Encephaloceles

Encephaloceles may occur as isolated malformations or in combination with other anomalies making up various syndromes or associations. The literature has been reviewed extensively elsewhere (23,109). Although encephalocele is the most commonly used term for all such lesions, cranium bifidum and cephalocele more properly describe the spectrum of malformations that includes both encephalocele and cranial meningocele (108).

Encephaloceles (Figs. 16–3 to 16–5) can be classified as occipital, parietal, or anterior (Table 16–1). Further subdivision of anterior encephaloceles can be made: visible (sincipital) and not directly visible (basal) (3,102). About 75% of all encephaloceles occur in the occipital region (9,63). Prevalence is said to vary from 1 in 2000 to 1 in 5000 live births. They are more common in African and Asian populations (29,33). Parietal encephaloceles account for approximately 10%–14% of all encephaloceles (9,63,84). Frontal encephaloceles are much less common than occipital encephaloceles in the United States, the ratio being 1 : 6 (33). African studies, however, show a 1 : 1 ratio. Encephaloceles are very common in Thailand, Burma, and India (18), prevalence being about 1/3500 live births (42). The frequency of basal encephalocele appears to be comparatively low, an undocumented prevalence being 1/35,000 live births (106).

At present, it is not possible to know how frequently other anomalies occur with encephaloceles because surveys in the literature have focused primarily on signs and symptoms, natural history, treatment, and treatment outcome (9,17,26,63,77,84,85). Although associated anomalies are mentioned and even tabulated, such data cannot be used for several reasons. First, associated anomalies are not always properly broken

A B C

Fig. 16–4. *Encephalocele*. (A–C) From left to right: frontal encephalocele, frontonasal encephalocele, and frontonasal malformation with flattened encephalocele. (From MM Cohen Jr and RJ Lemire, Teratology 25:161, 1982.)

down. In some series, anomalies that occur with encephalocele and with spina bifida are lumped together. In other surveys that deal only with encephaloceles, associated anomalies cannot always be sorted on the basis of the anatomic location of the encephalocele. Second, associated anomaly categories may be too inclusive. Primary and secondary anomalies are not always separated. Thus, the total number of associated anomalies is confounded in patients with only one anomaly in the total number, and there is no way to break the anomalies down on a per patient basis. Finally, there are a number of problems with ascertainment bias in some surveys and problems with sample size in others (23).

Conditions with encephaloceles are discussed under the following headings: chromosomal syndromes, monogenic syndromes, teratogenic causes, disruptive causes, various associations, and miscellaneous conditions occasionally associated with encephaloceles.

Chromosomal syndromes. Encephalocele has been reported with several chromosomal syndromes, including trisomy 18 on occasion (5,108). It has also been noted with Turner syndrome (14), but this finding can be questioned. With some Turner syndrome abortuses, severe lymphedema of the posterior neck area can mimic cephaloceles and care should be taken not to confuse the two. An encephalocele was said to be present in one patient with dup(1q) karyotype (45), but a photograph of the affected infant shows apparent anencephaly of the meroacrania type. Moeschler et al (89) reported a patient with del(13q) syndrome with a large occipital encephalocele, severe microcephaly, and Type 1 Arnold-Chiari malformation. Schinzel (96) cited a case with meningocele.

Hsia et al (62) reported a sporadic instance of a syndrome with many clinical similarities to the Meckel syndrome but with some differences. The condition was thought to be caused by a chromosomal anomaly. Features of the pseudo-Meckel syndrome included occipital encephalocele, absent olfactory tracts and bulbs, absent corpus callosum, Arnold-Chiari malformation, cleft palate, wide aorta originating from the right ventricle, atretic pulmonary valve, narrow pulmonary artery arising from a blind lumen to the left of the aortic origin, patent ductus arteriosus, ventricular septal defect, single coronary artery, accessory spleen, talipes equinovarus, and hallucal hammertoes. No polydactyly was observed

Fig. 16–5. *Encephalocele*. Transsphenoidal encephalocele with herniation into the posterior nasopharynx. (From JM Lieblich et al, Ann Intern Med 89:910, 1978.)

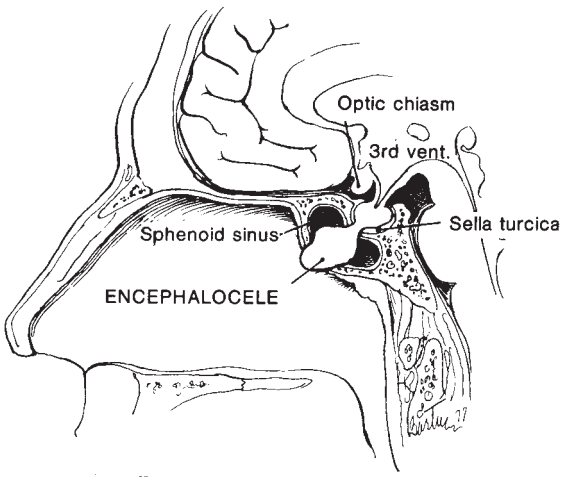

Table 16–1. Classification of sincipital and basal encephaloceles

Location	Boundaries (bones)	Presentation
Sincipital		
Frontoethmoidal		
Nasofrontal	Cribriform plate of ethmoid Nasal process of frontal Frontal process of maxillary	Midline at root of nose
Nasoethmoidal	Ethmoid Frontal Nasal	On one or both sides of nose
Nasoorbital	Lacrimal Frontal	Superior medial angle of orbital cavity; displaces eye laterally; may be bilateral
Interfrontal		
Craniofacial cleft		
Basal		
Sphenoorbital	Superior orbital fissure	Enters orbit, causing exophthalmos
Sphenomaxillary	Superior orbital, then inferior orbital fissure	Pterygopalatine fossa
Transethmoidal	Defect in cribriform plate	Anterior nasal fossae
Sphenoethmoidal	Sphenoethmoidal suture	Posterior nasal fossae
Sphenopharyngeal	Defect in sphenoid	Rhinopharynx, sphenoid sinus

(Adapted from G Avanzini and G Crivelli, Acta Neurochir (Wien) 22:205, 1970; C Suwanwela and N Suwanwela, J Neurosurg 36:201, 1972; J Warkany et al, Mental Retardation and Congenital Malformations of the Central Nervous System, Year Book Publishers, Chicago, 1981.)

and retinal dysplasia, a consistent feature of the Meckel syndrome (81), was conspicuously absent. Lymphocyte study of 15 metaphase spreads showed a karyotype of 46,XX,t(3p+;?). The proximal part of the elongated short arm of chromosome 3 showed the usual banding pattern with quinacrine fluorescence. The origin of the translocated distal portion could not be determined with certainty, although it was thought to have arisen from the long arm of either chromosome 10 or chromosome 6. Karyotype was normal in both parents and in a normal brother of the proband.

Monogenic syndromes. *Meckel syndrome* is the best known malformation syndrome with occipital encephalocele and has been reviewed extensively elsewhere (51,61,81,86,87,91). Features include polydactyly, polycystic kidneys, holoprosencephaly, microphthalmia, retinal dysplasia, various cardiac anomalies, orofacial clefting, ambiguous external genitalia, and various other abnormalities. Occipital encephalocele occurred in 39 of 49 cases tabulated from the literature (86). The syndrome has autosomal recessive inheritance.

Cryptophthalmos syndrome consists of extension of the skin of the forehead covering one or both eyes, unusual hairline, ear anomalies, total or partial soft tissue syndactyly of the fingers and toes, notching of the wings of the nose, and genital anomalies such as micropenis, hypospadias, clitoromegaly, vaginal atresia, and incomplete development of the labia. The syndrome has autosomal recessive inheritance. Approximately 10% of reported cases have been associated with encephalocele. In some instances, osseous defects of the calvaria occur without encephalocele (104).

Dyssegmental dysplasia is etiologically heterogeneous with an autosomal recessive severe form (*type Silverman-Handmaker*) and an autosomal recessive milder form (*type Rolland-Desbuquois*). Both types are usually lethal. Facial features in both consist of mild blepharophimosis, flat nasal bridge, hypoplastic supraorbital ridges, micrognathia, and cleft palate. Occipital encephalocele, occipital bone defect, and hydrocephaly have been noted in some instances. The neck is short. Radiographic findings include short, broad tubular bones with metaphyseal widening, accelerated carpal bone maturation, bowing of the legs as well as the thighs and forearms, short broad pelvis with widely flared iliac wings, vertebral anomalies, and small thorax (1,32,52,55).

Knobloch syndrome in 5 of 10 siblings was reported in 1971 by Knobloch and Layer (72). Features included high myopia, vitreoretinal degeneration, retinal detachment, and occipital encephalocele. Several other sibships have been described (27,94,97,99,115). Inheritance is autosomal recessive and the gene has been mapped to 21q22.3 (99). Encephaloceles tend to be small, commonly with normal cognitive development. Atretic encephalocele, scalp defect, and pigmented hair tuft of the parieto-occipital midline have been noted (27,97,115). Other associated anomalies have included hypoplastic lung, dilated pulmonary lymphatics, dextrocardia, PDA, pyloric stenosis, duplicated renal collecting system with bifid uvula, and spina bifida occulta at L5-S3 (27,72,115).

Roberts syndrome is characterized by growth deficiency, severe hypomelia, cleft lip-palate, prominent eyes with hypertelorism, large phallus, and other anomalies. Inheritance is autosomal recessive, and heterochromatic puffing and centromere separation have been observed cytogenetically. Encephalocele was a feature of one case reported by Freeman et al (44). However, care should be taken not to confuse nuchal cystic hygroma in the fetus, also observed in some cases, with encephalocele.

Walker-Warburg syndrome, also known as Warburg syndrome, HARD±E syndrome, and Chemke syndrome, consists of hydrocephaly, agyria, occipital encephalocele in about 50%, microphthalmia, and/or anterior and posterior chamber abnormalities including corneal opacity, cataract, persistent primary vitreous, and retinal dysplasia. Genitourinary abnormalities are present in some cases. Inheritance is autosomal recessive (4,13,15,23,35,39,93,113). Early demise is characteristic, and recognition of the syndrome is essential for proper genetic counseling of families at risk. Although agyria is a feature of the syndrome, the condition should not be confused with *Miller-Dieker lissencephaly* syndrome (101,105). In the latter disorder, the cerebral cortex is thickened. In Walker-Warburg syndrome, the cortex is atrophic and disorganized. Walker-Warburg syndrome and Meckel syndrome have in common both occipital encephalocele and retinal dysplasia. However, the neuropathologic malformations are entirely different, and polydactyly and polycystic kidneys, which are common in Meckel syndrome, are not features of Walker-Warburg syndrome.

Teratogenic causes. Maternal hyperthermia may be implicated as one cause of occipital encephalocele. Of 17 patients with isolated posterior encephalocele, Fisher and Smith (40) found that four of the mothers gave a history of at least 1.5°C above normal from prolonged fever early during pregnancy. Since Fraser and Skelton (43) implicated maternal hyperthermia as a teratogen that can produce abnormalities from 3 to 14 weeks of gestation, it seems possible that at least some instances of multiple anomalies with encephalocele arising around the same embryonic time may occur on this basis.

Warfarin embryopathy has been associated with a spectrum of malformations, most commonly nasal hypoplasia and bone stippling. The condition has been reviewed elsewhere (95). Various other abnormalities have been observed including limb shortening, low birthweight, optic atrophy, mental deficiency, hypotonia, seizures, and various other defects. Occipital encephalocele has been observed in two instances. Tejani (103) described a patient with nasal hypoplasia, occipital encephalocele, hydrocephaly, microphthalmia, and persistent truncus arteriosus. Warkany and Bofinger (109) reported two affected children with hydrocephaly. One had a huge occipital encephalocele and renal malformations.

Disruptive causes. Features of the *amnionic rupture sequence* have been reviewed elsewhere (9,57,64,69,78). Most instances involve digits or limbs with ring constrictions or amputations. In some cases, an affected newborn will have unusual orofacial clefts, encephaloceles, and other facial anomalies. Amnionic bands become entangled in the oral and nasal orifices and sometimes become attached directly to the face or cranium, producing bizarre disruptions. These encephaloceles are unusual because of their tendency to have (a) irregular surfaces, (b) asymmetric placement with respect to the midsagittal plane, (c) predominantly anterior placement, and (d) multiple sites of involvement. Other anomalies may also occur. Besides disruptions, deformations and malformations have been noted in some instances. Some reported malformations are not secondary to amnionic bands or oligohydramnios. Although the overwhelming majority of cases are sporadic, occasional familial instances have been recorded.

Frontonasal malformation. *Frontonasal malformation* (Fig. 16–4C) or median cleft face syndrome has been reviewed elsewhere (22,24, 31,98). The condition is characterized by a flattened nasofrontal encephalocele, hypertelorism, widow's peak, and wide-set nostrils with lack of elevation of the nasal tip. Occasionally encountered are notching or clefting of the nostrils or an unusual form of median cleft lip. A variety of extracephalic anomalies may be present in some cases. The most extensive review is that of Guion-Almeida et al (53). Most cases are sporadic. Causal genesis includes an autosomal dominant form; dup(2q); autosomal recessive Shanske syndrome; the syndrome of frontonasal malformation, agenesis of the corpus callosum, tibial hypoplasia, and hallucal duplication; and ophthalmofrontonasal dysplasia (53).

von Voss-Cherstvoy syndrome. Cohen (21) called attention to this entity in 1982 and named it von Voss syndrome. It has also been called von Voss-Cherstvoy syndrome (79) and DK phocomelia phenotype. Several cases have been reported (8,16,46a,65,79,107). The disorder is characterized by occipital encephalocele, radial ray defects, and urogenital abnormalities. Other findings have included aplasia or hypoplasia of the corpus callosum and, variably, hypoplastic lung, dextroposition of the heart, and thrombocytopenia. Affected sibs and parental consanguinity have been reported in two cases (3). Lubinsky et al (79) pointed out similarities to

del(13q) syndrome. Bamforth and Lin (8) noted fibroblast mosaicism for del(13)(q12).

Encephalocele/absent corpus callosum association. The association of encephalocele and absent corpus callosum has been observed repeatedly both as a binary combination and together with various other anomalies. McLaurin (84) noted absence of the corpus callosum in four of 13 parietal encephaloceles. Lieblich et al (75) and Avanzini and Crivelli (3) reported agenesis of the corpus callosum with transsphenoidal encephalocele. A posterior orbital encephalocele was observed with agenesis of the corpus callosum and cerebellar atrophy in a patient reported by Fargueta et al (38). Other cases of encephalocele and absent corpus callosum have been described by Mood (90). The combination also has been reported in *frontonasal malformation* and in von Voss-Cherstvoy syndrome (16).

Absent corpus callosum is part of the spectrum of holoprosencephalic disorders in some instances but not in others. The latter is assumed to be the case in the association discussed. The relationship of absent corpus callosum to holoprosencephaly has been discussed extensively by Marburg (82) and Loeser and Alvord (76). Encephalocele and agenesis of the corpus callosum as part of holoprosencephaly may occur in the Meckel syndrome (61,91) and has been observed with cyclopia in a patient with r(18) karyotype (25). Encephalocele and holoprosencephaly can be produced by the same teratogen in animals. DeMyer (30) was able to induce both malformations in rat fetuses with vincristine injected intramuscularly into pregnant rats 8.5 days following mating. The sporadic occurrence of cyclopia and encephalocele has been reported in the goat (67).

Encephalocele/clefting association. The binary combination of encephalocele and orofacial clefting has been reported on a number of occasions and the literature has been reviewed elsewhere (49). In some cases, a sphenopharyngeal encephalocele is associated with cleft palate. In these instances, it is possible to speculate that early encephalocele formation mechanically interfered with closure of the secondary palate. More commonly, sphenopharyngeal encephalocele is associated with cleft lip with or without cleft palate. The association of occipital encephalocele and cleft lip-palate has been noted (26) and the combination of encephalocele and oblique facial clefting has also been observed. Unusual orofacial clefts and encephalocele can be part of the amnionic rupture sequence. Unusual median clefts are observed occasionally with frontonasal dysplasia.

Encephalocele/craniosynostosis association. Craniosynostosis is found as a low-frequency anomaly with encephalocele. Lorber (77) noted two instances of premature sutural fusion in 20 cases of encephalocele. Craniosynostosis has been observed occasionally with the *Meckel syndrome* (91) in which occipital encephalocele is a common feature. Encephalocele has also been noted in acrocephaly (48), *craniotelencephalic dysplasia* (28), and *Apert syndrome* (112).

Three possible theories can be invoked to explain the association of encephalocele with craniostenosis, and each of the three probably has some validity, depending upon the particular case. In some instances, "blow-out" lesions, such as encephaloceles, may result in lack of growth stretch across the sutures producing craniosynostosis on this basis. When hydrocephaly is associated with encephalocele, surgically placed shunts with low-pressure systems may be implicated in which growth stretch at the sutural areas suddenly becomes totally deficient. Finally, in some patients with multiple anomaly syndromes, both encephalocele and craniostenosis may occur on a primary basis (20,23,71).

Encephalocele with Dandy-Walker and Arnold-Chiari malformations. Dandy-Walker defect has been reported in association with parietal encephalocele (84) but also may be observed with occipital encephalocele (92). Arnold-Chiari defect has been noted with occipital encephalocele by several authors (9,92), and several instances of combined Dandy-Walker and Arnold-Chiari defects with occipital encephalocele in the same patient have been noted (92).

Encephalocele/ectrodactyly association. The combination of occipital encephalocele and ectrodactyly has been observed in two sporadic instances (JM Opitz, personal communication). Mental deficiency was present in both cases. No other major anomalies were present and the condition is distinct from von Voss syndrome in which encephalocele and ectrodactyly also may occur.

Encephalocele/hypothalamic-pituitary dysfunction association. Transsphenoidal encephaloceles (Fig. 16–5) herniate through a defect in the floor of the sella turcica and present as epipharyngeal masses. In some instances, they may be small and not always readily appreciated. The encephalocele may occur by itself or together with other craniofacial anomalies. Including additional encephaloceles, optic nerve abnormalities, hypertelorism, and cleft lip-palate. Several patients have been reported with hypothalamic-pituitary dysfunction but with different patterns of involvement. Growth hormone deficiency, hypothyroidism, central hypogonadism, central adrenocortical insufficiency, vasopressin deficiency, and diabetes insipidus have been documented (75).

Encephalocele/Klippel-Feil/iniencephaly association. Occipital encephalocele has been reported in a number of instances of *Klippel-Feil anomaly* (26,77,85), and in iniencephaly apertus it is constant (10,59,74,100). Iniencephaly consists of a defect in the occipital bone around the foramen magnum, spina bifida of considerable degree, and retroflexion of the head on the spine (36). Lewis (74) divided various cases by the presence or absence of occipital encephalocele, calling the former iniencephaly apertus, the latter iniencephaly clausus. Gilmour (46) suggested that iniencephaly and Klippel-Feil anomaly are part of a spectrum. Both conditions seem to have several features in common (73). Further evidence of the association of these defects is found in the experimental work of Warkany and Takacs (110) who produced the lesion in rats with streptonigran.

Encephalocele/myelomeningocele association. Lorber (77) and Mealey and co-workers (85) have observed several instances of occipital encephalocele associated with myelomeningocele. DeMyer (30) was able to produce encephalocele in some rat fetuses and spinal dysraphism in others by administering vincristine to pregnant rats at 8.5 days. The same combination of defects was produced by the administration of salicylates to pregnant rats (47). Wilner (114) described a mother with meningocele who gave birth to a girl with myelomeningocele. Lorber (77) noted that eight siblings of seven infants with occipital encephalocele had myelomeningocele.

Encephalocele/oculo-auriculo-vertebral spectrum. *Oculo-auriculo-vertebral spectrum* is a well-known condition affecting aural, oral, and mandibular growth together with anomalies of the eyes and vertebral column. It has been observed with occipital encephalocele occasionally (Fig. 16–3), and such cases have been reviewed by Cohen (19) and Herrmann and Opitz (56). Minne and Gernez (88) reported occipital encephalocele with absent lung, which is intriguing because hemifacial microsomia has also been observed with absent lung. Frontonasal dysplasia, which occurs with cranium bifidum and flattened encephalocele, has been reported on a number of occasions with dysplastic ears, ear tags, and epibulbar dermoids.

Miscellaneous and/or occasional involvement. A number of miscellaneous conditions have occasionally been associated with encephalocele. Several authors have documented the binary combination of encephalocele with various congenital heart defects (26,41,63,77,85, BD Hall, personal communication). In a case associated with one of the *Ehlers-Danlos syndromes* (34), the encephalocele was not congenital, but acquired. Rarely, occipital encephalocele has been recorded in infants of diabetic mothers (37). Other conditions occasionally reported with encephalocele have included *Marfan syndrome* (83),

neurofibromatosis (58, JW Hanson, personal communication), Poland anomaly (M Bull, personal communication), polysplenia syndrome (KL Jones, personal communication), *rubella syndrome* (11,68), TAR syndrome (RJ Gorlin, personal observation), *lateral nasal proboscis* (2), and *tuberous sclerosis* (12,66). Patients with the combination of encephalocele, ptosis of eyelids, epicanthic folds, and single maxillary central incisor have been observed (MJ Stephan, personal communication). Lateral meningocele syndrome has been reviewed by Gripp et al (50).

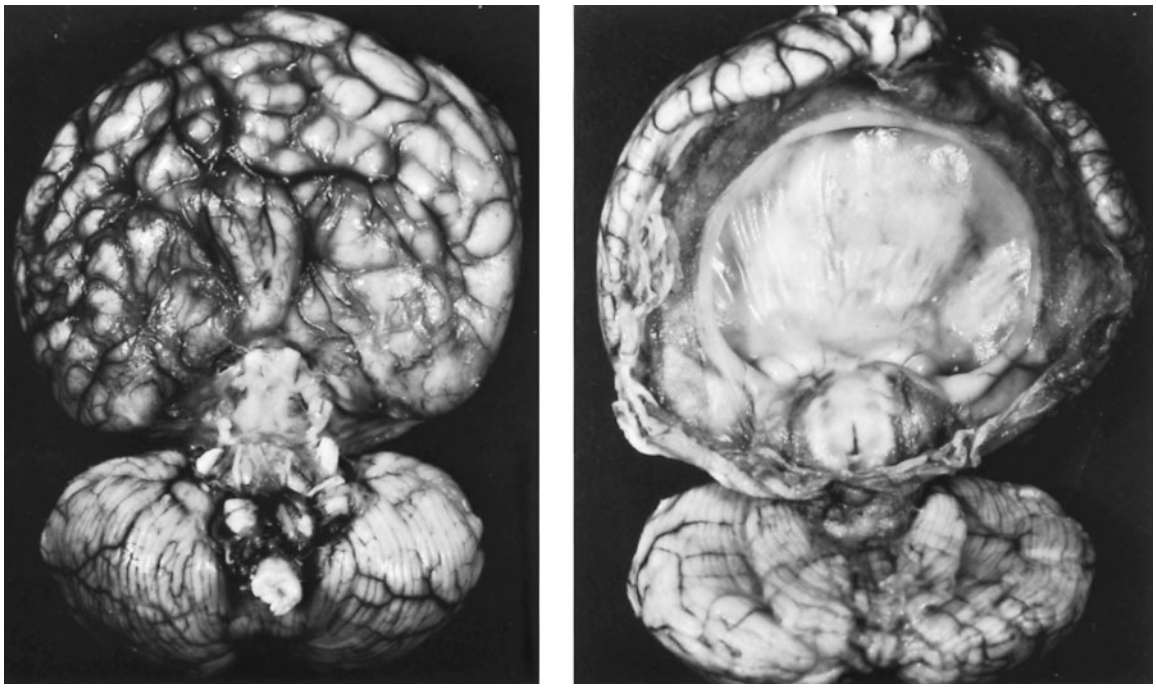
The holoprosencephalic disorders

Holoprosencephaly is a malformation sequence in which impaired midline cleavage of the embryonic forebrain is the basic feature. The prosencephalon fails to cleave sagittally into cerebral hemispheres, transversely into telencephalon and diencephalon, and horizontally into olfactory and optic bulbs (Fig. 16–6). The condition can be graded according to the degree of severity as alobar, semilobar, or lobar holoprosencephaly. Various gradations of facial dysmorphism are commonly associated with holoprosencephaly including cyclopia, ethmocephaly, cebocephaly, median cleft lip, and less severe facial dysmorphism (Fig. 16–7).

Exhaustive reviews and bibliographies are those of Cohen (19,20), Cohen and Gorlin (22), Cohen and Sulik (24), Cohen et al (25), DeMyer (29), DeMyer and Zeman (30), DeMyer et al (31), Ming and Muenke (52), Muenke (57,58), and Siebert et al (78). Central nervous system studies include those of DeMyer (29), DeMyer and Zeman (30), and Probst (67). Coverage for other topics include historical aspects (4,24,77), animal studies (10,24,83), epidemiology (19,28,41,48,49,68), genetic heterogeneity and recurrence risk (8,19,22,62,69,78), and molecular studies (7,34,52–56,60b,71–73,87).

Epidemiology. Croen et al (28) found a birth prevalence of 1.2 per 10,000 (n = 121). Rasmussen et al (68) found an overall birth prevalence of 0.86 per 10,000 (n = 63). The rate increased from 0.58 per 10,000 from 1968 to 1972 to 1.2 per 10,000 from 1988 to 1992. Other estimates have been discussed by Cohen (19). The frequency of holoprosencephalic abortuses is high, being approximately 40 per 10,000 (49).

Birthweights tend to be low except in holoprosencephalic infants of diabetic mothers. The sex ratio in alobar holoprosencephaly has a 3 : 1 female predilection. In contrast, the sex ratio is 1 : 1 in lobar



A B

Fig. 16–6. *The holoprosencephalic disorders*. Holoprosencephalic brain, alobar type. (A) Dorsal view showing pancake-like structure without corpus callosum or septum pellucidum. Diencephalon and telencephalon are uncleft. (B) Ventral view showing absent olfactory bulbs and tracts and no interhemispheric fissure. (From W DeMyer and PT White, Arch Neurol 11:507, 1964.)

holoprosencephaly. Major facial dysmorphism occurs more frequently in females than in males, especially with cyclopia (19). Holoprosencephaly has been described in MZ twins (15).

Molecular studies. A number of mutations in several genes have been identified as causative of holoprosencephaly (86a). About 5% can be explained in this way (60a). The best known of these is *sonic hedgehog* (7,37,53,59,72,73,76). Mutations involve loss of function. Only 23% of autosomal dominant families with holoprosencephaly have sonic hedgehog mutations (7q36). A mutation in a sporadic case is very rare (1 in 184 cases). Other known gene mutations involve *TGIF* (34,63), *SIX3* (64a,86), *ZIC2* (14) and *patched* (54). Several other candidate genes, such as lanosterol synthase (21q22.3), have been discussed by Roessler and Muenke (71). In Smith-Lemli-Opitz syndrome, caused by Δ7-sterol reductase mutations, 2%–4% have holoprosencephaly (42,56). Probably at least 12 genes are involved.

Chromosome abnormalities. There is a plethora of associated chromosome abnormalities. About 40% have an anenploidy, most commonly trisomy 21 (28). However, we have listed in Table 16–2, a number of chromosome findings. A few of these such as del(7q) represent deletion of the *sonic hedgehog* gene, others *patched* mutations at 9q22.3, still others *TGIF* mutations at 18p11.3 (the *TGIF* gene is involved in the retinoic acid pathway), etc. The numerous references in the older literature and in the 1990 edition of this text to association with del(18p) probably refer to *TGIF* mutations. Wallis et al (87) have noted that at least 12 loci and various teratogens can effect holoprosencephaly, among them mutations in the *SIX3* gene on 2p21. Jervine has been used as an experimental teratogen.

Diagnosis and recurrence risk. Conditions with holoprosencephaly or arhinencephaly (19,20,24) are listed in Table 16–2. Diagnosis is based on the overall pattern of abnormalities, chromosome analysis, molecular studies in selected cases, and family history. Careful examination of the proband's family for microforms of holoprosencephaly is essential, especially for anosmia or hyposmia, mild hypotelorism, microcephaly, or single maxillary central incisor (24). Cohen and Gorlin (22) noted that in the presence of a holoprosencephalic proband, sibs with cleft lip-palate but without holoprosencephaly per se should probably be regarded as microforms of the disorder. A family history of short stature, endocrinopathy, or various types of central nervous system anomalies other than holoprosencephaly may be significant (24).

For nonsyndromic cases, if the findings are consistent with autosomal dominant holoprosencephaly and the family is negative for sonic hedgehog mutations, the risk for an obligate carrier is on the order of 16%–21%; the risk for an incomplete form or microform is on the order of 13%–14%; and the overall effect for some risk, either mild or severe, is on the order of 29%–35% (19). Affected sibs in the absence of familial microforms in more than one generation, are consistent with autosomal recessive inheritance (19). A sporadic case with negative family history except for consanguinity certainly suggests that the recurrence risk may be as high as 25% (19). For sporadic, nonchromosomal, nonsyndromic holoprosencephaly, a recurrence risk of approximately 6% may be given. This risk is based on the genetic study of Roach et al (69) of 30 families with holoprosencephalic probands; only two of their pedigrees represented examples of familial holoprosencephaly. A skewed sex ratio exists (males have more mutations in *Sonic Hedgehog* than do females) in familial holoprosencephaly and in those with single maxillary incisor (81).

Central nervous system. In alobar holoprosencephaly (Fig. 16–6), a small monoventricular cerebrum lacking interhemispheric division is present. The thalami and the corpora striata are undivided across the midline. Olfactory tracts and bulbs are always absent as is the corpus callosum, although a few commissural fibers may cross the midline (29). DeMyer (29) further subdivided alobar holoprosencephaly depending upon the degree to which the dorsal lip of the holotelencephalon rolls over

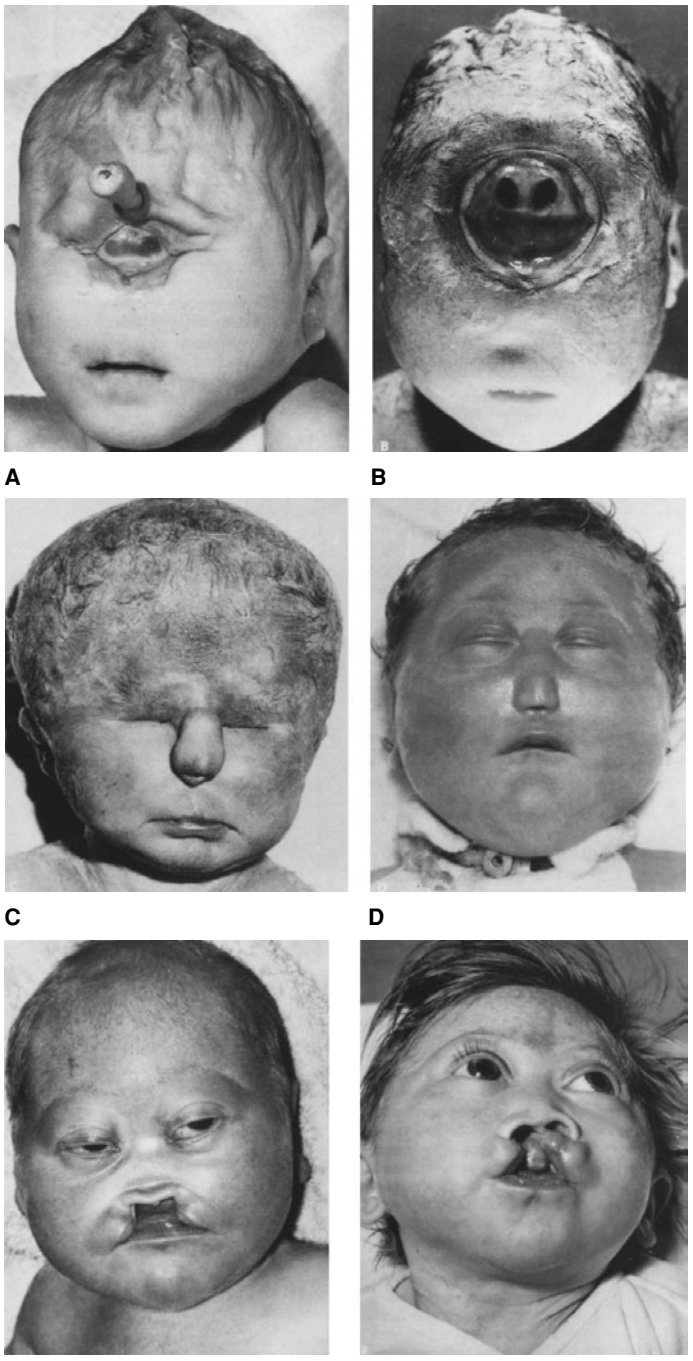


Fig. 16–7. *The holoprosencephalic disorders.* (A) Cyclopia with proboscis. (B) Cyclopia without proboscis. (C) Ethmocephaly; note separate eye sockets. (D) Cebocephaly; note hypotelorism and centrally situated blind-ended nostril. (E) Premaxillary agenesis form. (F) Facies associated with some degree of formation of corpus callosum and septum pellicidum.

to cover the membranous ventricular roof. The three common external configurations of alobar holoprosencephaly are the pancake type, the cup type, and the ball type.

In semilobar holoprosencephaly, rudimentary cerebral lobes are present and although the interhemispheric fissure is never complete, it may be present posteriorly. Commonly, the olfactory tracts and bulbs are absent, but in some instances, they may be hypoplastic. The corpora striata are continuous across the midline. The corpus callosum is

not a distinct bundle, although some commissural fibers may cross the midline (29).

In lobar holoprosencephaly, the brain has well-formed lobes that may be of normal size. Although a distinct interhemispheric fissure is present, there may be some midline continuity of the cingulate gyrus. The olfactory tracts and bulbs may be absent or hypoplastic and the corpus callosum may be absent, hypoplastic, or normal. Midline cleavage of the thalami and the corpora striata may be incomplete (29).

At the mild end of the holoprosencephalic spectrum are malformations such as absence of the corpus callosum and arhinencephaly (absence of the olfactory tracts and bulbs) (28). Defects of the corpus callosum result from a variety of different mechanisms (24,29). In some instances, absence of the corpus callosum clearly represents the holoprosencephalic spectrum. In other instances, isolated absence of the corpus callosum is not related to the holoprosencephalic spectrum (24,29). Robin et al (70) described syntelencephaly as a distinct variant of the holoprosencephalic spectrum of midline brain anomalies.

Other central nervous system anomalies may sometimes be present. Although the hindbrain usually develops normally, it may be hypoplastic since the descending fiber tracts fail to develop. Absence of the inferior vermis has also been observed in a number of cases (20).

In alobar holoprosencephaly, electroencephalography shows various abnormal waves, ranging from asynchrony between the right and left sides of the head to synchronous and asynchronous spikes. In lobar holoprosencephaly, multifocal spikes are common (29).

Patients with alobar holoprosencephaly may be completely amented. However, evidence of vision, hearing, and social smiling has been observed in some cases with median cleft lip, lateral cleft lip, or less severe facial dysmorphism. Length of survival is correlated with facial type. With cyclopia, ethmocephaly, and cebocephaly, 50% may survive for 1 to 2 days. With median cleft lip, 50% survive for 4 to 5 months. Of infants with less severely malformed or normal faces, 50% may survive as long as 12 to 18 months (5).

In general, patients with semilobar or lobar holoprosencephaly tend to have better survival rates than do patients with alobar holoprosencephaly. At the less severe end of the holoprosencephalic spectrum, patients may be mildly or moderately retarded and may have sufficient intelligence to live freely in society (29).

Face. In a classic article, DeMyer et al (31) discussed a graded series of facial anomalies that occur with holoprosencephaly (Fig. 16–7). The face predicts the brain approximately 80% of the time. The other 20% of the time, the facial features are nondiagnostic (20,29). In cyclopia, the most extreme variant, a single median eye with varying degrees of doubling of the intrinsic ocular structures is associated with arhinia and usually with proboscis formation above the eye. In ethmocephaly, two separate hypoteloric eyes are associated with arhinia and supraocular proboscis formation. In cebocephaly, hypotelorism is associated with a blind-ended, single-nostril nose, located in normal position. With median cleft lip, hypotelorism is associated with a flat nose and a median cleft due to agenesis of the primary palate. Less severe facial dysmorphism may include hypotelorism or hypertelorism, lateral cleft lip and/or iris coloboma (24).

Agnathia holoprosencephaly differs from classic holoprosencephaly in that there is no lower jaw. This is discussed under *agnathia*. A proboscis seems to occur less often than in the usual severe forms of holoprosencephaly.

A number of minor anomalies have been found with holoprosencephaly (3,9,24,38,45,46). Single maxillary central incisor (9,20,26) and, much less commonly, absence of the nasal septal cartilage (38) can be useful markers in autosomal dominant holoprosencephaly. Other identified defects have included stenosis of the pyriform aperture (2,3), absence of the upper labial frenum (45), and absence of the philtral ridges (46).

Kjaer et al (43) demonstrated that the palate differs among the various forms of holoprosencephaly. In all forms, the premaxillary area is highly malformed. A fan-shaped area behind the premaxilla is broadest in cyclopia and lessens as the severity of the condition lessens.

Differential diagnosis. Hypotelorism may be observed with metopic synostosis. Isolated median cleft lip can occur with normal brain development (24,83). Cohen (21) and Verloes and Koulischer (85) described an oroacral syndrome with absent anterior maxillary teeth without cleft lip or palate but with reduction defects of the fingers and toes. Martínez-Frías et al (47) classified four general types of proboscis formation: holoprosencephalic, lateral nasal, accessory, and disruptive. Stelnicki et al (80) described a craniofacial malformation with prosencephalic duplication. In *Binder phenotype*, hypoplasia of the anterior nasal spine occurs with normal intelligence; the facial appearance may appear "arhinencephaloid." Agenesis of the corpus callosum may occur as an isolated anomaly independent of holoprosencephaly or may occur as a component in a variety of nonholoprosencephalic syndromes. The relationship between holoprosencephaly and septo-optic dysplasia or with *Rieger syndrome* remains speculative. Unilateral arhinencephaly has been noted in a patient with *oculo-auriculo-vertebral spectrum*. Single maxillary central incisor may occur as an isolated defect, with hypothalamic hamartoma and sexual precocity, and also with coloboma and hypomelanosis of Ito. Isolated *agnathia* can occur independently of holoprosencephaly (20,24). Jespers et al (40) described two sibs with hypoplasia of

the corpus callosum and/or cerebellar hypoplasia, Robin sequence, Hirschsprung disease, and other anomalies.

Laboratory aids. Any patient suspected of having holoprosencephaly by physical examination and neurologic observation and testing is a candidate for computed tomography (CT) scanning (24). Patients with holoprosencephaly should have a banded chromosome study and molecular studies in selected cases. Antenatal diagnosis with ultrasound during the third trimester has been reported. The diagnosis of alobar holoprosencephaly is virtually certain when hypotelorism is found in association with absence of the midline echo. Sonographic demonstration of orofacial clefting may be helpful. In semilobar and lobar holoprosencephaly, sonographic diagnosis is difficult or impossible (24).

Some syndromes with holoprosencephaly or arhinencephaly not discussed further in the text but cited in Table 16–2 include:

- *Aprosencephaly*—Facial features of anencephaly but intact cranium.
- *Hartsfield syndrome*—Premature synostosis of coronal and metopic sutures, hypertelorism, cleft lip-palate and ectrodactyly.
- *Genoa syndrome*—Holoprosencephaly and primary craniosynostosis involving the coronal and lambdoid sutures.
- *Martin syndrome*—Holoprosencephaly, median cleft upper lip, microcephaly, mental retardation, hypertelorism, downslanting palpebral tissues, large pinnae, club foot, spinal anomalies, chronic constipation.
- *Grote syndrome*—Holoprosencephaly, hydrocephaly, octodactyly, absent tibial bones, cardiac malformations.
- *XK aprosencephaly*—Aprosencephaly and cerebral dysgenesis, digital and genital anomalies.
- *Steinfeld syndrome*—Holoprosencephaly with median cleft upper lip, short forearms, absent thumb, cardiac defects, renal anomalies, absent gallbladder.
- *Lambotte syndrome*—Intrauterine growth retardation, semilobar holoprosencephaly (25%), mental retardation, microcephaly, large pinnae, hypertelorism, flat face, hooked nose, narrow mouth, retrognathia.
- *Perrin syndrome*—Anosmia, hypogonadotrophic hypogonadism, mental deficiency, congenital ichthyosis.
- *Johnson syndrome*—Anosmia, hypogonadotrophic hypogonadism, alopecia, conductive deafness, protruding dysplastic pinnae.
- *Fitch syndrome*—Arhinencephaly, absent corpus callosum, hydrocephaly, absent left diaphragm, VSD, absent fifth fingernails.
- *COH syndrome*—Arhinencephaly, polymicrogyria, hydrocephaly, cloverleaf skull, duplication of thumb, micropenis, bifid scrotum.
- *Aicardi syndrome*—Chorioretinal lacunae, agenesis of corpus callosum, mental deficiency, arhinencephaly, flexion spasms, rarely holoprosencephaly and/or cleft lip.

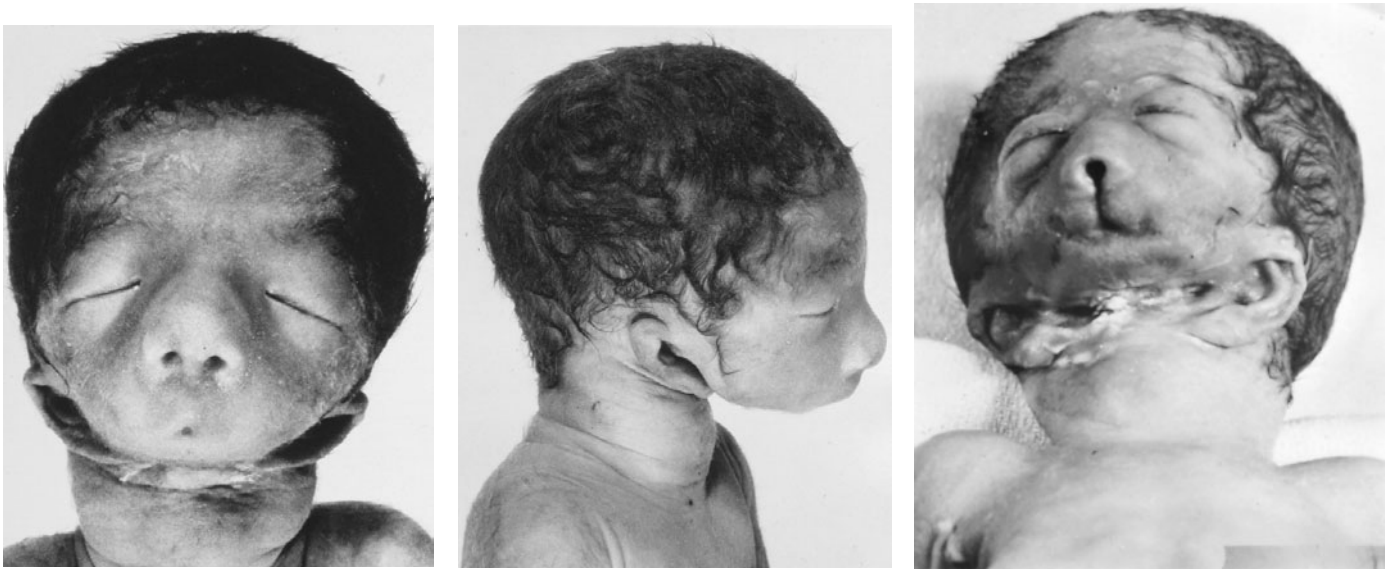
Otocephaly (agnathia)

The primary malformation in otocephaly is agnathia, with malplacement of the external ears with or without fusion, microstomia, and persistence of the buccopharyngeal membrane likely being secondary effects of absence or hypoplasia of the mandibular arch (Fig. 16–8). The condition is lethal since oropharyngeal abnormalities result in an impatent or poorly functioning airway. Many cases have been recorded (1,2,9,11,14–18,23, 25,28–32). Possibly the first case was described by Kerckring in 1717 (see 23). An excellent anatomic study was carried out by Lawrence and Bersu (14). The maximal prevalence is almost certainly less than 1/70,000 births (23). The terms agnathia, synotia, and otocephaly, for all practical



A B C

Fig. 16–8. *Otocephaly.* (A–C). Note tendency of ears to fuse in midline, absence of mandible. Note separate but tiny mouth in A. Note unified nose and mouth in C. (C courtesy of HW Emonds, Washington, DC.)

purposes have approximately equivalent meanings, even though the first term specifically refers to absent mandible, the second term to fused ears. To date, all cases of isolated agnathia have been sporadic. It has been suggested that otocephaly may be caused by mutations in FGF8 (28a). Pauli et al (23) reported a recurrent-pattern syndrome in two nonrelated infants who had agnathia, situs inversus, unilateral renal agenesis, renal ectopia, absent ribs, and vertebral anomalies.

With isolated agnathia, the average gestation is 32.7 weeks and birthweights are commonly below the tenth centile. Polyhydramnios has been a feature of most pregnancies (2). Prenatal diagnosis has been achieved (9a). Most affected infants die within the first few hours or days of life (23). There have been less affected examples that have lived and transmitted the condition to a child (5a).

Craniofacial features. The mandible is either absent or hypoplastic. Although some authors have claimed that the mandible is never completely absent (11), radiography and dissection have failed to reveal any evidence of a mandible in a number of cases (3,23,28,31).The oral aperture may be absent (astomia), but more often is a minute opening 2–3 mm in diameter with its long axis usually rotated 90°. The buccopharyngeal membrane may persist, and microglossia of extreme degree may be present low in the pharynx. The external ears are malformed, ventrally placed, and approach each other or fuse in the midline (Fig. 16–8). Ear canals may be atretic and middle ear anomalies may occur in some cases. Rarely, the external ears may be absent. The palate may be cleft. The palpebral fissures slant downward (2,23).

Other craniofacial features have been reported including hypertelorism, proptosis, blepharophimosis, epibulbar dermoid, microphthalmia, synophrys, cleft lip, choanal atresia, abnormal inner ear and vestibular apparatus, bilobed epiglottis, and rudimentary vocal cords (23,25).

Other abnormalities. Miscellaneous anomalies have included cerebellar hypoplasia, septum pellucidum cavum, agenesis of the left calcar avis (20,23), situs inversus totalis, unilateral renal agenesis, renal ectopia, cystic kidney, Müllerian duct agenesis, cryptorchidism, vertebral anomalies, absent ribs, Sprengel deformity, talipes equinovarus, VSD, pulmonic stenosis, PDA, patent foramen ovale, and unlobated lungs (2,8,9,23).

Differential diagnosis. Isolated agnathia should be distinguished from *agnathia-holoprosencephaly* (3,4,6,7,10,12,13,21,22,24,26). The most extreme example is otocephaly-cyclopia (4). As in cyclopia, there is alobar holoprosencephaly. A defect in prechordal mesoderm is thought to be responsible (2). Agnathia-holoprosencephaly-situs inversus has been described by several authors (16,23,26–27a). Porteous et al (26) described affected sibs with agnathia–holoprosencephaly.

Nasal aplasia (arhinia), heminasal aplasia with or without proboscis, and their associations

The nose begins its development by the appearance bilaterally of the nasal or olfactory placodes on the lower outer portion of the fronto-nasal prominence around the 28th day (53). Proliferation of ectomesenchyme around the placodes and programmed cell death result in the formation of primitive nostrils (nasal pits) that ultimately extend in a funnellike (choanal) tube to the stomodeum. Migration of neural crest cells causes horseshoe-shaped ridges to appear on either side of the nostrils, becoming the medial and lateral nasal prominences. The cartilaginous septum is formed by neural crest cells that persist between the two nasal sacs, i.e., posterior extension of the nasal pits. At the deepest portion of the sacs, there is the oronasal membrane that normally ruptures during the second month. Rupture is necessary for patency of the nostrils; otherwise choanal atresia results. Due to selective growth of the facial prominences, the medial nasal prominences move toward one another, finally forming the nasal bridge, philtrum, primary palate, and columellar area. The lateral nasal prominences form the lateral sides of the nose. The primitive nostrils fill with epithelial plugs. If there is agenesis of both nasal placodes or sacs or failure of the plugs to resorb, nasal aplasia results; if one placode is missing or if only one plug resorbs, heminasal aplasia results (40).

