatidylinositol 3-kinase–like domain. It is thus realized that the clinical spectrum of AT caused by *ATM* mutations may be broader than previously thought (6).

The role of ataxia-telangiectasia heterozygotes in breast cancer has been controversial (1,8,14,23,26,93).

Clustering of missense mutations in *ATM* was found in a sporadic T-cell leukemia (88). Occasional missense mutations in *ATM* were also found in tumor DNA from patients with B-cell non-Hodgkin lymphomas (B-NHL) and a B-NHL cell line (88).

Facies and appearance. Somatic growth is retarded. The face is described as thin, and the expression is relaxed, dull, impassive, or sad (Fig. 13–90). The patient often stoops with the shoulders drooped and the head held to one side. Mild athetoid movements may be noted around the shoulders. Growth is markedly diminished in over 65% of patients (69).

Central nervous system. The ataxia is of the cerebellar type and usually becomes apparent between 3 and 6 years of age (92). The truncal ataxia is slowly progressive. The ability to walk is usually lost after

Fig. 13–90. *Ataxia-telangiectasia*. Note rigid facies marked by staring expression and prominent bulbar conjunctival vessels. (From SJ Miller and W Gooddy, Brain 87:581, 1964.)

10 years of age. Eventually there may be dyssynergia and intention tremor of the upper extremities. Hypotonia and diminished tendon reflexes are noted. Speech is slow, slurred, and often scanning (dysarthric). Dystonia and peripheral neuropathy are noted in 70%.

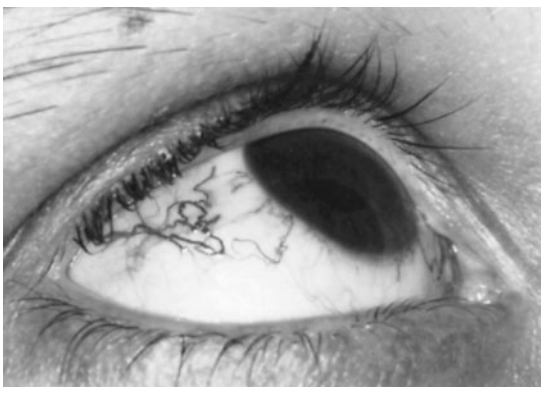
Mental deficiency is usually not apparent until the child reaches the age of 9 years, when mental development begins to taper off. This has been noted in about 30%.

Brain imaging studies show there is cerebellar atrophy, and, on necropsy, degeneration of Purkinje and granular cells without reactive gliosis (84). Degenerative changes have also been noted in spinal cord and ganglia, brainstem and peripheral nerves.

Eyes. Usually between 3 and 6 years, fine, symmetric, bright-red streaks are noted in the temporal and nasal areas of the conjunctiva. The telangiectasia has been shown to be venous and nonhemorrhagic (38) (Fig. 13–91).

Strabismus, poor convergence, photophobia, and nystagmus are commonly found. In all affected, movement of the eyes is slow and interrupted, halting midway on lateral and upward gaze (apraxia). This movement is often accompanied by rapid blinking. Fixation nystagmus is present in over 80% (69).

Fig. 13–91. *Ataxia-telangiectasia*. Telangiectasia of bulbar conjunctiva. (From G Karapati et al, Am J Dis Child 110:51, 1965.)



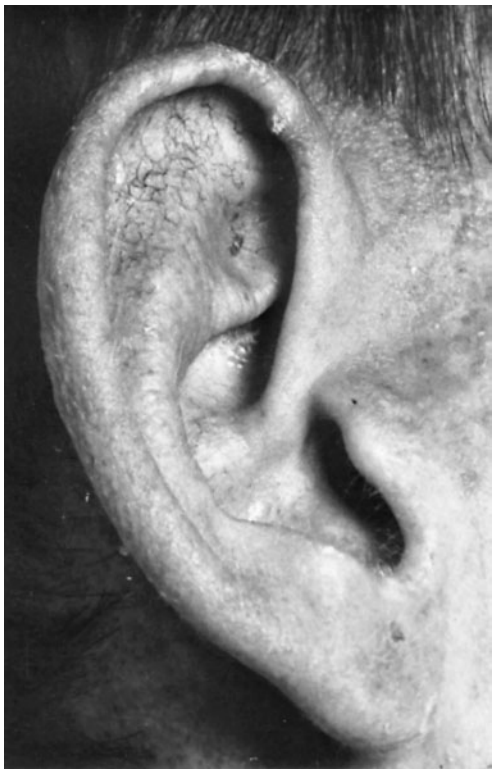


Fig. 13–92. *Ataxia-telangiectasia*. Telangiectasia of pinna. (From M Ruiter, Hautarzt 15:667, 1964.)

Skin. The cutaneous telangiectasia is first noted on the ears, butterfly area of face, bridge of nose, and periorbitally (Fig. 13–92). The distribution is not always correlated with sun-exposed areas (17). With time it extends to the neck, antecubital and popliteal areas, and the dorsum of hands and feet. Heterozygotes have increased numbers of telangiectases (17).

With continued sun exposure and/or aging, the skin tends to become sclerodermatous in appearance, with a mottled pattern of hyperpigmentation and hypopigmentation (poikiloderma). Café-au-lait spots have been noted in 35% (17). Diffuse graying of the scalp hair is noted in about 40%, even in young patients (17). Seborrheic dermatitis, follicular keratosis, and hirsutism of the arms and legs are constant features (9,11,69). A few patients have acanthosis nigricans (17), possibly related to insulin resistance (68). Approximately 15% are generally hirsute (17).

Even though telangiectasia is the classic cutaneous finding of ataxia-telangiectasia, cutaneous granulomas may be the presenting sign in this condition (22).

Respiratory system. Recurrent sinopulmonary infections have occurred in 75%–80% (11,64). These may vary in severity from acute rhinitis with otitis media to chronic bronchitis, recurrent pneumonia, bronchiectasis, and bronchiolitis obliterans (42).

Neoplasia. There is a high frequency (about 20%) of malignancy, usually lymphoreticular of T-cell type (17,27,38,51,61,67,76,77): non-Hodgkin lymphoma (45%), acute lymphocytic leukemia (25%), carcinoma (20%), Hodgkin disease (10%). Few B-cell lymphomas have been reported (45). Various types of cancer have included adenocarcinoma of the stomach, medulloblastoma, glioma, and carcinoma of skin, gallbladder, liver, larynx, ovary, breast, and parotid gland (17,34,37, 48,54,74,77,89). There is some evidence that young parents of affected children have a five-fold higher rate of cancer and autoimmune disease than do control parents (15,17,77).

Sexual maturation. Sexual maturation is retarded, with female hypogonadism being almost uniform (53).

Oral manifestations. Telangiectasia of the hard and soft palate has also been reported (10,11,64,87). Nasal mucosal involvement with telangiectasia may be inferred from recurrent episodes of epistaxis (64). Drooling has been noted in the vast majority of patients (11,69), but its cause has not been established (9). Speech, as noted, is often of the bulbar type. Oropharyngeal lymphosarcoma of the palate has been noted in several cases (36,73).

Differential diagnosis. Ordinarily considered in differential diagnosis are cerebral palsy, structural anomaly or neoplasm of the posterior fossa or foramen magnum, or any of several degenerative or metabolic disorders such as Friedreich ataxia, hepatolenticular degeneration, Pelizaeus-Merzbacher disease, and Hallevorden-Spatz disease. The *Nijmegen breakage syndrome*, an autosomal recessive condition with microcephaly, immunodeficiency, and chromosome instability, must be excluded. Conley et al (19) and Wegner et al (90) described still another disorder of immunodeficiency, chromosome instability, microcephaly, defects of skin pigmentation, and anal stenosis/atresia.

Laboratory aids. Synthesis of antibodies and certain immunoglobulin subclasses is disrupted due to disorders of B-cell and helper T-cell function. This has been characterized as a decreased production of α-globulin, particularly IgA and IgE in over 60% (9). IgG_2 is usually decreased (56). Probably all patients have IgA_2 deficiency (95).

In the blood, relative and absolute numbers of T cells are usually decreased. Whereas the number of B cells is usually elevated, T-helper cells are diminished and defective (29,86). Functionally, there is a defect in cellular immunity. The defect in T cells is manifested by poor stimulation to mitogens, antigens, and allogenic cells—that is, there is failure to respond to phytohemagglutinin (PHA), delayed homograft rejection, an inability to sensitize to dinitrochlorobenzene, and decrease in in vitro lymphocyte transformation (9,36,51,61).

Serum α-fetoprotein and carcinoembryonic antigen levels are elevated in 90% (29,75,89,91,92). There is an altered cell cycle (7) and an elevated frequency of in vivo somatic cell mutations.

Primary gonadal failure is indicated by hypoplastic uterus and absence of ovarian follicles (96). Bizarre nuclear change or cytomegaly has been noted in myocardium, endocrine organs, liver, and central nervous system.

The thymus usually appears vestigial, lacking corticomedullary differentiation and Hassall's corpuscles. Lymph nodes exhibit depletion of lymphocytes in the deep cortex (T-dependent areas), whereas follicles remain intact. The tonsils are hypoplastic, often exhibiting poor germinal follicles and secondary crypt formation.

Over 50% with ataxia-telangiectasia have abnormal glucose tolerance, but rarely with glycosuria and never with ketosis, implying insulin resistance (5,51,68).

Fibroblastoid and lymphoblastoid cells are hypersensitive to the cytotoxic and clastogenic action of ionizing, and radiomimetic chemical agents such as bleomycin, adriamycin, and hydrogen peroxide, reflecting a defect in response to DNA damage or a relative resistance of DNA synthesis (20,27,28,41,58,60). There is radiosensitivity to the chromosomes of heterozygotes (59).

Initially random chromosome breakage followed by a translocation involving the long arm of chromosome 14 and either the short or long arm of chromosome 7 has been found. In the final stage, a (14;14) translocation may be identified in some patients (39,50,51). Increased chromosome breakage has been used in prenatal diagnosis of this disorder (71). There is a different pattern in lymphocytes and fibroblasts (47).

An exfoliated epithelial cell micronucleus test obtained from the mouth or urine yields 4- to 14-fold values in homozygotes and elevated levels in 70% of heterozygotes (65).

CAT scans and magnetic resonance imaging (MRI) should be of help in diagnosing cerebellar atrophy.

The large size of the *ATM* gene, 66 exons spanning approximately 150 kb of genomic DNA, together with diversity and broad distribution of mutations in AT patients greatly limits the utility of direct mutation screening as a diagnostic tool (18).

Both AT homozygotes and heterozygotes showed significantly increased levels of radiation-induced chromatid damage. Thus, the G2-phase chromosomal radiosensitivity assay can be used for the detection of AT heterozygotes. Along with molecular genetic analyses, it may be used to determine the potential involvement of *ATM* mutations in tumor risk or tumor development (82).

A dominant form of chromosomal instability syndrome was reported by Ishikawa et al (41a).

Focal dermal hypoplasia (Goltz-Gorlin syndrome)

Goltz et al (25) in 1962 and Gorlin et al (27) in 1963 defined a syndrome of focal dermal hypoplasia (FDH) consisting of asymmetry of face, trunk, and extremities; atrophy, telangiectasia, and linear hyperpigmentation of skin; localized cutaneous deposits of superficial fat; multiple papillomas of mucous membranes and periofacial skin; and abnormalities of skeleton, especially the extremities. Another example is that of Šalamon et al (67). The earliest case report appears to be that of Jessner (41) in 1921. Over 250 cases have been reported under a variety of names. An excellent survey of early cases was carried out by Braun-Falco and Hofmann (6). The reader is referred to several comprehensive reviews (6,23,25,26,30,54,79,88,91).

Approximately 95% of the cases have been sporadic examples and only about 10% have occurred in males (7,9,18–20,22,26,30,43,48,62, 66,72,74,82,83,89). There have been a few familial examples, mostly mother–daughter (25,50,63,66,75,91,92), but father–daughter transmission has been described (10,15,28,48,52). The transmitting parent is usually only mildly affected. The evidence suggests that the disorder is X-linked dominant, lethal in male hemizygotes, and with markedly reduced fertility in the female (16,91). Happle (33) suggested that affected males might be explained by mosaicism. The male cases cited earlier are always new mutations. An XXY state may explain some cases.

In 1988, Friedman et al (21) described a child with FDH who was found to have a terminal deletion of the short arm of the X chromosome with the breakpoint in Xp22.31. Schnur et al (70) and Naritomi et al (58) confirmed that FDH and MIDAS syndrome map to the same site and are probably allelic.

In a study of a father and daughter, both affected, Gorski (28), in 1991, suggested that FDH is associated with nonrandom X inactivation consistent with X-linked inheritance, with mosaicism for a mutant FDH allele, in the father. Irvine et al (38), in 1996, reported a child with a markedly skewed inactivation pattern in the proband, but random in her mother. Bellosta et al (4), in 1996, reported a family with affected females in 3 generations, consistent with X-linked dominant transmission with lethality in the male.

Facies. Mild microcephaly is common. The face and/or skull are asymmetric and the scalp hair sparse and brittle in about 30% (31). The nasal alae may be notched or underdeveloped (10). Due to midface hypoplasia, there is often mild relative mandibular prognathism. (Fig. 13–93). The pinnae are usually outstanding and poorly modeled. The auditory canals may be narrow (Fig. 13–94A).

Skin and skin appendages. Asymmetric skin lesions, present at birth in 50%–75%, include thin skin with linear or reticular hyperpigmentation or hypopigmentation, and telangiectasia (30,73). The lesions follow the lines of Blaschko (32). There is focal absence of skin at birth in 15% (30). The iliac crest area, groin, and posterior aspects of the thigh frequently show subcutaneous fatty collections, varying in color from tan to yellow or pinkish yellow (Fig. 13–95). Howell and Freeman (36) and Ishii et al (40) have suggested that it is heterotopic fat, not fat herniation. Supernumerary nipples are common (90). The breasts are often significantly asymmetric (42). In childhood, arborescent papillomas appear in the axillae, in the periumbilical area, or around the anus and vulva

Fig. 13–93. *Focal dermal hypoplasia*. Note multiple frambesiform lesions on lips, coloboma of iris, strabismus, thin hair.

in 50%–60% (30,53,73). Those in the genital area may be mistaken for condyloma acuminatum (11). Stature is short in 15%.

Spotty hypotrichosis of the scalp or pubic hair has been found in 25% (30,80). The fingers and toenails may be absent, poorly developed, or spooned or grooved in 50% (Fig. 13–96). The epidermal ridges of the fingertips may be hypoplastic. Hidrocystomas (93) and apocrine nevi (86) have also been reported.

The population doubling time of fibroblasts in affected skin is double that of normal skin fibroblasts (84). These fibroblasts have a decreased amount of hyaluronic acid-derived disaccharide unit (delta Di-HA) (69).

Eyes. Approximately 40% have anomalies of the eyes. These have been extremely well reviewed in a number of articles (7,56,81,90). Among the more common findings are coloboma of the iris, choroid, retina, and optic nerve (40%), microphthalmia (15%), and strabismus (15%). Unilateral anophthalmia (39), obstructed tear ducts with associated photophobia (44,64), corneal opacifications (50), ectopia lentis (6%), lenticular opacities (47), optic atrophy, aniridia (3%), nystagmus, and conjunctival papillomas have also been reported.

Central nervous system. Mental retardation, usually mild, has been documented in about 15% (11). Mixed hearing loss has been manifested in a number of cases (19,23,27,30,45,53,66,82). Myelomeningocele, hydrocephalus, agenesis of corpus callosum, and Arnold-Chiari malformation have been found (1,2,61).

Musculoskeletal system. Short and asymmetric stature is found in at least 25%. Syndactyly (75%), brachydactyly (60%), and oligodactyly (45%) are extremely common (Fig. 13–96). Postaxial polydactyly and clinodactyly have been found in a number of cases. The extremities, or parts thereof, are often asymmetric. Complete hemimelia of a limb has been reported (1,39). Brachydactyly can result from shortened phalanges, metacarpals, or metatarsals. The combination of split hand with syndactyly and absence of rays, the so-called lobster-claw hand, has come to be recognized as a striking feature of this condition (24). Rib anomalies have been reported (19). Midclavicular aplasia or hypoplasia (pseudarthrosis), apparently limited to the right side, is common (26).

Scoliosis (25%), spina bifida (7%), and congenital hip dislocation (17,26,29,34) are found. Osteopathia striata has been found in at least 20% (3,5,10,18,20,36,45,48,59,88) (Fig. 13–96C). Several authors have noted multiple giant cell tumors of long bones (12,42,51,71,78). An osteochondroma has also been reported (12a). A rudimentary tail (23) and a split sternum (14) have been documented.

Genitourinary system. Hydronephrosis (7,30), bifid ureter and renal pelvis (45), horseshoe kidney (48,77), hypoplasia of clitoris and labia (49,90), and cryptorchidism (19,72) have been sporadically described.

Miscellaneous findings. Umbilical hernia and/or omphalocele has been reported in 10%–15% (6,11,16,20,23,26,34,44,66,68,87). Diaphragmatic hernia (46,60), diastasis recti (6), and anterior displacement

A B

Fig. 13–94. *Focal dermal hypoplasia*. (A) Dysmorphic pinna with scarring of lateral neck. (B) Hamartomatous mass of dorsum of tongue. (From Gordjiani et al, Eur J Dermatol 9:618, 1999.)

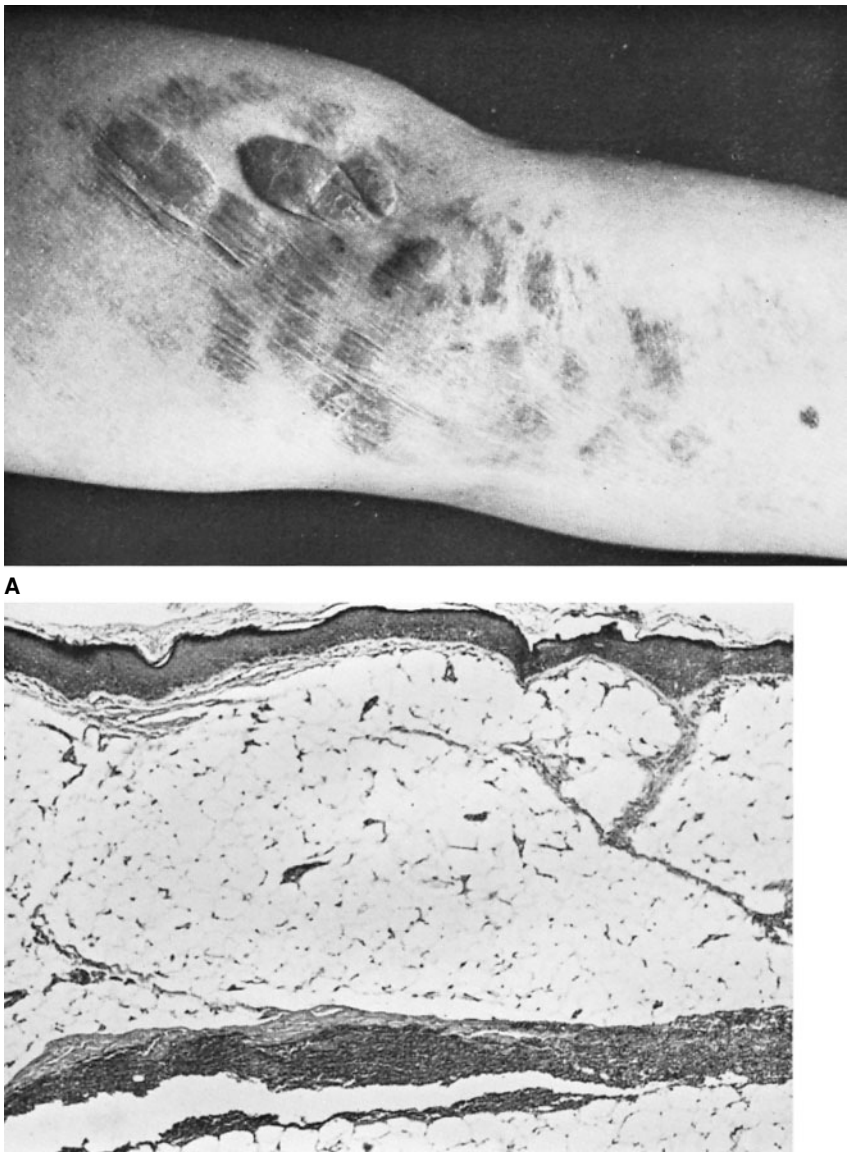

Fig. 13–95. *Focal dermal hypoplasia*. (A) Multiple sacular growths presenting in antecubital area. (B) Photomicrograph of focal dermal defect showing subcutaneous fat covered only by epithelium.

of anus (90) have been found. Intestinal malrotation and mediastinal dextroposition may also be present (38,60). Papillomatosis of the larynx has been described (29). Severe vascular anomalies have been described (31). Papillomatosis of the larynx has been described (29). The reader is referred to a detailed comprehensive article for other anomalies (30).

Oral manifestations. The most frequent dental findings is hypodontia or oligodontia, although supernumerary teeth have been reported (30). The teeth may be small with dysplastic enamel, irregularly spaced, malocclusion, and with delayed eruption (8,85) (Fig. 13–97).

Arborescent papillomas of the lips, gingiva, dorsum and base of tongue, and perioral skin have been noted in 40%–50% (22a,44,90). They have even been reported in the esophagus (93). Hamartoma of the tongue dorsum has been noted (29) (Fig. 13–94B).

Cleft lip and/or cleft palate have also been described (1,13,19,26, 64,73,87) as well as lateral oral cleft (1,57). The reader is referred to the detailed article of Hall and Terezhalmy (30) for other minor oral anomalies.

Differential diagnosis. Nevus lipomatosis superficialis (Hoffmann-Zurhelle) is characterized by neutral fat-bearing cells adjacent to blood vessels in the middle and upper layers of the skin (34). In differential diagnosis, *incontinentia pigmenti* and *Rothmund-Thomson syndrome* should be excluded (6). Some overlap with *EEC syndrome* has been cited, but we feel that both are generally distinctive (65). The patient documented by Sule et al (76) surely has *Delleman syndrome*.

Clavicular pseudarthrosis as an isolated finding is a right-sided anomaly in 90% of the cases and may be inherited as an autosomal dominant trait. Rarely it is bilateral (55). It is also found in the *Floating-Harbor syndrome*.

Laboratory aids. Skin biopsy of a fatty lesion demonstrates normal adipose cells in the corium. Less specific changes are found in the scarlike areas (23,34). Radiographic studies may show osteopathia striata and numerous skeletal changes previously described (Fig. 13–96).

Hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome)

The syndrome, characterized by familial occurrence of multiple capillary and venous dilations of skin and mucous membranes with repeated hemorrhage, was mentioned in 1864 by Sutton (81) and in 1865 by Babington (5). Rendu (71), in 1896, reported a patient with recurrent epistaxis and numerous dilated vessels on the face and oral mucosa. Osler (56), in 1901, gave a full account of the syndrome, and Parkes Weber (57), in 1907, pointed out that the condition becomes worse with age. The descriptive term "hereditary hemorrhagic telangiectasia" was suggested by Hanes (32), in 1909, and is now widely used, although various eponyms are still employed (31). There have been several excellent reviews (2,9,30,42,45) and discussion regarding diagnostic criteria (77a).

Estimates of frequency have ranged from 1 in 2500 to 1 in 40,000 (29). The syndrome is recognized more commonly among whites, but has been reported among all ethnic groups (66). It is rarely detected in infants (52).

Inheritance is autosomal dominant (24) with less than complete penetrance (63), making, at times, for difficult counseling. The lethal homozygotic state (78) is less than certain.

Linkage has been established to chromosome 9q34.1 (28,34,50,76) in some families, to 12q13 in others (39,65,88). The two major genes, termed *HHT1* and *HHT2*, each encode transmembrane proteins that participate in signaling through receptors of the TGFβ receptor family. The former gene (*HHT1*) encodes endoglin, which binds two ligands related to TGFβ (23,77). Endoglin is thought to alter the response to these ligands. *HHT2* encodes activin receptorlike kinase 1, which also binds a similar set of ligands in the presence of a TGFβ receptor (9,40). These glycoproteins, abundant on endothelial cell, and bound to TGFβ, modulate migration, proliferation, adhesion, composition, and organization of extracellular matrix (14). Both nonsense and missense mutations have been found. Both genes act through haploinsufficiency. It is possible that alteration of one or more of these factors causes the vascular dysplasia (48). A third gene has been described in one large family with hepatic involvement. Linkage has been excluded from both chromosomes 9 and 12 (60).

Hereditary hemorrhagic telangiectasia should be considered a generalized pleomorphic angiodysplasia of almost any organ. The telangiectases are direct arteriovenous connections without an intervening capillary bed. The telangiectasias are bright red, violaceous, or purple, and pinpoint, spiderlike, or nodular. When a glass slab is pressed on them, they blanch. Often the patients are pale, and they may have a history of fatigue and weakness caused by bleeding from the telangiectases, with resultant anemia. The hemorrhage, often nontraumatic, is the most severe complication and becomes more frequent with advancing age. It has been postulated that the hemorrhages are aggravated by anemia, thus producing a vicious cycle.

Skin. Telangiectases are observed on the facial skin (35%), especially on the cheeks, ears, and nasal orifices (Fig. 13–98). They may also occur on fingers, toes, and nail beds in about 40%. Usually appearing in the second to third decades of life and increasing in number and size with age, rare cases without external signs of the syndrome occur. The lesions may be purpuric. In elderly persons, spiderlike configurations may be seen.

Nasal mucosa. Telangiectases of the nasal mucosa are common. Approximately 95% experience recurrent epistaxis, which tends to become more severe with time in over 65% (63,70). Epistaxis usually precedes the appearance of telangiectasia on the skin, appearing in childhood or young adulthood (10–20 years) in 50% (1,63). Bleeding from the nose may be oozing, sometimes persisting continuously for several days. Profuse hemorrhage may be initiated by sneezing or coughing. Death due to hemorrhage has occurred in 2%–4% (49).

Other mucous membranes. The mucosa of the upper and lower gastrointestinal tract is often (20%–40%) involved, resulting in melena and hematemesis, which manifest most often in the 5th and 6th decades (70,86). The conjunctiva (35%) or retina (10%) (12,19) may be sites of telangiectasia. When located in the bladder, vagina, or uterus, telangiectases may lead to genitourinary bleeding.

Lungs. Multiple thin-walled aneurysms or arteriovenous malformations in which a pulmonary artery and pulmonary vein are connected may be found in both lungs. There is a special predilection for the lower posterior lobes (84). Approximately 5%–15% of those with hereditary hemorrhagic telangiectasia have pulmonary A-V malformations (61,70).

Fig. 13–98. *Hereditary hemorrhagic telangiectasia*. Note numerous telangiectases on face and lips.

Fig. 13–99. *Hereditary hemorrhagic telangiectasia*. Close-up showing lesions of lips and tongue.

However, Piepgras and Sielecki (61) found that 50% have A-V malformations. Conversely, about 60% of those with pulmonary A-V malformations have hereditary hemorrhagic telangiectasia (18). However, recent genotype–phenotype studies have suggested that the frequency of A-V malformations depends on the specific gene mutation (34,47,64), more cases being associated with HHT1 (45,49a). The A-V shunts are right-to-left, producing, especially when multiple, cyanosis, profound dyspnea, fatigue, and polycythemia. Virtually all patients with cerebral abscesses have pulmonary A-V shunts.

Brain. Various neurologic symptoms, such as brain abscess, migraine headaches, stroke, seizures, transient ischemia attacks, and intracerebral hemorrhage are frequent in patients with the syndrome, particularly in those with pulmonary arteriovenous malformations (35,62,64,67,79,89). Brain abscess, transient ischemia, and ischemic stroke occur only in those with pulmonary A-V malformations and a right-to-left shunt, which permits the passage of emboli into the cerebral circulation (59). Román et al (73) found more than 200 reported cases with involvement of the nervous system. Approximately 60% of these were secondary to pulmonary arteriovenous fistulas. On CT scan about 5% of those with HHT have A-V malformations (49a,89). Adams et al (2) stated that about 5% of patients with arteriovenous fistulas develop cerebral abscesses. Conversely, virtually all patients reported with hereditary hemorrhagic telangiectasia and cerebral abscess had pulmonary arteriovenous fistula. Cerebral abscess must be considered a serious complication of hereditary hemorrhagic telangiectasia (20,63,73).

Other findings. Almost any other organ may be affected by angiodysplasias: bone, liver, spinal cord, and heart (10,33,46,51,70,73).

Intrahepatic arteriovenous fistulas, found in 17% of those with type 2 HHT, have also been reported to cause encephalopathy (32,49a). Duodenal ulcer has been found in about 5% but in almost 20% of those with gastrointestinal bleeding.

Oral manifestations. The lips and tongue (especially the dorsum and tip) are sites of telangiectasia in about 60% (Fig. 13–99). The palate, gingiva, buccal mucosa, and mucocutaneous junctions may be similarly affected in about 20%. Recognition of oral lesions has often led to the correct diagnosis. Bleeding from the mouth is second in frequency to epistaxis. It has been noted in about 20% (8). Hemorrhage from the gingiva and buccal mucosa occurs less frequently than from the lips and tongue. A dramatic report of bleeding from telangiectasia of the tongue was given by Bean et al (8). Philips (59) mentioned a fatal outcome after gingival bleeding. Gingival hemorrhages may become manifest at a rather late age. Labial lesions are more common (about 85%) in those with gastrointestinal bleeding. Dental prophylaxis has caused bleeding from lip telangiectases (59). Even toothbrushing should be carried out with great care in patients with gingival telangiectasia.

Pathology. Angiographic studies have demonstrated three different vascular abnormalities: aneurysms, arteriovenous communications, and angiomas (27). Histologically, the telangiectases are found just beneath the epidermis. Their walls are extremely thin, consisting of a single layer of endothelial cells on a continuous basement membrane. The telangiectases are not associated with new formation of vessels but consist solely in marked dilatation.

The small vascular lesions range from dilatation of postcapillary venules to dilated convoluted venules that connect directly to dilated arterioles. As the lesions become mature, the venules develop excess layers of smooth muscles without elastic fibers. Mononuclear cells, principally lymphocytes, collect in the perivascular spaces during the process (13). The arteriovenous malformations are merely much larger direct connections between arteries and veins.

Differential diagnosis. Scrotal angiokeratomas are present in 10%–20% of normal males over 50 years of age (7,66). Sublingual phlebectases (caviar spots) are present in about 15% of healthy males under 40 years (68) and in 50% of males and 20% of females between 50 and 60 years of age. Caviar spots increase with age, so that 60% of males and 75% of females between 70 and 79 have them (7). Spider nevi have been noted in over 45% of healthy school children (4) and in about 15% of normal adults (7). Cherry angiomas (de Morgan spots) are seen in 90% of patients over 40 years of age (75). Phlebectasia of the lips or oral mucosa was noted by Bean (7) in about 50% of normal individuals over 40 years of age. Autosomal dominant phlebectasia of the lips was described by Reed (69). There is a plethora of types of angiomatosis that may affect oral structures. The interested reader should carefully peruse the works of Bean (7,8) and Mulliken and Young (53). Labial involvement is common in *Fabry syndrome*, and oral angiomas occasionally occur in *Maffucci syndrome*. Multiple phlebectasia of the oral cavity (lower lip, oral floor, buccal mucosa, palate), jejunum, and scrotum is a

Fig. 13–100. *Blue rubber bleb nevus syndrome*. Note multiple bladderlike lesions of skin. (Courtesy of O Jumbou, Nantes, France.)

nongenetic, age-dependent association first described by Rappaport and Shiffman (68). Most patients have been males over 40 years of age. The scrotal lesions (Fordyce angiokeratomas) are round, raised, red to black, well-defined lesions less than 4 mm in diameter. Phlebectatic lesions are present in the wall of the jejunum, less often of the ileum or cecum. A number of patients have also had gastric or duodenal ulcer (68,75). Conversely, Gius et al (25) found that 25% of patients with peptic ulcers exhibit phlebectatic lesions of the lower lip.

Strawberry nevi with severe developmental delay, unusual facies, and flexed fingers has been noted (85). Massive lymphangiomatosis, lipomatosis, and hemangiomatosis has been described (55). *Facial angiomatosis, supraumbilical raphé, and non-union of the sternum* is a recognized syndrome.

Bean (7,8) defined the blue rubber bleb nevus syndrome as multiple, vascular, nipple, or bladder-like lesions of the skin and mucous membranes of the gastrointestinal tract that may be accompanied by gastrointestinal bleeding and hepatic and pulmonary angiomas. The lungs, liver, spleen, joints, and subcutaneous tissues are occasionally involved. The disorder has autosomal dominant inheritance. Oral and facial angiomas have been noted in several cases (6,37,38,80) (Fig. 13–100). The gene has been mapped to the short arm of chromosome 9 (22).

Autosomal dominant multiple glomus tumors exhibit only cutaneous involvement (74). Multilocular hemangiomatosis, separable from the above by the tendency of these lesions to disappear before the second year of life, may also involve the mouth (26,36). Katz and Askin (41) described oral lesions in a patient with multiple hemangiomas with thrombocytopenia, a variant of the Kasabach-Merritt syndrome. Also present were intraosseous angiomas and hepatosplenomegaly. Takato et al (82) reported a giant hemangioma of the parotid gland associated with Kasabach-Merritt syndrome. LaDow et al (43) noted a maxillary angioma in a patient with von Hippel syndrome, and Tasanen (83) described oral, retinal, and encephalic angiomatosis in a patient with thrombocytopenia. Arteriovenous aneurysms of the mandible and retina with hematemesis and epistaxis were described by Bower et al (11). The acral arteriovenous tumor is found on the face or less often on the extremities of middle-aged individuals (16). Vascular malformations (cavernous and capillary angiomas, A-V malformations), especially involving the oral mucous membranes and the skin and soft tissues of the extremities, were reported in an extremely large kindred (58).

Telangiectasia is also seen in CREST syndrome (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia), a form of scleroderma (21). This nonhereditary syndrome has marked female predilection. The various components of the syndrome characteristically appear at various times in a patient's life (72). Only rarely does the disorder present prior to puberty; in these cases, Raynaud's phenomenon first becomes evident (87). Calcinosis is usually limited to the areas of sclerodactyly. Telangiectasias of the face (especially of the cheeks, nose, and lips), oral mucosa, hands, and upper trunk are the most common. The nasal mucosa is characteristically spared. Primary biliary cirrhosis has been described in several individuals. CREST syndrome patients usually exhibit antinuclear and anticentromeric antibodies (24).

Laboratory aids. The hemoglobin and erythrocyte count may be lowered because of hemorrhage. When telangiectases are suspected in the gastrointestinal tract, gastroscopy and sigmoidoscopy may be done. To diagnose arteriovenous fistulas, angiography, computed tomography, and nuclear magnetic resonance (NMR) imaging are extremely helpful (28,54,84).

Hereditary hemorrhagic telangiectasia has been reported concomitantly with thrombocytomegaly, primary thrombocytopenia (17), hemophilia A (44), but most often with Von Willebrand's disease (3,15).

Table 13–4. Comparison of clinical findings of autosomal dominant and recessive forms of pseudoxanthoma elasticum

Characteristics	Dominant I (%)	Dominant II (%)	Recessive I (%)	Recessive II (%)
Cutaneous changes				
Classical peau d'orange and flexural rash	100	25	75	
Macular rash		70	15	
General increase of extensibility	10	65	10	
General cutaneous PXE				100
Vascular disease				
Angina	55			
Claudication	55			
Hypertension	75	10	20	
Hematemesis	10	5	15	
Ophthalmic abnormalities				
Severe choroiditis	75	10	35	
Angioid streaks	35	50	50	
Washed-out pattern		15	2	
Prominent choroidal vessels		20		
Myopia	25	50	5	
Blue sclerae	10	40	10	
Other findings				
High-arched palate		55	15	
Joint hypermobility		35	5

Acrolabial telangiectasia

Millns and Dickens (1) described blue lips, blue nails, and blue nipples in a mother and two daughters. There was also discrete telangiectasia of the chest, elbows, and dorsa of hands, varicosities of the lower legs, and migraine headaches. The syndrome is probably different from the hereditary benign telangiectasia reported by Ryan and Wells (2).

Pseudoxanthoma elasticum

Originally described by Rigal (51), in 1881, and Balzer (4), in 1884, and grouped with the xanthomatoses, the syndrome of alterations of the skin, recurrent severe gastrointestinal hemorrhages, weak peripheral pulses, and failing vision was identified as a separate nonxanthomatous entity and named by Darier (15) in 1896. Angioid streaks were added to the syndrome by Grönblad (23) and Strandberg (59) in 1929, although they had been described as early as 1889 by Doyne (17). Various types have been described. Thorough reviews are those of McKusick (36) and Neldner (41). An excellent historic review was written by Pope (45). Classification has been recently reported by Lebwohl et al (33).

The data presented represent the average of the various types. If ascertainment is made from skin changes, then 65% of patients are female, although this may be due to cosmetic concerns. However, it has also been suggested that there may be an estrogen effect, based on the aggravation of cardiac symptoms during pregnancy (54). The actual risks of serious complications during pregnancy, however, may be overstated (74). If angioid streaks are used for discernment, there is no sex predilection. The combined prevalence of all types has been estimated at 1/40,000 by Altman et al (1) and 1/70,000 to 1/100,000 by Struk et al (60).

The primary alteration in PXE is calcification of elastic fibers due to the accumulation of polyanions within the fibers that may play a role in increased calcium binding (35). Gordon et al (21) found evidence that increased, abnormal catabolism of proteoglycans occurred because of increased secretion of serine protease. Baccarani-Contri et al (2) also suggested defective matrix production.

Elevated lysine and hydroxylysine levels in collagen (6) and raised glutamine, asparagine, glutamic acid, and aspartic acids in the elastin (7) have been discovered. There is some evidence that a relationship may exist between hyperphosphatasemia and PXE (38). Also see Differential diagnosis.

Pseudoxanthoma elasticum is genetically heterogeneous, but most cases have autosomal recessive inheritance (36,62). Pope (45–47) suggested that there are two recessive and two dominant forms. The alleged clinical differences are delineated in Table 13–4. However, Stutz et al (61), because of marked variability in expression, could not support two autosomal recessive types. Neldner (41) could not separate distinct phenotypes among 100 patients. Parental consanguinity is seen in at least 20% of those with a recessive form.

Viljoen (67) surveyed 81 patients with PXE in South Africa and Zimbabwe. Three had autosomal dominant PXE, type I, 3 autosomal dominant, type II, 19 autosomal recessive, type I, and 6 autosomal recessive, type II disease. However, 50 individuals of Dutch-French Huguenot extraction had a distinct clinical subgroup characterized by autosomal recessive inheritance, mild to moderate cutaneous and cardiovascular changes, but severe visual impairment by age 50 due to macular neovascularization and hemorrhage (16).

In 1997, Struk et al (60) reported linkage of PXE to 16p13.1. They suggested that allelic heterogeneity with different variants of a single disease gene residing on 16p13.1 accounts for both recessive and dominant forms of PXE. They commented on a more common autosomal recessive form and a less common autosomal dominant pattern of inheritance. Van Soest et al (66), in 1997, mapped an autosomal recessive PXE from a genetically isolated population in the Netherlands also to 16p13.1.

Mutations in a gene encoding ABC transporter cause both the dominant and recessive disorders (5a,33a,52). The gene is in the ATP-binding cassette superfamily which is involved in multidrug resistance.

Fig. 13–101. *Pseudoxanthoma elasticum*. Skin becomes thickened and markings are accentuated by yellowish papules, especially around neck, axilla, elbows, and groin. (From T Heyl, Arch Dermatol 96:528, 1967.)

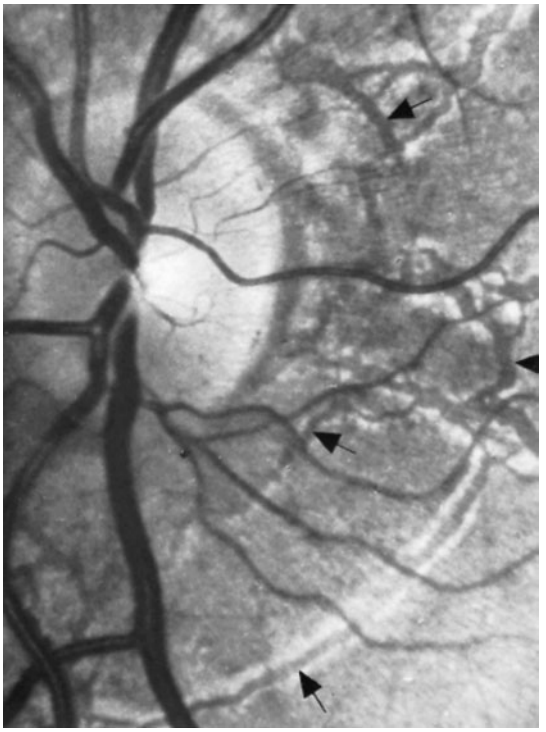

Fig. 13–102. *Pseudoxanthoma elasticum*. Arrows point to angioid streaks. Egg shell "fractures" in Bruch's membrane, usually grouped around optic disks, mimic appearance of blood vessels. (Courtesy of WF Hoyt, San Francisco, California.)

Skin. The skin becomes thickened and the markings are accentuated by raised, yellowish, flat papules, especially about the mouth, neck, axillas, elbows, groin, and periumbilical area (28). A few yellowish papules on the neck or axilla to virtually general cutaneous involvement have been described in association with calcification of the subcutis (27). These changes, usually recognized after the second decade, may appear as early as the third or fourth years of life. The yellowish skin becomes inelastic, redundant, thickened, and grooved, the normal skin marking becoming accentuated so that the skin resembles coarse-grained leather, especially on the neck and in the axilla (Fig. 13–101), Miescher elastoma has also been noted (36,55), and epidermal perforation was found in one woman with hypertension and chronic renal failure who was subsequently diagnosed as having PXE. Acne was present in 42% of patients in one study (68).

Ultrastructural changes consist of granular changes in elastin fibers (24). They exhibit an increased affinity for cationic stains (53). Thready material found in lesions consists of fibrinogen, collagenous protein, and glycoprotein (73).

Eyes. Visual disturbances have been noted in almost 30% of older patients (16). Funduscopic examination demonstrates atypical drusen and white, brown, or gray streaking (angioid streaks) in over 85% (10,11). The streaks probably appear in the second decade or later. They present as a ring around the optic disc extending outward beneath the retinal vessels. Although resembling vessels, they actually represent discontinuity in Bruch's membrane (Fig. 13–102). Retinal hemorrhage, followed by organization, eventuates in loss of visual acuity. Less often there is senile macular degeneration or central chorioretinitis (8,36,65). Other eye findings have included myopia in 26% and bilateral cataracts in 5% of 19 patients with PXE (68).

Cardiovascular system. By the third decade, there may be weakness or absence of pulses in the arms and legs, accompanied by variable degrees of intermittent claudication in about 20% (10,37). Radiographic examination has revealed calcification of peripheral arteries, especially those of the lower extremities, in about 15% (18). Renovascular hypertension has been noted in about 20% (18). Angina pectoris occurs in at least 50% of the patients (10), and abdominal angina due to stenosis of the celiac artery is common (36). Congestive cardiac failure is found in about 70% (50). Careful coronary artery evaluation is required in young patients with PXE, even though asymptomatic, because coronary artery disease seems to be frequent (29).

Lebwohl et al (31,32) reported that 71% had echocardiographic evidence of mitral valve prolapse. Others found mitral valve prolapse in only 18%; however, they suggested that mitral valve prolapse may be more common in the dominant forms of PXE.

Hemorrhage, especially gastrointestinal, occurs in 15% (13) because of involvement of small blood vessels. A number of patients have had peptic ulcer (1). Bleeding may occur in the retina, kidney, uterus, or bladder (8). Epistaxis (10) and hemarthrosis have been recorded. Aneurysms of the internal carotid artery have also been reported, and there is one report of ruptured aneurysm of the anterior spinal artery (30).

Oral manifestations. The skin about the mouth may become redundant, the nasolabial folds and skin creases becoming accentuated and producing a saggy appearance. The mucosal surface of the lips, especially the lower one, may exhibit yellowing intramucosal nodules (15,19,36) in about 10%. The buccal mucosa, soft or hard palate, and tonsillar areas may be similarly affected (10,39,46,47) (Fig. 13–103). The vaginal, gastric, and rectal mucosas have also been involved (10,20). Ultrastructural study of oral lesions showed large numbers of thickened and twisted collagen fibers (14). Highly arched palate has been occasionally noted, particularly in the autosomal dominant form (51).

Other findings. Neurologic deficits may result from complications of hypertension and cardiovascular disease: aneurysmal dilation of vessels, subarachnoid and intracerebral hemorrhage, bilateral carotid occlusion, psychiatric disorders, and seizures (10,18,25).

Mamtora and Cope (34) described two cases of pulmonary opacities, and cited two other cases. Jackson and Loh (26) reported a case of pulmonary involvement; lung biopsy showed deposition of calcium in arteries, arterioles, and venules, as well as in alveolar lumina and septa.

Fig. 13–103. *Pseudoxanthoma elasticum*. Mucosal surface of lower lip exhibits yellowish intramucosal nodules. (Courtesy of RM Goodman, Tel Aviv, Israel.)

Prick and Thijssen (49) described several skeletal anomalies, including dysplastic vertebrae and fibro-osseous dysplasia and transverse sclerotic bands of the metaphyseal regions of long bones. Joint hyperextensibility has also been noted in a few cases.

Hashimoto's thyroiditis, hypothyroidism, hyperthyroidism, and diabetes mellitus have also been occasionally reported (40).

Berde et al (5) summarized the pregnancy histories in seven women with PXE and noted that five suffered severe gastrointestinal hemorrhage during one or more pregnancies. In four, the bleeding that occurred during pregnancy was the first such episode in their lives. It is suggested that a diagnosis of PXE be considered for any patient with gastrointestinal hemorrhage, especially if routine clinical and endoscopic examination fails to reveal the cause, and if raised yellow plaque-like lesions are seen in the stomach by endoscopy (12,58). In one instance of intrauterine growth retardation, it was suggested that maternal vascular compromise led to chronic uteroplacental insufficiency (9). Miscarriage during the first trimester of women with PXE is increased (69).

Differential diagnosis. Angioid streaks may also be seen in Paget's disease of bone. A combination of Paget's disease and PXE has been described by Woodcock (72), Shaffer et al (56), and others (36). Angioid streaks have also been seen in sickle-cell disease, possibly because of iron deposits in Bruch's membrane (23), and in osteoectasia with macrocranium (hyperphosphatasia). Angioid streaks in combination with tumoral calcinosis and hyperphosphatemia have been noted in several families (3). The clinical skin changes in senile elastosis somewhat resembles those on PXE. They may be seen in the Ehlers-Danlos syndrome, following trauma, and in other disorders (24). Pseudoxanthoma elasticum-like changes have also been found in patients treated with high doses of D-penicillamine (64).

Laboratory aids. The involved skin or mucous membrane presents a characteristic microscopic picture. The changes are observed in the middle and lower part of the corium. The elastic tissue appears as fragmented masses, presenting a granular structure that is due at least in part to the presence of calcium salts demonstrated by von Kossa staining (Fig. 13–104). The amount of normal collagen fibers is reduced, whereas reticulum fibers are present in large amounts. The finding of calcium salts in ostensibly normal elastic fibers indicates that calcification is the primary event in PXE (14). Increased amounts of calcium have also been found in the skin on microincineration (33). Photographs of the fundus following injection of fluorescent dye clearly demonstrate the angioid streaks (57).

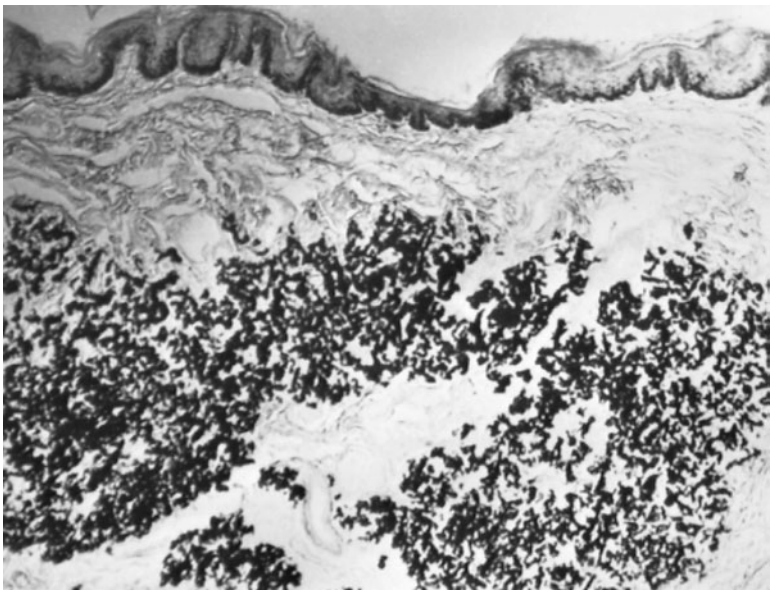

Fig. 13–104. *Pseudoxanthoma elasticum*. Elastic tissue appears fragmented and granular because of presence of calcium salts (von Kossa stain). (From T Heyl, Arch Dermatol 96:528, 1967.)

Using light and electron microscopy, Vogel et al (71) noted differences in appearance between elastic fibers in patients with dominant and recessive forms. In addition, patients with the dominant condition had only an unusual aggregation of small and large collagen fibrils. However, Pierard (44) did not find any significant differences between dominant type I and recessive type I skin biopsies, stating that variations among individuals were greater than variation between the two types. Hausser and Anton-Lamprecht (24) described specific ultrastructural changes.

Progeria (Hutchinson-Gilford syndrome)

Progeria, consisting of dwarfism, early aging, and characteristic craniofacial appearance, was first described by Hutchinson (35) in 1886 and Gilford (26,27) in 1897 and 1904. Approximately 85 cases have been recorded to date (5,48). The frequency of progeria is about 1 per 4 to 8 million live births with a 2:1 male/female ratio (6). Autopsies have been performed in fewer than a dozen cases (3,27,57,63). Good reviews on the subject are those of Badame (4) and Beauregard and Gilchrest (6). An early review is that of Gabr (22).

The patient reported by Feingold and Kidd (19), followed only until 22 months of age, had prominent eyes and prognathism, although early scleroderma, anterior hair loss, and a horse-riding stature certainly suggest progeria, as do the three sibs reported by Monue et al (45). Rodriguez et al (55) described a lethal neonatal form.

Since the aging process is accelerated in progeria, cultured fibroblasts from affected individuals possibly might show an earlier appearance of altered gene products or a more severe disturbance of such products. Enzyme thermolability studies from cultured fibroblasts (32) were consistent with both possibilities, showing a significantly higher percentage of heat-labile glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, and hypoxanthine-guanine phosphoribosyltransferase. No significant association between HLA type and progeria has been detected (8). Sister chromatid exchange frequencies in progeria have not differed significantly from normal (13).

Aminoaciduria has been documented (60). Hypermetabolism has been suggested by some (60,62), but denied by others (55). Many patients have exhibited elevated cholesterol or phospholipid levels (54,65). Rosenthal et al (57) suggested that progeria was a disease of intermediate lipoprotein metabolism. Villee et al (65) reported unresponsiveness to growth hormone, relative insulin resistance, and highly cross-linked collagen. Hyperglycemia and insulin resistance were documented by Rosenthal et al (57).

In 1993, Clark and Weiss (11) observed a glycoprotein of M(r) 200 kDa that was consistently present in protein preparations from progeria fibroblasts and that was absent, or markedly reduced, in preparations from control fibroblasts. This glycoprotein, observed in progeria fibroblasts in vitro, could reflect a perturbation in glycosylation that may underlie the connective tissue defects seen in progeria.

Affected sibs were reported by Franklyn (21), Lejman (39), Maciel (41), and Mostafa and Gabr (46), and affected cousins by Khalifa (37). Consanguinity has been noted in a few instances (21,37,46). Monozygotic twins concordant for progeria were reported by Viégas et al (64). However, autosomal recessive inheritance is debatable, as most cases have been sporadic and the consanguinity rate is low. It may be dominant, the few familial cases representing gonadal mosaicism. Fathers of affected children tend to be older (36). Brown et al (10), in 1990, described identical twins with progeria who developed heart failure at the age of 8 and died within one month of each other. Cytogenetic analysis from a post-mortem skin biopsy revealed an inverted insertion of chromosome 1 described as XY, inv ins (1;1)(q32;q44q23) in 70% of cells. The seriousness of the condition with its early demise during teenage years may have an effect on many parents as far as having further offspring (9).

Growth. Average birth weight is 2.7 kg. Growth proceeds almost normally until the first year, when it essentially plateaus until about 10 years of age. By the end of the first decade, height is approximately that of a normal 3-year-old; only rarely do patients exceed 110 cm in height or 15 kg in weight (14). There is no sexual maturation.

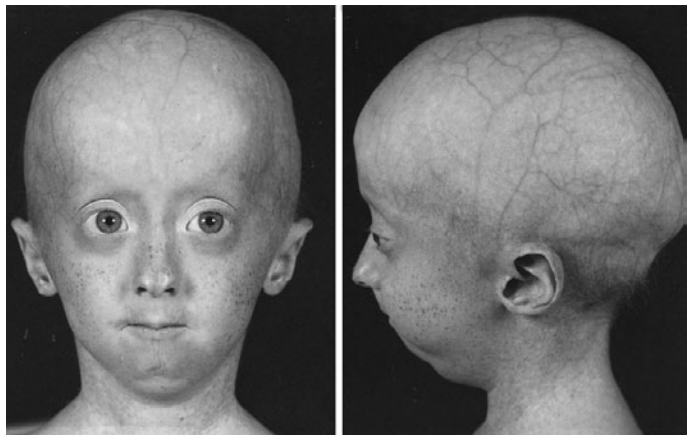
Abdenur et al (1), in 1997, reported that elevated GH levels are characteristic of this disease and that an elevated basal metabolic rate could be the cause of the failure to thrive seen in Hutchinson-Gilford progeria. Combined nutritional therapy and growth hormone treatment improved the growth velocity, increased the levels of growth factors, and resulted in decreased basal metabolic rate. However, the response to these therapies decreased over time and did not seem to prevent the progression of atherosclerotic disease.

Performance. Intelligence is normal. The voice is high-pitched and squeaky (25,56,58). Hearing may be deficient (47).

Craniofacial appearance. During the second year of life, scalp hair is lost and replaced by downy fuzz. Eyebrows and, occasionally, eyelashes are lost. The face is disproportionately small in relation to the cranium, although, in fact, head circumference is usually 2–4 cm smaller than average. Frontal and parietal bossing occur together with prominent scalp veins. The ears are small without lobules and the nose is thin and rather beaked (Fig. 13–105). Micrognathia and delayed dental eruption of the permanent teeth are common features, the deciduous dentition often being retained. The mandibular angle may be increased. The plane angle is steep and the anterior fontanel is open. There are no frontal sinuses and mastoid development is poor. Teeth may be crowded because of mandibular hypoplasia with normal teeth. However, teeth have been irregular in form, small, discolored, and deficient in number in most cases (34,67). Microscopic evidence of senile changes in the dental pulp has been reported (2,12,14,56).

Musculoskeletal system. The chest is narrow or pyriform and the abdomen protuberant. Mild flexion of the knees results in a horse-riding

Fig. 13–105. *Progeria.* (A,B) Face is small in comparison with cranial vault. Lashes are absent, brows are sparse. Note beaklike nose, mandibular hypoplasia, absent earlobes, prominent scalp veins. (From L Atkins, N Engl J Med 250:1065, 1954.)



A B

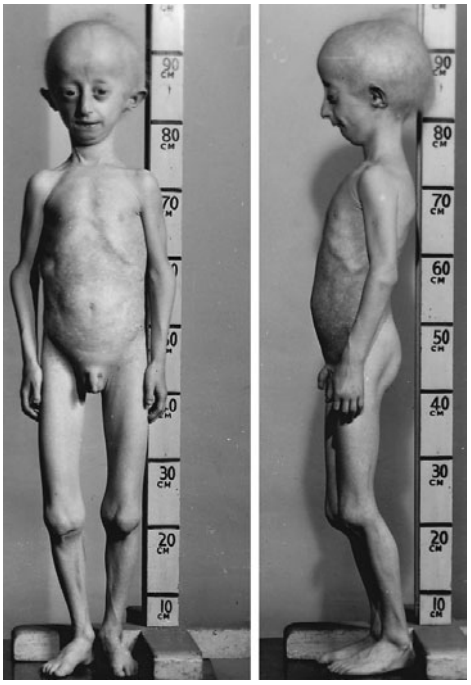


Fig. 13–106. *Progeria*. Clavicles are short, hands, elbows, and knees contracted, giving "horse-riding" stance. Note senile appearance. (From L Atkins, N Engl J Med 250:1065, 1954.)

stance (Fig. 13–106). The bones are delicate and osteoporotic, although bone maturation is normal. The joints of the extremities become prominent and limited in extension from periarticular fibrosis, which appears in some patients as early as the sixth year. Less frequently affected are the spine, elbows, and knees. Hip pain, subluxation, and eventual hip dislocation result from degenerative changes in the acetabulum (24,44).

Radiographically, terminal phalanges undergo progressive osteolysis and become abnormally short and taper abruptly to pointed ends (Fig. 13–107A). The clavicles also undergo progressive osteolysis. Coxa valga and acetabular degeneration are constant findings. There may be some predilection for fracture of the humeral shaft. There is also loss of muscular and subcutaneous fat. The calvaria is remarkably thin, the anterior fontanel is open, and frontal sinuses are often absent. The neurocranium is normal in size and configuration. Mastoid development is poor (2,3,21,23,38,43,44,49). Osteosarcoma has been reported by King et al (38).