The reader is referred to Rontal and Duritz (47) and Leperchey et al (29) for discussion of the pathoembryology. This subject is discussed thoroughly by Gorlin and Cohen (20).

Complete aplasia of the nose (*arhinia*) has been recorded on several occasions (3,5,6,10,11,15,16,19,30,33,43,49,51,52) (Fig. 16–9). In some there is no nose, in others a blind-ended pit is present (19). Hypoplasia of the midface is often present (15,19,27,30,37,54). In complete nasal aplasia, ipsilaterally displaced eye, colobomata, microphthalmia, anophthalmia, congenital cataract, Peters anomaly, absence of olfactory bulbs and tracts, and absence of nasolacrimal duct have been noted (19,28,38,50,51,54,59). A few patients have associated cleft palate (30,49). A duplicated thumb has been reported. Intelligence has been normal.

It has been reported in sisters (49) and as an autosomal dominant condition by Thiele et al (54). All other examples have been isolated cases. Arhinia has been seen in association with mandibulofacial dysostosis (6). Prenatal diagnosis has been made (17a).

Aplasia of half the nose (*heminasal aplasia, hemirhinia*) may be found without a nasal proboscis (Fig. 16–9D) (7,14,24,27,50,51,55,60) or, more often, found in association with other anomalies of the facial region. All have been isolated cases. Frequently there is a blind-ended lateral nasal proboscis (Fig. 16–9) (1,4,7–12,14,17,18,26,27,31–37,39,41,42,55,57–61). For examples not cited here, the reader is referred to two publications (12,33). The proboscis, about 2–4 cm in length and 0.5–1 cm extends from an area just lateral to the nasal root. Rarely, a proboscis may be located in the midline with a normal nose (18), attached to an eyelid (4), or lateral to the eye (2). There are examples of bilateral proboscides (48) (Fig. 16–9).

Bony abnormalities in the involved area(s) lack the cribriform plate, nasal septum deviated to unaffected side, loss of structures of the lateral wall of the nasal chamber on the affected side, absence or hypoplasia of the paranasal sinuses on the affected side, absent nasal bone, and disrupted lacrimal bone (16,47,54).

In addition to cleft lip and/or palate or submucous cleft palate (4,6,39,50,52), also discussed in Chapter 23, anomalies of the eye region are common with nasal aplasia but especially with heminasal aplasia. The ipsilateral eye is nearly always laterally displaced. Other eye anomalies include coloboma of the lower lid (1,8,17,32,36,42,45–47), coloboma of the upper eyelid (45,55), coloboma of the iris, choroid, and optic nerve (4,18,19,31,35,49,50,55), microphthalmia and anophthalmia (4,19,36,39,48–50), nystagmus (4,30,50), Peters anomaly (49), cataract (18,50,51), and doubling of lens or globe (31,34). The nasolacrimal canal is disturbed in its formation and epiphora or dacryocystitis is common.

Intelligence is normal with rare exceptions (34).

Hodgson and Saunders (23) reported that the homozygous state for mutation of the aniridia gene results in absence of nose, eyes, and adrenal glands. We wonder whether the sisters described by Ruprecht and Majewski (49) and the family described by Thiele et al (54) may represent a mutation in the *PAX6* gene. However, other genes such as *MSX1* and *2*, *SIX3*, *BMP4* and *7*, *SOX6*, and *GFG8* should also be investigated (21). Trisomy 9 mosaicism, we suspect, is aleatory (25).

Bosma syndrome refers to hypoplasia of the nose, eyes, hyposmia, hypogeusia, inguinal hernia, and hypogonadotrophic hypogonadism with normal intelligence (13,21,22).

Aprosencephaly

Aprosencephaly is a rare, lethal malformation sequence of the central nervous system. It resembles anencephaly, but the scalp and cranium are intact with fused sutures. Head circumference is greatly reduced. The eyes protrude (1–8) (Fig. 16–10).

There is absence of the telencephalon and pyramidal tracts, lateral and third ventricles, rudimentary diencephalic and mesencephalic structures, primitive cerebellar hemispheres, posterolateral clusters of premature neural cells in the medulla, normally formed spinal cord and retinal dysplasia within normally formed globes (Fig. 16–11). There is a perivascular mesenchymal proliferation seen only in the central nervous system.

If genitalia and limb abnormalities are present, the term *syndrome aprosencephaly* or *XK aprosencephaly* is used (6,7). Limb anomalies include absent or hypoplastic thumbs and halluces, clinodactyly, and clubfoot.

Anogenital/urinary anomalies comprise hypoplastic penis, cryptorchidism, atresia ani, and agenesis of the kidney, ureter, and bladder.

Cardiac anomalies are ASD, VSD.

Oral anomalies although rare, include cleft palate, bifid uvula, and wide gingiva.

Inheritance may possibly be autosomal recessive (1). However, del(13q) has also been reported (2,8).

Chapter 17
Syndromes Affecting the Central Nervous System

Myotonic dystrophy (Steinert syndrome)

Myotonic dystrophy is characterized by myotonia, progressive muscle wasting, cataracts, and variable mental deficiency. The diverse progressive clinical manifestations relate to multiple system involvement that includes the eye, heart, endocrine system, gastrointestinal tract, skeleton, and skin. An excellent comprehensive and historically interesting monograph on myotonic dystrophy has been written by Harper (24). A cogent editorial on molecular diagnosis is that of Suthers et al (58).

Early reports of myotonic dystrophy date from Hoffmann (26), in 1896, and from Rossolimo (48), in 1902, but delineation of myotonic dystrophy as a condition clearly distinct from myotonia congenita (Thomsen's disease) was first made by Steinert (55) and Batten and Gibb (3) in 1909.

Myotonic dystrophy has autosomal dominant inheritance with greatly variable penetrance and clinical presentation and course. The prevalence is estimated at 4–15/100,000 population (53). This may be an underestimate because of the high frequency of stillbirth and neonatal death in families with this disorder. There may be a higher frequency among the French Canadian population (35). In genetic counseling of a heterozygous female, the risk for an affected child is approximately 10% but after having one, it increases to 20%–35% (32). There is no evidence that the homozygotic state is more severe than the heterozygotic state (68).

Molecular genetic studies have mapped the gene to band 19q13.2–q13.3, and a large number of flanking markers have been found (22,52,58). The mutation identified to be the cause of myotonic dystrophy consists of a trinucleotide (CTG) repeat that undergoes expansion in female, and less often male, meiosis. Severity varies with the number of repeats. Unaffected individuals have between 5 and 30 copies. Patients with mild symptoms have 50–80 repeats, while more severely affected patients have expansion up to 2000 or more copies (19). The number of repeats increases with transmission from an affected mother to child, thus explaining the phenomenon of anticipation (increase in severity in successive generations) (12,22,23,25,28,63). This is correlated with hypermethylation (54). Also there has been a report on the decrease in size of the repeat (29). There are a few examples of the congenital form having been transmitted from a mildly affected male (4,9,38). The CTG repeat segment is transcribed and is located in the 3′ untranslated region of a protein kinase gene (8). There is some evidence that there is mitotic instability of the repeat throughout life, resulting in expansion (34). There is a second gene that maps to 3q in which triplet repeats do not play a role. The calves are enlarged like those with Duchenne muscular dystrophy (44,60).

Congenital myotonic dystrophy was first described by Vanier (65) in 1960 and has subsequently been delineated in several clinical reports (41,61). Infants with the neonatal form vary widely in clinical presentation. Problems vary from mild hypotonia, feeding problems, and talipes to severe respiratory insufficiency, leading to death. There is reduced fetal movement. Other findings may include hydramnios, decreased fetal activity, facial diplegia, cleft palate, cryptorchidism, hip dislocations, and thin ribs on chest radiograph (37,56). Several infants have pleural effusion and hydrops fetalis (16,51). In those who survive, mental retardation (IQ less than 65) and language delay are found in all. Myotonia is rarely elicited in the newborn period, and electromyogram (EMG) and muscle biopsy changes are inconsistent in this age group (46). However, follow-up reveals hypotonia and delayed motor development (47). The reader is referred to a 2000 review of pathogenesis (58a).

Infants with the neonatal form are almost exclusively born to mothers with myotonic dystrophy who may manifest few or no symptoms of their disorder at the time of their infant's birth, hence, the importance of the use of trinucleotide repeats to estimate the degree of expansion of the gene (vide supra).

The disorder has multiple and variable manifestations affecting every organ system. The usual age of onset is approximately 20–25 years, but isolated symptoms may precede definitive diagnosis by several years. At least 80% are affected by age 50 (6). These estimates do not reflect those with neonatal presentation and those whose symptoms are so mild as to escape detection. Average age of death has been estimated at between 45 and 50 years. Death generally results from respiratory illness or cardiac failure.

Facies. Facial weakness is an early and consistent recognizable feature of myotonic dystrophy. The face changes with time, becoming narrow, expressionless, and masklike with progressive muscle wasting. There is bitemporal hollowing and the eyes appear sunken. Premature baldness is striking. There is diminished ability to close the eyes, inability to wrinkle the forehead, whistle, or puff out the cheeks with air. The face in congenital myotonic dystrophy is particularly notable with a triangular open mouth due to jaw muscle weakness (Fig. 17–1). Gazit et al (18) discussed the cephalometric aspects of myotonic dystrophy.

Eyes. Cataracts are observed in over 85% of older individuals with myotonic dystrophy. Slit lamp examinations in younger individuals may reveal bilateral iridescent or multihued dust-like lens opacities and posterior subcapsular zones. This is very useful in presymptomatic detection, being seen in all (2,46). Cataracts are rare in congenital myotonic dystrophy. Retinal abnormalities of peripheral pigmentary changes, macular degeneration, and abnormal dark adaptation are quite common (50). Electroretinographic changes may be noted in presymptomatic patients (16). Ptosis is extremely common, but not invariable, even in severely affected patients. Other less common eye abnormalities include strabismus, blepharospasm, extraocular muscle weakness, keratoconjunctivitis, blepharitis, and decreased intraocular pressure.

Auditory system. Hearing loss has not been widely recognized but appears to be common. Wright et al (67) reported moderate to severe, usually sensorineural, hearing loss in 17 of 25 patients. It is more frequent in older individuals (59,66).

Hair and skin. Early frontal balding, as noted above, is very common in males, the extent appearing to parallel the severity of the muscle disease (23). A very unusual benign skin tumor, calcifying epithelioma of Malherbe or pilomatrixoma, has been observed to segregate with myotonic dystrophy in approximately 3% of reported families (17,24,33). These examples are multiple in approximately 70% of those cases. The nature of this association is unclear but unlikely to be coincidental.

Central nervous system. Apathy, inertia, reluctance to seek medical advice, and social decline are common, and efforts to help may not be welcomed. Hypersomnia is very common and has been observed even after correction of alveolar hypoventilation, suggesting a central cause. Probably all patients with the congenital form and some with childhood

A B

Fig. 17–1. *Myotonic dystrophy.* (A) Characteristic expressionless face, ptosis of eyelids, temporal and buccal hollows, and slack mandible. (B) Compare facies in 12-year-old. (A from HH Thayer and J Crenshaw, J Am Dent Assoc 72:1405, 1966.)

onset have mild to moderate mental retardation (43). Thus, mental retardation correlates with onset of neuromuscular symptoms, and size of CTG expansion, but not with severity of weakness or sex. MRI scans in mentally retarded individuals may show generalized or focal cerebral atrophy, focal white matter abnormalities, especially in the anterior temporal lobe, and increased skull thickness (14,27).

Cardiovascular system. Cardiac involvement is common and not confined to severely disabled patients. Most patients have cardiac conduction defects, and sudden death has been reported frequently (31). Approximately 50% exhibit first-degree heart block or other arrhythmias such as atrial flutter (10,62). Hypotension is common. Few patients have signs of cardiac failure, despite histopathological changes of cardiomyopathy. In one family, 30% exhibit mitral valve prolapse (57,62).

Respiratory system. Involvement of the diaphragm, shown by elevation on X-rays and functional studies, results from both weakness and myotonia. Alveolar hypoventilation, frequent in patients with either mild or severe disease, may have a central component. Aspiration pneumonia is due to weakened chest wall and diaphragmatic musculature as well as to possible central nervous system factors. Moderate restriction and lung volume with mild hypoxemia can be observed in myotonic dystrophy patients without clinical dyspnea (30).

Hypersomnia has been a frequently noted clinical symptom, occasionally attributed to alveolar hypoventilation. Sleep apnea can be a serious complication and may be worsened by procedures such as a pharyngeal flap designed to reduce velopharyngeal insufficiency, which is also common (13). Anesthesia, which may pose special risks in the infant, pregnant patient, and adult with myotonic dystrophy, has been the topic of several reviews (1,7,37).

Gastrointestinal system. Multiple dysfunctional aspects of gastrointestinal motility have been observed repeatedly with a resultant wide array of symptoms including esophageal reflux, gastric retention, megacolon, cholelithiasis, malabsorption, and constipation in 80% (31). Manometric studies of intestinal motility have confirmed abnormal motility patterns (20,39). Infants with neonatal presentation may exhibit poor sucking and swallowing, delayed gastric emptying, and recurrent vomiting (6). Intestinal pseudoobstruction has been reported (10).

Musculoskeletal system. The age of onset is difficult to determine because of the long asymptomatic period. Median age of onset is 20–25 years, and at least 80% are affected by age 50 (6). The striking and severe clinical variant, known as congenital myotonic dystrophy, which occurs in approximately 20% of patients born to affected mothers, is due to anticipation.

In most patients, the earliest neuromuscular symptoms are weakness and wasting of facial and jaw muscles. Extraocular muscles produced ptosis, weakness of lip closure, and limited extraocular movements. Jaw weakness due to atrophy of masseters results in sagging jaw and temporomandibular joint dislocation. Sternocleidomastoid weakness and wasting are prominent, while posterior neck and shoulder girdle muscles are less affected. Limb involvement early in the course is usually mild and first noticed in the small muscles of the hands and feet, wrist extensors, and foot dorsiflexors. Proximal limb weakness occurs much later, allowing most patients to remain ambulatory throughout their lives. It is unusual for patients to be confined to a wheelchair, even when affected severely otherwise.

The other striking neuromuscular abnormality observed is myotonia, which consists of a delay in relaxation of normal muscle contractions (Fig. 17–2). It is best elicited in the hand or with percussion of the tongue, as generalized myotonia is rare. Many patients seem unaware of the myotonia, even if obvious on exam. Those who are aware of it usually described it as stiffness, which is often aggravated by cold.

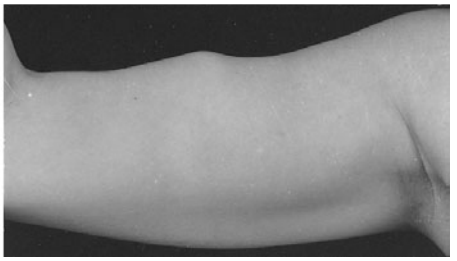
In congenital myotonic dystrophy, the disease begins before birth and results in much more severe manifestations. This severe form is nearly always inherited from the affected mother. During pregnancy, diminished fetal movements and polyhydramnios are common. At birth, respiratory distress is frequent and is the major cause of mortality. Facial and jaw muscle weakness and wasting are severe, resulting in a tented upper lip and contributing to severe feeding problems. Generalized hypotonia is present and usually severe. Other abnormalities may include talipes, gracile ribs, congenital hip dislocation, undescended testes, and hernias. The weakness and hypotonia slowly improve during infancy, and virtually all surviving children learn to walk. Speech and swallowing difficulties usually improve, but residual problems persist.

Electromyogram changes are striking, and consist of excessive insertional activity, other signs of electrical irritability, and myotonic potentials. The latter are repetitive potentials that wax and wane in frequency and amplitude, resulting in the so-called dive-bomber sound.

There is no single muscle pathologic change that is diagnostic, but the overall pattern is distinctive. The most characteristic changes on muscle biopsy include increased central nuclei, nuclear chains, ringed fibers, sarcoplasmic masses, type 1 fiber atrophy, increased fiber splitting in muscle spindles, and increased arborization of nerve endings. Less prominent changes include small angular fibers, moth-eaten fibers, type 2 fiber hypertrophy, and increased fibrosis.

Radiographic changes include calvarial hyperostosis and large paranasal sinuses, small sella turcica, prognathism, or micrognathia.

A



B

Fig. 17–2. *Myotonic dystrophy*. (A,B) Myotonic response to percussion of thenar eminence and biceps muscle.

Other changes such as thin ribs in infancy, kyphoscoliosis, and talipes are probably secondary to inactivity and muscle weakness (Fig. 17–3).

Endocrine system. Multiple endocrine abnormalities have been noted with testicular atrophy, infertility, and hypogonadism observed in 60%–80% of affected males. Females may have dysmenorrhea and symptoms of ovarian dysfunction. Postprandial hyperinsulinemia is a common finding, probably being secondary to total body insulin resistance. The risk for diabetes mellitus had been estimated to be approximately 5%. Colloid goiter and hypothyroidism are occasional associated findings. *Klinefelter syndrome* is associated with higher frequency than chance (11).

Oral manifestations. Lingual myotonia and/or velopharyngeal incompetence resulting in slow nasal and indistinct speech may be the initial sign (49). Retention of saliva in the oral cavity and a high rate of dental caries are common. Gazit et al (18) studied a series of patients cephalometrically and found increased interocclusal distance, increased face height, increased height of the palatal vault, narrow maxillary arch, increased crossbite, open bite, tongue thrust, and mouth breathing (Fig. 17–4). Recurrent jaw dislocation is common (31).

Differential diagnosis. Congenital myotonia is rare in myotonic dystrophy as in other myotonic syndromes but can be seen occasionally in myotonia congenita, a heterogeneous phenotype with both dominant and recessive modes of inheritance. The differential diagnosis of the neonatal presentation of myotonic dystrophy may include congenital myasthenia gravis, *Moebius syndrome*, and *Prader-Willi syndrome*. In the older patients, differential diagnosis includes various myotonia congenita syndromes, paramyotonia congenita, *Schwartz-Jampel syndrome*, different forms of periodic paralysis, and other types of muscular dystrophy (5). Patients with *facioscapulohumeral muscular dystrophy* have similar weakness and wasting of the face and sternocleidomastoids, but the posterior neck and shoulder girdle muscles are more severely affected. Distribution of the weakness is proximal rather than distal. They also have retinal vascular abnormalities that differ from the retinal dystrophy and cataracts observed in myotonic dystrophy, and lack involvement of other systems.

Fig. 17–3. *Myotonic dystrophy.* Radiograph of newborn of affected mother. Note remarkably thin or gracile ribs.

Laboratory aids. Diagnosis is aided by electromyographic studies, particularly of forearm and hand musculature. Occasionally muscle biopsy may be helpful. Slit-lamp evaluation of the eyes is valuable in the diagnosis of at-risk family members, and electroretinogram abnormalities may be even more sensitive in the detection of asymptomatic affected individuals.

Fig. 17–4. *Myotonic dystrophy.* Pronounced anterior open bite. (From HH Thayer and J Crenshaw, J Am Dent Assoc 72:1405, 1966.)

Direct estimation of the size of CTG repeats can be done by Southern blotting. Normal individuals have up to 37 repeats, while affected have 50 to several thousand in peripheral leukocytes (42).

Both prenatal and presymptomatic diagnosis are possible using flanking markers or by determining the size of the CTG repeat (45).

Although no specific microscopic feature is pathognomic for myotonic dystrophy, combined histologic changes on muscle biopsies are characteristic in myotonic dystrophy. Biopsy is rarely necessary for the diagnosis of this disorder, but may be helpful in patients with minimal myotonia and progressive muscle wasting, in those with minimal weakness and a negative family history, and in children in whom the differential diagnosis of congenital hypotonia may be extensive. Microscopic features include increased central nuclei, nuclear chaining, ringed fibers, type 1 fiber atrophy, terminal innervation, sarcoplasmic masses, and muscle spindle abnormalities.

An abnormal electroretinogram has proven useful in distinguishing asymptomatic gene carriers.

Isolated lissencephaly sequence (classical lissencephaly)

Isolated lissencephaly sequence (ILS) consists of classical lissencephaly (smooth brain) and subtle facial abnormalities and was first delineated by Dobyns (3,5). Children with the same brain anomaly with more severe craniofacial abnormalities are classified as having either Miller-Dieker syndrome (4), Baraitser-Winter syndrome (14), or any of 10 syndromes (8) (Table 17–1). An especially helpful paper is that of Allanson et al (1).

At least two types have been described, an autosomal dominant disorder mapping to 17p13.3 (*LIS1*) (1b) and an X-linked form mapping to Xq22.3–q23 (*XLIS* or double cortin). Patients with ILS associated with mutations of *LIS1* are designated as having ILS17, and those with mutations of *XLIS* as having ILSX. A large majority of patients are sporadic, and the empiric recurrence risk is less than 5% (the 7% risk cited by Dobyns et al (5) included two sibs with probable polymicrogyria). However, X-linked inheritance has been observed in several families, which makes genetic counseling more complicated. A three-generation family with X-linked mental retardation and Dandy-Walker complex has been described (N. Philip, personal communication, 2000). All were tall with macrocephaly, deep-set eyes, and prominent chin. An X-linked lissencephaly family with absent corpus callosum and ambiguous genitalia has been noted (T. Annick, personal communication, 2000). Currently available laboratory testing is able to detect the mutation in approximately 75% of patients (vide infra) (12,13). Among patients with mutations of *LIS1*, none of the parents have been carriers and no recurrence has yet been observed. Among boys in whom mutations of *XLIS* were detected but not found in their mothers, no recurrence has yet been observed. This suggests that the rate of parental germinal mosaicism is low, and such families may be given a recurrence risk of less than 1%. When mutation analysis is negative or has not been performed, the standard recurrence risk of 5% should be modified based on sex of the proband. In families with a female proband, no recurrence in sibs has been reported, so the recurrence risk is probably significantly less than 5%. In families with a male proband, the possibility of X-linked inheritance may be further evaluated using MRI scan. Carrier mothers with mutations of *XLIS* have so far always had a mild form of lissencephaly known as subcortical band heterotopia, which can be identified by a high quality brain MRI scan. When a band is detected, the mother is a carrier and counseling for X-linked inheritance should be given. When no band is detected on a high-quality brain MRI, the mother is unlikely to be a carrier. The quality of the MRI and experience of the reviewer are important because the subcortical band heterotopia may be subtle in these women.

An autosomal recessive lissencephaly with cerebellar hypoplasia mapping to 7q22 is due to mutations in the *RELN* gene (9).

Table 17–1. Lissencephaly sequence

Features	Manifestations
Frequent	
Brain	Classical lissencephaly and associated anomalies
Brain function	Severe or profound mental retardation, decreased spontaneous activity, early hypotonia, subsequent hypertonia, seizures, poor feeding
Craniofacial	Microcephaly, bitemporal hollowing, micrognathia
Occasional	
Brain	Somewhat small cerebellar vermis with cortical dysplasia, hypoplasia of corpus callosum
Brain function	Infantile spasms
Prenatal	Polyhydramnios, decreased fetal movements
Perinatal	May require resuscitation, contractures

(Modified from WB Dobyns, Birth Defects 23(1):225, 1987.)

Craniofacial features. The facial features are subtle and consist of prominent forehead, bitemporal hollowing, and somewhat small jaw (3,4) (Fig. 17–5A). The head circumference is usually normal at birth, but head growth is slow so most become microcephalic. Some have a few subtle features reminiscent of Miller-Dieker syndrome, but not sufficient for diagnosis. Cleft palate has been described (10).

Central nervous system. All patients have classical lissencephaly and associated malformations (Fig. 17–5B). The malformation consists of diffuse agyria-pachygyria with an abnormally thick cortex containing

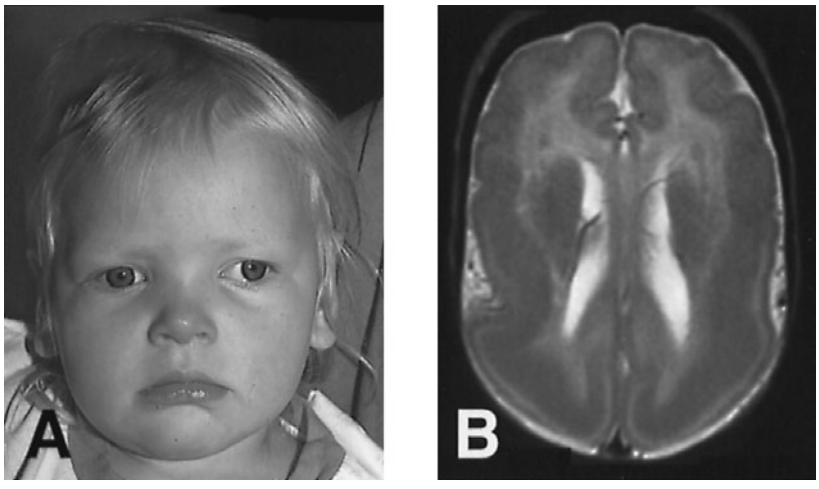

Fig. 17–5. *Isolated lissencephaly sequence.* (A) Essentially normal facial appearance, although with subtle prominence of forehead. (B) Cranial MRI of same patient shows grade 3a lissencephaly with frontal pachygyria and posterior agyria and thus a greater posterior than anterior gradient.

many heterotopic neurons deep to the normal cortex, thus comprising a malformation of neuronal migration (2,3). The severity varies more than in Miller-Dieker syndrome, varying from complete agyria (grade 1) to complete pachygyria (grade 4) (5,8,13). An anterior to posterior gradient is usually apparent (8). Patients with mutations of the *XLIS* gene usually have more severe gyral malformation anteriorly, whereas those with *LIS1* mutations usually have more severe malformation posteriorly. Associated abnormalities consist of enlarged body and posterior horn of the lateral ventricles, mild hypoplasia of the corpus callosum, and frequent cavum septi pellucidi et vergae. Pathological studies also demonstrate involvement of the cerebellum and inferior olives, but this is rarely apparent by imaging studies.

Other anomalies. Other abnormalities include transverse palmar creases, clinodactyly, mild distal contractures, prominent sacral dimples, cryptorchidism, and small penis (5). An X-linked form has been noted with ambiguous genitalia (11). Lissencephaly III, a recessive disorder, has stippled epiphyses and loose thick skin (1a).

Clinical course. Pregnancy may be complicated by diminished fetal movements and polyhydramnios, presumably secondary to poor fetal swallowing movements. Growth parameters including head circumference are most often normal but may be at or just below the 2nd centile. Some newborns appear normal, but many have some clinical evidence of the syndrome, such as hypotonia, feeding problems, and apneic spells with cyanosis. Only a few have seizures during the neonatal period (5).

The major clinical manifestations observed in all affected children consist of profound mental retardation, intractable epilepsy including frequent infantile spasms, and feeding problems that predispose to recurrent aspiration and pneumonia (5,6). During infancy, most affected children have moderate hypotonia with frequent arching spasms or opisthotonus, which gradually disappears over the first two years of life. Almost all children are subject to recurrent seizures that often prove difficult to control. They most commonly begin at 3–4 months of age, but may start anytime during the first year of life, or rarely, even later. The seizures often include infantile spasms, which are observed in more than two-thirds of affected children during the first year. True infantile spasms have rarely been observed in children up to age 3 years, which is very unusual.

Differential diagnosis. The classical form of lissencephaly also occurs in *Miller-Dieker syndrome (MDS)* and *Baraitser-Winter syndrome*. The differential diagnosis is discussed in more detail in the section on MDS. Kerner et al (10) described lissencephaly in sibs with cleft palate and severe cerebellar hypoplasia.

Laboratory aids. The brain malformation may be detected by obvious MRI or CT scan, although the former is more accurate, especially for subcortical band heterotopia. Chromosome analysis has always been normal except for two patients with balanced translocations, one disrupting *LIS1* and the other disrupting *XLIS* (1,5). However, currently available laboratory testing is able to detect the mutation in approximately 75% of patients (12,13). Heterozygous submicroscopic deletions of *LIS1* are detected in only approximately 20% of patients using the fluorescence in situ hybridization (FISH) with probe D17S379 that is approximately 150 kb telomeric to the gene. However, this increases substantially to approximately 40% of patients using FISH with a *LIS1*-gene specific probe. At this time, FISH studies using a LIS1-specific probe should be carried out in all patients with lissencephaly. Point mutations of *LIS1* are detected in approximately 24% and point mutations of *XLIS* in approximately 12% of ILS patients by direct sequencing and Southern blots. Currently, these studies are available only in a few research labs.

Miller-Dieker syndrome

Miller-Dieker syndrome (MDS) consists of classical lissencephaly (smooth brain) and a group of characteristic facial abnormalities associated with deletions of a large region in the short arm of chromosome 17. This syndrome was first described by Miller (15) and Dieker et al (2) and the eponym was first used by Jones et al (12). Children with the same brain anomaly who lack the striking facial changes are classified as having isolated lissencephaly sequence (ILS), which is discussed in the prior section (Table 17–2). The facies is discussed by Allanson et al (1).

Genetics. Miller-Dieker syndrome is caused by large visible or submicroscopic deletions of 17p13.3 that include the *LIS1* gene and other loci at least 150 kb telomeric to *LIS1* (1a,4,6,8,14,17,18). Smaller deletions or intragenic point mutations of *LIS1* cause ILS. It has recently been renamed *PAFAH1B1* as it appears to function as the β subunit of platelet activating factor acetylhydrolase brain isoform (11).

In families in which one parent carries a balanced rearrangement of 17p13.3, the risk of recurrence is relatively high. In a study of 12 families in which there was a reciprocal translocation involving the MDS critical region in 17p13.3, the overall risk for abnormal pregnancy outcome was 29%, or 38% when unexplained pregnancy losses were not considered in the total (16). This is within the upper range of the reported risk for unbalanced offspring of carrier parents assessed through liveborn aneuploid offspring. The miscarriage rate (22%) was higher but not significantly higher than the population frequency of approximately 15%. Only two families with pericentric inversions of chromosome 17 have been reported, with recurrence observed in one of the two families (10).

Pregnancy is often complicated by diminished fetal movements and polyhydramnios, presumably secondary to poor fetal swallowing movements. Growth parameters, including head circumference, are most often normal but may be at or just below the 2nd centile. Some newborns appear normal except for the craniofacial anomalies, but most have some clinical evidence of the syndrome, such as hypotonia, feeding problems that predispose to hyperbilirubinemia, and apneic spells with cyanosis. Only a few have seizures during the neonatal period.

The major clinical manifestations observed in all affected children consist of profound mental retardation, intractable epilepsy including frequent infantile spasms, and feeding problems that predispose to recurrent

Table 17–2. Features of Miller-Dieker syndrome

Features	Manifestations
Frequent	
Brain	Type I (grade 1–3) lissencephaly, lissencephaly sequence, midline calcification
Brain function	Lissencephaly sequence
Craniofacial	Lissencephaly sequence, relatively high forehead. Low nasal bridge, telecanthus, epicanthal folds, upturned nares. Long, thin upper lip, prominent alveolar ridges
Body	Abnormal palmar creases, clinodactyly, camptodactyly. Cryptorchidism, sacral dimples
Growth	Small at birth, severe postnatal growth deficiency
Occasional	
Brain and brain function	Lissencephaly sequence
Prenatal, perinatal	Lissencephaly sequence, prolonged neonatal jaundice
Craniofacial	Vertical wrinkling of forehead
Body	Congenital heart defect, polydactyly, visceral anomalies, sacral tail
Cause	
Chromosomes	Visible rearrangement of (17)(p13.3) in 60%

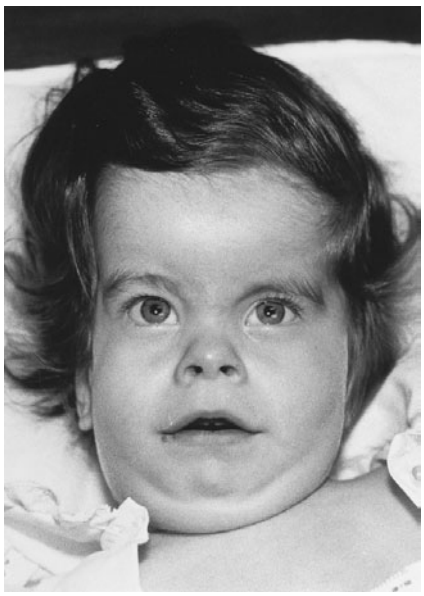
(Modified from WB Dobyns, Birth Defects 23(1):225, 1987.)

aspiration and pneumonia (7,8). During infancy, most affected children have moderate hypotonia with frequent arching spasms or opisthotonus, which gradually disappear over the first two years of life. Almost all children are subject to recurrent seizures that often prove difficult to control. They most commonly begin at 3–4 months of age, but may start at anytime during the first year of life or rarely even later. The seizures often include infantile spasms, which are observed in more than two-thirds of affected children during the first year. True infantile spasms have rarely been observed in children up to age 3 years, which is very unusual.

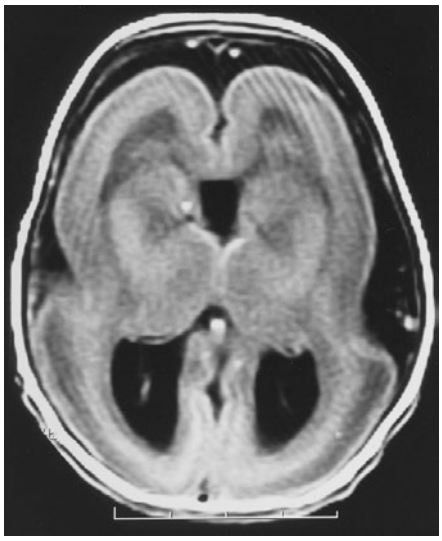
Craniofacial features. The defining facial features consist of prominent forehead, bitemporal hollowing, short nose with upturned nares, low nasal bridge with prominent skin folds leading down and outward to the cheeks, flat midface, thick upper lip with downturned vermilion border, and small jaw (Fig. 17–6A) (5,6). The head circumference is usually normal at birth, but head growth is slow so many become microcephalic. They often have a prominent occiput and large anterior fontanelle in infancy. The skin over the mid-forehead is vertically furrowed in many children during infancy, although this feature is lost with growth. Less constant abnormalities include telecanthus, epicanthal folds, low-set and posteriorly rotated ears with abnormal helices, high and narrow palate, and late eruption of teeth.

Central nervous system. All patients have severe classical lissencephaly and associated malformations (Fig. 17–6B). The malformation consists of diffuse agyria and pachygyria with abnormally thick cortex containing many heterotopic neurons deep to the normal cortex, thus comprising a malformation of neuronal migration (3,5). The severity may differ somewhat among patients, who may have complete (grade 1) or nearly complete (grade 2) agyria, or mixed agyria and pachygyria (grade 3) (9). Less severe grades do not occur in MDS. An anterior to posterior gradient is apparent with the lissencephaly either more severe posteriorly than anteriorly or equally. Associated abnormalities consist of enlarged body and posterior horn of the lateral ventricles, mild hypoplasia of the corpus callosum, and frequent cavum septi pellucidi et vergae. Pathological studies also demonstrate involvement of the cerebellum and inferior olives, but this is rarely apparent by imaging studies. A few patients have small midline calcifications in the region of the septum pellucidum or genu of the corpus callosum.

Other anomalies. Limb anomalies are relatively common and include transverse palmar creases, clinodactyly and mild distal contractures, with camptodactyly and polydactyly observed rarely. Congenital heart defects occur in approximately 65%, with patent ductus arteriosus and ventricular septal defects being the most frequent. Urogenital anomalies have included prominent sacral dimples, cryptorchidism, and small penis. Severe anomalies such as unilateral renal agenesis, bilateral collecting system and hydronephrosis are observed much less frequently. A few have had omphaloceles. In general, more severe anomalies involving regions other than the face and brain, especially more severe congenital heart malformations, are much more frequent in patients with large chromosome deletions or unbalanced derivative chromosomes (5,6).



A



B

Fig. 17–6. *Miller-Dieker syndrome.* (A) Prominent forehead, bitemporal hollowing, short nose with anteverted nares, prominent upper lip with downturned vermilion border especially toward the corners, and mildly small jaw. (B) MRI shows classical lissencephaly with diffuse agyria. On this image, no gradient can be seen although, in most cases, patients with Miller-Dieker have a posterior to anterior gradient. (A from WB Dobyns et al, J Pediatr 102:552, 1983. B courtesy of WB Dobyns, Chicago, Illinois.)

Differential diagnosis. The classical form of lissencephaly may occur without other major anomalies. This is known as *isolated lissencephaly sequence* (ILS). It has also been observed in children with the Baraitser-Winter syndrome, which consists of trigonocephaly, shallow orbits, ptosis, and colobomas with variable lissencephaly. The cobblestone type of lissencephaly occurs in Fukuyama congenital muscular dystrophy, muscle-eye-brain disease and *Walker-Warburg syndrome*. Several different types of microlissencephaly (smooth brain surface with head circumference at birth less than −3 standard deviations) have been observed including microlissencephaly with a thick cortex (probably the same as Norman-Roberts syndrome), "lissencephaly with extreme neopallial hypoplasia," microlissencephaly with thin cortex (one type the same as the "radial microbrain"), and in *Neu-Laxova syndrome*. Several other types have also been described including lissencephaly with cleft palate, simian creases, long distal thumbs and halluces and cerebellar hypoplasia (13), lissencephaly with ambiguous genitalia, and the Winter-Tsukuhara syndrome.

Laboratory aids. The brain malformation may be detected by magnetic resonance imaging or computerized tomographic scan. Chromosome analysis has shown visible deletions of 17p13.3 in approximately two-thirds of the cases, with deletions of the same region demonstrable by fluorescence in situ hybridization (FISH) in the remainder (6,8). Children with ILS never have visible deletions, but may have deletions detected by FISH. For those with an inherited chromosomal abnormality, prenatal diagnosis is possible.

Walker-Warburg syndrome (HARD±E syndrome, Warburg syndrome, cobblestone lissencephaly)

Walker-Warburg syndrome (WWS) is the most severe of a small group of "muscle-eye-brain" syndromes that also includes Fukuyama congenital muscular dystrophy (FCMD) and muscle-eye-brain disease (MEB). It is observed worldwide, whereas FCMD has been documented in only Japan and Korea, and MEB has been seen predominantly in Finland. Milestones in delineation of the syndrome include the first known description by Walker (18), the first detailed eye studies (9), the association of retinal nonattachment and hydrocephalus (19), the first notation of multiple affected sibs suggesting autosomal recessive inheritance (1), the first general delineation of the syndrome (11,13), and the recognition that WWS was often associated with congenital muscular dystrophy (3,4,17). The term HARD±E syndrome for hydrocephalus, agyria, retinal dysplasia with or without encephalocele was introduced by Pagon et al (12), then changed to Warburg syndrome (11) and finally to Walker-Warburg syndrome (5,20).

Inheritance is clearly autosomal recessive based on many observations of parental consanguinity and multiple affected sibs with normal parents. Walker-Warburg syndrome and related syndromes all have autosomal recessive inheritance. The gene for FCMD has been mapped to chromosome 9q31 (16), whereas the MEB gene has been excluded from this region, indicating that at least two genes must cause the muscle-eye-brain syndromes (14). In addition, a few patients with congenital muscular dystrophy due to laminin $\alpha 2$ (merosin) deficiency have had small patches of agyria in the occipital regions. Prenatal diagnosis has been accomplished by ultrasound, although no series of patients has been reported to determine the success of this approach (2).

Walker-Warburg syndrome consists of cobblestone lissencephaly, retinal dysplasia or other retinal abnormalities, frequent anterior chamber anomalies, and congenital muscular dystrophy (4) (Figs. 17–7 to 17–9). The current diagnostic criteria for WWS and related syndromes were established at several workshops on congenital muscular dystrophy, and are summarized in Table 17–1 (6–8).

Most children with WWS have profound mental retardation and hypotonia, mild distal spasticity and poor vision. Some present with macrocephaly and severe progressive hydrocephalus, whereas others have microcephaly and sometimes occipital cephaloceles. Children with less severe brain involvement still have moderate to severe mental retardation. The median survival is only four months, although some patients may live more than five years. Those with longer survival have seizures, feeding problems and susceptibility to pneumonia (4).

Craniofacial features. Many have a dysmorphic facial appearance but none of the anomalies is specific except for visible abnormalities of the eyes. Typical facial abnormalities include macrocephaly or microcephaly, puffy face, low-set and malformed ears, epicanthal folds and small jaw (Fig. 17–7A). Some have cleft palate and dysmorphic pinnae.

Central nervous system. The brain abnormality, called cobblestone lissencephaly, is pathognomonic for the muscle–eye–brain group of syndromes. This consists of (*a*) "cobblestone cortex" consisting of atypical agyria-pachygyria and polymicrogyria with a pebbled texture due to fibroglial tissue covering the surface and obstructing the subarachnoid space, (*b*) white matter dysmyelination and cystic changes that are more severe in WWS than in FCMD or MEB, (*c*) enlarged lateral and third ventricles, sometime with hydrocephalus, (*d*) brainstem hypoplasia, and (*e*) cerebellar (especially vermis) hypoplasia, which may be associated with Dandy-Walker malformation and usually small occipital cephaloceles (approximately 25%). All of these are apparent on cranial MR imaging (Figs. 17–7B,C and 17–8) (4). On microscopic exam, the cortex is thick and totally disorganized with no discernible horizontal layers, neurons that lie at irregular angles, and abnormal vascular channels and fibroglial bands that divide the cortex into sheets that again lie at irregular angles (3,4,17,18,20).

Eyes. Eye anomalies often involve both the anterior and posterior chambers. These include unilateral or bilateral microphthalmia, angle

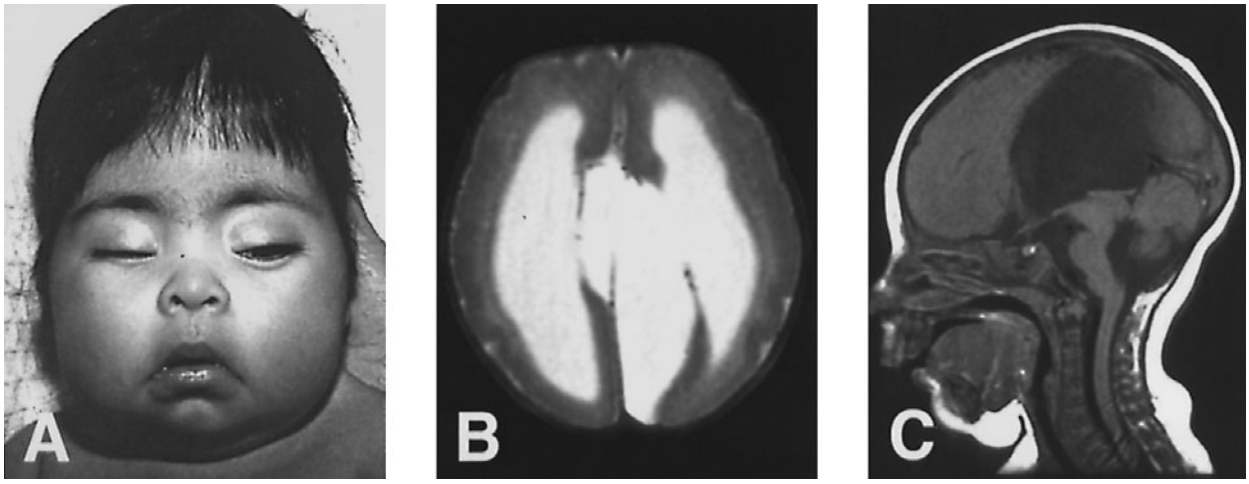

Fig. 17–7. *Walker-Warburg syndrome.* (A) Round face with puffy cheeks, ptosis, subtle prominence of left eye suggesting that it is larger than right, low nasal bridge, short nose with upturned nares, downturned corners of the mouth and slightly small jaw. (B) Cranial MRI of different patient shows cobblestone dysplasia (lissencephaly) with very irregular pebbled brain surface and irregular cortical white matter border, hydrocephalus with a large midline cyst. (C) Hypoplastic brainstem and cerebellum with upward rotation of the cerebellar vermis and small retrocerebellar cyst consistent with a mild Dandy-Walker malformation. (Courtesy of WB Dobyns, Chicago, Illinois.)

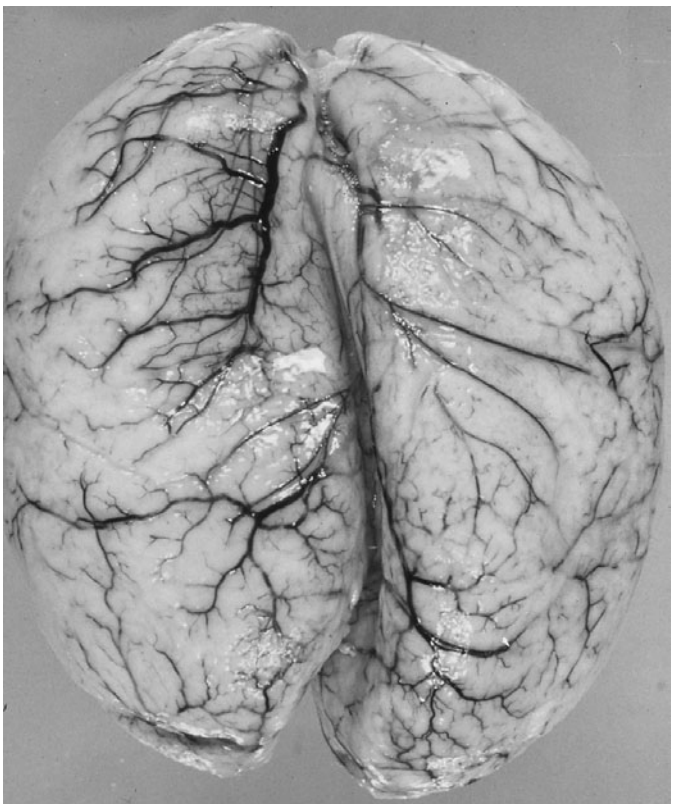
anomalies causing congenital glaucoma and sometimes buphthalmos, iris hypoplasia, corneal opacity due to abnormal adhesions to the iris or lens such as observed in Peters anomaly, cataracts, persistent pupillary membrane, persistent posterior hyaloid artery, persistent hyperplastic primary vitreous, retinal nonattachment or detachment, retinal dysplasia, optic nerve hypoplasia, and other less severe retinal and optic nerve abnormalities (4) (Fig. 17–9).

Fig. 17–8. *Walker-Warburg syndrome.* Agyria-smooth lateral surfaces of cerebral cortex with absence of normal convolutions. Only narrow Sylvian fissure is identified.



Neuromuscular system. Most, although perhaps not all, patients have congenital muscular dystrophy or a less specific myopathy (4). This may not become apparent until after the first year of life in children with the related MEB, and the same is probably true for WWS (15). The simplest way to document this is with serum creatine kinase, which may be elevated 5–10 times the upper limit of normal. Otherwise, muscle biopsy is required.

Other findings. The puffy appearance is most common in severely affected children, and may involve the entire body, especially the dorsa of the hands and feet. Some male patients have had genitourinary anomalies such as micropenis and cryptorchidism. Many other anomalies have been observed in occasional patients such as omphalocele.

Differential diagnosis. Differential diagnosis includes other syndromes with lissencephaly, polymicrogyria or hydrocephalus, Aicardi syndrome, and intrauterine infections such as toxoplasmosis or cytomegalovirus that cause hydrocephalus and eye abnormalities (4). Dandy-Walker malformation has been observed in association with many different types of anomalies (10).

Laboratory aids. The brain abnormalities are best delineated by MRI although CT scans usually show these well enough to establish diagnosis. Abnormalities of the eyes may be investigated further by electroretinograms that usually demonstrate attenuated responses, visual evoked potentials that show unusual giant potentials and orbital ultrasound that may demonstrate major posterior pole abnormalities such as persistent hyperplastic primary vitreous, retinal nonattachment and colobomas in patients in whom severe anterior chamber anomalies prevent adequate visual inspection. The muscle changes may be investigated by serum creatine kinase levels that are often greatly elevated, electromyography, and muscle biopsy (4). However, there are no molecular anomalies detected prenatally (8a.)