Cardiovascular system. Cardiac murmurs appear after 5 years of age, followed by diastolic systemic hypertension and cardiomegaly. Atherosclerosis is early and severe, and anginal attacks and cerebrovascular accidents have been experienced as early as 7 years of age, but, in most instances, death occurs by approximately 14 years of age (5,17,42,62) from myocardial infarction or congestive heart failure. However, a 45-year-old man had been documented (48). Baker et al (5) reviewed the cardiovascular abnormalities.

Skin and skin appendages. The skin is thin, atrophic and often pigmented, with sparse subcutaneous fat (29). Scleroderma-like changes have been recorded in some patients. Veins are especially prominent over the scalp and thighs. Electron microscopic studies of scalp hairs reveal abnormal longitudinal depressions with minor cuticular defects. The nails are thin, yellow, atrophic (Fig. 13–107B), or absent (3,12,20, 56,61,63,69).

Differential diagnosis. Several patients with *Hallerman-Streiff syndrome* have been erroneously labeled as having progeria. It may mimic scleredema of infancy (18). Occasionally patients with *Bloom syndrome, mandibuloacral dysplasia*, or *Cockayne syndrome* have also mistakenly been thought to have progeria (52). *Werner syndrome* is also a condition of premature aging. Other progeroid syndromes have been discussed elsewhere including the *Ehlers-Danlos syndromes, Wiedemann-Rautenstrauch (neonatal progeroid) syndrome, De Barsy syndrome, Mulvihill-Smith syndrome*, acrogeria (15), metageria (28), acrometagyria (30), and a unique disorder described by Ruvalcaba et al (59). The patient of Green (31) surely had a form of Ehlers-Danlos syndrome. Delatycki et al (16) described a lethal neonatal progeroid syndrome that may have X-linked inheritance. Perhaps another example is that of Le Merrer et al (40). We suspect that the brothers reported by Parkash et al (50) and Ramesh and Jain (53) had mandibuloacral dysplasia. Other patients represent a distinct progeroid disorder (51,66). Still another unknown progeroid condition is that of Hagadorn et al (33). The patients of Grossman et al (32) had Seckel syndrome or Cockayne syndrome.

Laboratory aids. Marquart et al (43) reported increased secretion of fibronectin and collagen by fibroblasts of an affected patient. There is reported increase in urinary hyaluronic acid (68).

Werner syndrome

The syndrome, first delineated by Werner (59) in 1904, consists of shortness of stature, premature graying of hair (canities), baldness, scleropoikiloderma, trophic leg ulcers, juvenile cataracts, hypogonadism, diabetes mellitus, calcification of blood vessels, and osteoporosis. Confusion with Rothmund-Thomson syndrome occurred until Oppenheimer and Kugel (42), Thannhauser (56), and Greither (23) clearly separated the two syndromes.

The frequency of the disorder was estimated to be between 1 and 20 cases per million population in the United States (9). It appears to have a high frequency in Sardinia (5) and Japan (9). Over 150 cases have been reported (9,15,24,34,36,45).

Autosomal recessive inheritance has been established (9,19). In the United States, parental consanguinity has been found in 20%–35% (9), while in Japan it is 70% (19).

In a study of 21 Japanese families, Goto et al (20), in 1992, demonstrated close linkage of the gene (*WRN*) to a group of markers on chromosome 8. The region was narrowed down to 8p11.1–21.1 by Yu et al (61) in 1994. In 1996, Yu et al (62) identified the *WRN* gene by positional cloning. The predicted protein showed significant similarity to DNA helicases. Gray et al (22), in 1997, and Huang et al (26) confirmed that Werner syndrome (WS) protein is indeed a DNA helicase.

For DNA replication, recombination, repair and transcription, the unwinding of double-stranded DNA by helicases is essential (12). Werner syndrome (WS) patients represent defects in at least three different types of biological function. First, WS cells show prolongation of the S-phase of the cell cycle, diminished frequency of initiation of DNA features implicating *WRN* in DNA replication (46,60). Second, an increased frequency of chromosomal rearrangements and DNA deletions is present in cells with mutations in *WRN*. This suggests that *WRN* plays a role in DNA recombination (14). Third, the hypersensitivity of WS cells to the DNA damaging agent 4NQO suggests that *WRN* has also a function in the repair of damaged DNA (41). Homozygous mutations, all of which lead to truncation of the protein, lead to Werner syndrome (4).

Matsumoto et al (31,32), in 1997, defined the genomic structure of the gene, identified 35 exons, and found the common mutation among Japanese. Later, several different types of mutations of *WRN* were reported in WS patients (21,43,62,63). In 1998, Marciniak et al (30) determined nucleolar localization.

Most or all of the mutations have been null mutations and not a single missense mutation had been identified. This would suggest that the heterozygous carriers of *WNR* would have a Werner helicase activity approximately 50% of normal. With a high carrier prevalence of 1/150 to 1/200, a vulnerable carrier state could have potential implications in public health.

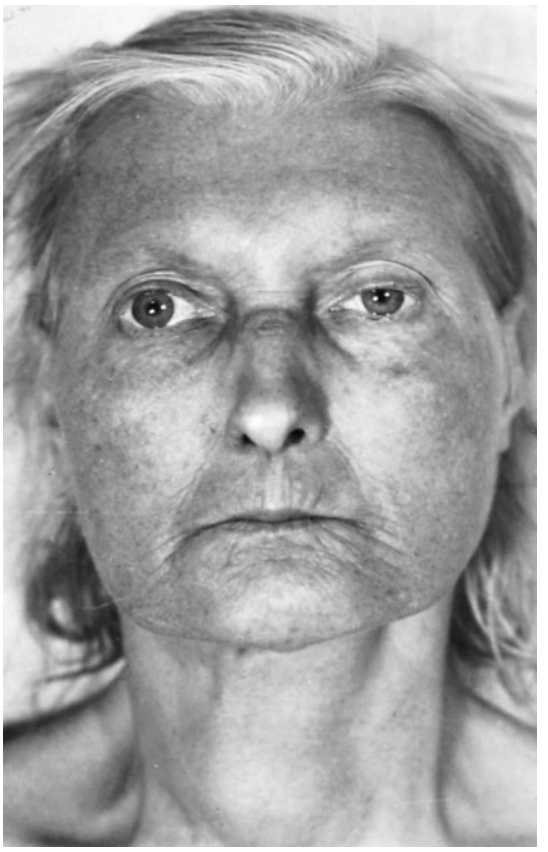
The disorder becomes apparent in the third and fourth decades of life. Graying of the hair occurs at about 20 years, skin changes and loss of hair by 25, cataracts by 30, diabetes mellitus by 35, and death at about 45 years.

Short stature, due to arrest of growth at puberty, is a constant feature. Mean height is 157 cm for males and 146 cm for females (9,65). Weight is low, relative even to the short stature. Thinness of arms and legs and diminution in size of hands and feet are striking. In contrast, the trunk is often stocky and the abdomen protuberant (Fig. 13–108). Patients characteristically develop abnormally high-pitched, sometimes squeaky, or less often, hoarse voices due to vocal cord atrophy.

Fig. 13–108. *Werner syndrome*. Aged appearance together with marked thinness of arms and legs. (Courtesy of S Jablonska, Warsaw, Poland.)

Facies. The combination of atrophic skin changes, baldness, and graying hair (80%) gives these patients, even while young, an appearance of being 20–30 years older than their age. Although the cheeks are full, the nose assumes a pinched or beaked appearance due to hypoplasia of nasal cartilages (Fig. 13–109).

Fig. 13–109. *Werner syndrome*. Premature graying of hair, aging of skin. (Courtesy of S Jablonska, Warsaw, Poland.)



Skin. The principal areas of skin involvement are the face and distal extremities, especially the feet. There is atrophy of the skin over areas depleted of adipose tissue, connective tissue and musculature. This results in shiny smooth skin that adheres to the underlying tissues, giving a sclerodermoid appearance. In about 40% there is ischemic ulceration (Fig. 13–110). The eyes appear protuberant because of loss of circumorbital tissues. The ears may become stiff and inelastic. Circumscribed hyperkeratoses develop over bony prominences and on the soles, and may become ulcerated, with slow or no healing (49).

Localized or, less commonly, generalized hyperpigmentation, depigmentation, and telangiectasia occurring on the arms and legs are seen in nearly all patients with the term "poikilodermatous" then being applied. Some have generalized lentiginosis (28).

Eyes. Senile cataracts, another cardinal feature seen in 95%, are invariably bilateral, usually posterior, cortical, or subcapsular, and homogeneous or striate. They have abrupt onset during the third or fourth decade. Retinitis pigmentosa, senile macular degeneration, chorioretinitis, and corneal calcification have also been described (27,44,49).

Hair. Premature loss and graying of scalp hair with onset usually before 20 years is characteristic and seen in almost all patients (Fig. 13–109). Generalized hair loss involving the scalp, eyebrows, eyelashes, and body (axillary and pubic) hair may be secondary to hypogonadism.

Musculoskeletal system. Osteoporosis and profound wasting of the musculature of the legs, feet and hands are noted in at least 40% (Fig. 13–110). The feet are usually flat. Soft-tissue calcification has been observed in 35%, especially in the tendons, ligaments and synovia of the knees, elbows, and ankles (9). The tissues adjacent to these areas may also exhibit soft-tissue calcification similar to that observed in scleroderma (48).

Cardiovascular system. Patients develop severe, often generalized atherosclerosis. Calcification occurs in peripheral (Mönckeberg) vessels of the legs and in the mitral and aortic valves and coronary vessels in about 20% (9,48). Peripheral vascular disease further complicates or promotes atrophy and ulceration of the skin.

Endocrine system. Diabetes mellitus has been recognized in 45%–60% (9). However, the usual complications of diabetes (nephropathy, retinopathy, neuropathy) have not been observed. Neither the vascular disease nor the cataracts are well correlated with the diabetes mellitus.

Hypogonadism occurs in both sexes. Most males have small testes and penis, with diminished pubic hair. Women have poorly developed genitalia and breasts, and some never develop secondary sex characteristics. Menses are sparse and irregular. However, there are valid reports of men who have sired children and women who have borne children.

Central nervous system. Some patients may be mentally retarded (48), and about one-third may have mild neurologic deficits, such as loss of deep-tendon reflexes, paresthesias, and dizziness (9).

Oral manifestations. The skin around the mouth is often radially ridged (64) (Fig. 13–109). Frenkel (11) described atrophy of the oral mucosa.

Neoplasia. Over 10% have an unusual array of both benign and malignant neoplasms (meningiomas, paragangliomas, adenomas of the pituitary, thyroid, and adrenal glands); various malignant epithelial neoplasms (basal and squamous cell carcinomas of the skin, especially melanomas); adenocarcinoma of the thyroid, stomach, ovary, and liver; and malignant connective tissue tumors (fibrosarcomas, neurofibrosarcomas, leiomyosarcomas, osteosarcomas) (2,9,19,25,34,37,42,47–49,55,58,64). German (16) presented a critical analysis of reported tumors.

Differential diagnosis. In *Rothmund-Thomson syndrome*, the onset of skin changes and cataracts occurs during the first 10 years of life. Photosensitivity is present in about 35%. The skin also shows telangiectasia, scaling, and pigmentary changes. Skin cancer is a prominent feature.

Progeria, in contrast to Werner syndrome, has very early onset. There is severe dwarfing, nearly complete alopecia, absence of subcutaneous fat, and characteristic facies. Generalized atherosclerosis leads to early death.

Acrogeria refers to thin skin largely limited to the distal extremities (6). The subcutaneous vascular pattern is usually evident over the trunk. Several so-diagnosed patients really have *Ehlers-Danlos syndrome*. A definite inheritance pattern has not been established. Small stature and micrognathia have been present in several cases. Mulvihill and Smith (35) reported a syndrome of *premature aging, microcephaly, unusual facies, multiple nevi, and mental retardation*.

Mandibuloacral dysplasia is characterized by early onset, small mandible, and brachytelephalangy. Inheritance is autosomal recessive.

Metageria, an autosomal recessive disorder apparent at birth, is characterized by normal height and diabetes mellitus of early onset. There is no loss of hair and no cataracts. The skin is dry, atrophic, and mottled. The face is pinched with a beaked nose (17).

Myotonic dystrophy frequently has its onset in the second and third decades. Cataracts, diabetes mellitus, premature frontal baldness, and atrophy of the skin are features of the disorder. Testicular atrophy occurs, but the external genitalia are otherwise normal. Inheritance is autosomal dominant.

A Werner-like syndrome has been reported in three brothers (33), but in our opinion (RJG), they have *mandibulo-acral dysplasia* (Fig. 13–111).

Laboratory aids. Karyotypes of long-term cultured skin fibroblasts show multiple, variable, predominantly stable, essentially random translocations that are clonal in nature (variegated translocation mosaicism) (8,50–52,54). In contrast, lymphocyte cultures are only rarely reported to be abnormal (53). However, an increased number of chromosome breaks has been found (40).

Cultured fibroblasts have a greatly reduced potential for in vitro growth and a reduced lifespan (51). Bauer et al (1) found enhanced collagen

synthesis. There is a slower rate of DNA replication (13,39), but repair function appears to be normal. An altered immune mechanism has been noted (7,38), but further studies need to be carried out.

Increased urinary hyaluronic acid has been found by several investigators (3,10,18,29,57).

DNA testing of WRN mutations is possible for the diagnosis of both Werner syndrome patients and heterozygote carriers.

Mulvihill-Smith syndrome (premature aging, microcephaly, unusual facies, multiple nevi, and mental retardation)

Mulvihill and Smith (7) described a male with low birth weight, somatic anomalies and mild to moderate mental retardation, multiple pigmented nevi of the face, neck, and trunk, micropenis, and hypospadias (Fig. 13–112). A similar example in a female was reported by Wong et al (12). However, intelligence was normal.

The craniofacies is characterized by microcephaly, broad forehead, fine scalp hair, sparse facial hair, disproportionately small face with reduced lower facial height, small pointed chin, and marked micrognathia. Facial subcutaneous fat is deficient. Some have cataracts (6). There is moderate progressive sensorineural hearing loss. The voice is high pitched and hoarse. The ears are lobeless. Oligodontia is a constant feature. Approximately 10 cases of this condition have been described (1,2,4,5,9–11).

Ohashi et al (8) described a 30-year-old deaf, microcephalic, and severely mentally retarded woman with pigmented nevi and freckles, but also with immunodeficiency. The patient had severe T-cell dysfunction, severe verruca vulgaris of the hands, and a chronic, active Epstein-Barr virus infection. They suggested that immunodeficiency is a late development. The parents are first cousins, which suggested autosomal recessive inheritance. Some of these findings have been noted in WHIM syndrome (5a).

Bartsch et al (2) restudied a patient previously reported by Tympner et al (11) as a condition with "progressive combined immunodeficiency and ectomesodermal dysplasia." This patient, on follow-up, exhibited keratoconus (9) and locomotor ataxia and died of gastric carcinoma at 23 years (3).

De Silva et al (4) reported a 5-year-old boy with physical features suggestive of this condition. He had lymphopenia, low IgG2 and IgG4 immunoglobulins, and an absent in vitro proliferative response to pokeweed mitogen. Skin fibroblast growth was slow in culture, and the cells had a large number of inclusions.

One must exclude *Leopard syndrome*.

Wiedemann-Rautenstrauch syndrome

In 1977, Rautenstrauch and Snigula (12), believing that they were dealing with progeria in sibs, described a new progeroid syndrome that was recognized as such by Wiedemann (18), who two years later noted two unrelated male children. Approximately 20 examples have been described (1–5,6a,8–18). Inheritance is clearly autosomal recessive (2,3,11,12,18).

An aged facies is present from birth. Children are born small for dates and subsequent growth is slow. IUGR occurs late during the third trimester, with variable onset (7). Frontal and biparietal bossing, together with small facial bones (pseudohydrocephaly), gives the child a hydrocephalic aged appearance. The anterior fontanel is large and closes late. The sutures tend to persist. Scalp hair tends to be sparse but is of normal consistency. The scalp veins are prominent (16). The nose is small and beaked and the ears are low set and posteriorly angulated. The facial bones are hypoplastic, producing a triangular face. With time, the nose appears beaked. The mouth is small and the chin is somewhat prominent (13,14). Natal incisors are noted in 75% (5a,11,13) (Fig. 13–113). The syndrome is usually lethal by 7 months, but a few have survived into adolescence.

Subcutaneous fat is generally deficient, allowing the veins and muscles to become prominent, but lower-back fat accumulates during infancy (5). The abdomen is prominent. Height is short. The hands and feet are large with long fingers and toes. Radiologic studies done soon after birth show partial nonossification of the atlas and hypoplastic iliac bones but after 1 year, the changes have disappeared (8). There is delayed bone age and delayed closure of the anterior fontanel.

Mental and, especially, motor development are usually deficient (11). Horizontal nystagmus is noted with limited visual acuity (13). There is progressive neurologic degeneration by the age of 5 years. Lack of head control, hypotonia, severe truncal ataxia, dysmetria, and intension tremor are common. Martin et al (8) found extensive demyelinization of the central nervous system with an occasional tigroid pattern and large

D

Fig. 13–112. *Mulvihill-Smith syndrome (premature aging, microcephaly, unusual facies, multiple nevi, and mental retardation).* (A,B) Microcephaly, broad forehead, sparse facial hair, disproportionately small face with reduced lower facial height, and numerous pigmented nevi of face and neck. (C,D) Note other patient similarly affected. (A,B courtesy of O Bartsch, Lübeck, Germany. C,D from M Baraitser et al, J Med Genet 25:53, 1988.)

amounts of neutral fat and myelin breakdown in macrophages, a picture characteristic of pure sudanophilic leukodystrophy (15).

Cryptorchidism has been noted (1,13), as well as enlarged penis (10,18). Recurrent respiratory tract infections are common. Most of the children die prior to the age of 5 years.

Arboleda et al (1), in 1997, reported increased levels of prolactin, testosterone, estradiol, and T4, with normal TSH levels and increased serum triglycerides and very-low-density lipoprotein in one case. They proposed that disturbance in the mechanism of bone maturation as well as hormone and lipid metabolism may be important in the etiology of the Wiedemann-Rautenstrauch syndrome. Study of collagen has not been fruitful (13).

A form of sudanophilic leukodystrophy has been suggested (8). Prenatal ultrasound diagnosis has been accomplished (3).

To be excluded are other sudanophilic leukodystrophies, *Cockayne syndrome, Hallermann-Streiff syndrome*, *progeria* and various progeroid syndromes, and *Berardinelli-Seip* and other lipodystrophic syndromes. We cannot accept the cases of Hou and Wang (7) and Hagadorn et al (6).

Rothmund-Thomson syndrome

The syndrome of infantile poikiloderma, cataracts, and hypogonadism was described independently by Rothmund (49), in 1868, and Thomson (57), in 1923. Over 200 cases have been reported to date (64). Especially good reviews of the syndrome are those of Taylor (56), Greither and Dyckerhoff (17), Rodermund and Hausman (44), Vanscheidt et al (61), Vennos et al (64), Vennos and James (63), and Moss (38).

The syndrome has autosomal recessive inheritance. A significant female excess (35,55,56) has been reported but was not supported by our survey. Parental consanguinity has been present in about 16% (4,34,35,42,47,49,51,60). The syndrome has been found in identical twins (15). Report of the condition in mother and son (20) raises the question of genetic heterogeneity. However, this may represent pseudodominance, that is, a female homozygote marrying a carrier male and producing an affected child. There also appears to be a verrucous type with warty hyperkeratoses that has a tendency to malignant degeneration (13,16,45,47,66) (vide supra).

A number of chromosome anomalies have pointed to chromosome 8 (10,33,67). Kitao et al (28) and Lindor et al (33a) noted that mutations in *RECQL4*, a helicase, located at 8q24.3, result in Rothmund-Thomson syndrome. Compound heterozygotic brothers have been described (33a). However, there is surely genetic heterogeneity (64a).

Several authors (27,38,41) reported reduced DNA repair.

Craniofacial features. A large head with frontal bossing and broad low nasal bridge has been described (3,44,53,57,58). However, microcephaly has also been mentioned (12,22,46,57,58). The eyebrows and lashes are sparse in at least 50% (Figs. 13–114 and 13–116).

Table 13–5. Clinical features of Rothmund-Thomson syndrome

Feature	Percent
Poikiloderma	100
Short stature	100
Musculoskeletal abnormalities	95
Hypogonadism	94
Thin hair	65
Abnormal teeth	59
Cataracts	45
Dysplastic nails	42

Adapted from DG Starr et al, Clin Genet 27:102, 1985.

Skin and skin appendages. Dermatologic features have been extensively discussed by Rook et al (47). The skin of the cheeks and ears, uninvolved at birth, becomes red and swollen at about 3–6 months of age. The buttocks and the extensor surfaces of the hands, forearms, legs, and thighs then become involved but usually to a lesser degree, the exposed surfaces being more severely affected. The trunk is often spared. The inflammatory phase soon subsides and leaves areas that manifest varying combinations of pigmentation, depigmentation, atrophy, and telangiectasia. The dull-brown, irregular macular or reticular pigmentation usually follows the appearance of the atrophy and telangiectasia (Figs. 13–115 to 13–117).

Sensitivity to sunlight in the form of blister production is seen in at least 33% (13,15,34,47,53,56). It is usually more severe in early life. Scalp, pubic, and axillary hair is often somewhat sparse, and may be almost absent in some patients (4,46). Eyebrows and lashes are frequently missing or severely diminished (4,15,23,34,35,46,53,56–58) (Fig. 13–116) (Table 13–5).

Warty hyperkeratoses, especially over the joints (21,35,46,52,57, 58,66), appear in 25% between 6 and 10 years of age. Late-developing squamous cell carcinoma and palmoplantar keratoses have been found in about 35% (8,12,16,20,32,35,45–47,51,65). Malignant eccrine poroma has been found in one case (60a). Nail dystrophy has been noted in at least 25% (4,23,34,35,53,56).

Central nervous system. Mental retardation of variable degree has been found in about 10%.

Endocrine system. An endocrine disorder, most frequently hypogonadism, occurs in about 25% (4,23,35,46,50,53). Scanty menstruation is common, and few affected women have borne children. Micropenis has been noted (53). The combination of Rothmund-Thomson syndrome and Addison disease has also been reported (31).

Musculoskeletal system. At least 65% have been markedly short (2). The growth retardation has been proportionate (4,7,12,19,20, 23,46,49,50,53). The limbs are often slender or delicate, the terminal phalanges abbreviated, and acrocyanosis may be severe. Soft tissue contractures may be an important cause of disability in the older patient (19).

Absence of thumbs and occasionally rudimentary ulnae and radii have been reported (3,29,39,42,47,52,57,58,61) (Fig. 13–115). Jäckli (23) described bipartite patella and bone sclerosis. Several authors (7,18,29,49,56,58) noted cystic areas similar to fibrous dysplasia; others have reported osteogenesis imperfecta (43,48). Phalangeal tufts may be resorbed (36).

Eyes. Anterior subcapsular, perinuclear, and posterior stellate cataracts have been described in 50%–75% (4,34,35,49,53,56). The cataracts are bilateral and usually appear between the fourth and seventh years (35), although they may appear earlier (53) (Fig. 13–117). They are complete and semisolid and produce loss of vision within weeks.

Various eye anomalies less frequently encountered include band keratopathy, microcornea, and strabismus (30).

Neoplasia. Osteosarcoma (1,7a,11,13,14,18,24,29,31a,34a,37,41a, 42,48,54,54a,55,59,62), fibrosarcoma (8), and late-developing squamous cell carcinoma (vide supra) have also been described. Oral squamous cell

A B

Fig. 13–114. *Rothmund-Thomson syndrome*. (A,B) Skin of cheeks and ears, uninvolved at birth, assumes a poikilodermatous appearance about the third to sixth month of life. There is similar involvement of legs, thighs, and buttocks.

carcinoma has also been noted (35). Cataracts do not seem to occur in those with cancer.

Other findings. Gastric carcinoma (11) and hypertension have been noted (9). Low vitamin A levels have been reported by Sexton (51) and Whittle (66). Taylor (56) found an abnormal peak in the α_1-globulin fraction of the blood.

Oral manifestations. Microdontia, multiple crown malformations, delayed and ectopic eruption, supernumerary and congenitally missing teeth, and short conical roots have been mentioned (5,23,35). Bifid uvula has also been noted (22,28).

Differential diagnosis. A somewhat similar syndrome in adults is *Werner syndrome* consisting of short stature, premature graying of hair, scleropoikiloderma, trophic ulcers of legs, arteriosclerosis, juvenile cataracts, hoarse and high-pitched voice, hypogonadism, osteoporosis, and diabetic tendency. It also has autosomal recessive inheritance. In contrast to Rothmund-Thomson syndrome (Table 13–5), patients with Werner syndrome are essentially normal until 20–30 years of age, when the hair becomes gray. Skin changes and cataracts develop after the hair changes color. Short stature and atrophy of muscle and subcutaneous fat of the distal extremities are more pronounced in Werner syndrome. Arteriosclerosis, diabetic tendency, and osteoporosis are not seen in Rothmund-Thomson syndrome. Skin involvement in Werner syndrome

Fig. 13–115. *Rothmund-Thomson syndrome*. Similar involvement of hands with hypoplasia of thumbs. (From RK Oates et al, Australas Paediatr J 7:103, 1971.)

Fig. 13–116. *Rothmund-Thomson syndrome.* (A,B) Affected 2- and 4-year-old sibs showing characteristic facial poikiloderma. (Courtesy of S Alexander, Barking, Essex, England.

is different from that in Rothmund-Thomson syndrome. In the former, the forearms, hands, and face are chiefly involved. Hyperkeratotic areas are present on the soles, and ulcers are present over the heels, toes, and ankles.

In *gerodermia osteodysplastica*, there is premature senescence of the skin, nanism, and various anomalies of the eye (including microcornea and congenital corneal opacities), bony anomalies, and yellowish teeth,

Fig. 13–117. *Rothmund-Thomson syndrome*. Bilateral cataracts. (Courtesy of GB Sexton, London, Ontario, Canada.)

presumably due to an enamel defect. *Cockayne syndrome* consists of primordial short stature, flexion deformities, kyphosis, hyperostosis of skull bones, sensitivity to sunlight, and various eye anomalies such as optic atrophy, retinal degeneration, and cataract. The child appears prematurely senile, with sunken eyes, prognathic mandible, and carious teeth. *Bloom syndrome* is characterized by dwarfism, sunlight sensitivity, chromosomal breakage, a tendency to develop leukemia, and autosomal recessive inheritance. There is some superficial resemblance of Rothmund-Thomson syndrome to *focal dermal hyperplasia*, a disorder that also has poikilodermatous changes and for which it has been mistaken (25). One should also exclude Clericuzio syndrome (neutropenic poikiloderma), an autosomal recessive disorder seen in the Navaho. It is characterized by postinflammatory poikiloderma neutropenia, chronic sinopulmonary infections, thick toenails, and epidermal inclusion cysts of the elbows and ear rims. In contrast to Rothmund-Thomson syndrome, Clericuzio syndrome does not have photosensitivity, alopecia, cataracts, or congenital malformation (C Clericuzio, personal communication, 2000).

The reader is referred to the comprehensive analysis by Kaufmann et al (26) of disorders associated with growth hormone deficiency.

Laboratory aids. Growth hormone deficiency has been reported (23).

Cockayne syndrome

Cockayne syndrome (CS) is characterized by cachectic dwarfism, premature aging, mental deficiency, microcephaly, intracranial calcifications, neurologic deficits, retinal pigmentary abnormalities, sensorineural hearing loss, and photosensitivity. It manifests defective repair of damage induced in DNA by ultraviolet light.

Cockayne (8), in 1936, described proportionate dwarfism with retinal atrophy and deafness in two sibs, and 10 years later published a brief review of their progress (9). The syndrome becomes apparent at around the second year of life, but pre- and perinatal onset has been observed (25,38,45,60,68,69). Based on this difference of onset, it has been proposed that classical examples of CS, with onset at age 2 years or later, be classified as CS type I and the prenatal or neonatal cases be CS type II (37). The latter has been called CAMFAK syndrome (69). Patton et al (52) dispute this belief. The disorder has been reported in a female patient with normal intelligence and onset at age 19 years, with worsening at age 23 during a second pregnancy (29).

Complementation studies indicate genetic heterogeneity (30) (vide infra). Four types have been identified.

The disorder has autosomal recessive inheritance (8,9,17,25,38,51–53). Familial cases as well as increased parental consanguinity have been observed.

Lehmann (32), in 1982, studied cultured cells from patients with Cockayne syndrome for complementation in cell-fusion studies. The gauge of complementation was sensitivity to UV irradiation as measured by RNA synthesis after exposure. Three complementation groups were found. Mayne and Lehmann (42), also in 1982, suggested that the defect in Cockayne syndrome (CS) resides in the repair of transcribed genes; this was confirmed by Venema et al (74), in 1990. They reported that CS fibroblasts have lost the preferential repair of active genes but are proficient in overall genome repair (47).

Henning et al (22), in 1995, demonstrated that the type I or *CSA* gene maps to chromosome 5. They cloned the gene and found that the

CSA cDNA uniquely and specifically corrects UV sensitivity in CS-A cells. Mutations of *CSA* were identified in all CS-A cell lines.

Fryns et al (16), in 1991, presented a patient with late-onset Cockayne syndrome who had interstitial 10q21.1 deletion in all his cells. In 1992, Troelstra et al (71) studied the *ERCC6* gene and showed that it corrects the repair defect in type B CS cells (CS type II). In keeping with nomenclature recommendations (34), the *ERCC6* gene was referred to as *CSB*. Neither the site nor the nature of the mutation correlated with the severity of the clinical features. Severe truncations were found in patients with either classic or early-onset forms of the disease (40,62).

Between the two complementation groups of CS-A and CS-B, 80% of the patients have been assigned to the CS-B complementation group.

Czeizel and Marchalko (15) used the designation "Cockayne syndrome III" for the disorder in a teenage girl with clinical manifestations of Cockayne syndrome but with high intelligence.

Greenhaw et al (18), in 1992, reported sibs with clinical manifestations consistent with De Sanctis–Cacchione syndrome, which is a subgroup of *xeroderma pigmentosum* (XP) with severe neurologic and developmental involvement. The patients did not have characteristic physical features of Cockayne syndrome. Fibroblasts derived from these patients showed a failure of recovery of RNA synthesis after UV irradiation and a normal level of unscheduled DNA synthesis. These findings were consistent with the laboratory findings of Cockayne syndrome but not those of xeroderma pigmentosum. Later, in 1996, Itoh et al (27) assigned these patients to Cockayne syndrome complementation group B by cell fusion studies.

Stefanini et al (65), in 1996, analyzed cell cultures from 22 Cockayne syndrome patients from different countries and racial groups. They detected no racial, clinical, or cellular distinctions between the two complementation groups of CS-A and CS-B.

Damage to actively transcribed DNA is preferentially repaired by the transcription-coupled repair (TCR) system. Van Gool et (72) and Cooper et al (12), in 1997, suggested that Cockayne syndrome may represent a defect in TCR.

Wood (79), in 1991, stated that 3 patients with XP complementation group B also exhibited clinical manifestations of CS. The locus of *XPB* is at 2q21. A patient with XP/CS was reported by Hwang et al (26) in 1996 to have a frameshift mutation in XPB, a subunit of transcription factor TFIIH and a $3' \rightarrow 5'$ helicase involved in DNA repair.

Cleaver (7), in 1994, pointed out that mutation in the XPD gene, the locus of which is at 19q13.2–q13.3, has also been associated with Cockayne syndrome. XPD is also a subunit of the transcription factor TFIIH with a $5' \rightarrow 3'$ helicase activity in DNA repair.

Vermeulen et al (75,76) reported genetic studies of 2 patients with clinical characteristics of Cockayne syndrome but with a biochemical defect typical of xeroderma pigmentosum. These were assigned to XP complementation group G.

In 1997, Nouspikel et al (49) studied the nature of the molecular defect in the first 3 documented cases of combined XP-G and Cockayne syndrome, reported by Jaeken et al (28), Vermeulen et al (75), and Hamel et al (21). They found a common mutational pattern in the 3 patients with XP-G/CS that was distinct from the one found in 2 sibs with XPG (48) with XP phenotype but no CS symptoms. *XPG* gene encodes a structure-specific endonuclease that nicks damaged DNA 3′ to the lesion during nuclear excision repair (NER). Nouspikel et al (49) found that the 3 XP-G/CS patients had mutations that were predicted to produce severely truncated XPG proteins. In contrast, the two XP-G patients without CS were able to make full-length XPG protein, but with a missense mutation that inactivated its function in NER. According to their results, XP-G/CS mutations abolish interactions required for a second XPG function and the loss of this second function leads to the CS clinical phenotype. (See also the sections on Xeroderma pigmentosum and Trichothiodystrophy.)

Habraken et al (20), in 1996, suggested that mutations in *XPB*, *XPD*, and *XPG* that cause Cockayne syndrome produce a defect in interaction of their encoded proteins with CSA protein, CSB protein, or both. At transcriptional pause sites, the human equivalent of nuclear excision repair factor 3 (NEF 3), along with CSA and CSB proteins, may facilitate the resumption of transcript elongation. A deficiency in the rate of elongation of certain transcripts, stemming from the mutational inactivation of *XPB*, *XPD*, *XPG*, *CSA* and *CSB*, is considered to be the etiologic origin of Cockayne syndrome.

Fig. 13–118. *Cockayne syndrome*. Note marked enophthalmos and horse-riding stance. (Courtesy of RL Summitt, Nashville, Tennessee.)

Facies. Lack of subcutaneous facial fat, particularly of the cheeks, gives prominence to the facial bones. This feature, combined with microcephaly, sunken eyes, thin often beaklike nose, and large ears, gives the patient a birdlike appearance (Figs. 13–118 and 13–119).

Eyes. Enophthalmos is a virtually constant feature. The retina is studded with fine, speckled pigment of salt-and-pepper type, with the greatest concentration in the macular area. Optic atrophy and arteriolar narrowing are common (6,9,25,39,41,78). Cataracts develop by adolescence (9,10,19,25,70). A poor response to mydriasis with homatropine or Neosynephrine has been noted (10). Corneal dystrophy with recurrent epithelial erosions, nystagmus, and photophobia are less frequently observed (5,41,70). Histopathologic examination of the eyes demonstrated optic atrophy, retinal pigmentation, loss of nerve fibers and myelin sheaths, and atrophy of retinal nerve fibers and ganglion cell layers, findings consistent with those observed in demyelinating disease (35).

Skin. Photosensitivity is a prominent feature (25). Dermatitis appears on the sun-exposed parts of the body by the second year of life, with a butterfly arrangement on the face (36,78). The forehead is spared, but the pinnae and chin are involved. The photodermatitis may result in scarring and pigmentary changes in older patients (56). Seborrheic dermatitis may also be present. The scalp hair and, sometimes, the eyebrows are diminished (17). Subcutaneous fat appears to be decreased throughout the body except for the suprapubic areas (17). Microdissection studies of the eccrine sweat glands have demonstrated these glands to be abnormally small for the patient's age (30). Remarkably, in striking contrast with xeroderma pigmentosum, another disorder with UV hypersensitivity, no significant increase in skin cancer is noted (46).

Fig. 13–119. *Cockayne syndrome*. Sixteen-year-old male who experienced marked mental and somatic retardation, eye difficulties, deafness. Note wizened appearance, photodermatitis of sun-exposed areas, horse-riding stance. (Courtesy of RM Paddison, New Orleans, Louisiana.)

Musculoskeletal alterations. Proportionate dwarfism is the most prominent feature of the disorder. Growth retardation becomes evident during the second year of life after a normal gestation, birth weight, and infancy. Kyphosis and osteoporosis are frequent (17,39,52,55,78). The limbs are disproportionately long, and the hands and feet disproportionately large (52,60). Flexion contractures may involve the ankles, knees, and elbows. The interphalangeal joints of the hands and feet may show periarticular thickening (Fig. 13–119).

Radiographic studies show abnormalities in the skull, extremities, and spine. There is increased thickening of the bones, particularly the skull base and calvaria, most noticeable in the frontal and parietooccipital regions (25,39,55,60). Often there is associated osteoporosis (55). Platyspondyly with tonguelike protrusion of the anterior aspects of the vertebral bodies, hypoplasia of the iliac wings and acetabular roofs, brachydactyly, and marble epiphyses in the terminal phalanges of the hands have been described as characteristic (1,64).

Nervous system. Progressive neurologic signs include cerebellar ataxia, choreoathetosis, moderate to severe mental deficiency, sensorineural deafness, and blindness (63). Neuropathologic studies of the brain have shown microcephaly, widespread mineralization in the cortex, basal ganglia, and cerebellum, and patchy demyelinization, often severe, in the subcortical white matter (14,25,43,57). Biopsy of the sacral nerve showed the main pathologic change to be segmental demyelination and remyelination with onion-bulb formation and moderate decrease in the number of myelinated fibers (50). Normal intelligence has been reported in one patient (31). CAT scans show strio-pallido-dentate calcinosis (Fig. 13–120).

Other findings. Hypertension and renal disease are frequent complications. Elevated peripheral vein renin and deposits of immunoglobulins and complement in the kidney vessels and glomeruli have been reported (23). Undescended testes (19), small breasts, and oligomenorrhea (29) have also been noted.

Oral manifestations. An increase in dental caries has been reported by most authors (9,19,36,41,57). In some patients, numerous permanent teeth were congenitally absent (17,57–60). Atrophy of alveolar processes (6,60), condylar hypoplasia (13), and short conical roots (59) have also been observed.

Differential diagnosis. CS is one of a group of disorders that has certain common characteristics. The photosensitivity may suggest *Bloom syndrome*, Hartnup disease, *xeroderma pigmentosum*, or erythropoietic porphyria. Bloom syndrome has many of the features of CS except for the neurologic and ophthalmologic findings. Both have reduced IgA levels (8). No patient with CS has been reported with leukemia or lymphoma, and chromosomal breakage is absent (52,78). Patton et al (52) have suggested that Cockayne syndrome overlaps strongly with *cerebro-oculo-facial-skeletal syndrome. Rothmund-Thomson syndrome* is not a neurologic disease; although cataracts are seen in about half the patients, there are no retinal changes. Xeroderma pigmentosum is characterized by multiple cutaneous malignancies in light-exposed areas. Skin cancers have not been reported thus far in the photosensitive areas in patients with CS. Cases of CS with xeroderma pigmentosum have been described (44,56) (vide supra). *Progeria* does not feature photosensitivity, neurologic

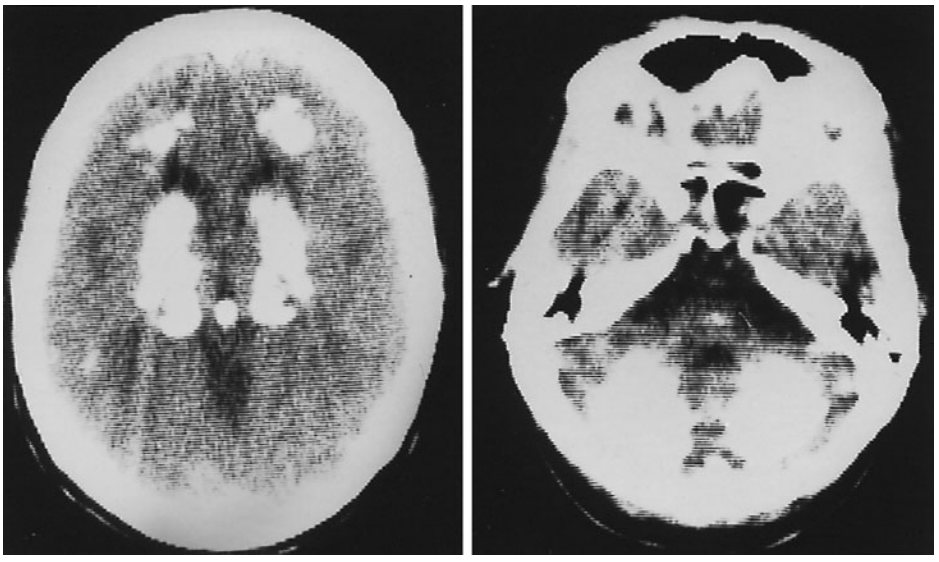

Fig. 13–120. *Cockayne syndrome*. CAT scan showing calcification of basal ganglia and dentate nuclei. (From MG Smits, Clin Neurol Neurosurg 85:145, 1983.)

disease, or retinal changes, and the phenotype is quite different from that of CS.

Laboratory aids. Cells from patients with CS demonstrate defective repair of damage due to ultraviolet (UV) radiation and mitomycin C, but they have normal unscheduled DNA synthesis and repair normally in the presence of caffeine (caffeine interferes with normal postreplication repair). This suggests a defect in either replication or excision repair and not in postreplication repair (24,53,54,58,61). The degree of hypersensitivity to UV radiation varies from patient to patient, possibly reflecting clinical and cellular heterogeneity for CS (52,68). Studies of complementation groups in patients with CS have shown patients to belong to group A, B, and C (32). UV treatment of fibroblasts obtained from obligate heterozygotes has yielded conflicting results (53,77). Thus, no reliable method to identify heterozygotes presently exists (51).

Thymic hormone serum level has been found to be undetectable or significantly reduced in patients with CS, whereas T lymphocytes and mixed lymphocyte functions are normal (2). These findings indicate premature immunological aging.

Prenatal diagnosis is possible using an assay of the colony-forming ability of UV irradiated cells, obtained from the amniotic fluid (67). CS cells are significantly more sensitive to UV radiation than normal control cells.

Hyperinsulinemia and hyperlipoproteinemia but normal growth hormone levels have been noted in several patients (11,13,17).

Autopsy findings have included pancreatic islet hyperplasia, atrophy and fibrosis of ovaries, and atrophic epidermis with small hair follicles and sweat glands (66).

Prenatal diagnosis has been effected by Lehmann et al (33). Cultured amniocytes exhibit significantly reduced RNA synthesis after irradiation with UV light.

Xeroderma pigmentosum

Xeroderma pigmentosum (XP), originally described by Hebra and Kaposi (30) in 1874 and named by Kaposi (40) in 1882, is characterized by defective excision repair of DNA damaged by ultraviolet light (UV). When exposed to sunlight, the UV radiation induces thymine dimers and other damage in the DNA of human cells (69). Normal individuals have several mechanisms for repairing damaged DNA. These mechanisms are absent to various degrees in patients affected with XP. Not only UV radiation but certain chemicals, carcinogens, and ionizing radiation can induce severe damage to patients with XP (71). Based upon the cellular ability to repair DNA after UV irradiation of cultured fibroblasts (see Laboratory aids), XP had been divided into nine subgroups classified as complementation groups A through I and XP "variant." More recently, however, the complementation groups have been limited to seven, from A to G (4). All have autosomal recessive inheritance (vide infra). These groups are defective in excision repair of DNA following UV damage. The XP "variant" had normal excision repair but abnormal replication of UV damaged DNA (9,31,53). The XP "variant" in Japan has been subdivided into caffeine-resistant and caffeine-susceptible subgroups based on the capability of XP cells to achieve caffeine potentiation of UV lethality. Patients with caffeine-resistant cells do not develop neoplasms (28). Excellent surveys on the subject are by Cohen and Levy (11) and Bootsma et al (4).

Division into the various complementation groups is based on (a) the rate of UV-induced unscheduled DNA synthesis in fibroblast colonies, measured in percentage of the value obtained from normal fibroblasts, and (b) the UV dose required to reduce fibroblast colony-forming ability in vitro. The degree of sun sensitivity, neurological abnormalities, and other clinical manifestations associated with XP varies from group to group (20,23,35,93).

De Sanctis and Cacchione (14) described a form of XP associated with severe neurologic abnormalities. This phenotype and variants can be associated with any of the complementation groups, most often group A and, occasionally, group D. The complementation groups tend to segregate differently in various populations (2,33,42,47,55,57,71).

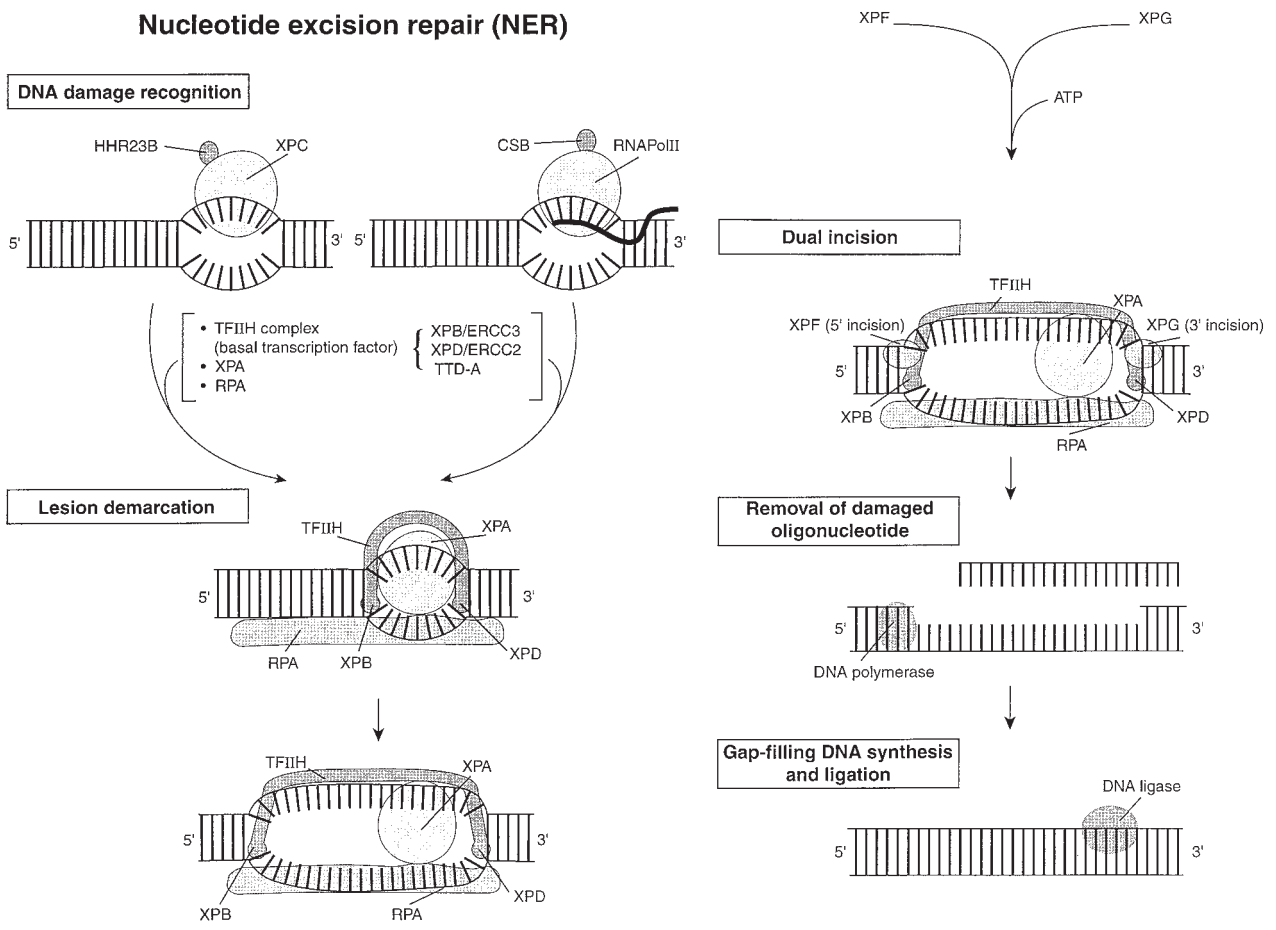
Jung (36) and Jung and Bantle (38), using the term "pigmented xerodermoid," describe a group of patients presenting solar cutaneous degeneration with eventual development of skin neoplasms after the age of 30. Cleaver et al (8) suggested that cells from patients with pigmented xerodermoid have the same post-UV synthesis and repair abilities as cells from patients with XP "variant." Pigmented xerodermoid may well represent XP "variant" with late onset (2). Follow-up studies of one patient, originally reported by Jung (36), showed that in that kindred the condition had autosomal recessive inheritance (32). Anderson and Berg (1) reported a family with a variety of XP possibly having autosomal dominant inheritance. Other authors have reported similar families (36,47). This autosomal dominant variety represents a mild form of XP, possibly within the range of complementation group E. Imray et al (34) suggested 100% penetrance. Affected individuals present marked xeroderma, dark pigmentation, and freckling with severe erythematous reaction when exposed to sunlight. Tumors seem to be rare in these patients, and non-neurological abnormalities have been reported (34,47). Laboratory studies demonstrate decreased cell survival, reduced DNA repair synthesis, increased chromosome breaks, but normal sister chromatid exchange (34).

In Japan, most patients with XP belong to group A and the XP "variant." In Europe and in the United States, group C is the largest (43), followed by groups D and A (2). Combining all varieties, XP occurs in 1 in 250,000 in the general population of the United States and Europe (2,71), with the prevalence in Japan estimated as 1 in 40,000 (2). It has been described in all races (2). The degree of parental consanguinity is quite high (72).

Xeroderma pigmentosum is divided into seven complementation groups, A to G (vide supra). Bootsma et al (4), in 1998, compared the clinical and cell-biological characteristics of these groups, including in the XPD group the patient originally classified as XPH. XPA and XPC have relatively high frequency, XPD and XPF have intermediate frequency, and the other three are rare.

Research in understanding the XP mutations has progressed by cloning human DNA repair genes by using UV-sensitive Chinese hamster cells as recipients for DNA-mediated gene transfer. The human genes correcting the rodent repair defects are termed excision-repair cross-complementing, or ERCC, genes.

XPA, XPB, XPC, XPD, XPE, XPF, and XPG are involved in the different steps of nucleotide excision repair (7,92) (Fig. 13–121).



A

Abbreviations:

XPC - HHR23B complex: recognizes DNA damage

RNAPolⅡ - CSB: RNA polymerase - Cockayne syndrome B protein recognizing the DNA damage

TFⅡH Complex: a multiprotein factor (encoded by nine different genes and including XPB, XPD, and TTD-A) involved both in transcription and in DNA repair

XPA: DNA binding protein recognizing the DNA lesion

RPA: replication of protein A

XPB: bidirectional helicase incising the damaged strand

XPD: bidirectional helicase incising the damaged strand

TTD-A: protein with mutation associated with trichothiodystrophy A

XPF: protein excising the damaged oligonucleotide

XPG: protein excising the damaged oligonucleotide

Process of Nucleotide Excision Repair

Recognition of the site of DNA damage occurs either by the XPGHHR23B complex or by RNA polymerase (RNAPolⅡ) and Cockayne syndrome protein (CSB). Then DNA at the region of the lesion is opened by the action of RPA, XPA, and the bidirectional XPB/XPD helicases of TFⅡH. The damaged strand is incised on both sides of the injury by the repair-endonucleases XPF and XPG, followed by excision of the lesion-containing oligonucleotide and gap-filling DNA synthesis.

B

Fig. 13–121. *Xeroderma pigmentosum.* (A) Nucleotide excision repair (NER). (B) Legend for (A). (Modified from GS Winkler, JHJ Hoeijmakers, Nat Genet 20:106, 1998, and A Stary, A Sarasin, Cancer Surveys 26:155, 1996, with permission.)

The steps involved in nucleotide excision repair (NER) are as follows (7,92): The recognition of DNA damage can occur either by the XPC-HR23B complex (vide infra) or by RNA polymerase and Cockayne syndrome B protein (CSB) (Fig. 13–121). The initial steps involve also the DNA-binding proteins XPA and XPE. Subsequently, the DNA around the lesion is opened by the concerted action of RPA (replication protein A), XPA, and the bidirectional helicases XPB and XPD, which are components of the transcription factor TFIIH (Fig. 13–121). The damaged oligonucleotide region is then incised by the repair endonucleases ERCC1-XPF at the 5′ and XPG at the 3′ side. Following this, the lesion-containing oligonucleotide is excised. During all this process, the remaining single-strand template is protected by the single-strand binding protein RPA (Fig. 13–121). The gap is then filled and repaired with the action of DNA polymerase and ligase.

XPA is located at 9q34.1. It encodes a hydrophilic protein of relative molecular mass of 31,000. It has a zinc finger motif, which indicates that it interacts with DNA. This interaction is part of an enzyme complex that makes an incision near damaged sites (Fig. 13–121). Tanaka et al (80), in 1990, found that most Japanese patients with type A XP have a splice site mutation. Park and Sancar (64), in 1994, concluded from their studies that the XPA, ERCC1, and ERCC4 proteins form a complex that participates in both damage recognition and incision activities. Li et al (52), in 1995, demonstrated that the association between *XPA* and *ERCC1* is a necessary step in the nucleotide excision pathway.

States et al (77), in 1998, analyzed the mutation of XPA cell lines from 19 American and European patients. Patients with more severe disease, often with neurologic complications, had mutations in the DNA-binding region of XPA. Patients with milder skin disease had mutations in the C-terminus of the protein, which interacts with the TFIIH transcription factor.

XPB, xeroderma pigmentosum of complementation group B, has clinical and cytobiological characteristics of both XP and Cockayne syndrome (CS). The gene *XPB* has been shown to be the same as *ERCC3*, which was assigned to 2q21 (87) and was cloned in 1990 by Weeda et al (86). The nucleotide sequence predicted a protein of 782 amino acids comprising conserved motifs, strongly suggesting that the protein is a DNA repair helicase with a $3' \rightarrow 5'$ action (92) (Fig. 13–121). Weeda et al (88), in 1991, described the genomic architecture of the *XPB/ERCC3* gene. It consists of at least 14 exons spread over approximately 45 kb. In 1997, Weeda et al (89) assigned the defect of two patients with a mild form of trichothiodystrophy (TTD) to the complementation group B of XP. The *XPB* gene product is a component of the transcription factor TFIIH.

The *XPC* gene was mapped to 3p25 by Legerski et al (49). It encodes a highly hydrophilic protein composed of predicted 823 amino acids. Li et al (51) identified mutations in 5 XPC cell lines. *XPC* and *HHR23B* genes have products which form a tight complex (83) (Fig. 13–121).

The defect in XPD cells was found to be corrected by the *ERCC2* gene (19). This gene encodes a DNA repair/transcription helicase with a $5' \rightarrow 3'$ action (92) (Fig. 13–121). This helicase is also part of the TFIIH factor complex. TFIIH, a 9-subunit complex, has an essential function in two processes: initiation of transcription by binding to the promoters of protein-encoding genes and nucleotide excision repair (NER) (92) (Fig. 13–122). The NER system removes a wide variety of lesions, including UV-induced photoproducts, in a multistep "cut-and-paste" reaction involving 20–30 proteins (92). The XPB and XPD helicase subunits of TFIIH unwind the DNA, opening the helix locally, to form an open DNA intermediate necessary in both the transcription and repair processes (Fig. 13–121).

XPD provides a perplexing example of the complexity of genotype–phenotype relationships. Mutations that severely compromise the function of *XPD* are lethal. However, mutations with milder effects result in a heterogeneity of phenotypes, including at least three distinct disorders: xeroderma pigmentosum (XP), Cockayne syndrome (CS), or trichothiodystrophy (TTD) (61,92).

Coin et al (12), in 1998, provide a detailed account of the biochemical defects caused by the *ERCC2* mutations of XPD. An important effect appears to be the interaction of XPD with p44, which is still another TFIIH subunit and which stimulates the helicase activity of XPD. Mutations in the XPD C-terminal domain, as found in most patients, prevent the interaction with p44, resulting in a decrease in XPD helicase activity and explaining the nucleotide excision repair (NER) defect.

There appear to be 2 types of XPE: a DNA damage binding (DDB) protein-positive form and a DDB protein-negative form. Keeney et al (41), in 1993, purified the DDB protein. It appeared that it is a

A

heterodimer, with polypeptides of 124 and 41 kD. Mutations in the smaller component of the heterodimeric protein were demonstrated by Nichols et al (56), in 1996.

In 1996, Sijbers et al (75) isolated a human gene that corrected the repair defects of XPF. The gene, *ERCC4*, encodes a 905-amino acid polypeptide. The ERCC4, or XPF protein, was purified from mammalian cells in a tight complex with ERCC1. This complex is an endonuclease responsible for the 5′ incision during repair (Fig. 13–121). The *ERCC4* gene map locus is at 16p13.2–p13.1 (75). Sijbers et al (75,76), in 1996 and 1998, identified a 4-nucleotide deletion and a point mutation in XPF patients.

XPG has one of the smallest series of cases. Norris et al (58) described patients with mild cutaneous changes but no UV-induced skin tumors. *XPG* and *ERCC5* were found by Nounspikel and Clarkson (59) as well as Shiomi et al (74) to be identical. Habraken et al (25), in 1994, demonstrated that XPG is a single-strand-specific DNA endonuclease, involved in nucleotide excision repair. They suggested that XPG nuclease acts on the single-stranded region created as a result of the combined action of the XPB and XPD helicases at the DNA damage site. O'Donovan et al (62) showed further that XPG cleaves the damaged DNA strand on the 3′ side of the lesion during excision repair (Fig. 13–121).

Nounspikel et al (60) demonstrated that patients with the combined phenotype XP-G/CS have mutations that would produce severely truncated XPG proteins. In contrast, certain XPG patients without CS were able to make full-length XPG protein, but with a missense mutation that inactivated its function in nucleotide excision repair.

Some patients with xeroderma pigmentosum have normal DNA repair rates. These belong to the "variant" form. Excision repair is normal, but postreplication repair is defective (50). It is characterized by a defect in conversion of newly synthesized DNA from low to high molecular weight after UV irradiation.

Face and skin. Marked sensitivity to sunlight, especially wavelengths from 2800 to 3100 Å, is noted early in life, following minimal sun exposure. The majority of children with the various types of XP experience severe sunburn reactions which taper off by adulthood. The skin not exposed to the sun is generally within normal limits. The areas exposed to the sun first develop freckles, generally before the second year of life (17,18,21,72,95,96). With progressive exposure to the sun, the freckles become larger and vary from light to dark brown in color (Fig. 13–122). In addition, macular areas of hypopigmentation occur, resulting in a "salt-and-pepper" appearance of the skin. The second stage of skin involvement is characterized by atrophy and telangiectasia with the development of scaly patches and small spiderlike hemangiomas. Skin atrophy on the face can be so severe as to interfere with normal opening of the mouth or eyes. Loss of scalp hair is frequent (95). Some patients, especially those with severe neurological manifestations, present loss of subcutaneous fat. This seems to be a generalized process not related to sun exposure (2). Reaction to sunlight, ranging from mild to severe, varies from patient to patient. Those presenting acute sensitivity are more prone to develop neurological abnormalities (2). The third stage is the development of actinic keratoses, papillomatous growths, and neoplasms as early as 2 years of age (43). The neoplasms encompass both ectodermal and mesodermal tumors: keratoacanthomas (72), squamous cell carcinoma, basal cell carcinoma, melanoma (53), fibrosarcoma and angiosarcoma, as well as benign lesions such as angiomas and fibromas (2). The most frequent neoplasms are basal cell carcinoma followed by squamous cell carcinoma and melanoma. The tumors tend to arise in areas of solar keratoses. This specificity indicates a direct mutagenic effect of sunlight and possibly other carcinogens (6).

Basal and squamous cell carcinomas have been reported in 45%, and melanoma in 5% (47). In about half of these cases, the melanomas are multiple (82). However, the frequency of melanoma has varied from 0% in Japanese series (79) to around 50% in the United States (70). The latter probably represents a highly skewed sample. Sixty-five percent of the melanomas and 97% of the basal and squamous cell carcinomas arise in the face, head, and neck (47). Melanoma and its metastases have been reported to undergo spontaneous regression in some patients (53). The propensity to develop skin neoplasms varies with the complementation group. Patients in group A tend to present basal cell carcinomas very early in life, whereas patients with the XP "variant" develop the same tumors after the second decade (43). In general, more than 50% of the patients develop cutaneous neoplasms before age 10, in contrast to the general population in which over 50% of patients with skin neoplasms are over 60 years old (46). There is marked affinity for patients in group A to develop multiple squamous cell carcinomas and, with less frequency, basal cell carcinoma, and, rarely, malignant melanoma. Similarly, patients in complementation group E tend to develop basal cell carcinoma in large proportions. The D group is more prone to have multiple melanomas. This will explain the fact that melanomas in Japanese patients are extremely rare, because in Japan group D is very rare (18,37). Heterozygotes are clinically normal and, in general, do not present sun sensitivity, but skin tumors seem to be four times higher than in the general population (78).

Eyes. Ocular involvement occurs in 40% (47). Most patients have marked photophobia and conjunctivitis with profuse lacrimation (72,95). The bulbar conjunctiva may exhibit pigmentation and telangiectasia. With severe involvement, the eyelids often lose their lashes, and ectopion, entropion, or symblepharon may complicate the clinical picture (2,16,17,45,47). Squamous cell carcinoma and melanoma of the conjunctiva, ulceration of the cornea, and iritis with synechia or iris atrophy have been described (21,29,84) (Fig. 13–123).

Central nervous system. Approximately 20% have neurologic abnormalities, the onset generally being after age 5 (47). Neurological abnormalities are observed largely in patients from complementation groups A, B, D, and G. Patients in group A tend to develop neurologic problems before age 7, whereas those in group D exhibit neurologic damage after this age (45). Only one patient from group C has presented severe CNS complications (27). This patient also had systemic lupus erythematosus. Rarely, patients from the other groups have CNS manifestations (6). The majority are in group A, with the more severe cases classified as De Sanctis–Cacchione syndrome (37,57). Clinically there may be spastic-ataxic gait and athetoid movements of the head and arms of variable degree (69). Areflexia, apparently due to lower motor neuron involvement, has been described (71). Pyramidal and extrapyramidal signs are common, and speech is often disturbed (14). Sensorineural hearing loss has been noted in several cases (47). Patients with De Sanctis-Cacchione syndrome present marked mental retardation and retarded physical development. The mental retardation is progressive and becomes evident during the first year of life. Abnormal electroencephalographic changes

Fig. 13–123. *Xeroderma pigmentosum*. Squamous cell carcinoma arising on palpebral conjunctiva.

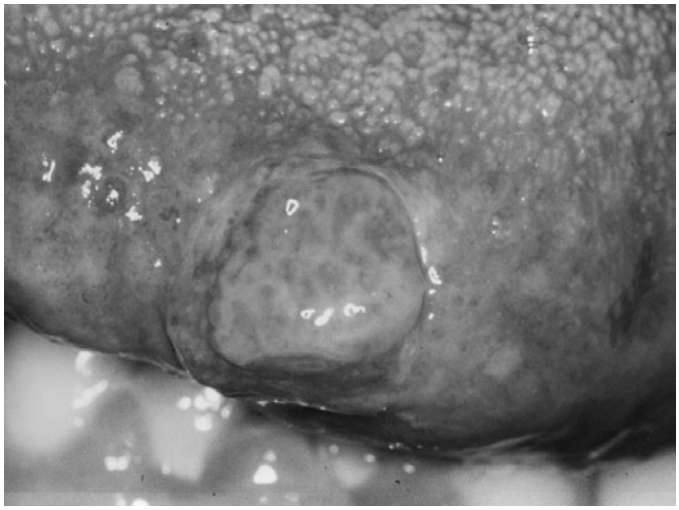

Fig. 13–124. *Xeroderma pigmentosum*. Squamous cell carcinoma arising on tongue tip. (From H Plotnick and A Lupulescu, J Am Acad Dermatol 9:876, 1983.)

(diffuse dysrhythmia with poorly developed alpha rhythm and with occasional paroxysmal burstlike slow-wave discharges) have been noted (10). Microcephaly, small brain, and diffuse mild cerebral and olivopontocerebellar neuronal loss have been found at autopsy (10,69,81). Nonaffected relatives exhibit a higher incidence of mental retardation and microcephaly than the general population (90). Brain atrophy, ventricular dilation, marked cortical atrophy, and thickening of the calvaria with excessive pneumatization of the frontal sinuses have been found by computed tomography in patients with De Sanctis–Cacchione syndrome (26,28). Peripheral neuropathy has been described and several nerve biopsies have suggested severe damage in both myelinated and unmyelinated fibers (26).

Oral manifestations. Areas of hyperpigmentation occur on the lips and anterior tongue (2). Squamous cell carcinoma of the lips, developing as early as age 14 (95), is frequent. Similar neoplasms of the tip of the tongue have been described (29,65,85,96). A 1987 survey of the literature (47) showed a total of 13 XP patients with squamous cell carcinoma of the tip of the tongue, two tumors arising in the gingiva and one in the palate (Fig. 13–124). Nearly 50% were below 14 years of age. Patients as young as 3 years of age have been reported with malignant oral neoplasms (46). These findings contrast with those in the general population of the United States, in which less than 1% of patients with oral or pharyngeal cancer are younger than 20 years (13).

A so-called "cheilo-nasal prominence" form of XP, characterized by profuse involvement of lips and nose starting in early childhood, has been described by Kraemer and Slor (45). This represents complementation group C, with marked actinic cheilitis, which eventually develops into carcinoma.

Other findings. Nuclear atypia of hepatic and pancreatic cells (78) and gonadal hypoplasia (14,33) have been reported.

Histologic features. Skin changes consist of hyperkeratosis, acanthosis, and areas of epidermal atrophy (72). A chronic inflammatory infiltrate of the epidermis can be observed, as well as abnormal accumulation of melanin in the basal cell layer. With increasing age, these changes become accentuated and eventually neoplasia occur. The histopathology of the neoplasms is identical to that of the same neoplasms arising in the general population.

Electron microscopic studies of sun-exposed and nonexposed skin reveal various abnormalities in melanin synthetic activity as well as phagocytosis of melanosomes by fibroblastlike cells (24,67).

Differential diagnosis. To be excluded are *Cockayne syndrome, Bloom syndrome*, and *Rothmund-Thomson syndrome*, drug-induced and allergen-induced photosensitivity, as well as erythropoietic protoporphyria light eruption (Hutchinson summer prurigo). Cockayne syndrome and xeroderma pigmentosum have been reported to occur simultaneously in two patients (55,71). One patient belonged to complementation group B and the other to group H. Thrush et al (81) reported sibs with an unclassified form of XP characterized by progressive dementia, chorea, sensorineural hearing loss, corticospinal tract degeneration, peripheral neuropathy, and skeletal abnormalities.

Laboratory aids. Autoradiographic determination of UDS is used to demonstrate DNA-excision repair of UV damage to DNA. Autoradiographs show a positive reaction in the nuclei of UV-irradiated cells after incorporation of tritium-labeled thymidine during the non-S phase. If fused fibroblasts from two different XP patients exhibit the reaction, they belong to two different complementation groups (2).

Fibroblasts from patients with XP have 10%–20% of normal ability to repair DNA probably due to an abnormal endonuclease activity (71). Increased chromosomal breakage has been found in fibroblasts, but not in lymphocyte cultures (67). Abnormalities in C and D chromosome groups (22) have been found in lymphocytes and cultured nontreated fibroblasts from patients with XP. Sister chromatid exchanges (SCE) are increased in cultured lymphoblastoid cells and fibroblasts following UV radiation (39). The number of SCEs has been found to correlate with the onset, severity, and prevalence of clinical symptoms and neoplasia. This reflects the mutation rate and the mutagenicity induced by UV radiation (39). However, it should be pointed out that similar changes occur in Cockayne syndrome, a disorder not prone to cancer production (73). Immunologic studies have demonstrated that some patients exhibit delayed rejection of skin grafts and reduced induction of lymphocytes by PHA. A decrease in T3-positive lymphocytes has also been noted (94). Elevated IgE level has been noted (68).

Prenatal diagnosis is possible (3,66,68,70). UDS studies after UV radiation in cultured fibroblasts obtained from obligate carriers have generally shown normal DNA repair levels (47,66,91). Reduced repair activity in heterozygotes has also been reported (5,15). There is a higher-than-expected (about 80%) association with blood group O. PCR technique can be used in lieu of complementation tests (44).

Sural nerve biopsy of two sibs with type A showed marked reduction in the number of large and small myelinated fibers (63).

Endocrine-candidosis syndrome (candidosis, idiopathic hypoparathyroidism, and hypoadrenalcorticism)

The association of mucocutaneous candidosis with polyglandular autoimmune disease, especially idiopathic hypoparathyroidism and idiopathic hypoadrenalcorticism, has been known for many years, the first reference probably being that of Thorpe and Handley (40) in 1929. However, it has required almost five decades for analysis of enough cases to see recognizable patterns of occurrence.

The syndrome is manifested as variable combination of (in approximate order of decreasing frequency) superficial mucocutaneous candidosis, hypoparathyroidism, hypoadrenocorticism, ovarian atrophy, keratoconjunctivitis, alopecia, intestinal malabsorption, pernicious anemia, diabetes mellitus, hepatitis, and thyroiditis (7,16,18,39).

Neufeld et al (29) divided autoimmune polyglandular syndromes into three distinct types, plus a miscellaneous type. Type I includes at least two of the following: chronic mucocutaneous candidosis, acquired hypoparathyroidism, and idiopathic hypoadrenalcorticism with or without autoimmune disease. It is also known as APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy). The complete triad is present in only one-third of the cases. Type II includes idiopathic hypoadrenalcorticism plus autoimmune thyroid disease and/or insulin-requiring diabetes, but no hypoparathyroidism or chronic mucocutaneous candidosis. It subsumes the so-called Schmidt syndrome (14). In contrast to type I, which has early onset (12 years), type II typically becomes evident in midlife (30 years). Type III patients manifest autoimmune thyroid disease *without* Addison disease but with at least one associated organ-specific autoimmune disease, such as insulin-dependent diabetes, pernicious anemia, vitiligo, and/or alopecia. We will not be concerned with type III disease here.

The cell-mediated immune defects may well be unique. In nearly all cases, there is limited ability of lymphocytes to proliferate in response to *Candida* antigen. Response to mitogens and other antigens is essentially normal. It is possible that the defect is mediated by a humoral factor in type I patients (5,8,20,22,23,42). At least one patient has died of fulminating chicken pox (13). There are several excellent reviews of these autoimmune syndromes (10,13,16,22,29).

Candidosis is usually the first component to appear, most observers reporting its presence during the first 6 years of life. It is followed from 3 months to 13 years later by the other components. Idiopathic hypoparathyroidism and hypoadrenalcorticism become manifest most frequently during the prepubescent period; the former has a mean of about 5 years, the latter at about 8.5 years.

Ahonen et al (4), in 1990, reported data on 68 patients from 54 families, ranging from 10 months to 53 years. They emphasized the broad clinical spectrum and mentioned that some of the manifestations did not appear until the fifth decade. Candidiasis was the initial manifestation in 60% of the patients and was present in all patients. Hypoparathyroidism was present in 79%, adrenocortical failure in 72%, and gonadal failure in 60% of female patients over 13 years and in 14% of male patients over 16 years of age.

Zlotogora and Shapiro (47), in 1992, reported on 19 families from an Iranian Jewish community with 23 persons affected with type I. Hypoparathyroidism was found in 96%, and 91% were diagnosed by the age of 20 years. The prevalence of the condition among Iranian Jews was estimated to be between 1:6,500 and 1:9,000, which is comparable to the high frequency among Finns. However, the Iranian Jews showed relative rarity of candidiasis and absence of keratopathy.

Heredity. Whereas type I has autosomal recessive inheritance (3,5, 12,24,31,35,39,44–46), type II appears to be HLA linked (B8, DW3, DR3) and exhibits familial aggregation, but does not appear to have single gene inheritance (10,29). A high frequency of type I has been found in Finland and among Iranian Jews (47).

Aaltonen et al (1,2), in 1994 and 1997, mapped the gene of APECED to 21q22.3. Even though Björses et al (6) provided independent evidence for linkage of the Iranian Jewish variety to the same chromosomal region, the presence of different haplotypes suggested a variety of mutations in the same gene. The AIRE protein, located in the cell nucleus, is mutated (6).

In 1997, Nagamine et al (27) and the Finnish-German APECED Consortium (11) independently isolated the gene responsible for APECED and designated it *AIRE* (*a*uto *i*mmune *r*egulator). The gene consists of 14 exons and its protein contains motifs suggestive of a transcription factor including 2 zinc finger (PHD-finger) motifs. Nagamine et al (27) found a mutation in the Swiss (arg 257-to-ter) and another in the Finnish (lys 83-to-glu) APECED patients. The Finnish-German Consortium (11) discovered 5 *AIRE* mutations, one of which was the common Finnish mutation.

Endocrine systems. Idiopathic hypoparathyroidism, eventually present in about 80%, is commonly asymptomatic initially. Serum calcium is reduced and serum phosphorus is elevated in the absence of significant disease of the genitourinary and gastrointestinal systems. Tetany is not evident unless calcium levels are significantly reduced. Furthermore, parathormone injection results in increased serum calcium and in elevated urinary phosphorus excretion. At necropsy, absence of the parathyroid glands or their replacement with fat has been noted (16).

Hypoadrenalcorticism is found in about 65% of type I patients. Often initially silent, it appears soon after the signs of hypoparathyroidism (29). Lassitude, anorexia, progressive weakness, hypotension, and progressive pigmentation of the skin and mucous membranes signal its onset.

Laboratory findings confirm the low serum sodium and high potassium levels. Death from adrenal crisis may result, and necropsy shows adrenocortical atrophy of the "cytotoxic type."

Autoimmune thyroid disease, also initially subtle, has been diagnosed in only 10% of type I cases but in 70% of type II examples (29). It has been shown to be primary, since thyroid-stimulating hormone (TSH) does not produce a rise in thyroid-131 uptake or alter the protein-bound iodine levels.

Insulin-requiring diabetes mellitus is found in only 2%–4% of type I cases, but in over 50% of type II cases (29). Diabetes insipidus has been reported in sibs with the disorder (29). The relation of Candida infection to the endocrine glands is not known. It has been suggested that candidosis is a superficial expression of undetermined abnormalities already present in the host that favor the development of the infection as well as the endocrinopathies.

Primary gonadal failure (almost exclusively ovarian) has been reported in 10%–15% of type I cases and in 3%–4% of type II patients (7,9,29,35).

Skin and skin appendages. The skin is dry, and the hair of both body and scalp usually brittle and diminished (Fig. 13–125). Eyebrows and axillary and pubic hair are remarkably sparse. Total alopecia may develop spontaneously in 25%–30% of type I cases (18,29). Fingernails and toenails are frequently thin, ridged, and brittle, and often are the site

Fig. 13–125. *Endocrine-candidosis syndrome*. Note generalized skin pigmentation, especially marked over face, midtrunk, and knees. (From JA Whitaker, J Clin Endocrinol 16:1374, 1956.)

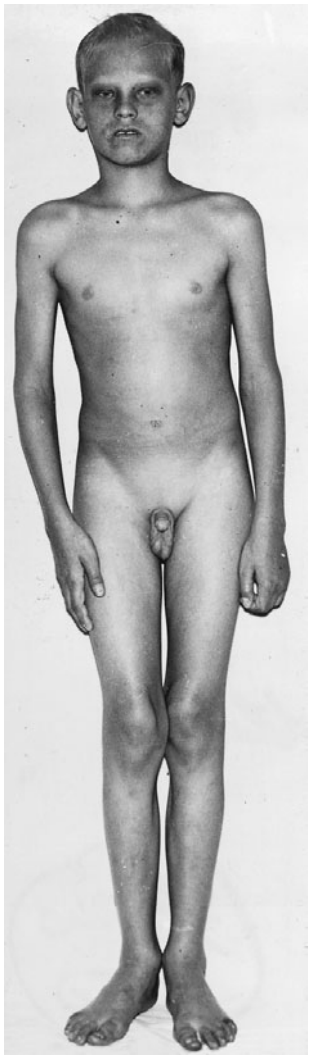

Fig. 13–126. *Endocrine-candidosis syndrome*. Candidosis of fingernails. (From KH Sjöberg, Acta Med Scand 179:157, 1966.)

of *Candida* infections (Fig. 13–126). If infected, the nails become brown, irregular, and thickened with a crumbled outer edge. Vitiligo is present in 10% of type I patients and in 5% of type II patients (12,29). Premature graying of the hair has also been noted.

Central and peripheral nervous system. Increased cerebrospinal fluid pressure, associated with papilledema, intracranial calcification, epileptiform seizures, and mental retardation have been noted (13,32,41) (Fig. 13–127). Muscle twitchings and cramps, tetany, abdominal pain, paresthesias, and rigidity are seen. The neurologic findings have been especially well reviewed by Jordan and Kelsall (19).

Ocular findings. Several patients have manifested photophobia, blepharospasm, recurrent blepharitis, corneal pannus, keratoconjunctivitis, corneal scarring, loss of eyebrows and/or eyelashes, and cataracts (13,18,29,43) (Fig. 13–128).

Gastrointestinal findings. Malabsorption has been noted in 25% of type I cases (29). Autoimmune chronic active hepatitis occurs in 10%–15% of type I cases, but not in type II cases (9,17,29,34,45).

Fig. 13–127. *Endocrine-candidosis syndrome*. Skull radiograph exhibiting extensive basal ganglion calcification. (From JDM Gass, Am J Ophthalmol 54:660, 1962.)

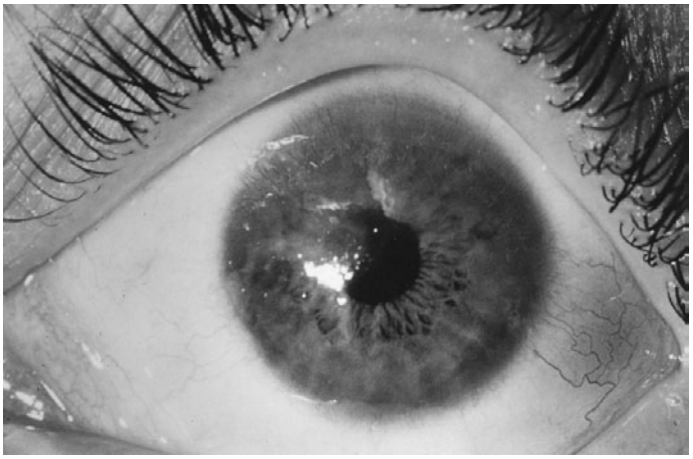

Fig. 13–128. *Endocrine-candidosis syndrome*. Keratoconjunctivitis. Note peripheral corneal vascularization and irregular, slightly raised, confluent nodular opacities in midperiphery of cornea. Lower paracentral cornea is not involved. (From JDM Gass, Am J Ophthalmol 54:660, 1962.)

Blood findings. Pernicious anemia is found in about 15% of type I cases but very rarely in type II patients (29).

Oral manifestations. Candidosis, present in about 75% of type I patients (26,29,33), may be superficial or deep seated and may involve the lips, tongue, buccal mucosa, palate, and larynx with thick, creamy-white plaques (Fig. 13–129). The mucosa between the plaques is often hyperemic, and the tongue may be smooth and devoid of papillae. Perleche, or angular stomatitis, may extend over a considerable portion of the perioral skin. Similar involvement of the anal and vaginal mucosae has been described.

With the advent of Addison's disease, areas of splotchy melanin pigment are seen in the mouth, especially on the buccal mucosa and palate.

The teeth are chalky with pitted crowns or transverse hypoplastic bands of enamel in 80% (13,23,26,28,37,38) (Fig. 13–129B). Involvement, however, is usually of mild degree (15,16,19,45) and appears to be independent of the hypoparathyroidism (26), probably being the result of autoimmune abnormalities. Dental age is probably normal (26). Late dental eruption has been found in some patients (19,35) but not in others (26). Impacted teeth (26,37) have also been found. The occurrence of squamous cell carcinoma of the oral cavity has been reported (25,35).

Differential diagnosis. Because of the wide spectrum of the syndrome, differential diagnosis must include the differential diagnosis of each of its components. This runs an exceedingly wide gamut.

Oral and perioral candidosis, possibly as a secondary factor, may also be seen in association with an underlying malignant process (leukemia, lymphoma, iatrogenically prolonged antibiotic or corticosteroid therapy). It is also seen in acrodermatitis enteropathica and in zinc deficiency. Chronic mucocutaneous candidosis is also seen in association with primary immunodeficiencies, both those with predominantly T lymphocyte defects (AIDS, severe combined immunodeficiency. DiGeorge sequence), and occasionally with other disorders (myeloperoxidase deficiency, chronic granulomatous disease). Chronic mucocutaneous candidosis can also occur by itself in a late-onset or familial form or it can be found in association with thymoma with or without myasthenia gravis (21,36). An autosomal dominant endocrine-candidiosis syndrome that is the same as *Witkop syndrome* was reported by Okamoto et al (30). Both T and B cells were reduced. Autoantibody abnormalities were not detected, but adrenal deterioration was noted. Pisanty and Garfunkel (32) reported five families in which hypoparathyroidism and candidosis were found with mental retardation. It was not determined whether this autosomal recessive syndrome is the same as endocrine candidosis, type I.

Laboratory aids. There are no specific diagnostic aids for the syndrome other than those used in the diagnosis of the individual components. Laboratory examinations to determine calcium and phosphorus levels, tests for kidney function, and the Ellsworth-Howard tests and levels of serum parathormone are necessary to establish the diagnosis of idiopathic hypoparathyroidism. Chvostek and Trousseau signs are positive when the calcium level is sufficiently low. Calcium and phosphate levels should be checked every 6 months after the diagnosis of mucocutaneous candidosis is made. Hypoadrenalcorticism is established on the basis of the clinical findings, low serum sodium and high potassium levels, low plasma cortisol and/or aldosterone levels, and adrenal antibodies. Sodium and potassium levels should be periodically checked after the diagnosis of hypoparathyroidism has been established. Hypothyroidism is established on finding low serum thyroxine and high serum thyrotropin. It, like the diabetes, is often overlooked.

Blood should be examined for evidence of pernicious anemia. Ophthalmologic study should be carried out for corneal surface abnormalities by use of rose bengal, fluorescein, or Schirmer testing.

Immunologic abnormalities should be investigated: autoantibodies (both organ and nonorgan specific), cell-mediated immunity, and HLA linkage (42,46).

In family studies, or for prenatal diagnosis, molecular testing of the specific mutation may be used for the diagnosis of type I (27).

Epidermolysis bullosa

Epidermolysis bullosa (EB) includes several hereditary vesicular disorders that involve the skin and often oral and other mucosas. The vesicles usually arise at points of trauma. For some types, however, heat may be the precipitating factor, or blisters may arise spontaneously.

The name "epidermolysis bullosa" is technically improper because cytolysis of the epidermis is observed in only three or four of the subtypes. Nevertheless it is preserved because of its many years of usage.

EB is presently classified according to various combinations of inheritance, scarring, and location of bullae. Because many of the clinical manifestations in the various subtypes of EB can be similar if not identical, it is imperative that proper typing of patients be accomplished with electron microscopic, immunofluorescent, and immunohistochemical studies (52a,59,64).

Recent progress has been made in understanding the molecular basis of the various types of EB. This progress was achieved by studying the structural features of the epidermis and dermal–epidermal junction. The molecular cloning of genes encoding proteins critical for the integrity of these cutaneous layers has helped in this process, thus explaining also many of the clinical manifestations (28, 47) (Fig. 13–130). The interested reader is referred to the works and reviews of Bergenholtz and Olsson (11), Haber et al (64), Gedde-Dahl and Anton-Lamprecht (59), Gedde-Dahl (58), Schnyder (134), Abahussein and Al-Zayir (1), Bruckner-Tuderman (17,18), Cooper and Bauer (35), Fine (48,49,53), Tabas et al (140), Christiano and Uitto (28), Bonifas et al (13), Hovnanian and Christiano (70), Marinkovich et al (91), Nomura et al (109), and, especially, Fine et al (52a).

The present classification of EB is based primarily on the level at which the cleavage that forms the bulla takes place. This is combined with the resultant clinical signs (e.g., scarring) and the type of inheritance (76). Thus, the basic classification is as follows (see also Table 13–6):

Type I: Intraepidermal forms, characterized as nonscarring varieties having autosomal dominant, recessive (vide infra), and X-linked forms.

Table 13–6. Epidermolysis bullosa[a]

Type	Inheritance	Gene map locus	Onset	Skin	Face	Oral mucosa	Teeth	Corneal erosions	Nails	Hands	Feet	Seasonal variation	References
I. *Intraepithelial blister formation (simplex - EBS)*													
A. *Major variants of nonscarring EBS*													
1. Weber-Cockayne variant	AD	12q13 17q1–q21	First to third decade	EB of hands and feet; scarring	No	9% intraoral blistering	No	No	Dystrophy	Yes	Yes	Summer	13,47a,51,119
2. Koebner variant	AD	12q13 17q12–q21	Birth to third year	EB simplex, generalized; scarring (24.1%)	±	23.1% intraoral blistering	No	No	Dystrophy	Yes	Yes	Warm weather	25,27,47a,51, 72
3. Herpetifomis, Dowling-Meara variant	AD	12q13 17q12–q21	First month	Herpitiform lesions Scarring (55.8%) Milia (68.8%) Hyperkeratosis palms and soles	Yes	62.5% intraoral blistering	Some	Some	Dystrophy 27.7%	Yes	Yes	No	45,47a,51,84, 104
B. *Minor variants of nonscarring EBS*													
1. EBS with anodontia/ hypodontia (Kallin syndrome or Nielsen-Sjölund syndrome)	AR			Blisters common Childhood alopecia with brittle hair Localized to hands and/or feet		Erosions	Anodontia or hypodontia		Thickened or curved	Yes	Yes		51,101
2. EBS with mottled pigmentation	AD	12q13	Birth to infancy	2–5 mm hyper- or hypopigmented spots	No	No	No	No	Longitudinally curved	Yes	Yes	No	18,51 52,73,140
3. EBS with limb-girdle muscular dystrophy (EB-MD)	AR	8q24	Birth	Generalized Scarring, alopecia		Frequent	Rarely defective enamel	Rare	Dystrophy common	Yes	Yes		26,39, 85,110,132
4. EBS Ogna variant	AD	8q24	Early childhood	Generalized, especially hands and feet	No	No	No	No	Onychogryposis of great toes	Yes	Yes	Summer	51,106
5. EBS, Mendes da Costa variant, macular	XR	Xq27.3–qter	First to third year	Mainly extremities	No	No	No	No	No	Yes	Yes		51,86a,98a,144a
6. EBS, recessive	AR	17q12–q21		Generalized	No	No	No	No		Yes	Yes		69
7. EBS, superficialis	AD		Birth/ infancy	Generalized or extremities		Common	Conjunctival vesiculation	Common					51
II. *Junctional epidermolysis bullosa (JEB) with hemidesmosome defect (atrophicans group)*													
A. *Nonscarring JEB, major variants*													
1. Generalized, with atrophy, gravis (Herlitz)	AR	18q11.2 1q32 1q25–q31	First days	Blisters, erosions, crusts, scarring, atrophy	Yes	Yes	Yes	Rarely	Yes, dystrophic or absent	Yes, at infancy	Yes, at infancy	No	20,28, 51,76,114–116,143
2. Generalized, atrophic, benign epidermolysis bullosa (GABEB) (Mitis or Disentis)	AR	1q32 10q24.3	At birth	Blisters. Scarring common but focal	No	Yes	Yes	No	Yes, dystrophic or absent	Yes	Yes	Summer	51,91,110

3. Generalized, inversa variant	AR	1q31	First days		No	Rarely	Yes	Yes	Yes	No	No	No	28,51,58
4. Junctional EB with pyloric atresia (EB-PA) (Carmi syndrome)	AR	17q11–qter		Aplasia cutis congenita, axillary pterygia	Ectropion Ear and nose deformity	Variable involvement	No	No	Variable involvement	Contracted fisted hand	Arthrogryposis	No	54,83,88, 110,117
B. *Nonscarring JEB, minor variants*													
1. JEB, localized, minimus (with atrophy)	AR		Birth	Blisters, atrophy present		Common	Enamal hypoplasia	No	Absent				51
2. JEB, localized, progressive	AR		5–8 years	Blisters. Atrophy variable	No	Present	Enamel hypoplasia	No	Dystrophic or absent	Mild finger contractures	Yes	No	51
3. JEB, cicatricial variant	AR		Birth	Blisters. Scarring and atrophy common, scarring alopecia		Common	Enamel hypoplasia	Infrequent	Absent	Present			51,60
III. *Dermolytic blister formation (dystrophic group) with scarring*													
A. *Major variants*													
1. EB dystrophica albupapuloidea, Pasini variant	AD	3p21.3	Birth	Blisters, milia, scarring, atrophy	Yes	Mild erosions	No	No	Dystrophic or absent	Yes	Yes	No	51
2. EB dystrophica, Cockayne-Touraine variant	AD	3p21.3	Birth to 5th year	Blisters, milia, scarring atrophy	No	Rare	No	No	Dystrophic or absent	Yes	Yes	No	24,41, 51,81,119
3. EB dystrophica, localized (Bart syndrome type)	AD	3p21.3	Birth	Congenital localized absence of skin; blistering	Yes				Dystrophy or absence	Yes	Yes		33,51
4. EB dystrophica, gravis Hallopeau-Siemens variant	AR/AD	3p21.3	Birth	Blisters, milia scarring, atrophy	Yes	Severe erosions, scarring, microstomia, ankyloglossia	Caries	Rare	Absent	Severe mitten deformities and contractures		No	32,51,57, 63,71
B. *Minor variants*													
1. EB dystrophica, localized (minimus)	AD		Early childhood	mild or absent lesions after early childhood		No			Yes	Acral distribution			51
2. EB dystrophica, localized	AR	3p21.3											55
3. EB dystrophica, pretibial	AD	3p21.3	Childhood or adolescence	Pretibial scarring and atrophy	No	No	No	No	Yes		No	No	30,51,99
4. EB dystrophica, inverse variant	AR		Neonates	Neck, groin, axilla, blisters, scarring atrophy	No	Yes	No	No	Variable	No	No	No	51
5. EB dystrophica, centripetal variant	AR		Birth	Centripetal spread		No		No	Dystrophic or absent				51
6. EB dystrophica, mitis	AR		Birth	Generalized		Mild		No	Dystrophic or absent				51
7. Transient bullous dermolysis of the newborn	AD		Birth, amelioration after age 1 year	Blistering	Yes	Yes				Yes	Yes		51
IV. *Acquired phenocopy of dystrophic EB (EB acquisita)*			Adult		No	Slight	No	No	Yes	Yes	Yes	No	

[a] Classification according to consensus report by the Subcommittee on Diagnosis and Classification of the National Epidermolysis Bullosa Registry (53).

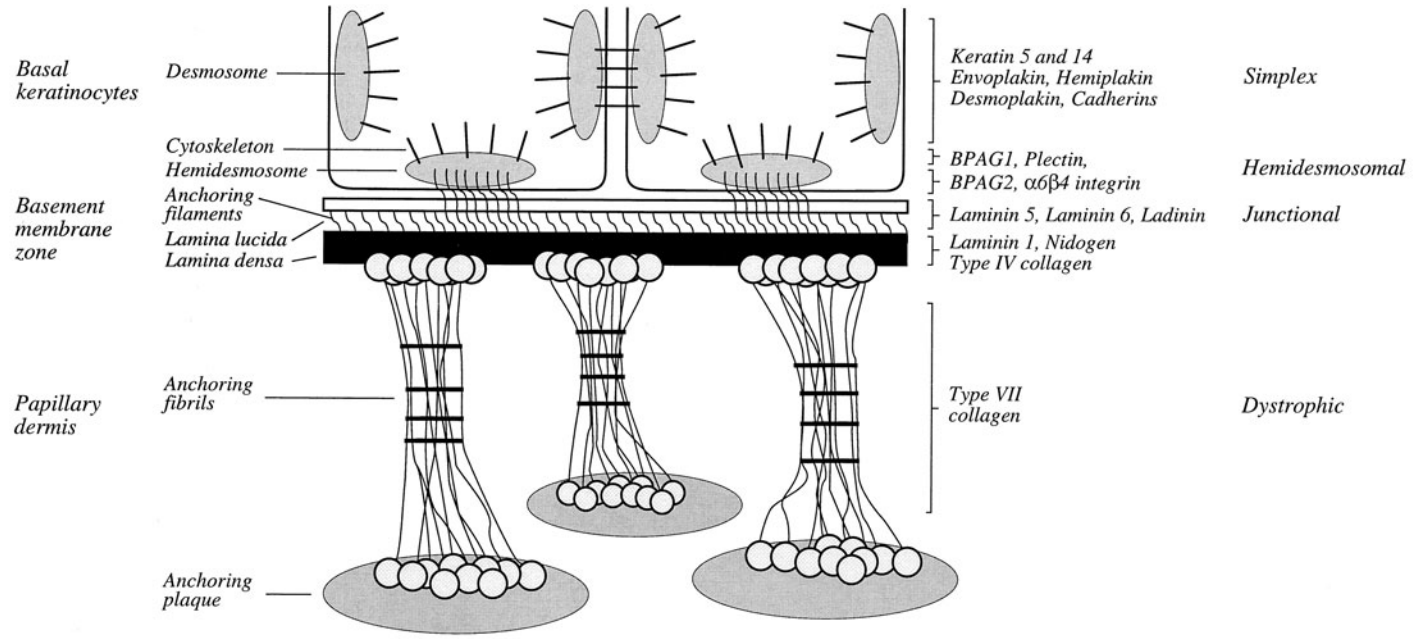

Fig. 13–130. *Epidermolysis bullosa*. The complexity of the cutaneous basement membrane zone. The figure depicts basal keratinocytes at the lower part of the epidermis which is separated from the underlying papillary dermis by a dermal-epidermal basement membrane. Ultrastructurally recognizable attachment complexes are indicated on the left, while the specific structural components within each layer are indicated on the right. Also note the level of tissue separation within different subgroups of epidermolysis bullosa as shown on the right. (Modified from J Uitto and AM Christiano, J Clin Invest 90:687, 1992, with permission.)

Type II: Junctional forms, characterized primarily by skin atrophy, with autosomal recessive inheritance.

Type III: Dermal forms, characterized by atrophy and scarring, with autosomal dominant and recessive varieties.

Type IV: Acquired (nonhereditary) variety known as EB acquisita.

Here, in the text, only those types presenting oral mucosal and/or dental manifestations will be described. A more complete list is presented in Table 13–6.

EB simplex Koebner type

Systemic manifestations. Sites of friction or trauma are most frequently involved. Nails are affected in about 20%. Healing does not result in scarring and/or pigmentation. The disorder, which usually appears neonatally or during infancy when the child begins to crawl, involves principally feet, hands, and neck, but rarely ankles, knees, trunk, and elbows (Fig. 13–131). After the third year of life, usually only hands and feet are affected. The nails are normal. The condition generally improves

Fig. 13–131. *Epidermolysis bullosa, dominant simplex type*. (A) Nonscarring blisters of feet. (B) Oral vesicles seen in about 2% of patients.

A B

markedly at puberty. Heat also seems to be an important precipitating factor in blister production (19). This type of EB must be differentiated from the Weber-Cockayne type, in which only the feet are affected. This latter form of EB more commonly (70% vs. 40%) appears at less than 1 year of age, and does not present oral involvement. It should be differentiated also from the Dowling-Meara type, in which serous and hemorrhagic blisters occur on any part of the body, but most frequently on the palms and soles, around the mouth, and on the trunk and neck (45).

Oral manifestations. Occasional intraoral blister formation is seen. The lesions are not as pronounced as those in the more severe types of EB. They can occur at any intraoral location. Tooth alterations are not present (58,63) (Fig. 13–131B).

Histologic study reveals cleavage through the basal layer, with nuclei on the blister floor, i.e., above the PAS-positive basement membrane. Adjacent to areas of separation, the basal cells are vacuolated, with displacement of the nucleus to the epidermal end of the cell. These alterations have been confirmed ultrastructurally (113,126). No histochemical abnormality has been observed (87).

Inheritance and genetics. Inheritance is autosomal dominant. Linkage of epidermolysis bullosa simplex to keratin gene loci has been reported (99). These phenotypes are caused by mutations in either the keratin 5 gene (*KRT5*) at 12q13 (74) or the keratin 14 gene (*KRT14*) at 17q12–q21 (25,27,74). (Fig. 13–130). The Koebner type of EBS is not fundamentally distinct from the Dowling-Meara type, which is also caused by mutations in keratin 5 or 14 genes (45,85,110). However, the Dowling-Meara type is severe and reveals, by electron microscopy, the presence of large cytoplasmic clumps of tonofilaments (4). Clinical severity is related to the location of point mutations within the keratin polypeptides. Point mutations in the most severe forms have been clustered in the highly conserved ends of K5 or K14 (85).

EB simplex with muscular dystrophy (MD-EBS). Several authors (52,81,108) have described an autosomal recessively inherited EB simplex with muscular dystrophy of the limb-girdle type (52,108) or congenital myasthenia gravis. It has been suggested that myasthenia gravis is an independent finding (52). Appearing at birth, the disorder becomes generalized but more severely involves the extremities. Milia are common. Oral mucosal involvement is frequent. A mild atrophic scarring has been seen in most patients.

In 1996, Gache et al (55) found that skin samples from MD-EBS patients did not react with 3 antibodies of the intermediate filament-associated protein plectin (Fig. 13–130). Moreover, plectin was not detected in skeletal muscles of these patients. Gache et al (55) also observed deficient immunoreactivity against the hemidesmosomal protein HD1. It is strongly suggested that plectin and HD1 are closely related and that defective expression of plectin results in an aberrant anchorage of cytoskeletal structures in keratinocytes and muscle fibers, leading to cell fragility. It has been also postulated that plectin functions in muscle as a putative attachment protein mediating binding of actin to membrane complexes. This would explain the cutaneous fragility and muscular weakness in these patients (44,57,118,138).

Inheritance and genetics. Inheritance is autosomal recessive. The disease segregates with markers in the 8q24.13-qter region where the plectin gene maps (Fig. 13–130). Various mutations and deletions in the *plectin* gene have been reported (26,86,100,115,118,125,138,147). A protein truncation test has been used for the detection of premature termination codon mutations (39).

EB atrophicans generalisata gravis (Herlitz type)

Systemic manifestations. This type of EB, inherited as autosomal recessive, was originally described by Herlitz and Pearson under the name of EB letalis. As a number of infants with this form survive into adulthood, the term *letalis* should be discarded. Because affected infants have survived the first months of life, it may be assumed that in the past several cases have been misdiagnosed (37).

Fig. 13–132. *Epidermolysis bullosa, recessive letalis type*. Extensive skin involvement. (From EB Brain and JS Wigglesworth, Br Dent J 124:255, 1968.)

Usually the vesicles, often hemorrhagic, are noted at the base of the fingernails within the first few hours of life. The nails soon become loose and are shed (62). This is followed by involvement of the trunk, umbilicus, face, scalp, and extremities. The palms and soles are never affected. There seems to be an absence of reaction to traumatic provocation. A number of affected infants die within the first few months of life, usually from secondary septic infections (Fig. 13–132). The patients who survive do not present fusion of the digits. Their hands and feet are affected only to a minor degree (64). Anemia, growth retardation, and nail dystrophy are frequently present (59,64). With age, the healing process is retarded or arrested, leaving large excoriated areas.

Light microscopic examination demonstrates epidermal–dermal cleavage that follows the rete ridge contour. Inflammatory changes are not originally present (89,127). Vesicles at the dermoepidermal junction in the stratum germinativum of intact skin have been demonstrated (11,87).

Electron microscopic appearance, originally reported by Pearson (113), demonstrated separation between the plasma membrane of the basal cell and the basement membrane. The basic defect is hypoplasia of hemidesmosomes and lack of the subbasal dense plate (Fig. 13–130) (66,67).

A late-onset variety of junctional epidermolysis bullosa associated with mental retardation has been reported as a distinct autosomal recessive syndrome (104).

The cumulative risk of death in junctional epidermolysis bullosa is 37.4% by 1 year of life and 45.6% by age 5 years. Then it remains at that level through at least age 40, suggesting that the risk of mortality in junctional EB is primarily of concern during infancy and childhood (49).

Oral manifestations. Bullae, which are remarkably fragile and hemorrhagic, are found in nearly all patients, especially at the junction between the hard and soft palates (8). Oral ulcerations as well as blistering can be observed at birth or shortly thereafter (67). Hypoplastic and pitted enamel affecting principally the molars is also seen. Enamel formation is abnormal, leading to extensive caries (22). Histologic study reveals cleavage between the epithelium and connective tissue. The cells of the basal layer seem quite palisaded as a result of extracellular vacuolization. Perioral and perinasal crusted and granular hemorrhagic lesions tend to

develop between the sixth and the twelfth months of life (59,64,156). These lesions are believed to be pathognomonic for the Herlitz type of EB in older patients (113).

Arwill and coworkers (8) ultrastructurally investigated skin as well as oral mucosa in four cases of the Herlitz form. In contrast to those in the normal infant, the gingiva and skin exhibited fewer hemidesmosomes and tonofilaments. The initial changes consisted of edema of the subepithelial connective tissue, degeneration of mitochondria, and electron-opaque perinuclear zone that, upon dissolution, frees remnants of tonofibrils and mitochondria and widens intercellular spaces between epithelial basal cells. Although the desmosomes remained intact, minute vesicles were found between the basement membrane and the basal cell membrane in the intermediate zone. The lamellated pattern of the hemidesmosomes disappeared, replaced by a granular substance. The hemidesmosomes show abnormal association with the keratin filament network in junctional forms of epidermolysis bullosa (101).

Arwill and colleagues (7) appear to have been the first to have performed microscopic and microradiographic studies on the teeth in the Herlitz form of the disease. The enamel, lamellar in appearance, varied in thickness from 50 to 400 μm, the outer and inner zones being more markedly mineralized than the intermediate zone. Outside, and at varied distances from the surface, were free globular structures exhibiting variable mineralization. The cervical enamel was more highly mineralized than the incisal edge. In the permanent teeth there was folding at the dentinoenamel junction, which was normal in the deciduous teeth.

Decalcified sections showed intense proliferation of dental lamina and inner and outer enamel epithelium. The latter also manifested metaplasia to stratified squamous epithelium. Numerous vacuoles containing epithelium were observed. The enamel stroma was hyalinized, lamellar, and, at times, globular. Vascular proliferation was marked about the tooth germs, and hemorrhage was noted in the dental sac and stellate reticulum.

Brain and Wigglesworth (15) also investigated the deciduous dentition of an infant with the Herlitz form of EB, noting that the enamel was only 40 μm thick. There was no organized prism structure, and some parts appeared laminated. Globules resembling enamel were distributed between the hypoplastic layer of enamel and the outer enamel epithelium. The reduced enamel epithelium was extensively disorganized. Vesiclelike structures were present adjacent to tooth crowns.

Inheritance and genetics. The inheritance is autosomal recessive. In 1991, Carter et al (23) characterized a human keratinocyte extracellular matrix (ECM) glycoprotein complex termed *epiligrin*. Later, it was found that epidermolysis bullosa atrophicans generalisata gravis (Herlitz type) is caused by mutations in any one of 3 polypeptides of laminin 5 (Fig. 13–130). These are the laminin 5 α3, β3, and γ2 chains, according to the nomenclature of Burgeson et al (20).

Kivirikko et al, in 1995 (78), reported a homozygous nonsense mutation in the α3 chain gene of laminin 5 (LAMA3) in lethal (Herlitz) junctional epidermolysis bullosa. McGrath et al, in 1996 (97), studied a newborn with first-cousin parents of Pakistani origin. The proband had extensive blisters and erosions. Electron microscopy of the skin revealed scanty, rudimentary hemidesmosome-anchoring filament complexes and tissue separation within the lamina lucida. A homozygous nonsense mutation was found by molecular studies. In 1995, Vidal et al (151) found a homozygous single bp deletion in the transcripts encoding the 2 isoforms of laminin α3A and α3B in a patient with Herlitz junctional epidermolysis bullosa.

Pulkkinen et al, in 1994 (115), also found homozygosity for a nonsense mutation in the *LAMB3* gene in a patient with Herlitz junctional epidermolysis bullosa. A year later, in 1995 (117), they elucidated the exon/intron organization of the human *LAMB3* gene. In 1996, Kivirikko et al (79) examined 14 families with Herlitz type. In over 50% of the mutant *LAMB3* alleles they found two recurrent nonsense mutations (79,119). Compound heterozygosity for nonsense and missense mutations in the *LAMB3* gene has been reported in nonlethal junctional epidermolysis bullosa (98). Maternal uniparental disomy of chromosome 1 with reduction to homozygosity of the *LAMB3* locus has also been reported (121).

Finally, based on the new nomenclature for laminin chains and their isoforms (20), the *LAMNB2* or *LAMC2* gene coding for the γ2 chain was found to be mutated in certain patients with the Herlitz type of junctional epidermolysis bullosa (2,9,116,120).

While the molecular basis of many of the classic forms of junctional EB is now well understood on the basis of laminin 5 mutations, there is a group of patients in which blisters form in and around the hemidesmosome (HD) (28). The hemidesmosomes are attachment structures critical for the stable association of epidermis and dermis. (Fig. 13–130). They extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane (28). Five major components of HD have been identified. These are polypeptides named HD1-HD5 (28). HD1 is considered to be closely related to plectin (55). HD2 and HD4 are bullous pemphigoid antigen BPAG1 and BPAG2/COL17A1, respectively (Fig. 13–130). HD3 and HD5 correspond to the β4 and α6 of integrins, respectively. BPAG2/COL17A1 and $\alpha 6\beta 4$ integrin mutations are responsible for generalized atrophic benign EB and junctional EB with pyloric atresia, respectively (see Table 13–6).

Based on mutation analysis, prenatal diagnosis (34,92,95,96,123, 142,149) and preimplantation genetic diagnosis (38) have been performed in families at risk for Herlitz junctional epidermolysis bullosa.

Dominant dystrophic (hypertrophic) form (Cockayne-Touraine type). This form of epidermolysis bullosa is characterized by flat, pink, scar-producing bullae of the ankles, knees, hands, elbows, and feet, in decreasing order of frequency (41). Milia are common but less numerous than in the recessive dysplastic type. The nails are usually (80%) thick and dystrophic. In contrast to recessive dystrophic cases, the conjunctiva and cornea are never involved. Approximately 20% show changes before the age of 1 year (109). Improvement seems to occur with age. Hyperhidrosis of palms and soles may also occur.

Oral manifestations. The consensus favors the view that teeth are not affected. Touraine's often-quoted statement (144) that 20% manifest oral bullae would appear to be essentially substantiated by other studies (41), but series have been small. Oral milia were noted by Andreasen and associates (3). (Fig. 13–133). These milia are not retention cysts, but epidermoid cysts that originate from detached islands of epithelium in areas of earlier bulla formation.

Fig. 13–133. *Epidermolysis bullosa, dominant dystrophic type*. Milia of palate. (From JO Andreasen et al, Acta Pathol Microbiol Scand 63:37, 1965.)

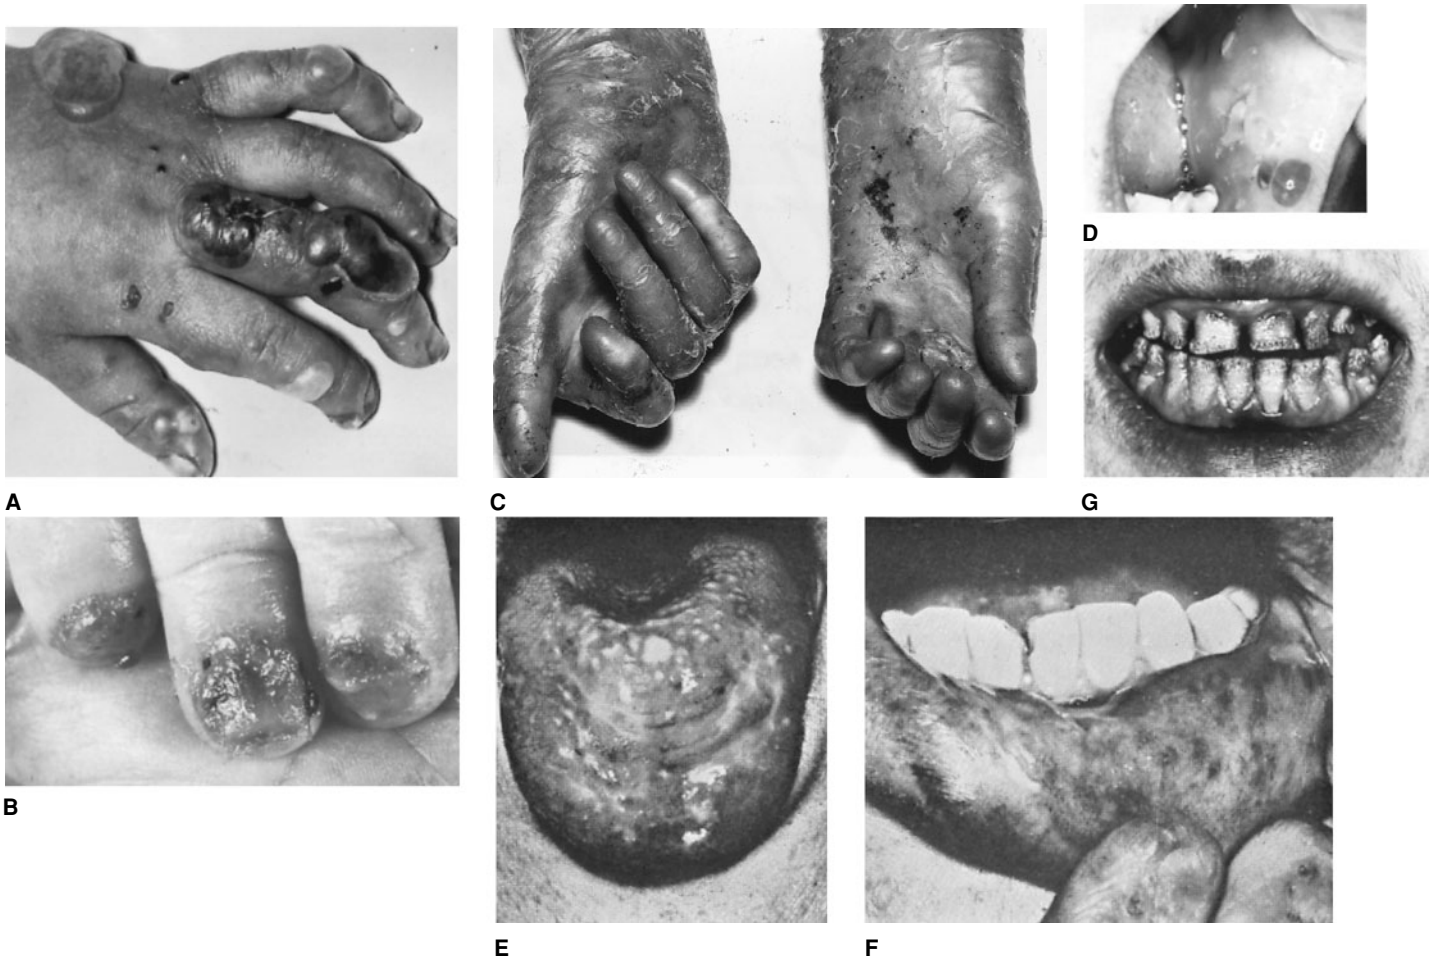

Fig. 13–134. *Epidermolysis bullosa, recessive dystrophic type*. (A) Extensive blister formation of hand. (B) Destructive lesions of fingernails in newborn. (C) Severe involvement of hands. Note dystrophy of nails. (D) Bullae of buccal mucosa. (E) Dorsum of tongue exhibiting numerous scars and complete loss of papillae. Often mobility is limited. (F) Labial mucosa showing extensive scarring. Also note nail dystrophy. (G) Pitted enamel. (A courtesy of A Lodin, Stockholm Sweden. C,E and F from D Winstock, Br J Dermatol 74:431, 1962. G from OE Rodermund, Dermatol Wochenschr 153:350, 1967.)

Inheritance and genetics. Inheritance is autosomal dominant. Many extensive families have been reported (24,124). It is possible that Cockayne-Touraine, Pasini, and Bart types represent different expressions of the same mutant gene (14). Kon et al (82) reported novel glycine substitution mutations in COL7A1, revealing that the Pasini and Cockayne-Touraine variants of dominant dystrophic epidermolysis bullosa are allelic.

Scarring EB with dermolytic blisters (Hallopeau-Siemens type). The extensive studies of Gedde-Dahl (58) and Gedde-Dahl and Anton-Lamprecht (59) suggest that this group of disorders has very significant heterogeneity.

Bullae are usually manifested at or shortly after birth, arising at sites of pressure or trauma or appearing spontaneously (Fig. 13–134). In infants, the most commonly affected areas are feet, buttocks, scapulas, elbows, fingers, and occiput. In older children, hands, feet, knees, and elbows are most often involved. When a bulla ruptures or its roof peels off, a raw painful surface is evident. The fluid contained in the bulla is at first sterile but may become secondarily infected and bloody. Upon healing, the bullae often are followed by keloidal scars, causing contraction. They are frequently associated with miliumlike cysts. The scars may lead to loss of bony structures or to interference with growth and resultant dwarfism. Formation of clawhand and the enclosure of the hand in a glovelike epidermal sac have been noted frequently (16,155) (Fig. 13–134A). The Nikolsky sign is often present. The nails may be extremely involved, often being dystrophic or absent (58) (Fig. 13–134B,C). Hyperhidrosis of palms and soles is an inconsistent finding but may be marked. Hair may be deficient.

The eyes have been subject to a number of changes: essential shrinkage of conjunctiva, nonspecific blepharitis, symblepharon, conjunctivitis, and keratitis with corneal opacity and vesicle formation (58).

Hoarseness and, rarely, aphonia and dysphagia may occur as a result of bullae of the larynx or pharynx. Laryngeal stenosis may eventuate from scarring. Involvement of the esophagus may result in complete obstruction (10,68).

Changes are essentially limited to the hands, feet, and esophagus. The esophagus (most often the upper half) may become segmentally stenotic in childhood, with consequent dysphagia (10,152). The metacarpals become slender and overconstricted and distal phalanges become pointed and claw-like (16,155).

By ages 25 and 35, 23.7% and 51.0%, respectively, of patients with the Hallopeau-Siemens variant have developed at least one squamous cell carcinoma (112). In addition, the cumulative risk of malignant melanoma in this variant was found to be 4.1% by age 12 (49). Angiosarcoma has also been reported as a complication (133).

Little increased risk of death occurs in recessive dystrophic EB patients until after the age of 20. By age 40, however, the risk of death is 33.3%, coinciding with the timing of squamous cell carcinomas in this patient population (49).

Oral manifestations. Although a considerable number of authors have remarked on the teeth having hypoplastic enamel with great susceptibility to dental caries, delayed eruption, and frequent retention, there is little documentation concerning frequency of these manifestations (40,77,93,154). We share with Rodermund (129) the belief that there is no correlation between the degree of cutaneous involvement and the degree of dental involvement. Pockmarked enamel was handsomely illustrated by Rodermund (129) (Fig. 13–134G). Excellent histologic studies of unerupted teeth have been published by Delaire and colleagues (43) and by Arwill and coworkers (7). Both groups noted hypoplasia of enamel with absence of prismatic structure. Extracted teeth were examined by Crawford et al (37), who found accentuation of enamel tuft formation extending from the dentinoenamel junction to the enamel surface. Additionally, irregular dentinal foldings and indentations were found at the dentinoenamel junction.

Oral mucosal involvement occurs soon after birth, vesicles apparently forming from the negative pressure involved in the sucking reflex (Fig. 13–134D) (157). Although oral bullae are said to occur in a least 16%, our impression is that the percentage is much higher. The lingual mucosa appears thick, gray, and smooth and may become bound down (Fig. 13–134E,F). Repeated blistering with scar formation may lead to ankyloglossia, tongue atrophy, elimination of buccal and vestibular sulci, and perioral stricture (12,37) (Fig. 13–134F). Severe periodontal disease with alveolar bone resorption had also been noted (40). Even routine dental management may cause the eruption of bullae on lips and oral mucosa (12). Diminished oral opening following scarring after blistering as well as ankyloglossia due to the same cause have been reported (12). The slightest abrasion from normal tooth brushing may cause serious sequelae. Other oral changes, the frequencies of which have not been established, are atrophy of the maxilla with resultant relative mandibular prognathism, increased mandibular angle (16), and oral carcinoma (80,128,132). Histopathologic changes in the oral mucosa were well demonstrated by Arwill and associates (6). The bullae occur below the PAS-positive basement membrane (87). Hemidesmosomes and tonofibrils are absent or decreased in numbers. Lowe (87) also noted an increase in elastic and pre-elastic fibers in the corium. Hitchin (69) described defective cementum.