Familial dysautonomia (Riley-Day syndrome, hereditary sensory and autonomic neuropathy type III)

Riley et al (39), in 1949, described a syndrome involving autonomic, sensory, and motor dysfunctions: absence of overflow tears, vasomotor instability, hypoactive deep-tendon reflexes, relative indifference to pain, feeding difficulties, and absence of lingual fungiform papillae. Subsequently, Riley et al (37,38) and others (3,7,8,17,28) presented thorough reviews of its clinical picture. An earlier report is that of Aring and Engel (1).

The syndrome has autosomal recessive inheritance (19). Nearly all patients have Ashkenazic Jewish ancestry, the great majority stemming from eastern Europe (Galicia, Bukovina, Ukraine, Romania, and parts of Austro-Hungary) (7). In Israel, the frequency of the disorder is approximately 1/3700, heterozygotes in this population being 1:30 (19). Cases in non-Jews are rare, but well documented (18,26,27,30). Parental consanguinity has been noted in at least 5%. The syndrome maps to 9q31–q33 and prenatal diagnosis has been established (5,11). Mutations in *ICAP* cause the disorder (40a).

Approximately 30% have breech presentation in contrast to 3%–8% of normal infants (4). Premature rupture of membranes occurs in approximately 30% (4). Meconium staining (35%) is approximately three-fold normal (4). Stature is small even at birth (3). Approximately 25% die of pulmonary infection by the age of 20 years. Recurrent bronchopneumonia is common, probably because food is frequently aspirated (12). Respiratory arrest during sleep is more common during adolescence (2). Diagnosis is extremely difficult in the neonate, especially in the premature infant (34).

Facies. A fixed, sad, empty or frightened expression with a slit-like mouth (grimace) and a peculiar lingual rolling movement are typical (3,38) (Figs. 17–10 and 17–11). The face is thin, frequently asymmetric, with a pale to grayish color except during excitement. External strabismus is common.

Nervous system. In the newborn, approximately 60% have poor or no suck with 25%–30% exhibiting hypotonia and/or hypothermia. Regurgitation and difficulty in swallowing appear soon after birth, and the infant fails to produce overflow tears with the usual stimuli (20). Especially marked are lethargy, somnolence, and unresponsiveness. Other virtually constant signs are absent to diminished deep-tendon reflexes, motor retardation and/or motor incoordination, hypotonia, breath-holding spells, hypersalivation, dizziness or ataxia on change in position, postural hypotension, paroxysmal hypertension, emotional lability, and relative indifference to pain (38). However, many of these children do not like their feet or scalp to be touched (dysesthesia). The indifference to pain may result in Charcot joints as the child ages. Older patients tend to have increased dysfunction in pain sensation, proprioception, and vibratory sense due to neuron depletion (4,33). There is relative insensitivity to hypercapnia and hypoxia (8). Many manifest alternate bouts of diarrhea and constipation. Skin blotching, abnormal sweating, erratic temperature control, and cyclic vomiting are seen frequently (20). Approximately 80% exhibit growth retardation. Severe progressive scoliosis, found in 55%, appears around the eighth or ninth year of life (28,38). Intelligence is normal (3,44). Speech is often monotonous, slurred, and dysarthric with an unusual nasal quality (7).

A B

Fig. 17–10. *Familial dysautonomia.* (A, B) Fixed expression, asymmetric thorax, scoliosis, genu valgum due to Charcot joint-like changes. (B courtesy of VA McKusick, Baltimore, Maryland.)

Defective nerve condition (6) and a reduction in the number of unmyelinated nerve fibres, no myelinated nerve fibers greater than 12 μm in a diameter, and abnormally short internodal length of small myelinted nerves have been demonstrated in the sural nerve (4,32). Sensory neurons in the spinal ganglia are decreased (33). There is paucity of cells in the geniculate and scarpa ganglia (43).

Skin. A macular erythema, varying in color from pink to bright orange and located principally on the trunk and limbs, especially during periods of emotional excitement or eating, is common. Cold hands and feet, verging on acrocyanosis, and excessive sweating after the first month of life are constant features (4,28). Severe burns have resulted from indifference to pain in some patients.

Eyes. Constant features are decreased tearing, absent corneal reflex, and immediate papillary constriction in response to subconjunctival instillation of methacholine (3,34,38). Neuroparalytic keratitis sicca or corneal ulceration has been noted in at least 30%. The eye changes can be so severe that blindness may result (9). Myopia and retinal vascular tortuosity are also frequently observed (7,17). Optic atrophy has been reported (40).

Fig. 17–11. *Familial dysautonomia.* Characteristic slitlike mouth. (Courtesy of AA Reitman, Garden City, New York.)

Oral manifestations. Quite characteristically, the mouth is transversely elongated into a horizontal slit (Fig. 17–11). Smith et al (41) reported absence of fungiform papillae on the tongue (Fig. 17–12). Rarely, some are present but are atrophic (13). Circumvallate papillae are also absent or greatly reduced in number (15,28). Sensitivity to sweet and salty taste is diminished (14). Pearson et al (31) were unable to find nerve fibers traveling to the rudimentary papillae. The parents of some patients may have decreased numbers of fungiform papillae (31,38).

Excessive drooling and diminished gag reflex or swallowing disturbance occur in approximately 80% (28). However, excess saliva is produced because of denervation supersensitivity (23). Dental caries is infrequent, perhaps because of ample saliva, reduced taste sensibility, and a consequent lowered desire for sweets (23,26). However, plaque accumulation, periodontal disease, anterior dental trauma, and small jaws are common (7,22,25). The teeth have been shown to be somewhat smaller than normal (24). Orodental self-mutilation has been found in 35% (21,22). These may take the form of ulcers of the lips, buccal mucosa, or tongue (21) as in Riga-Fede disease (10,21,35,36).

Differential diagnosis. No disorder exactly mimics familial dysautonomia, but many progressive sensory neuropathies have similar features (7) (Table 17–3). Absence of fungiform and circumvallate papillae is an important specific clinical finding. Fungiform papillae may also be absent in Behçet syndrome.

There is some resemblance to congenital *sensory neuropathy with anhidrosis*, a disorder characterized by sensory deficit (diminished knee jerks, deficient taste discrimination, failure of axon flare after histamine injection) but differing from familial dysautonomia in that there are normal tear secretion and failure to produce miosis or to alter taste thresholds after methacholine administration. Suzuki et al (42) summarized cases of dysautonomia in non-Jewish infants. Most were atypical examples, probably representing other disorders.

Laboratory aids. Patients show a wheal but little to no pain or axon flare on intracutaneous injection of 0.01 ml of 1:10,000 histamine phosphate and a strong reaction to norepinephrine and related drugs (3,16). Some affected children fail to respond to a pinprick. There is immediate pupillary constriction with 0.0625% pilocarpine eyedrops. This test is

helpful but not pathognomonic and there are 5%–15% false positive responses. Taste acuity for salty and sweet foods is absent in familial dysautonomia (15). An increased homovanillic acid to vanilmandelic acid (HVA/VMA) ratio has been reported in the urine of affected patients (15,36). Heterozygotes have normal ratios (10). Prenatal diagnosis, using linked genetic markers, has been used successfully (11,29).

Lesch-Nyhan syndrome [hypoxanthine-guanine phosphoribosyltransferase (HGPRT) deficiency]

Lesch-Nyhan syndrome is an X-linked disorder, largely limited to males, resulting from deficiency of the enzyme hypoxanthine phosphoribosyltransferase (HPRT). The syndrome is characterized by hyperuricemia, uric acid stones, spasticity, choreoathetosis, mental retardation, and compulsive, aggressive and self-mutilating behavior (30). Although the disorder has been noted earlier (5,34), Lesch and Nyhan (21) first described the complete syndrome in 1964 and Hoefnagel et al (16) soon after demonstrated X-linkage. Female heterozygotes have two cell populations but always exhibit normal enzyme activity in the blood. Carriers must be identified by deficient enzyme activity in hair root lysates. However, fully affected females have been described (2,31, 46,51), some possibly explained by extreme lyonization, others possibly by uniparental disomy.

More than 250 patients have been reported (28,29), and several multiple case series have been published (6,47,49).

Genetics and biochemistry. The human HPRT gene has been mapped to the distal end of the long arm of the X chromosome (Xq26–Xq27). Using cloned DNA probes, molecular analysis has shown that the gene is present as a single copy of approximately 44 kb in length with 9 exons (19,24,43,49). Mutations are quite heterogeneous and may affect enzyme expression, catalytic activity, or protein stability in vivo (39). Gibbs and co-workers (11,12) described HPRT mutation detection by ribonuclease A cleavage and by direct DNA sequencing of in vitro amplified cDNA. Davidson et al (7) used polymerase chain reaction (PCR) to identify mutations in HPRT in RNA from B-lymphoblasts. Heteroduplex detection has also been used to screen for mutations (4).

Hypoxanthine phosphoribosyltransferase catalyzes the transfer of the phosphoribosyl moiety of 5-phosphoribosyl-1-pyrophosphate (PRPP) to either hypoxanthine or guanine to form inosine monophosphate or guanosine monophosphate. These reactions are considered to be *salvage pathways* or alternate metabolic routes for hypoxanthine and guanine that lead to formation of uric acid-the end product of purine catabolism, which is subsequently excreted unchanged in the urine (41). Substrates and products of the reactions are regulators of other purine metabolizing enzymes; hence, HPRT influences multiple steps in purine metabolism (43).

Complete deficiency of HPRT activity is the usual finding in males expressing the Lesch-Nyhan phenotype, although some neurological deficits are present in approximately 20% of patients with significant partial HPRT deficiency (6,14,23,33). In other individuals with partial deficiency (Kelley-Seegmiller syndrome), hyperuricemia and gout may be the only manifestations (1).

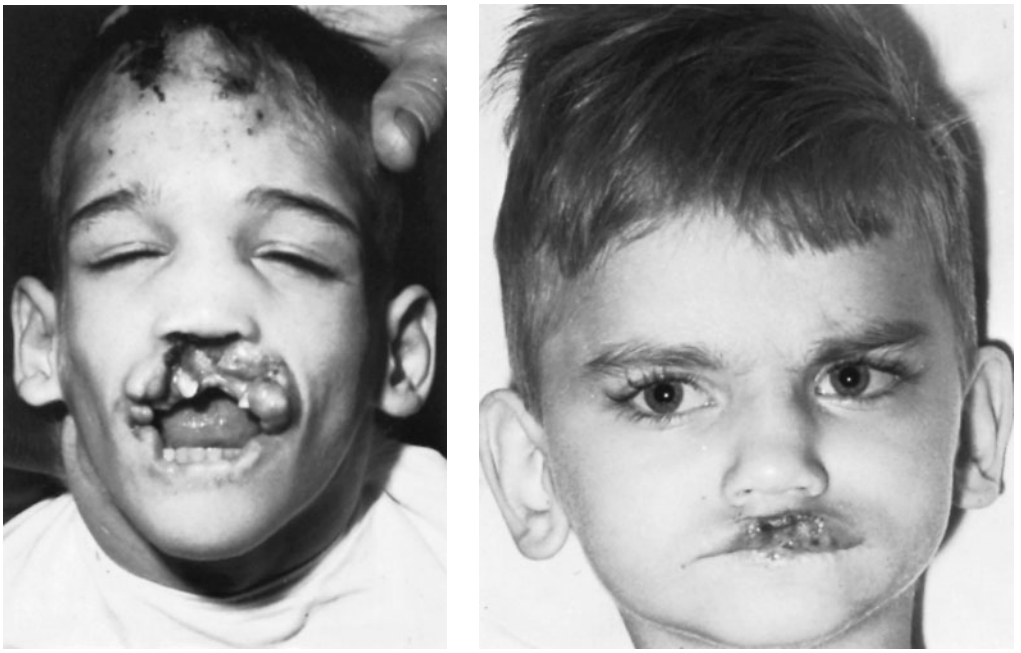
Pathogenesis. Neurochemical studies suggest that dopamine is reduced to one-half their normal levels (17,50). This specific deficit in the basal ganglion dopamine system may be instrumental in the development of behavioral changes (9,38,46a). This area of the brain is highly dependent on HPRT activity to maintain purine pools, and synaptic function is regulated by purine nucleotides (22,43).

Patients with HPRT deficiency also develop gout. This is directly related to increased de novo purine synthesis that arises from lack of feedback inhibition from the products of the HPRT reaction. The excess purines are converted to uric acid which, being of limited solubility, crystallize in situ. Tissues with high urate concentrations, particularly the kidney and joints, are prone to crystal-induced damage.

There is a partial defect in the adrenocortical 11β-hydroxylation of steroids (48).

Growth. Patients are normal at birth but growth failure is evident at the time neurological changes appears—after the second year of life (48). The height and weight of older patients are usually below the third centile. Delayed osseous maturation may occur, but is usually less severe than delay in linear growth. The onset of puberty may also be delayed. Christie et al (6) found microcephaly in only 6 of 16 patients (39%) for whom head circumferences were reported.

Neurological features. Patients are usually not identified clinically until neurological symptoms are noted. Some delay in motor development and hypotonicity becomes significant at approximately 4–6 months of age. Some infants cannot support their head. Others may have dislocated hips. Dysphagia is not rare. Choreoathetosis develops in all patients, but other nonspecific neurological features are also found, including opisthotonus (89%), scissoring (63%), upgoing toes (58%), and, less frequently, pure dystonia (21%) (6,37,42). Although self-mutilation is said to be present in all cases, exceptions have been reported (21,47). The average age of onset for self-mutilating behaviors is approximately



A B

Fig. 17–13. *Lesch-Nyhan syndrome.* (A) Self-mutilation of lips. (B) This boy and his brother have Lesch-Nyhan syndrome. Brother is more severely affected neurologically. (A courtesy of D Hoefnagel, Hanover, New Hampshire. B courtesy of B ter Haar, Nijmegen, The Netherlands.)

2 years but varies widely (4 months to 4 years) and has been delayed until the second decade in some instances (6,20,40,44). Self-mutilation most often involves biting, the lips and tongue being the most common targets, followed by fingers and shoulders (Fig. 17–13). Pain is perceived, but mutilation can only be inhibited by physical restraint. Other destructive behaviors include head-banging or chin-banging, which may lead to mutilations of the ears or nose, and aggressive behavior toward other people (biting, hitting, kicking, pinching, verbal aggression). Mental deficit varies widely and normal intelligence has been recorded. Most children will talk but speech is always dysarthric, presumably on the basis of choreoathetosis (6). Severely affected children are never capable of ambulation.

Hyperuricemia and gout. Urinary uric acid concentrations are always increased. Retrospectively, most parents (95%) have reported that orange sand or orange crystals were present in their infants' diapers even before the onset of neurological problems (6). If untreated, hyperuricosuria may progress to symptomatic nephrolithiasis (hematuria), obstructive uropathy, and permanent renal damage (18). This has been described as the most common cause of death in untreated patients in the first decade of life. Gouty arthritis is uncommon, but other features of gout including auricular tophi (28,36) and subcutaneous nodules (38) have been described.

Other features. Megaloblastic anemia observed in some patients has been associated with low serum folate (37,42). An increased rate of infection has also occurred, but this may be more a consequence of the neurological handicap than of the biochemical defect (6,37,42). Testicular atrophy is common (6).

Differential diagnosis. If self-mutilation occurs, there should be little difficulty recognizing *Lesch-Nyhan syndrome*. Among the mentally handicapped, however, some degree of self-mutilation is not that uncommon, particularly if autism is also present (47). Self-mutilation has been associated with *de Lange syndrome* and is seen in those with *congenital indifference to pain syndromes*. Individuals with conditions related to Lesch-Nyhan syndrome with similar clinical findings but without an enzymatic defect have been described (25,35,37,42). Conversely, in ostensibly normal patients with hematuria, episodes of oliguria and azotemia, a variant of HPRT has been found (45). An unusual variant with mild mental retardation, spastic gait, pyramidal tract signs, short stature, proximally placed thumbs, and clinodactyly of the fifth fingers has been reported (32). Self-mutilation can result from many causes (15).

Laboratory aids. Assay of HPRT enzyme in skin fibroblast, hair root lysates, or lymphocyte cloning may be used to identify heterozygous or hemizygous states. Similarly, assays of amniocytes, chorionic villus tissue, or even 8-cell preimplantation embryos provide a reliable basis for prenatal diagnosis (3,8,10,13,27,52).

The elevated morning urinary uric acid/creatinine ratio (often 2–5 times normal) is a useful screening test to detect individuals with undifferentiated neurological signs. Although the normal ratio (usually 0.2–0.6) varies with age and individual, results must be compared with those of age-matched controls, the urinary ratio reliably identifies Lesch-Nyhan patients and other hyperuricemic conditions (26). Serum urates are elevated, but may not be, in up to 10% during infancy.

Preimplantation genetic diagnosis has been carried out (32a).

Hereditary sensory syndromes with oral mutilation

There are many varieties of hereditary sensory and autonomic neuropathy that present as inability to perceive pain with subsequent trauma to and/or infection of both soft and hard tissues. The patient may receive extensive burns or fractures or osteomyelitis and perceive no discomfiture. Some patients destroy their own eyes or bite off their lips, tongue, or fingers.

Dyck (10) and Dyck et al (11) proposed a classification of these conditions based on mode of inheritance, natural history, and population of neurons or axons affected, under the name *hereditary sensory and autonomic neuropathy* (HSAN). These disorders were divided into five forms. HSAN type I, autosomal dominantly inherited, was previously reported under a large variety of names, among them hereditary perforating ulcers of the feet and hereditary sensory radicular neuropathy. Symptoms start between the second and fourth decades. The main manifestations are in feet and legs and particularly with variable degree of peroneal muscular atrophy. The gene maps to 9q22.1–q22.3 (34). Biopsy of peripheral nerves demonstrates diminished numbers of both myelinated fibers (MF) and unmyelinated fibers (UF), especially of cutaneous nerves. Hereditary sensory and autonomic neuropathy types II, III, IV, and V are congenital and all have autosomal recessive inheritance. Type II is characterized by pansensory neuropathy mostly manifested in the limbs, with less tendency to affect the face and trunk. It is an abnormality of cutaneous rather than deep nerves, which are small and formed mostly of unmyelinated fibers that are atrophic and decreased in number. In these patients, MF tend to be absent from cutaneous nerves. Consanguinity among the parents of these patients (31) as well as affected sibs (31,44) has been reported. Type III is *familial dysautonomia* associated with various degrees of pansensory disturbance. The gene maps to 9q31–q33 (3). In familial dysautonomia, biopsy demonstrates altered afferent neurons and gamma motor neurons with great reduction in UF and an absence of MF greater than 12 μm in diameter.

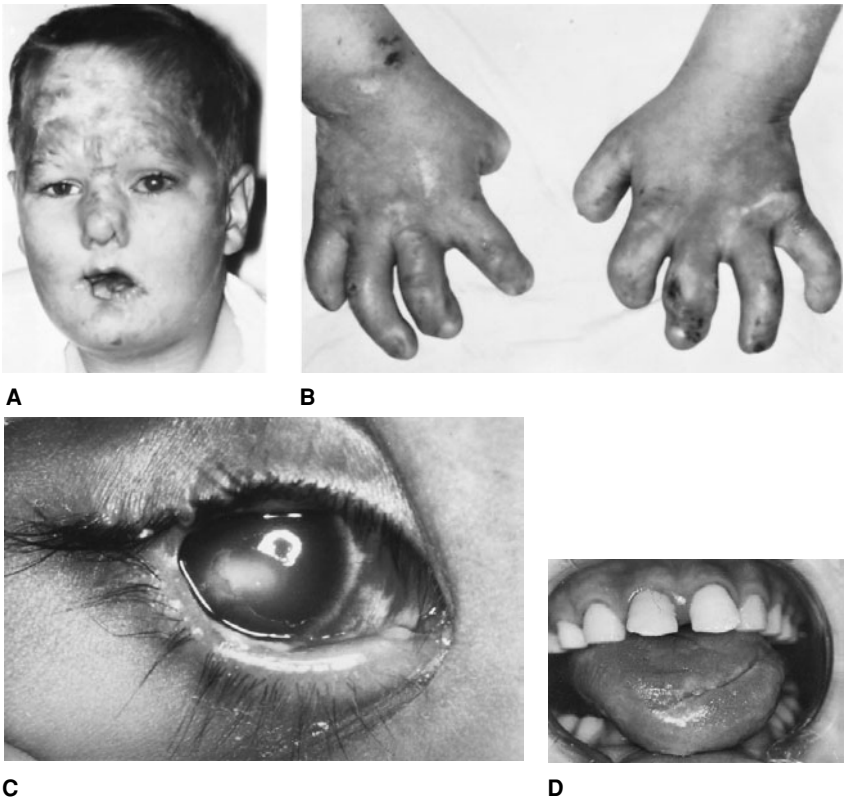

Fig. 17–14. *Hereditary sensory syndromes with oral mutilation.* (A) Five-year-old male chewed off anterior tongue and lower lip. Repeatedly traumatized nose, eye, forehead. Parents were first cousins. (B) Hands of same child. (C) Active corneal ulcer. Patient had tarsorrhaphy. (D) Deep scar, disappearance of lingual papillae. (C from R Yagev, Am J Ophthalmol 127:322, 1999. D from A Amano, Oral Surg Oral Med Oral Pathol Oral Radiol Endod 86:425, 1998.)

Type IV has been described as congenital insensitivity to pain with anhidrosis, unexplained fever, failure to thrive, and mild mental retardation (Fig. 17–14). At least 40 cases have been described (2). In this type, biopsy of peripheral nerves demonstrates complete absence of UF but normal or near normal large MF. Autopsy, performed in one patient, demonstrated the brain to be normal, but small neurons in the dorsal root ganglia were absent as well as the dorsolateral fascicular tract. The spinothalamic tract in the spinal core was absent (43). Consanguinity (4,21,22,24,47) as well as affected sibs [4,29,37(cases 2 and 3),42,45,48] have been found. The gene maps to 1q21–q22 (20). The gene, *TRKA*, encodes a high-affinity receptor for nerve growth factor (14a,29). Surely, over 100 patients have been reported (1). There seem to be many cases in Japan. Type V is similar to type IV, but without mental retardation (Table 17–4). Histology demonstrates marked decrease in A delta fibers and minimal decrease of C fibers. Good reviews are those of Donaghy et al (8), Gwathmey and House (16), Rosemberg et al (40), and Amano et al (1).

Earlier examples have been cited in the third edition of this text.

The usage of the terms indifference and insensitivity to pain should be discouraged because neither reflects the true nature of the conditions being discussed. For the purpose of clarification, we will use the term *hereditary nonneuropathic analgia* (HNNA) to refer to the condition characterized by universal lack of pain sensation but with perception of nociceptive stimulation, and with no alterations in sweating or other autonomic functions. Additionally, nerve biopsy should demonstrate normal peripheral nerve histology. Consanguinity (12,28) and affected sibs (19) have been reported in HNNA.

Type I does not present oral manifestations and type III is discussed in this chapter. Types II, IV, V, and HNNA are discussed here because they present variable degrees of oral and/or paraoral mutilation. Table 17–4 shows a schematic differentiation among the entities discussed.

Facies and general appearance. Frequent scarring of the face and corneas, with mutilation of the lips, arms, and legs, as well as phalangeal amputation due to self-mutilation have been noted in type II HSAN (11,32,45,48), type IV HSAN (24,27,37,42), type V HSAN (10), and HNNA (39) (Fig. 17–14). Corneal ulceration is especially common in type IV HSAN (49).

Anhidrosis. Anhidrosis is limited to type IV HSAN. The resultant hyperpyrexia may result in death in approximately 20% (40).

Musculoskeletal system. Osteomyelitis, aseptic necrosis, fracture, Charcot joint, and distal necrosis with spontaneous resorption of toes and fingers are virtually constant features in all these conditions (9,10,11,13, 15,17,18,23,33,35,38,41,42,44–48). The complications have been ascribed to lack of pain sensation—the patient failing to recognize trauma and then healing poorly (46). Several patients have exhibited loose joints.

Nervous system. In type II HSAN there is absence of reaction to painful stimuli most marked in the extremities. In some patients the lack of sensation may affect almost the entire body but present islands of normal sensation (10,11,48). Patients may have occasional seizures. Temperature sensation is reduced and touch sensation is markedly decreased. There is also lack of sweating over arms and legs (48). Anosmia has also been reported (45).

In type IV HSAN patients present with various degrees of mental retardation. Lack of pain sensation is almost universal but islands of normal sensation can be found. Temperature and touch sensation are slightly reduced. Hypohidrosis, but with variable degree, is typical (4,7,11,14,26, 27,30,42,48). Horner syndrome has been occasionally documented (37), as well as absence of Lissauer's tract and of small dorsal root ganglion cells and axons (21,43).

Type V HSAN has been described in only a few patients (11,25,36). These patients have universal lack of pain sensation, markedly reduced temperature sensation, moderate reduction in touch sensation, and peripheral hypohidrosis. The main difference with the other types of HSAN and HNNA is found in the abnormal histology of peripheral nerves (11).

In HNNA there is total absence of reaction to painful stimuli over the entire body. Deep-tendon reflexes are intact. The corneal and gag reflexes are often absent or diminished (28); taste, touch, sweat, temperature sensation, joint position sense, tickling, itching, and vibration are generally normal (11,28).

Intelligence has ranged from dull to normal. Patients with mental retardation generally represent examples of type IV HSAN (IQ-range 40–80)

Table 17–4. Hereditary sensory syndromes

Condition	Inheritance	Mental retardation	Oral lesions	Deep tendon reflexes	Touch sensation	Temperature sensation	Axon reflex	Tears	Sweat	Abnormal histology	Childhood manifestations	Other manifestations
HSAN Type I, hereditary radicular neuropathy	AD	No	No	±	Reduced+	Reduced++	No	Normal	Distal loss	Yes	No	Feet and legs peroneal atrophy
HSAN Type II, congenital sensory neuropathy	AR	No	Yes	Absent or reduced	Reduced++	Reduced+	No	Diminished	Distal loss	Yes	Yes	Mostly arms and legs
HSAN Type III, familial dysautonomia (Riley–Day)	AR	Could be retarded	Yes	Decreased	Normal	Reduced±	Yes	Absent	Erratic	Yes	Birth	Yes
HSAN Type IV, congenital sensory neuropathy + anhidrosis	AR	Could be retarded	Yes	Decreased	Reduced±, some normal	Reduced±	Yes	Normal	Absent or reduced	Yes	Birth	Yes
HSAN Type V	AR	No	Yes	Normal	Reduced++	Reduced±	Yes	Normal	Absent peripheral	Yes	Birth	Yes
HNNA	AR	Normal or reduced	Yes	Normal	Normal	Normal	Yes	Normal	Normal	No	Birth	Yes

(see Table 17–4). However, one can have normal intelligence with HSAN type IV (5). Recent studies (12) tend to support the theory that HNNA is not due to neuropathic alterations but possibly to an endogenous analgesic peptide disorder in which the patient produces abnormally high levels of opiate and nonopiate analgesic substances.

Oral manifestations. Lack of pain sensation results in severe oral mutilation (Fig. 17–14A). In nearly all, the tongue and lips are especially subject to injury, with resultant scarring. This has been seen in type II HSAN (11,32,45,48), type IV HSAN [14 (case 1),24,33,37–39,42 (case 1),44,46 (case 1, same as 29),47,48 (case 2, same as 44)], type V HSAN [11 (case 1)] and in HNNA.

Oral involvement becomes apparent as soon as the teeth appear and may lead to early diagnosis (44). Bruxism is present in approximately 50%. Extensive decay is not accompanied by toothache, and teeth may be lost early on this account (39). In approximately 80%, patients have painlessly extracted their own teeth (1,44). Oral burns are noted in 25%. Thrush (45) described a fibrous cord buccal to the teeth in each of his type II HSAN patients.

Differential diagnosis. Lack of pain sensation also occurs in leprosy, oligophrenia, hysteria, multiple sclerosis, postleukotomy state, and asymbolia (45). Asymbolia for pain is a form of aplasia associated with lesions of the supramarginal gyrus of the parietal lobe, usually due to trauma, tumor, or infection. Analgia may also be seen in syringobulbia and syringomyelia, but in these conditions temperature sense is also lost. Proper classification of patients presenting with congenital absence of pain sensation can be achieved only by careful clinical and neurological study, including testing of sensory and autonomic functions, as well as by histologic studies of peripheral nerves (sural nerve biopsy). The reader interested in a detailed differentiation of these entities is referred to the excellent work of Dyck et al (10,11).

Patients with *Lesch-Nyhan syndrome* also show signs of self-mutilation, especially of lips and hands, but they usually have severe mental retardation, choreoathetosis, and hyperuricemia. Critchley et al (6) described an autosomal recessively inherited syndrome characterized by acanthocytosis and neurologic disorder without lipoproteinemia. Tongue, lip, and buccal mucosal biting leading to severe mutilation resulted from uncontrollable, jerky movements that generally occurred at night. Patients responded normally to pain stimulation, but deep-tendon reflexes were absent. Self-mutilation is also seen in Tourette syndrome and *Brachmann-de Lange syndrome* (1).

Decreased sweating may also be seen in *hypohidrotic ectodermal dysplasia* and *Fabry syndrome*.

Laboratory aids. Histaminic flare is normal in HNNA, but is diminished or absent in HSAN types II, IV, and V (11,46). Fabbri et al (12) have found high levels of analgesic peptides such as opioid and calcitonin in the cerebrospinal fluid of a patient with HNNA. Injection of this lyophilized fluid in the lateral cerebral ventricles of rats induced deep analgesia.

Cranial nerve syndromes involving III, IV, V, VI

These arise from areas in which cranial nerves are geographically located in close approximation. Lesions in the following areas cause recognizable syndromes:

- Orbital apex syndrome (Rollet syndrome)
- Superior orbital fissure syndrome (Rochon-Duvigneau syndrome)
- Sphenoidal fissure syndrome (no eponym, same as above)
- Petrosphenoidal space syndrome (Jacod syndrome)
- Cavernous sinus syndrome
  a. Lateral wall of cavernous sinus (Foix syndrome)
  b. Cavernous sinus cavity (Jefferson syndrome)
- Apex of petrous bone syndrome (Gradenigo syndrome)

The signs and symptoms result from an intracranial lesion arising from the floor of the middle cranial fossa. It could involve the nerves that pass through the foramen ovale, foramen rotundum, and superior orbital fissure. Tumors extend along any of these paths to produce ophthalmoplegia by involvement of the third, fourth, and sixth nerves and blindness or optic atrophy by spread to the optic nerve itself.

Anatomical guidelines The foramen ovale transmits the mandibular division of the fifth cranial nerve (V3); the foramen rotundum, the maxillary division of the trigeminal (V2); and the superior orbital fissure, the III, IV, VI as well as the first or ophthalmic division of the trigeminal nerve (V1).

The apex of the orbit encompasses the area of the superior orbital fissure plus the optic foramen. There is considerable overlap between the syndromes as the same nerves traverse different anatomical locations.

It should be noted that there is not always a clear difference between the orbital apex syndrome and the superior orbital fissure syndrome.

The superior orbital fissure syndrome was first described by Rochon-Duvigneau (27) in 1896. If the lesion is more anteriorly situated and also includes the optic foramen and hence the optic nerve, the condition is called the orbital apex syndrome of Rollet (also called Jacod syndrome, see below).

Clinical features

Orbital apex (Rollet) syndrome. The syndrome is characterized by pain in the region of V1 plus involvement of III, IV, and VI due to juxtaposition. Paralysis occurs either simultaneously or in succession. Resultant ptosis, proptosis, ophthalmoplegia, fixation and dilation of the pupil, blindness, and anesthesia of the upper eyelid and forehead occur. It differs from Jacod (petrosphenoidal) syndrome in which pain is largely over the V2 area. Blindness arises from optic nerve involvement (32,35). The syndrome can be difficult to differentiate from the superior orbital fissure syndrome that shares manifestations but in which there is no blindness.

Superior orbital fissure (Rochon-Duvigneau) syndrome. There is total ophthalmoplegia due to involvement of III, IV, and VI as well as sensory changes due to involvement of V1. Hence, ptosis, proptosis of eyeball, fixation and dilatation of pupil, and anesthesia of upper eyelid and forehead are present, as noted above. Rarely, V1 and V2 are both involved.

The syndrome may be secondary to fracture of the zygomatic complex with edema and bleeding or facial fractures of the Le Fort II and III types, infections of the retrobulbar space, meninges, cavernous sinus and CNS, a neoplasm arising in the nose and extending through the orbital floor after traversing the pterygopalatine fossa (Behr pterygopalatine fossa syndrome or Dejean orbital floor syndrome), or a retrobulbar hematoma in the cavernous sinus and in the orbital muscle cone space. Lesions causing the superior orbital fissure syndrome can easily extend to involve the cavernous sinus (14,21,28,34).

Petrosphenoidal space (Jacod) syndrome. The syndrome may be confused with the superior orbital fissure syndrome. Further confusion occurs because the orbital apex syndrome is often used synonymously.

The main clinical difference from the orbital apex syndrome is that pain is in the V2 distribution (8,18).

Cavernous sinus (Foix) syndrome. This disorder is due to tumors (rarely pituitary), intracranial aneurysms, or thrombosis involving the cavernous and/or lateral sinuses. Ophthalmoplegia results from involvement of III, IV, and VI. Although pain is experienced in both the V1 and V2 areas, it is most severe over V1 (3,8,11,19).

When thrombosis occurs, the patient is acutely ill with fever, headaches, and pain around the eye that is proptosed and swollen because of conjunctival edema. There is usually complete ophthalmoplegia with a fixed pupil.

Apex of the petrous bone (Gradenigo) syndrome. This consists of sixth nerve palsy, diplopia, strabismus, lacrimation, and pain behind the eye, that is, in the V1 region (10,13). The syndrome is uncommon since the antibiotic era (mastoid infection) (12,32), but has been reported following gunshot wound (2) or surgery (15). Horner syndrome may be present, but is rare.

Other syndromes involving eye movements

Duane syndrome. Named after Duane who fully described it in 1905, the syndrome is characterized by limitation of eye movement. On lateral gaze, the abducted eye becomes retracted and the eye opening narrows. In 15%–20%, the condition is bilateral.

Etiology is unknown although aberrant peripheral innervation has been postulated. The clinical features include profound loss of abduction, partial deficiency of adduction, ocular retraction on attempted adduction, oblique movement of the eye (both up and down) on adduction, narrowing of palpebral fissures on adduction, and defect of convergence.

In the study of 62 cases by O'Malley et al (24), 62% were female, and 65% involved the left eye. Esotropia occurred in 53% and amblyopia in 20%. Approximately 15% had anisometropia. Nearly all cases were isolated. In one case, transmission was from mother to daughter. The other involved concordance in monozygotic twins. There appears to be genetic heterogeneity, one mapping to 2q31, the other to 8q13 (1,1a).

The coexistence of Duane syndrome and *Marcus Gunn phenomenon* has been noted (17).

Fisher variant of Landry-Guillain-Barré syndrome. In 1956, Fisher (6) described three patients with acute external ophthalmoplegia, ataxia, and hyporeflexia. Ptosis and some degree of internal ophthalmoplegia (facial and bulbar weakness) can occur, but characteristically there is impairment of conjugate upward and lateral gaze, often leading to complete ophthalmoplegia. Usually it is benign with recovery complete. There is often a preceding upper respiratory tract infection but etiology is unknown. Hypersensitive response to a virus is probable (9).

Tolosa-Hunt syndrome. The main criteria for diagnosis (16,25,30) have been summarized by Dornan et al (4): steady nonthrobbing pain, often preceding ophthalmoplegia by several days, and paresis of any of the nerves passing through the cavernous sinus, that is, III, IV, VI, and V1 (sympathetic nerves and II occasionally involved). Symptoms may last for days or weeks. There is no obvious lesion and attacks may be repeated.

Remission is either total or subtotal. Etiology is unknown (29).

Syndromes of V

It must be emphasized that a single cranial nerve is rarely involved in a pathological process. Because of the intimate association of V with III, IV, and VI in the cavernous sinus and elsewhere, a host of eponymic syndromes exist. Diffuse processes, such as brain tumors at the base of the skull or tumors that invade the cranium from the nasopharynx, may involve the last four cranial nerves in combination with the fifth, but this is less common.

See the previous discussion for nerve V involvement in the orbital apex syndrome, superior orbital fissure syndrome, and syndromes of the cavernous sinus. Trigeminal neuralgia is discussed in "Some Disorders of Facial Pain" later in this chapter.

Other syndromes involving the Vth cranial nerve during its peripheral course

Raeder (paratrigeminal) syndrome. This syndrome is characterized by unilateral facial pain/headache with a trigeminal distribution. The pain is mostly in and around the eye. In addition, there is ptosis, miosis, and hyperemia because of an oculosympathetic defect (20).

Multiple parasellar cranial nerve involvement of III, IV, V, and VI can occur. Four of five patients originally described by Raeder had other cranial nerve involvement. Decreased sensation and muscular weakness in all three divisions of V have been described.

The syndrome is a combination of a Horner-like syndrome with ipsilateral motor and sensory V dysfunction. Neoplasms of the middle cranial fossa or in the space adjacent to V—hence paratrigeminal—are often responsible. Facial anhidrosis is absent. It is often seen in males in the fourth to sixth decades, but trauma has also been implicated.

There must be involvement of V. Evidence for this may be decreased sensation in the distribution of V, weakness, pain of the tic douloureux type and distribution, and pain over the ipsilateral part of the face. Facial pain in the distribution of V alone, although it may be present, is not sufficient (22).

Pterygopalatine fossa (Behr) syndrome. This syndrome, resembling that of Trotter (see Table 17–5), is because of a tumor or metastases in the pterygopalatine fossa, located behind the maxillary sinus and below the inferior surface of the sphenoid. It contains V2, the spheno-palatine ganglion, and the internal maxillary artery. The main symptoms are pain in the upper teeth, loss of sensation over the inferior orbital foramen, paralysis of the pterygoids, and blindness.

Trotter syndrome. First described by Trotter (31) in 1911, the syndrome consists of unilateral deafness, pain over V3, ipsilateral defective mobility of the soft palate, and subsequent trismus. A sensation of ear pressure, distention of the tympanic membrane, or repeated middle ear infections are common. The syndrome results from invasion of the lateral wall of the nasopharynx by tumor, usually an anaplastic carcinoma. Immediately below the sinus is the attachment of the levator veli palatini muscle, just laterally is the foramen ovale, and posteriorly is the opening to the eustachian tube. As the tumor extends, it compresses the tube (causing deafness) and invades the palatal musculature (decreasing pain in the temporal area, ear, lower jaw, teeth, and tongue, and resulting in anesthesia over the mental area). Trismus results from extension of the tumor into the pterygoids. The syndrome is seen most often in males during the third and fourth decades. There are usually no symptoms because of nasopharyngeal obstruction (23,31). The use of computer tomography has vastly aided diagnosis (7).

Godtfredsen (cavernous sinus-nasopharyngeal tumor) syndrome. Tumors arising in the nasopharynx, in addition to extending into the skull and producing ophthalmoplegia and trigeminal neuralgia, may also be associated with paralysis of the tongue. This is produced by compression of the hypoglossal nerve by enlarged, involved, retropharyngeal lymph nodes (11).

Syndromes of cranial nerves involving the midbrain and pons

Syndromes of the midbrain and pons are presented in outline in Table 17–5.

Table 17–5. Cranial nerve syndromes involving midbrain or pons

Syndrome	Location	Signs
Midbrain		
Weber	Base of midbrain anterior to red nucleus	Ipsilateral III Contralateral hemiparesis
Claude	Tegmentum, red nucleus, and brachium conjunctiva	Ipsilateral III (sometimes IV), sometimes reduction of conjugate gaze to opposite side. Contralateral ataxia dysmetria, dysdiadochokinesia
Benedict	Tegmentum; destruction of red nucleus where third nerve crosses it	Ipsilateral third plus contralateral movement disorder—Parkinsonian tremor, athetosis, hemibalismus
Nothnagel	Tectum	Paralysis of lateral gaze plus ataxia—unilateral or bilateral
Parinaud	Pretectum (pinealomas, craniopharyngiomas)	Paralysis of upward gaze and of convergence Pupils are responsive
Pons		
Millard-Gubler	Ventral pons VI, VII Corticofacial and corticospinal fibers before decussation	Facial paralysis, paralysis of adduction of eye Contralateral hemiparesis
Inferior syndrome of Foville	Caudate one-third of pons Supranuclear VI and VII medial lemniscus spinal root of inferior cerebellar peduncle	Lateral conjugate gaze toward side of lesion Crossed hemiparesis with diminished pain and temperature sensation Homolateral cerebellar signs
Superior syndrome of Raymond-Cestan or superior type of Foville	Rostral pons Includes medial lemniscus, spinothalamic tract Superior cerebellar peduncle	Paralysis of conjugate gaze to size of lesion Diminished pain, touch, temperature, vibration and position sense Cerebellar signs (ataxia), athetotic or ballistic movement, all on the opposite side
Brissaud and Sicard	Anterolateral and inferior pons, pyramidal tract before it crosses VII nucleus	Hemifacial spasms, crossed hemiparesis

Marcus Gunn phenomenon [jaw-winking and winking-jaw syndromes (Marcus Gunn and inverse Marcus Gunn syndromes), Marin Amat phenomenon]

The short communication by Marcus Gunn (23) (often erroneously hyphenated), in 1883, describing the syndrome of unilateral congenital ptosis and rapid exaggerated elevation of the ptotic lid on moving the lower jaw to the contralateral side, stimulated immediate interest in this problem. By 1895, 33 cases had been reviewed by Sinclair (32) and since then at least another 200 cases have been published (2,3a,5,6,16,28,31,33). The syndrome is seen in approximately 5% of cases of congenital ptosis of the eyelid (28).

The name "jaw-wink" syndrome is not well chosen for the symptom is not a wink but an exaggerated opening of the eye. However, the term has been used so long and extensively that until the cause is clarified, its use will probably be continued. Although usually sporadic, there have been a few familial cases involving two generations (10,14,19,20,28). There is neither sex nor side predilection.

The cause is unknown, but it was originally assumed that the syndrome was based on aberrant innervation of the levator palpebrae superioris from the motor branch of V because of the close approximation of the nuclei of III and V. However, a supranuclear, or at least a combined supranuclear-nuclear, involvement has been suggested, and the view has gained support (28,33). The levator muscles on both sides are atrophic (22). A good review of theories of etiology has been compiled by Simpson (31).

The ptosis is congenital in over 90%. It may, however, arise spontaneously in older persons (14,31). Ordinarily the lid cannot be raised to any significant degree. Seven percent of patients have experienced the syndrome without having ptosis (28), and 3% have bilateral ptosis (5,8,30,35).

Superior rectus palsy has been found in 25% and double elevator palsy in another 25%. Between 35% and 60% exhibit amblyopia or strabismus (8,28). Correction of the strabismus was accompanied by opening the mouth in one patient (26). The pupillary and corneal reflexes are normal. The pupil in the ptotic eye may be smaller, but true Horner syndrome is not present. Marcus Gunn syndrome may be seen in association with Duane retraction syndrome (17) and with neurocristopathies (6,25).

Approximately 40% manifest the syndrome both on depressing the mandible and on moving it to the side opposite the ptotic eye (Fig. 17–15). Another 40% need only to have the jaw depressed. However, in some individuals the syndrome may be produced by movement of the lips, whistling, smiling, clenching the teeth, chewing, puffing out the cheeks, protrusion of the tongue, or sucking (8,28). It may even be precipitated by swallowing or, rarely, by moving the jaw to the ipsilateral side, or to both sides. The syndrome has also been triggered by closing the other eye. The syndrome may even temporarily disappear. Several muscles and cranial nerves come into play during these acts; the most important appears to be the external pterygoid. That the masseter and temporal muscles play no significant role was demonstrated by Dupuy-Dutemps (9). A comprehensive review of critical jaw movements was made by Simpson (31). Cleft lip has been found but is probably a chance association (2,28). CHARGE association has been noted in a case (35).

The so-called winking-jaw syndrome (inverse Marcus Gunn syndrome, corneomandibular reflex, pterygocorneal reflex) is manifested by a brisk movement of the mandible to the contralateral side when the cornea is touched. The jaw may also be thrust forward (13,34). The term inverse Marcus Gunn syndrome has also been used to refer to brisk ptosis of the upper eyelid on moving the mandible to the contralateral side (21) (Fig. 17–16). Both jaw-winking and winking-jaw syndromes are considered to be release phenomena because of a supranuclear lesion, caused either by malformation or by severe cerebral or brainstem lesions, that reunites the orbicularis oculi and external pterygoid muscles, which phylogenetically belong together (33,34).

The so-called Marin Amat (21) syndrome appears to be an intrafacial reaction on the part of regenerating facial nerve following facial palsy (1,12,18,27a,29,33,34). A partially ptosed eyelid droops further when the mandible moves from side to side.

Eye bobbing (elevation and depression of the globe) may also occur with mandibular movement. Synkinetic stimulation of the muscles of mastication and the superior rectus muscles has been suggested (27).

Some disorders of facial pain

Because of the plethora of possible combinations of involvement of cranial nerves, both within and outside the cranial cavity, a considerable number of eponymic syndromes have been created to describe these conditions. The interested reader is referred to some extremely comprehensive reviews (1–13). Attanasio (1), for example, lists 40 causes for facial pain. Those deemed to have greater importance are considered here.

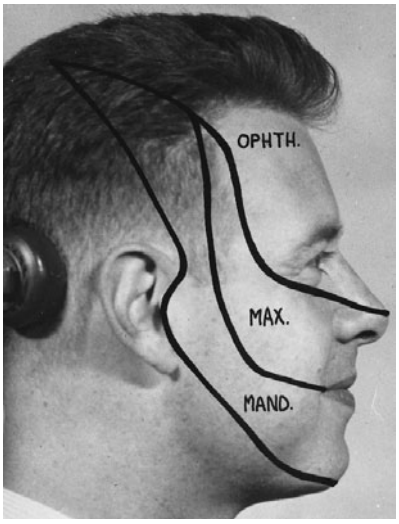
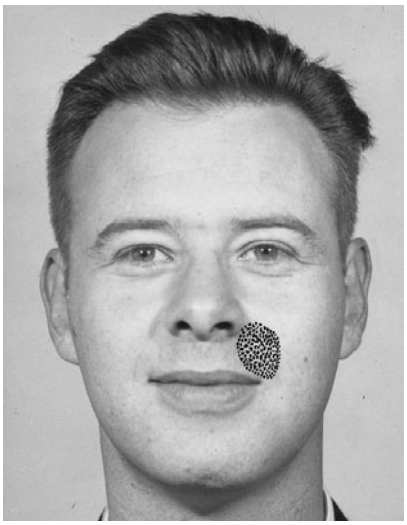
Trigeminal neuralgia (tic douloureux). Trigeminal neuralgia is characterized by extreme severe recurrent episodic attacks of unilateral pain distributed over a branch or, after many years, more than one branch of V (Fig. 17–17A). The reported incidence per 100,000 inhabitants in the United States is 2.7 for men and 5.0 for women (13). The pain may occur spontaneously or may be initiated by stimulation of a trigger zone that most often extends from the lateral border of the nose to the angle of the mouth (Fig. 17–17B). The pain may vary in intensity but, along with pain resulting from kidney stones, may be one of the most dreadful and dreaded pains experienced by humans. It occurs suddenly, without warning, a single spasm often lasting from 30 to 60 seconds. Because these brief paroxysms are repeated at short intervals, the pain may be



A



B

Fig. 17–17. (A) *Trigeminal nerve.* Areas supplied by the three sensory branches of the trigeminal nerve. (B) Trigeminal neuralgia. Most common "trigger zone" area.

stated to have lasted for a longer duration (1,4). The severe paroxysms not uncommonly are preceded by electric shock sensations lasting for only a few seconds. The severe pain disappears rapidly, but occasionally a patient may have a mild residual ache or burning that persists for several minutes. With time, a chronic burning facial pain may gradually develop (6).