Inheritance and genetics. Inheritance is autosomal recessive or dominant. In 1993, Hovnanian and Christiano (70) and Uitto et al (146) demonstrated linkage between a PvuII polymorphic site of the COL7A1 and dystrophic epidermolysis bullosa (Fig. 13–130).

Type VII collagen appears to be restricted to the basement membrane zone beneath stratified squamous epithelia. Within the cutaneous basement membrane zone, type VII collagen localizes to the lamina densa and sublamina densa areas in the upper papillary dermis (57,103). The severe autosomal recessive dystrophic form has been found to be associated with type VII collagen deficiency (17).

Christiano et al (29–31) found mutations in type VII collagen in patients with recessive dystrophic epidermolysis bullosa in the Bart form (103). Later, in 1996 (32,33), they stated that the COL7A1 gene is unique among the collagen genes in that different glycine substitutions can result in a spectrum of dystrophic epidermolysis bullosa phenotypes and patterns of inheritance. Hovnanian et al (73), in 1997, characterized 21 mutations in the COL7A1 gene, 18 of which had not been previously reported, in patients from 15 unrelated families with recessive dystrophic epidermolysis bullosa (RDEB). Fourteen of the 21 mutations created premature termination codons and consisted of nonsense mutations, small insertions, deletions, and splice site mutations. An additional 7 mutations predicted glycine or arginine substitutions in the collagenous domain of the molecule. Genotype–phenotype correlations suggested to Hovnanian et al (73) that the nature and location of these mutations are important determinants of the phenotype. Hammami-Hauasli et al, in 1998 (65), studied naturally occurring COL7A1 mutations and showed that some, but not all, glycine substitutions in collagen VII interfere with biosynthesis of the protein in a dominant negative manner. Three point mutations in exon 73 caused glycine substitutions in the triple helical domain of collagen VII and interfered with its folding and secretion. In contrast, the glycine substitution in another segment of the triple helix remained phenotypically silent. Thus, collagen VII is a remarkable exception among collagens in that the biologic consequences of the glycine substitutions depend on their position within the triple helix.

Hovnanian et al (72) reported DNA-based prenatal diagnosis of generalized recessive dystrophic epidermolysis bullosa in pregnancies at risk for recurrence.

Oral manifestations of other forms of EB. *Epidermolysis bullosa acquisita* rarely presents oral manifestations, but they have been described (107). This form of EB is nonhereditary and manifests in adulthood with blister formation, especially in areas of trauma. It may be associated with other systemic diseases, such as amyloidosis, multiple myeloma, diabetes mellitus, and inflammatory bowel disease. The last association may represent a gastrointestinal cutaneous syndrome with immune pathogenesis (143).

Scarring or cicatricial junctional type of EB has autosomal recessive inheritance. Patients present at birth with skin blisters and lack of nails. There is marked disfigurement, especially of hands and feet. The skin blisters heal with scar formation, producing marked atrophy, especially around the nares. Occasionally a diminished oral opening is noted. Patients present intraoral blisters that are found at any site but are not as profuse or as severe as those in some other forms of EB. All patients with this condition have been reported either as having extensive dental caries or as being edentulous. Further studies are needed to assess whether there is some form of enamel defect present. Since this type of EB has definite ectodermal alterations (anonychia), an enamel defect is within the realm of possibility (62).

EB nonscarring atrophicans generalisata mitis (R-EBA-MITIS), epidermolysis bullosa junctionalis, disentis type, inherited as an autosomal dominant disorder, presents oral and dental alterations. Oral mucosa can be the site of blisters, especially trauma-related; nodular excrescences on the palate and gingiva have also been reported (61). Teeth can present pitting of enamel, conducive to extensive caries (113).

A possible new variety of EB has been reported by Nielsen and Sjölund (106): *epidermolysis bullosa, late-onset localized junctional, with mental retardation, in two sisters*, offspring of nonconsanguinous parents. These patients presented hemorrhagic blisters localized to hands and feet associated with partial alopecia, onychogryposis, anodontia, and an amelogenesis imperfecta-like condition. Light microscopy showed intraepithelial bullae formation. No EM studies were reported.

Epidermolysis bullosa associated with pyloric atresia has also been described. Autosomal recessive inheritance has been found (19,21, 36,42,83,84,91,102a). The gene has been mapped to 17q11–qter. Mutations in the a6 and b4 integrin chain genes have been reported (115,122, 130,141,150) (Fig. 13–130). These patients not uncommonly have erosions and/or subepithelial cleavage in the respiratory, gastrointestinal, and urinary tracts. Obstruction of the ureterovesical junction and a high incidence of a peculiar form of aplasia cutis congenita may also occur. Prenatal diagnosis has been accomplished microscopically (105). Direct first trimester molecular prenatal diagnosis of junctional epidermolysis bullosa with pyloric atresia has been reported (114,136).

Differential diagnosis. Recognition of EB is seldom difficult, even without assessing its entire clinical, genetic, and histologic character. In infants and children, the syndrome may be occasionally confused with conditions such as bullous impetigo (so-called pemphigus neonatorum), Ritter disease, porphyria congenita, congenital syphilis, or juvenile bullous dermatitis herpetiformis. In older patients, differential diagnosis includes pemphigus, drug eruptions, dermatitis herpetiformis, and bullous erythema multiforme.

It has been noted that in EB, pulling up a strip of cellophane adhesive tape will cause the top layers of the skin to adhere to the tape. The phenomenon is not seen in Ritter disease or in generalized impetigo. The lesions of porphyria are generally confined to chronically sun-exposed areas. Only the exposed skin is fragile; epidermolysis bullosa shows no localization of skin fragility.

The differential diagnosis should include *Kindler syndrome* characterized by bullae formation since birth on pressure areas that, on healing,

leave atrophic scars. In addition, affected individuals present severe photosensitivity and poikiloderma. The oral mucosae are atrophic and present multiple white macules (137).

Laboratory aids. Microscopically, the bullae are intraepidermal in the nonscarring forms, at the level of the epithelial dermal junction in the trophic forms and subepithelial or intradermal in the scarring forms. Unfortunately light microscopy is not useful in differentiating among the severe types of EB. Periodic acid-Schiff (PAS) stain is useful in subdividing the various types of EB according to the location of the basement membrane, but is unreliable because during the process of blister formation there will be retraction in the actual position of the basal membrane. The basal membrane remains attached to the dermis in EB simplex and junctional types, whereas it remains adherent to the epidermis in dystrophic types of EB.

Ultrastructural examinations are essential for an accurate diagnosis of EB types; neither regular light microscopy nor clinical presentation is sufficient or adequate for proper diagnosis.

Tonofilaments, which are the intercellular bindings of basal cells, have been shown to be defective in intraepidermal types of EB. Junctional types of EB are characterized by defects in anchoring filaments of hemidesmosomes, whereas primary or secondary destruction of the anchoring fibrils that extend from the basal lamina into the dermis are observed in the dermal types of EB (66).

Other pathogenetic mechanisms for certain types of EB include degradation of collagen through collagenase and gelatinase (131). Excessive secretion of collagenase by dystrophic fibroblasts from patients with simplex and dystrophic forms of EB has been reported (111).

Immunofluorescent mapping studies are used to differentiate among various types of EB by detecting the presence of four structural components within the skin basement membrane: bullous pemphigoid antigen, laminin, type IV collagen, and lamina densa antigen-1 (LDA-1). The diagnosis is made by identifying the location of these antigens and their relation to the level of cleavage in a freshly induced blister (50).

Prenatal diagnosis of the various types of EB is possible through fetoscopy with fetal skin sampling, electron microscopic studies (5), and immunofluorescent mapping (51). However, with recent advances in molecular diagnostics, the study of gene mutations after amniocentesis or CVS is the most reliable and safest method (28,46). Preimplantation diagnosis has also been accomplished (38).

At present, the definitive and precise diagnosis as well as the classification of epidermolysis bullosa are made on the basis of molecular studies of gene mutations (28).

Hyalinosis cutis et mucosae (lipoid proteinosis, Urbach-Wiethe syndrome)

The syndrome, consisting of yellow nodular infiltration of skin and mucous membranes and intracranial calcifications, was first described by Siebenmann (54) in 1908. Other cases were reported in the 1920s, but credit is given to Urbach and Wiethe (60,61,65), who defined the condition and applied the terms "lipoidosis cutis et mucosae" and "lipoid proteinosis" (37). The history of the syndrome has been reviewed by Laymon and Hill (37) and Gordon et al (20). Approximately 200 patients have been described.

The syndrome is transmitted as an autosomal recessive trait (20). It has appeared in sibs (16,25,32,52,55,58,61); in about 20% of cases there has been parental consanguinity (6,7,35,38), Many patients have been of Dutch or German ancestry. Almost a quarter of all reported cases of lipoid proteinosis have been in residents of South Africa. Stine and Smith (56) estimated the coefficient of selection for the lipoid proteinosis gene to be 0.07 in the Afrikaner population of South Africa. They suggested that this may be a pleiotropic gene that has a dominant effect in selection, even though the clinical manifestations follow a recessive pattern.

Skin and skin appendages. Discrete or confluent yellow-ivory nodules, from pinhead to matchhead in size, are found on the face, neck, axillas, and hands early in life. However, late onset is possible (25a). The perineum and scrotum have also been involved (20). Some patients develop bullous lesions of the face and upper extremities that have sometimes been described as impetigenous (13,20,34,52); on healing, these lesions leave hyperpigmented, pitted, atrophic patches (14,20,31) (Fig. 13–135). Brown-yellow, wart-like, hyperkeratotic lesions occur on the knees, elbows, and interarticular surfaces of the fingers (4,14,20,31,44, 45,46,53) (Fig. 13–136). With time, there is generalized skin thickening.

Diffuse or patchy alopecia of the scalp hair is common (6–8,21,23, 34,40,41,46,57,58).

Ophthalmologic abnormalities. Beadlike excrescences (moniliform blepharosis) are found on the upper and lower eyelid margins in almost all patients (30,31), followed in some cases by loss of cilia (23,37,46) (Fig. 13–136A). Fundus changes, consisting of sharp or poorly demarcated small, round, gray-white or yellow-white lesions were seen in 9 of 20 patients described by Heyl (26); in addition, vascular tortuosity was found. Finlay (14) described significant abnormalities in a 16-year-old legally blind patient who had visual problems since age 7. Other investigators noted drusenlike changes in patients as young as 23 and 34 years of age (49,51). On histologic examination, Marquardt (39) felt these lesions differed from classic drusen because they extended into the choriocapillaris. Histochemically they were identical to the skin lesions. Glaucoma was seen in several cases (18,39).

Central nervous system. Bilateral intracranial calcifications, found in at least 70%, have been located in the hypothalamus (41) and above the pituitary fossa in the hippocampus, falx cerebri, or temporal lobes (7,14,19–21,32,36,37,41,44,52,62,64,68); these abnormalities are more often seen in individuals over 10 years of age (20). Calcification has been localized to the head of the caudate nucleus, globus pallidus, and amygdaloid nucleus (44). Adolphs et al (1) suggested that the human amygdala may be indispensable to recognize fear and multiple emotions in facial expressions. Seizures have been reported (7,26,37,38,44) (Fig. 13–137). Emsley and Paster (11) reported two patients with long-standing memory impairment, paranoia, and bilateral temporal lobe calcification.

Larynx and other mucosal involvement. The voice in almost all patients is hoarse from birth (14,21,30,63), infancy (15,53), or from the first few years of life (13,28,53), and a low-pitched cry has been described (9,44); these findings testify to early laryngeal involvement (8). Laryngoscopic examination reveals yellow-white plaques on the epiglottis, aryepiglottic folds, and interarytenoid regions (9,13,20,30,46,47). The cords are thickened (9,53,68) and nodular (17,22,68). Extension of the infiltration to the tonsils and pharynx may result in severe dysphagia (14,44,48) and dyspnea, necessitating tracheostomy (5,20).

Other mucosal surfaces, such as the vulva, esophagus, stomach, and rectum, are also affected (7,20,21,27,61). Wartlike lesions have been found in the main bronchi (45).

Oral manifestations. Oral manifestations have been summarized (4,29). Oral mucous membranes are extensively infiltrated with yellow-white, elevated granules and pea-size plaques, which usually appear before puberty and gradually increase in severity (29). The lower lip is usually more severely affected than the upper, and has a cobblestone appearance (Fig. 13–138A). Radiating fissures may appear at the angles of the mouth (13,34,37) and on the lips (67) and tongue (21,30).

The tongue becomes firm or woody, thick, large, and restricted in mobility (1,3,5,34,40). The dorsum loses its papillae (13,30,35,44,51). There is usually marked infiltration of the lingual frenulum, which becomes inelastic (5). Ulcers may develop (6,114,21,26,63,66) (Fig. 13–138B–D).

With infiltration of the buccal mucosa, the opening of the parotid duct may become stenotic, with ensuing retrograde parotitis (4,6,26,27,34, 37,38,44,45,57). The soft palate and uvula may also be involved (55) (Fig. 13–138E). Affected individuals may not be able to open their mouths widely (20).

Specific dental abnormalities have not been documented. However, patients have been described as having lost their teeth at an early age (14), perhaps due to dental caries, resulting from obstruction of the orifices of major salivary gland ducts, as well as hyalinization of minor salivary glands. Gingival hyperplasia may be present, due to diffuse deposition of hyaline-like material (48).

Differential diagnosis. Conditions to be considered include amyloidosis, colloid milium adenoma sebaceum, *pseudoxanthoma elasticum*, and porphyria cutanea tarda.

Laboratory aids. Several investigators noted an increase in $\alpha 2$ and γ globulin levels and a diminution in the concentration of albumins (20,21,32), but these changes have been denied by others (37).

On light microscopic examination of the skin, there is hyalinization of the superficial connective tissue, beginning about the small and medium-sized blood vessels and sweat glands. Concentric laminar thickening of the stroma around these structures is noted (12). Hyalinization later extends more deeply (2) (Fig. 13–139). Biopsy of oral mucous membranes has also shown hyalinization, which may replace mucous gland acini (21,55). Histochemical study (21) has revealed the presence of carbohydrate but little or no lipids. The hyaline material stains intensely with the PAS procedure (53,59), thus appearing to be a glycoprotein, either free or loosely bound to collagen (16,27,53). Ultrastructural studies have been carried out on the hyaline material (10,25,36,42,50). Several authors (42,44) have suggested that it represents an altered collagen. Ishibashi (33), by electron microscopy, determined that the hyalinization was an accumulation of type IV collagen and laminin. Concentric layers of basal laminae are seen surrounding blood vessels in an onionskin arrangement (20,42,43). Fat has been demonstrated in fibroblasts (7).

On biochemical analysis, Harper et al (24) found reduced amounts of collagen in skin; however, the proportion of type III to type I collagen was elevated. In addition, the amount of type V collagen was five times normal. Immunologic studies showed a patchy, diffuse, widely distributed type III collagen, with increases in types IV and V collagen (26,45). An abnormal pattern of collagen cross-linkage was also found. Fleischmajer et al (17) concluded that the hyaline material originated from overproduction of noncollagenous proteins.

Results of studies of Bauer et al (2) suggested that the disorder was a lysosomal storage disease; cultured fibroblasts displayed a three- to four-fold increase in total hexuronic acid. Studies of cultured fibroblasts by Shore et al (53) found a lipid content similar in quantity and distribution to that of control cells.

B

Fig. 13–140. *Restrictive dermopathy.* (A,B) Fixed facies with hypertelorism, small nose, low-set dysmorphic pinna, small tight mouth, and micrognathia.

Restrictive dermopathy (late fetal epidermal dysplasia, type II)

Witt et al (28) and Toriello (22), in 1986, defined a lethal syndrome characterized by rigid, tightly adherent skin with generalized joint contractures, unusual facies, pulmonary hypoplasia, abnormally large placenta, short umbilical cord, and skeletal alterations. Toriello et al (23) reported two earlier examples in 1983, and Lowry et al (14) and Schnur et al (20) probably described the same condition. Approximately 20 additional examples have been reported (4,5,7–10,12,13,15–19,21,25–28).

Inheritance is autosomal recessive (9,14,16,22). There may be a Hutterite type and a non-Hutterite type (2,6).

Prematurity (about 32 weeks), polyhydramnios, and decreased fetal movement late in pregnancy, and short umbilical cord are common features. Intrauterine growth retardation is severe. Death is usually due to pulmonary hypoplasia (8,9,14,28).

The fixed facies manifests hypertelorism, with or without ectropion, small thin nose, apparently low-set anomalous pinnae, small tight open O-shaped mouth, and micrognathia. The temporomandibular joint is fixed. Submucous cleft palate has been described (23) (Figs. 13–140 and 13–141A). Choanal stenosis (14,27) and usually natal teeth (27) have been documented.

The chest is small and barrel shaped with increased AP diameter. Breast buds are prominent. There are dorsal kyphosis and rocker-bottom feet (Fig. 13–142). The lungs are hypoplastic. The internal organs are otherwise normal.

Additional findings in individual patients included blepharophimosis, skin tear in the frontal neck and inguinal area, absent eyelashes, a wide ascending aorta, and dextrocardia (22).

In some examples, the skin has a rigid, thick, smooth, and shiny shell-like structure, whereas in others there are extensive erosions (Fig. 13–141B). Histologic skin changes include orthokeratotic hyperkeratosis, hypoplastic pilosebaceous structures and sweat glands, absence of dermal rete ridges, and thin dermis with collagen bundles aligned parallel to the epidermis (22,28). Fetal hyperkeratinization of the skin is probably the primary defect (3,11). Electron microscopy of the epidermis exhibits lack of keratin filaments and abnormal globular shape of the keratohyalin granules (9). Fibroblasts display increased expression of the alpha-1 and alpha-2 subunits of integrin, which are responsible for collagen binding (5), a finding not supported in one study (22).

Radiologic changes include wide fontanels and sutures, and overtubulation of all long bones with modeling defects of the proximal humeri and distal radii and ulnae (Fig. 13–143) (19). There is deficient ossification of the distal or midportion of the clavicles and generalized fixed flexion contracture at all joints, including fingers and mandible. The ribs are sometimes thin and dysplastic. The scapulae are abnormally shaped and positioned (19). The prenatal sonographic findings have been described (24).

Setleis syndrome

Setleis syndrome is characterized by bitemporal scarring that resembles forceps marks, periorbital puffiness with wrinkling of facial skin, abnormalities of eyebrows and lashes, flat nasal bridge with bulbous nasal tip, and increased mobility of facial skin associated with severe redundancy of soft tissues (12,16,18). Nearly all patients have been from isolated towns in Puerto Rico. A few others have been of Basque, German, Italian, Japanese, and Arabic origin (1,2,4,5,13,14,20). Two sets of affected sibs and consanguinity indicate autosomal recessive inheritance (12). In 1992, Kowalski and Fenske (10) described two new patients and suggested that Setleis syndrome be classified as FFDD III (focal facial dermal dysplasia with additional features). They called FFDD II the autosomal recessive form of FFDD without additional features and referred to the autosomal dominant form as FFDD type I or Brauer syndrome. There has been some suggestion that the gene maps to 1p36.21 to 1p36.13 (19).

Craniofacial features. Features include "forceps marks" scarring bitemporally (rarely unitemporally), periorbital puffiness, eyebrows that angle sharply upward and outward but are deficient laterally, distichiasis of upper lids and astichiasis of lower lids (Fig. 13–144), flat nasal bridge, bulbous nasal tip, nasal septum extending below alae nasi, redundant skin and soft tissues, alopecia, thin scalp hair, low frontal hairline, and, in some instances, downslanting palpebral fissures (50%), epicanthic folds, chronic blepharitis, thick lips and cleft chin (6,12,16–18). Tsukahara et al (19) presented a follow-up on a previously reported patient and reported previously undescribed additional manifestations as an aberrant hair pattern and linear skin lesions on the forehead, short palpebral fissures, cone-shaped teeth, and pectus carinatum.

Other findings. Hypo- and hyperpigmentation of the skin have been recorded in 65% (7). Abnormal palmar creases have also been noted in 35% (12).

Differential diagnosis. A disorder known as focal facial dermal dysplasia has been documented with autosomal dominant inheritance (3,8,11,15). Real forceps marks, of course, are not accompanied by other features of Setleis syndrome. Ward and Moss (21) suggested that Setleis syndrome (FFDD III) and Brauer syndrome (FFDD I) are a single disorder. A similar opinion was also expressed by Kaplan et al (9). We agree.

Goeminne syndrome

Goeminne (1) described a family in which males had congenitally progressive muscular torticollis with facial asymmetry, multiple spontaneous keloids that appeared at puberty, cryptorchidism, chronic progressive pyelonephritis with hypertension, varicose veins of the legs, and multiple pigmented cutaneous nevi (Fig. 13–145). Female carriers were less severely affected. The literature on the familial occurrence of each component was extremely well reviewed by Goeminne (1). The gene has been mapped at Xq28, distal to the G6PD locus. It probably represents the most distal gene on the X chromosome (3). Sands (2) reported minor stigmata in a female with translocation involving this area of the X chromosome.

Fig. 13–145. *Goeminne syndrome*. Facial asymmetry, torticollis, numerous keloids of arms and thorax. (From L Goeminne, Acta Genet Med Gemellol (Roma) 17:439, 1968.)

Tongue atrophy, linear skin atrophy, scarring alopecia, and anonychia

The syndrome was independently described by Sequeiros and Sack (2) and Cohen et al (1) in 1985. The patients were isolated examples, the first being one of monozygous twins. All three were premature. Hence, it can be assumed that the condition is not a single gene disorder but may result from some form of intrauterine injury.

The condition is characterized by skin atrophy with linear alternation of depressed scarlike areas and intervening ridges of essentially normal skin. At birth the involved skin areas are friable, with a vesiculobullous eruption followed by gradual scabbing. Symmetrical reticulated scarring involves at least 75% of cutaneous surfaces. Scars on the trunk and head are cobblestonelike and, in some areas, are oriented along skin cleavage lines. On the limbs, the reticulated pattern follows the long axes of the extremities. The palms, soles, and face are not involved. Scarring alopecia and congenital absence of one or more toenails are evident. Abnormal sweating, heat intolerance, and febrile convulsions were seen in all three patients. A scarlike lesion of the dorsum of the tongue was found in two of the three (Fig. 13–146).

Histologically, all showed thickening of the dermis, increase in collagen density, or decrease in elastic fibers. The skin lesions look somewhat like those of *Bazex syndrome*.

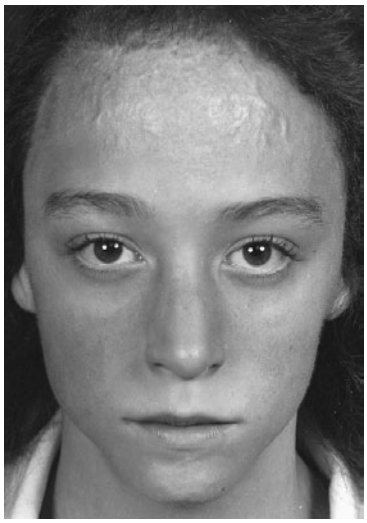
Keratitis-ichthyosis-deafness syndrome (KID syndrome)

Burns (6), in 1915, reported a syndrome characterized by congenital atypical ichthyosiform erythrokeratoderma, palmoplantar keratosis, and sensorineural hearing loss. At least 30 cases have been reported. Some have been well documented (1–3,5,8,9,15,18,19,22,24,26,32,33,38, 39,42,45,47–49) and others less well (6,11,16,20,28,35,46). Nearly all have been isolated, but examples have been noted in two generations (31). There is no sex predilection. Skinner et al (45) suggested the term KID syndrome as an acronym to refer to *K*eratitis, *I*chthyosis and *D*eafness.

Caceres-Rios et al (7) reviewed sixty-one patients from the literature. All had cutaneous and auditory abnormalities, and 95% also had ophthalmologic defects. The frequencies of clinical features were as follows: neurosensory deafness in 90%, erythrokeratoderma in 89%, vascularizing keratitis in 79%, alopecia in 79%, and reticulated hyperkeratosis of the palms and soles in 41%. Caceres-Rios et al (7) considered that the KID acronym does not accurately define this condition, since the disorder is



A

C

B

Fig. 13–146. *Tongue atrophy, linear skin atrophy, scarring alopecia, and anonychia*. (A) Note sparcity of hair and skin lesions over scalp and forehead. (B) Linear/reticular array of shiny, wrinkled, and pitted skin of forearm and dorsa of hands. (C) Similar lesions of lower legs. (A–C from J Sequeiros and GH Sack Jr, Am J Med Genet 21:669, 1985.)

not an ichthyosis (scaling is not the main cutaneous feature) and keratitis is not present in all patients early in the course of the disorder.

Extensive cutaneous mycoses have been described in these patients (17,43).

Postnatal growth deficiency has been evident in about 50% of the cases.

Skin. Congenital erythrokeratoderma principally involves the cheeks, nose, chin, ears, and limbs, especially the extensor and flexor surfaces of the elbows and joint areas of the knees, hands, and feet, and on the buttocks. Eyebrows, lashes, and scalp hair are scant. In some cases, scalp involvement results in partial or complete alopecia (Fig. 13–147A–C). The nails are frequently thickened and dystrophic. There is palmar and plantar hyperkeratosis characterized by a stippled or dotted pattern (26,40) (Fig. 13–147D). Microscopically, the skin changes most clearly resemble lamellar ichthyosis, the keratin layer having a basket weave pattern. A prominent granular layer is present. Recurrent bacterial and mycotic (especially candidal) infections of the skin are found in 40%. Cutaneous squamous cell carcinoma has been noted (13,25,42).

Ears. Hearing loss, found in nearly all patients, is sensorineural, usually bilateral, congenital, and often severe. The patient of Cram et al (8) had only mild hearing loss while one patient (28) had more severe conductive deafness.

Eyes. Severe bilateral vascularized keratitis, preceded by photophobia, appears in early childhood and not uncommonly is complicated by corneal ulceration, which leads eventually to at least partial blindness (Fig. 13–147E).

Nervous system. Intelligence is normal. Reflexes appear to be decreased, and often there are motor disturbances, especially fine motor. Tight heel cords, pes cavus, and contractures of the knees and elbows are seen in about half the patients (8,32,34,41,44). Wilson et al (50) presented evidence for a recessive form associated with progressive cirrhosis and mental retardation. Cerebellar hypoplasia has been documented (18,19).

Oral manifestations. Occasionally the oral mucosa is the site of generalized or linear leukokeratosis or, occasionally, furrowing. Squamous cell carcinoma of the tongue (1,22) and oral leukoplakia (13,26) have been reported. Perhaps proclivity to oral cancer reflects a complication of mucocutaneous candidosis (27).

Inheritance and genetics. Both dominant and recessive forms have been described (10,13,42,50). Langer et al (23) suggested spontaneous new mutation as the basis of the disorder. Kone-Paut et al (21) reported KID syndrome in two half siblings born to the same unaffected mother.

Differential diagnosis. Cases with overlap, but far less certain diagnosis, are those of Ruzicka et al (37) in which the patient had brachydactyly, clinodactyly, accessory cervical ribs, and carcinoma of the thyroid.

The patient with ichthyosis vulgaris, sensorineural hearing loss, pili torti, and tooth anomalies reported by Braun-Falco and Landthaler (4) must represent another entity. It may well be that the deafness is fortuitous. A syndrome of severe ichthyosis hystrix and sensorineural hearing loss reported by Gülzow and Anton-Lamprecht (14) may be related to the disorder reported by Morris et al (29) and Myers et al (30). Possibly, the patient reported by Freire-Maia et al (12) also belongs in this category. There is some overlap with *endocrine candidosis*.

The kindred described by Desmons et al (10) must have a different condition. They reported three sibs with congenital ichthyosiform erythrokeratoderma and profound congenital sensorineural hearing loss, but all had hepatomegaly. Autosomal recessive inheritance is likely in the kindred of Desmons et al (10).

Laboratory findings. Hyperimmunoglobulin E has been found by a few investigators (15,34). Absence of lymphocyte stimulation by Candida has been described (5,15).

Acrodermatitis enteropathica

This condition was first described in 1943 by Danbolt and Closs (1). It is characterized by cutaneous lesions of irregular plaques of vesicles and bullae, on an erythematous base. There may be satellite vesicles, bullae and pustules on the skin around the plaques. Typically, the lesions are at the mucocutaneous orifices and on the distal parts of the extremities (mouth, eyelids, knees, nails, anogenital areas) (Figs. 13–148 and 13–149). The nails usually have paronychia and dystrophic changes. Hair loss occurs early in the disease and involves the eyebrows, eyelashes, and scalp, resulting in alopecia totalis. Intractable diarrhea accompanies the skin changes (1,2,4). The inheritance is autosomal recessive.

Histologic examination of a bullous lesion shows acanthosis with large intraepidermal vesicles containing single and clumped acantholytic cells, neutrophils, and eosinophils (5).

Moynahan (6), in 1974, reported successful treatment with the oral administration of zinc sulfate. Since then, other reports (2,7) have confirmed the excellent results of continuous zinc sulfate therapy with resolution of the skin lesions, regrowth of hair, and arrest of the diarrhea.

Although the basic pathophysiology of the disease is still unclear, there is sufficient evidence to suspect that the defect is in zinc metabolism or absorption. In 1976, Evans and Johnson (3) suggested the absence of a low-molecular-weight zinc-binding factor as the possible cause of deficient zinc absorption. This factor is produced by the pancreas, binds dietary zinc, and transports it into the epithelial cells.

Atrichia, somatic and mental retardation, and skeletal anomalies

Schinzel (9) described a female patient with severe somatic and mental retardation, almost complete absence of body hair, ichthyosiform hyperkeratosis of the skin of the lower legs, nail dysplasia, small hands and feet with short fifth fingers and toes, and complete cutaneous syndactyly of toes 4 and 5 (Figs. 13–150 and 13–151).

Radiographic studies revealed fusion of several vertebral bodies, humeroradial ankylosis, fusion between talus and navicular, lunate and triquetral, proximal metacarpals 4 and 5, and hip dislocation (Fig. 13–152).

Pfeiffer and Volklein (6) and Mosavy (5) reported sibs with absence of body hair, short stature, microcephaly, and mental retardation. Del Castillo et al (2) described sibs with atrichia, mental retardation, and papular lesions (follicular cysts) of the skin. Similarly affected sibs were documented by Damste and Prakken (1) and Lowenthal and Praaken (4).

Atrichia, mental retardation, seizures, and hypergonadotrophic hypogonadism were reported in sibs by Richieri-Costa and Frota-Pessoa (8), Wessel et al (10), Pridmore et al (7), and Devriendt et al (3).

Barraquer-Simons partial lipodystrophy syndrome

The Barraquer-Simons lipodystrophy syndrome is a subtype of the partial lipodystrophies, the so-called cephalothoracic type (2,3,11). The patients gradually lose their subcutaneous fat in clearly demarcated, generally symmetric areas of the body over several years. Usually the face is affected first, with loss of retroorbital and periorbital tissue, resulting in the sinking of the eyes deeply into the sockets (Fig. 13–153). The buccal fat pads disappear. Loss of fat spreads caudally and stops mostly above or at

Fig. 13–150. *Atrichia, somatic and mental retardation, and skeletal anomalies*. (A,B) Microbrachycephaly, baldness, absence of eyebrows and lashes, large prominent nose, short philtrum, relatively large dysmorphic pinnae. (From A Schinzel, Helv Paediatr Acta 35:243, 1980.)

the middle of the thighs. This results in a relatively obese appearance of the unaffected parts of the body. Patients develop a progeroid appearance (5,10). Onset is usually prepubertal.

The histological examination of the lipodystrophic skin shows not only an absence of fatty tissue, but also abnormalities of the dermo-epidermal junction with hyaline bodies. Leukocytoclastic vasculitis of the dermal vessels has been noted (8).

In addition to the loss of fat and the clinical manifestations affecting the skin, abnormalities of other systems, in particular the renal and nervous systems, have been described (4,6,7,11). In a review of 25 patients (11), 14 had renal disorders and 10 had abnormalities of the central nervous system. Seven were mentally retarded, 1 had epilepsy, 2 showed an abnormal pneumoencephalogram, and 2 other cases had nerve deafness.

The disorder is rare and of unknown cause. Approximately 80% are females. While most cases were sporadic (1) and, in fact, discordant in identical twins, similarly affected relatives were reported in the families of four patients, suggesting autosomal dominant inheritance (9,11). Lipoatrophy of the face resembles the appearance in a variety of disorders such as *Cockayne syndrome, SHORT syndrome*, and *Berardinelli-Seip syndrome*.

There is decreased serum complement C3 being diminished in 70%. Decreased synthesis and increased catabolism have been alleged. The presence of C3 nephritic factor, an immunoglobulin that activates complement, has been found (4,12).

Bazex-Dupré-Christol syndrome

In 1964 and 1966, Bazex et al (1,2) described a complex genodermatosis with hypotrichosis and a generalized state of "atrophoderma." Patients develop basal cell carcinomas on the face between the ages of 15 and 25 years. "Pinched" nose with hypoplastic alae and a prominent columella may be another characteristic manifestation of the disorder (Fig. 13–154). Affected persons have lesions resembling "multiple ice-pick marks" on the dorsa of hands and elbows dating from early infancy (Fig. 13–155). These lesions are fairly specific to this syndrome because they are seen in only one other inherited condition, X-linked dominant chondrodysplasia punctata. However, the term "atrophoderma" is not appropriate, since histologic studies do not show atrophy (8).

On scanning electron microscopy, hairs have a twisted and flattened or smooth appearance (3) (Fig. 13–156).

Several reports of pedigrees describing the condition in many generations are suggestive of X-linked dominant inheritance (3–7,9–12).

Using microsatellite markers of the X chromosome in three families with Bazex-Dupré-Christol syndrome, Vabres et al (11) found evidence for assignment of the gene to the Xq24–q27 region.

Diagnosis of this syndrome is sometimes difficult. Multiple basal cell carcinomas also occur in *nevoid basal cell carcinoma syndrome*. However, pits of the palms and soles, as well as skeletal anomalies, are absent in the Bazex-Dupré-Christol syndrome.

Costello syndrome

Costello, in 1971 (7) and in 1977 (8), reported two unrelated children with mental retardation, short stature, curly hair, coarse facies, loose skin of the hands and feet, and nasal papillomata. These papers were essentially unrecognized until 1991, when Der Kaloustian et al (12) and Martin and Jones (29) reported additional patients and named the condition Costello syndrome. Since then, around 40 cases have been described (2,3,6–10,13–19,21,24,28,32,35–38,40,44,46–53). A debate still rages whether the facio-cutaneous-skeletal (FCS) syndrome is the same as Costello syndrome (3,4,11,12,29,35,45,53). Although affected sibs were reported (2,22,53), all other examples have been isolated (3,6–10,13–19,21,24,28,32,35,37,40,46–52). Consanguinity was found by Borochowitz (3) and Franceschini et al (16). We agree with Lurie (27), that Costello syndrome appears to have sporadic autosomal dominant mutations, the sib pairs representing gonadal mosaicism. Advanced paternal age has been demonstrated (22,27). A chromosomal translocation [46,XX,t(1;22)(q25;q11)] associated with this condition has been reported (10). Cultured fibroblasts from Costello syndrome patients do not assemble elastic fibers, a fundamental deficiency of elastin-binding protein (20a).

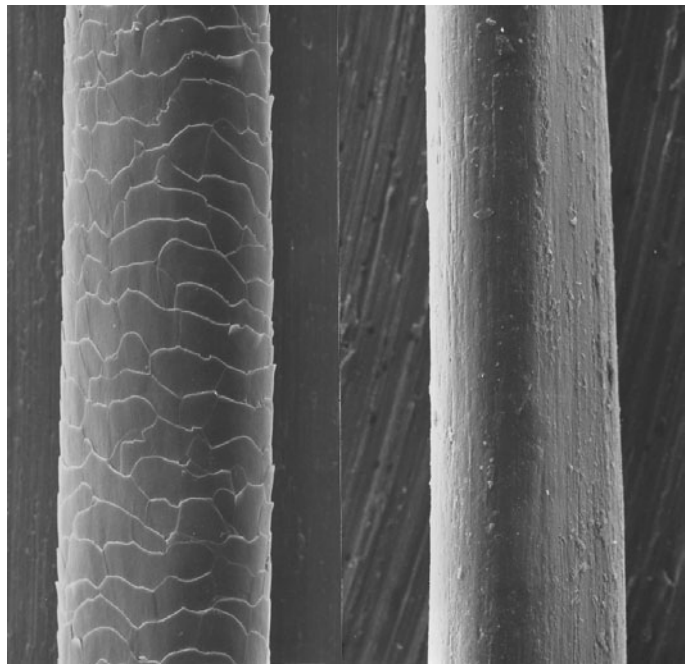
A

B

Fig. 13–155. *Bazex-Dupré-Christol syndrome*. (A,B) Note patch of follicular atrophoderma (ice pick marks) over lateral elbow. (From A Kidd et al, J Med Genet 33:493, 1996.)

Polyhydramnios is noted in 50% (18,22). Almost 90% are large for dates. Poor suck and poor growth postnatally are noted in 100% (24,28,46,48). Delivery by C-section is frequent.

Facies. There is relative macrocephaly in 100% with a somewhat hirsute forehead (Fig. 13–157). The hair is curly in 75% and the eyebrows are thick in 75%. The pinnae are usually low-set (65%) and posteriorly angulated, with large lobes in 45%. Depressed nasal bridge (75%), bulbous nose, epicanthic folds, thick lips (80%), and strabismus (65%) are common and combine to give a coarse facies in 100%. The mouth appears wide in 90%. The tongue is large in 80%. Papillomata appear progressively from 2 to 15 years in the nostrils, on the face, and around the mouth (17) and are usually not present in the newborn (52). The voice may be hoarse in some cases due to papillomata of the vocal cords (40,47,53). The neck appears short in at least 60%. Fryns et al noted blue sclerae (17) (Fig. 13–157A).



A B

Fig. 13–156. *Bazex-Dupré-Christol syndrome*. (A,B) Scanning electron micrograph of (A) normal hair and (B) hair from a patient showing complete absence of cuticular scales. (From A Kidd et al, J Med Genet 33:493, 1996.)

Skin and appendages. The skin, especially of the neck, hands, and feet, is thickened, loose, and velvety in feel in 100% (Fig. 13–158). The skin color is darker than normal in 20% and acanthosis nigricans is seen in about 30% (12,14,16,22,29,32,46,47). Deep creases become evident on the palms and soles in at least 60%. Pigmented nevi may present on the soles (45). Mori et al (30) described elastic fiber degeneration. The skin over the digital pulps is loose, like that of one whose hands have been in water overly long, in 100% of the patients. With age, palmar and plantar hyperkeratoses are noted. The nails are thin, deeply set (25), and hyperconvex in 40% (28). The nails are dysplastic in 60%.

Papillomata are found, with age, not only in the nose but over the joints, extremities, periorally, or perianally (13). Pigmented nevi appear to be increased (11).

Intelligence. IQs have ranged from 50 to 80. Most patients have a pleasant, happy outgoing nature (28,46).

Musculoskeletal. Increased A-P diameter of chest (55%), tight Achilles tendons (55%), inguinal hernias (60%), and hyperextensible metacarpophalangeal and interphalangeal joints (80%) with ulnar deviation, wide phalanges, talipes, increased carrying angle with decreased range of motion at the elbow (9), kyphoscoliosis, large or late-closing anterior fontanel (35%), and osteoporotic long bones have been found. Bone age is delayed.

A B

Fig. 13–157. *Costello syndrome*. (A) General view of the body. (B) Note coarse appearance of face and perioral papillomata. (From VM Der Kaloustian et al, Am J Med Genet 41:69, 1991.)

Cardiovascular. Hypertrophic cardiomyopathy (2,11,19,22,35,53), mitral value prolapse (28), VSD, ASD, and pulmonic stenosis have been described in over 50% (3,4). Arrhythmias such as atrial ectopic tachycardia, supraventricular tachycardia, and atrial fibrillation have been reported in about 60% (41,50).

Urogenital. Cryptorchidism has been noted in 10% (16).

Miscellaneous. Ganglioneuroblastoma, acoustic neuroma, epitheliomata, bladder carcinoma, and embryonal rhabdomyosarcoma have been found (2a,15,16,19a,23,29,30a,35,40a,53). Hypothyroidism, late puberty, and growth hormone deficiency have been documented.

Laboratory findings. Sialuria has been reported in two unrelated patients (14). C Anichini (personal communication, 1997) also found sialuria. Moreover, high IgM level was detected during the early infantile period of another patient (32).

In a Japanese patient who died of rhabdomyolysis at the age of 6 months, the major pathological findings were fine, disrupted, and loosely constructed elastic fibers in the skin, tongue, pharynx, larynx, and upper esophagus, but not in the bronchi, alveoli, aorta, or coronary arteries (30). The degeneration of elastic fibers was confirmed in a second patient with Costello syndrome. Expression of elastin mRNA in the patient's fibroblasts was normal. Since elastic fiber degeneration was observed, it is speculated that a defect in elastin microfibrils might be responsible for the pathogenesis of Costello syndrome (30). Loss of anastomosing points in elastic tissue has been demonstrated (50). Hyperplasia of collagen fibers in the skin, hyperplasia of the mucous glands in the bronchus, narrowing of the pulmonary artery, degeneration of the atrial conduction system, calcification and ballooning of skeletal muscle fibers with infiltration of macrophages, and myoglobin deposition in the collecting ducts of the kidney were also observed (30).

Differential diagnosis. Various congenital *cutis laxa syndromes, Noonan syndrome*, and *cardio-facio-cutaneous syndrome* share some findings (5,9,13,20,26,31,33,34,42,43), as do *Weaver syndrome* and *Donohue syndrome (leprechaunism). SCARF syndrome (skeletal abnormalities, cutis laxa, craniosynostosis, psychomotor retardation, and facial abnormalities)* (25) needs to be considered. All patients with cutis laxa–macrocephaly–short stature–delayed psychomotor development should also be investigated (1,39).

Macrocephaly, cutis marmorata telangiectatica congenita, and syndactyly (Van Lohuizen syndrome)

Although the term "cutis marmorata telangiectatica congenita" was coined by Van Lohuizen (32), the condition has been known by a plethora of names (12). In 1974, Way et al (34) reviewed 41 examples of congenital telangiectatic cutis marmorata and Pehr and Moroz (22), in 1993, described 126 affected. The former noted 50% to have associated anomalies, the latter 68%. Moore et al (18), in 1997, reporting 13 unrelated children, formally defined the syndrome of abnormalities of somatic growth, abnormal facies, abnormalities of the brain, and congenitally mottled skin. Clayton-Smith et al (3), in 1997, presented 9 affected children. Many additional examples have been described (1,2,4,5,7b,11–33). All cases have been sporadic (12).

The infants are large at birth, mean weight being +2 SD. However, with age, the weight and height centiles decrease, in some cases falling below the 3rd centile by age 4 years (29). Fetal hydrops has been noted in a few cases (3).

Craniofacial anomalies. Macrocephaly (+4 SD, at birth and increasing with age even with shunting), squared frontal bossing, increasing dolichocephaly, high forehead, deep-set eyes, full cheeks and facial and/or cranial asymmetry (including cerebral ventricles), and philtral/nasal/upper labial nevus flammeus are common features (3,25) (Fig. 13–159). Cleft palate has also been described (13).

Eyes. There have been reports of glaucoma, usually associated with nevus flammeus (15,22,24). Retinal detachment (23) has also been noted.

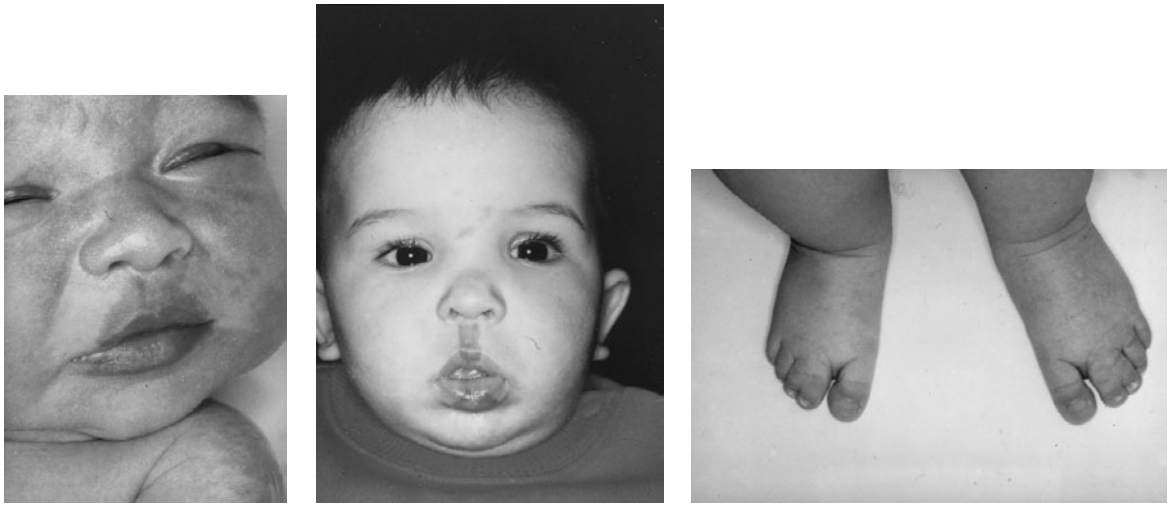
Skin. Congenitally mottled skin is due to prominent capillaries and veins. Intermixed are telangiectasias, capillary and cavernous hemangiomas, nevus flammeus, and varicose veins (4) (Fig. 13–160). It may, however, be absent (7a). Nevus flammeus of the nose and/or philtrum and upper lip is frequent (Fig. 13–159A,B). The cutis marmorata may fade with age, but it may persist (25). It is exaggerated with crying. Dilated veins of the head, neck, and trunk, even to the degree of venous aneurysms, are seen (25). After 1 year of age, capillary angiomas of the scalp may be noted.

The skin is loose, stretchable, and velvety to the feel. Less often, the joints are hyperextensible, and hernias are more common than normal. Doughy subcutaneous tissues are a constant feature. Aplasia cutis congenita associated with Adams-Oliver syndrome has also been described (7,30).

Extremities. The shoulder girdle is narrow due to poor musculature. An almost constant feature is mild body or limb asymmetry, especially of the lower limbs. Girth differences are more marked than differences of length (6,11)

Terminal transverse limb defects as part of Adams-Oliver syndrome, as noted above, have been reported in association with cutis marmorata telangiectatica congenita (7,30). Variable syndactyly of toes 2–4 is an almost constant feature (3,10) (Fig. 13–159C). Toes 1–2 are widely spaced. The fingers, less often than toes, may exhibit 3–4 syndactyly. Postaxial polydactyly has been noted in perhaps 30% (3).

Central nervous system. Congenital hypotonia (76%), which normally resolves within 12 months, megalencephaly, and hydrocephalus (85%) are described. Developmental delay has been noted in probably



A B C

Fig. 13–159. *Macrocephaly, cutis marmorata, telangiectatica congenita, and syndactyly* (*Van Lohuizen syndrome*). (A,B) Note philtral superficial angioma. (C) Syndactyly 2–3 of toes. (From J Clayton-Smith et al, Clin Dysmorphol 6:291, 1997.)

90% (3,18,29,31). The megalencephaly is accompanied by MRI findings of CNS dysgenesis with protrusion of the cerebellar tonsils through the foramen magnum (Chiari I), lumbar syrinx, and hydrops of optic nerves (1a).

Fig. 13–160. *Macrocephaly, cutis marmorata, telangiectatica congenita, and syndactyly* (*Van Lohuizen syndrome*). Note severe cutis marmorata. (Courtesy of B Moroz, Montreal, Canada.)

Other findings. Vascular anomalies with hypoplasia of the right iliac and femoral veins (19), as well as double aortic arch (21) have also been described in this condition. One patient was reported with congenital hypothyroidism (22).

Diagnosis. One must exclude a plethora of macrocephalic conditions (8). Several patients with congenital hemihyperplasia clearly have the syndrome (26,27,33). Halal and Silver (10) reported a father and son with cutis marmorata telangiectatica congenita, joint hypermobility, and hemangiolipomas. Perhaps this was an example of *Ruvalcaba-Myhre-Smith syndrome*. *Klippel-Trenaunay-Weber syndrome* and *Sturge-Weber syndrome* must also be excluded. Excellent discussions of differential diagnosis are those of Cohen and Zalar (4) and Powell and Su (25). The patient reported by Meyer (17) merely has a variant of Van Lohuizen syndrome.

Cutis verticis gyrata

Cutis verticis gyrata, described by McDowell (20) in 1893, is characterized by folds or furrows in the scalp that resemble the convolutions of the cerebrum (34). Unna (35) coined the term in 1907. There is no underlying skull defect. Associated findings include microcephaly, chronic seizures, mental retardation and spastic tetraplegia (9,26,28). The syndrome is seen in about 1 in 100,000 males and 2.6 in 10,000,000 females (2,3). In institutionalized males, the prevalence is about 0.2%–4% (2,32). Etiology is diverse (3) (vide infra). An excellent review of the early literature is that of Polan and Butterworth (29).

The folds may be present at birth (primary) or appear later in life (secondary) (Fig. 13–161). Among numerous reports, about 50% are concerned with each type. Those with mental retardation and/or other central nervous system anomalies generally appear to develop the skin folds after puberty (4,19).

The furrows are usually longitudinal, but a few may be transverse. They are usually at the vertex but may be located at other sites on the scalp (14). Cortical and subcortical atrophy with ventricular dilatation has been reported (21), with polymicrogyria in others (34). There is also an increased frequency of eye abnormalities: strabismus, nystagmus, cataract, keratoconus (2).

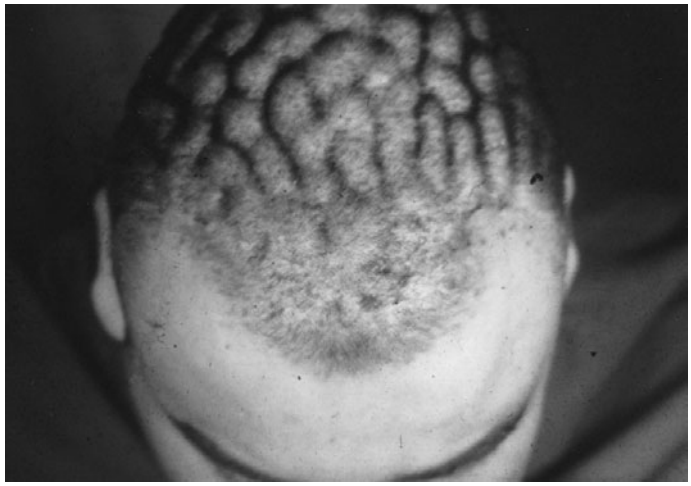

Fig. 13–161. *Cutis verticis gyrata*. Extreme example.

Endocrinological disorders have included hypergonadotrophic hypogonadism, but other studies have not shown significant changes (25).

Fragile sites have been reported by some authors (21,32) and denied by others (7). We suspect that they are aleatory.

The cutaneous anomaly may be an isolated finding (primary essential) (8,11,22) or secondary to chronic skin disorders or infiltration of the skin with tumor or leukemic cells, amyloid, nevi, fibromas, or neurofibromas (5,6,10,12,13,18,24,27). Melanoma has been reported to occur in those with nevus cell nevi (12). The skin lesions may also be seen in *pachydermoperiostosis*. Other conditions having cutis verticis gyrata are acromegaloid changes and corneal leukoma inherited as a dominant disorder (31) and thyroid aplasia and mental retardation with possible X-linked inheritance (1). It may also be seen in acromegaly (10,23), with *Turner syndrome* (17,30), and with *Noonan syndrome* (16), presumably resulting from lymphangiectasia in the latter two conditions. Cerebriform intradermal nevus must be excluded (15). A recessive syndrome involving retinitis pigmentosa, cataracts, and deafness has been reported (20a).

Facial hemangiomas, sternal nonunion, supraumbilical midline raphé, vascular anomalies, and Dandy-Walker malformation (PHACES)

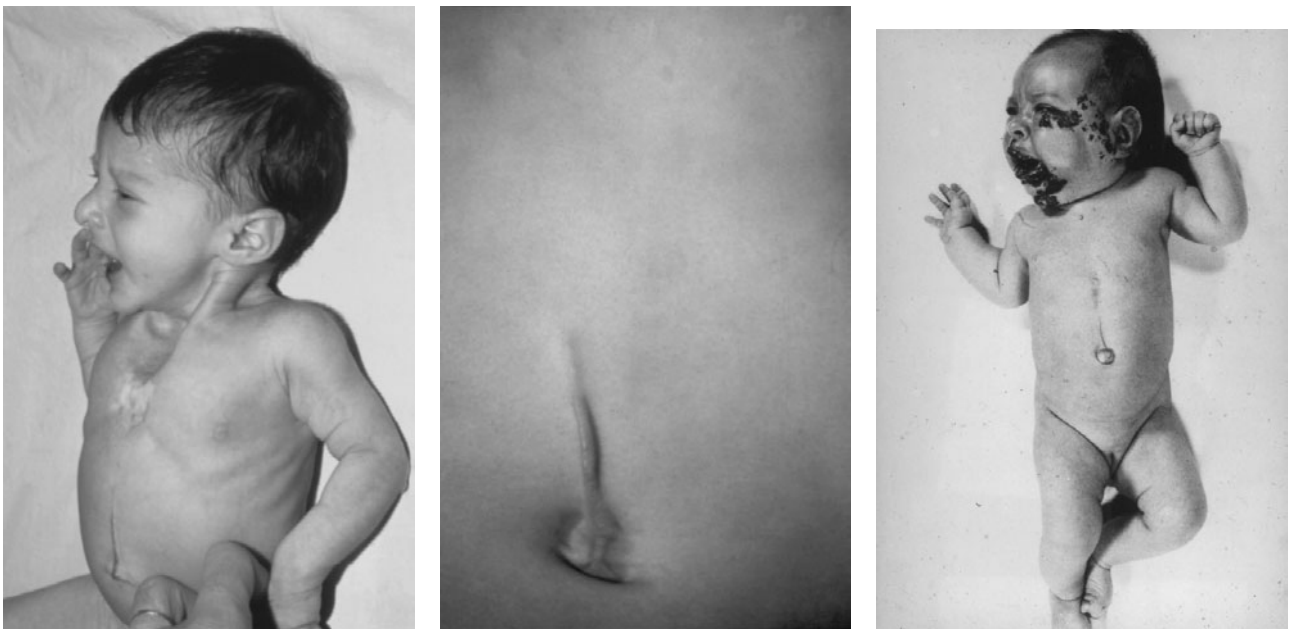
Leiber (18) and a host of earlier investigators noted the syndrome in binary, tertiary, or quaternary form in various combinations. These have been documented by Gorlin et al (11). Frieden et al (7) suggested use of the term PHACES syndrome for *P*osterior fossa CNS anomalies, *H*emangioma, *A*rterial anomalies, *C*oarctation of the aorta and *C*ardiac anomalies, *E*ye anomalies, and *S*ternal defects.

There is no reason to believe that the syndrome has a genetic basis. Haque (13) noted facial hemangioma and nonunion of the sternum in a male born to consanguineous parents. A sister had only non-union of the sternum. We have seen sisters with nonunion of the sternum and teardrop-shaped umbilicus in the first and facial hemangiomas in the second.

The marked female predilection demonstrated by Gorlin et al (11) for the *triad* of facial hemangiomas with non-union of the sternum and supraumbilical raphé (20F:1M) contrasts sharply with the 1:1 sex ratio for the *binary* combination of sternal non-union and supraumbilical raphé. However, the skewed sex ratio appears not to hold if other vascular anomalies are added (Fig. 13–162).

Sternal non-union. Sternal defects (cleft sternum, bifid sternum) is classified as superior, inferior, or complete and really represents embryonal non-union. Inferior sternal clefts are very rare and usually associated with other abnormalities of midline fusion (pentalogy of Cantrell). In this syndrome, the anomaly ranges from a notch in the upper manubrium to complete separation of the sternal bars, resulting in what appears clinically to be sternal agenesis (Fig. 13–162A). Depending on the degree of nonunion of the sternal bands, during respiration and crying, there is sinking and bellowing of the upper chest into and out of the concavity. The pulsations of the heart and aorta are evident in the same space. The clavicles and nipples are widely separated.

Fig. 13–162. *Facial hemangiomas, sternal nonunion, supraumbilical midline raphé, vascular anomalies, and Dandy-Walker malformation* (*PHACES*). (A) Note suprasternal repaired defect and supraumbilical raphé. (B) Supraumbilical raphé. (C) Facial angiomata and supraumbilical raphé.



A B C

Supraumbilical raphé. The cutaneous raphé, often resembling a well-healed scar, extends upward from the umbilicus by several centimeters, but fails to reach the sternal defect (Fig. 13–162B). Embryologically, supraumbilical midline fusion occurs later than infraumbilical midline fusion (2). During the 8th week in utero, the mesoderm reaches and fuses in the midline, supporting the overlying ectodermal epithelium. Absence of this supporting mesoderm results in necrosis of the overlying epithelium (21). We have seen a few patients with aplasia of skin of the upper sternal area. Zullino (34) has also noted this finding.

Hemangiomas. Hemangiomas may be present at birth, but far more often appear during the first few weeks or months of life (Fig. 13–162C). They usually are small tumors, most commonly located on the face (forehead, cheeks, lips, chin, ear, and preauricular area), only rarely manifesting below the shoulder. Occasionally, hemangiomata have been reported to involve the larynx and trachea. Subglottic, lingual, and gingival lesions have been noted (3). These have been extensively cited by Gorlin et al (11). Hersh et al (14) described small bowel and pancreatic involvement.

Vascular anomalies. Right aortic arch arises from persistence of the right dorsal aorta, a remnant of the six pairs of aortic arches that are formed during the late 4th and 5th weeks of fetal life. If there is no double arch, then there has to be involution of part of the left dorsal aorta. With mirror-image branching, the segment of the left dorsal aorta distal to the left 7th intersegmental artery involutes, but when the left subclavian artery arises aberrantly, the left 4th arch has involuted and the left distal dorsal aorta persists. Pascual-Castroviejo (22,23), utilizing carotid angiography to examine the vertebral basilar system of children with facio-cutanous vascular lesions, proposed two groups of patients. The first group had unilateral facial hemangioma; various intracranial and extracranial arterial anomalies, the most striking being the absence of the ipsilateral carotid arteries and persistence of intracranial or extracranial embryonal arteries; anomalies of the aortic arch; and hypoplasia of the cerebellum, ranging from unilateral partial deficit to severe hypogenesis associated with Dandy-Walker malformation. Pascual-Castroviejo further suggested that the more marked the severity and extent of the hemangioma, the more extensive the intracranial vascular anomalies. Three of 7 patients he described had congenital heart malformations. The second group had unilateral facial hemangioma extending to involve the parotid, orbital, lingual, and maxillonasal areas, the blood flow being across several branches of the external carotid artery. The internal carotid artery exhibits dilatation from its origin to at least the zone of the carotid siphon. In some cases, the aneurysmal dilatation extends from its origin to its terminus, producing a mega-arterial system ipsilateral to the facial hemangioma (22,26,28). Bilateral facial hemangioma is paralleled by intracranial vascular involvement, more often in the zone of the carotid siphon and the Circle of Willis. A female predilection was found in both groups of anomalies. Gorlin et al (11), however, did not support the separation into the two divisions proposed by Pascual-Castroviejo (22,23) because there was overlap of the two groups mentioned above with the syndrome of defective sternal union, supraumbilical raphé and facial hemangioma. Rizzo et al (28) described a boy with supraumbilical raphé, hypoplasia of the right shoulder girdle, short right humerus, radius, and ulna; right camptodactyly; and short sternum. The right subclavian artery terminated just distal to the origin of the internal mammary artery. Geller et al (8) reported a male with supraumbilical raphé and sternal non-union. Hemangiomas involved not only the face but the limbs, groin, trunk, and soles. There was also macrocephaly, unilateral microphthalmia, absent corpus callosum, hydrocephalus, and various cardiac anomalies (hypoplastic right ventricle, pulmonary stenosis, ventricular septal defect, patent ductus arteriosus, and right aortic arch). The female patient (Case 8) of Reese et al (27) exhibited sternal non-union, midline abdominal raphé, facial and ipsilateral hemangioma of upper limb and trunk, contralateral optic nerve hypoplasia, aortic arch dilatation, coarctation of descending aorta, aberrant subclavian artery, and hypoplastic contralateral ear. They further described seven female patients with facial hemangiomas (some involving the upper trunk), some with ipsilateral microphthalmus, and most with Dandy-Walker or other posterior fossa abnormalities. Pasic (24) described a female with hemangiomas of the brain, face, and neck associated with sternal non-union, supraumbilical raphé, aneurysm of the aortic arch involving the innominate artery and left carotid artery, anomalous origin of the coronary arteries, left superior vena cava, micrognathia, and cervical cyst. Gorlin (personal communication, 1994) saw a child with extensive hemangioma of the face, neck, and back with a double aortic arch, double aortic coarctation, single carotid artery, and stridor due to unknown cause. Schneeweiss et al (31) described two male and two female patients with facial hemangioma and coarctation of the aorta. Three had congenital aneurysm of a subclavian or innominate artery; the other had mitral insufficiency. Valvular aortic stenosis was present. Schieken et al (30) described the association of facial hemangiomas, aneurysm of the ascending aorta, and occlusion of the right innominate artery and tricuspid aortic valve in a female with superior sternal cleft. Góh and Lo (9) reported 2 female patients with facial hemangioma, cerebellar hypoplasia, and coarctation of the aortic arch. Mizuno et al (20) noted a 5-year-old girl with facial hemangioma, ipsilateral optic atrophy, ipsilateral cerebellar hypoplasia, internal carotid arterial stenosis, basilar artery occlusion, and saccular aneurysm of the left carotid siphon. No mention was made of sternal abnormalities or of supraumbilical raphé.

Vaillant et al (33) reported a male infant with facial, lingual, shoulder, and laryngeal angiomas. Right aortic arch with coarctation was found. The left and right common carotid arteries and left subclavian artery arose successfully from the aortic arch. Honey et al (16) reported a male infant with multiple hemangiomas of the face, right aortic arch, coarctation of aorta, and ventricular septal defect.

Kishnani et al (17) reported a female infant with hemangioma, supraumbilical midline raphé, and coarctation of aorta with a right aortic arch. The hemangiomas involved the gingiva and tongue as well as the face. Similar examples are noted by Crisponi et al (5a).

Enroljas and Gelbert (6), in their survey of 175 cases of superficial hemangiomas, noted (a) aortic arch interruption and laryngeal hemangioma, (b) coarctation of the aorta, (c) intracranial arterial anomalies, (d) imperforate anus, (e) microphthalmia, and (f) Dandy-Walker anomaly and/or cerebellar hypoplasia. All were female infants.

Dandy-Walker malformation. Dandy-Walker malformation has been seen in combination with facial hemangiomas and mental retardation by a number of authors (6,9,12,14,15,28,29,31). Hall and Gilmore (12) described female twins of unknown zygosity born to consanguineous parents. One twin had Dandy-Walker malformation at autopsy at 5 1/2 months. The other twin had facial hemangioma and Dandy-Walker malformation, seizures, and mental retardation.

Patel and Gupta (25) described an infant female with facial hemangiomas, Dandy-Walker malformation, and retroorbital and parasagittal venous malformations. Matsue et al (19) reported cerebellar hypoplasia and vascular abnormalities.

Sacral hemangiomas have been associated with imperforate anus and bony abnormalities of the sacrum as well as lipomeningomyelocele and skin tags (10).

Diagnosis. About 10%–12% of children develop hemangiomas and 70%–90% of these are noted by age 1 month. Classical hemangiomas have a significant 3–7F:1M predilection (6). Hemangiomas and vascular malformations are discussed extensively on pp. 577–578 and by Burns et al (4). Hemangiomas of the overlying skin may be seen with underlying spinal dysraphism, lipomeningocele, and tethered cord syndrome (21).

Hyperkeratosis palmoplantaris striata, pili torti, hypohidrosis, oligodontia, and sensorineural hearing loss

Egelund and Frentz (2), in 1982, reported 14-year-old female with lusterless coarse terminal scalp hair, sparse eyebrows and lashes, hyperkeratosis of palms and soles, generalized hypohidrosis (except for palms) oligodontia, and moderate nonprogressive midfrequency sensorineural hearing loss.

Braun-Falco and Landthaler (1) described an 18-year-old female with ichthyosis vulgaris, pili torti, hypodontia, and sensorineural hearing loss. Both parents had hearing loss but none of the other stigmata.

Pili torti, usually occurring as an isolated finding, has been described in an autosomal dominant pattern with absence of lower premolar teeth (3). In looking at the pedigree, we cannot say whether the two traits were independently inherited.

Palmoplantar hypokeratosis, hypotrichosis, hypodontia, enamel and dentin dysplasia, cleft palate, strabismus, and cryptorchidism

Šalamon et al (1) described an apparently unique young male with desquamative, erosive lesions of the palms and soles that appeared at age 5. Sweating was reduced. The teeth had defective enamel and dentin, and there was a deficient number of teeth. In addition to cleft palate, strabismus and cryptorchidism were found.

Congenital hypertrichosis universalis (Ambras syndrome)

Congenital hypertrichosis universalis with unusually excessive deposits of hair on the face, ears, and shoulders has been reported since the Middle Ages. Over 150 affected individuals have been described, variously characterized as "hair man," "dog men," and "human werewolves" (4–6,14,15). It has been called "Ambras syndrome" (2).

Approximately 10 cases have been reported in the literature. The entire body is covered with fine, long hair except in areas where no hair normally grows: palms, soles, dorsal terminal phalanges, and mucosa. The forehead, eyelids, nose, cheeks, and preauricular region are uniformly covered with hair, which often reaches an enormous length if not shaved. The hair is light-colored, silky or golden. Only the scalp hair, eyebrows, eyelashes, and axillary hair are darker. Long curls protrude from the external auditory canal, and often the eyelashes are long. The generalized hypertrichosis is usually present at birth (3,10,12) (Fig. 13–163).

The face is triangular and coarse with marked intercanthal distances. Broad palpebral fissures, long prominent nasal bridge with a rounded

A B C

Fig. 13–163. *Congenital hypertrichosis universalis* (*Ambras syndrome*). (A) Three-week-old with extensive hirsutism. Notice that hands and feet are not involved. (B) Three-year-old. (C) Four-day-old with similar involvement. (From FAM Baumeister et al, Clin Genet 44:121, 1993.)

tip, broad interalar distance, anteverted nares, short lower lip, and a flat sulcus mentolabialis (3,10). Both dentitions are retarded in eruption. The upper molars and premolars are very often absent (3,12).

In Ambras syndrome, the follicles of the body hair extend into the subcutis. The hair is pigmented and medullary (1), being of the vellus type.

The Ambras syndrome differs from other congenital hypertrichoses in the pattern of hair distribution and associated anomalies. In the other syndromes, the facial hair is accentuated in the frontal, temporal, and preauricular regions. The eyebrows are bushy and sometimes confluent. The external ears are seldom hairy and never to such an extent as in the Ambras syndrome. On the back, the hair streams from the sides, converges at the midline, and often forms a whorl over the spine, resembling that found in familial or racial hypertrichosis. Congenital hypertrichosis lanuginosa has a different hair growth pattern at birth. The entire body is covered homogeneously with fine blond hair except for the hands and feet (8,9,13). During the first year of life, hair shedding begins over the trunk, progressing to the arms and legs. The face is glabrous. An incisor has been present at birth, and there have been supernumerary teeth (13). Glaucoma has been noted in another child (9).

Autosomal dominant inheritance has been demonstrated (10). X-linked dominant inheritance was also suggested (10), and the gene has been mapped to Xq24–q27.1 (7). There has been an association with pericentric inversion (8)(p11.2;q22) (1,2).

Congenital ichthyosis, follicular atrophoderma, hypotrichosis, and hypohidrosis

In 1998, Lestringant et al (2) reported on five Bedouin sibs (three girls and two boys) with diffuse congenital ichthyosis, patchy follicular atrophoderma, generalized and diffuse nonscarring hypotrichosis, and marked hypohidrosis. The parents were first cousins.

In the five patients studied, ichthyosis was congenital, non-erythrodermic, involved the great flexures, and family history was typical of autosomal recessive inheritance (2).

Electron microscopic studies failed to demonstrate the typical structures of classical autosomal recessive lamellar ichthyosis, such as lipid vacuoles, elongated membrane structures, and abnormal vesicular keratosomes. Steroid sulfatase activity was normal.

The patients were reminiscent of *Bazex syndrome* (1,3,4). However, ichthyosis is not a component of that disorder (2).

Ichthyosis follicularis, atrichia, and photophobia (IFAP) syndrome

The syndrome of ichthyosis follicularis, alopecia, and photophobia (IFAP) was first recognized by MacLeod (6) in 1909 in three brothers (11). Since then, only 11 male patients have been reported from 9 families (1–3,5–7,13). In one family, two maternal uncles were probably also affected (7).

The skin shows ichthyosiform hyperkeratosis, ichthyosis follicularis, and lack of sebaceous glands. Alopecia is noted in all the patients. Dystrophic nails may be present in some.

The ears may be large and dysplastic. Enamel hypoplasia may be present. Photophobia may also be observed.

Findings that are often present include growth and psychomotor retardation, chill-like seizures accompanied by fever, a tendency to infection, and skeletal abnormalities (5).

In one patient, olivocerebellar atrophy, a peculiar malformation of the temporal lobes, and mild inner cerebral atrophy were noted (5). These findings may, in part, explain the neurological symptoms of IFAP syndrome patients.

Although the genetic basis of IFAP syndrome is unclear, X-linked inheritance is probable because all reported patients are males. An association between X-linked ichthyosis and microdeletions or a contiguous gene defect in the chromosome regions Xp22.3–p22.2 and Xq28 has been suggested (4,8,11).

In differential diagnosis, a very similar syndrome must be taken into account. It was reported in two daughters of a man who presented with alopecia and follicular keratosis from early childhood, thus suggesting autosomal dominant inheritance (9). This disease shares, with IFAP syndrome, keratosis follicularis including the scalp, trunk and extensor aspects of the arms and legs, and noncicatricial alopecia. Other defects such as scaling between the hair follicles, and true ichthyosis are absent. Two other cases reported by van Gelderen (12) and Schinzel (10) also share abnormalities with IFAP syndrome but can be distinguished by the absence of ichthyosis follicularis (12) and photophobia (10,12).

Johnson-McMillan syndrome

Johnson et al (2), in 1983, reported a large family with autosomal dominant alopecia, hyposmia or anosmia, conductive hearing loss, microtia, and hypogonadism (Fig. 13–164). Another case was added by Johnston et al (3) in 1987. Still another example in a mother and son was described by Hennekam and Holtus (1). Both mother and son exhibited facial nerve palsy, multiple truncal café-au-lait spots, and mild developmental delay. The mother also had hyposmia and growth retardation, while the son exhibited hypotrichosis, conductive hearing loss, and microtia.

Laryngo-onycho-cutaneous syndrome (LOGIC syndrome)

In 1986, Shabbir et al (5) reported 22 patients they designated *laryngo-onychocutaneous syndrome*. Ainsworth et al (1,2), and Phillips et al (4), and Bedlow et al (3) added examples. Ainsworth et al (1,2) suggested the acronym *LOGIC* to indicate the following salient features: *L*aryngeal and *O*cular *G*ranulomatosis *I*n *C*hildren from the Indian subcontinent.

In most cases, death occurs during childhood.

Dermal and submucosal granulomas produce skin lumps and weak hoarse cry and voice due to laryngeal involvement. The submucosal tissues are massively inflamed, and the philtrum breaks down. The conjunctival, oral, tracheal, and esophageal mucosae are also involved. Within the first few months of life, skin ulceration, conjunctival scarring with symblepharon at the lateral fornix, and loss of nails due to nail bed granulomas are seen. The skin lesions break down, bleed, and become crusted. The esophagus becomes constricted.

Amelogenesis imperfecta of both dentition has been described in some patients (1–5).

Phillips et al (4) and Bedlow et al (3) found abnormal hemidesmosomes and consigned this to the group of junctional *epidermolysis bullosa* or cicatricial pemphigoid.

To date all affected have been Muslim families of Punjabi origin. Nearly all families have been consanguineous. Inheritance is autosomal recessive (1–5).

Kindler and Weary syndromes

Kindler (11), in 1954, described a syndrome of neonatal bullae, photosensitivity, and atrophy of the skin of the hands and ears. Weary et al (19), in 1971, reported a similar condition. There has been disagreement as to whether these reports illustrate the same disorder. Approximately 70 cases have subsequently been described.

Inheritance was thought to be autosomal recessive because of parental consanguinity (8–10,14,17). However, the vast majority of examples have been sporadic, and it has been suggested that there is genetic heterogeneity (7), Kindler syndrome having autosomal recessive inheritance while Weary syndrome has autosomal dominant transmission.

Skin. Acral cutaneous bullae are congenital or appear during the first few days of infancy. They appear to follow trauma or sun exposure. There is spontaneous regression of bullae formation in late childhood. This is followed by the appearance of reticular skin pigmentation (4).

Photosensitivity ranges from relatively mild sunburn (9,11,17) to severe blister formation (8). It is manifested as facial erythema following minimal sun exposure. Poikiloderma, beginning with erythema and red patches, appears around 3–5 years and involves the face, spreading to the chest, upper back, abdomen, groin, and arms and legs. It is manifest by speckled pigmentation, atrophic areas, and wrinkled skin. The poikiloderma persists throughout adult life. The dorsa of the hands are especially marked by cutaneous atrophy, less often the abdomen, thighs, knees and elbows. Hyperkeratosis of the palms and soles has also been noted (11,17). The fingers and/or toes may rarely be proximally webbed (7).

Histologically, the poikilodermic skin changes are characterized by epidermal atrophy with decreased thickness of the stratum spinosum and orthohyperkeratosis. There is focal vacuolization of the basal layer, vascular ectasia, and melanophages in the upper dermis. The bullous lesions show intraepidermal cleft formation or dermatoepidermal clefts under an intact basal layer (2,11,14,17).

Oral manifestations. Few case reports comment on the oral findings: white mucosal patches (8,17), gingival swelling and bleeding (1,8,9,11), atrophy of oral mucosa (9), erosions (10,12,13), and pigmentation of the lips (10). Restricted mouth opening has also been noted (5,8,15). Squamous carcinoma of the lower lip was noted (1).

Other mucosal involvement. Dysphagia, which has been reported in several cases, may result from esophageal strictures (1). Urethral

meatal stenosis as well as anal fissuring and stenosis have been noted (1,2,17). Ectropion of the lower eyelid has also been described (1,8,17).

Diagnosis. Some investigators have proposed that Kindler syndrome has congenital bullae, frequent photosensitivity, poikilodermia with onset after 1 year, mucosal involvement, and autosomal recessive inheritance. Weary syndrome, in contrast, has cutaneous bullae that are not congenital, no photosensitivity, acral keratotic papules, no mucosal involvement, and autosomal dominant inheritance. The position of the blister cleavage level is variable in Kindler syndrome and intraepidermal in Weary syndrome.

Because of infantile cutaneous bullae, one must exclude *epidermolysis bullosa*. Weary syndrome should be excluded on the basis of different inheritance pattern, absence of photosensitivity, and onset of poikiloderma within the first year of life. Various examples of Weary syndrome have been cited (3,6,7,16,18,19). *Rothmund-Thomson syndrome, xeroderma pigmentosa*, and *dyskeratosis congenita* must also be excluded.

Infantile systemic hyalinosis

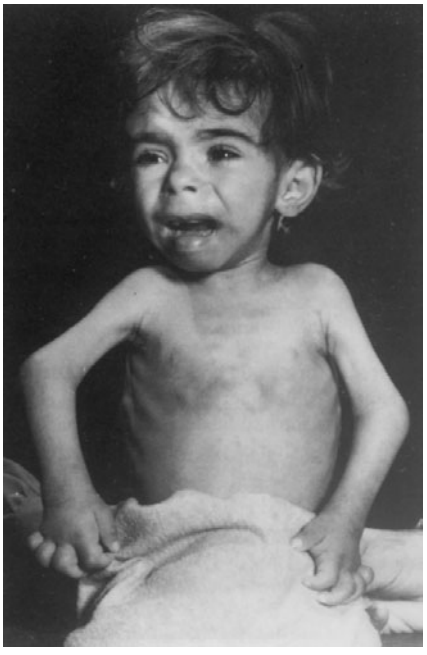
Nezelof et al (7), in 1978, and Landing and Nadorra (5), in 1986, defined a disorder of collagen characterized by thickening and nodularity of the skin, joint contractures, osteoporosis, and gingival enlargement. Other cases have been added (1–4,6,8,9), some having been erroneously labeled as examples of Winchester syndrome (2,6).

Failure to thrive dates from the neonatal period with death usually occurring before the third year of life, most before the second. There is associated severe diarrhea and wasting and recurrent severe infections.

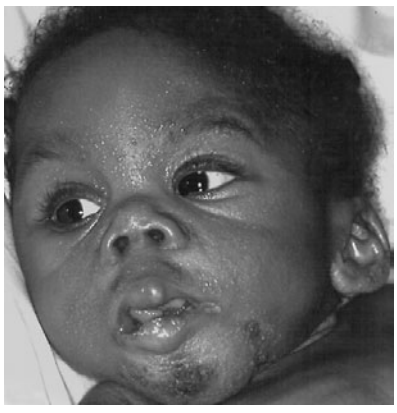
Facial changes include frontal bossing, deep-set eyes, downslanting palpebral fissures, low-set large pinnae, small mouth, and short neck (Fig. 13–165).

Pearly papular nodules appear about the face, especially around the nose, mouth, chin, and lower abdomen (Fig. 13–165B,C). The skin is diffusely firm. Fleshy nodes are evident around the anal margin (Fig. 13–166A). The skin over the metacarpophalangeal joints and malleoli is nodular and hyperpigmented (Fig. 13–166B).

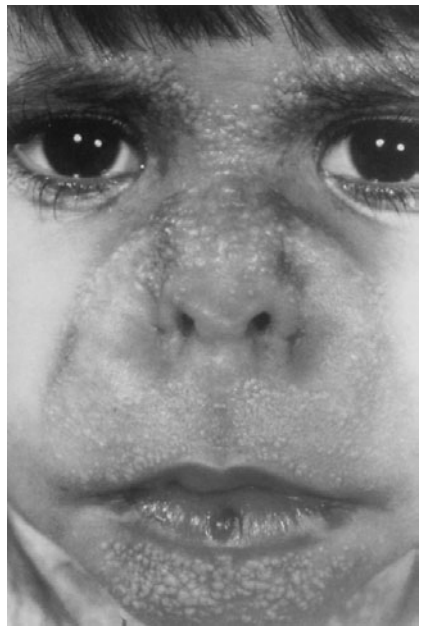
Fig. 13–165. *Infantile systemic hyalinosis*. (A) Pain and restriction of joints, especially those of hands and feet. Note swollen lower lip. (B) Numerous pearly papules of face and ears as well as nodules of lips and gingival hyperplasia. Observe velvety perioral pigmentation. (C) Compare with patients seen in A and B. Note numerous pearly papules of nose, brows, perioral and skin area. (A from DB Dunger et al, Eur J Pediatr 146:615, 1987. B from EE Sahn et al, Pediatr Dermatol 11:52, 1994. C from MT Glover et al, Pediatr Dermatol 9:255, 1991.)



A



B



C

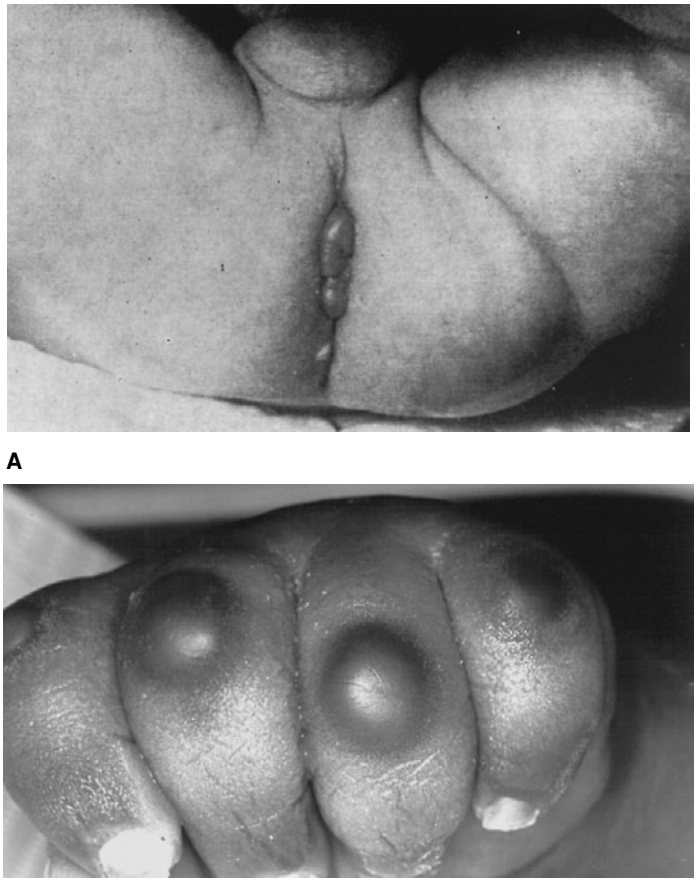


Fig. 13–166. *Infantile systemic hyalinosis*. (A) Perianal nodules at 16 months. (B) Hyperpigmented nodular plaques over proximal interphalangeal joints of hands. (A from C Nezelof et al, Arch Franc Pediatr 35:1063, 1978. B from EE Sahn et al, Pediatr Dermatol 11:52, 1994.)

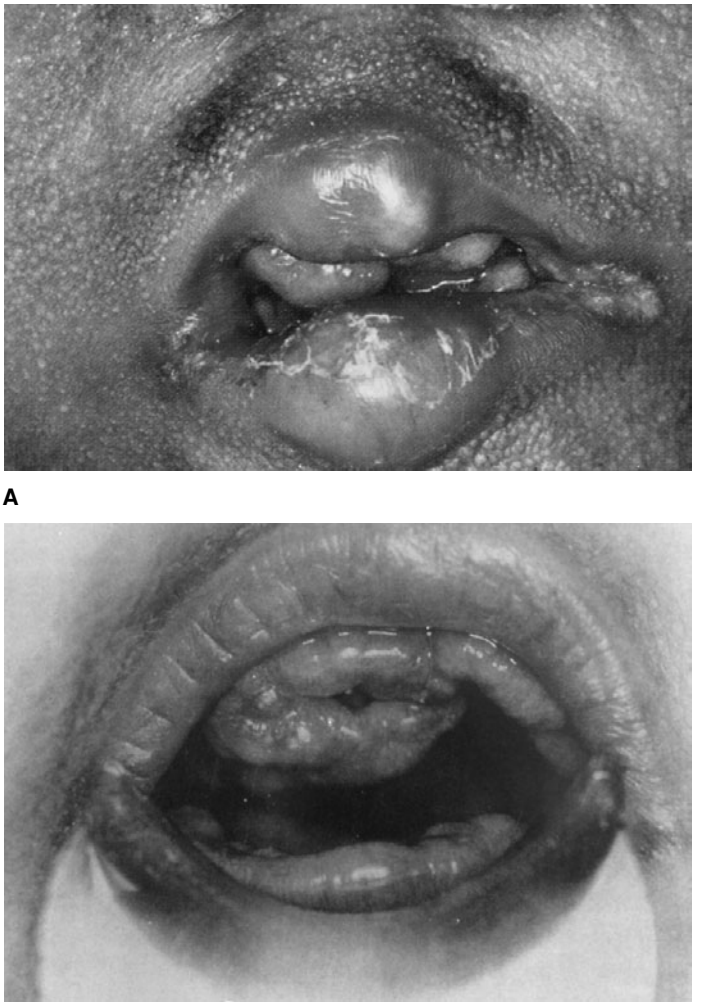

Fig. 13–167. *Infantile systemic hyalinosis*. (A) Lip nodules and perioral papules. (B) Gingival enlargement. (A from EE Sahn et al, Pediatr Dermatol 11:52, 1994. B from MT Glover et al, Pediatrics 87:228, 1991.)

There is gross soft flabby enlargement of gingival tissue which becomes evident about the time of initial tooth eruption. The teeth may become entirely covered (Fig. 13–167).

Microscopic examination reveals widespread deposits of hyaline material in skin, endocrine glands, muscle, and gastrointestinal tract shown to be type VI collagen. The collagen can be identified by use of fluorescent antibodies to type VI collagen (1).

Hypoproteinemia may result in generalized edema. Intestinal lymphangiectasia and hyaline deposits are evident on jejunal biopsy. This is associated with protein-losing enteropathy. Hypoproteinuria may result in generalized edema. Serum protein, but especially serum albumin, is low. Bloody diarrhea may be noted.

Painful joint contractures (arthrogryposis) are evident within the first few months of life. The patient often lies supine in a frogleg position with little spontaneous movement. Generalized bone demineralization is a constant feature (Fig. 13–168). The fingers are thickened and spindled, held in extension at the metacarpophalangeal joints and flexed at the interphalangeal joints.

Normal parents with multiple affected sibs suggest autosomal recessive inheritance (5). Consanguinity has also been noted (1,3,4,5).

One must exclude *juvenile systemic hyalinosis* (*Murray-Puretiç-Drescher syndrome*) and *Winchester syndrome*.

Linear skin defects and microphthalmia (MIDAS syndrome)

The syndrome of linear skin defects and microphthalmia was first described by Ropers et al (18) in 1982, but was defined and expanded by Al-Gazali et al (1,2) in 1988–90 and many others (3–16,20,21). Happle

Fig. 13–168. *Infantile systemic hyalinosis*. Well-circumscribed defect in ulna with generalized bone demineralization. (From EE Sahn, Pediatr Dermatol 11:52, 1994.)

et al (10) termed the condition the MIDAS syndrome (*MI*crophthalmia, *D*ermal *A*plasia, *S*clerocornea) (Fig. 13–169).

Overlapping both Aicardi syndrome and Goltz (focal dermal hypoplasia) syndrome, the syndrome reflects deletions and translocations involving the distal short arm (Xp22.3) of the X chromosome (6,11,21). It requires a mosaic state for survival. In XY patients, this results in nullisomy for Xp which is lethal (2,4). In XX patients (even XX males), deletion and unbalanced translocations of the region cause short stature and cutaneous and ocular defects (13). An X/Y translocation has been documented on several occasions (14,18,19). Approximately 20 cases have been described, all but a few in females. It has been seen in a mother and daughter (14). An affected mother has given birth to an anencephalic fetus (13).

Lindsay et al (13) suggested that *Aicardi syndrome* and *Goltz syndrome* are due to involvement of the same gene or genes, the *different patterns* of clinical expression being due to *different patterns* of X-inactivation. However, Mücke et al (15) suggested that they represent different entities, due to mother–daughter involvement.

Short stature (3rd–10th centiles) has been attributed to deletion of a pseudoautosomal gene for height (1,2,12).

Skin. The hypoplastic skin defects are asymmetric, linear, less often stellate or reticular, erythematous, and essentially limited to the anterior face and neck, rarely the upper torso (Fig. 13–169A,B). Later, the scars become hyperpigmented. Nail dystrophy has been described (8,16). In one biopsied example, the hypoplastic area showed smooth muscle hamartoma (16).

Eyes. Severe microphthalmia (1–3,7,9,10,12,13,16,17,20), sclerocornea (1–3,7,12–15), cataracts, orbital cysts, chorioretinal abnormalities, microcornea (13), and glaucoma (14,15) have been reported (Fig. 13–169C).

Ears. Several authors have described malformed pinnae (3,7,16).

Central nervous system. Hydrocephalus, mental retardation (13), normal intelligence (3,13), infantile seizures, and agenesis of the corpus callosum (3,8,16,17) have been documented. Profound hearing loss has been demonstrated (17).

Heart. Oncocytic cardiomyopathy (which has its own ample literature) is probably more common than has been reported. This results in refractory arrhythmias, AV block, and cardiac arrest (5,10,12,16). ASD and VSD have also been noted (12,17).

Genital anomalies. A variety of anomalies has been reported: hypertrophic clitoris, hypoplastic uterus, dysgenetic testis, small phallus, hypospadias, and ovotestis (14,15,17).

Miscellaneous findings. These include hyperextensible joints (13), diaphragmatic hernia (3), nasal cyst (13), anterior placed anus (7), and imperforate anus (17).

Diagnosis. The syndrome is distinct from both Aicardi syndrome (agenesis of corpus callosum, infantile seizures, chorioretinal lacunae, developmental delay) and *focal dermal hypoplasia*. The skin lesions in the latter are far more extensive in location and in nature (10).

Melanoleukoderma, hypodontia, hypotrichosis, somatic and mental retardation, and infantilism

Berlin (1), in 1961, reported four sibs, two male and two female, the products of a consanguineous union, with somatic and mental retardation, hypotrichosis, hypodontia, and melanoleukoderma.

The sibs, of Iranian descent, had mottled skin exhibiting various nuances of brown, gray, yellow, and white. Most of the skin was affected, including that of the face. The hair became gray early. Telangiectases were noted on the lips. Palms and soles were hyperkeratotic.

Adult height was about 150 cm. Mild mental retardation was evident in all three sibs. Build was slender. There was some hypermobility of the fingers.

The facies was somewhat unusual with sparse eyebrows, flat saddle-shaped nose, full lips, and deep furrows around the eyes and mouth.

Hypospadias, micropenis, and small testes were noted in the males. Puberty was delayed, and there was impotence. Females matured normally.

Trichothiodystrophy (Tay syndrome, IBIDS syndrome)

The trichothiodystrophies (TTDs) are a heterogeneous group of disorders. After proposing a tentative classification of 7 groups based on clinical classifications, we will concentrate on the group associated with defects in DNA repair mechanisms.

The finding common to all types of trichothiodystrophies is fragile and poorly growing hair which, on polarization, shows a pattern of bright and dark bands. There is involvement of the scalp hair, eyebrows, and eyelashes (Fig. 13–170) (20). Body, axillary, and pubic hairs may also be affected. The nails, in certain cases, may be friable, thinned, demonstrating horizontal splitting, longitudinal ridging, and koilonychia with erythroderma or photosensitivity.

Pending identification of specific mutations in the different categories, Sybert (27) has proposed the following classification:

Type A: The hair is abnormal. The nails may or may not be affected (27).

Type B: (Sabinas syndrome). The hair is affected; the nails may or may not be abnormal. Mental retardation is present (27).

Type C: (Pollitt syndrome). The hair is affected; the nails may or may not be abnormal. The teeth may be carious. Mental retardation, retarded bone age, and folliculitis are present (27).

Type D: (*b*rittle hair, *i*nfertility, *d*evelopmental delay, *s*hort *s*tature; BIDS; hair-brain syndrome). The hair is affected; the nails may or may not be abnormal. Mental retardation and short stature are present. Gonadal dysfunction may be noted in some cases (27).

Type E: (*i*chthyosis with BIDS, or IBIDS; Tay syndrome). The hair is affected, but the nails may or may not be. Mental retardation and short stature are present. The following manifestations may be noted in certain cases: decreased gonadal function, lenticular opacities or cataracts, failure to thrive, "progeria" with loss of subcutaneous tissue, microcephaly,

Fig. 13–170. *Trichothiodystrophy*. (A,B) Sparse broken eyebrows, eyelashes, and scalp hair; thickened epicanthic folds and protruding ears. (C) Dysplastic nails. (A,B courtesy of M Pittelkow, Rochester, Minnesota.)

ataxia, and erythrodontia. These patients may present as collodion babies in the newborn period (27).

Type F: (*p*hotosensitivity with IBIDS or PIBIDS). This group manifests all the features of group E, plus photosensitivity (27).

Type G: (trichothiodystrophy with immune defects). The anomalies of the hair are associated with chronic neutropenia or immunoglobulin deficiency. Mental retardation may or may not be present (27).

Two brothers were reported with a severe variant of trichothiodystrophy leading to death at 12 weeks and at 6 months, respectively. Clinical manifestations included brittle hair, failure to thrive, recurrent infections, cataracts, and angioendotheliomas of the liver at autopsy (19). There was also a report of a patient with TTD associated with urologic malformation and primary hypercalciuria (16).

It is important to remember that there is significant overlap in clinical manifestations of these groups. However, it is reported that 50% of TTD patients exhibit photosensitivity and deficiency in nucleotide excision repair (NER) (30). A classification based on specific mutations may be more reliable (vide infra). A good review is that of Tolmie et al (29a).

Anomalies of the hair. Under polarizing light, hairs show a pattern of light and dark bands (Fig. 13–171A) (20). The hair shaft may be twisted and nodes, as in trichorrhexis nodosa, may be observed. Scanning electron microscopy reveals abnormal cuticle formation (Fig. 13–171B) and irregular twisting and transverse fracturing of hairs (trichoschisis) (20). Abnormal whorled and irregular arrangement of microfibrils may be noted by transmission electron microscopy (9,12,27,30).

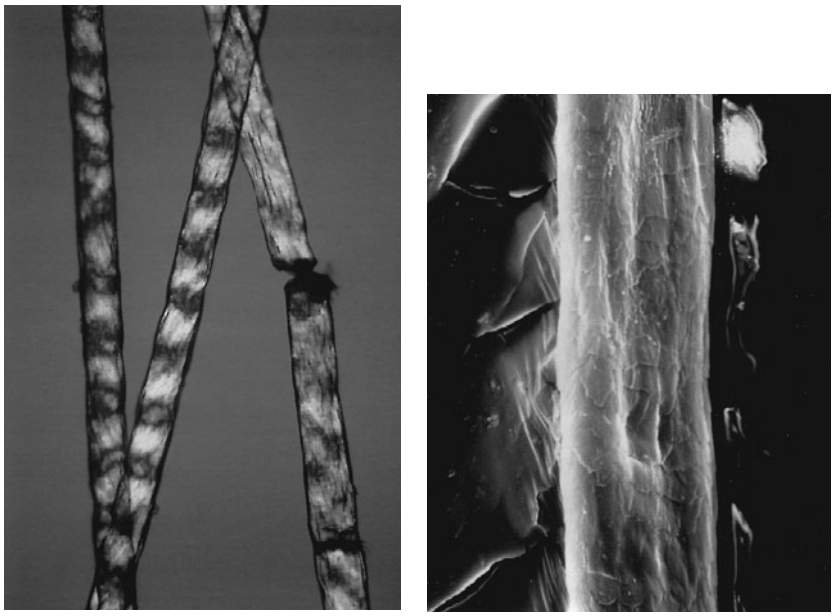
In all types of trichothiodystrophy, the hair shows a decrease in cystine to 10%–50% of normal, reflecting a decrease of ultrahigh sulfur proteins. The nails are deficient in high sulfur proteins as well (9,27).

Heredity. The photosensitive form of trichothiodystrophy (TTD) has autosomal recessive inheritance. Like xeroderma pigmentosum (XP), TTD is characterized by persistence of unrepaired DNA damage produced by exposure to UV light (6–8,17,23,24). However, unlike XP, TTD patients do not have an increased frequency of skin cancers (21).

Nucleotide excision repair (NER) (31) is the most versatile of DNA repair systems. It recognizes and eliminates a wide variety of DNA lesions, in particular those induced by ultraviolet light (1,10,14). NER requires the products of at least 20 genes (23). The NER process has five steps: recognition of the DNA lesion (by DNA-binding protein XPA), incision of the damaged strand on both sides of the lesion (by bidirectional helicases XPB and XPD), excision of the damaged oligonucleotide (by XPF and XPG), and DNA synthesis to fill the gap and ligation (Fig. 13–122) (23).

The NER defect of photosensitive TTD patients has been assigned to three complementation groups. The large majority of cases (90%) fall into the same group as XP-D and the TTD/XP-D group (23,25). The XP-D and the TTD/XP-D patients carry mutations on the same repair gene, mostly located in the C-terminal region (2,28). XPD is one of the subunits of the transcription/repair factor TFIIH. It interacts specifically with p44, another subunit of TFIIH. This interaction results in the stimulation of the $5' \rightarrow 3'$ helicase activity of XPD. Mutations in the XPD C-terminal domain prevent the interaction with p44, thus explaining the decrease in XPD helicase activity and the NER defects in TTD (3). No mutations on the XPD gene have been found in the nonphotosensitive TTD patients. Recently, one family was found to belong to the XP-B complementation group, called the TTD/XP-B group (32,34). A third kindred constitutes a distinct NER-deficient group, TTD-A (26). Because of strong evidence that most of the clinical features of TTD patients can be correlated with a defect in transcription, the notion of "transcription syndromes" has been proposed for TTD disease (3,10,18,32,34).

All cultured cells isolated from photosensitive TTD patients are sensitive to the killing effect of UVC irradiation and present a reduced level of DNA repair synthesis (22). In cell lines from photosensitive TTD patients, the extent of cellular responses to UV irradiation is remarkably heterogeneous, even within the same complementation group (15,23,25).



A B

Fig. 13–171. *Trichothiodystrophy*. (A) Microscopic views of hair from patient between cross-polarizers. Turning microscope stage about 10° (5° on each side of position of maximum extinction) causes dark patches to become bright and bright patches to become dark (arrows). (B) Scanning electron micrograph shows notable ridging and fleeting along longitudinal hair axis. Also note cuticle damage. (A courtesy of M Pittelkow, Rochester, Minnesota. B from VH Price et al, Arch Dermatol 16:1375, 1984.)

In spite of the sensitivity to UV irradiation, and in contrast to XP, TTD patients do not have a predisposition to cancer, even though they exhibit low DNA repair efficiency due to mutation in the same DNA repair gene, the XPD gene (23). It has been estimated that XP patients present more than a 200-fold increment in all forms of skin cancer, whereas no skin cancer has yet been reported to be associated with the TTD syndrome (23).

XPB and XPD proteins have a dual function, both in nucleotide excision repair of DNA damage and in basal transcription. Mutations in the XPD gene can result in three distinct phenotypes: XP, TTD, and Cockayne syndrome (CS). Studies revealed that most mutation sites differed between XP and TTD. However, there are three sites at which the same mutation is found in XP and TTD patients. Since the corresponding patients were all compound heterozygotes with different mutations in the two alleles, the alleles were tested separately. The mutations that are found in both XP and TTD patients behaved as null alleles, suggesting that the disease phenotype was determined by the other allele (29).

A slight transcription deficiency in a gene regulating a major pathway in immunosurveillance could be produced with "XP mutations," markedly reducing the natural killer activity of the cell. This may not occur with "TTD mutations" (23). Conversely, TTD-specific mutations on the XPD gene may affect pathways that result in the clinical features of the TTD syndrome, such as brittle hair, nail and dental anomalies, or developmental and mental retardation (23). The recently generated mouse model of TTD (4) should provide a suitable experimental model to shed additional light on the pathophysiologic processes of this condition.

The essential problem, then, is to find factors that may modify the response of cells to the deleterious effects of UV light in sun exposure, thus avoiding the development of cancer. In this respect, striking differences have been found between XP and TTD cells. Cells from XP patients are very low in catalase activity, whereas in TTD cells, catalase activity is normal (33). Low catalase activity results in the accumulation of H_2O_2 in XP cells. This can cause an overload of free radicals that damage DNA and favor tumor progression. The presence of low catalase activity, together with low DNA repair capability, may partly explain the increased risks of tumor production in XP as compared to TTD. It was recently reported that low catalase activity in XP fibroblasts is directly related to decreased intracellular levels of the cofactor, NADPH (11).

Moreover, among the major responses of human cells to DNA damage is accumulation of the p53 tumor suppressor protein, which plays a crucial role as a cell-cycle checkpoint. There is prolonged p53 protein accumulation in trichothiodystrophy fibroblasts dependent on unrepaired pyrimidine dimers on the transcribed strands of cellular genes (5).

Differential diagnosis. The conditions that should be considered in the differential diagnosis and ruled out are Netherton syndrome, Menkes disease, and Sjögren-Larsson syndrome.

Laboratory aids. Prenatal diagnosis is possible by measurement of repair of UV-induced DNA damage in chorionic villus cells or cultured amniocytes. Measurement of cystine in specimens of hair may also confirm a clinical diagnosis (9,27).

CHIME neuroectodermal dysplasia syndrome

CHIME syndrome is a rare neuroectodermal disorder first described by Zunich and Kaye in 1983 (3–6). It presents with *C*olobomas of the eyes, *H*eart defects, *I*chthyosiform dermatosis, *M*ental retardation, and *E*ar defects. Six children with this syndrome have been reported (1).

The anomalies of the eyes include retinal colobomas, hypertelorism, and (1), in one case (2,4,5), cloudy corneas. The cardiac anomalies consist of tetralogy of Fallot, transposition of great vessels, peripheral pulmonic stenosis, and ventricular septal defect (1). The skin presents with a migratory ichthyosiform rash, associated with hyperproliferative overgrowth of the epidermis with thick palms and soles (1). Mental retardation is present in all patients. It may be associated with cerebral atrophy, seizures, and wide-based gait (1). The ears have overfolded helices, and conductive hearing loss is present in all reported patients (1).

Other anomalies associated with this condition may be neonatal macrosomia, brachycephaly, flat broad nasal root, short philtrum, wide mouth, full lips, and widely spaced teeth. Cleft palate was present in two patients. The nipples were small, low-set, and, in one patient, supernumerary (1). Skeletal anomalies included broad second toe, hyperextensible joints, clinodactyly, brachydactyly, deep plantar creases, or clubfoot (1). The urinary system presented with duplicated ureters in one case and obstruction of the ureteropelvic junction in another (1). One patient developed acute lymphocytic leukemia.

The cause of CHIME syndrome is still unknown. Autosomal recessive inheritance is possible. The diagnosis is important to make because of the potential for associated congenital heart disease, neurologic compromise, and possible development of malignancy (1).

The differential diagnosis includes Rud syndrome, Refsum disease, Sjögren-Larsson syndrome, Netherton syndrome, *KID syndrome*, and *trichothiodystrophy*.

Chapter 14
Syndromes with Craniosynostosis: General Aspects and Well-Known Syndromes

The craniosynostoses are etiologically and pathogenetically heterogeneous. Premature sutural fusion may occur alone or together with other anomalies, making up various syndromes. Over 90 syndromes are known. Several reviews are available (1–4), the most exhaustive review being that of Cohen and MacLean (4).

Craniosynostosis has been observed in white, black, and Asian populations (1). Birth prevalence is approximately 343–476 per one million newborns (4–12). Sagittal synostosis is the most common type, with percentages ranging from 56% to 58%. Coronal synostosis occurs less frequently, with estimates varying from 18% to 29%. With sagittal involvement, the male-to-female preponderance is 3:1. With coronal involvement, there is usually, but not always, a slight predilection for females. Metopic and lambdoid synostoses are uncommon and lambdoid synostosis is frequently confused with posterior deformational plagiocephaly (1,4).

Most cases of isolated craniostenosis are sporadic, but familial instances are known: coronal, 14.4%; sagittal, 6%; metopic, 5.6% (6–10). Familial lambdoid synostosis is rare (6). Associated anomalies are more frequent in coronal series than in sagittal series. The types of anomalies most commonly associated with syndromic craniostenosis are limb defects, ear anomalies, and cardiovascular malformations (1,2).

The main craniosynostosis syndromes are discussed in this chapter. Other syndromes are discussed in Chapter 15.

Apert syndrome (acrocephalosyndactyly)

Apert syndrome is characterized by craniosynostosis, midfacial malformations, and symmetric syndactyly of the hands and feet, minimally involving digits 2, 3, and 4 (4,9,14,17). Apert (2) is credited with the discovery of the syndrome, although the condition was reported earlier by Wheaton (61) and others. Park and Powers (43) reported an extensive study of the disorder in 1920. The most extensive reviews are those of Cohen and Kreiborg (7–16), Kreiborg et al (28–31), and Cohen and MacLean (17). In 1960, Blank (4), in examining 54 cases, divided acrocephalosyndactyly into typical and atypical clinical categories. Typical, or Apert type, included only those patients who had a middigital hand mass consisting of osseous and soft tissue syndactyly of digits 2, 3, and 4. More than 500 cases have been reported to date.

Birth prevalence of Apert syndrome is estimated to be 15–16 per one million newborns and the syndrome accounts for about 4%–5% of all cases of craniosynostosis (18,57). Although most cases are sporadic, representing new mutations, autosomal dominant transmission with complete penetrance has been reported many times (1,3,17,18,34, 49,50,58,59). Increased paternal age has been associated with sporadic cases (21,57). Wilkie et al (62) discovered two mutations in the linker region between IgII and IgIII on FGFR2: Ser252Trp and Pro253Arg. Origin of new mutations is exclusively of paternal origin (39). Ser252Trp accounts for approximately two-thirds of the cases; Pro253Arg is found in about one-third (18,52,62). Genotype/phenotype correlations have been reported by Slaney et al (52). Ser252Trp is more frequently associated with cleft palate and Pro253Arg is more commonly found with severe syndactyly (58a). Rarely, other Apert mutations are found: Pro252Phe (42), acceptor splice site mutation (44), and *Alu* insertions (41) (Fig. 14–1). The structure of the ectodomain has been reported (46a).

Craniofacial features. During infancy, there is a wide midline calvarial defect that extends from the glabella to the posterior fontanel that gradually fills in with bony islands that coalesce. The coronal area is fused at birth. Only the lambdoid suture forms interdigitations visible on radiographs and on dry skulls. Head circumference is larger than the 50th centile at birth (11,16,17,29).

Hyperacrobrachycephaly is commonly observed, and the occiput is flattened. The forehead is steep, and during infancy a horizontal groove that disappears with age may be present above the supraorbital ridges (Fig. 14–2A). Bulging at the bregma or slightly anterior to the bregma may be noted in some cases. The cranial base is malformed and often asymmetric (17,18,29). The anterior cranial fossa is very short. Shallow orbits expanded and prolapsed ethmoids, and orbital hypertelorism are associated. The clivus and anterior cranial fossa are short. The lesser sphenoidal wings slope upward and laterally. The great wings of the sphenoid are protruded. The cranial base angle is variable, but platybasia occurs most commonly (15). Cloverleaf skull may be observed in about 4% (15,17,22). The temporal fat pads are enlarged (53).

The middle third of the face is retruded and commonly hypoplastic, resulting in relative mandibular prognathism. The nasal bridge is depressed, and the nose is beaked (Fig. 14–2B). The nasal septum is often deviated (15,17,29).

Hypertelorism, proptosis, downslanting palpebral fissures, and, frequently, strabismus are observed. Absence of the superior rectus muscle

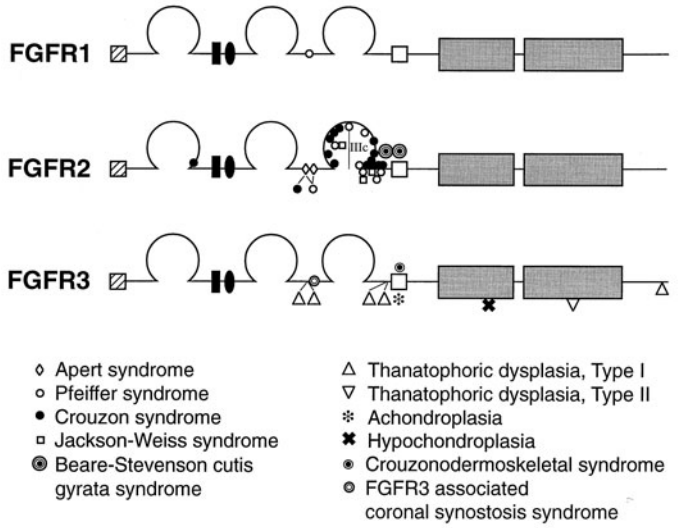

Fig. 14–1. Most mutations for major craniosynostosis syndrome are on FGFR2 with only one known mutation on FGFR1. Note mutations for short limb skeletal dysplasias (achondroplasia, hypochondroplasia, thanatophoric dysplasia, type I, and thanatophoric dysplasia, type II) on FGFR3. Fibroblast growth factor receptors 1,2,3. Hatched square = signal peptide. Solid oblong = acid box. Solid oval = CAM homology domain. Open square = transmembrane domain. Long oblongs = kinase domains 1 and 2. Three loops from left to right are immunoglobulin-like domains (IgI, IgII, IgIII). IIIc is alternatively spliced form of second half of IgIII. For clarity, only a few of the many mutations for Crouzon syndrome and Pfeiffer syndrome are shown on FGFR2. (From MM Cohen Jr, J Bone Min Res 12:322–331, 1997. Updated in: MM Cohen Jr, RE MacLean, Craniosynostosis: Diagnosis, Evaluation, and Management, 2nd ed., New York: Oxford University Press, 2000.)

has been reported (15,17,20,60). Structural alterations of the extraocular muscles have also been noted (9,15,17,35), indicating that ocular motility disturbances in the Apert syndrome may not be caused solely by mechanical factors. Albinoid findings have also been observed (36). Iris transillumination and depigmentation of the fundus are associated with absent or diffuse foveal reflexes. Unlike classical oculocutaneous albinism, however, visual acuity is not severely impaired, and pendular nystagmus is not observed. In some Apert syndrome patients, light hair color and pale skin are also noted (37).

The ears may appear low set in some instances. Minor anomalies of the ear may be noted on occasion (15,17). Otitis media is common in Apert syndrome. Middle ear disease is related to the high frequency of cleft palate (9,15,17) and may also be related to eustachian tube dysfunction compounded by obstruction of the epipharyngeal space (15). Congenital fixation of the stapedial foot plate has also been reported. The otologic manifestations have been reviewed by Bergstrom et al (3) and Gould and Caldarelli (23).

In the relaxed state, the lips frequently assume a trapezoidal configuration. The palate is highly arched, constricted, and usually has a median furrow (Fig. 14–3) (28,43,47,48). Lateral palatal swellings are present, which increase in size with age. These swellings have been shown to have excess mucopolysaccharide content, predominantly hyaluronic acid and, to a lesser extent, sulfated mucopolysaccharides (37,47). Cleft soft palate, or bifid uvula, is observed in 30% of cases (9,15,28). The hard palate is shorter than normal, but the soft palate is both longer and thicker than normal (9,15,28,47,48). Alterations in the nasopharyngeal architecture consist of reduction in pharyngeal height, width, and depth (15,47,48). The combination of reduced nasopharyngeal dimensions and decreased patency of the posterior nasal choanae poses the possible threat of respiratory embarrassment and cor pulmonale, especially in the young child (8,9,17). Solid cartilaginous trachea has been noted (17,38,40).

The maxillary dental arch is V-shaped with severely crowded teeth and bulging alveolar ridges. The maxillary hypoplasia, so frequently present in Apert syndrome, leads to compression of the dental arch, which becomes V-shaped. This results in irregular positioning of teeth and marked thickening of the alveolar process. Class III malocclusion is commonly present, with anterior open bite as well as anterior and posterior crossbite (28). Delayed dental eruption is a common finding (27,28).

Growth. Weight, length, and head circumference tend to be above the 50th centile in newborns. Birth measurements are explained by megalencephaly and increased head height (11).

The growth pattern in infancy and childhood consists of a gradual decrease in height so that most values fall between the 5th and 50th centiles. From adolescence to adulthood, the decrease in centiles becomes more pronounced. This two-step deceleration in height results from rhizomelic shortening of the lower limbs (11).

Central nervous system. The subject has been reviewed by Cohen and Kreiborg (7). A significant proportion of patients are mentally retarded. IQ has been studied at two large craniofacial centers. Lefebvre et al (32) assessed 20 children with a full battery of psychometric tests. Mean IQ was 73.6 with a range of 52–89. Patton et al (46) found that approximately half of their patients had an IQ greater than 70, although none had an IQ above 100 (n=29). Of 14 patients with IQs above 70, seven found suitable training or employment. Only 7% had IQs lower than 35. In patients who had craniectomies performed during the first year of life, no significant differences were found between retarded vs. nonretarded outcome. However, patients with normal intelligence and above average intelligence have been observed (17).

Fig. 14–2. *Apert syndrome* (A) Note turribrachycephaly, proptosis, and horizontal grooves above supraorbital ridges. (B) Note turribrachycephaly, hypertelorism, downslanting palpebral fissures, beaked nose, midface hypoplasia, and relative mandibular prognathism. (B from A Kahn Jr and J Fulmer N Engl J Med 252:379, 1955.)

Fig. 14–3. *Apert syndrome*. Note Byzantine arch-shaped palate.

Cohen and Kreiborg (7) reported absent or defective corpus callosum, defects of limbic structures, or both. Other frequent findings in their neuropathology series included megalencephaly and gyral abnormalities. Hypoplasia of cerebral white matter and heterotopic gray matter were found in some cases.

Progressive hydrocephalus is uncommon and has frequently been confused with distortion ventriculomegaly (7,17), which is very common.

Hands and feet. The hands and feet have been studied extensively by Cohen and Kreiborg (14). A middigital hand mass minimally involving the second, third, and fourth fingers is nearly always observed (Fig. 14–4A,B), but exceptions occur (6,45). Associated synonychia is variable in degree. The first and fifth fingers may be joined to the middigital hand mass or may be separate. When the thumb is free, it is broad and deviates radially. Some degree of brachydactyly involving all five fingers is usually present. The interphalangeal joints become stiff by 4 years of age (14,17).

Radiographically, the first metacarpal is normal. The proximal phalanx of the thumb is short, frequently narrow, and sometimes delta-shaped. The distal phalanx of the thumb is enlarged and trapezoidal in shape. The second to fifth metacarpals are shorter than normal and tend to be uniform in length. The proximal ends of the fourth and fifth metacarpals may be unsegmented (Fig. 14–4C). Osseous symphalangism of the proximal interphalangeal joints is visible radiographically by 4–6 years of age. Synostosis of adjacent distal phalanges occurs with age, most frequently between the third and fourth distal phalanges, but also between the second to fourth distal phalanges. Unsegmented carpal bones, particularly the hamate and capitate, may be observed. Other bony abnormalities of the hands have also been noted (14,17,51).

In the feet, syndactyly involves the second, third, and fourth toes (Fig. 14–4D). The first and fifth toes are sometimes free and sometimes joined by soft tissue union to the second and fourth toes, respectively. Toenails may be separate or partially continuous. The great toes are broad, and hallux varus is commonly observed (5,14).

The distal phalanx of the great toe is enlarged and trapezoidal. The proximal phalanx of the great toe is malformed. The second phalanges of the second to fifth toes are often absent. The first metatarsal is broad, shortened in some instances, and may exhibit partial or tarsal bone duplication. Symphalangism, fusion of the tarsal bones, six metatarsals, and other bony abnormalities may be observed in the feet (14,17,51).

Progressive calcification and fusion of the bones of the hands, feet, and cervical spine becomes visible radiographically with age (14,17,33,51). Imaging of the hands and feet has been described (19,25).

Skin. Acne vulgaris with unusual extension to the forearms may be seen in more than 70% (n=19) of patients at adolescence and thereafter. Frank comedones and pustules occurring on the face, chest, back, and upper arms may be very severe and hyperseborrhea is especially common (13,17,54). Steffen (56) does not accept this as a true acne vulgaris.