Trigger zones are not necessarily present, but when they occur, they will often aid in diagnosis. The trigger may be tripped by mastication, talking, shaving, a draft of air on the face, or even the vibration from a loud noise. Within the mouth, a trigger zone may be located on the gingiva or at the base of a single tooth, giving the patient the erroneous notion that it is dental in origin causing, at times, unnecessary extraction of teeth. We have seen several patients who became edentulous. The patient may avoid brushing the teeth or applying cosmetics so as to avoid these areas. Talking may so often trigger the pain that the individual often presents with an immobilized face, talking through the teeth, with eyes expressing fear, and pointing to but not touching the affected area. In extreme cases, the patient may even be afraid to eat or drink (7,11).

The pain usually (60%) begins in the second or third branch of the trigeminal nerve, but rarely may progress to involve all three branches. Trigeminal neuralgia occurs more often on the right side. Approximately 5% of patients have bilateral involvement. In these cases the disorder usually starts with unilateral involvement, only rarely being followed by involvement of the other side by months or even years. It occurs twice as commonly in women as in men, and over 70% of the cases are seen in persons over 50 years of age. However, approximately 15% experience the onset prior to the age of 40. More than half of the patients have remission of 6 months or more, but the time between remissions gradually decreases (1,9,10). The so-called SUNCT syndrome (*s*hortlasting, *u*nilateral, *n*euraligiform headache attacks with *c*onjunctival infection and *t*earing) seems to represent trigeminal neuralgia with autonomic signs (2).

Diagnosis depends on the history and description of the pain. There is no sensory loss. No physical signs or laboratory tests are diagnostic. Ordinarily, there is no difficulty in making the correct diagnosis.

In most cases, there is compression or distortion of the nerve root by an aberrant arterial loop and/or venous channel (6,8). Perhaps in 5%–10% neoplasms or arterial aneurysms that impinge on the trigeminal nerve may result in trigeminal neuralgia (1,6,8,12). It has also been estimated that approximately 2%–4% of cases of trigeminal neuralgia have been associated with multiple sclerosis, but usually there are other signs of neurologic deficit present in addition to the pain and the patients are usually in their third or fourth decade (3,4). If suspected, serum IgG should be measured. Rarely, dental disorders such as split tooth, interradicular periodontal abscess, or pulpitis may simulate trigeminal neuralgia (7). Facial pains of nondental origin that may occasionally resemble trigeminal neuralgia include periodic migrainous neuralgia, antral carcinoma, temporomandibular joint syndrome (myofascial pain dysfunction), temporal (giant cell) arteritis, post-zoster neuralgia, benign brain tumors, and atypical facial pain with personality changes.

There are several published cases of familial aggregation (5).

Glossopharyngeal neuralgia. Much rarer than trigeminal neuralgia (1:100 cases), glossopharyngeal neuralgia is characterized by unilateral paroxysmal stabbing pain in the posterior one-third of the tongue, pharynx, larynx, and soft palate lasting from a few seconds to a minute, followed by a burning sensation that may last from 2 to 5 minutes (3,6,7).

The pain usually extends to the ear. As in the case of trigeminal neuralgia, the pain is associated with a trigger zone that is usually located on the lateral wall of the pharynx, at the base of the tongue, or in the external ear area posterior to the mandibular ramus. Swallowing and talking usually trip the trigger, although it may also be precipitated by yawning, coughing, or consuming cold drinks. Trigger zones can often be

demonstrated in the tonsillar or pharyngeal area by touching these regions with a probe.

The syndrome seems to occur with equal frequency in both sexes, but involvement is slightly more common on the left side than on the right. Bilateral involvement is extremely rare, being seen in less than 1% of a series of 116 patients reported by Rushton et al (7).

The pain is usually of an intense, severe quality and occurs most often at night. It is followed by homolateral tearing and salivation caused by neuronal bombardment of the lacrimal and parotid glands. Between attacks, tinnitus, partial deafness, and facial tics may be experienced. Cocainization (10% cocaine or similar surface anesthetic agent) of the lateral pharyngeal wall and/or tonsil is ordinarily performed to ascertain whether one is dealing with true glossopharyngeal neuralgia, for this brings about immediate but temporary relief. Associated with the neuralgia may be bradycardia, hypotension, syncope, and cardiac arrest (1,3,4). These symptoms apparently result from activation of the glossopharyngeal-vagus complex that eventuates in cardiac slowing. This in turn will result in syncope or rarely cardiac arrest. Coughing is common during an attack of pain (2,5,8).

Approximately 55% occur after the fifth decade. When found in a younger age group (approximately 25% are younger than 40 years), it may be because of anomalous arteries at the cerebellopontine angle, inflammation of the arachnoid membrane, tonsillitis, perineural fibrosis, viral infection, or elongation of the styloid process (Eagle syndrome) (see below). Like trigeminal neuralgia, glossopharyngeal neuralgia may be associated with unpredictable remissions and recurrences.

Post-zoster neuralgia (geniculate ganglion syndrome, Ramsay Hunt syndrome, cephalic zoster syndrome). Herpes zoster (shingles) is an acute self-limited disease because of the varicella-zoster virus. Although herpes zoster may occur even in the newborn (assuming an intrauterine chicken pox infection), most cases are seen in older patients. Men and women are affected with equal frequency (2,3,8).

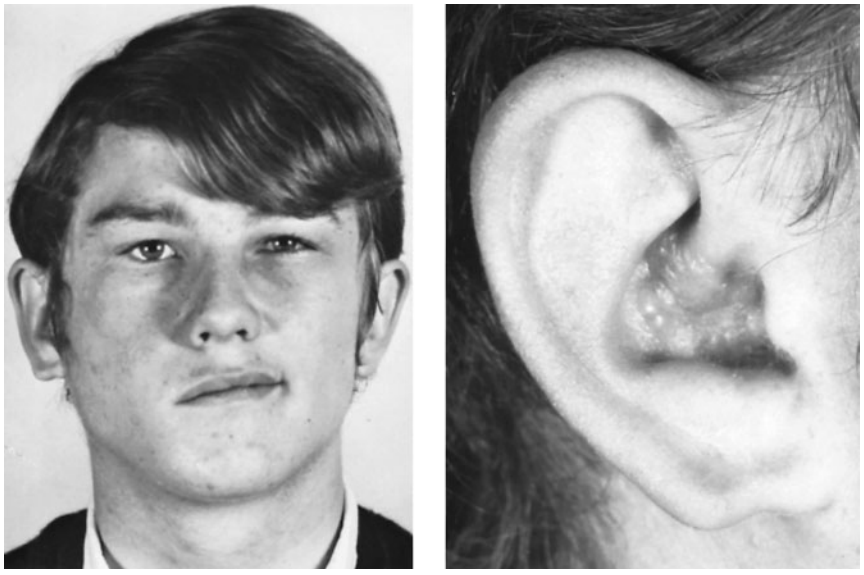
Injury to the nervous system is most severe in one or two dorsal root ganglia or in the corresponding sensory ganglia of the cranial nerves. There is inflammation of the white matter of the dorsal horn and, to a lesser extent, of the anterior horn. Similar involvement of the gray matter of the brainstem often accompanies involvement of the sensory ganglia of the cranial nerves.

Infection of the geniculate ganglion results in vesicular eruption of the external ear and oral mucosa, facial palsy of the lower motor neuron type, severe pain in the external auditory canal and pinna, and ipsilateral loss of taste and lacrimation. The syndrome comprises approximately 3%–9% of cases of facial palsy (Fig. 17–18). By measuring tear production, submandibular salivary flow, and evoked electromyography, one can estimate prognosis (6). There has been a consensus to limit use of the term Ramsay Hunt syndrome to those with involvement of the conchal zone and to exclude cases with involvement of other cranial or cervical nerves or ganglia.

Aleksic et al (1) have presented good evidence to support the contention of Ramsay Hunt that the syndrome arises from geniculate ganglionitis. The facial paralysis apparently results from interstitial neuritis with attendant edema within the bony canal. The combined loss of taste of the anterior two-thirds of the tongue and loss of lacrimation can be explained by a lesion at or proximal to the geniculate ganglion. Round cell infiltration of the facial nerve has been repeatedly demonstrated.

Pain in the ear is severe and paroxysmal and, as with zoster infection of other areas, it often precedes the cutaneous and mucosal lesions by a week. The ear becomes red and swollen followed by vesicular eruption of the auditory meatus and tympanic membrane. The concha, tragus, antitragus, anthelix and, rarely, the lobule may be involved. Rarely, there is no auricular eruption. Associated signs and symptoms may include diminished lacrimation, tinnitus, hearing loss, vertigo, nystagmus, hoarseness, and loss of superficial and deep sensation of the face. The regional lymph nodes are enlarged and tender. Pain persists for weeks after the eruption has disappeared. Among those 40 years or older, approximately one-third experience pain for months or even years.

Oral signs and symptoms include vesicles or eroded areas in the peritonsillar region, oral pharynx, and posterolateral third of the tongue, and pain in the same areas. Occasional loss of taste, diminished salivation,



A B

Fig. 17–18. *Cephalic zoster.* (A,B) Note peripheral right facial weakness and vesicular lesions of conchal area. (From SG Harner, Arch Otolaryngol 92:632, 1970.)

and palatal paralysis may be present. These changes may rarely precede the auricular signs (5).

Prior to the appearance of the cutaneous or mucosal lesions there is often a stinging sensation experienced in the area subsequently involved by the vesicles. The pustules form crusts that are shed after 2–3 weeks and generally the skin resumes its normal appearance. The trigeminal nerve is involved in 15%–20% of patients with herpes zoster, with the ophthalmic branch affected approximately 10 times as often as the maxillary and mandibular branches combined. The seventh, ninth, and tenth nerves may rarely (less than 1%) be involved (4,7).

Approximately 65% who manifest post-zoster neuralgia are over 70 years. It is rare in individuals less than 30 years of age. The neuralgia may last for many months or, in fact, even for years. Patients describe it as burning, aching, or boring. Not uncommonly it is associated with paresthesia in the involved area. The pain and paresthesia are often present throughout the day and may seriously interfere with sleep. In some cases, the patient may experience lancinating pain reminiscent of trigeminal neuralgia, but there is no trigger zone.

Still other facial pains

Cluster headaches (Horton's headache). Prevalence is at least eight times as common in men as in women and is noted in 1 in 1500 people. There is some familial aggregation (14). It usually appears between the ages of 30 and 45 years. It may be precipitated by alcohol, which is a vasodilator. The pain is unilateral, occurs with great regularity, and involves the region of the orbit and temple with occasional spread to the neck, upper jaws, or occiput. Its onset is rapid and may reach excruciating intensity and subside after a period varying from a quarter of an hour to 2 hours. The pain becomes so dreaded that in spite of being free of pain, the patient becomes emotionally exhausted. The attacks may occur as often as 5–10 times during a day, and are so severe that they may awaken the patient from sleep in the early morning hours (alarm clock headache). The patient then arises because attacks are more painful when the patient is recumbent. The pain is boring, burning, and is associated with hyperemia of the eye, profuse lacrimation, and stuffiness or obstruction of the nostril on the ipsilateral side. Often there is edema of the eyelid. Usually the attacks subside spontaneously after several weeks, although remissions are common. Narrowing of the pupil and palpebral fissure has been noted in approximately 15% of patients (1,2,4,5,9).

Atypical facial pain. Atypical facial pain is usually described by exclusion (7). It is not trigeminal neuralgia, glossopharyngeal neuralgia, post-zoster neuralgia, or pain secondary to disorders of the teeth, pharynx, ears, or eyes. It is usually poorly localized, intense, constant, and often described as deep. Frequently, the pain does not follow normal anatomic distribution of the trigeminal nerve, commonly crossing the midline or involving portions of the face not limited to the sensory distribution of a single nerve (15). The pain often is described as lasting for weeks, months, or years and being constant in quality. Atypical facial pain is more common than trigeminal neuralgia. Rushton et al (13), in a study of 100 patients, classified atypical facial pain under three headings: (*a*) psychogenic, (*b*) organic, and (*c*) indeterminate. Patients with psychogenic facial pain constituted over half of their 100 patients. Although the patient complained primarily of facial pain, there were associated depressive reactions, schizophrenia, or conversion hysteria. Most were in the fourth and fifth decades of life and there was a marked preponderance of female patients. Approximately half attributed the onset of the facial pain to a definite incident such as a dental procedure or being struck in the face. The diagnosis is justified when the pain does not follow normal anatomic distribution. There are no signs of organic disease and often there is a history of emotional illness (11,14,15). It typically affects middle aged females.

Organic facial pain. In one-third of their series of 100 patients, Rushton et al (13) further classified organic facial pain into five subgroups: (1) vasodilating pain, (2) dental disease, (3) neuritis, (4) neoplasms, and (5) miscellaneous organic conditions. Vasodilating facial pain resembles that of Horton's headache. The onset, character, and duration of pain are similar. However, the location is atypical, the pain being in the lower portion of the face in contrast to the head and eye pain of typical histaminic headache. But otherwise the duration of the pain and the numerous recurrent episodes within a 24-hour period closely simulate histaminic cephalgia. Furthermore, ergotamine tartrate stops the pain of a typical episode.

Dental disease. Atypical facial pain may be caused by previously unrecognized dental disease. The pain was poorly localized in the face and in no patient was it limited to the involved tooth until late in the course of the disorder. Clinical and radiographic studies were normal. Only late in the disorder was the final diagnosis of pulpitis made. Extraction of the responsible tooth stopped the pain. Several other authors have attributed a series of atypical facial neuralgia to incompletely healed tooth sockets (10,12).

Neuritis. Eight of the 100 patients described the facial pain as burning, itching, sticking, or jabbing. A slight but definite sensory loss limited to the division of the trigeminal nerve was exhibited in each instance.

Indeterminate facial pain. Fifteen of the 100 patients described by Rushton et al (13) were classified as having atypical facial pain of indeterminate cause. The duration of the pain was short compared with that in those with psychogenic facial pain. In at least half the patients, the pain started after the age of 50 years. Remissions were common and most of the patients derived substantial, although temporary, relief with the use of ordinary analgesics. Chewing, touching, or rubbing the face seemed to cause the pain to become worse, but other characteristics of trigeminal neuralgia were not present.

Angina pectoris. We have seen several patients who described pain in the mandible and neck upon exertion. This preceded pain in the chest by several weeks (7).

Trigeminal neuropathy. Trigeminal neuropathy is a protracted disorder of sensation confined to the distribution of the fifth cranial nerve either unilaterally or bilaterally. The term trigeminal neuritis is avoided here because that implies an inflammatory reaction for which it is extremely difficult to present histologic proof. It is to be contrasted with trigeminal neuralgia that is characterized by brief attacks of very sharp pain without sensory impairment. In trigeminal neuropathy, the pain is described as an ache or as burning, boring, pulling, or drawing (1,7). Some patients complain of paresthesia, others of pain involving the area supplied by any of the three divisions of the trigeminal nerve or combinations thereof. The discomfort may persist for hours, days, or weeks. In a study of 61 patients with trigeminal neuropathy, Goldstein et al (4) considered six possible etiologies: dental surgical procedures, mandibular denture pressure, nondental surgical procedures, mechanical trauma, stilbamide intoxication, and a miscellaneous group of causes. Approximately one-third of the patients noted onset of symptoms secondary to a dental surgical procedure, in most cases following tooth removal. Presumably this is because of injury to the sensory fibers of the trigeminal nerve resulting from needle puncture during anesthesia. Goldstein et al (4) suggested that it is advisable to caution patients with deeply impacted teeth that a sensory disturbance such as trigeminal neuropathy may follow removal of impacted third molars. Almost 5% experience dysesthesia after mandibular third molar extraction (5). They suggested that the patient should be seen frequently during the course of the neuropathy, especially if the patient becomes alarmed during nerve regeneration when a sensation of "pins and needles" or tingling may be manifest. Trigeminal neuritis may also occur following alveolar osteitis (dry socket). Pressure from a mandibular denture on the mental nerve at its exit from the mental foramen may produce trigeminal neuropathy. This usually results from extensive alveolar resorption because of periodontal destruction, causing the nerve at the mental foramen to lie on top of the alveolar ridge. Pressure from movement of a mandibular denture may produce pain or paresthesia over the distribution of the mental nerve. It is highly recommended that the reader peruse in detail the paper of Goldstein et al (4) for a variety of other causes for trigeminal neuropathy including such rare findings as intracranial aneurysms. The series of patients reported by Spillane and Wells (7) are extremely valuable. The combination of paresthesia and facial pain should cause the clinician to consider trigeminal neuropathy, tumors of the Gasserian ganglion or its sensory root, pontine tumors, and vascular abnormalities in the region of the ganglion. One should also consider multiple sclerosis. This has already been discussed in association with trigeminal neuralgia, but occasionally the only complaint is paresthesia of the face.

Nasopharyngeal and cranial lesions causing facial pain. Excellent reviews of the neurologic manifestations of malignant nasopharyngeal tumors are those of Thomas and Walz (2) and Devine et al (1). Prior to the onset of neurologic signs or symptoms, patients often present with pains in the head, face, or ear, swelling of cervical lymph nodes, and nasal or pharyngeal symptoms. These may antedate such obvious neurologic complications as diplopia, visual loss, or facial paresthesia by several years. Frequently several cranial nerves are involved that give rise to a host of eponymic syndromes. If only a single nerve is involved, Thomas and Walz (2) found the sixth nerve to be involved in over two-thirds of their patients, the fifth nerve in approximately half, and the ninth nerve in over a third. The most common binary combination is cranial nerves V and VI (Gradenigo syndrome). Somewhat less common are conditions discussed earlier such as the syndrome of the parapharyngeal space involving cranial nerves IX, X, and XII; the superior orbital fissure syndrome (III, IV, V, and VI); the petrosphenoidal syndrome of Jacod (II, III, IV, V, and VI); the Collet-Sicard syndrome (IX–XII); and unilateral involvement of all cranial nerves, the so-called Garcin syndrome. Most patients have either squamous cell carcinoma or lymphoepithelioma. The 5-year survival rate is approximately 25%. Encroachment of the tumor on the nasopharynx may be manifest as trismus. One of the most important symptoms is increased pain during the night. If the pain awakens the patient, it is almost certain that a nasopharyngeal tumor is present (2).

Dental pain. Hyperemia of the pulp and associated early inflammation are extremely difficult to localize. With progression, however, the clinical signs become more obvious. Extension of the inflammatory process to the periodontal ligament makes the diagnosis easier. An early sign of pulpitis is increased response to cold stimulation. With increased degeneration of the pulp, the response to cold appears to decrease and eventually disappears. This is followed by increased pain with application of heat that may be extremely severe. Patients will frequently put cold water in their mouths to assuage the pain. Subsequently, pulpal degeneration eliminates this symptom. The patient commonly will no longer complain about thermal stimuli producing a toothache. In the absence of clinical or radiologic evidence of dental caries, there is always the possibility of a hairline fracture of a tooth. This is usually not evident on the radiograph or on casual visual examination. At times, the use of a disclosing solution may reveal the crack. There may be painful response to percussion. Ordinarily, percussion is of little diagnostic aid in the early course of pulpitis, but as the inflammatory process extends through the apex of the tooth, painful response to percussion is nearly always noted. Referred dental pain often taxes the clinician's skills. Such pain rarely crosses the midline except in such cases in which the affected tooth is in the midline. Pain from either the maxillary or mandibular teeth may be referred to the ear region, whereas referred pain from infected teeth is nearly always limited to the quadrant of the jaw in which the tooth is located.

Symptomatic elongated styloid process (Eagle syndrome). The styloid process may exceed its mean length of 25 mm or the stylohyoid ligament may be mineralized in 4%–28% of the general population. Involvement is nearly always bilateral. Rarely does an elongated styloid process produce pain, whereas some of those of normal length may be symptomatic. Although it appears that a true clinical entity exists, there is no satisfactory pathophysiologic explanation. Eagle (4–6) focused attention on the elongated styloid process as a source of pain. There are many comprehensive reviews of the literature (1–3,7–10,12,13,15).

The syndrome presents clinically with pain in the throat that is frequently referred to the ear. Usually there is a sensation of a foreign body in the tonsillar area producing dysphagia. It is believed to be because of physical irritation of nerves or vessels passing near the elongated styloid

tip (7); in the absence of an elongated process, it has been ascribed to insertion tendinosis at the junction of the lesser horn and stylohyoid ligament.

The diagnosis is established by palpation of the styloid process through the tonsillar fossa, which in the case of a symptomatic styloid process produces pain. Symptoms similar to those of the classic elongated styloid process syndrome may also be observed in fractures of the styloid process (3,14).

Glossodynia (glossopyrosis, burning tongue, oral-lingual paresthesia). Alteration in sensation of the oral mucous membrane in the absence of observable alterations is of considerable problem to the clinician because it is so frequent and because the etiology is found so rarely. Although the lateral anterior border of the tongue is most frequently the site of the paresthetic alteration, other portions of the oral cavity may be involved, so technically the terms stomatopyrosis, stomatodynia, or burning mouth may be used.

As the tissues involved almost invariably look normal, there is only the statement of the patient to describe the sensation experienced. This may be reported as burning, itching, or pain of the mucous membranes. Our experience is consonant with that of other clinicians with regard to its marked predilection for middle-aged or older women. Although there have been an inordinate number of local and systemic disorders suggested (various deficiency states such as pernicious anemia and sundry vitamin deficiencies), it seems apparent that these are rarely etiologic. Fear of oral cancer or other psychological factors appears to play a major role. The patient commonly complains that spicy foods are causative, but they seem rather to make the condition more apparent to the patient, and are not etiologic. Several have experienced glossodynia following antibiotic therapy, the prolonged use of antihistaminics, and/or diuretics, but the precise relationship is not evident (1–8).

Oromandibular dystonia with blepharospasm (Meige syndrome, Brueghel syndrome)

Blepharospasm and oromandibular dystonia syndrome appears to be a disorder of basal ganglia. It presents in adult life, is usually nonprogressive, and is not genetic, although it has been reported once in three sisters (3). It has been referred to both as Meige syndrome and Brueghel syndrome, given that it has been alleged that Peter Brueghel the Elder illustrated the syndrome in the sixteenth century in one of his paintings. It most commonly occurs in the middle aged or elderly. There is a 2:1 female predilection (2). Approximately 150 cases have been reported (1–12).

It is characterized by spontaneous, repetitive, nonrhythmic symmetric dystonic spasms, first involving the orbicularis oculi muscles (blepharospasm) that begin unilaterally but soon become bilateral and progress to the muscles of the lower face, jaw, and tongue, making speech and swallowing difficult (Figs. 17–19A,B). The blepharospasm is often preceded by or associated with photophobia or tearing. The dyskinesia may fluctuate considerably from day to day, being aggravated by emotional stress and fatigue and disappearing with sleep. With time, the lower facial musculature becomes involved, being manifested as yawning, jaw opening, and abnormal tongue movements. It resembles the orofacial dyskinesia that is phenothiazine induced. Rarely do the muscles other than those of the head and neck become dystonic. It has occurred in association with parkinsonism (3,6).

In the adult form without blepharospasm, mutations have been mapped to chromosome 14q22 in the *GCH1* gene (9a).

Syndromes involving the VIIth nerve

We deal here with only the Melkersson-Rosenthal syndrome, asymmetric crying facies (cardiofacial syndrome), and autosomal dominant geniospasm (chin quivering).

Melkersson-Rosenthal syndrome. The syndrome consists of unilateral or bilateral facial paralysis, chronic swelling of the face (especially the lips) and lingua plicata (scrotal tongue). Familial occurrence has been described, but most cases have been sporadic (6,18). Smeets et al (9) described a translocation and suggested that the gene is located at 9p11. We are skeptical regarding its significance. A decreased CD4/CD8 ratio has also been documented in one patient (3). The syndrome is remarkably variable in its expression (5). Mair et al (7), studying 23 patients, found the triad in only 9, two signs in 13 patients, and a single component in the remaining patient. The reader is referred to a review of over 250 cases (17).

The swelling, noted in 75%, begins suddenly, in most cases prior to facial paralysis but sometimes after or simultaneously with it (2,4,8,15,16). It may begin during childhood but average age of onset is approximately 35 years (1). The upper lip is most affected (Figs. 17–20) and may be involved (Fig. 17–21). The swollen lip (40%) may assume large proportions—at times being three to four times thicker than normal. The edema recurs in most patients, resulting in permanent enlargement of the lips. The eyelids, nose, cheek, and chin may be affected in 20%. Lip swelling as a single phenomenon is known as Miescher cheilitis granulomatosa. It may well be related to Crohn's disease (12).

The facial palsy begins suddenly in childhood or adolescence. It is present in approximately 25%. It is peripheral and clinically indistinguishable from Bell's palsy. It may be partial, complete, or occasionally bilateral. Relapses often occur, but most patients ultimately recover. The paralysis may precede attacks of swelling by years. The paralyzed side does not always correspond to that of the swelling. Rarely, defects in taste over the anterior two-thirds of the tongue are noted (10,11,13).

Simultaneously with the swelling of the skin, the oral mucosa is often affected in a similar way. The swollen buccal mucosa is cushion-like, divided by furrows of varying depth. The buccal, palatal, and sublingual mucosa may be involved (Fig. 17–22A,B). Approximately 40% manifest lingua plicata, a condition found in 10% of the general population (Fig. 17–23). The gingivae are involved in 15% (14,17).

Histopathologic changes include lymphedematous alterations and/or noncaseating sarcoid-like granulomatous picture similar to those of Crohn's disease and sarcoidosis (1,4a) (Figs. 17–24).

The *Hughes syndrome*, sarcoidosis, Crohn's disease, allergic gingivostomatitis, and hereditary angioneurotic edema must be excluded.

Asymmetric crying facies (cardiofacial syndrome). In 1967, Cayler (3) was the first to point out the association of asymmetric crying facies with other congenital anomalies, especially those of the cardiovascular, genitourinary, and respiratory systems. Employing the term "cardiofacial syndrome," Cayler (4) and others (1,16) suggested that

between 5% and 10% of infants with asymmetric crying facies had congenital heart disease.

The frequency of the disorder in various series has ranged from 1 in 120 to 1 in 160 newborns (1,16,18,22). Some authors have found a left-sided predilection, whereas others have found none. Several authors reported autosomal dominant inheritance with variable expressivity (4,9,11,13,14,16). Monozygotic twins with concordance for Cayler syndrome have been reported (20). Both had tetralogy of Fallot and T-cell anomalies. However, discordance was found in monozygotic twins by Goodship et al (8). The spectrum of anomalies remarkably overlaps that seen in the *oculoauriculovertebral spectrum* and may in some instances be the minimal expression of it (6,22). There is also overlap with *velocardiofacial syndrome* and, in fact, the gene has been mapped to 22q11 (2,7,8).

Most authors attribute the defect to unilateral agenesis or hypoplasia of the anguli oris depressor muscle (15). However, Monreal (14) suggested that the side of the lip that pulls lowest is the abnormal one. Because the muscles involved act only to depress the lower lip margin, the defect does not interfere with sucking or smiling and does not foster drooling. The lips are symmetric at rest, the asymmetric facies becoming apparent only during crying. In most cases, lower facial weakness persists, but occasionally it may diminish to some degree (Fig. 17–25A,B). Lin et al (12) reported that 70% had associated findings. Pape and Pickering (17) noted that associated defects tended to occur on the same side as the partial lower facial palsy, but exceptions are many. The cardiovascular anomalies found in 45% most often include VSD, PDA, and tetralogy of Fallot. Also to be found may be right aortic arch, double aortic arch, pulmonic stenosis, coarctation of aorta, ASD, atrioventricularis, communis, tricuspid atresia, single ventricle, hypoplastic right ventricle, hypoplastic pulmonary arteries, and bicuspid aortic valve (11,18,19,23).

Skeletal anomalies, seen in 20%, may include hemivertebra, fused vertebrae, sternal and rib anomalies, and hypoplastic or absent radius and/or thumb (17).

Genitourinary anomalies, noted in 25%, may include absent or hypoplastic kidney, ectopic kidney, polycystic kidneys, bifid scrotum, hypogonadism, cryptorchidism, and hypospadias (17). Neuroblastoma has also been reported on one occasion (10).

Gastrointestinal tract anomalies are relatively rare (5%). They include tracheoesophageal atresia or fistula, laryngomalacia, bronchial stenosis, absent bronchus, absent lung lobe, and a variety of other anomalies such as anal stenosis, imperforate anus, and absent thymus have also been described. Failure to thrive is seen in 15% (12).

In one study, approximately 10% had either cleft lip/palate or isolated cleft palate (17). There are few reports of microcephaly and mental retardation (4,21). These and other central nervous system anomalies have been reported in 10% (12).

One must exclude Crisponi syndrome (5). This autosomal recessive syndrome, seen in Sardinia, is characterized by marked muscular contraction of facial muscles on touch or while crying, trismus, and salivation. Neck muscle hypertonia is evident. The face appears large with chubby cheeks, broad nose, anteverted nares and long philtrum, marked feeding problems, irregular hyperthermia, and camptodactyly. Early death occurs during an episode of marked fever.

Autosomal dominant geniospasm (chin quivering). First reported by Massaro (10) in 1894, hereditary geniospasm or chin quivering is characterized by paroxysmal, rhythmic up-and-down movement of the chin and lower lip. This arises from involuntary contractures of the mentalis muscle. Numerous additional families have been described (1–9,11–13).

These movements may vary in duration from seconds to hours. They may be triggered by anxiety. The geniospasms usually become evident in early infancy and tend to abate with age. The tongue may be inadvertently bitten (7,8).

Inheritance is autosomal dominant with approximately 80% penetrance (1,2,5,7,12). There is genetic heterogeneity. One of the genes has been mapped to 9q13–q21 (7).

Essential tremor can involve the tongue or jaw (7).

Gustatory lacrimation (paroxysmal lacrimation, crocodile tears syndrome, Bogorad syndrome, and gustolacrimal reflex)

The syndrome of lacrimation that accompanies eating was first described by Oppenheim (see 5) in 1913, and in far more detail, by Bogorad (3), in 1928, who called it the "syndrome of crocodile tears,"

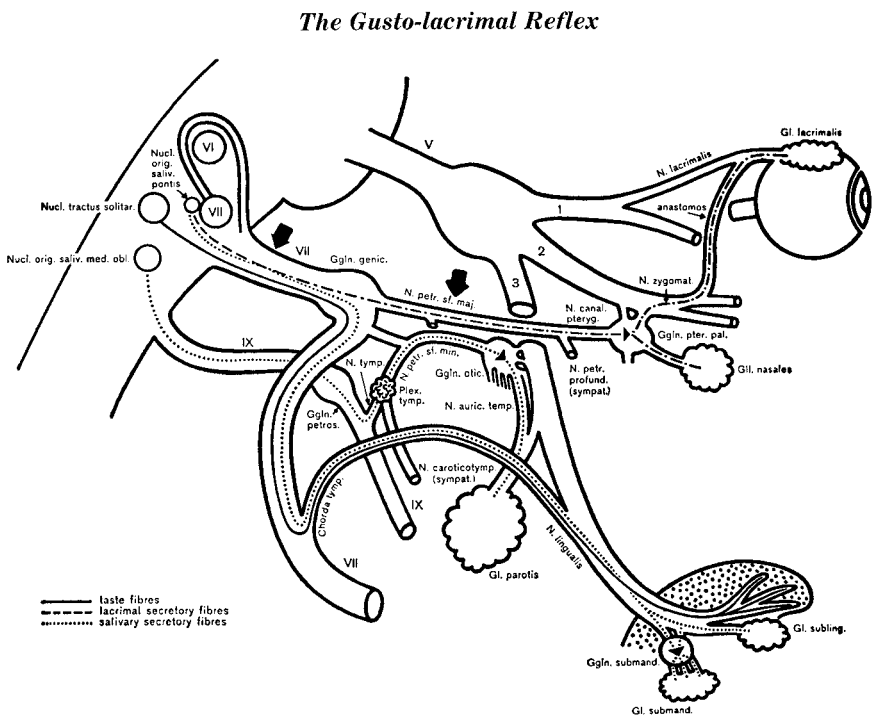

Fig. 17–26. *Gustatory lacrimation.* Diagram shows two possible mechanisms for production of the syndrome. Most often, lesion is proximal to geniculate ganglion and in regeneration, fibers destined for the submandibular and sublingual salivary glands may become interchanged with those for the lacrimal gland. The lesion may also be distal to the geniculate ganglion and involve interchange of fibers of the greater and lesser superficial petrosal nerves. [From A Axelsson and JE Laage-Hellman, Acta Otolaryngol (Stockholm) 54: 239, 1962.]

referring to the tale that the crocodile weeps hypocritical tears while devouring its victims (5). Since the original report, over 125 cases have been recorded. Ford (6,7) wrote the first report in English and linked the syndrome with gustatory sweating and flushing (auriculotemporal or Frey syndrome), both conditions caused by misdirected regrowth of nerve fibers. Ford used the term *paroxysmal lacrimation* to describe the disorder. To parallel the use of the term gustatory sweating and flushing, the present authors suggest the use of gustatory lacrimation. Axelsson and Laage-Hellman (2) have employed gustolacrimal reflex.

In so-called acquired cases, the syndrome has followed traumatic, neoplastic, or inflammatory conditions of the facial or greater superficial petrosal nerves (1,8,9,12,14,21). By the time motor function is becoming restored, the patient usually notices that when eating, tears flow from the eye on the affected side. The syndrome is not associated with the common form of Bell's palsy, in which the lesion is distal to the geniculate ganglion, but occurs only when the lesion is proximal to the ganglion (6). Five percent to 10% of cases of facial palsy are associated with crocodile tear syndrome (1,16,23,25). Rarely the syndrome is bilateral and/or congenital (10,11,13,22). The syndrome can be monitored by a thread test.

Congenital cases have usually been associated with abducens palsy or Duane syndrome (2,15,19,20). Ramsay and Taylor (18) postulated that the association of two conditions would be a lesion causing nuclear degeneration or dysgenesis in the vicinity of the abducens nucleus. The paradoxical aspects result from substitute innervation of the lateral rectus by fibers from the oculomotor nerve and lacrimal gland by fibers subserving salivation.

The facial nerve has several components: a motor component supplying the muscles of facial expression; a sensory component, which carries gustatory impulses from the anterior two-thirds of the tongue and proprioceptive impulses from the face; and an autonomic-parasympathetic component. These latter fibers arise in the superior salivary nucleus and provide secretory and vasodilatory function to the submandibular and sublingual glands via the nerve of Wrisberg, the chorda tympani, and the lingual nerve, as well as to the lacrimal gland via the nerve of Wrisberg, the greater superficial petrosal nerve, the vidian nerve, the sphenopalatine ganglion, and the zygomaticotemporal nerve. Proximal to the geniculate ganglion, all these components are in contiguity.

If a lesion occurs proximal to the geniculate ganglion, then during regeneration, fibers destined for the submandibular and sublingual glands may become partially interchanged with those destined for the lacrimal gland. Thus, when the gustatory stimulus is evoked, lacrimation is produced (Fig. 17–26).

In the exceptional cases cited by Boyer and Gardner (4), the syndrome appeared after surgery on the greater superficial petrosal nerve for relief of headache. During the course of surgery, the lesser superficial petrosal nerve was injured, as it runs only 2 mm lateral to the greater superficial petrosal nerve in the middle cranial fossa. In regeneration, the fibers of the two nerves became interchanged, producing the syndrome. This was proved by resection of the glossopharyngeal nerve, which abolished the disorder. The syndrome has also been seen in association with neurosyphilis, acoustic neuroma, vascular disease, and facial palsy in association with herpes zoster of the ear.

Facial contracture or diffuse facial muscle response is often associated with tearing. If, for example, the teeth are shown, the forehead may wrinkle and the eyelid close. Conversely, wrinkling the forehead or closing the eye may cause the corner of the mouth to be retracted and the nasolabial fold to deepen. This indicates that impulses formerly directed toward isolated muscle groups are diffusely distributed over the face, thus bolstering the concept of misdirected fiber regeneration. This has been called *the Marin Amat phenomenon.*

This syndrome should not be confused with lacrimation seen in association with facial paralysis, where the tearing is because of ectropion, which permits tears to flow out of the conjunctival sac. The latter is not associated with hypersecretion of the lacrimal gland and is unaffected by eating. The condition has been found in association with the *branchio-oto-renal syndrome* (17).

Crocodile tear syndrome has been found in association with Dandy-Walker syndrome in *Wildervanck syndrome* (8a).

Gustatory sweating and flushing-auriculotemporal and chorda tympani syndromes (Frey syndrome)

The earliest references to the syndrome of gustatory sweating and flushing appear to be those of Duphenix (8), in 1757, and Dupuy (9), in 1816. In 1897, Weber (43) recognized that the syndrome was related to the auriculotemporal nerve. However, the syndrome was brought to the attention of the medical public in 1923 by Frey (11). The syndrome is often referred to under her name. Several hundred cases have been published subsequently. Laage-Hellman (21–24) showed that the syndrome, far from being rare, is a virtually constant complication of conservative parotidectomy. Other investigators have found a 60% complication rate (18). Hogeman (17) presented an excellent historical survey.

It should be pointed out that the term auriculotemporal syndrome is misleading, as the skin innervated by the greater auricular nerve, the lesser occipital nerve, the long buccal nerve, or any cutaneous branch of the cervical plexus may be involved.

The syndrome is clinically manifested by sweating, flushing, a sense of warmth, and, sometimes, mild pain in the preauricular and temporal areas during eating of foods that produce a strong salivary stimulus. Rarely it may present as trigeminal neuralgia (4). The syndrome not only accompanies conservative parotidectomy (5,21,25) but may follow suppurative parotitis (9,11,16,32), herpes (7), direct trauma to the parotid region or mandibular condylar head (14,27,31,36,39) or diabetes (29,37). However, the preauricular approach to the joint is not associated with the syndrome (40). Some patients exhibit only sweating or flushing (17,21). The syndrome occasionally occurs in infants secondary to forceps trauma (2,3,6,33). A bilateral example has been described (19).

The etiology in most cases is damage to the auriculotemporal nerve. This nerve, in addition to supplying sensory fibers to the preauricular and temporal areas, carries parasympathetic fibers to the parotid gland and sympathetic vasomotor and sudomotor fibers to the skin of the same area. Injury to the auriculotemporal nerve denervates the sweat glands and vessels of the skin over its distribution, in addition to producing sensory disturbance (15).

Both the parasympathetic and sympathetic nerves of the face are cholinergic, hence compatible, and in the process of regeneration, parasympathetic fibers become misdirected and grow along sympathetic pathways (12,21–24). Thus, a gustatory stimulus produces sweating and flushing.

That the syndrome is caused by misdirection of parasympathetic fibers is shown by the ability of procaine, injected over the auriculotemporal nerve, to abolish the syndrome. Severing of the auriculotemporal, glossopharyngeal (12), or Jacobson (16) nerve, local atropine injection, blockage of the otic ganglion (13,17), and local application of 3% scopolamine hydrobromide cream (22), aluminum trichloride hexahydrate (35), or 1% glycopyrrolate cream (28) have all been shown to inhibit or abolish the reaction. Conversely, acetylcholine injection increases the phenomenon (13).

The time of the first appearance of the fully developed syndrome varies considerably. Most observers have noted its occurrence within 2 months to 2 years (average, 9 months) postoperatively (13,21–24). There are cases in which the syndrome has appeared in a few days after surgery. Misdirected regrowth of fibers cannot explain the few cases in which the syndrome has appeared a few days postoperatively (38); the alternate possibility of transaxonal excitation exists.

As a rule, once the syndrome appears, the area of skin involved increases (23) and remains increased for life (17). However, approximately 5% of patients (21) experience regression and disappearance of the symptoms. The area affected varies both in degree and in extent, in some persons being seen at the corner of the mouth or extending down to the angle of the mandible, an area supplied by the greater auricular nerve (21) (Fig. 17–27A). RJ Gorlin saw a patient whose sole area of gustatory sweating was a half-dollar-sized area near the corner of his mouth where he had driven a scissor blade many years prior to development of the syndrome. Presumably parasympathetic fibers came from those supplying the minor salivary glands of the cheek (Fig. 17–27B). A similar example was reported by Storrs (39). RJ Gorlin has seen two children with gustatory sweating involving the maxillary division of the trigeminal. In neither case was there history of prior trauma.

Related to the auriculotemporal syndrome is the *chorda tympani syndrome* (1,10,14a,41,42,44) in which the sweating and flushing are limited to the skin of the chin and submental region. This syndrome may accompany surgery or injury to the submandibular gland (21). It has been shown to be abolished by blockage of the lingual nerve proximal to the chorda tympani.

Gustatory otorrhea has also been reported (34).

The auriculotemporal syndrome should not be confused with excessive sweating sometimes seen in persons who have just eaten spicy or sour foods (26). In this case, the sweating appears limited to the forehead, tip of nose, and upper lip. Neither should it be confused with signs or symptoms of hysteria or postsympathectomy sweating.

To demonstrate sweating, the simplest method is application of the starch-iodine test (15 ml of 1% iodine, 5 ml castor oil, 80 ml of 95% alcohol) (21). A more quantitative estimate can be made by using plastic tape (13,20).

A B

Fig. 17–27. *Gustatory sweating and flushing-auriculotemporal syndrome.* (A) Following meals there is profuse sweating immediately in front of ear. This is demonstrated by starch-iodine test. (B) Patient drove scissors into cheek as a child. Severe sweating and flushing are noted at mealtime.

Gustatory rhinorrhea

Rhinorrhea following parotid surgery, maxillectomy, or septoplasty has been reported by several authors (1–5). Rhinorrhea, that is secretion of thin mucus from the nose during ingestion or other gustatory stimulation, has occasionally accompanied the *auriculotemporal (Frey) syndrome*. Vollrath (5) reported unilateral tearing and ipsilateral rhinorrhea accompanied by sweating 2 years following midface fracture. The etiology appears to be regeneration of damaged nerve fibers of the lesser superficial petrosal nerve. These fibers contain parasympathetic

components that lead to the parotid gland. The regeneration occurs through abnormal connections via the greater superficial petrosal nerve to the vidian nerve, the sphenopalatine ganglion, and the long sphenopalatine nerve to reach the nasal mucous glands. Fibers directed to the palatal mucous glands when misdirected would innervate nasal glands and mucosa. During maxillectomy or septoplasty, trauma to the sphenopalatal nerve is common.

Angelman syndrome

The syndrome was first described by Angelman (1), a British pediatrician, in 1965. Early authors used the name "happy puppet syndrome," a term we consider pejorative. Over 300 examples have been clinically described. The frequency has been estimated as 1 per 10,000 to 1 per 20,000 live births (14,40,45). Several excellent reviews are available (11,12,14,15).

Familial cases are noted in approximately 7% (13,54). Affected females are capable of reproduction (41a). The syndrome has been reported in sibs (3,13,25,29,32,52,60,62). These cases represent a mutation in the *UBE3A* gene or a small deletion in the center that controls imprinting on 15q (see below) (42,43). In these cases, there is neither deletion nor uniparental disomy (see below) (8,33). There is no sex predilection. Deletions of chromosome 15q11–q13 have been found in 65% (8,26,49,63). The same deletion is seen in Prader-Willi syndrome. In Angelman syndrome, the deleted chromosome is maternal in origin (16,22,23,33,37) while in Prader-Willi syndrome. the deletion is paternal (24,44). This results from genomic imprinting in which genes are expressed differently depending on whether they were inherited from the mother or the father. Angelman syndrome and *Prader-Willi syndrome* are located very close together and are oppositely imprinted. Uniparental paternal disomy, rarely (3%–5%) causes Angelman syndrome (9,37,38). Those with either deletion or uniparental disomy have a recurrence risk of less than 1% (58). Bottani et al (6), Gillessen-Kaesbach et al (30), and Fridman et al (27a) suggested that patients resulting from uniparental disomy are more mildly affected. Others have not substantiated this finding (54), except for pigment dilution, which is more marked in deleted cases. Maternal germline mosaicism has been suggested (38a). DNA methylation plays a role in the imprinting process (18,48). Approximately 25% of Angelman syndrome patients exhibit neither a deletion nor uniparental disomy. A dominant mutation or inversion in the imprinting center (5,17,29) accounts for 2-3%, and about 5% are due to a gene mutation (*UB3A/E6-AP*). No cause for the remaining 20% has been found (9,36,46,47,60). The gene codes for a ubiquitin-protein ligase involved in degradation of protein (36,60). There is up to a 50% recurrence risk in this group of cases if the mutation is present in the mother (47,58). The risks for recurrence is especially well addressed by Stalker and Williams (58).

Smeets et al (56) described a family in which a translocation between chromosomes 6 and 15 resulted in deletion of the paternally derived chromosome 15 in a patient with Prader-Willi syndrome and inheritance of two different copies of chromosome 15 from the father of a cousin with Angelman syndrome. Chan et al (13), Freeman et al (27), Webb et al (61), and Greger et al (31) discuss other chromosomal 15 abnormalities that can produce Angelman syndrome. At most these cases constitute a few percent. Recurrence risk is case-specific (58). An odd phenotype characterized by obesity and muscular hypotonia has been noted to be related to an imprinting defect (30a).

Facies. Although patients resemble one another markedly in later childhood, early diagnosis is often difficult for the facies is not evident in infancy (23,28). Head circumference, normal at birth, becomes microbrachycephalic with age due to occipital flattening. The scalp hair tends to be fair (70%) due to deletion of a pigment (P) gene (35). Prognathism (80%), midfacial retrusion (90%), frequent protrusion of the tongue (70%) with drooling and chewing (90%), thin upper lip 80%), macrostomia (75%), and pointed chin (95%) are characteristic (Fig. 17–28). The teeth are widely spaced (75%), probably due to tongue pressure. Cleft palate (44) and cleft lip (53) have been documented rarely.

Skeletal changes. Small stature has been noted in approximately 70%. Moderate progressive scoliosis and joint contractures may develop with time in approximately 35%. Only a few older patients have been described (51).

Eyes. The eyes appear deeply set. There is decreased pigmentation of the choroid and iris stroma in 70% and optic pallor or atrophy in over 40% (19). About 30% have Brushfield spots. Blue irises are noted in approximately 90% (14,45). Strabismus is documented in 40%. Keratoconus may develop in older patients (55).

Central nervous system. Patients have severe mental retardation with intelligence quotients below 40. There is no speech or, at most, a few words, but comprehension, especially of signs, is not as severely affected (34). Patients exhibit unprovoked and prolonged bursts of laughter. Motor development is always retarded with sitting at 12–20 months and walking at 3–6 years. Toilet training may not be achieved until 4 years (11). In approximately 50%, a cheerful smiling affect is noted after the first year of life. Generalized hypotonia is evident at birth in over 60% but changes in the extremities with time. Hypotonia in the trunk (90%) and hypertonia of the extremities (85%) produce a stiff jerky stiff-legged, broad-based gait. The arms are held flexed. All exhibit ataxia. Jerky movements become apparent during the first few months of life. Approximately 10% are never able to walk unaided. Deep tendon reflexes are brisk in 85%. One is impressed by their constant hyperactivity, hand flapping, ataxic uncoordinated movements, and tremulousness. These behaviors decrease with age. Probably 80% exhibit epilepsy beginning between 18 and 24 months of age. The seizures range from hypsarrhythmia, to myoclonic, to generalized grand mal types. The seizures may be difficult to control, but generally decrease in severity and number by 10 years of age when they may cease entirely (57). Electroencephalogram (EEG) changes have characteristic large amplitude slow spike wave pattern (2–3 cycles/sec) (7). Abnormal sleep patterns are present in 85%. Sleep appears to occur in short bursts. In most cases, this improves in late childhood but in infancy is truly vexing to parents. Melatonin is helpful in many cases (Wagstaff, unpublished, 1998). Those with UBE 3A mutations tend to be overweight later in life (47). Affected females are capable of reproduction (41a).

Slow feeding due to poor suck has been noted in infancy and frequent regurgitation or reflux is noted in 75% (57). Many parents report fascination with water and music.

Radiographically, there is flattening in the occipital region and tilting of the cranial base so that the sella turcica is obliquely positioned. Computed tomography scans show diffuse brain atrophy in 30% (23) and MRI demonstrates abnormally long Sylvian fissures with no branching point (41).

Laboratory aids. High resolution chromosome analysis in association with FISH studies have been used to establish deletion (4,59). Uniparental disomy is diagnosed by means of chromosome specific microsatellite markers (50,60). Methylation analysis, with a methylation-sensitive SNRPN probe will detect all cases of deletion, uniparental disomy, or imprinting mutation (39). All these studies have been validated for use on chorionic villus sampling or amniotic cells for prenatal detection of imprinting defects (9,10,20,21,59,64).