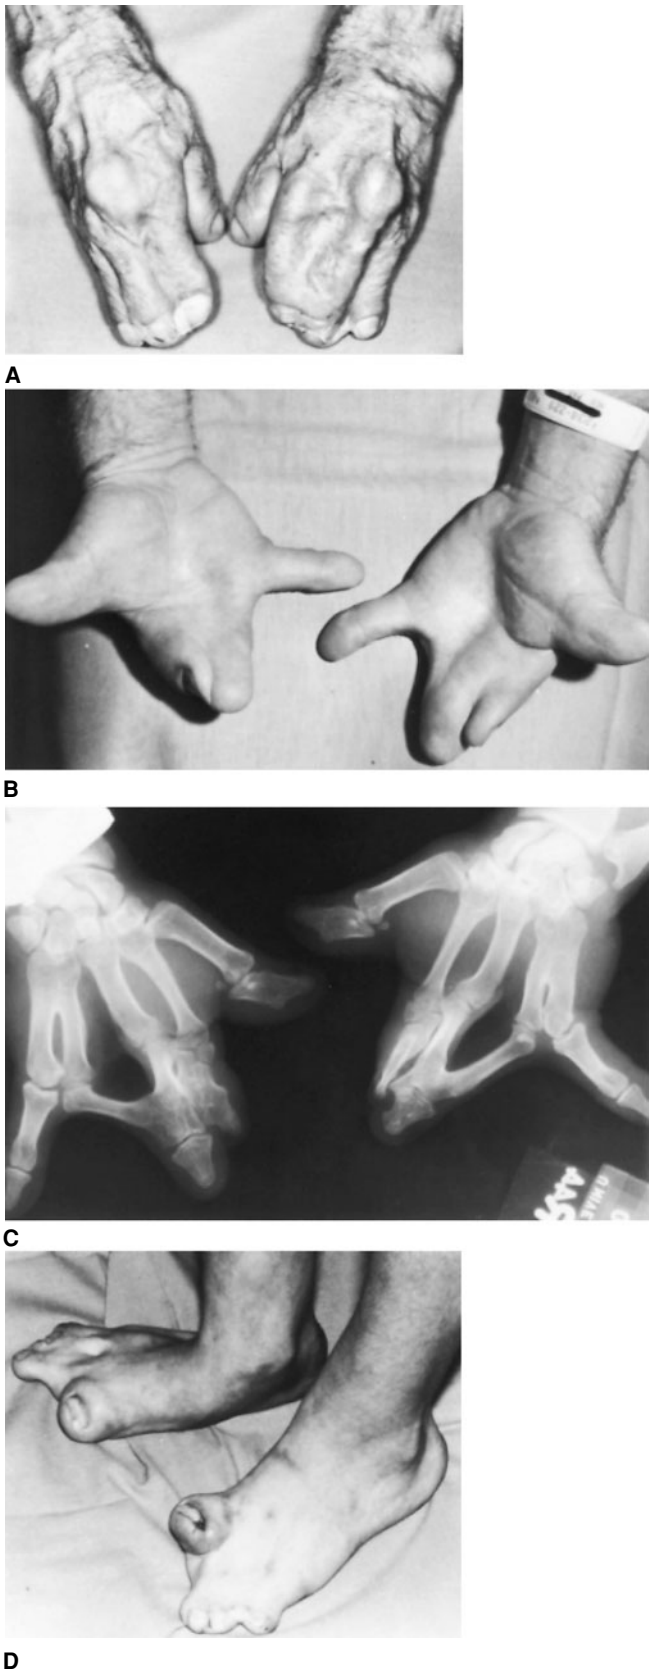

Fig. 14–4. *Apert syndrome*. (A) Syndactyly of second to fourth fingers. Note broad, radially deviated thumbs. (B) Mid-digital hand mass with first and fifth digits free. (C) Radiograph showing bony synostoses. (D) Syndactyly of second to fourth toes. Note broad, proximally placed halluces. (B and C from JM Opitz Helena, Montana. D courtesy of R Bauer, Innsbruck, Austria.)

Other findings. Final height attainment is commonly between the 5th and 50th centiles. This is due in part to mild rhizomelia of the lower limbs. Rhizomelia of the upper limbs may be more pronounced. In the series of Cohen and Kreiborg, 4% (n=55) exhibited severe rhizomelia (10). Progressive generalized bony dysplasia with limitation of motion at the shoulders with mild limitation at the elbows has been documented. Alterations in the pelvis have also been noted (10). Cardiovascular defects are found in about 10% and genitourinary anomalies are noted in approximately 10% (12). Cervical fusions, particularly involving C_5–C_6, have been found in 69% (30).

Differential diagnosis. Apert syndrome should be distinguished from *Pfeiffer syndrome, Saethre-Chotzen syndrome, Jackson-Weiss syndrome, Crouzon syndrome*, and *Carpenter syndrome*.

Prenatal diagnosis. Prenatal diagnosis of Apert syndrome has been reported (7,17,24,34). Diaphragmatic hernia has been noted as a presenting sign (63).

Crouzon syndrome (craniofacial dysostosis)

Crouzon syndrome is characterized by craniosynostosis, maxillary hypoplasia, shallow orbits, and ocular proptosis (Fig. 14–5). First described by Crouzon (12) in 1912, eighty-six published cases were reviewed by Atkinson (6) by 1937. Numerous publications on Crouzon syndrome have appeared (1–45), with the most complete study being Kreiborg's (26) monograph, which analyzes 61 cases. Cohen and MacLean (11) provided an exhaustive review.

Crouzon syndrome has autosomal dominant transmission. In Atkinson's review (6), 67% of the cases were familial and 33% were sporadic, representing new mutations. In Kreiborg's monograph (26), 44% were familial and 56% occurred sporadically. Increased paternal age at the time of conception was a statistically significant factor in new mutations in Kreiborg's study (26). Rollnick (40), Navarette et al (37), and probably Juberg and Chambers (23) reported examples of germinal mosaicism. Crouzon syndrome has a birth prevalence of 15–16 per one million newborns and Crouzon syndrome accounts for 4.5% of all cases of craniosynostosis (10). Variability of expression characterizes Crouzon syndrome. Nowhere is this more apparent than in the pedigree reported by Shiller (42; see also 20). The proband, the most severely affected member of the family, presented with cloverleaf skull. Several sibs manifested classic Crouzon syndrome. The affected mother and various other members of the family exhibited ocular proptosis and midface deficiency without craniosynostosis. In some instances, affected individuals with only subtle features of Crouzon syndrome are detected because they are related to a classically affected relative (11). On occasion, a normally appearing member of the family may harbor a Crouzon mutation (11).

Over 30 mutations for Crouzon syndrome are located on IgIII of FGFR2 (22) (Fig. 14–1). About half of a dozen of these are also found in Pfeiffer syndrome (9,11). Two extremely rare mutations have been reported: Tyr105Cys on IgI and Ser252Leu in the linker region between IgII and IgIII (9,11). A novel mutation, G362T, has been shown with apparent nonpenetrance (15a). The phenotype of the patient shown by Steinberger et al (43) does not resemble Crouzon syndrome. Spontaneous mutations are of paternal origin (18a).

Fig. 14–5. *Crouzon syndrome*. (A–D) Note various craniofacial shapes, shallow orbits, proptosis, divergent strabismus, hypertelorism, short upper lip, and midface hypoplasia. (Courtesy of P Tessier, Paris, France.)

Craniofacial features. Cranial malformation in Crouzon syndrome depends on the order and rate or progression of sutural synostosis. Brachycephaly is most commonly observed, but scaphocephaly, trigonocephaly, and, as already indicated, the cloverleaf skull may be observed (Fig. 14–5).

Craniosynostosis commonly begins during the first year of life and is usually complete by 2–3 years of age. In some cases, craniosynostosis may be evident at birth (11,26). Occasionally, no sutural involvement may be noted. Shallow orbits and ocular proptosis are diagnostic features of Crouzon syndrome. Diagnosis may be evident at birth or during the first year of life. On occasion, the phenotypic features of Crouzon syndrome may be absent and evolve gradually during the first few years of life. Various sutures may be prematurely synostosed, and multiple sutural involvement is found eventually in most cases (coronal and sagittal—20%; coronal, sagittal and lambdoidal—75%; sagittal and lambdoidal—4%) (26). Kreiborg et al (32) demonstrated earlier closure of sutures, fontanelles, and synchondroses in Crouzon syndrome than in Apert syndrome. Increased digital markings are common on skull radiographs (11,26). Anthropometric and cephalometric studies have been carried out (24,26,35,36).

Ocular proptosis, a feature occurring in 100% of the cases (n=61), is secondary to shallow orbits and results in a high frequency of exposure conjunctivitis or keratitis. Luxation of the eyeglobes has been observed in some cases. Exotropia is an extremely common finding (77%, n=60) (7,26). Poor vision occurs in approximately 46% (n=54), with optic atrophy found in 22% (n=45) and blindness in 7% (n=61) (26). Low-frequency findings include nystagmus, iris coloboma, aniridia, anisocoria, corectopia, microcornea, megalocornea, keratoconus, cataract, ectopia lentis, blue sclera, and glaucoma (6,11,26).

Approximately 50% (n=54) have lateral palatal swellings but only in a few instances are they large enough to produce the median pseudocleft palate appearance found so frequently in Apert syndrome (26,38). Cleft lip and cleft palate are anomalies of low frequency (26). Because of maxillary hypoplasia in Crouzon syndrome, the anteroposterior dimension of the maxillary dental arch is shortened. Dental arch width is also reduced, and the constricted arch gives the appearance of highly arched palate, although palatal height is normal by measurement. Unilateral or bilateral posterior crossbite is evident in two-thirds of Crouzon syndrome patients. Crowding of maxillary teeth is common, and ectopic eruption of maxillary first molars occurs in approximately 47% (n=17). Anterior open bite, mandibular overjet, and crowding of mandibular anterior teeth are also commonly observed. Aplasia of single teeth (rarely more), shovel-shaped maxillary incisors, and abnormal premolar morphology have been observed in Crouzon syndrome with the same low frequency found in the general population (26,38,39).

Central nervous system. Progressive hydrocephalus, chronic tonsillar herniation, and jugular foramen stenosis with venous obstruction occur with significant frequency (8,34). Headaches were found in 29% (n = 52) in Kreiborg's series (26). Seizures occurred in 12% (n = 52), and marked mental deficiency was found in only 3% (n = 61).

Other findings. Conductive hearing deficit is found in 55% (n=49) and atresia of the external auditory canals occurs in 13% (n=53) (26). Deviation of the nasal septum was observed in 33% (n=60) of Kreiborg's series (26). Calcification of the stylohyoid ligament was especially common, being found in 88% (n=60). Cervical spine anomalies were also common (30%, n=60). Fusion of C_2 with C_3 occurred with the highest frequency, but in some instances C_5 and C_6 were fused, and in still other instances, C_2–C_3 and C_5–C_6 fusions occurred in the same patient (31). Fusions were found in 18% in another series, and butterfly vertebrae were found (2). C_2–C_3 and C_5–C_6 were found with equal frequency. Solid cartilaginous trachea was reported by Devine et al (14), Sagehashi (41), and Davis et al (13). In Kreiborg's series (26), stiffness of the elbows was noted in 16% (n=61), and in two of these cases, subluxation of the radial heads was evident. Cubitus valgus was observed in one patient by VA McKusick (personal communication, 1982). Peromelia was recorded in one instance (18). Sacral, vertebral, and rib anomalies were also noted by Golabi et al (19). A tail was noted by Sagehashi (41).

Several radiographic studies of the limbs have been carried out (1–5,36). Carpal fusions were found in 12% (n = 34). Mild defects of the hands have been shown by using metacarpophalangeal profile patterning (1,5,36). Radiographic abnormalities of the elbows have been documented in some instances (3).

Differential diagnosis. Crouzon syndrome should be distinguished from simple coronal synostosis, craniosynostosis, *Apert syndrome*, *Pfeiffer syndrome*, *Saethre-Chotzen syndrome*, *Jackson-Weiss syndrome*, and particularly from *crouzonodermoskeletal syndrome*.

Pfeiffer syndrome

In 1964, Pfeiffer (37) described a syndrome consisting of craniosynostosis, broad thumbs, broad great toes, and a variable feature, partial soft tissue syndactyly of the hands. Eight affected individuals in three generations were noted in Pfeiffer's report. Other pedigrees consistent with autosomal dominant transmission have been noted by several authors (27,36,43,53,55). Penetrance has been complete, and expressivity has been very variable (4,44). In some cases the thumbs may be normal (4,42). Sporadic cases have also been noted (1–3,10–12,14,19,22,24,25,52). The most exhaustive review is that of Cohen and MacLean (10).

Muenke et al (16,32,40,46) and others (23,28,35,42,45) showed that mutations causing Pfeiffer syndrome are found on FGFR1 and FGFR2 (Fig. 14–1). Only one mutation is found on FGFR1 in the linker region between IgII and IgIII: Pro252Arg. Multiple mutations are known on

FGFR2 clustering on IgIII. About half a dozen of these mutations have also been found with Crouzon syndrome (10). For about 45% of cases, no mutation has been identified. Common mutations involve Cys278 and particularly Cys342. Ser351Cys is also common, occurring with a severe phenotype. However, not all patients have either broad thumbs or broad great toes so, by definition, do not have Pfeiffer syndrome. Splice site mutations account for perhaps 10% of those identified (M Muenke, personal communication, 1999). A Cys278Phe mutation has been found with severe craniolacunae (48). Spontaneous mutations appear to be of paternal origin (13a). Genotype-phenotype correlation has been studied by Cornejo-Roldan et al (10a).

Rutland et al (42), Schell et al (46), and Robin et al (41) suggested that clinical differences might exist between the mutation on FGFR1 and those on FGFR2. Severe craniosynostosis and midface hypoplasia, more pronounced ocular proptosis, and perhaps broader thumbs are more likely to be associated with mutations on FGFR2 than with the single mutation on FGFR1, although there is some overlap.

Clinical subtypes. Cohen (8) proposed three clinical subtypes of Pfeiffer syndrome with prognostic trends. He emphasized that such subtypes do not have genetic or nosologic status as separate entities; clinical overlap does occur (8,10).

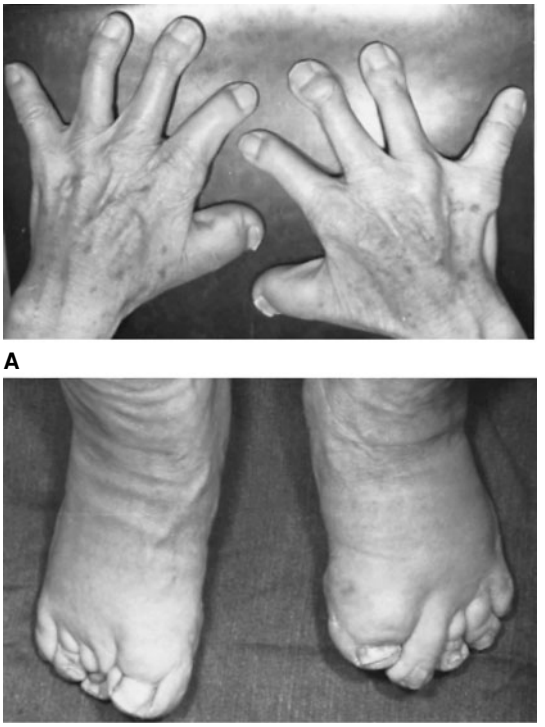
Classic Pfeiffer syndrome (type 1) is likely to be compatible with life and normal or near normal intelligence in most cases, with mild mental deficiency occurring in others. Autosomal dominant families have been recorded (8) (Figs. 14–6 to 14–8).

Type 2 Pfeiffer syndrome is characterized by cloverleaf skull, severe ocular proptosis, often severe CNS involvement such as hydrocephalus, elbow ankylosis/synostosis, broad thumbs and great toes, and a clustering of unusual low frequency anomalies that are frequently inconsistent from case to case (13,18,22,38,49,50) (Fig. 14–9A). The elbow ankylosis is not invariably present (1). All known cases have been sporadic (8). No classic type 1 pedigree has shown enough variability of expression to include a Pfeiffer cloverleaf case within the pedigree. One of us (MMC) cannot accept the example of the Pfeiffer syndrome mother and child reported by Soekarman et al (47). The son reportedly had cloverleaf skull, but the photographs do not suggest this interpretation.

Type 3 Pfeiffer syndrome is similar to type 2 but lacks cloverleaf skull (Fig. 14–9B). Hallmarks include severe ocular proptosis, shallow orbits, and marked shortness of the anterior cranial base. A clustering of unusual low frequency anomalies that are frequently inconsistent from case to case can be found with type 3 as well as with type 2. To date, type 3 cases have been sporadic (8,20).

Fig. 14–6. *Pfeiffer syndrome, type 1.* (A,B) Hypertelorism, downslanting palpebral fissures, and midface deficiency.

A B



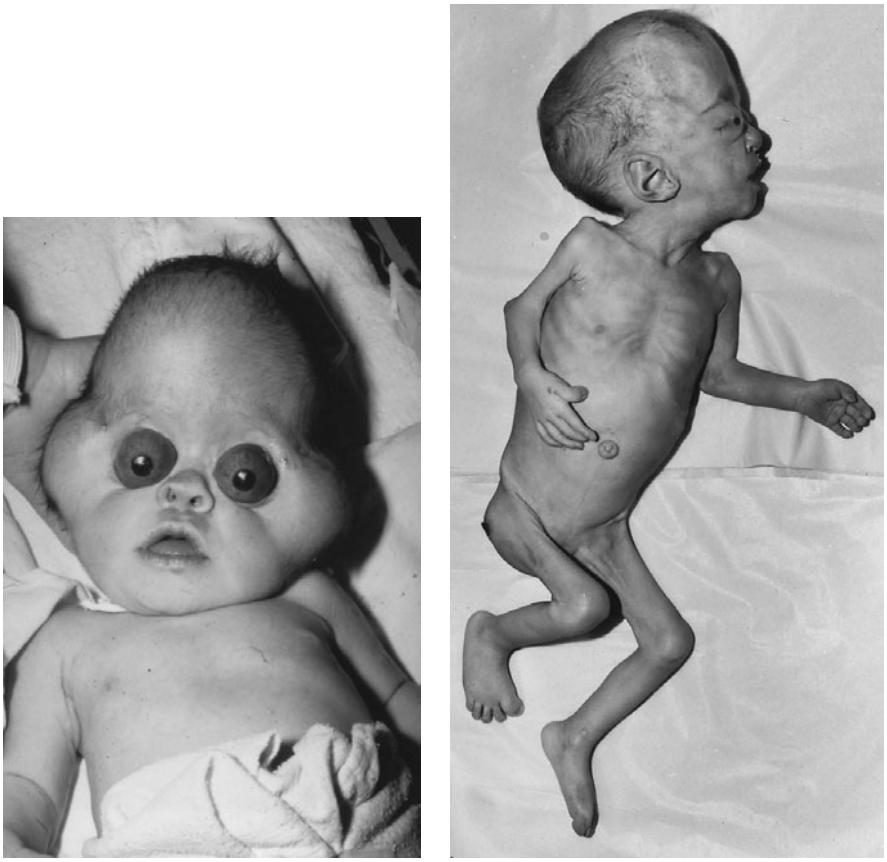
A

B

Fig. 14–7. *Pfeiffer syndrome, type 1.* (A) Broad radially deviated thumbs, brachydactyly, and clinodactyly of terminal phalanges. (B) Broad halluces and crooked toes.

Craniofacial features. The skull in type 1 is usually turribrachycephalic. Craniofacial asymmetry may be present in some instances. Maxillary hypoplasia and relative mandibular prognathism are observed. The nasal bridge is depressed. Hypertelorism, downslanting palpebral fissures, ocular proptosis, and strabismus are common (7,37,43) (Fig. 14–6).

Fig. 14–8. *Pfeiffer syndrome, type 1.* Radiograph showing malformed fused phalanges of thumbs, brachymesophalangy, symphalangism, fusion of proximal ends of fourth and fifth metacarpals.



A B

Fig. 14–9. *Pfeiffer syndrome*. (A) *Type 2*. Note cloverleaf skull and severe ocular proptosis. (B) *Type 3*. Premature synostosis of coronal suture. Note severe proptosis, hypoplastic supraoribtal ridges, and malar eminences, fixed hypertension of cervical spine, ankylosis of elbows, and pectus excavatum. Note broad thumb and great toes. (From MM Cohen Jr, Am J Med Genet 45:300, 1993.)

The nose may be beaked. The palate is highly arched, the alveolar ridges are broad, and teeth are crowded (7). Some affected individuals are fair and have prominent scalp veins. Natal teeth have been documented in type 3 Pfeiffer syndrome (2).

Central nervous system. Distortion ventriculomegaly, midline calvarial defect, progressive hydrocephalus, and cerebellar herniation are commonly encountered. Progressive hydrocephalus is found more frequently with Pfeiffer syndrome and Crouzon syndrome than with Apert syndrome (10,30). Central nervous system involvement occurs with much higher frequency in type 2 and type 3 patients than in type 1 patients (8,10). Gosain et al (15) reported morbidity and outcome of elevated intracranial pressure in patients with Pfeiffer syndrome. Mortality has been reported by Gosain et al (15) and Moore et al (29).

Hands and feet. The thumbs and great toes are broad (Fig. 14–7), usually with varus deformity (37). Mild soft tissue syndactyly may especially involve digits 2 and 3 and sometimes digits 3 and 4 of both hands and feet (7,37). Partial soft tissue syndactyly between toes 1 and 2 has also been reported (3,7,55). Brachydactyly may be observed and, in some cases, syndactyly is absent (7). Clinodactyly has also been noted (7,26,43).

Brachymesophalangy of both hands and feet is frequently present. Middle phalanges may be absent in some cases. The distal phalanx of the great toe is broad, and the proximal phalanx malformed. The first metatarsal is broad, may be shortened, and may be duplicated in some instances (7,26,27,37).

Accessory epiphyses in the first and second metatarsals and double ossification centers in the proximal phalanx of the great toe have been reported. Partial duplication of the great toe may be observed occasionally. Symphalangism of both hands and feet has been reported. Fusion of carpals and tarsals, in some instances involving the proximal ends of the metacarpals and metatarsals, respectively, has also been noted (7,27,36,55) (Fig. 14–8).

Other findings. Fused cervical vertebras and lumbar vertebras have been described (17,31). Shortened humerus, cubitus valgus, radiohumeral and radioulnar synostosis, abnormalities of the pelvis, coxa valga, and talipes calcaneovarus have been reported occasionally (7,10,27,43). Other abnormalities have included choanal stenosis, solid cartilaginous trachea, ventricular septal defect, patent ductus arteriosus, pyloric stenosis, umbilical hernia, malpositioned or imperforate anus, bifid scrotum, cryptorchidism, widely spaced nipples, ptosis of eyelids, corectopia, scleralization of the cornea, optic nerve hypoplasia, preauricular tag, absent external auditory canals, hearing deficit, bifid uvula, supernumerary teeth, and gingival hypertrophy (3,7,10,11,14,19,27,33,34, 43,49,51).

Differential diagnosis. Pfeiffer syndrome should be distinguished from *Apert syndrome*, *Crouzon syndrome*, *Saethre-Chotzen syndrome*, and *Jackson-Weiss syndrome*. Sporadic cases of Pfeiffer syndrome with coincidental stub thumb of normal thickness in the mother have been noted (21,39). Winter (54) suggested that several cases of Pfeiffer syndrome with prune belly (5,6,13) should be grouped as a separate syndrome, the Eaton-Bracero syndrome. However, Cohen and Barone (9) prefer to keep them in type 3, at least temporarily.

FGFR3-associated coronal synostosis syndrome (Muenke craniosynostosis)

Muenke et al (10) and Bellus et al (2) reported a unique point mutation on fibroblast growth factor receptor (FGFR3) causing a newly recognized autosomal dominant condition characterized by unilateral or bilateral coronal synostosis, a variety of minor anomalies, and remarkably variable expressivity. Other cases with this mutation have been described (4–6, 9,11,12).

Genetics. The identified mutation, FGFR3 Pro250Arg (2,9,11) may be the highest transversion rate currently known in the human genome (9) (Fig. 14–1). Muenke et al (10) reported 61 cases; autosomal dominant inheritance was observed in 12 of the families. Expressivity is extremely variable, but it is more often expressed in females (8). Golla et al (2) described a patient with cloverleaf skull; another affected member of the family had unilateral coronal synostosis with marked facial asymmetry. Muenke et al (10) described two sibs with bilateral coronal synostosis; the affected father had macrocephaly only. Gripp et al (6) found four mutations (Pro250Arg) among 37 sporadic cases of unicoronal synostosis (11%). It is particularly noteworthy that three fathers of unicoronal probands tested positive for the mutation themselves. None of the three fathers had craniosynostosis and had never come to medical attention previously. They were unaware of their 50% risk of passing the mutation on to their other children. Nonpenetrance was also found by Robin et al (12). It must be emphasized that the 50% recurrence risk is for the mutation per se, not for the phenotype. The prevalence of the abnormal phenotype in mutation carriers is unknown at present.

Craniofacial features. The craniofacial phenotype is variable. Coronal synostosis, either unilateral or bilateral, is common. Some patients have macrocephaly without craniosynostosis. One of us (MMC) observed a patient with macrocephaly and unicoronal synostosis. Midface hypoplasia, downslanting palpebral fissures, ptosis of the eyelids, and highly

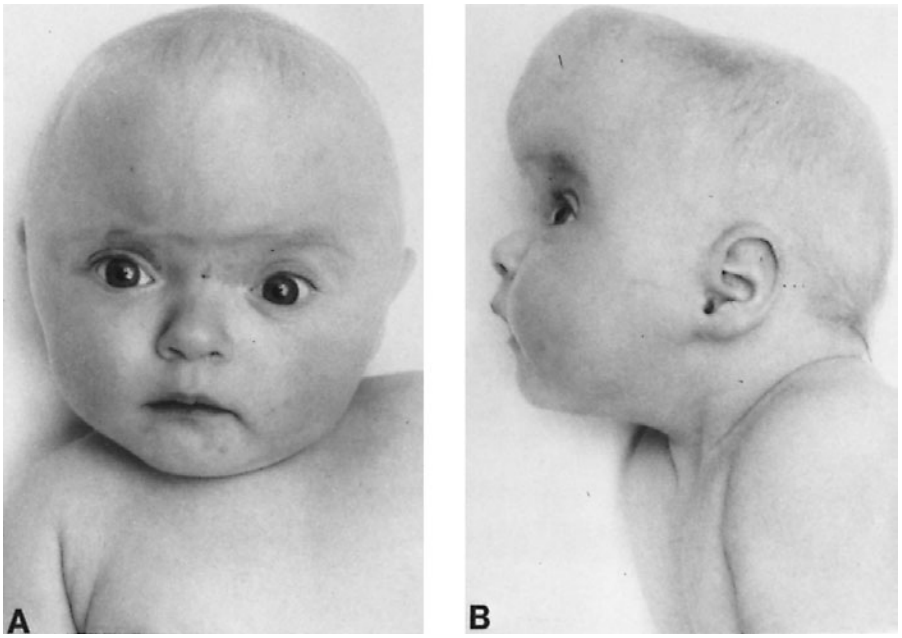

Fig. 14–10. *FGFR associated coronal synostosis (Muenke craniosynostosis).* (A,B) Unusual head form and facial asymmetry. (From IA Glass et al, Clin Dysmorphol 3:215, 1994.)

arched palate have been documented (10) (Fig. 14–10). Cloverleaf skull has been noted (4).

Performance. Developmental delay or learning disabilities have been found in 37% of patients (10). This is not related to craniosynostosis per se, but is part of the clinical spectrum in both familial and sporadic cases (11).

Other clinical findings. Brachydactyly has been observed in both the hands and the feet in some cases. Broad halluces have also been noted. However, medial or lateral deviation does not occur.

Radiographic findings. Thimble-like middle phalanges are particularly common in the hands. Cone-shaped epiphyses have been found in both hands and feet. Carpal and tarsal coalitions have been noted (5,10) (Fig. 14–11).

Diagnosis. All patients with nonsyndromic coronal synostosis, either bilateral or unilateral, should be screened for the Pro250Arg mutation in FGFR3. This is true for both sporadic and familial cases of coronal synostosis. Sporadic cases that test positive also require testing of the phenotypically normal parents. Some patients have macrocephaly without craniosynostosis. Patients with a mild Saethre-Chotzen-like phenotype or a Pfeiffer-like phenotype, who are FGFR1, FGFR2, and TWIST negative, should be screened for this particular mutation.

Adelaide type craniosynostosis (7), earlier reported as Jackson-Weiss syndrome (1) has been shown to have the Pro250Arg mutation in FGFR3 (10). The craniosynostosis-brachydactyly syndrome (3) has also been found to have this mutation (10). The large kindred of craniosynostosis suggestive of Saethre-Chotzen syndrome that did not map to 7p21 (13) also has this mutation (4).

Prenatal diagnosis. For molecularly proven families or sporadic cases, prenatal diagnosis is possible by chorionic villus sampling or amniocentesis.

Saethre-Chotzen syndrome

Saethre-Chotzen syndrome is characterized by a broad and variable pattern of malformations, including craniosynostosis, low-set frontal hairline, facial asymmetry, ptosis of eyelids, deviated nasal septum, brachydactyly, partial soft tissue syndactyly, especially of the second and third fingers, and various skeletal anomalies. Autosomal dominant inheritance is evident with a high degree of penetrance and variable expressivity (3,4,6,7,14,27,28). Incomplete penetrance was documented by Carter et al (6). A nice review of the present molecular status is that of Zackai and Stolle (45).

First recognized as an entity by Saethre (39) in 1931 and by Chotzen (7) in 1932, many authors have since reported affected families (1–4,6,7,11, 13,14,17,19,20,25–28,30,31,38,42). The most extensive early discussion and delineation of the syndrome was published by Pantke et al (28).

Saethre-Chotzen syndrome is caused by mutations in the *TWIST* gene located at 7p21 (5,23,24,32). The *TWIST* gene codes for a transcription factor containing a basic helix-loop-helix motif. Nonsense, duplication, missense, and frameshift mutations have been detected (9,16,29,35). Most mutations truncate the TWIST protein, resulting in haploinsufficiency. Loss-of-function may also be caused by missense mutations. Johnson et al (18) identified microdeletions of chromosome band 7p21.1 that are not detectable by conventional cytogenetic analysis unless a translocation is present. Balanced translocation has been reported (32,36,41,43). Both protein degradation and cellular mislocalization are causative mechanisms (9a).

Craniofacial features. Craniosynostosis is a facultative rather than an obligatory abnormality (1,14). When present, the time of onset and degree of craniosynostosis are quite variable. Brachycephaly or acrocephaly with coronal sutural synostosis is frequently observed, and involvement is often asymmetric, producing plagiocephaly and facial asymmetry (14) (Fig. 14–12). Trigonocephaly has also been observed (8,17). Cloverleaf skull was noted in one instance (RD Clark, personal communication, 1994). Frontal bossing, parietal bossing, and flattened occiput have been reported in various cases. Large late-closing fontanelles, large parietal foramina, ossification defects of the calvaria, and enlargement of the sella turcica have also been recorded (44). Calvarial hyperostosis was found in one family (1,7,14,28).

Low-set frontal hairline is commonly observed. Ptosis of eyelids, ocular hypertelorism, and strabismus are common. Occasionally, the forehead may be protuberant in association with metopic synostosis and hypotelorism. Blepharophimosis is evident in some cases. Tear duct stenosis may be a feature. Low-frequency findings have included epicanthic folds, optic atrophy, downslanting palpebral fissures, irregular eyelid margins, and sparse eyebrows medially with heavy eyebrows laterally (3,7,14,28).

The ears may be low-set, small, posteriorly angulated, or may have folded helices or prominent antihelical crura. Mild conductive hearing loss is common (10,28). Congenital atresia of the external auditory meatus has been documented (10).

Fig. 14–12. *Saethre-Chotzen syndrome*. (A,B) Acrocephaly, facial asymmetry, low hairline. (C,D) Son of man seen in A and B. Note eyelid ptosis.

The nasofrontal angle may be flattened in some instances. Maxillary hypoplasia with relative mandibular prognathism may be evident. The midface may be broad and flat in some cases. Deviation of the nasal septum is often found (14,28).

Oral anomalies include narrow or highly arched palate, cleft palate on occasion, malocclusion, supernumerary teeth, enamel hypoplasia, and other dental defects (3,14,28).

Performance. Intelligence is usually normal. However, mild-to-moderate mental deficiency has been observed in a number of cases (3,7). Significant learning difficulties were found in the patients with microdeletions reported by Johnson et al (18). Neonatal seizures, epilepsy, and schizophrenia have also been noted (3,7,10,39).

Hands and feet. Some degree of brachydactyly may be observed (28). Partial cutaneous syndactyly is present in some instances, most frequently between the second and third fingers, but sometimes extending from the second to fourth fingers (3,7,26,39) (Fig. 14–13). Clinodactyly, especially of the fifth finger, has been found in some cases (1,14). The distal phalanges may be hypoplastic, and, on occasion, finger-like thumbs have been noted (14). Dermatoglyphic findings have included single palmar creases, distally placed axial triradii, increased frequency of thenar and hypothenar patterns, increased frequency of fingertip arch patterns, and low total ridge count (1,3,14,28).

Fig. 14–13. *Saethre-Chotzen syndrome*. Soft tissue syndactyly between second and third fingers. (From CS Bartsocas et al, J Pediatr 77:267, 1967).

Partial cutaneous syndactyly between the second and third toes, but occasionally involving other toes, has been reported (3,7,22,39). Broad great toes and hallux valgus have been noted in some instances (14,28,39) and dorsiflexion of the fourth toes has been observed (3).

Radiographic features have been discussed by Anderson et al (2). The most common finding was an enlarged epiphysis of the distal phalanx of the thumb. Less commonly observed were pseudoepiphyses of the metacarpals. Bifid distal phalanges have been noted in some patients (19,22). Partial duplication of the first metatarsal has also been recorded (22).

Other findings. Short stature has been documented in some instances (1,28). Defects of the cervical and lumbar spine have been reported by several authors (7,28,39). Radioulnar synostosis was noted by Bartsocas et al (3) and short fourth metacarpals were reported by Aase and Smith (1). Friedman et al (14) documented short clavicles, limitation of motion at the elbows, small ilia, large ischia, and coxa valga. Legius et al (22) noted fused cervical vertebrae. Other findings have included cryptorchidism, renal anomalies, congenital cardiac defects, and imperforate anus (1,3,7,10,28). Escobar et al (11) reported a case with congenital adrenal hyperplasia. McKeen et al (26) observed an affected family in which multiple malignancies occurred, including nasopharyngeal carcinoma, Hodgkin's disease, and embryonal cell carcinoma of the testis. However, the Saethre-Chotzen syndrome and the familial malignancies were probably inherited independently. Etzioni et al (12) described a patient with Saethre-Chotzen syndrome and defective neutrophil chemotaxis. Boeck et al (4a) noted the co-occurrence of hyper IgE (Job) syndrome and Saethre-Chotzen syndrome. Russo et al (38) reported a case with renal tubular dysgenesis, which probably occurred coincidentally.

Differential diagnosis. Saethre-Chotzen syndrome is frequently confused with simple craniosynostosis. It is important to recognize that few anomalies in Saethre-Chotzen syndrome are obligatory and individual patients may not necessarily have craniosynostosis (14) or syndactyly or ptosis of the eyelids or facial asymmetry. The variability of expression found in Saethre-Chotzen syndrome can make clinical diagnosis difficult in some cases (29).

A patient with presumed Baller-Gerold syndrome with a *TWIST* mutation (15) had facial features of Saethre-Chotzen syndrome: craniosynostosis, brachycephaly, ocular hypertelorism, occipital ossification defect, and hallux valgus. The upper limb reduction defect was unilateral, which is not found in Baller-Gerold syndrome; limb defects are bilaterally symmetric. The father who also harbored the *TWIST* mutation had facial asymmetry and hallux valgus. Two conditions once thought to constitute separate nosologic entities—auralcephalosyndactyly (21) and Robinow-Sorauf syndrome seem to be examples of Saethre-Chotzen syndrome (22).

Diagnostic confirmation of Saethre-Chotzen syndrome is possible by identifying a mutation in the *TWIST* gene. Saethre-Chotzen-like patients who are *TWIST* negative should be tested for *FGFR3* Pro250Arg (*Muenke craniosynostosis*).

Laboratory aids. Fluorescent in situ hybridization (FISH) can be used to detect large deletions, but Gripp et al (15a), employing Southern blot analysis with a PCR generated probe, has improved the analytic methods of Johnson et al (18).

Carpenter syndrome (acrocephalopolysyndactyly)

Carpenter syndrome is characterized by craniosynostosis, commonly but not always preaxial polysyndactyly of the feet, short fingers with clinodactyly, and variable soft tissue syndactyly, sometimes postaxial polydactyly, and other abnormalities, such as congenital heart defects, short stature, obesity, and mental deficiency (Figs. 14–14 to 14–16). First described by Carpenter in 1901 (3) and 1909 (4), the syndrome was not recognized as a distinct nosologic and genetic entity until Temtamy's report (35) in 1966. Extensive reviews are available (5–7), the most complete being that of Cohen andMacLean (8). Approximately 45 cases have been recorded to date (1–6,9–12,14,17,30,33–37).

Affected sibs (3–5,11,14,15,19,22,24,25) have been reported, and sporadic occurrences (6,9–11,20,23,33–37) have been described. Consanguinity was noted in the case recorded by Der Kaloustian et al (9) and may also have been present in the sibs described by Rudert (28). Carpenter syndrome clearly has autosomal recessive inheritance.

Height is usually below the 25th centile, but in some instances may be above the 60th centile. Weight is often above average. Obesity of the trunk, proximal limbs, face, and neck is common (35).

Craniofacial features. Craniosynostosis usually involves the sagittal and lambdoid sutures first, the coronal being last to close. The calvaria may be grossly malformed in some instances, but variable in shape

Fig. 14–14. *Carpenter syndrome*. Asymmetric tower-shaped skull, short neck, soft tissue syndactyly of third and fourth digits. (From V Der Kaloustian et al, Am J Dis Child 124:716, 1972.

(Fig. 14–14). In many cases, unilateral involvement of the coronal or lambdoid suture produces marked cranial asymmetry (6,8). Wormian bones were noted in the anterior fontanel in one case (20). The cloverleaf skull anomaly has been observed in association with Carpenter syndrome (6). One instance of otherwise classic Carpenter syndrome did not exhibit craniosynostosis (8). Dystopia canthorum and mildly downslanting palpebral fissures are observed. Epicanthic folds, microcornea, corneal opacity, slight optic atrophy, and blurring of the disc margins have been reported in some instances (3,4,18,35). The ears appear low set (33,35) and the neck is short. Preauricular fistulas have been

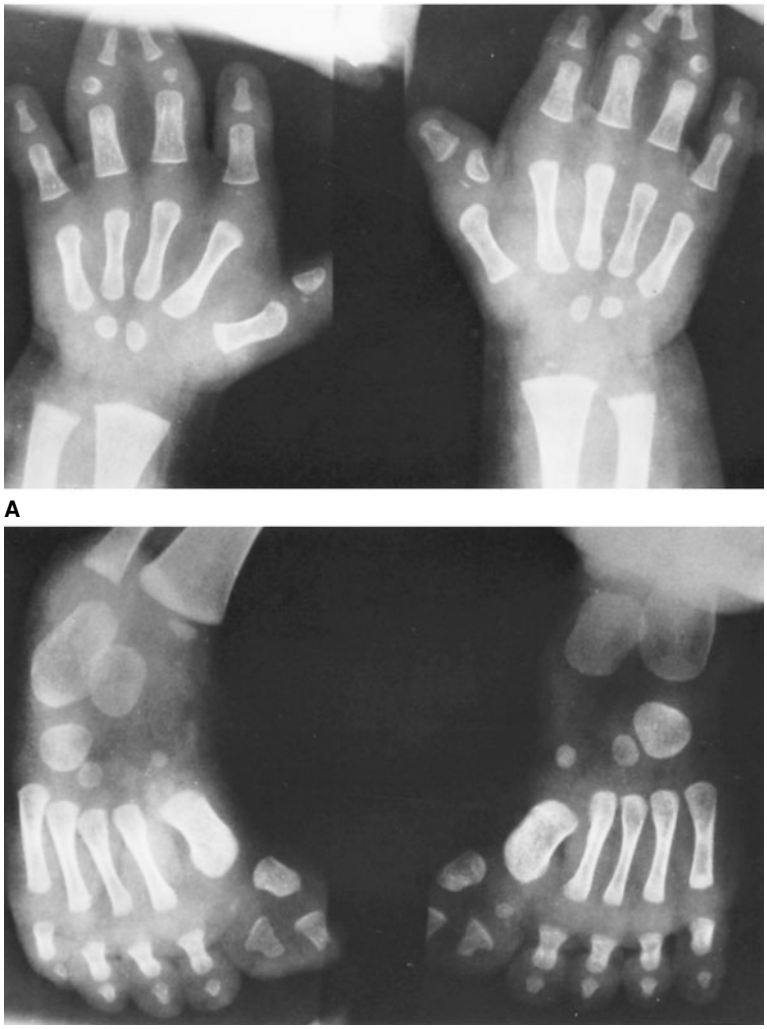

Fig. 14–16. *Carpenter syndrome*. (A,B) Note especially brachymesophalangy and agenesis of middle phalanges together with soft tissue syndactyly and clinodactyly of the third and fourth digits; also polysyndactyly of halluces, varus deformity, broadening of the first metatarsal, and absent middle phalanges. (From H Schönenberg and E Scheidhauser, Monatsschr Kinderheilkd 114:322, 1966).

noted (37). The mandible may be somewhat small, and the palate may be narrow or highly arched (8).

Performance and central nervous system. Mental deficiency has been a feature in many patients with Carpenter syndrome, but normal intelligence is also encountered (5,11,13,16,17,26,31,32,34,38). Warkany's patient was estimated to have an IQ of 70 (29). Early craniectomy may possibly prevent mental deficiency. However, normal intelligence has been observed without neurosurgical intervention. Furthermore, mental deficiency has been noted despite early craniectomy, suggesting a primary brain abnormality in at least some cases of Carpenter syndrome.

Hands and feet. The hands are short and the fingers stubby. Marked soft tissue syndactyly may be present, especially between the third and fourth fingers with less marked involvement between other fingers. In some cases, minimal or no syndactyly may be evident. Clinodactyly of the fingers, single flexion crease, and sometimes postaxial polydactyly may be observed. Radiographically, brachymesophalangy, or agenesis of the middle phalanges is evident (Fig. 14–16). A tongue-shaped projection may extend from the radial side of the epiphysis of the proximal phalanx of the second finger. Two ossification centers in the proximal phalanx of the thumbs have been reported (35,37).

Abnormalities of the feet include bilateral varus deformities and commonly but not always preaxial polydactyly with duplication of the second toes or halluces. Soft tissue syndactyly may be observed between the toes, and only two phalanges are present in each toe (35) (Fig. 14–15).

Cardiovascular anomalies. Congenital heart defects have been reported in approximately 33%. Anomalies have included VSD, ASD, PDA, pulmonic stenosis, and tetralogy of Fallot. Transposition of the great vessels and anomalous duplication of the superior vena cava have also been noted (7,8).

Other abnormalities. Genua valga and lateral displacement of the patellae are common. Other skeletal findings have included decreased hip-joint mobility, flaring of the ilia with poor development of the acetabula, coxa valga, absent coccyx, spina bifida occulta, and scoliosis (19,30,33,35). Umbilical hernia or omphalocele has been a feature in a number of cases. Other findings have included cryptorchidism, inguinal hernia, hydronephrosis, hydroureter, and accessory spleens (3,4,6,7,10,18,20,30,33,35,37).

Differential diagnosis. Carpenter syndrome is sometimes confused with *Apert syndrome, Bardet-Biedl syndrome*, and *Sakati syndrome*. The conditions known as Summitt syndrome (31,32) and Goodman syndrome or acrocephalopolysyndactyly type IV (13) represent examples of Carpenter syndrome (8,12,15). This problem is thoroughly analyzed elsewhere (8).

Cloverleaf skull (Kleeblattschädel)

Classically, cloverleaf skull or Kleeblattschädel consists of a trilobular skull with craniosynostosis. However, the degree of severity varies and different sutures may be involved in different patients. Holtermüller and Wiedemann (25) first identified the condition in 1960 and noted several earlier cases. Over 90 cases of the subject are known (1–7, 21–65). The most extensive reviews are those of Cohen (9–16,18), and Cohen and MacLean (18). An early case was described by Vrolik (60) in 1849. Another possible early example is that of Nettleship (45) in 1887.

Synostosis may involve the coronal, lambdoid, and metopic sutures, with bulging of the cerebrum through an open sagittal suture or, in some cases, through open squamosal sutures. Synostosis of the sagittal and squamosal sutures with cerebral eventration through a widely patent anterior fontanel may also be observed. Finally, a trilobular skull may occur with complete synostosis of all cranial sutures in some instances or with widely patent sutures and no evidence of craniosynostosis at birth in other instances.

When cloverleaf skull is severe, the ears are displaced downward, facing the shoulders. Midface hypoplasia and relative mandibular prognathism are frequently encountered. The nasal bridge is low and, in some cases, the nose may be beak-like. Severe proptosis, hypertelorism, and downslanting palpebral fissures are common. The eyelids may fail to close, leading to corneal ulceration and clouding. Venous distention of the scleras, eyelids, periorbital areas, and scalp has been noted (2,11–15,18,24,30,31,41) (Figs. 14–17 and 14–18).

Radiographically, the skull has a trilobular contour with marked convolutional impressions and a thin, distorted vault, giving a honeycomb appearance. Synostosis and shortening of the cranial base have been reported. The posterior cranial fossa is small (4,52,64) (Fig. 14–19). In some cases, shortening of the cranial base with concomitant distortion of the hindbrain may be responsible for cerebrospinal fluid obstruction at the level of the fourth ventricle (2,31), leading to hydrocephaly, which is commonly found with cloverleaf skulls. Obstruction of the cerebral aqueduct has been demonstrated in one instance (23). Hypoplasia and malformation of orbits, sphenoid, ethmoid, nasal bones, and maxilla are common. In one case (19), the orbits and zygomatic arches were absent.

Early demise has been noted in most cases, although there have been exceptions (23,64). One patient is known to have been 14 years old (23).

Fig. 14–18. *Cloverleaf skull*. Cloverleaf skull in infant with bilateral oblique facial clefts. Child also had intrauterine amputation of digits. (From A Schuch and HJ Pesch, Z Kinderheilkd 109:187, 1971).

Changes in skull shape were noted with age. At birth the skull was trilobular, but by 14 years of age, skull shape had changed dramatically.

As mentioned above, hydrocephaly is common (2,19,31). Psychomotor retardation (2,62), small cerebellum (2), cerebellar herniation, polymicrogyria (30), and various other brain anomalies (32) have been reported. Other findings have included iris colobomas, blindness, obstructed nasolacrimal ducts, absent external auditory canals, macrostomia, macroglossia, oblique facial clefting, cleft lip-palate, bifid uvula, highly arched palate, natal teeth, malocclusion, PDA, ASD, bicuspid aortic valve, common mesentery, absent lesser omentum, hypoplastic gallbladder, single umbilical artery, and omphalocele (2,10,18,19,20,23,30).

Fig. 14–19. *Cloverleaf skull*. Radiograph showing classic trilobular skull. (From MW Partington et al, Arch Dis Child 46:656, 1971.)

Cloverleaf skull is known to be both etiologically and pathogenetically heterogeneous (9,12,14,18,30). Kokich and co-workers (38) demonstrated heterogeneity at the anatomic and histologic levels in two different cloverleaf specimens. Although both exhibited premature fusion of the coronal, sagittal, and lambdoid sutures, the interrelationships and spacial orientation of their respective articulations and skeletal components differed markedly.

Etiologic heterogeneity has been demonstrated repeatedly (9,11–18). Cloverleaf skull is nonspecific—that is, the condition may be observed as an isolated anomaly or together with other anomalies making up various syndromes known to have different causes. Diagnosis is made on the basis of the overall pattern of anomalies. Syndromes associated with the cloverleaf skull anomaly include amniotic rupture sequence (57,63), Apert syndrome (51), Beare-Stevenson cutis gyrata syndrome (28), Carpenter syndrome (9), Crouzon syndrome (27,58), COH syndrome (18), osteoglophonic dysplasia (36), dup 4p (50), dup(13q) syndrome (42), dup(15q) syndrome (47), type 2 Pfeiffer syndrome (18,20,30,62), Saethre-Chotzen syndrome (8), Say-Poznanski syndrome (56), type 2 thanatophoric dysplasia (18,40,46), rarely type 1 thanatophoric dysplasia (18), Cumming syndrome (49), FGFR3-associated coronal synostosis syndrome (25), Loschge syndrome (43,44), osteocraniostenosis (59), Shprintzen-Goldberg syndrome (53), and Boston type craniosynostosis (61). Cloverleaf skull with "campomelic dysplasia of the craniosynostosis type" (37) may represent an example of Antley-Bixler syndrome. Cloverleaf skull has been reported with hypochondroplasia (3). Although craniosynostosis was evident, a rare finding, we cannot agree that there was cloverleaf skull.

It has been estimated that approximately 40% (n = 51) of all cloverleaf skull malformation cases represent thanatophoric dysplasia and about 20% represent Pfeiffer syndrome (30). The great variety of other malformations reported in association with the cloverleaf skull anomaly suggests that several unknown genesis syndromes in this group may become further delineated in the future (10,12,18). Ultrasonographic evaluation of affected fetuses may permit correct antenatal diagnosis of cloverleaf skull (4,6).

Chapter 15
Syndromes with Craniosynostosis: Miscellaneous Syndromes

Acrocephalospondylosyndactyly

Wells et al (277), in 1990, described a male infant with craniosynostosis, acrobrachycephaly, syndactyly of all extremities, midface hypoplasia, parrot-beak nose, exophthalmos, hypertelorism, exotropia, huge pinnae, and short upper lip. The hands and feet resembled those of Apert syndrome. In addition, there were block thoracic vertebrae with progressive loss of intervertebral discs and platyspondyly. The thin posterior ribs had a fan-like configuration.

Other extremity anomalies included: flared metaphyseal ends of humeri, dislocated radii with immobile elbows, a tail-like structure, and a solid cartilaginous tracheal wall.

The syndrome may represent a severe example of *Apert syndrome*, but molecular delineation remains unknown.

Acrocraniofacial dysostosis

Kaplan et al (139) reported an oculo-oto-palato-digital syndrome in two sisters. Features consisted of short stature, craniosynostosis involving the coronal suture, ocular hypertelorism, ocular proptosis, ptosis of the eyelids, downslanting palpebral fissures, high nasal bridge, anteverted nostrils, short philtrum, cleft palate, micrognathia, mixed hearing loss, proximally placed thumbs and great toes, bulbous digits, metatarsus adductus, and other abnormalities (Fig. 15–1). Consanguinity was noted, strongly suggesting autosomal recessive inheritance.

Antley-Bixler syndrome

Characteristic features of Antley-Bixler syndrome are craniosynostosis, dysplastic ears, arachnodactyly, radiohumeral synostosis, femoral bowing, and joint contractures. Antley and Bixler (11) reported a case in 1975 and Lacheretz et al (155) reported one a year earlier. Over 30 cases have been observed to date (10a,11,12,21,23,34,60,66–68,79,113, 116,124,123,144,155,162,175,204,216,222,224,234,241,280,283). Extensive reviews are those of Crisponi et al (60), Hassell and Butler (113), and Poddevin et al (207). The syndrome has also been known as trapezoidocephaly-multiple synostosis syndrome (11), multisynostotic osteodysgenesis (68), and acrocephalosynankie (6,155,273). Cohen coined the term Antley-Bixler syndrome in 1977 (41) and used it again in 1979 (44).

The syndrome has been observed in sibs four times (162,175, 241,280) and consanguinity has been noted in several instances (79,155, 175,257,283). Thus, autosomal recessive inheritance is supported. Reardon et al (214) have noted that 7 of 16 patients had abnormal steroid biogenesis, and R Kelley (personal communication, 2000) noted a block at the level of lanosterol 14-alpha-demethylase, the site of action of the azole antifungals that cause a phenocopy (vide infra). Virilization of a female due to disturbed androgen metabolism has been noted (226a).

Prenatal diagnosis (134,234) has been made by ultrasound, with immobility and flexion at the elbows being essential findings. Polyhydramnios has been noted as a feature of pregnancy.

Respiratory obstruction leads to early demise in about 55% (11,68, 222,224). However, there have been long term survivors. The prognosis for intellectual development may be reasonable in some cases with appropriate multidisciplinary management (175).

Craniosynostosis usually involves the coronal and lambdoid sutures, resulting in a brachycephalic head shape (Fig. 15–2). When viewed from the top, head shape may be trapezoidal. Craniofacial features include large anterior fontanelle, frontal bossing, ocular proptosis, low nasal bridge, large nose, midface hypoplasia, choanal atresia or stenosis, and

Fig. 15–1. *Acrocraniofacial dysostosis*. (A) One of two sisters with acrocephaly, hypertelorism, shallow orbits, ptosis, downslanting palpebral fissures, dysmorphic pinnae. Both had cleft palate and pectus excavatum. (B) Feet of one sib showing metatarsus adductus and fingerlike halluces. (C) Radiograph of feet of older sib showing metatarsus adductus and severe hypoplasia of first metatarsal and digital phalanges. (A–C from P Kaplan et al, Am J Med Genet 29:95, 1988.)

low-set protruding ears (11,68) (Table 15–1). Arnold-Chiari malformation has been found in one case (34a).

Trunk abnormalities consist of a tower-shaped rib cage, gracile ribs, narrow pelvis, vertically slanted ilia, limited hip abduction, and/or hip dislocation. Limb anomalies include radiohumeral synostosis, joint contractures, medially bowed ulnas, synostosis of carpal bones, arachnodactyly with camptodactyly, femoral bowing, femoral fractures, synostosis of tarsal bones, rocker-bottom feet, and camptodactyly of the toes (11,12,68,222,224,241) (Fig. 15–3). Crisponi et al (60) reported a case with radioulnar synostosis and Chabchoub et al (34) without radiohumeral synostosis.

Congenital heart defects and urogenital anomalies (absent and/or ectopic kidney, duplication of kidney and ureter, dilated ureter, hypoplasia of labia majora, fused labia minora, lower vaginal atresia and/or urogenital sinus and clitoromegaly) have been observed in some instances. Other abnormalities include atresia of the external auditory canals, absent nipples, imperforate anus, vertebral anomalies, and lumbar meningomyelocele (113,116,222,241,283). Feigin et al (79) reported a patient who had, in addition, esophageal atresia and trisomy 21 syndrome. An increased frequency of fingertip whorl patterns has been noted (216).

Table 15–1. *Antley-Bixler syndrome*

Findings	%
Craniofacial	
Brachycephaly/trapezoidocephaly	100
Frontal bossing	100
Proptosis	100
Deep nasal bridge	100
Midface hypoplasia	100
Dysplastic ears	100
Pear-shaped nose	100
Small mouth	100
Long philtrum	90
Wide anterior fontanel	90
Choanal atresia	60
Stenotic ear canals	40
Skeletal	
Long fingers, long palm	85
Femoral bowing	100
Radiohumeral synostosis	100
Neonatal fractures	100
Multiple joint contractures	90
Abnormal toe position	70
Rocker-bottom feet	70
Urogenital	
Renal malformation	50
Vaginal atresia	50
Fused labia minora	30
Hypoplastic labia majora	30

(Adapted from LF Escobar et al, Am J Med Genet 29:829, 1988.)

Differential diagnosis. Bowing of long bones is also found with *campomelic syndrome*. Keutel (143) reported two male sibs with radiohumeral synostosis, mesomelia, microcephaly, patent sutures, downslanting palpebral fissures, broad nasal bridge, micrognathia, dysplastic ears, micropenis, and cryptorchidism. Consanguinity was established.

Chun et al (39) reported a patient with presumed Antley-Bixler syndrome. The patient had very few of the anomalies of the syndrome but had several that were at variance with it. Clearly, the patient does not have Antley-Bixler syndrome. Chun et al (39) found a mutation on FGFR2 (Ser351Cys). Gripp et al (106) and Palleyn et al (212a) reported two other patients with the same mutation.

Fluconazole embryopathy resembles Antley-Bixler syndrome (4a, 164a,206).

Pincus et al (206) reported the otolaryngologic manifestations of Antley-Bixler syndrome. One photograph (their Figure 2) shows clear-cut Apert syndrome with mitten syndactyly. The patient also had radiohumeral synostosis, which can be found in Apert syndrome.

Iida et al (127) reported a patient with many of the features of Antley-Bixler syndrome, but radiohumeral synostosis was not observed and Iida's patient had cleft soft palate.

Armendares syndrome

Armendares and co-workers (15,16) described a heritable syndrome consisting of growth deficiency, craniosynostosis, retinitis pigmentosa, and other anomalies. Bone age was delayed, but intelligence was normal. Craniosynostosis involved both the coronal and sagittal sutures. Craniofacial features included microcephaly, cranial asymmetry, small face, scant eyebrows, short obtuse nose, micrognathia, highly arched palate, and either prominent or malformed auricles. Ocular findings included ptosis of the eyelids, epicanthic folds, primary telecanthus, downslanting palpebral fissures, diminution of visual acuity, irregular dispersion of the retinal pigment resulting in atypical retinitis pigmentosa, constriction of the visual fields, and narrowing of the retinal arteries. Limb anomalies consisted of short fifth fingers with clinodactyly, wide fourth interdigital spaces, and single palmar creases.

The syndrome was reported in three male sibs from a Mexican mestizo family, and consanguinity was evident. Thus, autosomal recessive inheritance seems likely. However, X-linked recessive inheritance cannot be ruled out at present. The reporting of other affected families should resolve the mode of inheritance.

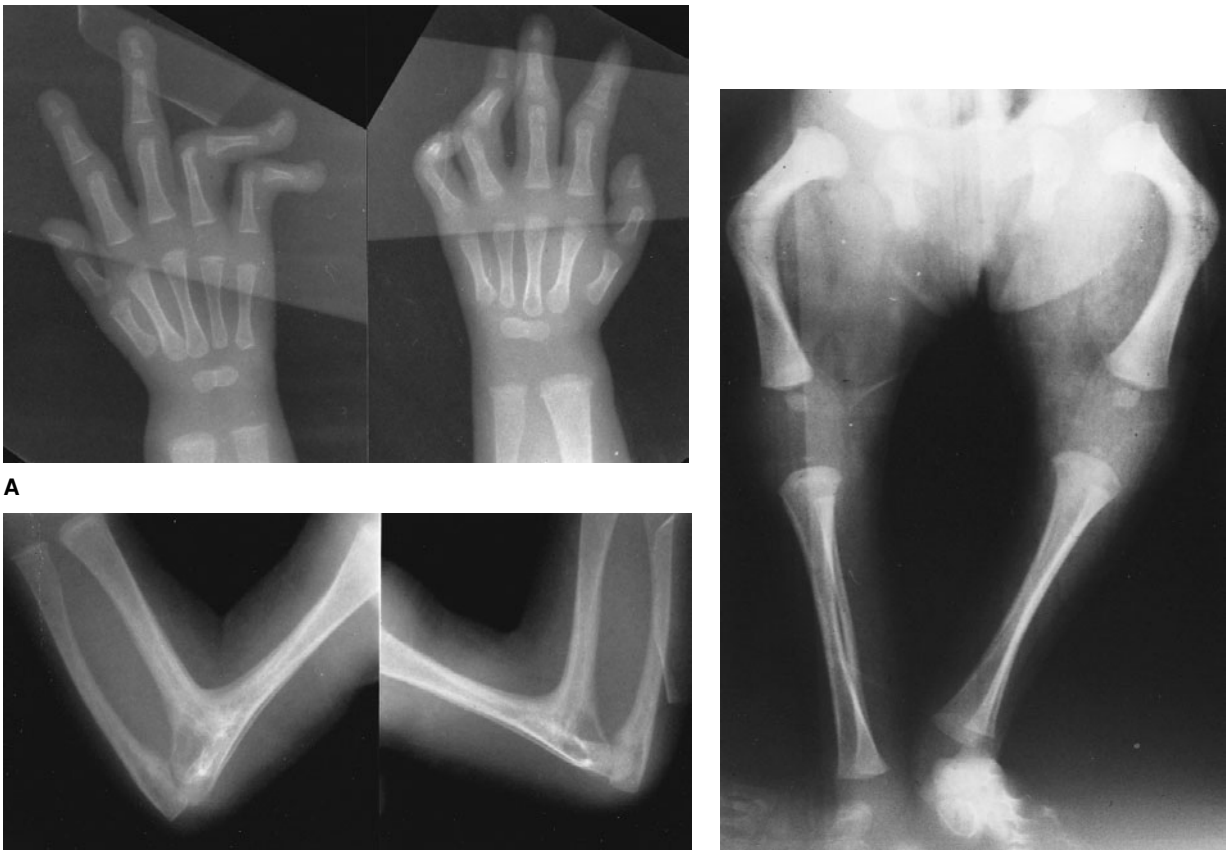

Fig. 15–3. *Antley-Bixler syndrome*. Radiographs. (A) Contractures, hypoplasia of terminal phalanges, and hamate-capitate fusion. (B) Bilateral radiohumeral synostosis. (C) Pronounced femoral bowing in a 6-week-old infant. (A,B from R Antley and D Bixler, Birth Defects 11(2):397, 1975. C from LK Robinson et al, J Pediatr 101:201, 1982.)

Fig. 15–4. *Baller-Gerold syndrome*. (A) Craniosynostosis and radial aplasia. (B) Note metopic ridging, short forearms (absent radii), and three fingers on each hand. (A from F Baller, Z Menschl Vererb Konstit-Lehre 29:782, 1950.)

Baller-Gerold syndrome

The original patients of Baller (17) and Gerold (96) had primary craniostenosis and preaxial upper limb malformations and, except for minor facial dysmorphism in one patient affecting the ear and the mandible, no other abnormalities were present (Fig. 15–4). The name Baller-Gerold syndrome was coined by Cohen in 1979 (45).

The delineation of the syndrome since then shows the addition of a large number of associated abnormalities including, among others, anal stenosis and/or malposed anus, and anomalies of the cardiovascular, genitourinary, skeletal, and central nervous systems (14,15,24,63,93,104,136, 164,167,194,200,213,217,219,231,232,246,262,268,282). Savarirayan et al (232) reported a congenital portal venous malformation in a 2-year-old patient.

Baller-Gerold syndrome has autosomal recessive inheritance. Verloes and Van Maldergem (271) reported that four of six sibs were affected. Gerold (96) also noted affected sibs. Consanguinity was documented by Gerold (96) and Pelias et al (200). Affected like-sexed dizygotic twins were described by Woon et al (282) and affected monozygotic twins were reported by Franceschini et al (85).

Diagnosis of Baller-Gerold syndrome can be more difficult than perhaps initially apparent (Table 15–2). The syndrome has phenotypic overlap with Fanconi anemia (78,226,265), VACTERL association (208,226), Roberts syndrome (118,126,191), and Rothmund-Thomson syndrome (209). Critical review of phenotypic overlap and differential diagnosis has been provided by Cohen and Toriello (58).

A patient with presumed Baller-Gerold syndrome with the only *TWIST* mutation known in the post-Helix II domain at this writing (Glu181Stop) (105), had facial features of Saethre-Chotzen syndrome. Furthermore, the upper limb reduction defect was unilateral, which is not found in Baller-Gerold syndrome; limb defects are bilaterally symmetric. Other family members with this mutation had no limb reduction defects (105), but did have several features of Saethre-Chotzen syndrome.

The work-up for this spectrum of patients should have the widest possible latitude; the diagnosis of Baller-Gerold syndrome is one of exclusion (58). Evaluation should include cytogenetic testing for Roberts syndrome and periodic hematologic screening for abnormalities suggestive of Fanconi anemia, which can first appear up to 10 years of age (232). VACTERL association has been discussed by Froster et al (86).

Table 15–2. Features of the *Baller-Gerold syndrome*

Features	Frequency
Growth	
Deficiency	8/9
Performance	
Sudden infant death	3/10
Mental and/or motor retardation	2/5
Cranial	
Craniosynostosis	10/10
Polymicrogyria	1/10
Facial	
Epicanthic folds	3/8
Prominent nasal bridge	3/9
Midline capillary hemangioma	2/7
Malformed ears	5/9
Low-set ears	2/9
Cleft palate	2/10
Bifid uvula	2/10
Highly arched palate	2/10
Micrognathia	2/10
Prominent mandible	2/10
Upper limbs	
Absent thumbs, radial hypoplasia or aplasia, associated limb defects	10/10
Other anomalies	
Cardiac[a]	2/10
Renal[b]	2/6
Anal[c]	4/7
Skeletal[d]	7/9

[a] Ventricular septal defect; subaortic valvular hypertrophy.
[b] Pelvic kidney; crossed renal ectopia.
[c] Anteriorly placed anus; imperforate anus; imperforate anus with perineal fistula.
[d] Lordosis at junction of skull and cervical spine; limited range of motion at shoulders, elbows, and knees; rib fusions and flat vertebrae in the dorsal area; absent vertebral bodies; sacral anomaly; anomalies of pelvic girdle and lower limbs; absent middle phalanges in fingers 2 and 5; absent middle phalanges in toes 2-5; metatarsus adductus.
(From MM Cohen Jr, Craniosynostosis: Diagnosis, Evaluation, and Management. Raven Press, New York, 1986.)

Beare-Stevenson cutis gyrata syndrome

In 1992, Hall et al (109) delineated the Beare-Stevenson cutis gyrata syndrome. Earlier cases had been reported by Beare et al (19), in 1969, and Stevenson et al (251) in 1978. Other cases were published by Andrews et al (10), Bratanic et al (26), and Krepelová et al (150).

Features consist of corrugated skin furrows, acanthosis nigricans, craniosynostosis, ear defects, anogenital anomalies, skin tags, and prominent umbilical stump. Cutis gyrata can affect the scalp, forehead, face, preauricular area, neck, trunk, hands, and feet (Fig. 15–5). Craniofacial appearance may be Crouzonoid or cloverleaf and some patients have been diagnosed initially as having Crouzon syndrome.

Intrauterine growth has been normal in all cases. Performance and life expectancy appear to be related to the presence or absence of cloverleaf skull. All cases to date have been sporadic.

Przylepa et al (212) reported two mutations for Beare-Stevenson syndrome on FGFR2: Tyr375Cys and Ser372Cys. Calda et al (31) also noted a case with Tyr375Cys. At this writing, there are three cases with Tyr375Cys and one with Ser372Cys.

Berant syndrome

In 1973, Berant and Berant (20) described a syndrome consisting of craniosynostosis involving the sagittal suture and radioulnar synostosis. Autosomal dominant inheritance with variable expressivity seems likely. Radioulnar synostosis was unilateral in some affected individuals and bilateral in others (Fig. 15–6).

Isolated sagittal synostosis may occur sporadically or may sometimes follow an autosomal dominant mode of transmission. Radioulnar synostosis may occur as an isolated abnormality, may be inherited as an autosomal dominant trait, or may occur as a broader pattern of anomalies, as in *XXXXY* or *XXXXX syndrome*.

CAP syndrome

Flanagan et al (82) reported two male sibs with *c*raniosynostosis, *a*nal anomalies, and *p*orokeratosis (CAP). The syndrome possibly has autosomal recessive inheritance, but X-linked inheritance and gonadal mosaicism cannot be ruled out at this writing.

Features include microbrachycephaly, bifid scrotum, anteriorly placed, imperforate anus, and erythematous plaques with central clearing on the cheeks, ears, fingers, toes, and posterior scalp (82).

Porokeratosis is characterized by annular, parakeratotic plaques with central atrophy. Many types are known including linear porokeratosis, punctate porokeratosis, and Mibelli porokeratosis. Patients with CAP syndrome cannot be classified as having any of these types but most closely appear to have the Mibelli type (82).

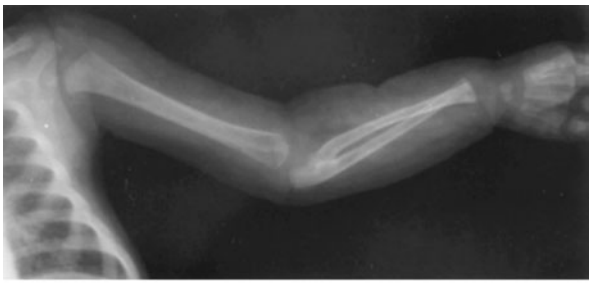
Fig. 15–5. *Beare-Stevenson cutis gyratum syndrome.* (A) Patient with cutis gyratum of facial skin, acanthosis nigricans. Note broad nasal bridge and unusual hairline. Patient also had cleft palate and natal teeth, but no evidence of craniosynostosis. (B) Malformed pinna showing indentation marks around tragal area in same patient. (C) Note palmar cutis gyratum. (D) Marked acanthosis nigricans in anogenital area of same patient. (A,B,D from JM Beare et al, Br J Dermatol 81:241, 1969. C from MM Cohen Jr, Am J Med Genet Suppl 4:99, 1988.)

Autosomal dominant inheritance of porokeratosis has been described in some instances. Porokeratosis may also be associated with UV light exposure, infectious disease, trauma, and immunosuppressive therapy.

Anal anomalies may be found in *Baller-Gerold syndrome* and *FG syndrome*. Porokeratosis has been reported in some instances of *trisomy 21 syndrome*. Poikiloderma is found in *Rothmund-Thomson syndrome* and *Bloom syndrome*.

Fig. 15–6. *Berant syndrome.* (A,B) Radioulnar synostosis in two affected members of the same family. (A,B from M Berant and N Berant, J Pediatr 83:88, 1973.)



A

Calabro syndrome

Calabro et al (30) reported a sporadic instance of a patient affected with synostosis of the coronal and metopic sutures, unilateral ulnar aplasia and oligodactyly, downslanting palpebral fissures, micrognathia, short neck, micropenis, cryptorchidism, and pulmonic stenosis.

Radial aplasia occurs with secondary ulnar involvement in *Baller-Gerold* syndrome. Radial aplasia and shortened ulnas are observed in *Herrmann syndrome*.

Calvarial hyperostosis

Pagon et al (198) reported an X-linked recessive form of calvarial thickening (Fig. 15–7). The cranial base, maxilla, and mandible were not affected. Although the coronal and sagittal sutures closed early, producing a Lückenschädel appearance, there was no evidence of increased intracranial pressure. Calvarial bone biopsy showed vacuolated histiocytes, suggesting a storage disease; however, at 18 years of age, one patient showed no evidence of neurologic deterioration or hepatosplenomegaly.

Chitayat hypophosphatemia syndrome

Chitayat et al (35) reported a syndrome in two brothers. The main features were renal hypophosphatemia, minor facial dysmorphism, intracerebral calcifications, and nonrachitic bone changes. Inheritance may be autosomal recessive or X-linked.

Abnormalities included dolichocephaly, sagittal synostosis, high forehead, malar hypoplasia, long philtrum, choanal stenosis, and dentin

A

B

Fig. 15–7. *Calvarial hyperostosis*. (A) Age 3.6 years. Note lateral frontal prominences. (B) Radiograph showing thickening in the basifrontal area (arrow) and supraoccipital bone. (From RA Pagon et al, Clin Genet 29:73, 1986.)

dysplasia with abscessed teeth. Intracerebral calcifications and nonrachitic bone changes were associated with hypophosphatemia, elevated serum alkaline phosphatase, and normocalcemia (35). Several renal hypophosphatemic syndromes are known including autosomal dominant, X-linked dominant, or autosomal recessive types (176).

Christian syndrome

In 1971, Christian et al (37) reported an autosomal recessive disorder consisting of microcephaly, craniosynostosis, arthrogryposis, and cleft palate. To date, the disorder has usually been referred to as the "adducted thumbs syndrome" (37,81,152), a term that Cohen found too nonspecific. Many features of the syndrome are secondary to abnormal development of the central nervous system. Ten cases have been recorded to date (37,81,152) (Table 15–3). Microcephaly, secondary craniosynostosis, and prominent occiput are accompanied by hypotonia, seizures, and mental deficiency. Ororespiratory problems include dysphagia, laryngomalacia, and pneumonia. An early demise is common. Facial features include a myopathic face, downslanting palpebral fissures in some instances, cleft palate or bifid uvula, micrognathia, low-set and posteriorly angulated ears, and torticollis (Fig. 15–8). Limb abnormalities include adducted thumbs, camptodactyly, limited extension at the elbows, wrist, and knees, and talipes equinovarus or calcaneovalgus. Hirsutism is frequently found.

Neuropathologic studies of one affected infant (37) showed dysmyelination with widespread glial proliferation in both the spinal cord and the brain. However, muscle biopsy in another patient (152) showed changes consistent with a myopathy rather than a neurogenic atrophy.

COH syndrome

COH syndrome represents a sporadically occurring case of cloverleaf skull, polymicrogyria, absent olfactory tracts and bulbs, proptosis, low nasal bridge, short upturned nose, downturned mouth, narrow palate, thumb duplication, small fifth fingers, micropenis, bifid scrotum, agenesis of the cervical thymic lobes, and bilobed lungs (Fig. 15–9). Chromosomes were normal. The mother, an unmarried primigravida, was normal and knew of no relatives affected with a similar set of anomalies. COH stands for Children's Orthopedic Hospital where the patient was seen as a newborn (48).

Table 15–3. *Christian syndrome*

Cranioectodermal dysplasia (Sensenbrenner syndrome)

Cranioectodermal dysplasia was first described by Sensenbrenner et al (243) in 1975 and named and expanded by Levin et al (163) in 1977. Over 10 cases have been recorded (9,73,94,95,161,163,233,243,266, 267,285). The syndrome consists of craniofacial, ectodermal, and skeletal abnormalities. Inheritance is autosomal recessive (73,163,285).

Development and intelligence are normal. Height is between the 3rd and 10th centiles. Several children have died before 7 years of age, usually from chronic renal failure with hypertension and proteinuria resulting from tubulointerstitial nephropathy (59a,73,233,266,267). Cardiac arrhythmia and interstitial pneumonia have caused death in two cases. Seizures may be noted on occasion.

The skull is scaphocephalic with synostosis of the sagittal suture. Frontal bossing and ocular hypotelorism are also found. Epicanthic folds, hyperopia, myopia, and nystagmus have been documented (59a,163). A symptomatic retinal photoreceptor dystrophy manifests during the first years of life as night blindness (73,267). The nose is small with anteverted nares. The lower lip is everted (163) (Fig. 15–10A–D).

Ectodermal abnormalities include fine, sparse, slow-growing hair with absence of the central pigment core of the hair shaft, short nails, and single palmar creases (285). Hypodontia, fused deciduous teeth, taurodontism, and microdontia have been noted (163).

Skeletal defects include generalized osteopenia, short narrow thorax, pectus excavatum, joint laxity, short limbs, stubby digits, fifth finger clinodactyly, and soft tissue syndactyly of the fingers and toes. The upper extremities exhibit more rhizomelic shortening than the lower extremities (163) (Fig. 15–10E).

Radiographic changes involve metaphyseal widening with flattened epiphyses of most long bones. However, the capital femoral epiphyses are small and round and ossify late. The fibulas are short and the semilunar notches of the ulnas are small (Fig. 15–10F,G). The vertebral bodies have short pedicles and convex superior and inferior surfaces. The sutures of the body of the sternum fuse prematurely (163).

Lammer et al (159) reported a boy with phenotypic features of cranioectodermal dysplasia but with different abnormalities of hair and bone. Growth, development, height, and limb lengths were normal. Bone changes consisted of indistinct medullary-cortical transition, particularly in the metacarpals, "bone within bone" changes in the vertebral bodies, and sclerosis of the anterior part of the vertebral bodies. Histologic study of the hair showed abnormalities of the internal root sheath of the hair follicle and hair shaft. In contrast, the change in cranioectodermal dysplasia consists only of absence of the central pigment core of the hair shaft.

Craniofacial dyssynostosis

Neuhäuser et al (189) described two affected sisters and five sporadic instances of craniosynostosis involving the lambdoidal and posterior sagittal sutures together with growth disturbance of the cranial base and minor facial anomalies (Fig. 15–11). They termed the condition craniofacial dyssynostosis. One of the seven patients had synostosis of the coronal suture as well. Four exhibited mental deficiency. Agenesis of the corpus callosum and interventricular lipoma were noted in one patient. Still another had PDA with possible VSD. All seven patients were of short stature. Spanish ancestry in four of seven patients and the occurrence of the disorder in two sibs suggest autosomal recessive inheritance. Other cases were reported by Al-Torki et al (7) and Morton (184a).

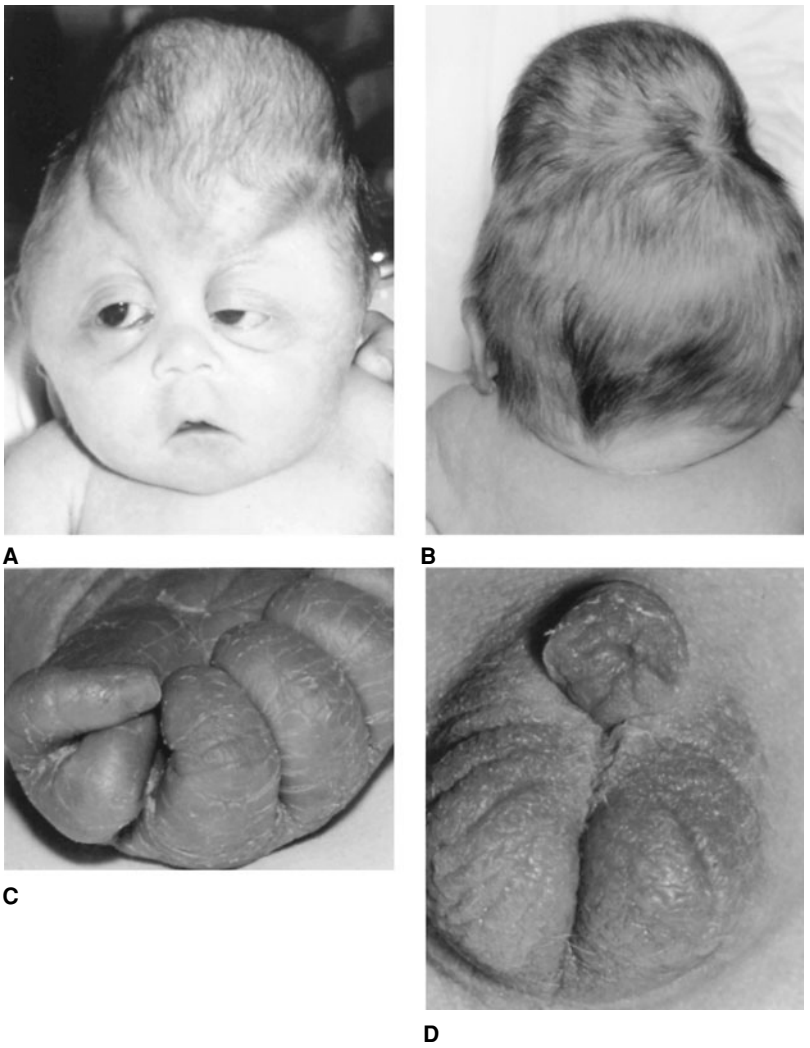

Fig. 15–9. *COH syndrome*. (A,B) Craniosynostosis, cloverleaf skull, and facial anomalies. (C) Preaxial polydactyly. (D) Micropenis and bifid scrotum. (From MM Cohen Jr, The Child With Multiple Birth Defects, Raven Press, New York, 1982.)

Craniofrontonasal syndrome

Craniofrontonasal syndrome (CFNS) was identified as a subpopulation of frontonasal dysplasia patients by Cohen (44), who also coined the term craniofrontonasal dysplasia. The condition was reported earlier by Reich et al (217) and at the same time as Cohen (44) by Slover and Sujansky (247). Craniofrontonasal syndrome has been reviewed elsewhere by Cohen (47), Young (284), Grutzner and Gorlin (107), and Saavedra et al (228).

Craniofacial features include brachycephaly, coronal synostosis, craniofacial asymmetry, frontal bossing, dry curly or frizzy hair, coronal ocular hypertelorism, broad nasal bridge, bifid nose, pterygium colli, sloping shoulders, and longitudinally grooved nails (Fig. 15–12). Other reported findings include mild soft tissue syndactyly, clinodactyly of the fifth fingers, hyperextensible joints, and scoliosis. Malocclusion, ear anomalies, broad toes and hallucal duplication, minor vertebral anomalies, unusual dermatoglyphics, developmental delay, curly hair, short clavicles, downsloping shoulders, pectus excavatum, and unilateral breast hypoplasia have also been noted (44,121,142,211,220,228,247).

Although most cases are sporadic and occur in females who are generally more severely affected than the few reported males, pedigrees showing vertical transmission have been recorded [44,71,107,121 (see Figure 1, pedigree 1),123,140,142,151,180,183,210,211,218,220,228, 236,250]. Male-to-male transmission has not been observed in any publications to date, although Reich et al (198) noted two instances in an abstract that has yet to appear as a documented publication. Many suggestions have been put forth including X-linked dominant inheritance (192,201,225), metabolic interference (205), and a semilethal mutation with similarities to the T-locus in the mouse (216). Craniofrontonasal dysplasia has been mapped to Xp22 (74).

Females make up the majority, with males being fewer in number and tending to be less severely affected (42,99,208,216) (Fig. 15–12D). Manifestations in males are confined to the craniofacial region, consisting of ocular hypertelorism, cleft lip and/or palate in several cases, and malocclusion (cross-bite or posterior open-bite) (208). Severely affected males are very uncommon. One of us (MMC) knows of two such males in the Netherlands. A third affected male from Australia is shown in the monograph of David et al (65). The patient shown by David et al (65) (p. 24, Fig. 15), through correspondence from David et al to MMC, was found to be male. Natarajan et al (187) reported two severely affected brothers.

Craniofrontonasal syndrome can be distinguished from *frontonasal dysplasia*. The female patient with presumed frontonasal dysplasia and Klippel-Feil anomaly reported by Fragoso et al (84) probably had CFNS. The patient reported by Reardon et al (214) with craniosynostosis and Poland anomaly is similar to the patient of Webster and Deming (276) and, as suggested by Reardon et al (214), probably had CFNS. The patient described by Erdogan et al (75) with craniofrontonasal dysplasia, Poland anomaly, and polythelia most likely had CFNS, not a newly recognized syndrome, as suggested by these authors.

The proband reported by Kwee and Lindhout (153) as an example of CFNS probably had *Greig cephalopolysyndactyly*. Since the latter syndrome has autosomal dominant inheritance, the severely affected male, presumed to have CFNS by Kwee and Lindhout (153,154) and seconded by Young and Moore (286), cannot be used as evidence for autosomal dominant inheritance of CFNS.

Fig. 15–10. *Cranioectodermal dysplasia.* (A) Age 23 months. Note rhizomelic shortening of limbs, especially upper limbs; small, narrow thorax with mild pectus excavatum; and dolichocephaly with short, thin hair. (B,C) Note dolichocephaly, short thin hair, frontal bossing, epicanthic folds, hypertelorism, and everted lower lip. (D) Microdontia (E) Brachydactyly. (F) Hand–wrist radiograph at age 4 years. Brachydactyly, osteoporosis with thin cortices and coarse trabeculae and mild clinodactyly of the fifth finger. (G) Radiograph showing flat irregular epiphyses and shortening of fibulae, both proximally and distally. (From LS Levin et al, J Pediatr 90:55, 1977.)

The family with three affected males and two affected females reported by Morris et al (184) has having CFNS probably represents another disorder. In their family, of six patients, only one had craniosynostosis, and affected males had manifestations such as short stature, delayed bone age, shawl scrotum, and hypospadias. Possibly their patients may have had *brachycephalofrontonasal dysplasia*, a dominantly inherited syndrome described by Teebi (260) and Stratton (252).

Craniomicromelic syndrome

Barr et al (18) reported a newly recognized lethal syndrome in two sisters who had coronal synostosis, relative macroturricephaly, short palpebral fissures, pinched nose with anteverted nares, protruding anterior nasal spine, low-set posteriorly angulated ears, micrognathia, microstomia, cleft palate in one sib, short limbs, hypoplastic lungs, absent/hypoplastic

Fig. 15–11. *Craniofacial dyssynostosis*. Posterior sagittal and lambdoidal synostosis. (Courtesy of JM Opitz, Helena, Montana.)

gallbladder, short intestine with ileal distention, hypoplastic uterus, and intrauterine growth retardation. Another example is that of Baralle and Firth (17a). Inheritance is probably autosomal recessive.

The combination of craniosynostosis, short limbs, and lethality limits the differential diagnosis. Both *thanatophoric dysplasia* and *Ives-Houston syndrome* have all three of these characteristics. However, both have more dramatically short limbs and distinctive radiographic features.

Craniorhiny

Mindikoğlu et al (181,182) reported an autosomal dominant syndrome of craniosynostosis and striking nasal abnormalities. MM Cohen Jr coined the name "craniorhiny." The skull shape was oxycephalic with recessed forehead and lack of nasofrontal angle (Fig. 15–13). Synostosis of the coronal suture was found radiographically with digital impressions in the anterior portion of the skull. Characteristic nasal changes consisted of a wide nose, anteverted nares, nasal hirsutism, and bilaterally symmetrical, spherical almond-sized cyst-like structures with small fistulas just below the nose. The nasolacrimal ducts were absent. Of four reported Turkish sibs, three were affected, as was the mother (181).

Craniosynostosis, Boston type

Boston type craniosynostosis is an autosomal dominant disorder with variable expression. Most commonly observed are fronto-orbital recession or turribrachycephaly. Less commonly observed are cloverleaf skull or frontal bossing (275). The disorder is caused by a mutation in MSX2: Pro148His (56a,131,186). Three other mutations on MSX2 cause parietal foramina by haploinsufficiency.

Craniosynostosis/ectopia lentis

Cruysberg et al (61) described craniosynostosis and ectopia lentis in monozygotic twin sisters. One sister had sagittal synostosis, the other

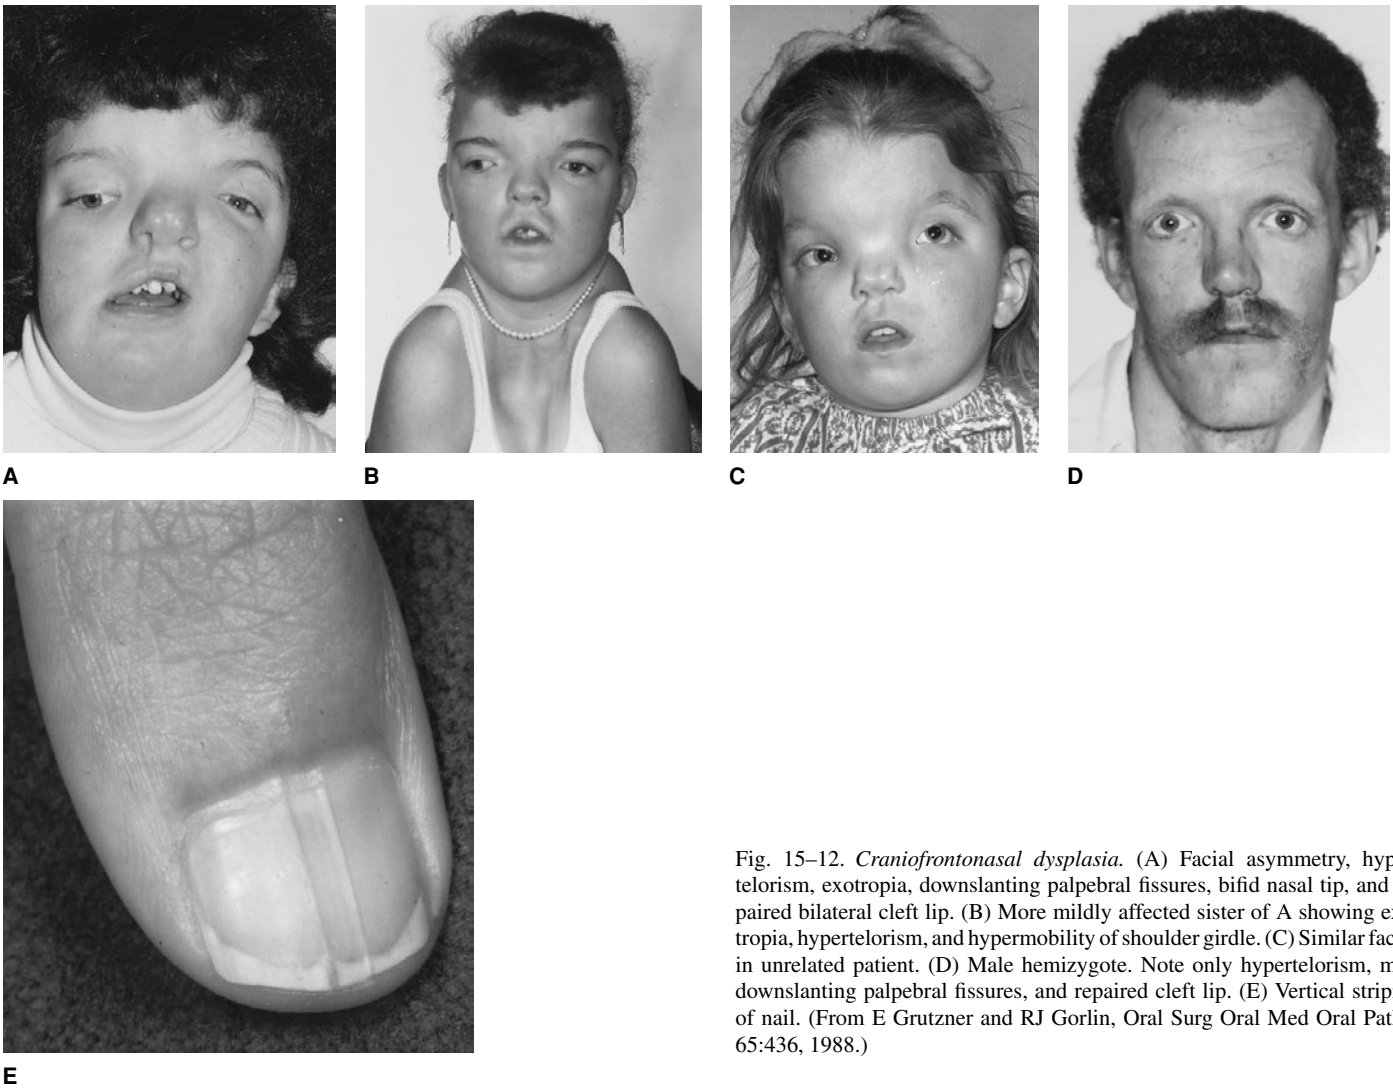

Fig. 15–12. *Craniofrontonasal dysplasia.* (A) Facial asymmetry, hypertelorism, exotropia, downslanting palpebral fissures, bifid nasal tip, and repaired bilateral cleft lip. (B) More mildly affected sister of A showing exotropia, hypertelorism, and hypermobility of shoulder girdle. (C) Similar facies in unrelated patient. (D) Male hemizygote. Note only hypertelorism, mild downslanting palpebral fissures, and repaired cleft lip. (E) Vertical striping of nail. (From E Grutzner and RJ Gorlin, Oral Surg Oral Med Oral Pathol 65:436, 1988.)

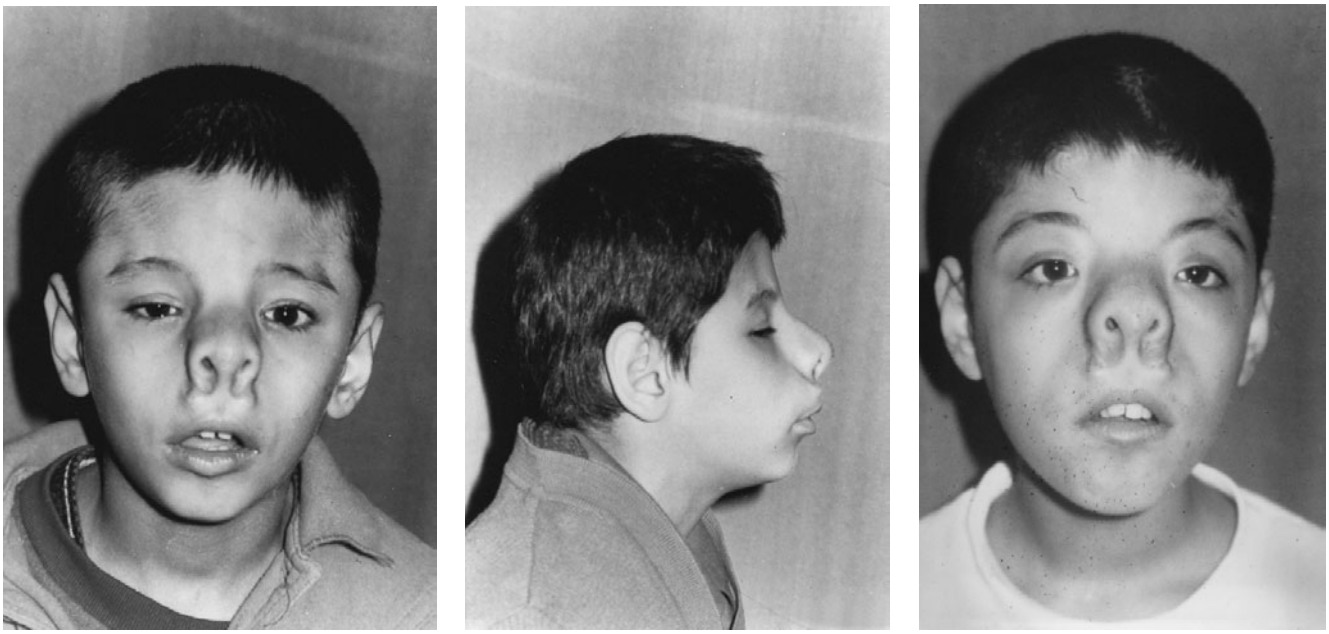

A B C

Fig. 15–13. *Craniorhiny.* (A–C) Coronal synostosis with lack of nasofrontal angle, wide nose, anteverted nares, and bilateral symmetrical spherical cyst-like formations just below nose. (From AN Mindikoğlu et al, Am J Med Genet 40:250, 1991.)

metopic synostosis. Both had hirsutism on the back, mild hyperlaxity of the elbows and knees, and hypoplastic toe nails. Inheritance may be autosomal dominant, possibly due to a new mutation; possibly autosomal recessive; or possibly X-linked, lethal in the male.

Ectopia lentis is rare in isolated cystathionine synthase and rare in *Crouzon syndrome* (47). It is common in *Marfan syndrome, cystathionine synthase deficiency*, and *Weill-Marchesani syndrome*.

Craniosynostosis, Philadelphia type

Robin et al (223) reported a five-generation autosomal dominant pedigree with a distinctive combination of sagittal synostosis and syndactyly. Dolichocephaly was found in seven of ten affected individuals. Nonpenetrance for craniosynostosis occurred only in females. The face was usually normal except for two patients who exhibited downslanting palpebral fissures. Soft tissue 2–5 syndactyly was found in most cases (7/8) with 3–4 syndactyly occurring in only one patient. Complete soft tissue 1–5 syndactyly of the feet was observed in all cases. Hand and foot lengths were below the 3rd centile.

Craniotelencephalic dysplasia

Jabbour and Taybi (130) and Daum et al (64) reported sporadic instances of a condition known as craniotelencephalic dysplasia. In both cases, premature closure of the sagittal, coronal, and metopic sutures occurred together with protuberance of the frontal bone and retarded neurologic development. A paramedian frontal encephalocele was present in one case (64) (Fig. 15–14).

Two affected sisters were reported by Hughes et al (120). One had septooptic dysplasia, absent olfactory nerves, agenesis of the corpus callosum, and lissencephaly. The occurrence of craniotelencephalic dysplasia in association with such central nervous system anomalies suggests that this combination probably represents a distinct autosomal recessive syndrome.

Because detailed studies of the brain were not possible in the two sporadic cases of craniotelencephalic dysplasia reported by Jabbour and Taybi (130) and Daum et al (64), it is not known whether they had similar central nervous system anomalies and therefore represent the same overall condition reported by Hughes et al (120). Final judgment as to the specificity or nonspecificity of craniotelencephalic dysplasia will have to await further studies.

Crouzonodermoskeletal syndrome

The association of Crouzon syndrome with acanthosis nigricans has been known for a long time (27,96a,145,215,256) (Fig. 15–15). H Curth, in private conversation with one of the authors (RJG), noted this association in 1948. More recently, an FGFR3 transmembrane mutation, Ala391Glu, has been reported (174a,179,186a,186b,242a,278). A still different variant, more resembling thanatophoric dysplasia or severe achondroplasia (SADDAN = *S*evere *A*chondroplasia with *D*evelopmental *D*elay and *A*canthosis *N*igricans), has another FGFR3 mutation, (Lys 650 Met) (259).

Cohen (56) indicated that this condition is completely separate from Crouzon syndrome for two reasons. First, it is caused by a highly specific mutation, which is 11 amino acids away from the common mutation for achondroplasia. In contrast, in exons 7 and 9 of the third immunoglobulin-like loop of FGFR2, more than two dozen mutations are known to cause Crouzon syndrome (55). Second, the phenotypes are entirely different. The FGFR3 Ala391Glu mutation is associated not only with acanthosis nigricans, but also with cementomas of the jaws (215,255,256). Furthermore, the interpediculate distances have been reported to narrow progressively from the upper to the lower spine, as in achondroplasia (255) (Fig. 15–16). There is also jugular foramen stenosis and intracranial venous hypertension and dilated scalp veins (186a). At this writing, the frequency with which vertebral alterations and cementomas occur in this syndrome is unknown because clinical manifestations have not been evident. Jugular foraminal stenosis with dilated scalp veins has also been described (145a). Certainly when a diagnosis of Crouzonoid phenotype and acanthosis nigricans is made, radiographic study should be instituted.

A mild disorder due to K650Q mutation in the FGFR3 gene has been reported (184a).

To call this disorder "Crouzon syndrome with acanthosis nigricans" shows that we are prisoners of our own conventional terminology. A specific mutation with a specific phenotype requires a specific name.

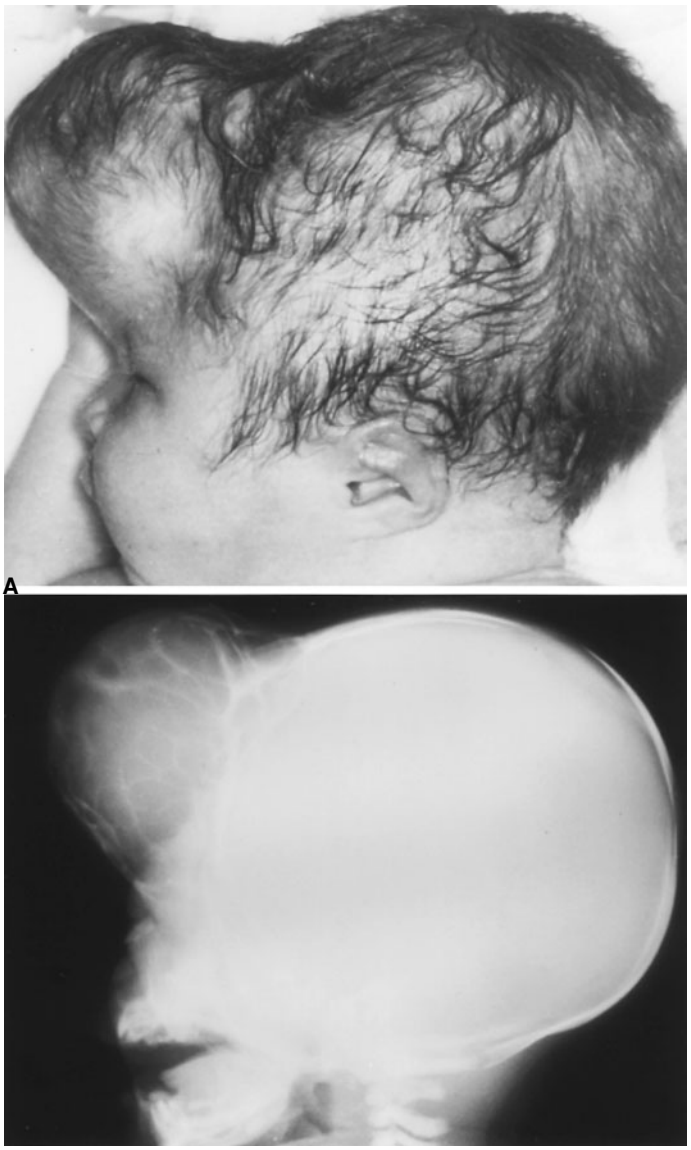

Fig. 15–14. *Craniotelencephalic dysplasia.* (A,B) Premature closure of the sagittal, coronal, and metopic sutures with protuberance of frontal bone. (From HE Hughes et al, Am J Med Genet 14:557, 1983.)

Elsewhere (56), Cohen proposed the name "Crouzonodermoskeletal syndrome." The term includes the Crouzonoid phenotype (*Crouzono*) acanthosis nigricans (*dermo*), and jaw cementomas and vertebral alterations (*skeletal*).

Curry-Jones syndrome

Temple et al in 1995 (261) reported five children with the Curry-Jones syndrome characterized by craniosynostosis (usually unilateral involving the coronal suture), facial asymmetry, preaxial polydactyly, variable syndactyly, and unusual skin lesions. The first two cases were presented at the David W. Smith Workshop on Malformations and Morphogenesis in 1986 and 1987. One case was described by Curry et al (62), the other by Jones (138). The name Curry-Jones syndrome was coined by Cohen in 1988 (48).

Affected skin is initially erythematous. Lesions then become pearly white and raised and finally become pale and atrophic with areas of scarring and hair growth. Distribution is linear and skin appears pigmented in a streaky or lace-like pattern. Some patients have freckling of the plantar surfaces of the feet (Fig. 15–17).

Agenesis of the corpus callosum and developmental delay have been found in three patients. Gastrointestinal obstruction has been associated with myelofibrosis of the bowel and the mesentery in some patients.

Elejalde syndrome

In 1977, Elejalde and his co-workers (74) described a spectacular overgrowth syndrome. Birthweights in three patients ranged from 4300g to 7500g. Features included a swollen globular body, omphalocele, short limbs, redundant neck skin, craniosynostosis, hypoplastic nose, and rudimentary auricles (Fig. 15–18). Three affected individuals in two sibships were recorded for which consanguinity was established. Thus, the Elejalde syndrome has autosomal recessive inheritance. Cell kinetic studies showed that fibroblasts from Elejalde syndrome patients completed the cell cycle in 63% of the normal cell cycle time. Since Elejalde's original cases were described, four other instances have been reported (36,174,190,264) (Table 15–4).

Autopsy findings showed enlarged kidneys with a thick fibrous capsule, lack of clear-cut differentiation between the cortex and the medulla, and multiple cysts. Excessive connective tissue was found throughout the body, except for the central nervous system. It was most prominent subcutaneously in the media of blood vessels, in the walls of the viscera, and interstitially in organs such as the pancreas and kidneys. Perivascular proliferation of nerve fibers was found in many viscera, particularly the spleen, thymus, colon, heart, and adrenal glands (49).

Fontaine-Farriaux syndrome

In 1977, Fontaine et al (83) described a sporadic occurrence of a newly recognized syndrome consisting of craniosynostosis, phalangeal hypoplasia with anonychia of the third, fourth, and fifth fingers, patches of lipodystrophy at the antecubital and popliteal fossae, aplasia of the abdominal muscles, genital hypoplasia, hypospadias, and cryptorchidism. Growth deficiency of prenatal onset and an early demise at 3.5 months were reported. Karyotype was normal. Autopsy findings included VSD, absence of the common mesentery, lissencephaly, absent interhemispheric fissure, and disorganization of the basal ganglia.

Fontaine-Farriaux syndrome is named after the first two authors of the report (83) to clearly distinguish it from another condition already known as Patterson-Stevenson-Fontaine syndrome, an autosomal dominant disorder characterized by micrognathia, dysplastic ears, ectrodactyly and syndactyly of the feet, and, in some instances, submucous cleft palate and mental deficiency (43).

Frydman trigonocephaly syndrome

In 1984, Frydman et al (87) reported a newly recognized autosomal dominantly inherited trigonocephaly syndrome. The proband had trigonocephaly, premature metopic synostosis, ridging of the metopic suture, mild synophrys, hypotelorism, S-curved lower eyelids, preauricular tag, omphalocele, large phallus, and a hemivertebra at L5. Mental development was normal. The father of the proband had trigonocephaly with marked ridging of the metopic suture, mild microcephaly, mild synophrys, S-curved lower eyelids, and hypotelorism. Intelligence was normal. Four other affected members of the family had trigonocephaly and normal intelligence.

Fryns craniosynostosis syndrome

Fryns et al (90) reported a mother and son with synostosis of the coronal and metopic sutures, an asymmetric long face, high narrow forehead, short upper lip, and highly arched palate. Sensorineural hearing loss of 35–45 dB in the low and middle frequencies was present in both mother and son.

Fig. 15–15. *Crouzonodermoskeletal syndrome.* (A) Note Crouzon-like facies with relatively mild acanthosis nigricans. (B) Marked brachycephaly, extensive acanthosis nigricans. (C,D) Typical Crouzonoid facies and acanthosis nigricans, especially evident circumorally. (A courtesy of J Mulliken, Boston, Massachusetts. B from BSN Reddy et al, J Dermatol 12:85, 1985. Gomez-López-Hernández syndrome (cerebello-trigeminal-dermal dysplasia)

Gomez-López-Hernández syndrome is a distinctive condition consisting of craniosynostosis, ataxia, trigeminal anesthesia, pons-vermis fusion, mental deficiency, short stature, parietal alopecia, ocular hypertelorism, corneal opacities, midface hypoplasia, low-set posteriorly angulated ears, clinodactyly, and hypoplastic labia majora (Fig. 15–19). Two unrelated Mexican girls were reported by López-Hernández (169). Chromosomes were normal in each girl. In both families, the parents were normal, consanguinity was denied, and there were no affected sibs. Another earlier case was reported by Gomez (98) who recognized the disorder as a distinct entity and named it cerebellotrigeminodermal dysplasia. Gomez (97) reviewed the subject extensively. To date, eight sporadic cases have been described, and males as well as females have been affected (27a,98,141,169,199,205) (Table 15–5). Only two of the six affected individuals had craniostenosis, which appears to be secondary to microcephaly, a variable feature of the syndrome (Fig. 15–20).

Fig. 15–16. *Crouzonodermoskeletal syndrome.* (A,B) A–P and lateral radiographs showing decreasing interpediculate distances as one goes down the lumbar spine. (C,D) Numerous cementomas of maxilla. (Courtesy of A Superti-Furga, Zürich, Switzerland.)

Gorlin-Chaudhry-Moss syndrome

In 1960, Gorlin et al (100) described a syndrome in two female sibs consisting of craniosynostosis, midface hypoplasia, hypertrichosis, and anomalies of the eyes, teeth, heart, and external genitalia. The name Gorlin-Chaudhry-Moss syndrome was coined by Cohen in 1975 (41). Autosomal recessive inheritance seems likely. Other cases have been observed (128). The condition should be distinguished from *Crouzon syndrome* and *Saethre-Chotzen syndrome* (209a).

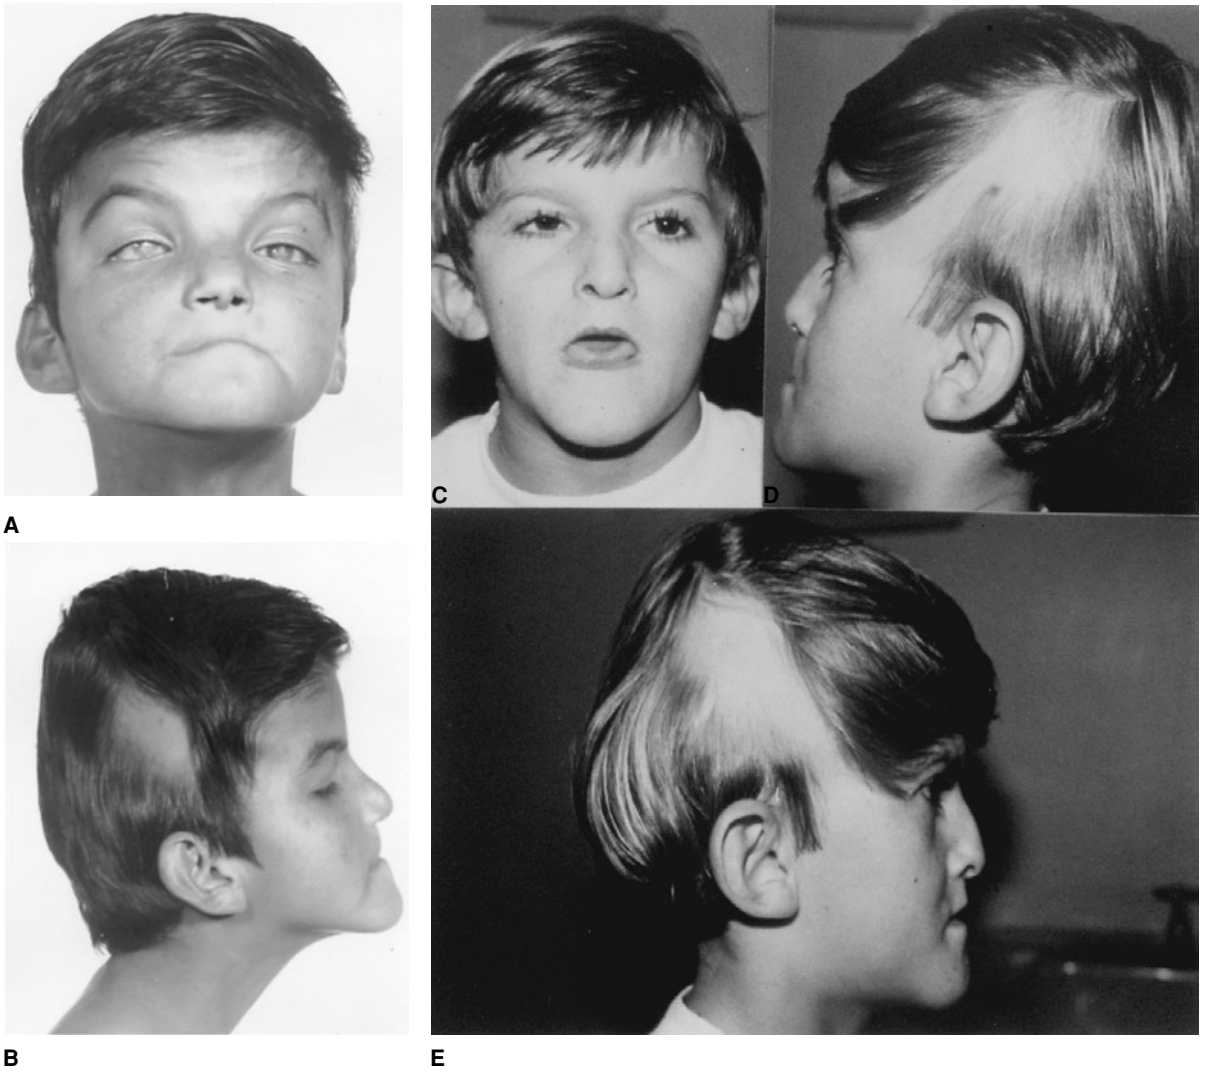

Fig. 15–19. *Gomez-López-Hernández syndrome* (*cerebello-trigeminal-dermal dysplasia*). (A,B) Craniosynostosis, focal parietal alopecia, low-set posteriorly angulated ears, and midface deficiency with relative mandibular prognathism. Note corneal opacities. (C–E) Frontal and side views. (A,B from A López-Hernández. Neuropediatrics 13:99, 1982. C–E from MV Muñoz et al, Am J Med Genet 72:34–39, 1997.)

The original sibs were short and of stocky build. Both held their heads in mild anteflexion when walking. Midface hypoplasia and depressed supraorbital ridges were observed but were more pronounced in the older sib. Hypertrichosis of the scalp, arms, legs, and back was noted. The scalp hairline was lower than normal. Downslanting palpebral fissures, inability to fully open or close the eyes, upper eyelid colobomas, microphthalmia, and hyperopia were reported. The younger sib had unilateral persistence of the iridopupillary membrane. Bilateral conductive hearing deficit was noted in both sibs (Fig. 15–21A–C).

Oral anomalies consisted of class III malocclusion, highly arched narrow palate, hypodontia, microdontia, and abnormally shaped teeth. Other findings included patent ductus arteriosus, pronounced hypoplasia of the labia majora, and umbilical hernia (Fig. 15–21D).

Radiographic examination of the skull showed premature synostosis of the coronal suture, brachycephaly, hypoplastic maxillary and nasal bones, ocular hypertelorism, lordosis of the petrous ridges, hypoplasia of the clivus, and elevation of the lesser sphenoidal wings.

Hall syndrome

In 1974, JG Hall (111) observed a patient with craniosynostosis and a Turner-like phenotype. Growth, however, was rapid, both height and weight being at the 97th centile. Mild mental deficiency was evident.

Significant dysmorphic features included unilateral synostosis involving the coronal suture, craniofacial asymmetry, downslanting and narrow palpebral fissures, midface deficiency, small ears, mild webbing of the neck with redundant skin, broad chest, low-placed and widely set nipples, and pudgy hands with mild hypoplasia of the nails (Fig. 15–22).

No similar condition was known in any member of the family. Both parents were normal, and consanguinity was denied. Chromosomes were normal. However, the proband was born following six second-trimester spontaneous abortions.

Herrmann syndrome

Herrmann et al (114) described a provisionally unique-pattern syndrome consisting of craniosynostosis, severe symmetrically malformed limbs, and cleft lip-palate. A chromosome study was normal.

The skull was microbrachycephalic. Synostosis involved mainly the coronal suture; the sagittal and lambdoid sutures remaining partially open. The metopic suture was patent. Ocular hypertelorism, occipital capillary stain, protruding dysplastic ears, deviation of the nasal septum, and cleft lip-palate were reported. Severe mental retardation was noted.