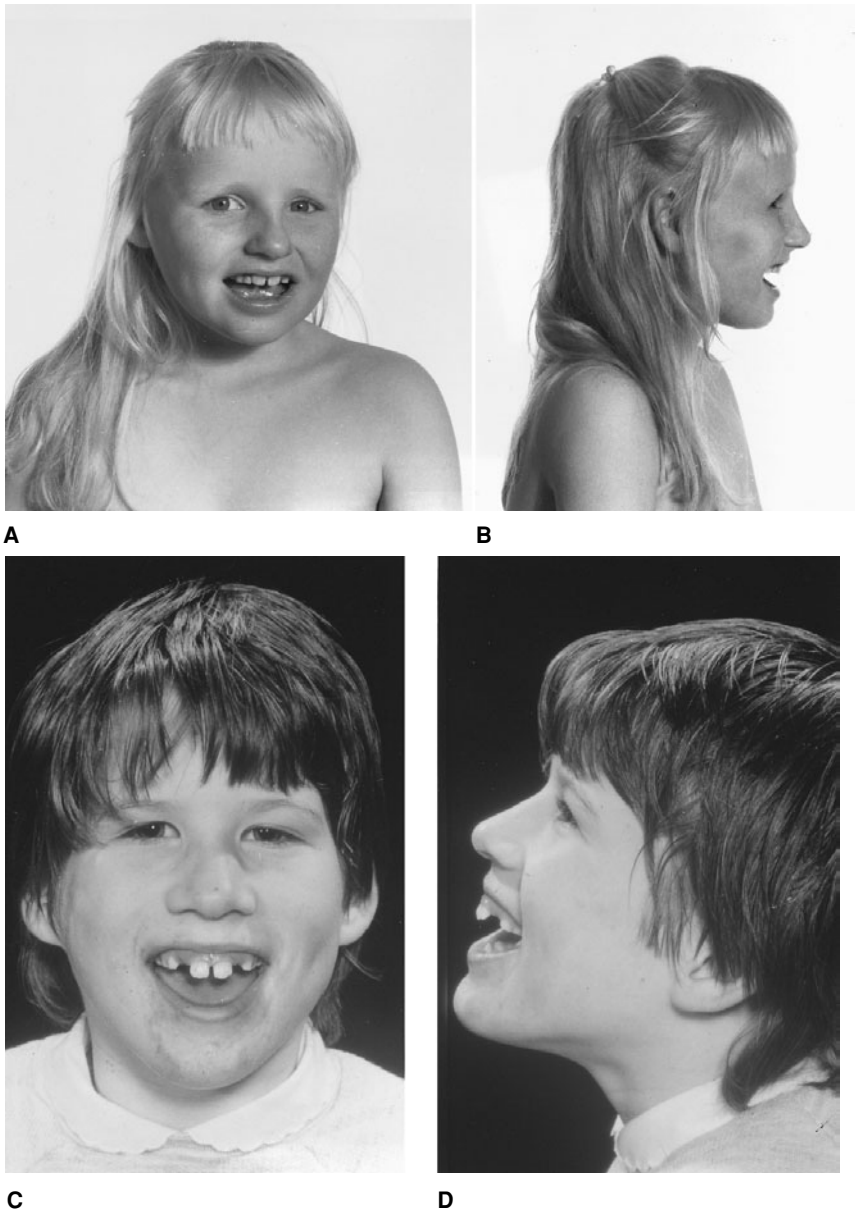

Fig. 17–28. *Angelman syndrome.* (A–D) Note protruding tongue, mandibular prognathism. Patients exhibit pointless activity, ataxic uncoordinated puppetlike movements, and unprovoked prolonged paroxysms of laughter. (A,B courtesy of J Tolmie, Glasgow, Scotland. C,D from M Baraitser et al, Clin Genet 31:323, 1987.)

Diagnosis. Rett syndrome must be excluded as must *ATR-X syndrome* and methylenetetrahydrofolate deficiency (2).

Syndromes of lower cranial nerves and medulla

In both nuclear and infranuclear lesions, simultaneous involvement of IX, X, and XI is common. The association of these three cranial nerves in various combinations with XII, the cervical sympathetic chain, and rarely the spinothalamic tracts has led to a plethora of eponymic syndromes, only a few of which are discussed here (Fig. 17–29). They may be roughly divided into central medullary lesions (approximately 10%) and peripheral lesions (approximately 90%). The central lesions may be vascular in origin (Avellis syndrome, Cestan-Chenais syndrome, Wallenberg syndrome, and Dejerine syndrome), or they may be due to other causes, such as syringobulbia, multiple sclerosis, poliomyelitis, neoplasms, or trauma (1,3,15,19,27).

Wallenberg syndrome was originally considered different from the other medullary syndromes, that is, those of Babinski-Nageotte and Cestan-Chenais, by the absence of motor signs in trunk and limbs. However, a unilateral infarction can extend contralaterally to catch the already crossed corticospinal fibers, and there may be little justification for designating these as separate disorders. In spite of the long list of eponyms, only two syndromes are of practical importance: (1) medial medullary syndrome—rare, and (2) lateral medullary syndrome—common. The other syndromes do not help with localization nor do they aid in identifying the vessels involved. Because they still appear in the literature, some of these will be mentioned. The lateral syndrome is that of Wallenberg, the medial is Dejerine syndrome, and where both medial and lateral are involved, Cestan-Chenais syndrome is the appropriate designation. Syndromes involving the medulla are listed in Table 17–6.

Avellis syndrome. This syndrome is usually because of occlusion of the vertebral artery. It is characterized by combined involvement of the nucleus ambiguus and spinothalamic tracts with ipsilateral paralysis and anesthesia of the soft palate, pharynx, and larynx, contralateral loss of pain and temperature sensation of the trunk and extremities, frequent

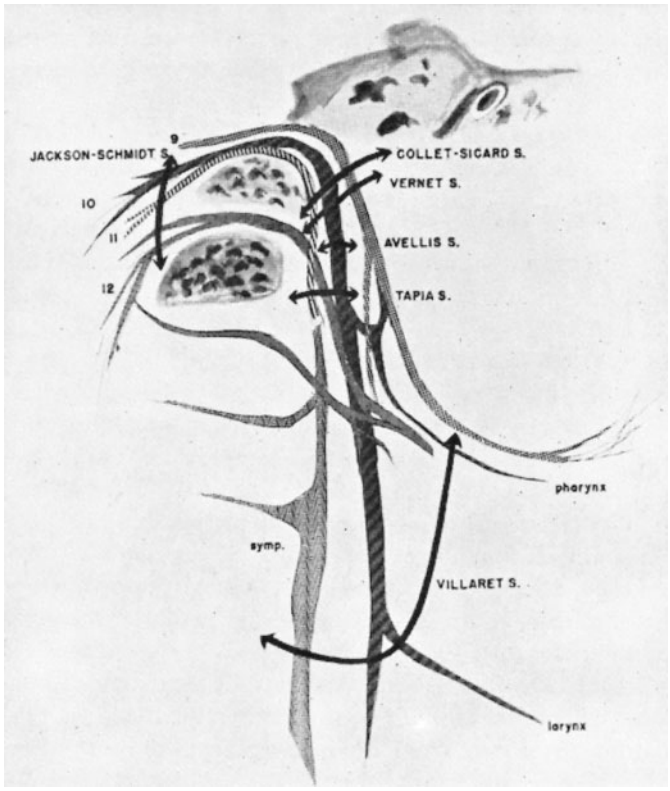

Fig. 17–29. *Syndromes of lower cranial nerves and medulla.* Diagram showing involvement of last four cranial nerves in several syndromes. (From SG Harner, Arch Otolaryngol 92:632, 1970.)

contralateral loss of proprioception and tactile senses, and, rarely, ipsilateral Horner syndrome (4,5,7,10,12).

Schmidt syndrome. This is now thought not to be a simple syndrome. The original report (one paragraph) did not localize the pathology with any clarity (29).

Jackson-Mackenzie syndrome. The original patient had multiple infarctions—so that the localizing value of the syndrome is limited.

Table 17–6. Syndromes involving the nuclei in the medulla

Syndrome	Other name	Comment
Avellis		Corticospinal tract, and X nucleus
Schmidt	Vago-accessory syndrome	Location uncertain; more than one lesion probable
Jackson–Mackenzie	Vago-accessory-hypoglossal syndrome	Corticospinal tract, and X, XII nuclei
Wallenberg	Lateral medullary syndrome	Spinal V, IX, X, XI lateral spinothalamic, spinocerebellar, pupillodilatory fibers
Cestan–Chenais	Lateral medulla syndrome plus medial medulla syndrome	
Babinski–Nageotte		Location uncertain; more than one lesion present
Dejerine	Anterior bulbar syndrome or medial medullary syndrome	Pyramids, medial lemniscus, hypoglossal fibers

Wallenberg syndrome. The main clinical features are ipsilateral paralysis and anesthesia of the soft palate, pharynx, and larynx, ipsilateral loss of the corneal reflex and anesthesia of the face for pain and temperature, ipsilateral Horner syndrome, ipsilateral ataxia, contralateral loss of temperature and pain sensation of the trunk and extremities, and, rarely, involvement of VI–VIII (18,38).

Dejerine syndrome. Hemorrhage or thrombosis of the anterior spinal artery (which supplies the pyramids, medial lemniscus, and emerging hypoglossal fibers) produces ipsilateral paralysis of the tongue, contralateral pyramidal paralysis of the arm and leg, and, occasionally, contralateral loss of proprioceptive and tactile sensation.

Cestan-Chenais syndrome. This syndrome indicates involvement of the lateral and medial medulla. It is caused by thrombosis of the vertebral artery below the point of origin of the posterior inferior cerebellar artery. It differs from the Wallenberg syndrome by the presence of pyramidal tract signs (hemiplegia and contralateral diminution of touch and proprioceptive senses). Pain and temperature sensations are normal (6).

Vernet (jugular foramen) syndrome. The syndrome is characterized by ipsilateral paralysis of IX, X, and XI with resultant paralysis of the soft palate, larynx, pharynx, sternocleidomastoid muscle, and part of the trapezius muscle, anesthesia of the posterior soft palate, and loss of sensation and taste over the posterior third of the tongue (34,35). Approximately one-half of the cases have been attributed to brain tumors. However, more recently, among 17 cases of Vernet syndrome, only two patients had neoplasms (32). In most there was no obvious cause. Full or partial recovery occurred within a month.

Villaret (retroparotid space) syndrome. The syndrome combines ipsilateral paralysis of the last four cranial nerves and Horner syndrome (enophthalmos, ptosis, miosis) (24,26). Occasionally, VII is also involved. The syndrome is because of a lesion in the retroparotid space, which is bounded posteriorly by the cervical vertebrae, medially by the pharynx, anteriorly by the parotid gland, laterally by the sternocleidomastoid muscle, and superiorly by the skull near the jugular foramen.

Collet-Sicard syndrome. The disorder is manifest by unilateral involvement of the last four cranial nerves. It was described in the injured of World War I by Collet and later by Sicard. The syndrome may also occur as a result of tumors, inflammatory lesions, aneurysm of the internal or external carotid (31), or fibromuscular dysplasia of the carotid (16). The lesion is typically extracranial and involves the jugular foramen and the anterior condylar or hypoglossal foramen through which XII passes. Currie (8) expressed doubt whether this syndrome should be preserved. The original patient might have had a lateral medullary syndrome with contralateral weakness and sensory loss because of an earlier infarction higher in the brain stem or in the medial medulla.

Tapia (vagohypoglossal) syndrome. The main features include unilateral paralysis of the muscles of the tongue, and unilateral paralysis of the vocal cord and soft palate (34). The pharynx, sternocleidomastoid, and trapezius muscles are usually spared. There is dysphonia but no dysphagia. The lesion is localized to the crossing of the X–XI nerves below the nodose ganglia (30). A finding of trauma is more common than finding tumors (2).

Garcin (half-base) syndrome. The syndrome is usually because of a malignant tumor invading the base of the skull, but meningiomas, basal meningitis, and trauma have all been implicated. Typical progression may be to complete ophthalmoplegia (13,21,23,24,26,28,37). It may be somewhat more common in Chinese due to high incidence of nasopharyngeal carcinoma. Tumors of the nasopharynx can cause all or nearly all cranial nerves on one side to become involved without signs of motor or sensory disturbances of the extremities and without evidence of

increased intracranial pressure (papilledema or spinal fluid changes). Radiographic alterations are often apparent in the skull base.

Progressive bulbar palsy. In adults, we shall consider briefly Duchenne syndrome, whereas in children, Fasio-Londe syndrome will be described.

Duchenne syndrome (progressive bulbar palsy, glossopharyngolabial paralysis). The condition is principally seen in individuals in their sixth and seventh decades. The syndrome can occur in amyotrophic lateral sclerosis in which it is characterized by a slowly ascending process that involves the motor nuclei of the medulla and often the pons and midbrain (9,22). XII is usually involved first. Early signs are bilateral fasciculations and atrophy of the tongue. X is then affected with resultant dysphagia for both liquids and solids, dysarthria, and thickened nasal speech. Atrophy and fasciculations of the palatal and pharyngeal musculature may be seen. Involvement of the nuclei of V and VII causes paralysis and wasting of the muscles of facial expression and mastication. The nucleus of the accessory nerve is less often affected (14,33).

Fasio-Londe syndrome. Childhood onset of progressive bulbar palsy may be part of infantile and childhood spinal muscular atrophies. Age of onset varies between 2 and 10 years. Unilateral facial weakness, dysphagia, and chewing difficulties are early signs. There is often spread to involve most lower cranial nerves. It is doubtful whether this condition is a pure progressive bulbar palsy distinct from the more frequent group of spinal muscular atrophies.

Horner syndrome. Horner syndrome is characterized by enophthalmos, miosis, partial ptosis, ipsilateral vascular dilatation, and anhidrosis of the face, neck, and arms. The syndrome may also be seen in association with involvement of V and X in Wallenberg syndrome. Alternating Horner syndrome has been described following cervical spinal cord injury (25). The cause is not known but movement of fluid within an intramedullary cystic cavity (posttraumatic) has been postulated (11). This stimulates the sympathetic nerve, causing the signs to alternate. Dural adhesions following a cervical spine injury were postulated by Ottomo and Heimburger (25).

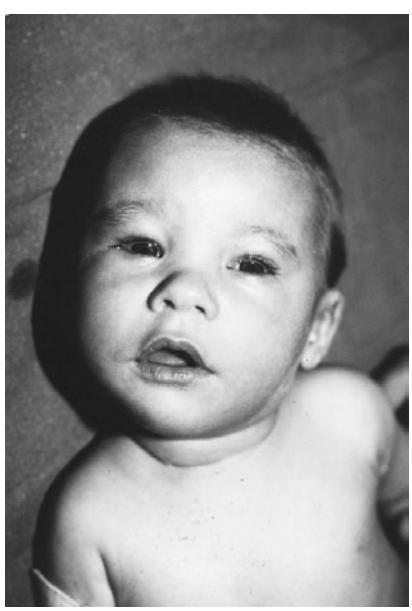
X-linked mental and somatic retardation, genital hypoplasia, and sensorineural hearing loss (Juberg-Marsidi syndrome)

Juberg and Marsidi (2), in 1980, reported a male child and two maternal uncles with mental and somatic retardation, unusual facies, microgenitalism, and sensorineural hearing loss. Mattei et al (3) described an additional large kindred with seven males. Tsukahara et al (7) reported another case.

Inheritance is clearly X-linked. The gene has been mapped to Xq12–q21 (1,5), being allelic to *X-linked alpha-thalassemia/mental retardation syndrome* (6,8). Methylation plays a role (1).

Clinical findings. Birth weight was low and growth did not exceed the 3rd centile. Head circumference was reduced. The two uncles reported by Juberg and Marsidi (2) died at 9 years and 20 months, respectively. One child described by Mattei et al (3) died at 10 months.



A

B

Fig. 17–30. *X-linked mental and somatic retardation, genital hypoplasia, and sensorineural hearing loss* (*Juberg-Marsidi syndrome*). (A) Face of patient showing high forehead, upslanting palpebral fissures, flat nasal bridge. (B) Genital hypoplasia in the same patient. (From JF Mattei et al, Clin Genet 23:70, 1983.)

Craniofacial findings. All had high foreheads, upslanting palpebral fissures, prominent epicanthal folds, and flat nasal bridge (Fig. 17–30A). The pinnae were hyperfolded with a large helix.

Ocular system. Small palpebral fissures were found in most of the affected. Light retinal pigmentation was noted in some of the affected (2).

Central nervous system. Severe global delay was evident in all affected. Hypotonia was evident in infancy. Most patients learned to walk. Some had seizures.

Musculoskeletal system. Camptodactyly of the second or third finger, clinodactyly of the index finger, asymmetrically sized halluces, and retarded bone age were found.

Genitourinary system. All affected had rudimentary scrotum, undescended testes, and micropenises (2,3) (Fig. 17–30B). Some had vesicoureteric reflex and small kidneys.

Auditory findings. Bilateral sensorineural hearing loss dating from infancy ranged from moderate to severe, but was not otherwise characterized because of severe mental retardation. In one child, hearing deficit involved higher tones below 60 dB.

Laboratory findings. Delayed bone ages was a constant finding.

Diagnosis. Renier et al (4) reported three male sibs and two maternal uncles with microcephaly, mental retardation, epilepsy, spastic paraplegia, and sensorineural hearing loss with X-linked inheritance. In Gustavson syndrome, an affected kindred similar to that of Juberg and Marsidi was described (1a) but the genitalia were normal.

Bobble-head doll syndrome

The term "bobble-head doll syndrome" was coined by Benton et al (1) in 1966 to refer to abnormal head movements or progressive tremors due to various lesions (ventricular cyst, arachnoid cyst, aqueductal stenosis, tumors of corpus callosum) that intermittently block the third ventricle and are associated with hydrocephalus. These mostly anterior-posterior but occasionally side-to-side movements disappear or decrease markedly following surgical drainage of the block. The movements are slower in rate (1–3/sec) than those in benign familial tremors and can be decreased or stopped by will. They disappear in sleep and in recumbent position. The movements are occasionally accompanied by trunk or hand tremor.

The tremor may be seen in infancy but nearly always occurs before the sixth year of life (1–6).

We object to the use of the term but await an alternative term.

Unilateral hypoglossal palsy

There have been a number of examples of unilateral hypoglossal (XII) palsy following flu shots or infectious mononucleosis (1–7). It usually appears about 3 weeks after onset of the disease or a few days after the injection and often clears spontaneously. There have been a few reports secondary to aneurysm or tumor. Some examples are idiopathic (Fig. 17–31).

The normal half of the tongue pushes the non-innervated half toward the weak side.

Neck-tongue syndrome

Neck-tongue syndrome is a rare disorder characterized by paroxysmal neck pain in combination with ipsilateral paresthesia of the tongue (1–6). About 30 cases have been described (1).

Rotation of the neck triggers the sensory signs ipsilaterally. Malformations, degenerative processes, and masses result in compression of the C_2 root. The lingual manifestations result from sensory fibers originating in the lingual nerve which joins the dorsal roots of C_2 by way of the hypoglossal nerves.

Chapter 18
Syndromes with Contractures

Fetal akinesia deformation sequence (Pena-Shokeir I syndrome, FADS)

Pena and Shokeir (29) and Punnett et al (32), in 1974, described children with intrauterine growth retardation, multiple congenital joint contractures, facial abnormalities, short gut, and pulmonary hypoplasia (Fig. 18–1). About 80 cases have subsequently been reported. The frequency has been estimated at 1/10,000 births. Shokeir (36) proposed that the syndrome be referred to as Pena-Shokeir syndrome, type I and that the cerebro-oculo-facial syndrome (COFS) be called Pena-Shokeir syndrome, type II. Moessinger (26) and Toriello et al (37) proposed abandonment of the term and replacement with *fetal akinesia sequence*. The disorder has been classified as a form of arthrogryposis. It is heterogeneous, the phenotype reflecting decreased fetal movement from many different causes (10,20,37): neurogenic atrophy (4,25), congenital myopathy (23), maternal myasthenia gravis (3,16,34), fetal edema (11), and oligohydramnios. The most critical survey is that of Hall (12). Porter (31) published a comprehensive review of the lethal arthrogryposes.

The phenotypic features have been found in sibs (9,29,37) and parental consanguinity (9,33,36) has been reported. Inheritance for at least some examples appears to be autosomal recessive (9,30,35), although more than half of the reported cases are sporadic. High levels of antibodies against human muscle acetylcholine receptors have been demonstrated (15,33,38).

In most cases, the infant is either stillborn or dies within the neonatal period. Only a few have survived (18,23). Polyhydramnios, short gut syndrome, small placenta, or short umbilical cord have been noted in 50% (4,18). Hydrops fetalis is a common finding. Most have intrauterine growth retardation that may have resulted from reduced muscle and bone mass secondary to prolonged immobilization and disuse.

Facies. Hypertelorism, high nasal bridge, depressed nasal tip, low-set malformed pinnae, microstomia, and microretrognathia are present in nearly all cases. Epicanthal folds are present in approximately 20%. The neck is short in 60% (Fig. 18–2). Macrocephaly has been noted in a few examples (9,19,28).

Musculoskeletal system. There are moderate contractures at the hips, elbows, wrists, knees, and ankles because of reduced intrauterine movement. The chest is small with an increased antero-posterior diameter. The lungs are severly hypoplastic. Comptodactyly and clubfeet or rockerbottom feet are essentially constant features. Mild webbing of the neck or elbows has been seen in a few cases (5,25,38) (Fig.18–2A).

Radiographic changes include micrognathia, long and narrow tubular bones, multiple joint dislocations, and malposition of fingers, especially angular subluxations at the interphalangeal joints (17) (Fig. 18–3). A few infants have exhibited variable polydactyly (17,32,37). Chen et al (6) emphasized that the gracile bones may predispose to multiple perinatal fractures.

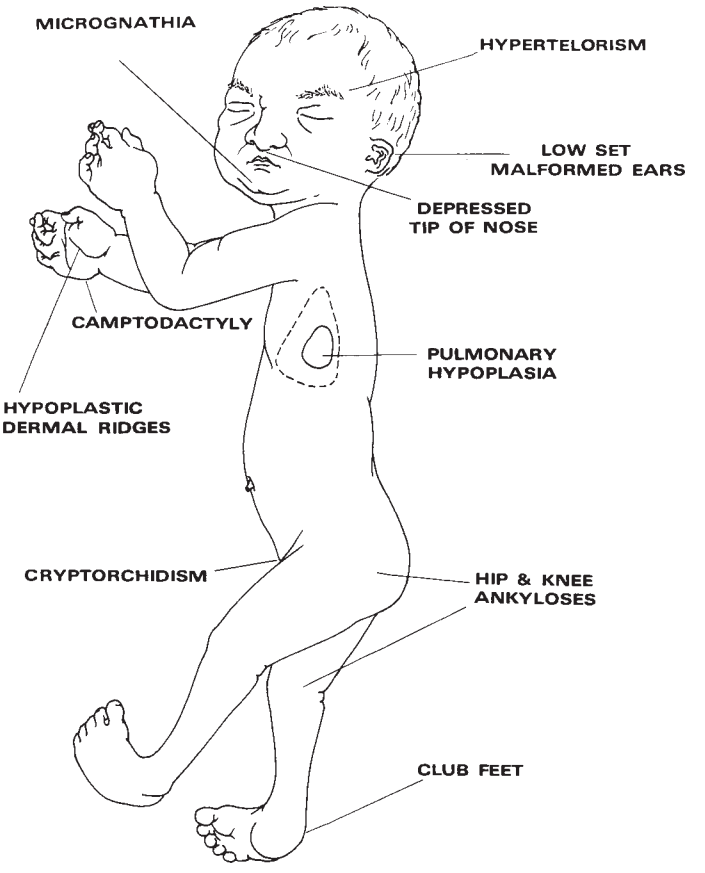
Genitourinary abnormalities. Probably all affected males have cryptorchidism and 20% have hypospadias. Clitoral enlargement and/or labial abnormalities are present in 15%. Various urinary tract anomalies occur in 30% (21).

Cardiac anomalies. Various congenital heart anomalies have been described in 25% (21).

Oral manifestations. Small mandible and cleft palate are frequent (37).

Pathology. Apart from measurable lung hypoplasia, present in nearly all cases, internal organs have been essentially normal, although laryngeal stenosis has been reported (1,6,17). Muscle biopsy may show focal atrophy and replacement with fibrous connective tissue or fat or may be normal. Neuropathologic findings consist of a marked paucity of anterior horn cells in the spinal cord and widespread neuronal loss in the central nervous system (2,10,19,25), or may be normal. Pathogenesis appears to be related to a number of different mechanisms in different families, resulting in muscle weakness and intrauterine fetal immobility. This is implied by the congenital joint contractures and webbing, and facial features (25). If any one of the phenotypic features is seen in a patient, the others should be looked for. Thymus and systemic hypoplasia has been noted (14a).

Fig. 18–1. *Fetal akinesia deformation sequence*. Main dysmorphic features. (Adapted from SDJ Pena and MHK Shokeir, J Pediatr 85:373, 1974.)



A B C

Fig. 18–2. *Fetal akinesia deformation sequence*. (A) Note suborbital creases, hypertelorism, nevus flammeus of forehead, micrognathia, arthrogryposis (camptodactyly, club feet), and pectus carinatum. (B,C) Similar phenotypes. (A from HH Punnett et al, J Pediatr 85:375, 1974. B from P Moerman et al, J Pediatr 103:238, 1983.)

Differential diagnosis. Arthrogryposis, a group of conditions of diverse etiology and characterized by congenital joint contractions and web formation, must be excluded (17). The anomalies of the extremities somewhat resemble those in *trisomy* 18 (27). Lung hypoplasia is much more prominent in Pena-Shokeir I syndrome. The syndrome of multiple ankyloses and facial anomalies must also be excluded (39).

Various recessive inherited *lethal multiple pterygium syndromes* have been reported. In addition to the ankyloses, camptodactyly, lung

hypoplasia, and facial abnormalities, multiple joint webs and/or cardiac hypoplasia were found (24). These conditions share many features of fetal akinesia deformation sequence (2,11,14) because both have decreased movement. There is some facial resemblance to *Potter sequence*.

Erdl et al (8) reported sibs with Pena-Shokeir phenotype who also exhibited endocrine hyperplasia, trilobate lung, and major CNS malformations.

Hall et al (13) reported an autosomal dominantly inherited disorder characterized by small mouth and jaw, limited jaw movement in infancy, mild short stature, mild microcephaly, large ears without an anthelix, and severe flexion contractures of the hands and feet that led to subluxation of fingers and club feet. A dominantly inherited syndrome of similar anomalies of the hands and rockerbottom feet because of vertical talus (digitotalar syndrome) but with no facial anomalies was described by Sallis and Beighton (34).

Laboratory aids. Sonography has been employed for prenatal diagnosis based on associated hydrops (22,28).

Cerebro-oculo-facial-skeletal syndrome (Pena-Shokeir II syndrome, COFS)

In 1974, Pena and Shokeir (15) reported a disorder consisting of microcephaly, cataracts, and other eye anomalies, characteristic facies, flexion contractures, and generalized osteoporosis. They revisited the syndrome in 1978 (16). It probably was described earlier in sibs by Lowry et al (13) although we cannot completely exclude the possibility that the sibs had Cockayne syndrome (5). The disorder is a form of fetal akinesia.

Affected sibs and parental consanguinity indicate autosomal recessive inheritance (15,21). There may be two types, one having more severe cardiac and renal problems (4). About 40 cases have been reported to date. A balanced translocation that involved 1q23 and 16q13 was reported by Temtamy et al (24). The original Manitoba kindred was shown to have a mutation in the Cockayne syndrome group B gene (14a).

About half of the infants are small for dates. There is failure to thrive. All exhibit progressive postnatal growth deficiency and progressive demyelinization of the central nervous system. Average life span is about 4 years.

Facies. Head circumference is small in 95%. At least 90% have microphthalmia and blepharophimosis. About 75% exhibit cataracts (7,10,12,22). In those that survive, the face is flat, and hypertelorism, small mouth, thin downward-slanting upper lip, micrognathia, cleft palate, and low-set pinnae are noted (20).

There is a prominent nasal root in 100%. The pinnae are large in 70%, and the upper lip overhangs the lower one. The chin is small in nearly all. The neck is not short (Fig. 18–4).

Musculoskeletal. Kyphosis and/or scoliosis are noted in 70%, and camptodactyly with overlapping fingers is a constant feature. Flexion contractures, especially of the elbows and knees, are noted in 80%. About 70% manifest rockerbottom feet because of vertical talus. Dislocated hips, acetabular dysplasia, coxa valga, and osteoporosis are also

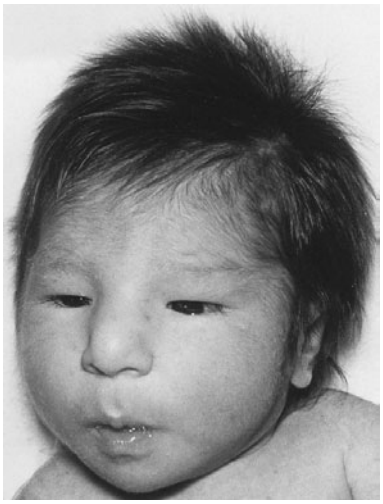

Fig. 18–4. *Cerebral-oculo-facial-skeletal syndrome*. Facies showing microcephaly, blepharophimosis, prominent nasal root, small mouth, micrognathia. (Courtesy of SDJ Pena, Winnipeg, Manitoba, Canada.)

frequent features. The second metatarsal may be proximally placed due to hypoplasia of the second cuneiform bones (Fig. 18–5).

Central nervous system. About 95% exhibit microcephaly and mental retardation. Perhaps 40% of those autopsied have had hypoplasia or agenesis of the corpus callosum, cerebellar hypoplasia, and intracranial groove foldings (12,21). Gershoni-Baruch et al (6) suggested addition of congenital muscular dystrophy. Intracranial calcification has been cited by a number of authors (1,3,12,19,24).

Other findings. The nipples are widely set in about 50%. Single palmar creases have been seen in about 30% and longitudinal foot groove folding in 70%. Renal anomalies have also been reported (18).

Differential diagnosis. There appears to be a form of COFS characterized by early death. The infants exhibit the facial and musculoskeletal anomalies of classic COFS syndrome. Low birthweight is common. Visceral anomalies include agenesis of the corpus callosum, cerebellar hypoplasia, renal hypoplasia or agenesis, horseshoe kidney, absence of hemidiaphragm, malrotation of colon, hypoplasia of spleen, and multiple foci of calcification of heart and kidneys (14,17). Whether this represents a different disorder or an allelic form is not known.

We are not entirely convinced that the COFS syndrome differs from the Bowen-Conradi syndrome found in Hutterites (2,8). The latter disorder is stated not to be associated with microphthalmia, blepharophimosis, cataracts, or large pinnae whereas COFS syndrome patients do not have dolichocephaly or cryptorchidism. There is otherwise a remarkable overlap in phenotypes.

Several authors have suggested that the COFS syndrome represents a severe allelic form of *Cockayne syndrome*. The usual pattern in Cockayne syndrome is normal growth until 2 years of age, then gradual delay in overall development, small head, and unsteady gait. Joint problems and kyphosis are mild. Arthrogryposis and *trisomy 18* must be excluded. Winter et al (25) noted an overlap with the *Neu-Laxova syndrome*. A COFS-like syndrome was reported in an infant with osteopetrosis and myopathic changes (11).

One must exclude *Pena-Shokeir syndrome, type I*, characterized by pulmonary hypoplasia. A condition called CAMFAK, characterized by microcephaly, cataract, and kyphosis and similar to Cockayne syndrome (23), must be excluded.

Laboratory aids. Hwang et al (9) found extensive necrosis of iliac crest cartilage cells. However, necrotic chondrocytes can also be seen in various chondrodysplasias: *achondroplasia, diastrophic dysplasia*, and *Dyggve-Melchior-Clausen syndrome*.

Neu-Laxova syndrome

Neu et al (20), in 1971, and Laxova et al (12), in 1972, independently reported sibs with a lethal syndrome of marked intrauterine growth retardation, ichthyosis, marked microcephaly, characteristic facies, and flexion deformities. At least 50 examples have been published. Cases resembling the COFS syndrome have been described (13,30). Consanguinity (2,4,5,9,11,12,14,17,19, 20,23,25,27,28,32) has been noted in 40%, and affected sibs (2,4,12–14,19,20,23,28,29,32) have been reported. Inheritance is clearly autosomal recessive. Curry et al (3) suggested that there is heterogeneity, one form having no edema and no increased fat layer (5) whereas the other form has a prominent fat layer (18) (vide infra). The syndrome may have a higher frequency in Pakistanis (17).

A history of multiple spontaneous miscarriages is frequent. Polyhydramnios is seen in 40%. The placenta is remarkably small for gestational age (4,5,10,23,27,32,33), and there is a short umbilical cord in 35% (1,5,7,10,13,20,23,27,29,32). In some cases, the umbilical cord has only two vessels. All have severe intrauterine growth retardation. At full term the infant usually weighs between 850 and 1500 g. Crown-heel length ranges from 25 to 35 cm. Nearly all are stillborn or die within hours after birth. The longest survivor lived approximately 8 weeks (14).

Many of the findings such as polyhydramnios, intrauterine growth retardation, generalized edema, deformed swollen limbs, osteopenia, and short survival can be explained by protein loss through skin fissures. Some structural deformities may be secondary to intrauterine mobility, similar to those seen in *restrictive dermopathy*.

Facies. Facial appearance is striking. There is microcephaly (OFC at birth 23–26 cm) in 85% and a markedly sloping forehead in 75%. There appears to be premature closure of sutures and fontanels, probably secondary to small brain size (9,12,13,18,20,22). The nose is flat and simple with a broad nasal bridge in 70%. The nares are usually small or, rarely, almost absent. The cheeks are full. The upper and lower eyelids exhibit extreme ectropion and are very hypoplastic, giving the impression that they are completely missing. Apparent hypertelorism is noted in 50%, and exorbitism is noted in 40% (20,23,34). The pinnae are low-set in 60% and very often large and deformed. The lips are everted. Bilateral cleft lip-palate has been seen (18,30). Micrognathia has been present in about 50%. The head appears to sit directly upon the shoulders in 75% (Fig. 18–6).

Musculoskeletal alterations. Most patients have short contracted limbs. The hands and feet are swollen and the digits hypoplastic, with or without nails in 60% (24). Frequently the fingers overlap. About 50% have rocker bottom feet. Syndactyly of fingers and toes is extremely common. A detailed anatomic study of the upper limbs was carried out by Shved et al (29).

The bones have a stick-like appearance due to undertubulation. There is underossification of the bones of the hands and feet. The ilia are dysplastic and there is poor ossification of pubic bones with lack of ossification of sacrum and coccyx. Possibly the condition termed by Spranger et al (31) cerebroarthrodigital syndrome is not specific for a single disorder since their patient 3 appears to have Neu-Laxova syndrome.

Central nervous system. Severe microcephaly (85%) with variable anomalies such as brain atrophy, agenesis of the corpus callosum (40%), dilated ventricles (25%), lissencephaly (40%), and holoprosencephaly, agenesis of vermis (40%), hypoplasia of corpora quadrigemina, and hypoplasia of the cerebellum (40%) have been found (13,17,20,21). There are reduced numbers of nuclei in the pons, cerebellum, and brainstem. The cerebellar cortex has a two-layer lamination. The anterior and lateral columns of the spinal cord are absent (13) (Fig. 18–7).

Urogenital. Both unilateral renal agenesis and hypoplasia of external genitalia have been reported in approximately 35% (12,13,22,23,27).

Skin. Scaly, yellowish ichthyotic skin has been described in approximately 50% (19). There may be massive accumulation of adipose tissue beneath the epidermis, surrounding atrophic muscle bundles (9,14,18).

Cardiac anomalies. Various anomalies have included ASD, VSD, PDA, and transposition of great vessels.

Oral manifestations. Cleft lip-palate has been reported in approximately 25% of the cases (9,18,22–24,32,33).

Differential diagnosis. There is some similarity (intrauterine growth retardation, lissencephaly, agenesis of corpus callosum, cataracts, joint contractures, overlapping fingers) to patients with *cerebro-oculo-facial (COFS) syndrome* that die at an early age (33). Silengo et al (30) suggested that they are the same disorder. Collodion baby and severe congenital ichthyosis must be excluded (6,27).

The skeletal alterations as noted above are seen in several clinically different disorders (26). Scott et al (26) and Elliott et al (4a) reported patients with long clavicles, 11 thick ribs, very short arms, hypoplasia of the metacarpals and phalanges, tall narrow ilia and diaphyseal widening.

A B

Fig. 18–6. *Neu-Laxova syndrome*. (A,B) Characteristic facies with globular head, widely opened palpebral fissures, protuberant globes, squashed nasal tip, rudimentary pinnae, small mouth, and short neck. Limbs are short; hands and feet are swollen with absent or hypoplastic digits without nails. (From CI Scott et al, Am J Med Genet 9:165, 1981.)

Perhaps the common denominator is a primary neural tube-neural crest dysplasia.

Restrictive dermopathy and harlequin fetus should be excluded.

Laboratory aids. The disorder has been diagnosed prenatally by ultrasonography at 6–8 weeks for accurate dating, at 12–16 weeks for reduced fetal limb movement, at 16–24 weeks for facial and skeletal abnormalities, the detection of intrauterine growth retardation, and polyhydramnios and at 34–36 weeks for lack of fetal swallowing, fetal edema, and ocular hypertelorism with exorbitism (2,8,15,16,18,22,25,28,32).

Multiple pterygium syndrome

Multiple pterygium syndrome was buried in the early literature, most often under the nonspecific diagnosis of arthrogryposis (21,35) or *Noonan syndrome* (10,31). The syndrome consists of growth retardation, multiple pterygia involving the neck, fingers, and antecubital, popliteal, and intercrural areas, and cleft palate. Credit should go to Matolcsy (22) for clearly defining the entity. Approximately 70 cases have been reported to date. The patient reported by Celiköz (4) clearly has this disorder. Thompson et al (38) have elegantly reviewed the evolution of the phenotype.

The syndrome has autosomal recessive inheritance. Affected sibs (3,5, 9,17,18,22,24,25,34–36,38) as well as parental consanguinity (10,12,38) have been reported. It is apparently more common among Arabs (24, 38,40). Recurrent chest infections, probably the results of congenital kyphoscoliosis, may result in early death (5,21,38). Approximately 75% are small for their gestational ages.

Facies. The palpebral fissures are mildly downslanting in 50%. There is mild ptosis of the lids in 30% and epicanthal folds in 15% (Fig. 18–8). Approximately 50% of the patients have puffiness around the eyes. The mandible is small in 60%. In some patients there is a central neck web (vide infra).

Musculoskeletal alterations. Growth is usually retarded below the third percentile, the patient's adult height rarely exceeding 135 cm.

The popliteal pterygia, noted in 45%, may markedly inhibit walking and, even if only mild, may produce bizarre stance and gait. Pterygia occur in the cervical area in 95%. They may resemble those seen in Turner and Noonan syndromes. They completely surround the neck rarely (Fig. 18–9). In approximately 15%, a pterygium extends from the chin to the sternum (11,26,43). In 50%, there is mild soft-tissue syndactyly between the fingers.

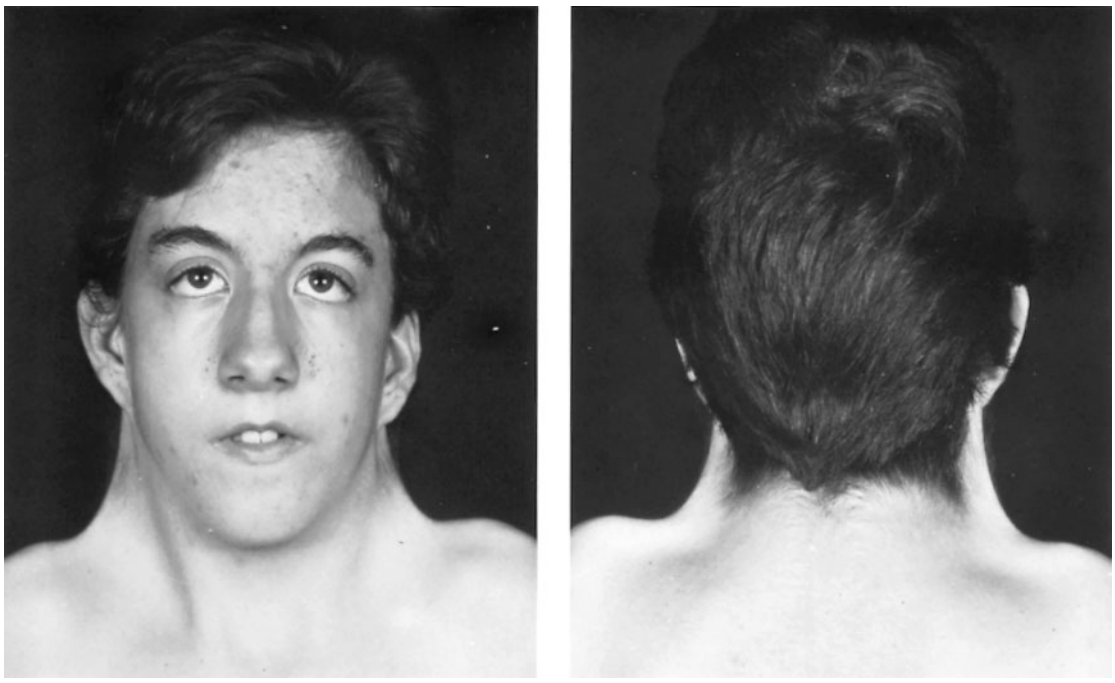
Flexion deformity of the digits, the thumbs being flexed and apposed, occurs in 60% (1,19,25,33) (Fig. 18–10). Talipes calcaneovalgus, either unilateral or bilateral, and rocker-bottom feet have been noted in 35% (1,30). Kyphoscoliosis, often congenital, and other vertebral anomalies (failure of posterior fusion of vertebrae, fusion of cervical vertebrae) are found in 60%. The axillae (55%) and antecubital fossae (35%) are the sites of webs. Intercrural webs are found in 40% of both males and females. In the presence of an intercrural web, the penis and scrotum are retropositioned. They may be associated with cryptorchidism and/or inguinal hernia (22,25). In females, the labia majora may be absent (1). Body asymmetry has been noted (40).

Abnormal fiber distribution has been described (41).

Radiographic changes include vertebral segmentation anomalies such as fusion of cervical vertebrae and rib anomalies (25%), tall narrow vertebral bodies (30%), vertical talus with talipes calcaneovalgus or equinovarus (65%), and camptodactyly of fingers and toes (65%) (38). The patellae may be absent.

Miscellaneous findings. Congenital heart defects have been found in 25% of those in whom a cardiac examination was recorded (9,12,30,38).

Fig. 18–8. *Multiple pterygium syndrome*. (A,B) Note antimongoloid obliquity of palpebral fissures, pterygium colli, low-set posterior hairline. [From C Scott, Birth Defects 5(2):231, 1969.]



A B

Fig. 18–9. *Multiple pterygium syndrome*. Pterygia of neck, axillas, and popliteal areas. [From C Scott, Birth Defects 5(2):231, 1969.]

Oral manifestations. Cleft palate has been found in approximately 35% (2,4–6,17,20,28), and a hearing deficit has been noted in several patients (29,38). Hennekam (14) reported three affected sibs whose tongues had flattened spoonlike tips (lingua cochlearis).

Differential diagnosis. The syndrome should be distinguished clearly from autosomal dominantly inherited *popliteal pterygium syndrome*. Although both share popliteal pterygium, the cervical, axillary, and elbow webbing as well as the finger contractures and vertebral anomalies and difference in inheritance pattern should furnish a clear distinction. There is also overlap with the *femoral hypoplasia-unusual facies syndrome*. Elbow webbing is discussed under *popliteal pterygium syndrome*. A possible new autosomal recessive form of multiple pterygia was noted by Aslan et al (2a).

Pterygia about the neck may be seen in *Turner syndrome, LEOPARD syndrome, Noonan syndrome*, and in some cases of *craniocarpotarsal dysplasia*. Pashayan et al (27) described multiple pterygium syndrome in a patient with mosaic *Klinefelter syndrome*. The patient also exhibited cataract and glaucoma. Some patients with *fetal akinesia sequence* have pterygium formation.

Fig. 18–10. *Multiple pterygium syndrome*. Marked flexion deformity of digits. [From C Scott, Birth Defects 5(2):231, 1969.]

A dominantly inherited syndrome of multiple pterygia, ptosis, and skeletal abnormalities has been reported by Frias et al (7). Short stature was not present. The skeletal anomalies included malsegmentation of vertebrae, pelvic dysplasia, and some carpal and tarsal bone fusion.

Kawira and Bender (15) described a dominantly inherited disorder of short stature, cervical vertebral anomalies, scoliosis, nuchal and axillary pterygia, and distal arthrogryposis.

Haspelagh et al (13) and other authors (32,39) have reported a syndrome of mental retardation, postnatal growth retardation, multiple pterygia with distal muscular wasting, hypogonadism, and characteristic facies (trigonocephaly, frontal bossing, epicanthal folds, low-set angulated pinnae, microretrognathia). Haspelagh syndrome has been shown to be due to an unbalanced reciprocal 6q/9p translocation (5a). Cleft palate was noted in two of four children. Another family with autosomal dominant inheritance did exhibit short stature (23).

Nuchal hygromas may be noted prenatally on ultrasound (8,42).

More lethal multiple pterygium phenotypes

Several additional lethal multiple pterygium phenotypes have been reported. Nearly all have autosomal recessive inheritance (1), but only one has been mapped as of 2000 (vide infra) (28). An X-linked recessive type has been documented (20) and mapped to Xq26 (14a). The pterygia may result from embryonic onset fetal akinesia from several causes (5). All are characterized by death or miscarriage during the second trimester and by the presence of multiple congenital contractures with skin webs across joints, apparent hypertelorism, cystic hygromatous masses in the neck with residual edema and loose skin, thin crowded ribs, and hypoplastic lungs and hearts (11,21). The pregnancies frequently are complicated by polyhydramnios. Cleft plate may be present. The conditions may not always be diagnosable prenatally (14). A survey of 36 published cases is that of de Die-Smulders et al (6). A consistent pathologic work-up was advocated by Froster et al (7).

Theories of pathogenesis include an abnormally fragile collagen (6) and aplasia of developing muscle fibers (22).

Distinction among the types is based on age of onset of intrauterine growth retardation, the extent of neck swellings, and whether and where bony fusions and modeling errors of the bones occur. The syndrome seems to represent a combination of jugular lymphatic obstruction sequence and fetal akinesia. Martin et al (19), however, have denied that such division can be made. Hall (10) presented a very lucid discussion of the problem. Hall (10) divided cases into three groups based on time of onset, timing and extent of neck swellings, and presence or absence of bone fusions. De Die-Smulders et al (6) separated cases into three groups: early, late, and the Finnish type. The first two categories were divided according to the presence of hydrops and/or hygroma colli and length of survival. The Finnish type (vide infra) had specific neuropathological changes in the spinal cord and brain stem.

The first of these disorders (Fig. 18–11A) was characterized by intrauterine growth retardation that is recognized at birth (8,9,15). Hypertelorism (95%), downslanting palpebral fissures (75%), short flat nose (95%), tented upper lip, hypoplastic alae, long philtrum, cleft palate (60%), micrognathia (100%), low-set malformed pinnae (95%), mild neck edema, small chest, and lung hypoplasia (90%) are evident. The

Fig. 18–11. *Lethal multiple pterygium syndrome*. (A) Eighteen-week fetus showing hydrops, nuchal edema, flat upturned nose, long philtrum, gaping mouth, receding chin and multiple pterygia. (B,C) Note cystic hygromas, small mouth, flat nose, talipes, and hand contractures. (A from G Isaacson et al, Am J Med Genet 17:835, 1984. B,C from H Chen et al, Am J Med Genet 17:809, 1984.)

A B C

abdominal musculature is decreased and there may be genital anomalies and atresia of the gut. The pterygia are tightly flexed. There is no bony fusion of the extremities.

The second form, illustrated by cases 2 and 6 of Chen et al (3), Clementi et al (4), and Lockwood et al (17) has short broad limbs and hypertelorism. There is marked cystic hygroma formation that extends from the neck to the mid-back (Fig. 18–11B,C). Generalized scalp edema is also evident. Intrauterine growth retardation is recognized at 20–30 weeks of gestation. Often there is hydramnios and swollen placenta. Fusion of bones (humerus–ulna, radius–ulna, spinous processes of vertebrae, epiphyseal cartilages of long bones) and clubfoot are prominent.

The third form [3 (cases 4,5),27] is characterized by hypertelorism, upward slanting palpebral fissures, open eyes, openmouth, hypoplastic nose, absent mandibular angle, micrognathia, and redundant skin at the nape. Some have cleft lip and/or cleft palate. The legs are thin with decreased muscle mass. There are fused long bone cartilages and failure of normal modeling of the femur and tibia. Intrauterine growth retardation is recognized at 19–25 weeks.

The fourth or Finnish form (12,13,28), has so far been limited to fetuses from Finland. Its incidence in that country is approximately 1 in 19,000 births. The gene has been mapped to 9q34 (18). There are intrauterine growth retardation, fetal hydrops, multiple contractures, and abnormal facies, especially micrognathia (Fig. 18–12A). Pulmonary hypoplasia and muscular atrophy, thin tubular bones that are fractured in 30%, paucity of anterior horn cells, and degeneration of descending tracts were evident at autopsy (Fig. 18–12B).

A possible fifth entity was reported by Robinson et al (24). Malignant hyperthermia was a major complications. An X-linked recessive form was characterized by defectively modeled long bones and broad ribs, clavicles, scapulae, and cystic hygroma (26). Still another type was reported by Spearritt et al (25) that does not conform to any of the aforementioned categories. This type has been subsequently labelled type III lissencephaly (23).

Most examples have been diagnosed during the second trimester by ultrasound because of cystic hygroma and hydrops (2,16,17). *Pena-Shokeir fetal akinesia sequence* shares many clinical features but does not exhibit cystic hygroma or hydrops. The placental changes resemble those of triploidy (22). Infants with the latter often survive the third trimester or are born alive.

Popliteal pterygium syndrome (facio-genito-popliteal syndrome)

The first recorded case would appear to be that of Trélat (50) in 1869. Fewer than 110 cases have been described to date. There have been many extensive reviews of the syndrome (8,11,15,17,33,38). Prevalence is approximately 1 per 300,000 births. Rintala and Lahti (41) suggested the term "facio-genito-popliteal syndrome."

Most have been isolated examples. The condition has been transmitted from an affected parent to one or more children (11,13,21,24,30,37,38). Although there have been affected sibs with normal parents (Escobar syndrome) (8,48), nevertheless, massive evidence suggests autosomal dominant inheritance with variable expressivity and incomplete penetrance (10,11,15,21,38,43). One study says the popliteal pterygium syndrome maps to the van der Woude region at 1q32 (29), another (44) that it does not. Excellent critical analyses are those of Hunter (23) and Froster-Iskenius (14).

Facies. The most obvious facial alterations are cleft lip and/or cleft palate and filiform adhesions between the eyelids (20%) (3,11,19,24, 28,33,35,36,49,51). Pits of the lower lip are common (vide infra). Rarely, there is choanal atresia (52a).

Cutaneous and musculoskeletal anomalies. Certainly the most striking and most common (70%) component, the popliteal web, extends from the heel to the ischial tuberosity, limiting extension and abduction as well as rotation of the leg (Fig. 18–13A,B). In all but a few cases (22,26,38,41,51), these webs have been bilateral. Along the free edge of the pterygium runs a hard, inelastic, subcutaneous cord or fibrous band or calcaneoischiadicus muscle (2). The sciatic nerve lies free within the web, deep to the fibrous band approximately halfway between the free edge and the apex, being covered by a fibromuscular septum. Special caution must be taken in repairing the skin fold. The popliteal vessels are normally situated in the popliteal space. In many cases, muscle groups are absent or muscle insertions are abnormal. There may be a minimal pterygium of a single limb (Fig. 18–13C).

Approximately 20% exhibit hypoplasia or agenesis of digits (9,16,20,21). Twenty percent have varus or valgus deformities of the foot (7,16,21,50), and over 50% manifest variable syndactyly of the second to fifth toes and in 15% in the fingers, most often 3–4 (5,6,7–9,11,12,16,20,23,37–39,42,46). Ectrodactyly may rarely occur (3). Spina bifida occulta has been documented in 20% and scoliosis or lordosis in 10% (16,26). Bipartite or absent patella has been documented rarely (38).

The skin over the hallux may have a somewhat pyramidal form, one vertex extending over the nail in approximately 40% (6,31,47). If present in a child with cleft lip and/or palate, *even in the absence of a distinct popliteal pterygium*, we believe that this anomaly is sufficiently distinct to make the diagnosis. The toenails, most often the second, are hypoplastic and triangular in approximately 30% (13,15,20,24,37,42,49) (Fig. 18–13D).

Genitourinary system. Anomalies in the male have included cryptorchidism in 40% (1,11,13,42), absent, cleft, or ectopic scrotum in 35% (5,7,16,37,41,42,53), small penis in 40%, and inguinal hernia in 10% (15,42) (Fig. 18–14A). In the female, absence or displacement of the labia majora in 60% (1,16,21,38,42) and enlarged clitoris in 20% (16,21,25,44) have been noted (Fig. 18–14B). Hypoplastic uterus has also been described (16).

An intercrural pterygium extending between the thigh, ventral to the anus, is found in approximately 20% (9,12,15) (Fig. 18–14C).

Oral manifestations. Cleft lip and/or cleft palate have been reported in approximately 85%. Pits or sinuses of the lower lip (11,15–21,24–28,33,35,38,39,50) have been noted in approximately 60% (Fig. 18–15A). Congenital bands or threads of mucous membrane extending between the jaws (syngnathia) have been reported in approximately 30% (2,4,5,7,10,20,21,28,33,37,38,41,49,52,54) (Fig. 18–15B). A band between gingiva and the lower lip has been described (32).

Differential diagnosis. The popliteal pterygia make this syndrome distinctive. It is possible that the patients described by Neuman and Shulman (32) with cleft palate, lip pits, oral mucosal adhesions, and ankyloblepharon represent incomplete expression of the syndrome. Lip pits and ankyloblepharon may each occur as an isolated phenomenon or in combination with cleft lip and/or cleft palate. Various extreme types of bifid scrotum may occur as isolated anomalies. *Hay-Wells syndrome* (*AEC*) includes both ankyloblepharon and cleft lip or cleft palate. Pterygia of the axilla, neck and antecubital, and popliteal areas constitute *multiple pterygium syndrome*. Pterygia-like alterations of the lower extremities occur as part of the caudal regression complex. Antecubital pterygia are seen as an autosomal dominant trait (34,45). They may also occur in association with the nail-patella syndrome.

Bartsocas-Papas syndrome is a lethal autosomal recessively inherited popliteal pterygium syndrome. Findings include low birthweight, mental retardation, mild growth retardation, microcephaly, filiform adhesions of eyelids, corneal ulceration, hypoplastic nasal tip, microstomia, cleft lip-palate, soft-tissue syngnathia, micrognathia, supernumerary nipples, aplastic labia majora, bicornate uterus, and lanugo hair. Anomalies of the extremities comprise popliteal pterygia, pes equinovarus, hypoplastic or absent phalanges, syndactyly of fingers and toes, and synostosis of hand bones. There are no vertebral anomalies.

Laboratory aids. Prenatal diagnosis has been accomplished ultrasonographically (37a).

Bartsocas-Papas syndrome

Bartsocas and Papas, in 1972, reported four sibs with what they interpreted as a lethal syndrome of popliteal pterygium, bizarre facial clefts and other facial anomalies, and abnormalities of the extremities. Subsequently, approximately 15 additional examples have been reported (1–6,9–13). We cannot classify the patient reported by Marquardt (8). The patients reported by Hennekam et al (7) were atypical. A case may have been reported as early as 1600 (15).

Inheritance is clearly autosomal recessive with both parental consanguinity (1,1a,3,11,13) and multiple affected sibs (1,1a,3,5,6,9,13) having been documented. Nearly all have been of circum-Mediterranean origin (10).

Birthweight tends to be low. In one example, there was polyhydramnios (7). At least 9 of 13 documented children died within the first few days of life, although there have been a few examples that have lived for years (2,4,13). In one child who was reported at the age of 8 years, intelligence was normal (13).

Craniofacies. The anterior fontanel may be wide (7). The scalp hair, eyebrows, and eyelashes are nearly always absent. Ankyloblepharon filiforme has been a constant finding. Corneal leukomas have been noted in approximately half the patients (1,1a,5,6,9,12). Most patients have upslanting palpebral fissures. Coloboma of the upper eyelids has been noted in at least one case (4). Most remarkable are the bizarre facial clefts that do not follow lines of fusion but extend into a cleft palate. The nasal tip is usually hypoplastic. Microphthalmia has been found in one patient (4). In an older patient, conical crown form was noted in the erupted incisor teeth (4). The maxilla is often hypoplastic. Variable soft tissue adhesions between the upper and lower jaws or between the upper and lower lip have been seen in the majority of patients (10a) (Fig. 18–16).

Extremities. Complete soft-tissue syndactyly of the fingers and toes with aplasia of the thumbs and absent nails is characteristic. Marked popliteal pterygia are a constant feature, much more severe than those seen in the autosomal dominant *popliteal pterygium syndrome* (Fig. 18–17). Talipes equinovarus is a virtually constant feature. Radiographically, there is agenesis of the first rays with symphalangism of digits 2–3 in the hands and 3–4 in feet, and agenesis of the fifth toes. There are reduced numbers of metacarpals and metatarsals, and in a few cases there have been rudimentary radius, ulna, and tibia.

Genitourinary findings. In females, there is aplasia of the labia majora and bicornuate uterus. Males exhibit hypoplastic penis, which is very often fused inferiorly with the scrotum.

Miscellaneous findings. Anomalies have included hypoplastic nipples, supernumerary nipples, anal atresia, absence of diaphragm, esophageal atresia, tracheo-esophageal fistula, and absent kidney (3,7).

Diagnosis. The findings are so characteristic that differentiation from other lethal popliteal pterygia syndromes is evident (5,6,11).

Chondrodystrophic myotonia (Schwartz-Jampel syndrome, osteochondromuscular dystrophy)

In 1962, Schwartz and Jampel (37) described a syndrome characterized by growth retardation, osteochondrodysplasia, continuous muscle contracture at rest, and unusual facies. The same children were reported by Aberfeld et al (1,2). An earlier case is that of Catel (8). Approximately 90 examples have been subsequently reported.

The syndrome has autosomal recessive inheritance. Affected sibs (3,4,6,10,13,17,19,22,25,32,43) and parental consanguinity (3–6,19, 31,36,42) have been noted. The neonatal form is especially common in the United Arab Emirates (3,4). An affected father and son were reported (30), but this may have resulted from uniparental disomy (39). Electromyographic abnormalities have been found in parents of affected children (32,43). Identical twins have been reported (34). The gene *HSPG2* maps to 1p26–p34 (14-29). Mutations are found in perlecan, the major proteoglycan in basement membranes (30). However there appears to be genetic heterogeneity (7,18), type 1B not mapping to this area (vide infra).

Most examples present in late infancy (type 1A) (11,12). However, a considerable number become evident in the neonatal period (types 1B and 2) (1,7,11,16,20,22,35,38). The latter have feeding, choking, or respiratory difficulty within the first few weeks of life (3,4,7,16,22).

Facies. The facies, usually normal at birth, is usually clinically recognizable at 1–3 years of age (Fig. 18–18). It has been documented during the neonatal period (12). There is then progressive tonic contraction of facial muscles into a pinched or frozen smile with puckered or pursed lips and narrow palpebral fissures because of medial displacement of the outer canthi. Ptosis of eyelids, micrognathia, and short neck are evident.

Eyes. In addition to ptosis, blepharospasm, and blepharophimosis, myopia is noted in approximately 50%. In a few cases, congenital cataracts have been observed.

Musculoskeletal alterations. Height is reduced below the 10th centile (40). Limitation of motion at the hips is evident usually within the first 6 months of life but rarely is there prenatal onset (12). Gait becomes waddling and progressively difficult because of stiff hips and knees and crouched stance. The child fatigues easily (Fig. 18–18A). There is hyporeflexia. Obstructive sleep apnea has been noted (9).

Skeletal changes (Table18–1) include pectus carinatum, kyphoscoliosis, lumbar lordosis, platyspondyly, iliac base shortening with acetabular hypoplasia, severe coxa vara, pes planus, and osteopenia, depending on the form of the syndrome (Fig. 18–19). The long bones may be bowed with metaphyseal widening with epiphyseal irregularity in type 2 (18,24,26,44). Occasionally cervical kyphosis may be marked.

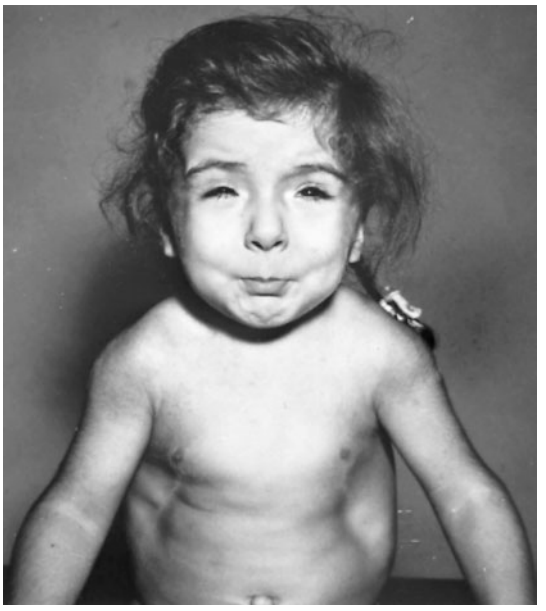
Giedion et al (18), surveying 86 examples, concluded that there were three forms. Type 1A is the classic form. It is recognized in childhood and exhibits only mild bone dysplasia. Type 1B is evident at birth, radiographically resembles Kniest dysplasia, and has poor prognosis because of severe respiratory and feeding problems. Type 2 is also evident at birth but the femora resemble those in Pyle disease. As noted above, there is evidence that type 2 does not map to 1p36.1–p34. There is good evidence that type 2 is the same as Stüve-Wiedemann syndrome (10,41).

Choking on cold liquids and mild muscular hypertrophy have been described during early childhood in the early onset forms (2,25). Difficulty in intubation has been discussed (12,22,44). Weakness is not a prominent feature. Myotonia is a constant feature but Moodley and Moosa (28) noted a child who did not have myotonia. Repetitive contracture decreases the myotonia. There is continuous muscle fiber activity at rest. It has been suggested that the abnormal discharges originate in the muscle component of the neuromuscular junction rather than the nerve, perhaps in the sarcolemmal membrane (16,40). There is no true myotonia since the continuous repetitive discharges are abolished with curare (16). Malignant hyperthermia during anesthesia may result in death (38,44).

Other findings. High-pitched voice and moderate generalized hirsutism have been reported (1,3,25,32,33,43). Mental retardation has been observed in 25%. The myotonia may result in drooling and indistinct speech.

Oral manifestations. The lips are pursed, that is, the perioral muscles are contracted. The palate is highly arched.

A



B

Fig. 18–18. *Chondrodystrophic myotonia*. (A) Note puckered mouth, mildly narrowed palpebral fissures, flexion at hips, knees, and elbows. (B) Three-year-old female. Note blepharophimosis, rigid facial expression, pigeon-breast deformity with lateral chest constriction. (A from WM Fowler Jr et al, J Neurol Sci 22:127, 1974. B from O Schwartz and RS Jampel, Arch Ophthalmol 68:52, 1962.)

Differential diagnosis. The facies resembles to some degree that of *craniocarpotarsal dysplasia*. There is some overlap in phenotype with *Marden-Walker syndrome*. Continuous muscle contraction at rest can also be seen in Isaacs-Mertens syndrome, stiff-man syndrome, and other

Table 18–1. Schwartz-Jampel syndrome

Bone dysplasia	Childhood	Birth	Birth
Radiologic changes			
Long bones	Mild, epimetaphyseal dysplasia, enlarged epiphyses at knees	Short limbed dysplasia with "dumbbell" femora (Kniest-like), epiphyses enlarged at knees.	Short limbed dysplasia with bowed legs becomes Pyle-like in childhood, epiphyses flat at knees
Spine	Mild platyspondyly	Moderate platyspondyly, coronal clefts	—
Pelvis	Narrow sacrosciatic notch	Some flaring of iliac wings, supraacetabular notch	—
Typical examples	Kozlowski and Wise (24) Schwartz and Jampel (37) Aberfeld et al (1,2) Giedion et al (18, case 1)	Horan and Beighton (20) Giedion et al (18, cases 2,3) Hunziker et al (21)	Al-Gazali et al (3,4) Giedion et al (18, cases 4,5)

Modified from A Giedion et al, Eur J Pediatr 156:221, 1997.

disorders. Congenital myotonia may be seen in *myotonic dystrophy*, dominant and recessive myotonia congenita, paramyotonia congenita, and other disorders (2). An autosomal dominant disorder with expressionless facies, microstomia, blepharophimosis, short stature, and distal arthrogryposis has been reported. Hearing loss was noted as well as cleft palate (19).

Spranger et al (40a) believe that *Burton disease, kyphomelic dysplasia*, and *micromelic chondrodysplasia* may be subsumed under Schwartz-Jampel syndrome.

Laboratory aids. Ultrastructural studies of muscle have shown inconsistent findings.

Standards for normal palpebral fissure size according to age have been established (15). Mollica et al (27) found reduced numbers of B and T cells. Ben Becher et al (5) and Kirschner et al (23) noted reduced IgA levels.

Prenatal diagnosis has been accomplished (21).

Fig. 18–19. *Chondrodystrophic myotonia*. Severe coxa vara. (From PR Huttenlocher et al, Pediatrics 44:945, 1969.)

Marden-Walker syndrome

Marden and Walker (17), in 1966, first reported a syndrome of failure to thrive, mental retardation, microcephaly, immobility of facial muscles, absent Moro and decreased deep-tendon reflexes, blepharophimosis, strabismus, micrognathia, anteverted nostrils, pectus carinatum or excavatum, muscle weakness and reduced muscle mass, multiple congenital joint contractures, arachnodactyly, kyphoscoliosis, and transverse palmar creases. Subsequently, similarly affected children were reported (1,4,5,7,8,15,20,22,24,25). Approximately 30 examples have been described.

Inheritance is autosomal recessive as affected sibs and parental consanguinity are documented (3,11–13,16,21).

Facies. The face appears mobile with sagging cheeks. Blepharophimosis is a constant feature. Ptosis and exotropia-esotropia are present in approximately 70%. The nostrils are anteverted. The ears are low-set and malformed in 85% (Fig. 18–20).

Central nervous system. Microcephaly is noted in approximately 60% (13,17,22,25). Mental retardation is severe. Decreased deep tendon reflexes and hypotonia are common. Dandy-Walker cyst and/or hypoplasia of cerebellar vermis and hemispheres have been described in 35% (5,6,18). There is reduction in anterior horn cells (21).

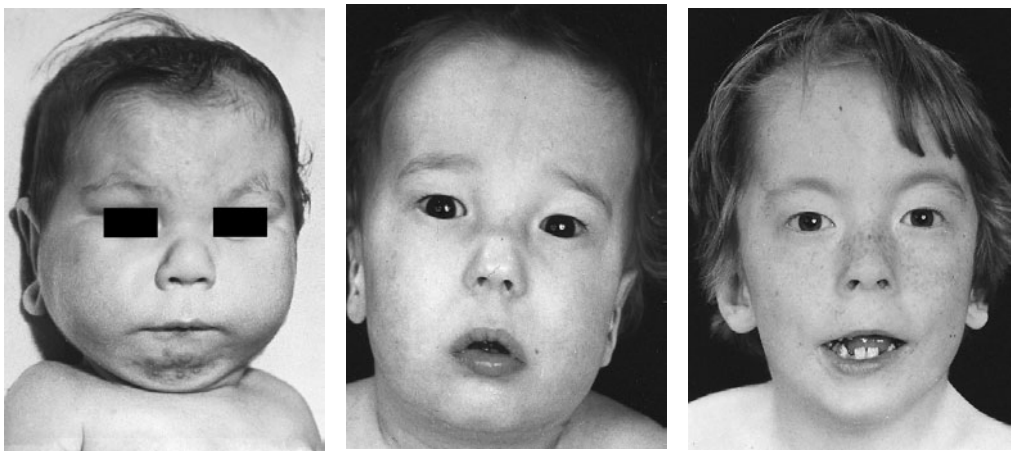
Musculoskeletal. Arachnodactyly (75%) (1,13,17,19,22), flexion contractures of the digits (65%) (13,17), talipes equinovarus (50%) (5,13,17,19), reduced muscle mass (100%) (5,13,17,19,22,25), contractures of the elbow, hip, and knee joints (95%), pectus excavatum and/or carinatum (60%) (13,19,25), and kyphoscoliosis (75%) (1,5,13,19,25) have been documented. The joint contractures tend to resolve during the first year of life. A single palmar crease has been found in 75%.

Heart anomalies. Various inconsistent congenital cardiac anomalies have been found (1,11,17,25).

Renal anomalies. Renal microcysts have been noted (2,17).

Oral manifestations. Cleft palate has been found in approximately 35% (1,3,14,17,19).

Differential diagnosis. There is some similarity to *Schwartz-Jampel syndrome*, but, in the Marden-Walker syndrome, failure to thrive, mental retardation, myopathy, and contractures are congenital rather than presenting at 1.5–2 years, and myotonia and generalized bone diseases are absent. An autosomal dominant disorder with expressionless face, microstomia, blepharophimosis, short stature, and distal arthrogryposis has been reported by Gripp et al (9). A *Marden-Walker-like syndrome* without psychomotor retardation with unusual facies and arachnodactyly, but



A B C

Fig. 18–20. *Marden-Walker syndrome*. (A) Blepharophimosis, short upturned nose, small mouth, micrognathia. (B,C) Facies of sibs. In addition to mental retardation, both had tall forehead, blepharophimosis, hypertelorism, and immobile facies. (A from JC Ramer et al, Am J Med Genet 45:285, 1993. B,C from F Howard and P Rowlandson, J Med Genet 18:50, 1981.)

without microcephaly, mental retardation, and hypotonia has been described (10,23). We view this syndrome as unrelated.

Laboratory aids. Fitch et al (5) found reduction in the size of scattered muscle fibers of both histochemical types. No percussion myotonia or myotonic discharges on the electromyogram were elicitable.

Marden-Walker-like syndrome without psychomotor retardation

Van den Ende et al (2) and Gupta et al (1) described children born to consanguineous couples. The unrelated children, one Brazilian, the other Pakistani, exhibited blepharophimosis, narrow beaked nose, hypoplastic maxilla, cleft palate or short palate, and everted lower lip (Figs. 18–21 and 18–22).

There is normal mentation and growth and development. Arachnodactyly and self-limiting joint contractures were noted.

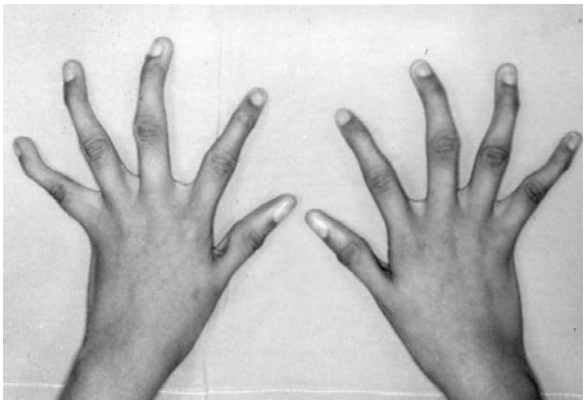
Craniocarpotarsal dysplasia (whistling face syndrome, Freeman-Sheldon syndrome, windmill vane hand syndrome)

In 1938, Freeman and Sheldon (14) described a syndrome characterized by microstomia, flat midface, talipes equinovarus, and ulnar deviation of the fingers. Unaware of this report, Burian (6), in 1963, described the same complex, utilizing the term "whistling face syndrome." Hall et al (18) and Bamshad et al (5) consider it to be a form of distal arthrogryposis most closely related to distal arthrogryposis, type 1. The disorder has also been suggested to be one of congenital myopathy (40). Confusion has been experienced in a large family regarding classification (27). A number of authors have tabulated and analyzed cases (2,4,10,29,33,41,48,54). Over 75 patients have been reported (2,33,36,37).

Although most cases have been sporadic, there are numerous examples of the disorder in two or more generations (2,4,10,12,15,18,25, 31–33,37,39,40,42,46,52,55). The condition has also been described in sibs with normal, in some cases, consanguineous parents (3,11,13,23, 28,35,43,53). Hashemi (20) found parental consanguinity in an isolated example. This suggests genetic heterogeneity but separation of phenotypes has not been possible with the exception of a milder variant (29,30) that has been mapped to 11p15.5–pter (vide infra). Sauk et al (44) pointed out the possible depiction of the condition in a pre-Columbian vase.

Facies. The stiff immobile, flat midface, full cheeks, small nose, long philtrum, puckered mouth, and H-shaped defect on the chin are striking but extremely variable features. Microstomia and long philtrum are constant, but such features as small nose with broad bridge, pronounced supraorbital ridges, deep-set eyes, micrognathia, and short broad neck are less frequent. The typical facies is present in only approximately 50% (4,12) (Figs. 18–23 and 18–24).

Eyes. Strabismus, epicanthus, and hypertelorism have been noted in over 60% (4,8,17,19,33,35,37,42). Approximately half of the



A

B

C

Fig. 18–22. *Marden-Walker-like syndrome with normal intelligence*. (A,B) Long fingers and toes, clinodactyly, and mild camptodactyly. (C) Slender metacarpals and phalanges. (From JJ van den Ende et al, Am J Med Genet 42:467, 1992.)

patients have exhibited downslanting palpebral fissures and ptosis (9,46,54) (Fig. 18–23B).

Nose. The nose is usually small. The nostrils are narrow, the alae being bent in approximately half the cases, simulating nostril colobomas. Near the tip, the alae are of normal thickness, but they thin dorsally to be inserted close to the columella. The nasolabial folds are evident only near the sides of the nose. The philtrum is long (Fig. 18–23).

Musculoskeletal system. Growth has been retarded below the third centile in approximately 30% of the cases (18). There is ulnar deviation of the fingers without bony abnormalities. Flexion contractures of the fingers are a common feature, the thumbs being adducted at the metacarpophalangeal joints. It should be emphasized, however, that the hands may be normal (38,47,51), and may improve with age (32).

Talipes equinovarus, occasionally unilateral, has been found in approximately 80% (Fig. 18–23). Moderate to severe kyphoscoliosis has been documented in approximately 60% (21). Frequently there is atrophy of the forearm and leg muscles, especially below the knees (6,39,40,45,52,54) (Fig. 18–23). Other less frequent anomalies include spina bifida occulta (45,49,54,55) and inguinal hernia (6,13,14,35,42).

The facial skeleton is small. The anteroposterior lengths of both base and cranium are short whereas facial height is relatively great. Most patients have exhibited a steep cranial base (42,54). In a few, the ribs have been broad and tapering near the costovertebral angle (38).

Other joints have occasionally shown limitations. Hall et al (18) found approximately 15% had limited movement at the hips and 5% at the elbow. Dislocation of the radial heads has been noted (13). Pterygia of the neck (31,54) or axillae (13) have also been described.

Other findings. A few children have suffered aspiration pneumonia or respiratory death (42), and a few were mentally retarded (4,13,42). A few experienced muscle rigidity following halothane anesthesia (24).

Oral manifestations. Microstomia may be marked, the intercommissural distance being approximately 65% of that for a child of the same age (9). The lips are pursed or held as in whistling in approximately half the cases. The hard palate is often highly arched and the mandible and tongue tend to be small. Frequently there is nasal speech. Rarely, there is cleft palate (32). Extending from the middle of the lower lip to the chin is a fibrous band or elevation that is demarcated by two paramedian grooves forming an H- or V-shaped scar-like structure in approximately 30%.

Differential diagnosis. Krakowiak et al (29) reported a large family in which 21 individuals in 5 generations exhibited a variant of Freeman-Sheldon syndrome: triangular facies, downslanting palpebral fissures, attached earlobes, prominent nasolabial folds, small mouth, and micrognathia. In addition, there were short stature, marked camptodactyly with ulnar deviation, and calcaneovalgus. Features that distinguished this variant from classic findings included feeding difficulties during early infancy and a different shaped mouth and chin. Chin grooves were not present. There was resemblance to the cases of Kawira and Bender (26), Moore and Weaver (34), and case 2 of Freeman and Sheldon (14). It was the variant that was mapped to 11p15.5. Differential diagnosis includes arthrogryposis, *Schwartz-Jampel syndrome*, and *Burton syndrome*. The Burton syndrome is an autosomal recessive condition characterized by microstomia, pursed lips, ectopia lentis, and skeletal changes similar to those of *Kniest syndrome* and *dyssegmental dysplasia, Rolland-Desbuquois type*. However, no coronal clefts were noted. Scattered dense patches of extremely broad collagen fibers were found scattered throughout the cartilage matrix (7). We believe the constellation of anomalies seen here is sufficiently characteristic to cause little confusion with other entities. It should be pointed out that ulnar deviation of the fingers (windmill fingers) may have autosomal dominant inheritance (1,16,24,30). However, it is possible that windmill fingers are the same as craniocarpotarsal dysplasia in which craniofacial expression has been minimal. A severe form of Freeman-Sheldon syndrome has been described with brain anomalies and sensorineural hearing loss (22,56). This is probably the same as *cleft palate, whistling face, distal arthrogryposis and mental retardation*.

Laboratory aids. Electromyography has shown hypoplasia of the musculature of the buccinator and some of the hand and foot muscles (6,18,44,45). Biopsy of the buccinator muscle has shown fibrous connective tissue replacement of muscle bundles (44,49).

Trismus-pseudocampylodactyly syndrome (Hecht-Beals syndrome)

The syndrome of limited oral opening and curvature of the fingers at all interphalangeal joints on dorsiflexion of the wrists (pseudocampylodactyly) because of shortened flexor muscle-tendon units was described independently in 1969 by Hecht and Beals (6) and by Wilson et al (22). The family originated in the Netherlands (2,10,17,21). The disorder has autosomal dominant inheritance with variable expressivity (1,2,6–8,13,14,17–19,22,23). Hall et al (5) classified the disorder as a form of distal arthrogryposis. Linkage studies (14) done on the family reported by Yamashita and Arnet (23) were not fruitful.

The patients are normally proportioned, but stature is often reduced to between the 3rd and 25th centiles (3).

Facies. De Jong (2), Mercuri (12), and Fukumori et al (3) described blepharochalasis in older individuals, and a quilted appearance of the cheeks (Fig. 18–25).

Musculoskeletal alterations. In addition to mildly reduced stature and limited oral opening, the distinguishing features of the syndrome are limited to abnormalities of the extremities that result from shortness of various skeletal muscles or flexor tendons.

The hands may be clenched at birth but loosen during infancy and childhood (21). On dorsiflexion of the wrist, because of shortening of the

Fig. 18–25. *Trismus-pseudocampylodactyly syndrome*. Kindred of affected father and several affected and normal children showing attempt to open mouth fully. [From *F Hecht* and *RK Beals*, Birth Defects 5(3):96, 1969.)

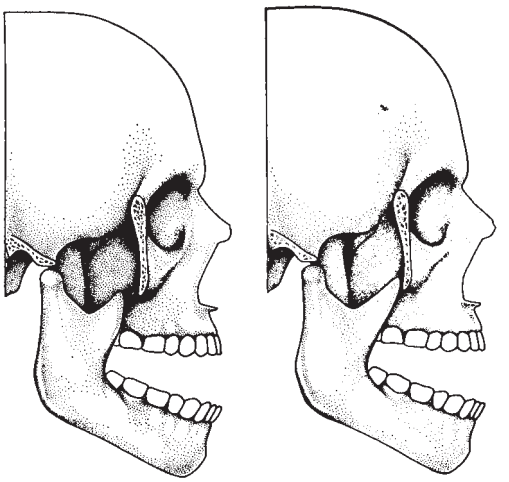

Fig. 18–27. *Trismus-pseudocampylodactyly syndrome*. Left, normal relationship. Right, enlarged coronoid process that prevents normal opening of jaws. (Courtesy of *RF Van Hoof*, Leiden, The Netherlands.)

flexor tendon-muscle unit, curvature of all fingers at each interphalangeal joint is noted. Upon volar flexion, all fingers are completely extended (Fig. 18–26). There is no associated muscular weakness, but there is mild limitation of dorsiflexion and supination at the wrist.

Leg or foot problems are found in at least 10%. Short leg muscles result in a variety of mild foot deformities: talipes equinovarus or calcaneovalgus, metatarsus varus, etc. Shortened hamstring muscles produce pelvic tilt with straight leg raising (16). Pes planus, hammer toes, and torticollis have also been noted (8,22).

Oral manifestations. The maximum aperture between the incisal edges of the upper and lower incisors ranges from 3 to 13 mm. This inhibits mastication, an affected individual requiring approximately twice as much time to consume a meal. Some infants cannot use a conventional nipple to feed. There may be difficulty with endotracheal intubation during general anesthesia.

The temporomandibular joints have been shown to be normal (8). The coronoid processes may be enlarged or distorted, unilaterally or bilaterally, and are often responsible for the inability to open the mouth widely because of their impingement on the zygomatic bones (Fig. 18–27). Fibrous bands extend from the maxilla to the mandible in the retromolar areas. The decreased opening may be secondary to shortening of the muscles of mastication, which in turn causes elongation of the coronoid processes (17). A hardened nodular cord has been noted in the region of the nasolabial furrow. Some patients have micrognathia (17).

Differential diagnosis. Inability to open the mouth must be differentiated from microstomia seen in a variety of disorders [*craniocarpotarsal dysplasia, chondrodystrophic myotonia* (*Schwartz-Jampel syndrome*), etc.]. Abnormalities, either congenital or acquired, of the temporomandibular joint may result in reduced jaw opening. Patients with the temporomandibular joint dysfunction syndrome cannot open their mouths widely, but this disorder can easily be differentiated from the syndrome under discussion.

Hall et al (4) reported a dominantly inherited disorder of small mouth with limited opening, outstanding pinnae, and flexion contractures of the hands.

Laboratory aids. Average opening between edges of incisor teeth is 49 mm (range 30–70 mm) in normal adults. From 8 to 12 years of age, the normal vertical distance is approximately 40 mm (range 25–55 mm) (6,9–11). This has also been our experience, but not that of Sheppard and Sheppard (15).

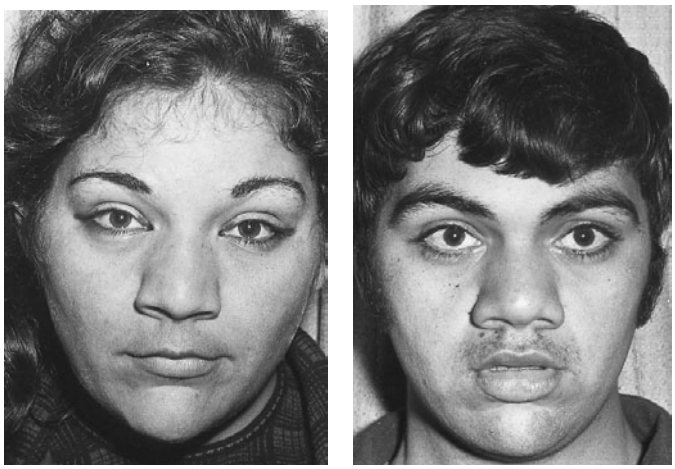
Unusual facies, camptodactyly with fibrous tissue hyperplasia, knuckle pads, and skeletal dysplasia

Goodman et al (1) described a consanguineous kindred of Jewish Iranian ancestry. Three sibs, two female and one male, manifested a broad nose with flared nostrils (Fig. 18–28). The hands and feet were especially large for stature. All digits of the hand except the thumbs were camptodactylous, the onset of which began around 10 years. Knuckle pads were noted on the second, third, and fourth fingers bilaterally (Fig. 18–29).

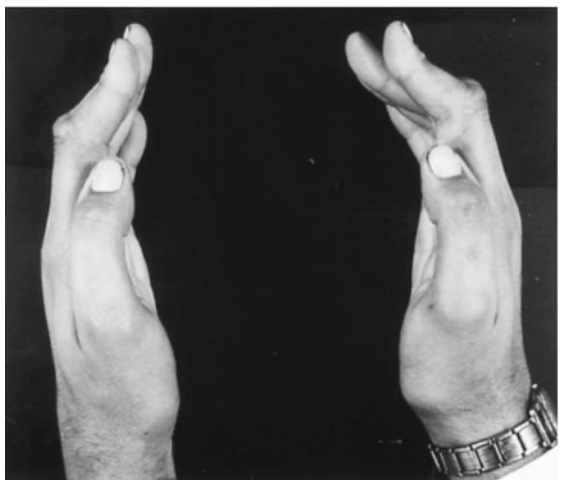


A B

Fig. 18–28. *Unusual facies, camptodactyly with fibrous tissue hyperplasia, knuckle pads, and skeletal dysplasia*. Note similar broad nose with round nostrils in sibs.

Fig. 18–29. *Unusual facies, camptodactyly with fibrous tissue hyperplasia, knuckle pads, and skeletal dysplasia*. Note camptodactyly and knuckle pads. (From *R Goodman et al*, J Med Genet 9:203, 1972.)

A



B

Hammertoes were bilateral. All had mild thoracic scoliosis. Each presented dull expression with low normal intelligence. Inheritance appears to be autosomal recessive.

Knuckle pads may be an isolated finding, associated with Dupuytren contractures, camptodactyly (3), or hypodontia.

Knuckle pads, leukonychia, hearing loss, and palmoplantar hyperkeratosis is known as Bart-Pumphrey syndrome (2). A dominant digitotalar dysmorphism has similar camptodactyly and rocker bottom feet (4).

Chapter 19
Branchial Arch and Oral-Acral Disorders

Oculo-auriculo-vertebral spectrum (hemifacial microsomia, Goldenhar syndrome)

In the 1960s, hemifacial microsomia was defined as a condition affecting primarily aural, oral, and mandibular development. The disorder varies from mild to severe, and involvement is limited to one side in many cases, but bilateral involvement is also known to occur, with more severe expression on one side. Goldenhar syndrome is considered a variant of this complex, characterized additionally by vertebral anomalies and epibulbar dermoids (55). The condition is now known to be extremely complex and heterogeneous. Thus, in the present edition we have employed the term oculo-auriculo-vertebral (OAV) spectrum.

The first recorded cases may have been those of Canton (21), in 1861, and von Arlt, in 1881 (6). An excellent early review is that of Geissmar (47). There are numerous important reviews in modern times (5,9,13, 20,26,27,42,57,88,91,100,126–128,143).

The many terms used for this complex indicate the wide spectrum of anomalies described and emphasized by various authors. The complex has been known as hemifacial microsomia, oculo-auriculo-vertebral dysplasia, facio-auriculo-vertebral dysplasia, Goldenhar syndrome, Goldenhar-Gorlin syndrome, first arch syndrome, first and second branchial arch syndrome, lateral facial dysplasia, unilateral craniofacial microsomia, otomandibular dysostosis, unilateral mandibulofacial dysostosis, unilateral intrauterine facial necrosis, auriculo-branchiogenic dysplasia, and facio-auriculo-vertebral malformation complex (73). These terms have been reviewed elsewhere (27). Systems of classification, OMENS-plus and others, have been advocated by Horgan et al (70), Vento et al (164), and Cousley (31).

Although there are no agreed upon minimal diagnostic criteria, the facial phenotype is characteristic when enough manifestations are present. In some instances, isolated microtia or auricular or preauricular abnormality may represent the mildest manifestation (12,57,90,128,155). Unilateral microtia or ear abnormality, including preauricular tags, has been suggested as a mandatory feature by some authors (128). Involvement is not limited to facial structures; cardiac, renal, skeletal, and other anomalies may also occur. In particular, the so-called "expanded Goldenhar complex" has demonstrated a wide spectrum of central nervous system malformations not previously appreciated (2–5,111,165). It has been suggested by several authors that invalid nosologic splitting, on the one hand, and inappropriate lumping on the other, complicate our understanding of this complex (26,27,68,105,110,156). Those with the Goldenhar end of the spectrum constitute only approximately 10% of the cases (128).

Poswillo (118) suggested a frequency of 1/3500 births, although he presented no data to support his conjecture. Grabb (57) estimated 1/5600 births. Stoll (147) noted a prevalence of 1/19,500 consecutive births. Melnick (91) recorded a frequency of 1/26,550 live births in a prospective newborn study. Our impression is that the true frequency is near that offered by Grabb (57). The male:female ratio is at least 3:2 (127,165); there is also a 3:2 predilection for right-sided ear involvement (25,127).

Poswillo (117–119), using an animal model, showed that early vascular disruption with expanding hematoma formation *in utero* resulted in destruction of differentiating tissues in the region of the ear and jaw. The severity appeared to be related to the degree of local destruction. Other theories involve disturbances in branchial arches or in various populations of neural crest cells that impede development of adjacent medial or frontonasal processes. The constellation of anomalies suggests their origin at approximately 30–45 days of gestation. This has been confirmed in humans by demonstration of disruption of vascular supply (55,124,146). Disturbance in chondrogenesis has also been espoused as a theory (32,54). A common pathway for CHARGE association and OAV spectrum has been suggested (163).

First and second branchial arch anomalies often combined with facial palsy have been observed in infants born to pregnant women exposed to thalidomide (95,130), primidone (63), and retinoic acid (83). The OAV phenotype has also been noted in infants with *diabetic embryopathy* (59). A transgenic mouse model has been created (104).

Several chromosomal anomalies have been associated including del(5p) (82,105), del(6q) (58), trisomy 7 mosaicism (69), del(8q) (161), trisomy 9 mosaicism (166), trisomy 18 (14,58), recombinant chromosome 18 (149), del(18q) (33), ring 21 chromosome (58), del(22q) (67), dup(22q) (65), trisomy 22 (78), 49,XXXXX (140), 49,XXXXY (81), and 47,XXY (116).

Discordance in monozygotic twins has been reported frequently (16,17,22,29,30,37,53,57,107,112,128,142,147). Rarely, concordance with variable expression including mirror imaging has been documented in monozygotic twins (126,133,138,156). Discordance has been reported in dizygotic twins (57,65,121,144), in twins of undetermined zygosity (15,52,108), and in triplets (154). The rarity of reports of concordance of the defect in twins supports the suggestion that the condition is sporadic in most families. The interested reader is referred to the excellent analysis of Burck (20).

Most cases are sporadic, but familial instances may also be observed. Within families, expression varies. For example, there are reports of ear and mandibular involvement in two first-degree relatives, and reports of isolated microtia or preauricular tags in one first-degree relative of a patient with ear and mandibular involvement (128). These reports support the suggestion that isolated microtia or preauricular tags may represent the mildest expression in some families (57,90,127,128,155). Affected individuals in successive generations have been observed (26,57,68,98,109,121,123,129,142,150,154,157). Affected sibs with normal parents have also been reported (57,77,79,136). Consanguinity was noted in a single sporadic instance (110). Although autosomal dominant and autosomal recessive inheritance have been suggested to explain the rare familial occurrence, etiologic heterogeneity is a more likely explanation for most cases. Using segregation analysis, Kaye et al (76) opted for autosomal dominant inheritance. Overall, it would be compatible with a low empiric recurrence risk of 2%–3% (57,128), and the usual discordance and rare concordance (13%) between monozygotic twins (171). Some families (50,68,121,148,150), probably representing 1%–2% of the cases, clearly manifest an autosomal dominant form with variable penetrance. Involvement tends to be bilateral, but without eye or vertebral involvement. D Kelberman (personal communication, 2000) indicated that the gene maps to 14q32 (76a). RJ Gorlin (2001) documented a large family that does not map to 14q32.

A branchial arch anomaly should be regarded as a nonspecific symptom complex that is etiologically and pathogenetically heterogeneous. Evaluation of first-degree relatives is important to exclude mild facial manifestations of the defect and various extracranial anomalies. Recurrence risk counseling should be provided on an individual family basis.