Radial aplasia and shortened ulna were observed bilaterally. The hands were in valgus position. Both fused and missing carpal bones were evident. Three metacarpals and three fingers were present on each hand,

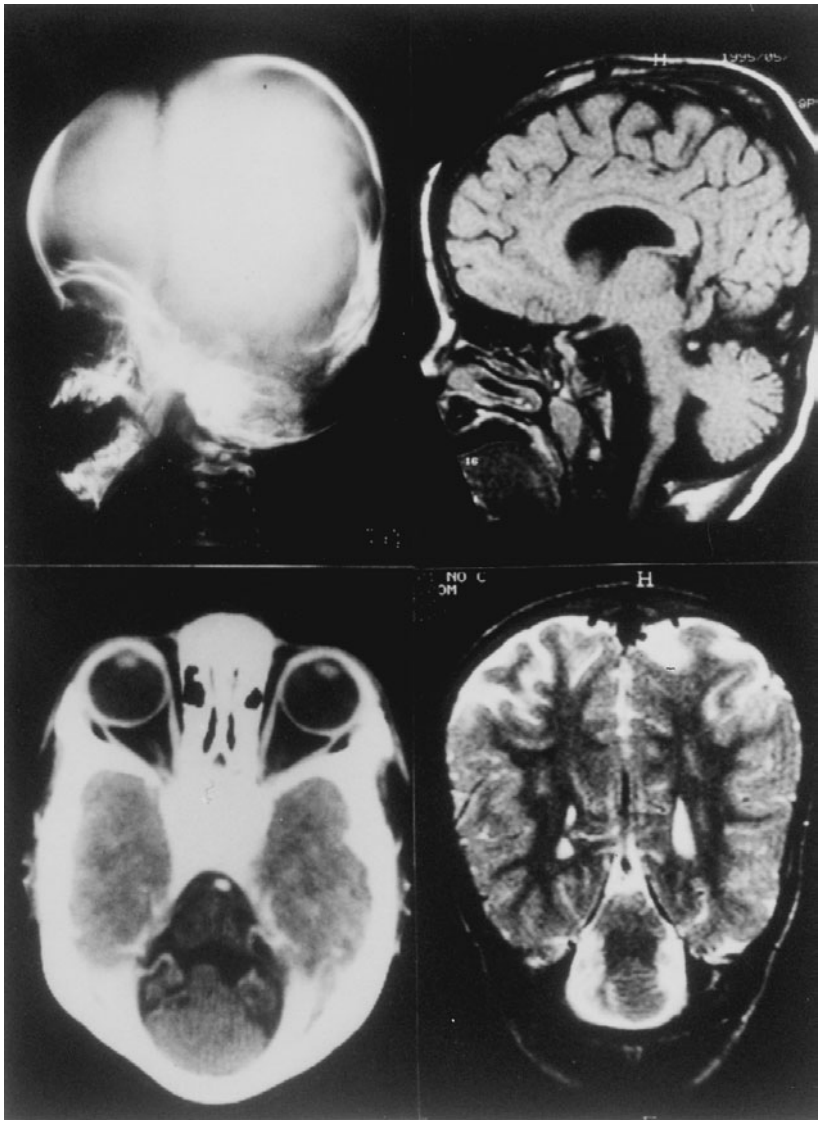

Fig. 15–20. *Gomez-López-Hernández syndrome* (*cerebello-trigeminal-dermal dysplasia*). Top left: Skull, plain radiograph showing a tower-like ridging of the occipital endocranial surface. Top right: Axial CT. Bottom left: Coronal MRI, long TR and long TE. Bottom right: Coronal MRI, short TR and short TE, showing small cerebellum and rhombencephalosynapsis. (From MV Muñoz et al, Am J Med Genet 72:34–39, 1997.)

the fourth and fifth metacarpals and fingers being absent. Two epiphyses were present in each metacarpal. The third finger was split with two separate fingernails (Fig. 15–23).

Congenital hip dislocation, dysplasia of the femoral heads and necks, ankylosis of the knees, and absent fibulas were reported. The feet were held in varus position, and the third and fourth toes on each foot were hypoplastic.

Other findings included narrow shoulders and thorax, slight depression of the lower sternum, and cryptorchidism. A remarkably similar patient was reported by Ladda et al (158).

Hersh syndrome

Hersh et al (115) described a syndrome in a brother and sister consisting of coronal synostosis in the brother, dolichocephaly in the sister, and shared features such as sensorineural hearing deficit, ocular hypertelorism, flat nasal bridge, broad nasal tip, micrognathia, and sparse curly hair. There was no evidence of syndactyly. Intellectual abilities and language skills were normal in the sister. The brother had low-average nonverbal intelligence with significant language delay and autistic-like behavior. Consanguinity was evident; the parents were first cousins. Thus, autosomal recessive inheritance of the Hersh syndrome seems likely.

Holoprosencephaly/craniosynostosis syndrome (Genoa syndrome)

Camera et al (32) reported two sibs with semilobar holoprosencephaly and primary craniosynostosis. Autosomal recessive inheritance is likely.

Both holoprosencephaly (50,51,57) and craniosynostosis (47,48) are heterogeneous. The face predicts the brain in about 80% of holoprosencephalic cases (69). In 20%, including the patients reported by Camera et al (32), the face is nondiagnostic. Craniosynostosis may occur secondarily in holoprosencephaly because of the associated microcephaly. The metopic suture may be fused specifically in some cases of holoprosencephaly. However, in the cases of Camera et al (32), craniosynostosis is both primary and multisutural.

Hunter-McAlpine syndrome

Hunter et al (122) described a syndrome in 1977 consisting of a characteristic facial appearance together with microcephaly, mental retardation, short stature, minor acral skeletal anomalies and, less commonly, craniosynostosis and congenital heart defects (Fig. 15–24). Autosomal dominant inheritance with reduced penetrance was evident. Thomas et al (263) reported a case with more severe skeletal abnormalities than previously described together with interstitial deletion of chromosome 17q. A third

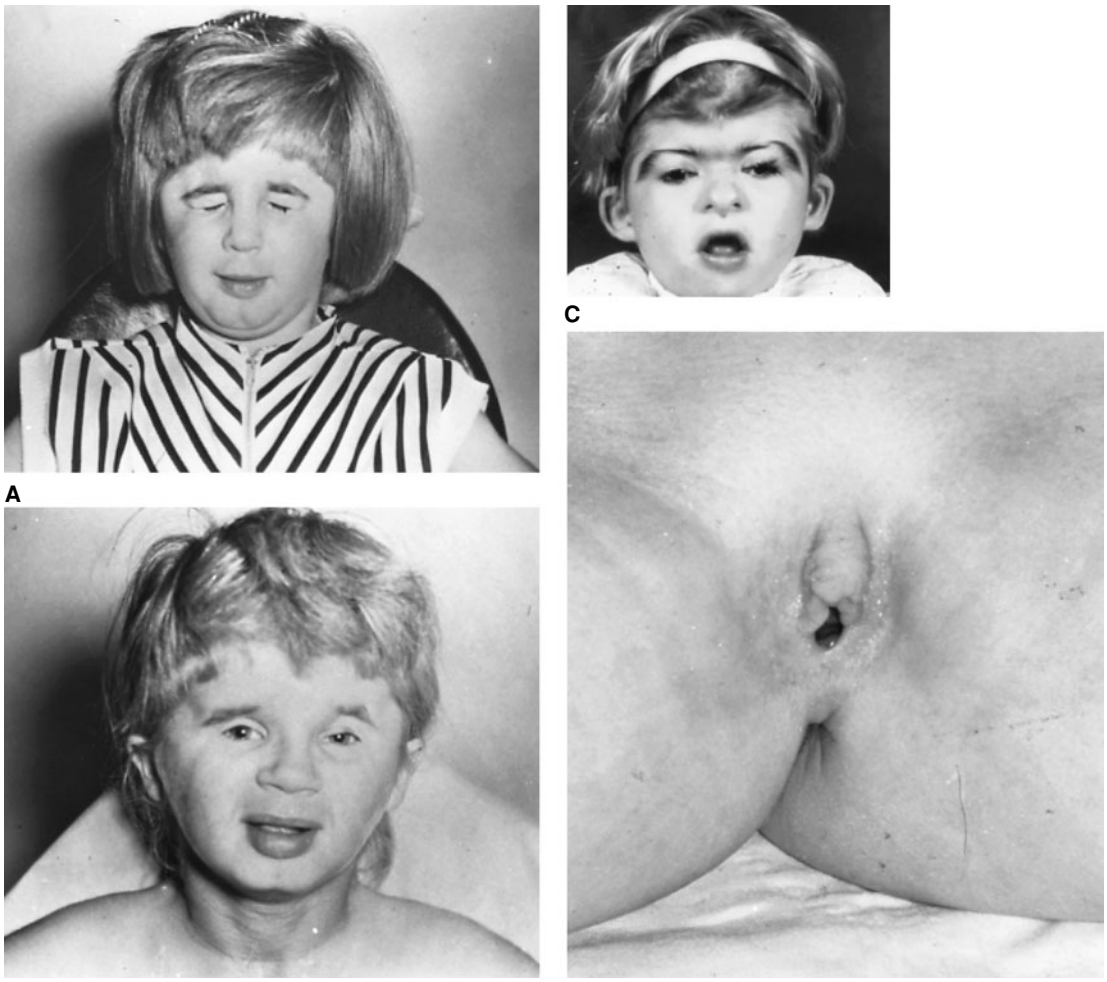

Fig. 15–21. *Gorlin-Chaudhry-Moss syndrome*. (A–C) Note hypertrichosis, severe midface hypoplasia, and eyelid ptosis. Patient in C is reminiscent of de Lange syndrome. (D) Hypoplasia of labia majora. (A,B,D from RJ Gorlin et al, J Pediatr 56:778, 1960. C courtesy of W Lenz, Münster, Germany.)

family was described (2). By using both the first and second authors' names from the original paper (122), Cohen proposed the designation "Hunter-McAlpine syndrome" to avoid confusion with mucopolysaccharidosis, types II-A and II-B (Hunter syndrome).

Facial features included almond-shaped eyes, small nose, and small downturned mouth. When craniosynostosis occurred, the coronal and lambdoid sutures were involved. Strabismus and mildly low-set ears were encountered in some instances. Skeletal anomalies included brachydactyly, cone-shaped epiphyses of the middle phalanges, clinodactyly, incomplete extension at the elbows, and spina bifida occulta in the lumbosacral region. Low-frequency findings included ASD and inguinal hernia.

The degree of mental deficiency ranged from mild, with minor motor and speech delay, to severe retardation, requiring institutional care. Affected individuals were frequently below the 3rd centile for head circumference and below the 3rd centile for height as well.

Hypomandibular faciocranial syndrome

Hypomandibular faciocranial syndrome consists of craniosynostosis, prominent eyes, deficient midface and zygomatic arches, short nose with anteverted nares, protruding lower face, minute oral aperture, persistent buccopharyngeal membrane, severe mandibular hypoplasia, and various extracephalic anomalies (Fig. 15–25). Several papers have been published (173,188,240). The disorder has been reviewed by Ludman et al (173). Two more examples were reported by Wilson and Kerr (280a).

Polyhydramnios is probably due to inability to imbibe significant amounts of amniotic fluid during intrauterine life. Early death occurred in two of the three recorded cases. One child was still living at age 4 1/2 years with severe mental deficiency.

Craniosynostosis is variable, affecting only the coronal suture in the two sibs observed by Schimke et al (240), but affecting multiple sutures in the case described by Ludman et al (173). The tongue was hypoplastic in one case and found as a remnant in another (240). In the patient of Ludman et al (173), the tongue was small but well developed except for a bifid tip, indicating incomplete fusion of the lateral lingual tubercles.

The term "hypomandibular faciocranial dysostosis" was coined by Cohen in 1988 (48), and the arranged order of the term ("hypomandibular faciocranial" rather than "craniofacial hypomandibular)" was used to emphasize the lower facial abnormalities, which are the most striking features of the condition. The findings of ASD, PDA, prominent labia minora, and bicornuate uterus demonstrate that extracephalic anomalies may also occur.

Affected sibs (188,223a,240) suggest autosomal recessive inheritance. However, gonadal mosaicism for a dominant mutation or an undetected microdeletion cannot be ruled out at this writing.

The condition is so distinct that differential diagnosis is academic. In *otocephaly*, severe hypognathia, hypoglossia, and microstomia occur together with low-set and sometimes fused ears.

Fig. 15–22. *Hall syndrome*. Unilateral synostosis involving coronal suture, craniofacial asymmetry, downslanting and narrow palpebral fissures, midface deficiency, mild neck webbing, and broad chest. Note Turner-like phenotype. (Courtesy of JG Hall, Vancouver, British Columbia.)

Ives-Houston syndrome

Ives and Houston (129), in 1980, reported a lethal, autosomal recessive syndrome consisting of intrauterine growth retardation, marked microcephaly with craniosynostosis, and severe malformations of the limbs, such as greatly shortened forearms, fused elbows, and the presence of two-to-four abnormal fingers (Fig. 15–26). The syndrome was discovered in a highly inbred, predominantly Cree Indian community in Northern Saskatchewan with 14 known instances.

Growth deficiency of prenatal onset was marked; birth weights varied from 450g to 1390g. At least six infants were in breech position at delivery. Four infants were stillborn; seven expired within 20 minutes following severe gasping; and three died of recurrent apneic episodes.

Severe microcephaly with complete craniosynostosis was evident in every case. Each had a small brain with primary sulci and gyri. Absence of the corpus callosum was noted in three instances. Facial features included short palpebral fissures, small eyes, prominent broad nose, micrognathia, and microstomia. Cleft soft palate was reported in one instance.

Upper limb anomalies were severe and consisted of fixed elbows and markedly shortened forearms. In four cases, only a single forearm bone was present, and it was not possible to determine whether it was a radius or an ulna. An abnormal and variable pattern characterized the hands. Two-to-four malformed digits were present. Most commonly, three digits were observed; two were well-developed central digits with a less well-developed index finger. A fifth finger, when present, had a tendency to arise from a bifid fourth metacarpal. A thumb was noted in only one instance. The legs were less severely affected. First metatarsals and great toes were shortened. The fourth and fifth toes were either hypoplastic or absent. Short legs and absence of the fibulas were noted in one case. Other findings included two or more narrow ribs, sacral segmentation defects, and, in some instances, hip dislocation.

Jackson-Weiss syndrome

Jackson and Weiss (133), in 1976, reported an autosomal dominant syndrome consisting of craniosynostosis, midfacial hypoplasia, and

abnormalities of the feet (Figs. 15–27 and 15–28). Eighty-eight affected individuals were examined and another 50 were reliably reported to be affected, thus making a total of 138. Penetrance was extremely high, and great variability in expression was observed. Some affected individuals had syndactyly of the second and third toes, usually mild, and broad great toes that deviated medially. The only consistent manifestation was some abnormality in the clinical or radiographic appearance of the feet. Minimal manifestations included short, broad first metatarsal, abnormally shaped tarsal bone, and calcaneocuboid fusion. In some instances, the first and second metatarsals were fused, the second and third metatarsals were partially fused, the tarsal bones were abnormally shaped, and fusion of the navicular and first cuneiform bone occurred. Some affected individuals showed no clinical or radiographic abnormalities of the face or skull. Only one instance each of 3–4 syndactyly of the fingers, preaxial polydactyly of the feet, and fusion of the phalanges in the thumb were observed. No mentally retarded individuals were detected in this family.

Escobar and Bixler (76) reported an autosomal dominant pedigree in which the "classic forms of the Pfeiffer and Apert syndromes as

well as transitional types . . . occurred . . . Several members of the family . . . [had] . . . a facial resemblance to Crouzon disease." Penetrance was very high.

Jabs et al (132) reported a mutation in the Jackson-Weiss family: Ala344Gly. The same mutation has also been found in a family with Crouzon syndrome (102,165,258). A discussion of the Jackson-Weiss phenotype in a patient with a P252R mutation in FGFR1 has been presented (225a). One family reported as having "Jackson-Weiss syndrome" (4) also called "Adelaide type craniosynostosis" (117) is known to have FGFR3-associated coronal synostosis syndrome (Pro250Arg) (185).

Even though the mutation for the Jackson-Weiss family has also been reported in a Crouzon family, caution is urged in genetic counseling. Most families with *Crouzon syndrome* breed true. Jackson-Weiss syndrome appears to be very uncommon. Perhaps the differences may be explained by modifying genes.

Fig. 15–27. *Jackson-Weiss syndrome*. (A) Hypertelorism, proptosis, and midface deficiency. (B) Severe acrocephaly. (A,B from CE Jackson et al, J Pediatr 88:963, 1976).

Jones craniosynostosis/Dandy-Walker syndrome

Dandy-Walker malformation and craniosynostosis may each occur as an isolated abnormality or as components of various malformation syndromes. Braddock et al (25) reported an autosomal dominant syndrome of sagittal synostosis and Dandy-Walker malformation.

This distinctive malformation syndrome was discussed with MMC by Kenneth L. Jones, one of the authors, in 1977 (42). Cohen listed the condition as Jones syndrome in a 1979 tabulation of craniosynostosis syndromes (45) and later devoted a one paragraph description to it in 1986 (47). The paper of Braddock et al (25) is the first report of Jones syndrome in detail.

Kozlowski craniosynostosis syndrome

Kozlowski et al (149) reported a 12-year-old girl with short stature, mental deficiency, coronal synostosis, fusion of C_2–C_3, severe Scheuermann-like kyphosis of the upper thoracic spine, hamate-capitate fusion, first rib gaps, and complete duplication of the internal genitalia with a double uterus. Facial dysmorphism was characterized by ocular hypertelorism, ptosis of the eyelids, short downslanting palpebral fissures, low-set ears,

A

Fig. 15–28. *Jackson-Weiss syndrome*. (A) Short, broad first metatarsals and abnormally shaped tarsal bones. Oblique views of patient's feet (not illustrated) showed calcaneocuboid fusion. (B) Short, broad first metatarsals, fused first and second metatarsals, partially fused second and third left metatarsals, abnormally shaped tarsal bones, and fused navicular and first cuneiform bones. Calcaneocuboid coalition is also present, although it cannot be seen on radiograph. In this patient, the face and skull were normal. (A,B from CE Jackson et al, J Pediatr 88:963, 1976).

enlarged tragus, and hypoplastic lobules. The thumbs were proximally placed with fixed flexion. Fifth finger clinodactyly and limited elbow extension were also observed.

Lampert syndrome

Lampert et al (160) reported a sporadic instance of a patient with craniosynostosis, long thin face, midface hypoplasia, mild micrognathia, long tapering fingers, postaxial polydactyly, congenital hip dislocation, hallux valgus, and absent uterus.

Lin-Gettig syndrome

Lin and Gettig (166) reported a syndrome of craniosynostosis, agenesis of the corpus callosum, severe mental deficiency, hypogonadism, and a distinctive facial appearance. Two affected brothers had midline sutural involvement (sagittal in one, metopic in the other), ptosis of eyelids, blepharophimosis, slanted palpebral fissures, epicanthic folds, thin lips, and a long hypoplastic philtrum. Hypertonia, long slender fingers, and contractures were also evident. Third degree hypospadias was striking. Karyotypes were normal. The syndrome may be autosomal recessive, although X-linked inheritance cannot be ruled out. One of the sibs had features suggestive of Opitz C trigonocephaly syndrome, although microcephaly, abnormal palate with midline furrow, oral frenula, loose skin, and digital and limb malformations were absent.

Lowry syndrome

Lowry (170), in 1972, described a syndrome in two male sibs consisting of craniosynostosis and fibular aplasia. Chromosome studies of one sib were normal. A 25-year follow-up of this patient was provided by Lowry in 1993 (171). The other sib died shortly after birth of respiratory distress, and no chromosome studies were carried out. Consanguinity was noted, suggesting an autosomal recessive mode of transmission.

In one patient, both coronal and sagittal sutures were synostosed. In the other, only the coronal suture was involved. The eyes were prominent in both cases, and strabismus was noted in one. A partial cleft of the hard and soft palates was observed in one patient, a highly arched palate in the other (Fig. 15–29A).

The fingers were normal, and single palmar creases were found in both cases. Absent fibulas, talipes equinovarus, and normal toes were also reported in both cases (Fig. 15–29B).

Other findings included cryptorchidism in both sibs; short sternum, pilonidal dimple, and normal intelligence in one sib; and large posterior fontanelle, Wormian bones, low-set ears with pointed helices, short webbed neck, and mild chordee in the other sib.

Lowry-MacLean syndrome

In 1977, Lowry and MacLean (172) reported a syndrome characterized by craniosynostosis, microcephaly, facial dysmorphism, ocular proptosis, glaucoma, cleft palate, delayed dentition, preauricular tags and pits, eventration of the diaphragm, congenital heart defect, narrow hyperconvex fingernails, growth failure, and mental deficiency (Fig. 15–30). Other cases have been described by Kousseff and Ranells (148) and Al-Torki et al (8). The name Lowry-MacLean syndrome was introduced by Cohen in 1978 (43) and 1979 (45). Al-Torki et al (8), noting that the father and the sister of their proband also had glaucoma, suggested autosomal dominant inheritance with variable expressivity.

All three reported patients had mental deficiency, but only the patient of Lowry and MacLean (172) had hypoplasia of the corpus callosum, hydrocephalus, and seizures. Congenital heart defects have been variable: ASD, pulmonic stenosis, and bicuspid pulmonic valve in the patient of Lowry and MacLean (172); pulmonic stenosis, PDA, and dysplastic valves in the patient of Kousseff and Ranells (148); and VSD and coarctation of the aorta in the patient of Al-Torki et al (8). One patient had hypospadias, cryptorchidism, and inguinal hernia (148) and one had osteoporosis (8).

Meier-Gorlin (ear-patella-short stature) syndrome

Meier et al (178), in 1959, Gorlin et al (101), in 1975, and others (22,28, 40,89,99,125,168) described an autosomal recessive syndrome of disproportionate short stature, microtia, micrognathia, and absent patellas. There have been several pairs of affected sibs (22,40,89,102a, 125,168,240a). The joints have restricted motion, laxity, or aseptic necrosis. Skeletal alterations include slender long bones, delayed

Fig. 15–29. *Lowry syndrome*. (A) Craniosynostosis with tower skull, ptosis of eyelids, and strabismus. (B) Radiograph showing fibular aplasia and talipes equinovarus. (From RB Lowry, J Med Genet 9:227, 1972.)

skeletal maturation, short ribs, hooked clavicles, flat or absent glenoid fossa, absent patellae, and clinodactyly of fifth fingers (22,40,99,125) (Table 15–6). Blount osteochondritis dissecans and bilateral aseptic necrosis of the lateral femoral condyles have been noted (99). Height is below the 3rd centile, but there may be some catch-up growth during adolescence (89). Hearing loss due to Mondini malformation has been documented (168). Craniosynostosis has been noted by Hurst et al (125) and Loeys et al (168). Cryptorchidism and clitoromegaly have been reported. The breasts may be hypoplastic (262a). Lacombe et al (157), postulated that the syndrome is similar to the short ear mouse phenotype, which is an osteochondrodysplasia due to a mutation within the BMP5 gene.

Fig. 15–30. *Lowry-MacLean syndrome*. (A,B) Ocular proptosis, divergent squint, mild downslanting of palpebral fissures, prominent nose, and low-set posteriorly angulated ears with abnormal helix and preauricular fistula. [From RB Lowry and JR MacLean, Birth Defects 13(3B):203, 1977.]

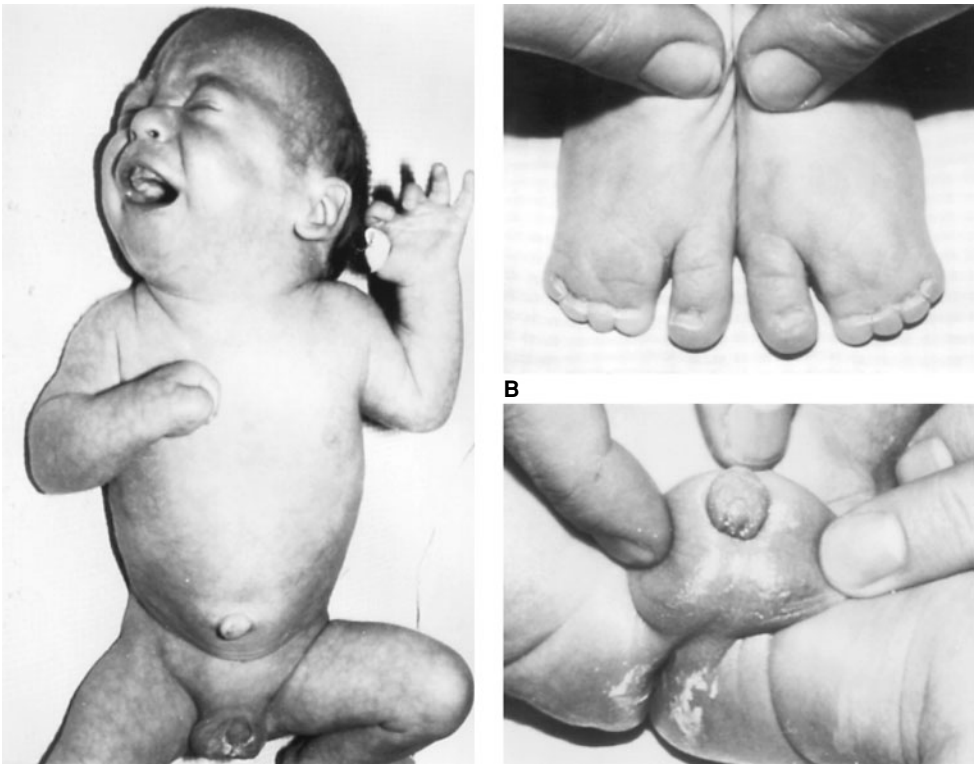

Fig. 15–31. *Pfeiffer type dolichocephalosyndactyly*. (A) Note dolichocephaly, micrognathia, and unilateral ectrodactyly. (B) Note bilateral syndactyly of second, third, fourth, and fifth toes. (C) Note perineoscrotal hypospadias. (From RA Pfeiffer et al, Eur J Pediatr 146:74, 1987.)

Osteocraniostenosis

Verloes et al (272), in 1994, reported a skeletal dysplasia in three unrelated fetuses, calling it osteocraniostenosis. Features included cloverleaf skull, microphthalmia, aniridia, extremely thin diaphyses, flared metaphyses, mild micromelic dwarfism, brachydactyly, and splenic hypoplasia. Whether the cases of "severe Hallermann-Streiff syndrome" reported by Dennis et al (70) really had osteocraniostenosis has been debated (70,270).

Histopathologic examination of the long bones showed abnormal metaphyseal cartilage and adjacent diaphyseal ossification, excessive modeling of the metaphyses, and, in one instance, dysplasia of the epiphyseal cartilage.

Pfeiffer type cardiocranial syndrome

Pfeiffer et al (203), in 1987, reported male and female siblings with sagittal synostosis, facial dysmorphism, and complex cardiovascular malformations. Cohen (68) named the condition Pfeiffer type cardiocranial syndrom in 1988. Other cases have been described by Stratton and Parsons (253), by Williamson-Kruse and Biesecker (279), and by Digilio et al (72), who noted male and female siblings.

Particularly common are growth deficiency, mental retardation, sagittal synostosis, ocular hypertelorism, downturned mouth, dysmorphic low-set ears, congenital heart defects, hypogonadism, and contractures of the large joints and fingers. Cardiovascular defects are both complex and highly variable, e.g., ventricular septal defect, atrial septal defect, and patent ductus arteriosus in one patient and tetralogy of Fallot, peripheral pulmonic stenosis, and atrial septal defect in another.

Anomalies in Pfeiffer type cardiocranial syndrome are facultative rather than obligatory. One of the siblings reported by Digilio et al (72) did not have craniosynostosis and the patient reported by Williamson-Kruse and Biesecker (279) had no cardiovascular defect. Two instances of affected male and female siblings (65,203) support autosomal recessive inheritance.

Pfeiffer type dolichocephalosyndactyly

Pfeiffer et al (204) reported a distinctive, sporadically occurring syndrome consisting of sagittal synostosis, facial dysmorphism, genitourinary anomalies, and limb defects (Fig. 15–31). Craniofacial features included dolichocephaly, upslanting palpebral fissures, inverse epicanthic folds, bilateral iris colobomas, atypical vessels in the fundus, possibly mild optic atrophy, highly arched palate, and micrognathia. Severe mental deficiency was evident. Perineoscrotal hypospadias and bilateral vesicoureteral reflux were also noted. Ectrodactyly of one hand and bilateral 2–5 syndactyly of the toes were observed. The karyotype was normal and the family history noncontributory.

Richieri-Costa overgrowth syndrome

Richieri-Costa et al (221) described two sibs, presenting with craniosynostosis, mental retardation, overgrowth, distal arthrogryposis, sacral dimple, and joint laxity. The fingers were slender. The hallux was long and in valgus position.

The face was long and thin and the skull dolichocephalic. The nasal bridge was broad and the philtrum short.

Inheritance is autosomal recessive.

Sagittal synostosis/auricular anomalies syndrome (Idaho syndrome II)

In 1977, Cohen (42) reported a patient with sagittal synostosis, auricular anomalies, and arachnodactyly. Findings included scaphocephaly, severe mental deficiency, small, low-set, posteriorly angulated ears, preauricular tags, tortuous ear canals, prominent occiput, downslanting palpebral fissures, dystopia canthorum, stellate iris pattern, highly arched palate, and micrognathia (Fig. 15–32). The neck was long. Other features included narrow thorax, pectus carinatum, mild winging of the scapulas, spina bifida at L5 cubitus valgus, mild genua valga, single palmar crease,

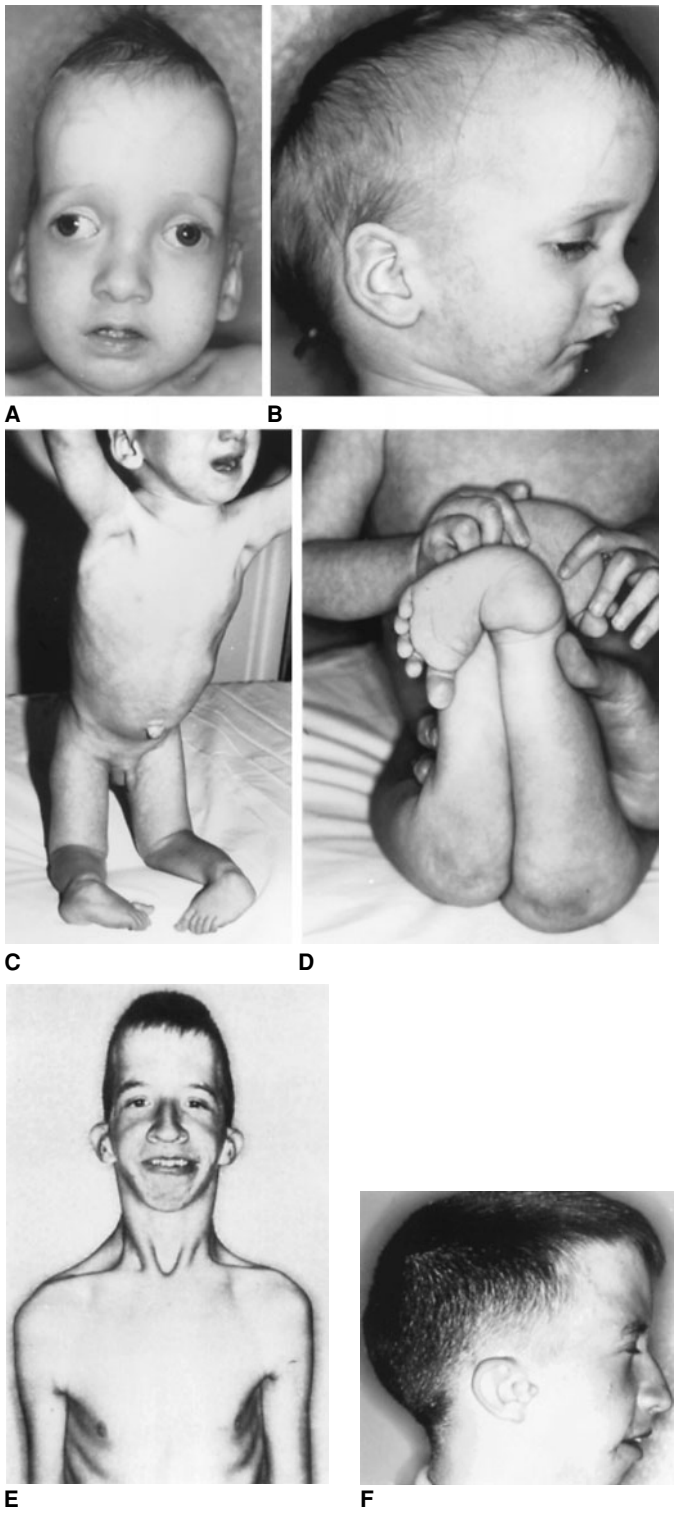

Fig. 15–32. *Sagittal synostosis/auricular anomalies syndrome* (*Idaho syndrome*). (A–D) Craniosynostosis involving sagittal suture, scaphocephaly, prominent veins, strabismus, overfolded helices, micrognathia, umbilical hernia, complete anterior dislocation of tibiae and fibulae with absent patellae allowing the knees to be flexed with the feet against the ventral surface of the body, and foot deformities. (E,F) *Idaho syndrome II*. Craniosynostosis with dolichocephaly, downslanting palpebral fissures, malformed ears, long neck, sloping shoulders, narrow thorax, pectus carinatum, and long arms. Note low-set posteriorly angulated ears with preauricular tags, and micrognathia. (A–D from MM Cohen Jr, The Child With Multiple Defects, Raven Press, New York, 1982. E,F from MM Cohen Jr, J Neurosurg 47:886, 1977.)

arachnodactyly, and bifid renal pelvis. The past history included seizures and bilateral inguinal hernias. The family history was noncontributory.

Sakati syndrome

Sakati et al (229) described a provisionally unique-pattern syndrome consisting of acrocephalopolysyndactyly, short limbs, congenital heart defect, ear anomalies, and skin defects. A chromosome study was normal. The condition should be distinguished from *Carpenter syndrome.*

The calvaria was large and the face was disproportionately small. The orbits were shallow and the eyes prominent. All cranial sutures were synostosed. The ears were dysplastic and low set. A unilateral ear tag was noted. Patches of alopecia with atrophic skin were present above the ears. Linear scar-like lesions were observed in the submental area. The palate was narrow and highly arched. Maxillary hypoplasia and crowding of the upper teeth were reported. The neck was short and the hairline low (Fig. 15–33).

Short arms, cubitus valgus, and short broad hands were evident. Fusion of the proximal interphalangeal joints of the fourth fingers and proximally placed thumbs were observed.

Extreme shortening of the legs and adducted feet were seen together with polysyndactyly (seven toes on one foot and six toes on the other). Radiographic examination showed bilateral coxa valga, lateral bowing of both femurs, hypoplastic tibias, deformity and displacement of the fibulas, and abnormal malposed tarsals and metatarsals. There were six metatarsals in each foot.

Other findings included a congenital heart defect, widely spaced nipples, cryptorchidism, small phallus, and inguinal hernia. Intelligence was normal.

Salinas syndrome

Salinas et al (230) reported a sporadic instance of multiple anomalies confined to the head and face. Features included acrocephaly with a prominent coronal suture thought to be fused, coarse dry hair, malar

Fig. 15–33. *Sakati syndrome*. Acrocephalopolysyndactyly, short limbs, congenital heart defect, ear anomalies, and skin defects. (From N Sakati et al, J Pediatr 79:104, 1971.)

hypoplasia with downslanting palpebral fissures, colobomas of the lower eyelids, small upturned nose, choanal atresia, cleft palate, midline cleft of the lower vermilion, and clefting of the mandibular symphysis.

San Francisco syndrome

In 1978, BD Hall (108) observed a striking syndrome of craniosynostosis, midface hypoplasia, ptosis of eyelids, bulbous nose, and small ears. The disorder followed an autosomal dominant mode of transmission.

Say-Barber syndrome

Say et al (239) reported two brothers with short stature, developmental delay, microcephaly, craniosynostosis in one of them, sloping forehead, beaked nose with high nasal bridge, highly arched palate, micrognathia, large protruding ears, flexion contractures, anal stenosis, hypoplastic patellas, scoliosis, small penis, small testes, and decreased subcutaneous fat (Fig. 15–34). Both brothers developed eczema during infancy and had recurrent infections and transient hypogammaglobulinemia.

Perandones et al (202) reported a third male patient with metopic synostosis, multiple infections, and a marked decrease in leukocyte chemotaxis. At this writing, the genetic basis of Say-Barber syndrome is not clear. However, two affected brothers and a third affected male suggest the possibility of X-linked inheritance.

Say-Meyer trigonocephaly syndrome

In 1981, Say and Meyer (237) described an X-linked recessively inherited syndrome consisting of craniosynostosis especially involving the metopic suture, developmental delay, and short stature. All three patients had vertical ridging of the metopic area together with hypotelorism. In two patients, the lambdoid sutures were also prematurely synostosed, and, in one patient, the sagittal suture was additionally involved. One of the three affected individuals had seizures. Low-frequency findings also included highly arched palate, secondary alveolar ridges, clinodactyly, and VSD. The syndrome needs to be further delineated.

Differential diagnosis includes Frydman trigonocephaly syndrome (this chapter) and Opitz C trigonocephaly syndrome (this chapter). Trigonocephaly may occur with mental deficiency in various chromosomal syndromes, most commonly with *del(9p)* (5) and *del(11q)* (33) and less commonly with *del(13q)* (196) and *dup(13q)* (119).

Say-Poznanski syndrome

Say and Poznanski (238) reported a distinctive syndrome with cloverleaf skull; polydactyly of the hands and feet; grossly abnormal metacarpals and metatarsals; angular ulnas with fusion to the midportion of the radial bones; short, wide clavicles; winged scapulas; unusually shaped ribs with abnormal spacing between them and with prominent costovertebral junctions; and widely separated ischia (Fig. 15–35).

Other findings included dilated ventricles, agenesis of the corpus callosum, micropenis, small testicular masses with rugae on either side of the penis, anteriorly placed anus, and a sacral dimple.

SCARF syndrome

SCARF is a mnemonic for *S*keletal abnormality, *C*utis laxa, *A*mbiguous genitalia, *R*etardation, and *F*acial abnormalities. The syndrome was reported in two male maternal first cousins, suggesting X-linked recessive inheritance (146).

Both patients had excess nuchal skin. The 7-year-old had a distinctive craniofacial appearance with sparse hair, low anterior and posterior hairlines, epicanthic folds, high nasal bridge, long philtrum, enamel hypoplasia, low-set posteriorly angulated ears, and short neck. Other finding included barrel-shaped chest, hypoplastic nipples, cryptorchidism, and

inguinal and umbilical hernias. Multiple nodular liver tumors were discovered by ultrasonography for which no definitive histopathologic diagnosis could be made. The 7-month-old had excess nuchal skin, micropenis, hypospadias, and bifid scrotum.

Shprintzen-Goldberg syndrome

Shprintzen and Goldberg (245), in 1982, described a recurrent-pattern syndrome of craniosynostosis, dolichocephaly, mental deficiency, ocular proptosis, ocular hypertelorism, downslanting palpebral fissures, strabismus, low-set anomalous ears, maxillary hypoplasia, micrognathia, arachnodactyly, hypotonia, camptodactyly, clubfoot, umbilical/inguinal hernia, and other skeletal and connective tissue defects (Fig. 15–36) (Table 15–7). The reader should be aware that this syndrome has nothing to do with *Goldberg-Shprintzen syndrome*. At least 15 cases have been reported (3,103,112,192,227,245,254). The syndrome has been extensively reviewed by Greally et al (103). Adès et al (3) reported four cases and Saal et al (227) noted a patient with cloverleaf skull. Hassed et al (112) observed a patient with cranial asymmetry, osteopenia, and hydrocephalus.

Earlier, in 1979, Cohen (44) used the term Montefiore syndrome to refer to the Shprintzen-Goldberg syndrome because Shprintzen and Goldberg had reviewed their patients with one of us (MMC) during a visit to the Montefiore Hospital. By 1982, Shprintzen and Goldberg (245) had published their paper. In 1986, Cohen (46) coined the term Shprintzen-Goldberg syndrome.

Fig. 15–36. *Shprintzen-Goldberg syndrome.* (A–E) Scaphocephaly, ocular proptosis, strabismus, micrognathia, pectus excavatum, arachnodactyly, camptodactyly of fifth fingers, and enlargement of palatal shelves. (From RJ Shprintzen and RB Goldberg, J Craniofac Genet Dev Biol 2:65, 1982.)

(From MM Cohen Jr, Craniosynostosis: Diagnosis, Evaluation, and Management. Raven Press, New York, 1986.)

At this writing, the etiology is still unknown. Sood et al (248) reported a patient said to have Shprintzen-Goldberg syndrome with a mutation in fibrillin 1 (FBN1): Pro1148Ala. Wang et al (274) and Schrijver et al (242) studied Pro1148Ala and concluded that it was a polymorphic variant rather than a disease-causing mutation.

Although there are similarities between Shprintzen-Goldberg syndrome and Marfan syndrome, there are also differences. Part of the problem is that as syndrome delineation has taken place, a widened clinical spectrum of sporadic cases has probably resulted in heterogeneity. Thus, what Shprintzen and Goldberg described originally has been expanded to mean "craniosynostosis with Marfanoid features."

The patients reported by Furlong et al (91), Lacombe and Battin (156), Shah et al (244), and Mégarbané and Hokayem (177) are phenotypically somewhat different from Shprintzen-Goldberg syndrome patients and have normal intelligence. The photographs of Furlong et al (91) show a patient who looks like he has Marfan syndrome, but with accompanying simple synostosis. Greally et al (103) described characteristics that appear to differentiate Shprintzen-Goldberg syndrome from the patients of Furlong et al (91) and Lacombe and Battin (156). These include hypotonia, developmental delay, hydrocephalus, ventriculomegaly, Chiari-I malformation, and C_2–C_3 vertebral anomaly in Shprintzen-Goldberg patients.

Differential diagnosis includes classic *Marfan syndrome* and the syndrome of arachnodactyly, abnormal cranial ossification, protruding eyes, and mental deficiency reported by Kosztolányi et al (147). *Antley-Bixler syndrome* and *sagittal synostosis/auricular anomaly syndrome (Idaho syndrome II)* are discussed elsewhere in this chapter.

Spear-Mickle syndrome

Spear and Mickle (249) reported a patient with several soft tissue tumors in the left frontal area of the scalp together with unilateral coronal synostosis and plagiocephaly, bifid nose, highly arched palate, lumbar meningomyelocele, cryptorchidism, thoracic kyphoscoliosis, hip dislocation, equinovarus deformity of one foot with calcaneovalgus deformity of the other, and elbow contractures. Chromosomes were normal and there were no other affected individuals in the family. The mother had been a frequent user of alcohol and heroin and the pregnancy had been ectopic.

Spondyloepiphyseal dysplasia/craniosynostosis syndrome

Nishimura et al (193) reported spondyloepiphyseal dysplasia, craniosynostosis, cataracts, micrognathia, cleft palate, and mental deficiency. Most features were present at birth. However, skeletal alterations and cataracts became more pronounced in early childhood. These authors evaluated four affected sibs—a finding consistent with autosomal recessive inheritance.

Coronal synostosis was associated with frontal bossing, bitemporal hollowing, ocular hypertelorism, midface hypoplasia, and short nose. Spondyloepiphyseal dysplasia resulted in mild micromelia during infancy and short trunk with thoracolumbar kyphoscoliosis in late childhood.

Ventruto syndrome

In 1976, Ventruto et al (269) reported a distinctive autosomal dominantly inherited syndrome consisting of brachydactyly, aplastic or hypoplastic nails, symphalangism, carpal and tarsal fusion, dysplastic hip joints, and craniosynostosis (Fig. 15–37). Five affected individuals were reported through three generations. The proband was first seen for acute leukemia.

Craniosynostosis involved the coronal suture. Strabismus was commonly observed. Anomalies of the hands and feet varied in severity and were not symmetric. The thumbs and great toes were not involved. Absence or hypoplasia of the middle and distal phalanges of the fingers was variable in degree and was associated with absence or hypoplasia of the nails. In some instances, both the middle and the distal phalanges were involved. In other instances, only the distal phalanges were affected. Symphalangism, when present, involved the proximal interphalangeal joints. First metacarpals showed brachymetapody. Carpal fusions involved the hamate and capitate or were more complex and involved the trapezium, trapezoid, capitate, hamate, and lunate.

Fusion in the tarsals involved the second and third cuneiform bones and/or other fusions such as between the first cuneiform and scaphoid, the calcaneus and cuboid, or the second cuneiform and second metatarsal. In some affected individuals, one or more cuneiform bones were absent. Brachymetapody involved the first metatarsal in several patients. The pattern of absence or hypoplasia of the middle and distal phalanges of the toes was similar to the pattern observed in the fingers. In the feet, symphalangism also involved the proximal interphalangeal joints. Pelvic radiographs showed osteochondritis or sclerosis involving the acetabular roofs but sparing the femoral necks.

Differential diagnosis includes isolated type-C brachydactyly and type-C brachydactyly with associated abnormalities. Type-C brachydactyly involves the proximal and middle phalanges of the second and third fingers, hypersegmentation of the proximal phalanges, brachymetapody, and symphalangism. Type-C brachydactyly also occurs with Legg-Perthes disease of the hip as a familial syndrome.

Wisconsin syndrome

Wisconsin syndrome consists of craniosynostosis, mental deficiency, upslanting palpebral fissures, microtia, and short fourth metatarsals with recessed fourth toes (Fig. 15–38). Chromosomes were normal and the patient was the only affected member of the family (195).

Chapter 16
Syndromes of Abnormal Craniofacial Contour

Anencephaly

Anencephaly is a congenital anomaly characterized by an open neural tube in the cephalic region with an exposed mass of degenerate neural tissue on the skull floor. The cranial vault is absent, producing characteristic bulging of the eyes and absence of the neck. Both the membranous neurocranium and the chondrocranium are grossly malformed (Figs. 16–1 and 16–2). Anencephaly is classified anatomically as meroacrania if the defect does not involve the foramen magnum, holoacrania if the defect extends through the foramen magnum, and holoacrania with rachischisis if spina bifida accompanies anencephaly (31).

The reader is referred to the following sources for extensive coverage: general aspects (29–31), classification (28,30,31), anatomy and morphology (10,14,22,30,35,36,41), pathogenesis (11,30), epidemiology (3,5,21, 34,39,46,55,60,63–65,67,75), twin studies (6,11,20,47,52,57,76,77), etiologic factors (9,16,18,25–27,49,56,66,68,70,77), associated anomalies (2,8,12,33,37,40,74), prenatal diagnosis (23,24,43–45), and recurrence risk (7,12,26,38,48,60,79).

Most epidemiologic studies include both anencephaly and spina bifida (ASB) because both arise by nonclosure of the neural tube, the closing of the anterior and posterior neuropores being 24 and 26 days, respectively. Neural tube defects (NTD) in spontaneous abortions is about 10 times higher than NTDs found at term. Of nine specimens in the series of Byrne and Warburton (5), ASB accounted for four of the cases and chromosomal abnormalities were noted in two. Wide divergence in birth prevalence has been recorded. Average prevalence is approximately 1/1000 births in the eastern United States, Denmark, Kenya, Malaysia, India, Taiwan, and South Africa. High prevalence has been observed in Ireland and Wales (3.05–6.79/1000), the remaining British Isles (approximately 2–3/1000), Egypt, and Lebanon. Low prevalence (0.1–0.6/1000) has been noted in France, Norway, Hungary, Czechoslovakia, Japan, and Yugoslavia. Overall, an east–west gradient occurs with higher prevalence in the British Isles followed by eastern North America, then western North America, and finally the Far East (28). Some studies have shown decreasing rates with time (34,55,60,64,66a,75), although the reasons for this are not known. Melnick and Marazita (39) showed that neural tube defects were nearly five times higher in Northern China than in Southern China.

Wide ethnic differences also occur. US whites have a rate of over 1/1000; native Americans, 0.32/1000; and blacks, 0.1–0.4/1000. Striking variation exists in Singapore with the Chinese having a rate of 0.62/1000, Eurasians 1.45/1000, Europeans 2.15/1000, and Sikhs 6.5/1000 (2,3,28).

Most studies show a higher frequency of anencephaly in females than in males, although the sex ratio has been close to 1 : 1 in some studies (28,31). The prevalence in twins is significantly higher than in singletons. The twin female-to-male sex ratio is lower than the singleton female-to-male sex ratio. Among twins, concordance for anencephaly is low (approximately 3.7%) (76,77). Anencephaly appears to occur with higher frequency among monozygotic than among dizygotic twins as same-sexed twins have a higher frequency than opposite-sexed twins. Furthermore, anencephaly seems to be relatively common in conjoined twins (20). It has been concordant among monozygotic (MZ) triplets (59). Concordance between MZ twins is about 7% (19). Neural tube defects are more common in spontaneous abortions (5).

A consistently reported epidemiologic factor has been a higher prevalence of ASB among poorer social classes (28). An epidemiologic study that strongly suggests etiologic heterogeneity is that of Khoury et al (21). After excluding cases of known cause, they divided their sample into two groups, isolated and syndromic (multiple malformations), and found marked differences in the epidemiology of the two groups. The isolated group showed marked predominance of females and whites, geographic variation with an east-to-west gradient, and decreasing rates over time. The group with multiple malformations showed no female predilection and occurred less often in whites, showed no geographical variation, and demonstrated little or no downward trend over time.

The etiology of many cases is unknown, although various factors are known to be responsible for some. The condition is clearly etiologically heterogeneous. Most instances occur sporadically, but a tendency toward familial aggregation of ASB is observed in some pedigrees. In other kindreds, instances of encephalocele or hydrocephaly may also be noted. Most cases appear to be multifactorially determined. Chromosomal, monogenic, and environmental causes have been reviewed by Holmes et al (16), Khoury et al (21), Toriello et al (70), and Farag et al (9). It has been suggested that nongenetic factors fall into two categories: immediate factors related to pregnancy and intergenerational factors related to a woman's growth and development (64). Multi-site closure of the neural tube has been discussed by Nakatsu et al (47a), Van Allen et al (72), and Seller (61).

Autosomal recessive and X-linked families have been recorded (9,70). The Meckel syndrome is most commonly observed with occipital encephalocele, but anencephaly has been noted on rare occasions (16). Holmes et al (16), Khoury et al (21), and van den Maldergem et al (73) have reviewed known chromosomal conditions in which ASB have been reported. Known teratogens include aminopterin (anencephaly or encephalocele in some cases), thalidomide (rarely anencephaly and/or spina bifida), and diabetic pregnancies (16,56). Postulated environmental causes have included influenza A, hyperthermia, alcohol ingestion during pregnancy, water softness, maternal zinc deficiency, organic solvents, dietary factors, and vitamin deficiency (18,25–27,49,66,78). Folic acid given during the first four weeks of pregnancy have been found to prevent about 50% of neural tube defects. Mothers of infants with neural tube defects have increased homocysteine levels (6,11,47,73a).

Theories of pathogenesis have been reviewed by Lemire et al (31). The primary defect is either in the neuroepithelium itself or in the surrounding mesoderm. Some lesions may be caused by reopening of a closed neural tube secondary to either an increase in the intraluminal pressure or to some defect in the neuroepithelium (13). Most experimental evidence favors the concept that anencephaly arises from a neural tube that fails to close (28).

Craniofacial features. Variation in central nervous system pathology is related to the extent of the neural tube defect as well as the gestational age. Generally, the more complete the absence of the cranial vault, the less likely nervous tissue is to be found on the cranial base. The cerebral hemispheres are soft, red-to-purple in color, and formless, being composed of thin-walled vascular channels distended with blood and separated by irregular masses of brain tissue. A thin covering of squamous epithelium and choroid plexus-like tissue may be present in some cases. The cerebellum may be normal or malformed (31). In some instances of meroacrania, brain tissue may bulge out, resembling an encephalocele. As a result, meroacrania has been misdiagnosed on occasion in the literature. Absence of skin covering separates meroacrania

A B

Fig. 16–1. *Anencephaly*.

from encephalocele (28). Anencephaly and holoprosencephaly may occur together (32). Diprosopus and facial clefting may also be associated (15).

The pituitary gland is almost always present, despite the assertion in the literature that it may be absent. The neurohypophysis is almost always hypoplastic, distorted, and frequently found in the craniopharyngeal canal, which usually remains open in anencephaly. The hypothalamus is absent as are the neural connections between the adeno-hypophysis and the central nervous system (31).

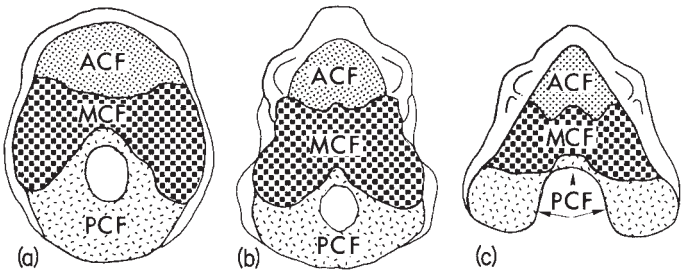
Craniofacial malformations may include hypoplastic and/or low-set ears, anomalous ear folds, absent helices, exotropia, ocular proptosis, small palpebral fissures, microphthalmia, clinical anophthalmia, subcutaneous nasal cleft, absent or incompletely defined philtrum, anomalous palate with midline grooving, cleft lip, cleft palate, bifid uvula, microstomia, prominent maxillary alveolar ridges, and mandibular prognathism (31). Short neck is common. The thyroid gland may be normal, small, or increased in size (31).

The craniofacial skeleton has been studied by a number of authors (10,14,22,35,36,41). In the facial skeleton, the frontal bone is severely affected with a marked increase in angulation. The superior orbital rims are directed posterolaterally. The orbital plate of the frontal bone usually cannot be identified. The zygomatic bones are severely affected and, in lateral view, have a rhomboid shape. Cephalometric study shows the mandible to be prognathic in every case (41).

In large cranial defects, the interparietal portion of the occipital bone is relocated anteriorly to approximate the frontal bone. Occipital components are rotated anterolaterally and inferiorly with lack of fusion of the chondrocranium posterior to the foramen magnum. The squamae of the frontal bone are collapsed horizontally and reduced in size, lying peripheral to the anterior cranial fossa to form most of the orbital roofs (14).

Changes in the cranial floor are caused by alterations in the size, form, or duration of the neural functional matrix. Sphenoid bone alterations result in a reduced cranial floor angle and a more vertically oriented clivus. Schematic drawings of the cranial fossae in meroacrania and holoacrania are compared with normal in Fig. 16–2. In both types, the anterior and middle cranial fossae are constricted laterally and the posterior cranial fossa is increased in lateral extension, but constricted anteroposteriorly. The lesser wings of the sphenoid have an anteroposterior orientation; the greater wings of the sphenoid have a reduced transverse dimension; and the lateral end of the petrous portion of the temporal bone is positioned more anteriorly (10).

Fig. 16–2. *Anencephaly*. Schematic drawing of the bones of the cranial floor in (a) a normal fetus, (b) a fetus with meroacrania, and (c) a fetus with holoacrania. Note the anteroposterior position of the lesser wings of the sphenoid and the reduced transverse dimension of the greater wings of the sphenoid (b and c) relative to the normal (a). The more anterior position of the lateral end of the petrous portion of the temporal bone is also evident in anencephaly. In holoacrania, the supraoccipital components are nonunited and widely divergent (c). ACF, MCF, PCF, anterior, middle, and posterior cranial fossa. (From HW Fields et al, Teratology 17:57, 1978.)



Associated anomalies. David and Nixon (8) in a study of 294 cases of anencephaly found that the most frequent single malformations were hydronephrosis (8%), cleft palate (8%), diaphragmatic hernia (5%), omphalocele (5%), cleft lip (4%), and horseshoe kidney (4%). Lemire et al (31) studied associated malformations in 68 cases and Melnick and Myrianthopoulos (40) reported a series of 36 cases. Especially significant are spinal retroflexion, scoliosis, talipes equinovarus or calcaneovalgus. Increased anteroposterior chest diameter, high diaphragm, eventration of the diaphragm, absent diaphragm, patent foramen ovale, hypoplastic heart, various other cardiac defects, anomalous lobation of lungs, hypoplastic lungs, hydroureter, hydronephrosis, hypertrophy of the bladder wall, hypoplastic ureters and/or bladder, hyperlobulated kidneys, absent ureters or bladder, undescended cecum, omphalocele, short intestines, and Meckel diverticulum (1,8,31,40,73). The adrenals are characteristically small. The frequency of the sternalis muscle may be as high as 50% in some series. In contrast, the frequency varies between 1% and 4% in the general population. The upper limbs are excessively long in relation to the lower limbs. On the average, arm length is about 12% greater than normal and a proximal-to-distal gradient exists, the upper arm being increased by 24%, the forearm by 16%, and the hand by 2% (31). Aganglionosis (37) and possible association with Waardenburg syndrome (33) have been noted as well as sirenomelia (50,51,53,54,58).

Differential diagnosis. Some cases of *amnion rupture sequence* may resemble anencephaly. Since the former is associated with limb amputations, ring constrictions, distal syndactyly, and tissue bands. In practice, little difficulty should be experienced in differentiating the two. Some authors discuss iniencephaly and anencephaly together (8,30). Both share a female preponderance; iniencephaly appears to be more common in areas

where anencephaly is common, and both may be accompanied by spina bifida. However, the time of onset for each of these malformations is different and families have not been observed with affected members of both types. Anencephaly may occur together with *holoprosencephaly* (32) and all such cases to date have been sporadic. Townes et al (71) reported a sibship with anencephalic male twins and a female infant with alobar holoprosencephaly, radial aplasia, and oligodactyly.

Wynne-Davies (78) carried out a family survey of 337 patients with multiple vertebral anomalies without apparent spina bifida. She found that vertebral anomalies were etiologically related to anencephaly and spina bifida, carrying a 5%–10% risk to subsequent sibs. However, some families with spina bifida and/or other vertebral anomalies are known to occur without anencephaly (17,63,69), suggesting further heterogeneity.

Diagnosis and laboratory aids. Diagnosis is based on the overall pattern of anomalies and family history. An attempt should be made to rule out known syndromes and environmental causes. Certainly chromosome study is indicated. Radiographic studies of the vertebral column in relatives of the proband are also indicated. The presence of an NTD in a first degree relative, second degree relative, or third degree relative of a fetus is an indication for amniotic fluid α-fetoprotein determination, although there is little evidence of an increased risk unless the affected relative is a parent or sib. Approximately 60% of newborns with NTDs have anencephaly. The risks for a neural tube defect in relatives of affected persons are as follows: father's siblings, 7%; mother's sister's children 13%; mother's brother's children 3%; father's sister's children 6%; and father's brother's children 4%. The combination of elevated maternal serum α-fetoprotein and low estriol is highly predictive of anencephaly (79). The success of maternal serum α-fetoprotein screening requires a well-organized program with strict adherence to protocol. In pregnancies with elevated amnionic α-fetoprotein level and a nondiagnostic ultrasound, acetylcholinesterase assay of amnionic fluid assumes major importance. In a pregnant woman with a previously affected child or an elevated maternal serum or amnionic fluid α-fetoprotein level, ultrasonography can be made longitudinally and transversely to specifically identify the NTD (23,24,42–45).

It should be borne in mind that elevated α-fetoprotein levels may be due to maltiming of pregnancy, twinning, congenital nephrosis, abdominal wall defects, hygroma colli, atresia of esophagus, and a host of other causes as well as anencephaly (4).