Extreme variability of expression is characteristic (Figs. 19–1 to 19–3). Approximately 50% have been noted to have other anomalies in addition

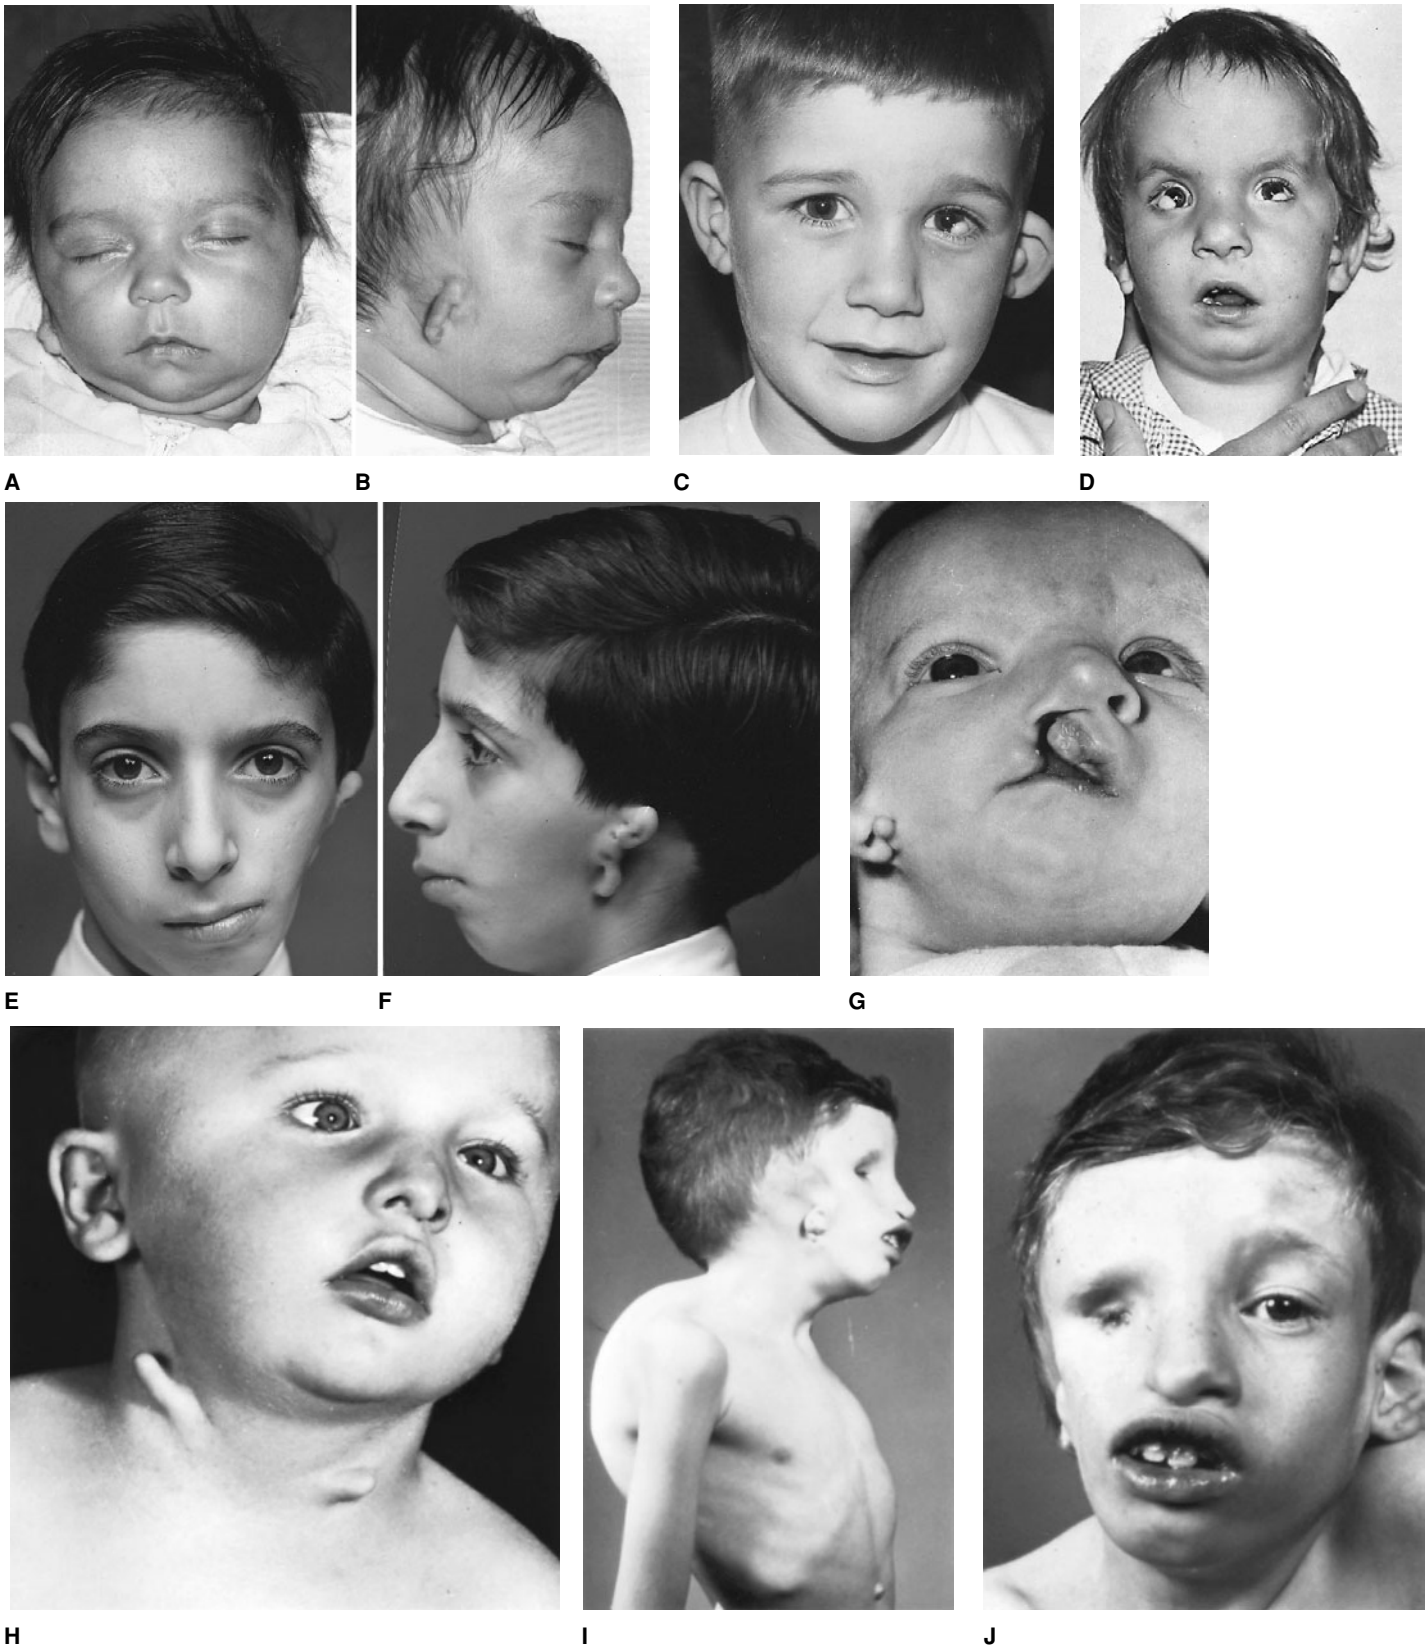

Fig. 19–1. *Oculo-auriculo-vertebral spectrum*. (A–J) Variable degrees of severity. Compare facies. Note cleft lip-palate, ear anomalies, and epibulbar dermoid in G. to the principal features of the defect (127). Not uncommonly the infants are small for their ages and may have feeding difficulties that may be related to cleft lip and/or cleft palate or an anatomically narrow pharyngeal airway. Obstructive sleep apnea diagnosed by all-night polysomnography and nasopharyngoscopy has been described (144). Scrupulous medical and nursing care in the first few weeks can often prevent the need for surgical gastrostomy (143).

Facies. Marked facial asymmetry is present in 20% but some degree of asymmetry is evident in 65% (146). This is because of both displacement and/or abnormality of the pinna and also to underlying abnormalities of skeletal support. The asymmetry may not be apparent in the infant or young child but can surface with growth, usually becoming apparent by age four. Adequate overlying soft tissues may mask the skeletal asymmetry (Fig. 19–1). Conversely, a deficient soft tissue mass overlying adequate bony structures may result in facial asymmetry (42). The exact relationship between bone and muscles of mastication is still hotly debated (163a).

The maxillary, temporal, and malar bones on the more severely involved side are somewhat reduced in size and flattened (131). Asymmetry may result from aplasia or hypoplasia of the mandibular ramus and condyle. Some patients manifest mild pneumatization of the mastoid region. Approximately 10%–33% of patients have bilateral involvement (22,57,127). The disorder is nearly always more severe on one side. Among 193 unilaterally affected patients studied by Rollnick et al (127), the right side was involved in over 60%. Frontal bossing can be noticeable at birth but becomes less apparent with time (55). The reader is referred to various anthropometric studies (39,40,74,145).

Eye. Blepharoptosis or narrowing of the palpebral fissure occurs on the affected side in approximately 10%. Unilateral palpebral shortening was noted in 6 of 57 patients studied by Mansour et al (88). Elevated orbit is seen in 7% (106). Clinical anophthalmia or microphthalmia has been described in several patients who also manifested severe mental retardation (2,9,25,26,89,143,165). Various retinal abnormalities have been

reported (89). Epibulbar tumors (Fig. 19–2A) are found in approximately 35% (9,52,88). They appear as solid yellowish or pinkish white ovoid masses varying in size from that of a pinhead to 8–10 mm in diameter. They occur most often at the inferotemporal quadrant at the limbus. The surface is usually smooth and frequently has fine hairs. They can occur at any location on the globe or in the orbit and can be dermoid (white solid masses), lipo-dermoid (yellow, movable, conjunctival), or dermis-like or complex (mesoectodermal). Unilateral epibulbar dermoids are seen in 50% (9). Bilateral lesions occur in 25% and have a tendency to be symmetrically placed in both eyes. However, multiple lesions can occur in the same eye. Lipodermoids are less common (25%), more often bilateral (20%), and more often superotemporal or inferotemporal (9). Vision may be impaired by encroachment on the pupillary axis, by lipid infiltration of the cornea, or as a result of astigmatism (9).

Removal of the masses can lead to scar formation with resultant leukoma.

Patients with epibulbar dermoids have a higher frequency of eyelid, extraocular, and lacrimal drainage abnormalities (9,62,88), microcornea, blepharoptosis (9), microphthalmia, and clinical anophthalmia (88,127). Unilateral colobomas of the upper lid are noted in approximately 20%, bilateral in possibly 3% (9) (Fig. 19–2B). Other ocular motility disorders, found in up to 25%, include esotropia, exotropia, and Duane syndrome (3,9,96,114). Choroidal or retinal colobomas, congenital cystic eye, Peters anomaly, and various other anomalies may be found occasionally (9,48).

Skin tags are the only characteristic of the syndrome that correlates with epibulbar dermoids for laterality (88). This association/localizing significance might be related to the fact that both are histologically choristomas.

Ear. Abnormalities ranging from anotia to an ill-defined mass of tissue that is displaced anteriorly and inferiorly, to a mildly dysmorphic ear are found in over 65% (Fig. 19–2C,D) (25). Farkas et al (39) showed no direct relationship between the degree of microtia and the extent of facial defect, whereas other authors have shown moderate correlation (42). Occasionally, bilateral anomalous pinnae are noted. Preauricular tags of skin and cartilage are extremely common, and may be unilateral or bilateral. Supernumerary ear tags may occur anywhere from the tragus to the angle of the mouth. They are more commonly seen in patients with macrostomia and/or aplasia of the parotid gland and epibulbar dermoids. Preauricular sinuses and/or tags are noted in greater than 40%. Narrow external auditory canals are found in more mild cases; atretic canals are seen in more severe cases. At times, small auricles with normal architecture are seen. Isolated microtia is considered a microform of OAV spectrum (12). Rollnick et al (127) require at least some ear involvement to confirm the diagnosis. Many previous studies included patients without ear involvement (57,134,155). Both conductive and, less frequent (15%), sensorineural hearing loss because of lesions of the middle and external ears, hypoplasia or agenesis of ossicles, aberrant facial nerves, patulous or absent eustachian tube, and skull base anomaly have been reported in greater than 50% (8,9,83a,97,135,164,170).

Central nervous system. A wide range of central nervous system defects may be associated with the OAV spectrum, and reported frequencies of mental deficiency appear to have ascertainment bias. For example, series preselected for severe central nervous system malformations have an inordinately high frequency of mental retardation, whereas those reported as treated patients from various craniofacial centers tend to have a low frequency. Most estimates range from 5% to 15% (143). Higher frequencies are those reported by Tenconi and Hall (37%) (155) and Wilson (82%) (165). Cohen (26) suggested an association between microphthalmia or clinical anophthalmia and mental retardation, as the eye is an outpouching of the primitive brain.

Neurodevelopmental studies (28) have shown that those with lower muscle tone, bilateral involvement, and cervical vertebral involvement have increased risk for delay.

Nearly all cranial nerves have occasionally been involved (5,120). Lower facial weakness occurs in 10%–20%, probably being related to bony involvement in the region of the facial canal (8,57). Abnormal course of the seventh cranial nerve (170) and unilateral aplasia of the trigeminal nuclei and the facial nerve (5,37) have been described, as well as trigeminal anesthesia (37,167). Other cranial nerves involved have included I (2), II (89), III, IV, and VI (3), and VIII, IX, and X (5).

The range of skull defects includes cranium bifidum, microcephaly, dolichocephaly, and plagiocephaly (5).

For the expanded oculo-auriculo-vertebral spectrum, brain malformations have been discussed especially well by Aleksic et al (5). Intracranial anomalies may include occipital and frontal encephaloceles, hydrocephaly, lipoma of corpus callosum, dermoid cyst, teratoma, Arnold-Chiari malformation, lissencephaly, arachnoid cyst, holoprosencephaly, porencephalic cyst, unilateral arhinencephaly, and hypoplasia of the corpus callosum (2,4,10,26,62,63,68,94,101,111,139,143,158,162,165). This group tends to be retarded or to suffer early death (139).

When flattened frontal encephalocele occurs, the patient appears to have frontonasal malformation together with ear tags, other ear anomalies, and even epibulbar dermoids (44,62). Since encephalocele is more common in the occipital region than in the frontal region, we suggest that cases of so-called frontonasal malformation with epibulbar dermoids and ear tags may represent oculo-auriculo-vertebral spectrum with the encephalocele expressed anteriorly (27).

Trachea and Lung. Approximately 5% have tracheo-esophageal fistula (19,92,115,125,151). Pulmonary anomalies range from incomplete lobulation to hypoplasia to agenesis, unilateral or bilateral, the absent lung usually being ipsilateral to the facial anomalies (Fig. 19–3F) (18,19,64,115).

Heart. A range of from 5% to 58% of patients with various forms of heart anomalies have been reported (46,80,99,115,143,155,165). Ventricular septal defect and tetralogy of Fallot with or without right aortic arch account for 65% of the anomalies, although no single cardiac lesion is characteristic. A wide variety of associated cardiac findings including transposition of the great vessels, tubular hypoplasia of the aortic arch associated with mild coarctation of the aorta, cardiomegaly, rare isolation of the left innominate artery with bilateral PDA (isolated or in combination with other anomalies), pulmonary stenosis, dextrocardia, double outlet right ventricle, and other aortic arch abnormalities have been described (115,127). Hypoplasia of the external carotid artery and situs ambiguus also have been noted (55).

Skeletal alterations. Facial anteroposterior and vertical dimensions are reduced on the affected side, especially in the lower face toward the otocephalic center (Fig. 19–3A–C). Approximately 10% have ipsilateral frontal plagiocephaly (106). The temporomandibular joint is anteroinferiorly displaced. Often the orbit is reduced in size and elevated in approximately 7% (106,146). Cervical spine, cranial base anomalies and torticollis occur with increased frequency. Skull defects also have been noted (26,62,94,101). This group seems to have a worse prognosis (165). Cervical vertebral fusions (Fig. 19–3E) occur in as many as 60%, whereas platybasia and occipitalization of the atlas are found in approximately 30% (7,41,56). Spina bifida, hemivertebrae, butterfly, fused and hypoplastic vertebrae, Klippel-Feil anomaly, MURCS association, scoliosis, and anomalous ribs (agenesis, bifidity, fusion, supernumerary) occur in at least 30% (Fig. 19–3D) (7,39,66,125,162). Talipes equinovarus has been reported in approximately 20% (38). Radial limb anomalies have been noted in approximately 10%. These may take the form of hypoplasia or aplasia of radius and/or thumb and bifid or digitalized thumb (55,92,98,165). Poland anomaly has been reported but may be aleatory (24). Caudal regression has also been noted (132).

Kidney. A variety of renal abnormalities have been reported: absent kidney, double ureter, crossed renal ectopia, anomalous blood supply to the kidney, hydronephrosis, hydroureter, and other defects (22,27,143).

Gastrointestinal anomalies. Imperforate anus with or without rectovaginal fistula has been described. Situs inversus has been described (54a).

Oral manifestations. At least 35% with agenesis of the mandibular ramus have associated macrostomia or pseudomacrostomia, that is, lateral facial cleft, usually of mild degree. In the presence of epibulbar dermoids, the frequency of macrostomia may be somewhat higher. It is nearly always unilateral and on the side of the more affected ear. Occasionally, there may be agenesis of the ipsilateral parotid gland, displaced salivary gland tissue, or salivary fistulas. Intraorally, there is decreased palatal width from the midline palatal raphe to the lingual surface of the teeth on the affected side. The palatal and tongue muscles may be unilaterally hypoplastic and/or paralyzed. Unilateral or bilateral cleft lip and/or cleft palate occurs in 7%–15% of patients (43,127). Cleft palate is twice as common as cleft lip with or without cleft palate (91). Tooth maturation is not affected significantly on the involved side (38,85). Canting of the occlusal plane and malocclusion are common (Fig. 19–2E). The

occurrence of a tongue-like structure projecting from the tonsillar pillar in place of a tonsil has been reported by several authors (93,137,141). In some cases there was partial aplasia of the soft palate, ear atresia, and facial palsy.

Approximately 35% have velopharyngeal insufficiency (86). Shprintzen (144) reported 12 patients with velopharyngeal insufficiency, and 2 of the 12 had cleft palate. Among the 10, the insufficiency resulted from asymmetry of movement of the lateral pharyngeal wall and dyssynchrony of palatal motion. Tongue restriction and hypernasality have been studied (134).

Differential diagnosis. The OAV spectrum is phenotypically variable and causally heterogeneous (126). It is essential to exclude various chromosome disorders and several syndromes with overlapping features. *Townes-Brocks syndrome* (72,160) consists of dysplastic ears, ear tags, and hearing loss in addition to thumb anomalies, anal defects, and renal anomalies. It has autosomal dominant inheritance. The *branchio-oto-renal (BOR) syndrome* is associated with mixed hearing loss, preauricular pits, branchial fistulas or cysts, anomalous pinnae, malformed middle or inner ear, lacrimal duct stenosis/aplasia, and/or renal dysplasia. There is autosomal dominant inheritance with high penetrance and variable expression. Families have been described in which first-degree relatives have varying features of hemifacial microsomia and/or BOR, suggesting that in some instances hemifacial microsomia may constitute a component toward the severe end of the spectrum of the BOR syndrome (129). Epibulbar dermoid may be an isolated finding. Corneal dermoids are usually isolated (61). Preauricular skin tags or nodules occur in approximately 1% of the normal population and may be familial (127,152).

The characteristic features of OAV spectrum are distinguishable from *mandibulofacial dysostosis*, *maxillofacial dysostosis, Nager acrofacial dysostosis*, and *postaxial acrofacial dysostosis*. Facial involvement in the OAV spectrum is usually asymmetric, with one side of the face more severely involved (127). Furthermore, there is far less hypoplasia of the malar bones present. Partial to total absence of the lower eyelashes has not been reported in the OAV spectrum. Preauricular tags occur less often in mandibulofacial dysostosis.

Colobomas in OAV spectrum affect the upper eyelid; in mandibulofacial dysostosis and Nager acrofacial dysostosis the notch is in the outer one-third of the lower lid. Upper eyelid colobomata may occur very rarely as an isolated finding (1).

Characteristics of the VATER association (vertebral anomalies, ventricular septal defect, anal atresia, T-E fistula with esophageal atresia, and radial and renal dysplasia), the *CHARGE association* (*c*oloboma, *h*eart disease, *a*tresia choanae, *r*etarded growth and development, *g*enital anomalies, and *e*ar anomalies and/or hearing loss), and the MURCS association (*Mü*llerian duct aplasia, *r*enal aplasia, and *c*ervicothoracic *s*omite vertebral dysplasia) overlap with the OAV spectrum. It has been pointed out that some patients share stigmata of both OAV spectrum and *frontonasal malformation*, *oculoauriculofrontonasal dysplasia*, and *ophthalmofrontonasal dysplasia* (23,26,34,44,45,51,60,62,63,102, 103,155,159). Duncan and Shapiro (36) discussed overlap with VATER association. Several authors have described OAV spectrum with complex malformations of left–right asymmetry (22,84,87).

Laboratory aids. Prenatal diagnosis by ultrasonography in severe hypoplasia of mandible, severe abnormality of the auricle, and cleft lip and/or cleft palate may be helpful in some cases (11,35,153). Polyhydramnios may be present. CT to see the middle ear bones when evaluating hearing. Radiographic analysis for skeletal findings is also indicated. The descent of the tegmen may, in association with microtia, be the most reliable clinical marker of OAV spectrum. The level of the tegmen below the base of the middle cranial fossa appears to bear a direct relationship to the severity of the disorder (113).

Oculoauriculofrontonasal spectrum (ophthalmofrontonasal dysplasia, Golabi-Gonzales-Edwards syndrome)

Some patients share the stigmata of both OAV spectrum and frontonasal malformation. Variously this has been termed oculoauriculofrontonasal dysplasia, ophthalmofrontonasal dysplasia, and Golabi-Gonzales-Edwards syndrome (1–15). It is debatable whether this hybrid condition merits a separate classification but cases will be summarized for the reader (1). At least 15 examples have been reported.

Since encephalocele is more common in the occipital region than in the frontal region, we suggest that cases of so-called frontonasal malformation with epibulbar dermoids and ear tags may represent oculo-auriculo-vertebral spectrum with the encephalocele expressed anteriorly (2).

As in *frontonasal dysplasia*, there is no single gene inheritance. Golabi et al (6) reported affected sibs. Toriello et al (15) suggested heterogeneity.

In addition to the usual facial stigmata of frontonasal dysplasia (ocular hypertelorism, wide nasal bridge) and oculo-auriculo-vertebral spectrum (microtia, skin tags, epibulbar dermoids, cleft lip, macrostomia), various other findings have been demonstrated. Only rarely are epibulbar dermoids absent (2,14) (Fig. 19–4).

Central nervous system. Four encephaloceles have been documented. Two were posteriorly located (4,14), two anteriorly placed (9,10). Mental retardation was noted (2,14).

Heart. Congenital heart anomalies have been reported rarely (5,14).

Skeletal anomalies. Fusion of the posterior aspects of C_2-C_3 has been found (6).

Diagnosis. A fetal example was reported by Kennedy et al (11). The child described by Guion-Almeida and Richieri-Costa (8) has many of the stigmata seen in oculoauriculofrontonasal spectrum.

Mandibulofacial dysostosis (Treacher Collins syndrome, Franceschetti-Zwahlen-Klein syndrome)

Mandibulofacial dysostosis (Figs. 19–5 to 19–7) involves structures derived from the first and second pharyngeal arch, groove, and pouch. Although the syndrome was probably first described by Thomson (63) and Toynbee (64) during 1846-1847, credit for its discovery is usually given to Berry (5) or, especially, to Treacher Collins (65) who described the essential components of the syndrome. Franceschetti and co-workers (15,16), during the 1940s, published extensive reviews of the disorder and coined the term *mandibulofacial dysostosis*. An excellent review is that of Dixon (8). The reader should enjoy the article by Winter (71).

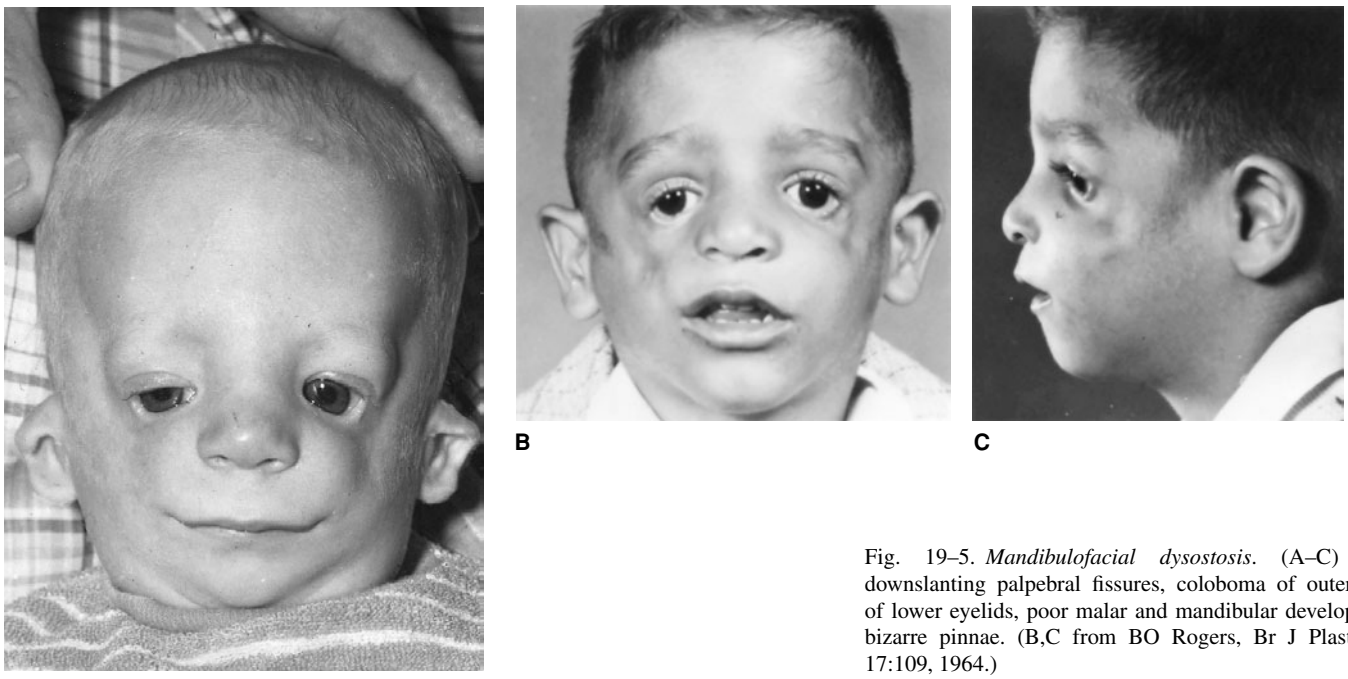
The syndrome has autosomal dominant inheritance with variable expressivity (10,57,60,68). Nonpenetrance is rare (39). Roughly 60% represent new mutations (16,28). Among these, the fathers tend to be older (28). Perhaps 450 or more cases have been published. The frequency is approximately 1 per 50,000 live births (57). The gene for the syndrome (Treacle or TCOF1) has been mapped to 5q32–33.1 (10–13,25,26,59a). The gene encodes a putative nucleolar phosphoprotein (71). The mutation leads to premature termination of the coded protein (8–12,14,20,66,72). A mild example has been found in association with an interstitial deletion, del(3)(p23;p24.12) (1). We assume that the severe example shown by Hansen et al (22) is the result of uniparental disomy producing homozygosity for the gene.

Poswillo (50), Sulik et al (61), and Wiley et al (69) employing mouse, rat, and hamster models gave teratogenic doses of vitamin A and isotretinoin and produced malformations of the craniofacial skeleton that closely resembled the syndromic features of human mandibulofacial dysostosis. Histological studies indicated that abnormalities of neural crest development occurred in these phenocopies but whether the principal defect is in migration or differentiation of the ectomesenchymal cells or their death in the condensing trigeminal ganglia or results from the effects on the first and second arch placodal cells following their release from the neural folds of neural crest cells into the developing cranial regions remains unclear (3,23,61). Apoptosis in the prefusion neural folds seems to play a critical role (12a).

Facies. The facial appearance is characteristic. Abnormalities are bilateral and usually symmetric (Fig. 19–5), but not always (70). The nose appears large but really is not (29); the appearance is secondary to hypoplastic supraorbital rims and hypoplastic zygomas. The face is narrow. Downward-sloping palpebral fissures, depressed cheekbones, malformed pinnae, receding chin, and large down-turned mouth are characteristic. Approximately 25% manifest a tongue-shaped process of hair that extends toward the cheek (56).

Skull. The calvaria is essentially normal, but radiographic studies reveal that the supraorbital ridges are poorly developed (40,45,60). The body of the malar bones may be totally absent but more often is grossly and symmetrically underdeveloped, with nonfusion of the zygomatic arches. The zygomatic process of the frontal bone is hypoplastic as are the lateral pterygoid plates and muscles. The mastoids are not pneumatized and are frequently sclerotic (62). The paranasal sinuses are often small and may be completely absent. The orbits are hyperteloric (29). The lower margin of the orbit may be defective and the infraorbital foramen is usually absent. The cranial base is progressively kyphotic (30,47) resulting in airway difficulties. The mandibular condyle and coronoid process are severely hypoplastic, flat, or even aplastic (Fig. 19–6). The undersurface of the body of the mandible is quite concave. The angle is more obtuse than normal, and the ramus is deficient. The condyle is covered with hyaline cartilage rather than fibrocartilage. The condylar neck is short. There is no articular eminence, and the articular area is atypically medial (19,21,42,55). There have been several excellent anatomic studies (3,6,23,33,41) and detailed craniofacial measurements (2,9).

Eyes. The palpebral fissures are short and slope laterally downward and, often (75%), there is a coloboma in the outer third of the lower



A B C

Fig. 19–5. *Mandibulofacial dysostosis*. (A–C) Note downslanting palpebral fissures, coloboma of outer third of lower eyelids, poor malar and mandibular development, bizarre pinnae. (B,C from BO Rogers, Br J Plast Surg 17:109, 1964.)

Fig. 19–6. *Mandibulofacial dysostosis*. Radiographs. (A) Lateral cephalogram showing extremely steep mandibular plane angle, antegonial notching, and mandibular deficiency. Soft tissue demonstrates prominent nasal contour, acute nasolabial angle, and lip incompetence. (B) Panorex X-ray showing prominent antegonial notching and open bite.

lid (Fig. 19–7). We have seen several patients in whom the downward slope is asymmetric. Approximately half of the patients have deficiency of cilia medial to the coloboma. Iridial coloboma may also occur. The lower lacrimal points may be absent as well as the Meibomian glands and intermarginal strip (22,37). The eye anomalies have been especially well reviewed by Franceschetti et al (17).

Ears. The pinnae are often malformed, crumpled forward, or misplaced toward the angle of the mandible. In the survey of Stovin et al (60), 51 of 63 patients had anomalous pinnae with meatal atresia and over one-third had absence of the external auditory canal or ossicle defect accompanied by bilateral conductive hearing loss in at least 55% (36). Pron et al (51), in a CT study, found normal, stenotic, and atretic external canals associated with 44,54, and 62 dB loss, respectively. Those without ossicles had flat conductive loss, whereas those with ankylosed or hypoplastic ossicles had flat (60%) or sloping (40%) audiograms. Kolar et al (29) found microtia in 60%. The auditory ossicles and cochlear and vestibular apparatus have been observed to be absent or severely malformed (24,32,37,41,49,62,67) and often asymmetric in severity (67). Radiographic and surgical studies have shown agenesis or hypoplasia of the mastoid, absence of the external auditory canal, narrowing or agenesis of the middle ear cleft, agenesis or malformation of the malleus and/or incus, monopodial stapes, absence of stapes and oval window, ankylosis of stapes in the oval window, deformed suprastructure of stapes, complete absence of middle ear and epitympanic space (36). The space may be filled with connective tissue. The inner ears are normal (24,32,37,41).

Extra ear tags and blind fistulas may occur anywhere between the tragus and the angle of the mouth. In one case, blind fistulas were found behind the ear lobes (21).

Nose. The nasofrontal angle is usually obliterated, and the bridge of the nose raised. The nose appears large (29) because of the lack of malar development and hypoplastic supraorbital ridges. The nares are often narrow, and the alar cartilages hypoplastic. Choanal atresia has been reported (35,42,58). Obstructive sleep apnea is not rare (27).

Mental status. Intelligence is usually normal. However, Stovin et al (61) reviewed 63 patients and found four who were mentally deficient. Other investigators have also noted mild mental retardation in their patients (21). We suspect that the "retardation" may be secondary to hearing loss.

Oral findings. The palate is cleft in approximately 35% (11,45, 48,60). Congenital palatopharyngeal incompetence (agenesis of soft palate, foreshortened soft palate, submucous palatal cleft, immobile soft palate) has been found in an additional 30%–40% (48). Rarely cleft lip-palate has been noted. Macrostomia, observed in approximately 15%, may be unilateral or bilateral. The elevator muscles of the upper lip are deficient (23). The parotid salivary glands may be absent or hypoplastic (23,38,41). Pharyngeal hypoplasia, a constant finding, may explain cases of neonatal death (59).

Differential diagnosis. *Oculoauriculovertebral spectrum* is easily excluded. The facies is so characteristic that little difficulty in diagnosis should be experienced. However, affected relatives may have minimal signs of the syndrome and must be closely examined. A sporadic case with minimal involvement can present difficulties in diagnosis.

Nager acrofacial dysostosis closely resembles mandibulofacial dysostosis. The thumbs are hypoplastic or absent, the radius and ulna may be fused or there may be absence or hypoplasia of the radius and/or one or more metacarpals. Lower lid colobomas are rarer, cleft palate more frequent, and the mandible more severely retarded in growth than in mandibulofacial dysostosis.

Dominantly inherited and X-linked maxillofacial dysostosis consists of bilateral hypoplasia of malar bones, downward-slanting palpebral fissures without colobomas, maxillary hypoplasia, open bite, and relative mandibular prognathism.

A similar facies has been seen in an autosomal recessive disorder found in Hutterites (34), in an autosomal dominant osteosclerotic disorder (31), and in a father and son with ectrodactyly (see EEC syndrome). Richieri-Costa (53) and Stovin et al (60) described autosomal recessive mandibulofacial dysostosis. Richieri-Costa et al (52) reported a woman with mandibulofacial dysostosis and tibial hemimelia. Robb et al (54) found mandibulofacial dysostosis with tracheoesophageal fistula, rectovaginal fistula, and anal atresia.

Laboratory aids. Midtrimester sonographic diagnosis has been accomplished (3,4,6,43). Fetoscopy has also been employed (46).

Autosomal dominant mandibulofacial dysostosis (Bauru type)

Marçano and Richieri-Costa reported a Brazilian family with 5 affected members having malar hypoplasia, cleft lip/palate, micrognathia, mild down-slanting palpebral fissures, and abnormal pinnae (Fig. 19–8).

Inheritance is autosomal dominant.

Fig. 19–8. *Mandibulofacial dysotosis (Bauru type)*. Thirty-one-year old woman with mild downslanting palpebral fissures, malar hypoplasia, repaired cleft lip and micrognathia. She also had hypoplastic tragus and ear lobes. (From ACB Marçano and A Richieri-Costa, Braz J Dysmorphol Speech Hear Dis 2:37–41, 1998.

Acrofacial dysostosis, type Nager (preaxial acrofacial dysostosis)

Nager acrofacial dysostosis is a mandibulofacial dysostosis associated with radial defects. Since the original description of the syndrome by Nager and DeReynier (38) in 1948, over 85 cases have been reported (1–11,14–17,19–26,28–32,34–36,38–45,48,51,52,54–56a,58–60).

Growth retardation is noted in 10% (5,6,16,59). Death during the neonatal period is documented in 20% (6,7,21,22,25,26,30,34,52,55,56a).

Most cases of Nager acrofacial dysostosis have been sporadic. Mildly to moderately affected sibs with apparently normal parents have been described (6,7,22,40,48,58), suggesting autosomal recessive inheritance. Single cases with consanguineous parents have lent some support to this concept (5,26,45,56a). Transmission from parent to child has been reported (1,21,28,31,35,59). One family with six affected individuals covering four generations was briefly presented (59). Advanced paternal age in sporadic cases has supported autosomal dominant inheritance (4,32,34). Manifestations within a family may be markedly consistent, as in the mildly to moderately affected father and son reported by Aylsworth et al (1). In contrast, Hall (21) described extreme intrafamilial variability: a mildly to moderately affected mother, whose son died minutes after birth with severe phocomelic Nager acrofacial dysostosis. Palomeque et al (43) described an extremely severe example. Bonthron et al (3) reported minor changes in parents. Genetic heterogeneity clearly challenges both diagnosis and counseling. Apparent recessive inheritance could represent nonpenetrance or gonadal mosaicism. Alternatively both autosomal dominant and recessive forms of the disorder may exist. One cannot assume that mild to moderate cases are more likely to be recessive whereas severe cases are dominant. After the birth of one affected child, a couple

A B

Fig. 19–9. *Preaxial acrofacial dysostosis (Nager).* (A,B) Note malar hypoplasia, slight downslanting of palpebral fissures, almost total absence of eyelashes, low-set, cup-shaped ears, and micrognathia. [A from FA Walker, Birth Defects 10(8):135, 1974. B from P Bowen and F Harley, Birth Defects 10(5):109, 1974.]

should be offered high resolution ultrasonography in a subsequent pregnancy. In one patient, a probably balanced chromosome 9q32 translocation was found (62). Another had deletion 1q12–q21 (56b).

Craniofacial findings. Abnormalities of the cranium have been described in 25% (14,16,21). Hypoplasia of the zygomata, maxilla, and mandible are almost constant features (Fig. 19–9). The palpebral fissures are down-slanting in approximately 100%. An estimated 80% have absence of the medial third of the lower eyelashes (4,11,20,25,26,29,32,36,40,58,59) with coloboma of the lower lid being noted in almost 50% (16,20,26,58,59). A high nasal bridge with upturned nasal tip is a constant feature. A tongue-like extension of hair onto the cheek is seen occasionally (20,25,26). Limited jaw movement secondary to functional ankylosis of the temporomandibular joints is present in approximately 25% (4,16,20,24,25,29,36,40). Greater than 20% have macrostomia (17,25,26,29,45,52), occasionally in association with lateral facial clefts (17,26). Abnormalities of the palate are frequent, and include cleft palate in over 60%, agenesis or partial agenesis of the soft palate (10,24), short soft palate (4,7,32), highly arched palate (11,26), submucous cleft palate (20), and bifid uvula (20,58). Cleft lip has been reported in 10%. Bilateral lateral palatine fistulae (32), broad palatine ridges (1), and hypoplasia of the epiglottis (7,30) have also been reported. Dental anomalies include enamel hypoplasia and oligodontia (32). Facial asymmetry is rare (36).

The auricles are dysplastic in 80%. Hypoplasia of the anthelix (20), tragus (4,20), antitragus (20), and helix (14,32) have been described. The pinnae are occasionally simple and small (16,21) with a preauricular tag (21,26,32,59), and are frequently low set and posteriorly angulated (6,22,30,36). In almost 85%, there is narrowing or atresia of the external auditory canal.

Conductive hearing loss of 50–70 dB, frequently congenital (21) and usually moderate (20), is noted in 85% of patients. Unilateral mixed hearing loss was described by Burton and Nadler (5). Even with normal pinnae, one may find ossicular abnormalities.

Musculoskeletal system. Radial ray abnormalities are a common feature of Nager syndrome (14,21). Varying degrees of asymmetric thumb hypoplasia or aplasia are seen in 75% (Fig. 19–10). Other thumb anomalies include stiff metacarpophalangeal joint (20), triphalangeal thumb (6,31,49), symphalangism (44), double thumb (15,19), and syndactyly between thumb and index finger with associated thumb hypoplasia (4,22). Radial hypoplasia or aplasia has been described in nearly all patients, with proximal radioulnar synostosis in 25% (35). These malformations frequently lead to reduced extension at the elbow. Marked reduction in size of the forearm is rare (56), but when present is usually associated with hypoplasia of humerus and ulna (5,22,45). Total absence of the forearm has rarely been reported (17,21,26). Other upper limb anomalies include synostosis of carpal bones (4,5,20), hypoplasia of thenar eminence (4,20,44), camptodactyly (26,30,36,55), and clinodactyly (7,26,36,44). Mild abnormalities of the lower limb include talipes (16,20,21,28), duplication of proximal hallucal phalanx (45), hypoplastic hallux (21), absent or hypoplastic toe (20,24,36,43), metatarsus varus (1), and absence of the distal interphalangeal creases of the toes (36). A few patients have been described with more significant lower limb anomalies, including absence of tibia and fibula (2,17,26,31) and frank phocomelia with hypoplasia of pelvis (26). Scoliosis (20,58), tightness of trapezius muscles leading to pseudopterygium colli and Sprengel deformity (12,20), hip dislocation (16,30,36), pes cavus (20), pectoral muscle hypoplasia (21), and pectus excavatum (16) are rare features.

Cardiovascular system. Tetralogy of Fallot (17,55), ventriculoseptal defect (26), and patent foramen ovale (52) occur rarely.

Genitourinary system. Vesico-ureteric reflux (20), unilateral renal agenesis (45), duplication of ureter (26), and bicornuate uterus (26) have each been noted in one patient.

Central nervous system. Intelligence is usually normal but intellectual handicap has been reported (6,20,43).

C

Fig. 19–10. *Preaxial acrofacial dysostosis (Nager).* (A) Absence of thumbs. (B,C) Preaxial involvement with missing phalanges and syndactyly. [A from FA Walker, Birth Defects 10(8):135, 1974. B,C from P Bowen and F Harley, Birth Defects 10(5):109, 1974.]

Ossicular defects have been confirmed at autopsy. These have included deformation of ossicles (4), absent incus with fused ossicular mass (32), stapedial footplate fixed to oval window (30), and absence of ossicles with rudimentary semicircular canals (17).

Miscellaneous findings. Autopsy has also revealed hypoplasia of the larynx and epiglottis (30) and abnormal septation of lungs (26,30). Cutaneous mastocytosis has been reported in two patients (39,60).

Diagnosis. Several entities must be considered in the differential diagnosis of Nager acrofacial dysostosis. In *Miller syndrome*, acrofacial dysostosis is associated with post-axial limb defects, and both upper and lower limbs are usually involved (37). Distinctive features include cup-shaped ears, cleft lip and/or palate, and accessory nipples. Although postaxial limb defects are most common, preaxial defects may be seen to a lesser degree, and abnormal thumbs, shortness of radius and ulna with or without radioulnar synostosis have all been described. Reynolds et al (47) reported an autosomal dominant acrofacial dysostosis syndrome with both pre- and postaxial involvement. There was mild congenital mixed hearing loss. Patients with *Fontaine syndrome* (12) have abnormal ears, retromicrognathia, cleft palate, and split foot with normal upper limbs. They do not show downward-slanting palpebral fissures, coloboma of the eyelids, or hearing loss. *Distal 2q duplication* syndrome shares some of the features of Nager acrofacial dysostosis such as down-slanting palpebral fissures, dysplastic external ears, and micrognathia (57,60). However, malar hypoplasia and defects of the external ear canal are absent, and hypertelorism and nystagmus, which are not seen in Nager acrofacial dysostosis, are frequent. Acral anomalies in the distal 2q duplication syndrome are usually limited to clinodactyly and camptodactyly of the fifth digit. No thumb defects have been described. We remain skeptical regarding the patient described by Fryns et al (13). *Oculo-auriculo-vertebral spectrum* may occasionally include radial defects but can usually be differentiated by the unilateral involvement of the ear, eye, face, and mandible, and the presence of epibulbar dermoids and vertebral anomalies. Sugiura (53) described a 6-year-old boy with hemifacial microsomia, absence of left radius and thumb, ventricular septal defect, and crossed renal ectopia. Gorlin et al (18) described a female infant with oculo-auriculo-vertebral spectrum phenotype and absence of the first left metacarpal with hypoplasia of the corresponding thumb. In 1971, Mandelcorn et al (33) reported a boy with hemifacial microsomia and acral anomalies, consisting of short ulna, four metacarpals, and four fingers on the left side, with hypoplastic humerus, short ulna, and three metacarpals, and two fingers on the right side. The facial features of Nager acrofacial dysostosis are similar to those in isolated *mandibulofacial dysostosis (Treacher Collins syndrome)*. The presence of preaxial limb defects distinguishes the two. External ear defects and cleft palate are more common in Nager syndrome, whereas lower lid colobomata are more frequent in mandibulofacial dysostosis.

In 1977, Kelly et al (27) described three males, two of them brothers, with preaxial limb anomalies with mild mandibulofacial hypoplasia. In addition, they showed intrauterine growth retardation with subsequent short stature, mental retardation, and genitourinary anomalies. All had sensorineural hearing loss. Autosomal recessive or X-linked recessive inheritance seems likely. The acrofacial dysostosis triphalangeal thumb syndrome described by Richieri-Costa et al (49) can be distinguished from Nager acrofacial dysostosis by the rarity of cleft lip and triphalangeal thumb in Nager syndrome. In 1983, Poissonnier et al (46) described a single male whose facial features were consistent with mandibulofacial dysostosis. In addition, there was hypoplastic scapulae and right humerus, hypoplastic or absent ulnae and fibulae, and absent fifth digito-metacarpal rays, in association with aplasia of the left hemidiaphragm and atrial and ventricular septal defects. In 1990, Rodriguez (50) described an apparently new autosomal recessive syndrome in three sibs with acrofacial dysostosis, predominantly preaxial limb deficiencies, rare postaxial limb anomalies, and cardiac and CNS malformations. The third sib showed marked similarity to Nager syndrome (50) as did that of Fryns and Kleckowska (12a).

Prenatal diagnosis. Ultrasonographic diagnosis has been reported (2).

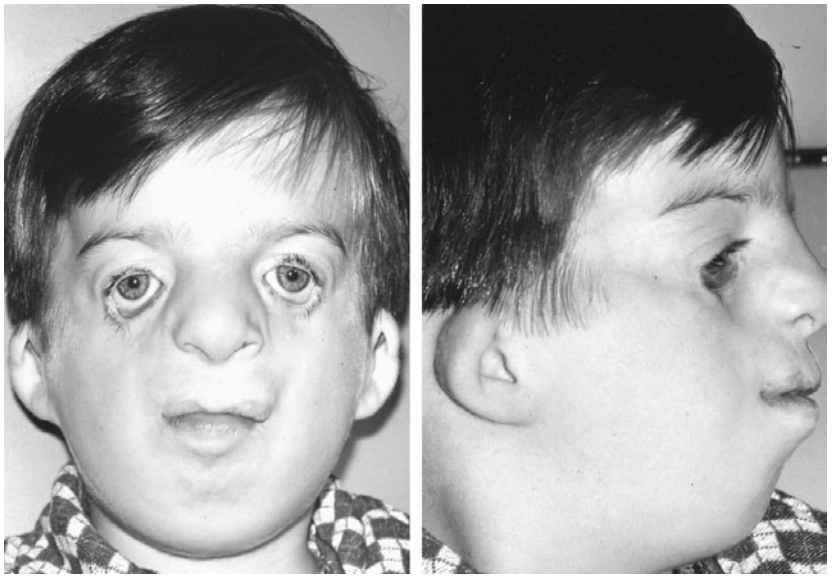
Postaxial acrofacial dysostosis, cupped ears, and conductive hearing loss (Miller syndrome, Genée-Wiedemann syndrome, Wildervanck-Smith syndrome)

Genée (10), in 1969, reported an infant with postaxial limb deficiency, cup-shaped ears, and malar hypoplasia. Wiedemann (25), in 1973, and Wildervanck (26), in 1975, noted similar patients. Miller et al (14), in 1979, presented details of three similar unrelated patients, one of which was previously reported by Smith et al (23) in 1975. An affected sib of a patient described by Miller et al (14) was briefly reported by Fineman (8). At least 25 patients have been described (2–6,8–21,23,26). A severe example was described by Poissonnier et al (18a).



A B

Fig. 19–11. *Postaxial acrofacial dysostosis (Miller or Wildervanck-Smith)*. (A,B) Characteristic facial appearance with downslanting palpebral fissures, ectropion of lower lids, repaired cleft lip, and malformed ears. (From MM Cohen Jr, Dysmorphic syndromes with craniofacial manifestations, in Oral Facial Genetics, RE Stewart and GH Prescott, eds, C.V. Mosby, St. Louis, 1976.)

Sibling pairs with normal parents have been reported (8,11,14–16). The parents of a sporadic patient were fifth cousins (21); thus it appears that the syndrome is transmitted in an autosomal recessive manner.

Craniofacial findings. Malar hypoplasia and lower lid ectropion are extremely common. Ectropion tends to become more obvious with age. Eyelid colobomata and eyelash anomalies were occasionally noted. Micrognathia is a constant finding (Fig. 19–11). Cleft lip and/or cleft palate was found in several cases (21). Other patients appeared to have a long philtrum. Supernumerary nipples were seen in almost 50% (6,13,16).

The ears, remarkably similar in reported cases, are small, simple, and cupped. Stenosis of the external auditory canal and hypoplasia of the middle ear were noted in two cases. Hearing loss was found in several patients (8,15,21).

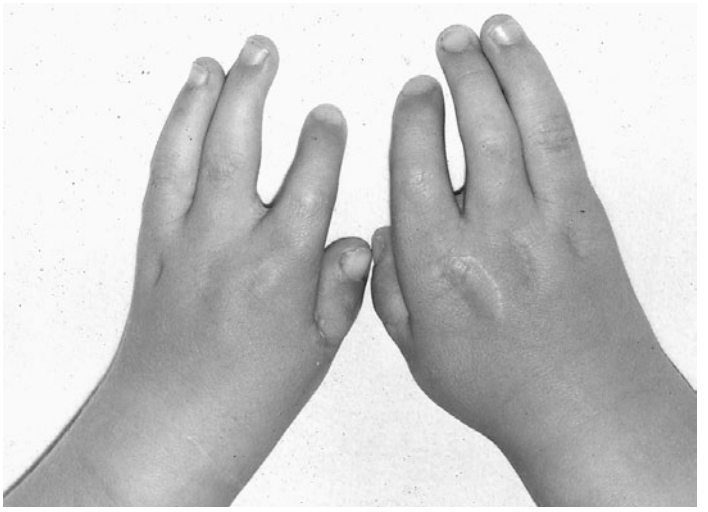
Musculoskeletal system. Almost all patients have bilateral absence of the fifth finger including the fifth metacarpal. Varying degrees of hypoplasia of the thumbs and syndactyly are occasionally noted. Forearm anomalies are extremely common, with ulnar hypoplasia being the most characteristic (Fig. 19–12A). Radioulnar synostosis has also been reported (15). It is possible that some patients have no digital anomalies (18). Absence of the toes on the lateral border of the feet was observed with rare exception (4,18) (Fig. 19–12B). The fifth toe was always involved, with occasional hypoplasia or absence of the third and fourth toes. Severe limb anomalies, rarely described, have included absent fibula, phocomelia, and hypoplasia of the pectoral girdle. Supernumerary vertebrae, vertebral and sternal segmentation anomalies, cervical ribs, and pectus excavatum have also been noted.

Sulik et al (24) postulated involvement of the apical ectodermal ridge of limb buds.

Other findings. Ogilvy-Stuart and Parsons (15) described midgut malrotation, gastric volvulus, and renal tract anomalies (reflux, hydronephrosis).

Diagnosis. Several disorders must be distinguished from this acrofacial malformation syndrome. The facial appearance is similar to that described in *Treacher Collins syndrome*, but distal limb anomalies are not part of that autosomal dominant condition. *Nager acrofacial dysostosis* includes preaxial hand deficiencies, normal feet, and a Treacher Collins-like face (3,22). The distal limb anomalies in Nager syndrome are most frequently hypoplasia or absence of the thumb and/or radius, as opposed to the predominantly postaxial limb anomalies in this condition. *De Lange syndrome*, *Weyers syndrome*, femur-fibula-ulna syndrome, and

Fig. 19–12. *Postaxial acrofacial dysostosis (Miller* or *Wildervanck-Smith*). (A,B) Postaxial agenesis of digits. (From MM Cohen Jr, Dysmorphic syndromes with craniofacial manifestations. In: Oral Facial Genetics, RE Stewart and GH Prescott (eds), C.V. Mosby, St. Louis, 1996.)



A

B

Schinzel-Giedion syndrome have ulnar ray defects, but differ in facial appearance and other clinical features. Allanson and McGillivray (1) and Falace and Hall (7) reported autosomal dominant inheritance of a syndrome of ectropion, facial clefting, and dental anomalies. The patient with four digits reported by Ruedi (22) appears to have Nager syndrome. The child reported by Danziger et al (5) has features of both Miller and Nager syndrome.

Acrofacial dysostosis, type Arens or Tel Aviv

Arens et al (1), in 1991, described a female child born to uncle/niece parents. There was intrauterine growth retardation, mandibulofacial dysostosis, low-set pinnae with narrow auditory canals, absence of the fifth rays in all extremities, camptodactyly of fingers, asymmetric syndactyly of fingers 3–5, and rudimentary polydactyly between digits 3–4. In addition, there was congenital hip dislocation, talipes, absence of distal phalanges of toes 2–3, and death at two months.

Inheritance may be autosomal recessive.

Reference (Acrofacial dysostosis, type Arens or Tel Aviv)

1. Arens R et al: A new form of postaxial acrofacial dysostosis? Am J Med Genet 41:438–443, 1991.

Acrofacial dysostosis, type Catania

Opitz et al (1), in 1993, reported a mother and four sons from Catania, Sicily with autosomal dominant inheritance of a previously undescribed acrofacial dysostosis. Wulfsberg et al (2) reported an affected mother and daughter (Fig. 19–13A).

Mild intrauterine growth retardation and short stature were constant features as was mild microcephaly.

The hair was coarse and curly with a low posterior hairline and widow's peak. The forehead was high with somewhat sparse lateral eyebrows. There was short nose, relatively long upper lip with thin vermilion and smooth philtrum, overjet or overbite, small posteriorly angulated pinnae, and small chin.

The hands exhibited brachydactyly (especially the thumb), transverse palmar creases, short fifth fingers with or without clinodactyly, fetal finger pads, and low total ridge count.

Mild mental retardation was evident in several of the patients. Inguinal hernia, hypospadias, and cryptorchidism were seen in the males.

Autosomal (less likely X-linked) dominant inheritance was noted.

2. Wulfsberg EA et al: Confirmation of the Catania brachydactylous type of acrofacial dysostosis: Report of a second family. Am J Med Genet 63:554–557, 1996.

Acrofacial dysostosis, type Palagonia

Sorge et al (1), in 1997, reported a family of four patients with a new type of acrofacial dysostosis characterized by short stature, pili torti, aplasia cutis verticis, oligodontia, mild soft tissue syndactyly of digits, malar hypoplasia, micrognathia, and normal intelligence (Fig. 19–13B). One patient had cleft lip. The family lived in Palagonia, Italy.

Skeletal changes included short fourth metacarpal, large atlas, small odontoid, and mild scoliosis.

Inheritance was either autosomal or X-linked dominant.

1. Sorge G et al: Another "new" form, the Palagonia type of acrofacial dysostosis in a Sicilian family. Am J Med Genet 69:388–394, 1997.

Acrofacial dysostosis, type Reynolds

Reynolds et al (1) described a family manifesting autosomal dominant inheritance of a previously undescribed acrofacial dysostosis syndrome. The craniofacial manifestations were those of mild mandibulofacial dysostosis and included prominent forehead, ptosis, downslanting palpebral fissures, malar hypoplasia, highly arched palate with dental malocclusion, and micrognathia (Fig. 19–13C,D). The pinnae were normal. However, mild congenital mixed type hearing loss was a feature.

The variable acral abnormalities predominantly affected the radial ray, manifesting as mild hypoplasia of the first metacarpal and first proximal

phalanx. This was more evident on metacarpal-phalangeal pattern profile than on clinical examination in some affected individuals.

There is some resemblance of the facies to that of *maxillofacial dysostosis*.

Reference (Acrofacial dysostosis, type Reynolds)

1. Reynolds JF et al: A new autosomal dominant acrofacial dysostosis syndrome. Am J Med Genet Suppl 2:143–150, 1986.

Acrofacial dysostosis, type Rodriguez

In 1990, Rodriguez et al (4) reported three male sibs with a lethal acrofacial dysostosis. Death occurred in the neonatal period for respiratory problems secondary to severe mandibular underdevelopment. Other examples have been described (1,3). A 100-year-old example has been reported (2).

In addition to severe micrognathia, there are malar hypoplasia, malformed pinnae with atretic canals, prominent nasal bridge and, in most cases, cleft palate (Fig. 19–13E,F).

Skeletal alterations are variable but include short or absent humerus, absent forearm, preaxial (predominantly) and/or postaxial digital anomalies, lower limb defects, including digital deficiencies, shoulder and pelvic girdle hypoplasia, and rib defects.

Cardiac malformations, CNS malformations, and absent lung lobation can also be seen.

To be excluded are *Genée-Wiedemann syndrome* and *Nager syndrome.*

Maxillofacial dysostosis, autosomal dominant

Peters and Hövels (3), in 1960, described autosomal dominant inheritance of maxillary hypoplasia, downward-slanting palpebral fissures, minor changes in the pinnae, and abnormal and retarded speech (Fig. 19–14). They employed the term maxillofacial dysostosis to differentiate the condition from mandibulofacial dysostosis. An earlier report by Villaret and Desoille (4) probably represents the same disorder. Other more recent reports (1,2) have confirmed the existence of the syndrome. Our combined experience suggests that the disorder is more frequent than the sparse number of reports indicates.

Maxillofacial dysostosis, X-linked (Toriello syndrome)

Toriello et al (5) reported two male sibs and their male first cousin with somewhat short stature, microcephaly, mild mental retardation, down-slanting palpebral fissures due to malar hypoplasia, sparse lateral eyebrows, outstanding pinnae, mild micrognathia, slightly webbed neck (Fig. 19–15), and cryptorchidism. All had mixed hearing loss of sufficient degree to warrant hearing aids. One had stenotic external ear canals. Inheritance may be X-linked. Ensink et al (2) described two brothers. Intelligence was normal. Zelante et al (6) also reported a single affected male. There is some resemblance to *maxillofacial dysostosis, autosomal dominant* (4).

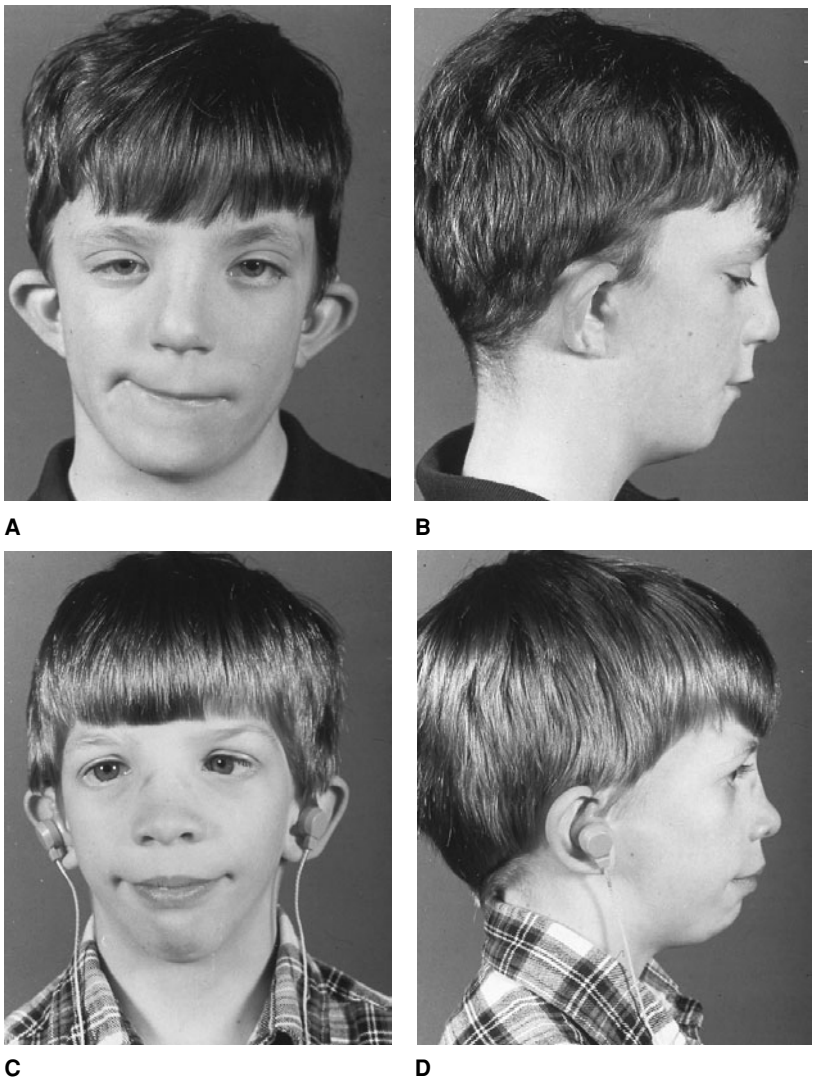

Fig. 19–15. *Maxillofacial dysostosis, X-linked.* (A–D) Two male sibs with microcephaly, downslanting palpebral fissures, sparse eyebrows laterally, outstanding pinnae, mixed hearing loss, mild micrognathia, and slightly webbed neck. (From HV Toriello et al, Am J Med Genet 21:137, 1985.)

Branchio-oto-renal syndrome (BOR syndrome)

Melnick et al (45), in 1975, first used the term branchio-oto-renal syndrome (BOR) to refer to patients with *b*ranchial cleft, fistulas or cysts, *o*tologic anomalies, including malformed pinnae, preauricular pits or sinuses, and hearing loss; and *r*enal anomalies of various types. Many other clinical features have subsequently been noted. Its prevalence is approximately 1/40,000 (20). The first summary descriptions were published in the nineteenth century (4,28,54,55). Early examples were reviewed by Anand et al (3). Excellent summaries by Fraser et al (19), Cremers and Fikkers-van Noord (12), and Allanson (2) are available.

The branchio-oto (BO) syndrome (44,47) has been thought to be distinct from the BOR syndrome based on molecular considerations (vide infra). The earpit-hearing loss syndrome had been considered a distinct entity (42). We suspect that the syndrome of renal pelviocalceal dysmorphism and sensorineural hearing loss is the same as BOR syndrome (50).

The BOR syndrome has autosomal dominant inheritance with variable expressivity (19,30,32,46,51). Penetrance is very high (12,19,20,26,52) but not complete (27). The gene has been mapped to 8q13.3 (1,31, 34,64,68). There is heterogeneity (64a), a second gene having been mapped to 1q31 (36). Kumar et al (35) stated that BOR syndrome and BO syndrome were not allelic whereas Vincent et al (67) demonstrated that they were allelic. The gene for BOR is the homologue for *Drosophila eyes absent* (1). In the mouse, expression of the gene occurs in all phases of the developing inner ear and in metanephric cells surrounding the ureteric branches that have just divided (1).

Craniofacial findings. Facial shape is frequently long and narrow with a constricted palate and deep overbite (10,19,45,46). Facial nerve paralysis (12,27,58) has been described in approximately 10% of cases and aplasia or stenosis of the lacrimal duct in 25% (8,12,19,47). Rarely, clinical features suggestive of lacrimal duct stenosis are actually due to misdirected seventh cranial nerve enervation leading to gustatory lacrimation (56). Occasionally, facial or mandibular asymmetry is found (27,51,58).

Ears. Anomalies of the external ear, noted in 30%–60%, range from severe microtia to minor anomalies of the pinnae, variously described as cup, flap, lopped, flattened, or hypoplastic (19,49) (Fig. 19–16). The external canal may be narrow, "malformed," or slanted upward in 30% (8). Helical or preauricular pits are present in 70%–80% (8,19). The pits are shallow, pinhead sized, with blind depressions in the helix of the ear near its upper attachment, or in the skin anterior to this site (12,27,46). Rarely, the pits communicate with the tympanic cavity (11).

Hearing loss has been reported in approximately 75%–95% (8,12,19): conductive, 30%, sensorineural, 20%, and mixed, 50% (12,13,23). Age of onset ranges from early childhood to young adulthood. Only rarely is there acute deterioration (22). All three types have been observed in different members of the same family (12,17,19,27,70).

Malformations of the ossicles include unconnected or fused stapes and incus (12,13,27). Inner ear malformations include bulbous internal auditory canal (8) and unilateral or bilateral malformed cochlea (12,16,17,19,46,53,62). The cochlea is often hypoplastic, with an acutely

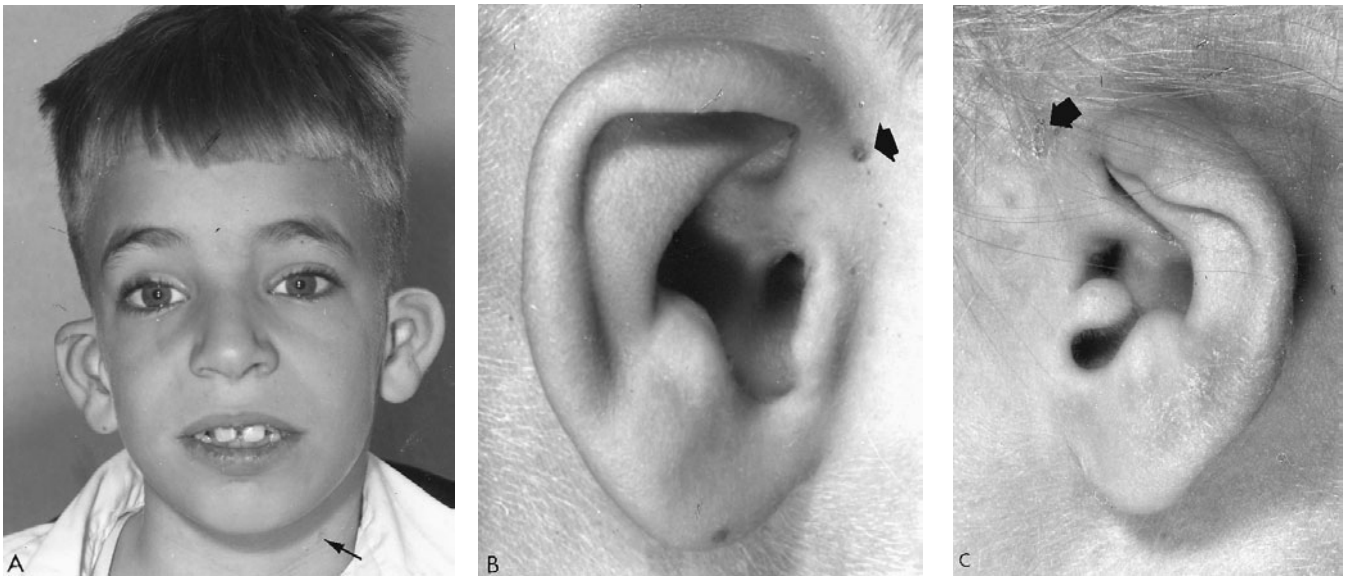

Fig. 19–16. *Branchio-oto-renal syndrome*. (A) Outstanding malformed pinnae. (B) Preauricular pit, marked by arrow. (C) Auricular appendage, grossly malformed ear, and preauricular pit.

angled basal turn, and a reduced number of coils (1 1/2 or 2, in comparison to the usual 2 1/2) (8,32,53,62,73). This is similar to but not characteristic of Mondini defect. However, Mondini dysplasia of the inner ear has been reported in this condition (17,22,46).

There is no vestibular alteration.

Branchial cysts/fistulas. Branchial cleft cysts or fistulas are reported in approximately 50%–60% (12,19). Branchial cleft cysts, fistulas, or sinuses, usually bilateral, are present on the external lower third of the neck, usually at the median border of the sternomastoid muscle. The fistulas may rarely open internally into the tonsillar fossa; they may drain fluid or become infected. Nipple-like cartilage rests can also be found.

Genitourinary system. Between 12% and 20% of affected individuals reported in the literature had diagnosed structural anomalies of the renal system (12,19). This is probably underreporting, as the renal anomalies may be so subtle that they can be missed on intravenous pyelography (20,27).

For accurate readings it is advisable to inform the radiologist of potential manifestations of the syndrome (27). One systematic study of 19 patients by intravenous pyelography showed 75% had a structural anomaly and 33% had functional anomalies of the renal system (12). Another study of 16 patients found 100% to have structural or functional renal manifestations (70). Some renal anomalies can remain asymptomatic (12); most are minor. Only approximately 6% have severe symptomatic renal involvement (7,16,17,20,47,57). If renal agenesis or severe hypoplasia is not present in infancy, the anomalies are not progressive (70).

Severe renal anomalies include bilateral renal agenesis (7,16,17,24,47) and polycystic kidneys (12,46). Structural anomalies can range from mild to severe and include hypoplastic kidneys (9,16,44,70), vesicoureteric reflux (10,27), crossed renal ectopia (7), bilateral bifid renal pelvis (27), uretero-pelvic junction obstruction (27), extra-renal pelvis (27), fetal lobulation (27), abnormal rotation of the kidney (70), and calyceal diverticuli or distorted calyceal system (19,46,70).

Mild structural anomalies include slight blunting of the calyces, blunted calyceal fornices without pyelonephritis or papillary necrosis, segmented hypoplasia of the superior pole, reduced renal parenchymal volume (12), and outpouching of the renal pelvis on the medial border of the kidney (12,46).

With regard to renal function, a small number of patients have disturbed concentration capacity and proteinuria, or reduced clearance of creatinine and diminished glomerular filtration rates (12,70). Histological studies may reveal prominent glomerular lesions (14,70) and irregularly shaped tubuli with swollen tubular epithelial cells (70). Segmental and focal hyalinization with dense immunoglobulin deposits of IgG, IgM, IgA, and C_3 along the basement membrane and in the mesangium have been observed (14).

Neither the presence/absence nor the severity of the renal defect may run true within families (7,16,17,24).

Diagnosis. Preauricular tags occur in 0.2% of live births and preauricular pits or sinuses in 0.8% of the normal population. Nonsyndromic preauricular pits or sinuses are far more common in blacks than in whites (44). Approximately 1/200 children with a preauricular pit has profound hearing loss (20,41). Autosomal dominant inheritance of isolated preauricular pits with approximately 85% penetrance (25) is well described (33,40). Preauricular pits and renal disease have been reported in a family in which there was no evidence of branchial anomalies or other features of the BOR syndrome (37). Some individuals had only preauricular pits, others only renal disease, while a third group had a combination of the two.

Branchial cleft sinuses are relatively common congenital anomalies that usually occur as isolated defects but may have autosomal dominant transmission (5,25,38,60,63,65,69). Several families have been reported in which the combination of preauricular pits and branchial fistulas is dominantly inherited without mention of hearing loss (6,48,51,59), although this was not ruled out audiometrically. Autosomal dominant preauricular pits and sensorineural hearing loss (18), autosomal dominant malformed auricules, preauricular tags or preauricular pits, and moderate conduction hearing loss (71) and branchial fistulas, malformed auricles, and hearing loss (43) have been reported. These may represent variable expressions of the BOR syndrome rather than distinct entities.

The branchio-oto-ureteral (BOU) syndrome (21) may also represent variable expressions of the BOR syndrome, particularly as Heimler and Lieber (27) have described a family in which some affected individuals have duplication of the collecting system and others have renal anomalies more characteristically associated with BOR syndrome. Still others have overlap with *OAV spectrum* (27,61). Fraser et al (21) proposed *duplication of the renal collecting system, external ear anomalies, and sensorineural hearing loss* as a separate entity, There is marked overlap between BOR syndrome and *otofaciocervical syndrome* (15), which is discussed later in this chapter. The latter lacks preauricular tags and lacrimal duct stenosis and has, in addition to features of BOR syndrome, unusual sloping

shoulders, short stature, and characteristic facies. There is some overlap with *Wildervanck syndrome.*

Several syndromes have been described with ear and renal anomalies including autosomal dominant dysmorphic pinnae-polycystic kidney syndrome (29), autosomal dominant dysmorphic pinnae-hypospadias-renal dysplasia syndrome (29), and autosomal recessive oto-renal-genital syndrome (72). We suspect that the syndrome described in 1994 by Marres et al (39) is really the BOR syndrome in chance association with commissural lip pits. Vincent et al (66) suggested a contiguous gene syndrome of BOR, *Duane syndrome*, a dominant form of hydrocephalus and aplasia of the trapezius.

Wildervanck syndrome (cervico-oculo-acoustic syndrome, Klippel-Feil anomaly plus)

The major clinical features of Wildervanck syndrome are fused cervical vertebrae, abducens palsy with retracted globe (Duane syndrome), and sensorineural hearing loss (55,56). Different phenotypic definitions are evident (34,53,56).

All cases with this triad of abnormalities are sporadic. The overwhelming majority of affected individuals reported are female, although a few males with the condition have been described (15). Several modes of inheritance have been proposed (11,28,29,56) and nongenetic causes cannot be excluded (7).

Facial and ocular findings. Facial asymmetry (4,15,16) and nonprogressive hemifacial weakness, present since birth, have been described (8). Unilateral or bilateral Duane syndrome is a major feature (6,8,14,16,29,34,35,39,50,55). Duane syndrome consists of abducens paralysis that prevents external rotation of the affected eye. On adduction, the lid fissure of the affected eye narrows, and the globe retracts (Fig. 19–17). Abducens paralysis without retraction has also been reported (4,13). Pseudopapilledema, unilateral epibulbar dermoid (8,15), and bilateral temporal subluxation of the lens (50) have been observed. Cleft palate may be present (4,16,29) and an anterior glottic web has been noted. Some have abnormal bony masses in the mandibular ramus region that have occasionally been reported as duplication phenomena (2,12,30).

Auditory system. Among patients having just Duane's anomaly (44), hearing loss, both sensorineural and conductive, has been found in approximately 15%. However, in Wildervanck syndrome, hearing loss is found in at least 30%. It may be sensorineural (15–17,24,29,35,37,50), conductive (4,10,13,26,44,45,48,49,51), or mixed (7,15,37). Although age of onset is usually in the first decade (7,47,54,55) and may be profound (29), the severity and age of onset have not been well documented. The loss may be unilateral (8,14,53). In addition, preauricular tags (8,15,37), cheek skin tags, malformation of the pinna (4), atresia or absence of the external auditory canal (8,13), abnormal and absent ossicles (8,32), ossified stapedial tendon (8), stenotic or short internal auditory meatus (14), stapes fixation (7), stapes gusher (9), abnormal semicircular canals (14,32), and underdevelopment of the bony labyrinth (Mondini deformity) (3,14,27,37,43,46,52,53,57) have also been described. Caloric areflexia is usually found (3,14,25,54).

Musculoskeletal system. Klippel-Feil anomaly, consisting of fusion of one or more cervical and sometimes thoracic vertebrae, is characteristic (4,7,8,13,15,18,29,55). The neck is short, thick, and webbed, and the head appears to sit directly on the trunk (4,8,14,16,50). Flexion, extension, and lateral mobility of the neck are severely restricted (4,13,14,16,29) and there may be torticollis (15). Spina bifida occulta (13,15,16), Sprengel deformity, hemivertebrae (8), fusion of ribs (8), absent ribs (8), kyphosis (8), scoliosis (8,14,15), and basilar impression (4,13–15) have been reported.

Central nervous system. A few authors describe mild (4,6) or severe (16) mental retardation. Facial paralysis and mirror movements (13) have been reported as has brainstem hypoplasia (5a).

Diagnosis. Differential diagnosis is complicated because many patients with Klippel-Feil anomaly have been incompletely described; some may have Wildervanck syndrome. Klippel-Feil anomaly and associated abnormalities have been particularly well reviewed by Helmi and Pruzansky (23). There is overlap with *oculo-auriculo-vertebral spectrum* (8,15). A number of unusual cases with some Wildervanck syndrome features are difficult to classify (5,6,29,33,50). Okihiro syndrome consists of autosomal dominant inheritance of Duane anomaly with congenital hypoplasia of the thenar eminence and sensorineural hearing loss (22,40). The hand anomalies resemble those seen in Stewart-Bergstrom syndrome (19). MURCS association (Rokitansky-Küster-Hauser syndrome) consists of *M*üllerian duct aplasia, *R*enal aplasia, *C*ervicothoracic *S*omite dysplasia. Vertebral defects occur from C_5 to T_1. Clinical manifestations include Klippel-Feil anomaly, absent uterus and vagina, renal agenesis, and conductive hearing loss (20,24,31,36,38,41,42).

The *unusual smiling face, cleft palate, and absence of middle ear space syndrome*, mislabeled by Wiedemann, consists of bilateral grooves, as if

A B

Fig. 19–17. *Wildervanck syndrome (cervico-oculo-acoustic syndrome)*. (A,B) Same patient at different ages showing asymmetry of head, severe cervical vertebral involvement, strabismus, arrested hydrocephaly, and sensorineural hearing loss.

smiling when the mouth is closed. Some of these patients have cleft palate, hearing loss, and partial duplication of the upper jaws as well as cervical vertebral fusion (53a). We have seen similar cases reported by C Morris (personal communication, 1998).

Townes-Brocks syndrome (lop ears, imperforate anus, triphalangeal thumbs, and sensorineural hearing loss, REAR syndrome)

Townes and Brocks (36), in 1972, described a family in which a father and five of his seven children displayed a syndrome of "satyr" ears with sensorineural hearing loss, imperforate anus, and triphalangeal thumbs. Similarly affected families have subsequently been described (2,4–7,9,15–17, 22,25,28,29,31,32,38) and the spectrum of anomalies expanded to include renal and cardiac defects. At least 65 cases have been published. An excellent review is that of Powell and Michaelis (20). The acronym, REAR (*r*enal-*e*ar-*a*nal-*r*adial) syndrome, has been used (17).

The syndrome has autosomal dominant inheritance with variable expressivity (21). The gene has been mapped to 16q12.1 (14,31). Mutations in *SALL1*, a putative zinc finger transcription factor gene, cause the syndrome (3,5,14,14a,19).

Ears. The satyr form of lop-ear anomaly with folding of the superior helix has been found in 25%–35% (23) (Fig. 19–18A–C). Additional ear anomalies include preauricular skin tags (40%), preauricular pits (5%),

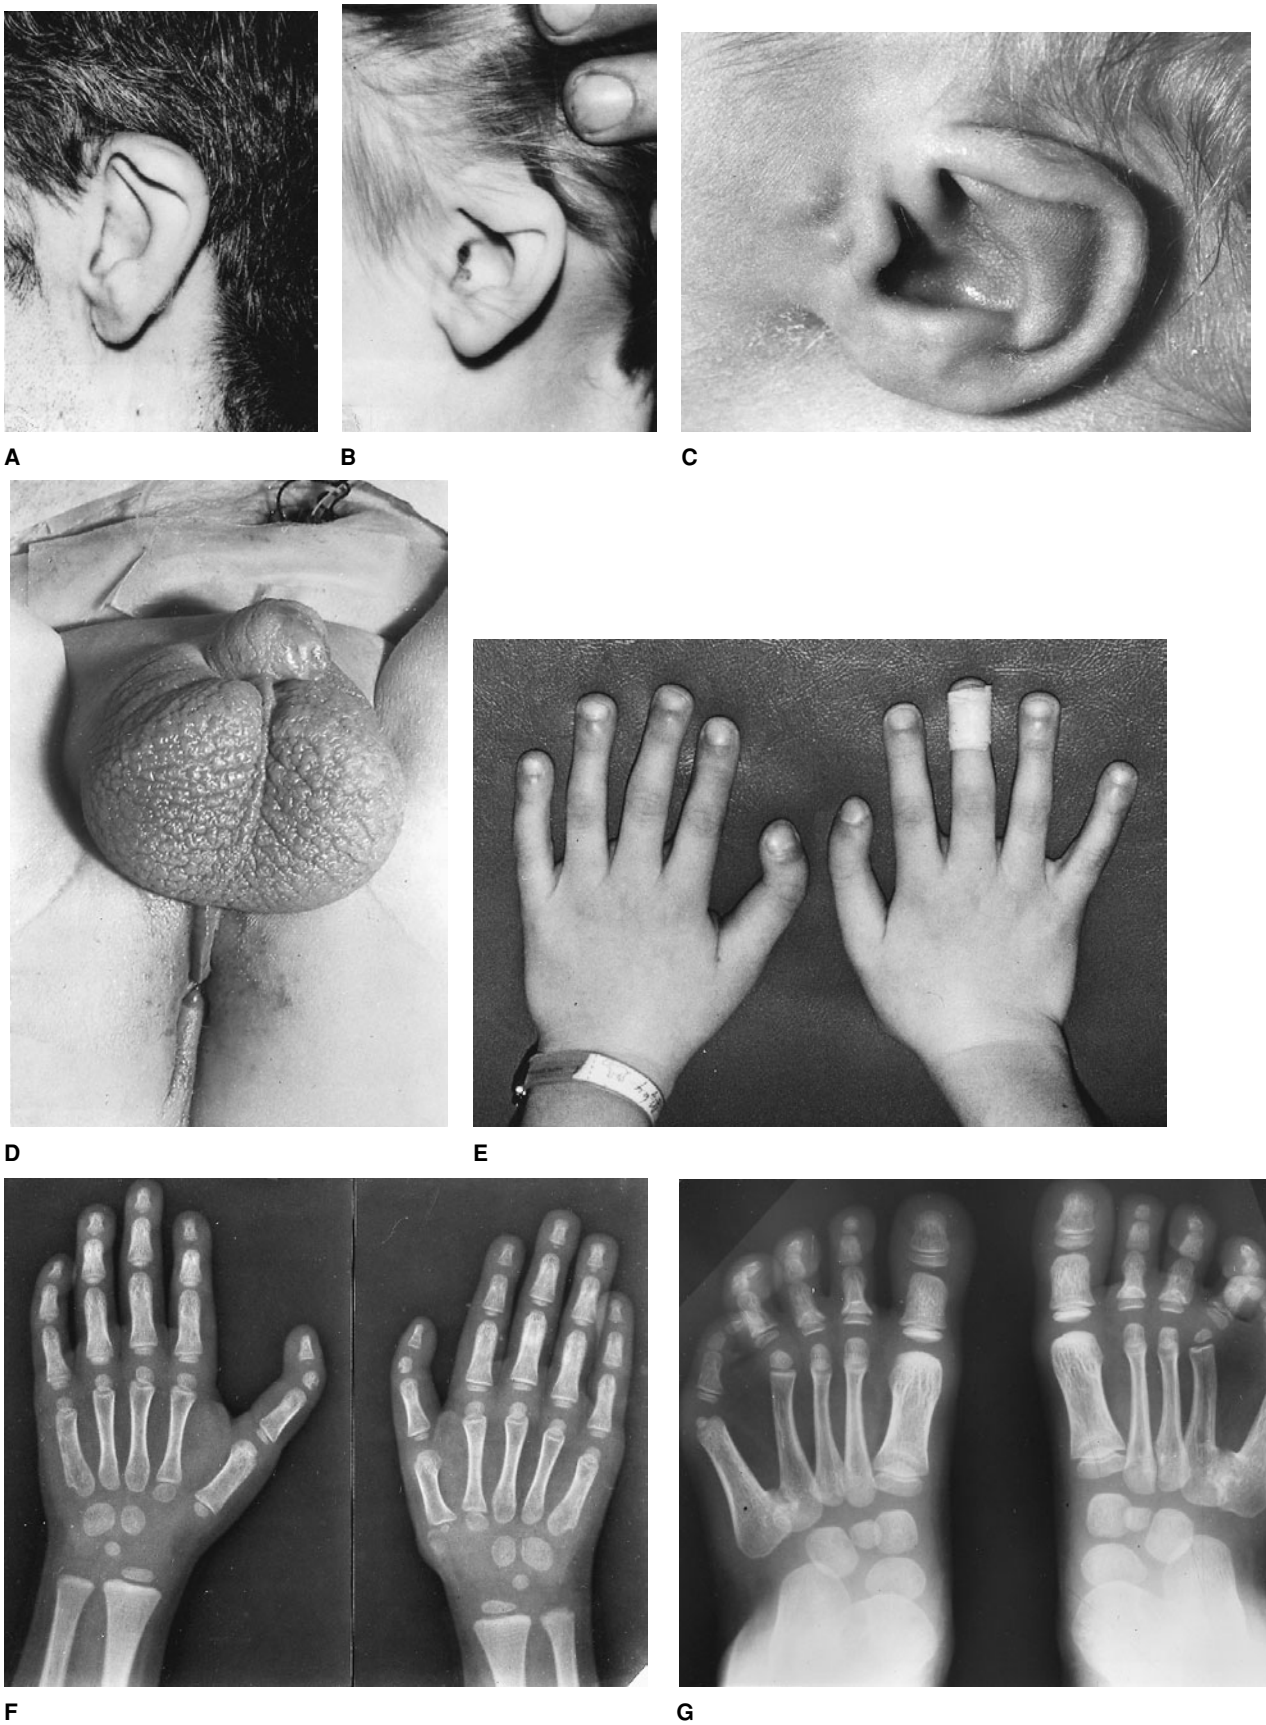

Fig. 19–18. *Townes-Brocks syndrome*. (A) Lateral view showing satyr form of lop-ear anomaly. (B) Another lateral view presenting similar abnormality. (C) Small satyr ear with preauricular protuberances. (D) Imperforate anus, prominent perineal raphé, scrotum bifidum, and glandular hypospadias. (E) Deviation of distal phalanges of thumb. (F) Note triphalangeal thumbs. Supernumerary thumbs had been surgically excised. Note accessory carpal bone and absence of triquetral bones. (G) Radiograph of feet. Note lateral displacement and fusion of proximal ends of fourth and fifth metatarsals. Also observe cone-shaped epiphyses at proximal end of first metatarsals and at proximal phalanges of second and third toes. (A,B,E–G from PL Townes and ER Brocks, J Pediatr 81:321, 1972; C,D from MACS de Vries-Van der Weerd et al, Clin Genet 34:195, 1988.)

and microtia (2,18,24), findings similar to those in *oculo-auriculo-vertebral spectrum*.

Among those with dysmorphic pinnae, 14 of 48 (30%) patients had congenital unilateral or bilateral sensorineural hearing loss. In childhood, it is mild (20–40 dB) and slowly progresses to 40–60 dB in adulthood (24,29). Ossicular anomalies can be found (6).

Gastrointestinal system. Anorectal anomalies constitute the most constant feature of this condition, having been found in 39 of 40 patients (5). Imperforate anus (usually high) has been found in 43% of 54 patients. It is associated with rectoperitoneal or rectovaginal fistula in 65% of cases (24). A midline peroneal raphe may extend from the site of the anal orifice to the scrotum (5,28). Anal anomalies may also include anterior placement (seven females), anal stenosis (15%) (24), or excess perianal skin without functional disturbance (six males) (23).

Musculoskeletal system. The skeletal anomalies are variable, but radial ray anomalies are present in more than 50% with triphalangeal thumbs (25%), bifid thumbs, broad thumbs, hypoplastic thumbs, supernumerary thumbs (25%), and distal ulnar deviation of thumbs all described (Fig. 19–18E–G).

Variable syndactyly of the second to fourth fingers has been seen (5,6). Absence of third toes, syndactyly of third and fourth toes, overlapping of second to fourth toes, clinodactyly of fifth toes, and pes planus have been noted in approximately 25%.

Hand radiographs have demonstrated broad bifid thumb with ulnar deviation, hypoplastic thumb, slender or bifid first metacarpal, pseudoepiphysis of the second metacarpal, absent triquetral and/or navicular bones, fused triquetrum and hamate, cone-shaped epiphyses, and short or fused metatarsals (5,6,9,36,38). Foot radiographs may exhibit duplication of tarsal bone, fused metatarsals, rocker bottom feet, and absent or small third toe.

Scoliosis has also been documented (3,11). These same patients had mental retardation.

Genitourinary system. Although renal anomalies were not part of the original description, 15% have been reported with a variety of findings including renal hypoplasia, unilateral renal agenesis, polycystic kidney, posterior urethral valves, ureterovesical reflux, meatal stenosis, and glandular hypospadias (5,7,9,29) (Fig. 19–18D). End stage renal failure has been noted (2,3,5,22,29).

Cardiovascular system. Congenital heart defects, seen in 10%, include tetralogy of Fallot, atrial septal defect, truncus arteriosus, and ventricular septal defect (2,6,9).

Central nervous system. Mental retardation has been noted in a few patients (3,11,38).

Diagnosis. The incidence of anal/rectal malformations varies from 1/1500 to 1/5000 live births (35). Most isolated malformations are sporadic although, in rare instances, autosomal dominant, autosomal recessive, and X-linked recessive inheritance have been reported (13,33,37,39). In approximately 50% of affected individuals, associated congenital anomalies can be found (6,8). Imperforate anus may be part of a complex association of vertebral defects, cardiac defects, tracheoesophageal fistula with esophageal atresia, and radial and renal defects known as VATER or VACTERL association (23). Auricular defects are rarely present in VATER association. However, anal malformations (55%), renal dysplasia or agenesis (45%), congenital heart anomalies (75%), ear anomalies (40%), and thumb anomalies (30%) show considerable overlap with Townes-Brocks syndrome (39). Quan and Smith (27) proposed that defective differentiation of mesoderm, prior to 35 days gestation, might be the pathogenetic mechanism in VATER or VACTERL association. Such a mechanism may be the basis for the clinical manifestations of Townes-Brocks syndrome as well.

Triphalangeal and/or bifid thumb may be inherited as an isolated dominant trait (34), in Fanconi anemia, or in association with cardiovascular anomalies in the Holt-Oram syndrome (10), Blackfan-Diamond syndrome (19), and *Baller-Gerold syndrome*. Aase and Smith (1) described a combination of congenital anemia and triphalangeal thumbs as an autosomal recessive syndrome. Triphalangeal thumbs have also been reported in association with hearing loss. What appears to be autosomal dominant *oculo-auriculo-vertebral spectrum* with anal stenosis has been labeled Townes-Brocks syndrome (12,20). The association of anorectal malformation with end stage renal disease and sensorineural hearing loss in several members of a three-generation family was reported by Lowe et al (18) but the association may have been one of chance. Finally, many of the features of Townes-Brocks syndrome, including preauricular tags, anal atresia, cardiac and renal malformations, are also seen in partial duplication 22 (*cat eye syndrome*), so careful chromosome studies are indicated, particularly if ocular anomalies are present (30).

Laboratory aids. Sensitivity testing to diepoxybutane should be done to rule out Fanconi anemia (26).

Oral-acral syndrome, type Verloes-Koulischer

Verloes and Koulischer (3), in 1992, described a woman with absence of the medial part of the upper alveolar ridge, including gingiva, frenulum, and tooth buds for the maxillary incisors and canines. Cohen (1), in the same year, described a boy with absent maxillary incisors and canines and asymmetric defects of hands and left first and second toes. de Silva and Verloes (2) added still another example in 1998. The child had absent fourth fingers of one hand and bilateral fifth finger clinodactyly. In all three cases, the upper lip receded because of the absence of the upper median alveolar ridge. Pathogenesis is unclear. Perhaps there is a vascular etiology, causing secondary disruption of an area of the maxilla and tooth buds. Digital development is similar to that in amniotic disruption syndrome.

Meier-Gorlin (ear-patella-short stature) syndrome

Meier et al (13), in 1959, reported a male with micrognathia, microtia, midface hypoplasia, ankylosis of knees, cryptorchidism, and agenesis of the patellae. Gorlin et al (7,8) described a male with microtia, absent patellae, and micrognathia. As an infant, his "knees bent backwards." There was unilateral cryptorchidism. Blount osteochondritis dessicans and bilateral aseptic necrosis of the lateral femoral condyles were found on radiologic examination. Subsequently, several additional examples have confirmed the syndrome (3–6,9,15,16).

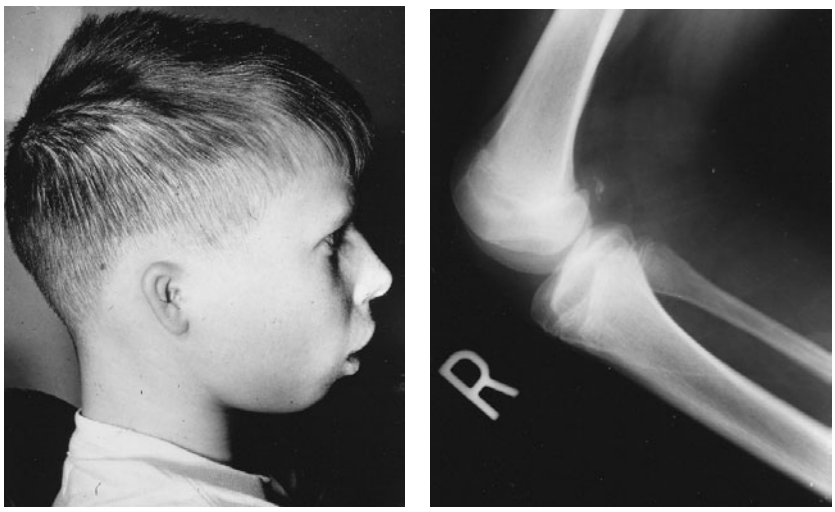
Inheritance is clearly autosomal recessive. In addition to parental consanguinity (11), there have been several pairs of affected sibs (3,5, 6,9,12,14a). Lacombe et al (11) postulated that the syndrome is similar to the short ear mouse phenotype. The murine disorder is an osteochondrodysplasia caused by a mutation within the bone morphogenetic protein 5 gene (BMP5).

Birth weight, length and head circumference have been below the 3rd centile in most cases. Height has been below the 3rd centile, but there may be catch-up growth during adolescence (6). Early closure of sutures (8,9), craniosynostosis (9,12), or prominent sutures (3) have been noted. Postnatal growth retardation can be marked (3,5). All had small pinnae and small mandibles; some also had small maxillae (Fig. 19–19). Several had full lips and small mouth. Hearing loss due to Mondini malformation has been noted (12). The nose is somewhat pointed.

Joint restriction (9), laxity (3,5,16), or aseptic necrosis (7,9) were observed as was clinodactyly of the fifth finger (3,5). The patellae were small or absent (Fig. 19–19). Long bones were slender and bone age delayed in all patients. The ribs may be short. Several patients had hooked clavicles (3,5,9,16). The glenoid fossa tended to be flat or absent and the epiphyses abnormal (3,5,9).

Clitoromegaly has been observed in two sisters (1).

The slight build may be confused with *3-M syndrome, Silver-Russell syndrome*, or *gloomy face syndrome*. The facies is mildly reminiscent of the symmetrical facial dysostoses (*mandibulofacial dysostosis, maxillofacial dysostosis*, and others in this group). The so-called small patella syndrome (coxo-podo-patellar syndrome) is an autosomal dominant



A B

Fig. 19–19. *Meier-Gorlin (ear-patella-short stature) syndrome*. (A) Microtia, micrognathia. (B) Agenesis of patellae. [From RJ Gorlin et al, Birth Defects 11(2):39, 1975.]

disorder characterized by small and subluxated patella, delayed patellar bone age or absent patella, occasional unusual facies (broad nasal bridge, anteverted nares, long philtrum, prominent lower lip, micrognathia), long tapered fingers, increased space between hallux and second toe, metatarsus adductus, ischiopubic rami defect with infraacetabular notch, abnormal scapulae, and short middle phalanges of second and fifth fingers (10).

A patient with a recessive form of small patella syndrome had absent ischia and inferior pubic rami as well as cleft palate. Also noted were hypotonia, macrocephaly, genu recurvatum, and delayed bone age. It was mentioned that the pinnae were small (1). Another recessive family has been poorly documented (2).

Various other small patella syndromes are discussed by Sandhaus et al (14). The autosomal recessive genito-patellar syndrome consists of absent patellae, scrotal hypoplasia, renal anomalies, unusual facies, and mental retardation. Among other findings are coarse facies, large nose, microcephaly, flexion deformities of the knees and hips with club feet, agenesis of corpus callosum, cryptorchidism, multicystic kidneys, hydronephrosis, and pulmonary hypoplasia. Radiographic changes are those of hypoplasia of the ischia and brachydactyly (5a).

Carnevale syndrome

Carnevale (1) described two male sibs, the offspring of a consanguineous marriage, who manifested down-slanting palpebral fissures, ptosis of the upper eyelids, and convergent strabismus. They had limited extension of the forearms and hip dysplasia. Both exhibited mild mental deficiency, cryptorchidism, and partial agenesis of the abdominal musculature with diastasis (Figs. 19–20 and 19–21).

Fig. 19–20. *Carnevale syndrome*. Note ptosis, strabismus, limited extension at elbow, partial agenesis of abdominal musculature with diastasis, and cryptorchidism. (Courtesy of F Carnevale, Bari, Italy.)

Hypertelorism-microtia-clefting syndrome (Bixler syndrome, HMC syndrome)

*H*ypertelorism, *m*icrotia, and *c*left lip and palate (HMC syndrome) was described in two sibs by Bixler et al (2,3), in 1969 (Fig. 19–22). Schweckendiek et al (9), in 1976, reported identical twins with the same condition, and there have been several isolated case reports (1,5,8). A so-called Bixler syndrome variant is clearly an example of *oculo-auriculo-vertebral spectrum* (6).

Involvement of two of four sibs with normal parents in the original kindred strongly suggests autosomal recessive inheritance.

Four of six individuals with this condition had growth retardation. Broad nasal root with broadening of the nasal tip, which in extreme cases was bifid (1–3), was common. All six had ocular hypertelorism. Unilateral cleft lip and palate was present in five of six individuals, the older twin reported by Schweckendiek et al (9) being the exception. In four of five cases, the lip/palate anomaly was right-sided. Other facial anomalies included asymmetry, microstomia, and mandibular arch hypoplasia. The external ears in the original two sisters (2,3) were markedly abnormal, with bilateral absence of the tragus and anterosuperior helix. In both, one external auditory meatus was absent, whereas the other was atretic. Both male twins (9) exhibited right microtia. The second twin had ipsilateral atresia of the external auditory canal. In both twins the left ear was simple without folding of the helix. The boy described by Baraitser (1) had bilaterally malformed pinnae and stenosed external auditory canals. The patient of Fontaine et al (4) had bilateral dysplasia of the external ears with patent external auditory canals. The two original sisters (2,3) had bilateral conductive hearing loss, whereas one of the twins had unilateral conductive hearing loss (9).

Tomography has revealed bilateral atresia of the external auditory canals with hypoplasia of the left stapes and incus and of the right stapes and malleus. Mild limb anomalies, including bilateral thenar hypoplasia and shortening of the fifth fingers, were noted in the familial cases (2,3).

Sisters (2,3) had congenital heart disease with atrial septal defect in the older girl and endocardial cushion defect in the younger. Six other close maternal family members had congenital heart disease, suggesting this may represent an independent genetic defect, given that congenital heart disease was not noted in the other cases.

Renal anomalies found in several patients included left pelvic kidney (2,3), crossed ectopia of kidney (2,3), unilateral duplication of renal pelvis, and stenosis of ureter (9).

Skull radiographs showed a steep mandibular angle, short mandibular ramus, shortened upper facial height, depressed nasal floor, and decreased cranial flexure angle (2,3).

In *frontonasal malformation*, patients have a wide spectrum of anomalies that includes marked hypertelorism, bifid nose, cranium bifidum occultum, and occasionally cleft lip and/or palate (5). Some similar features are found in *oto-palato-digital I (OPD I) syndrome*, including conductive hearing loss, cleft palate, and growth retardation (5). However, the facial and skeletal alterations found in the OPD syndrome are not present in HMC syndrome. *Oculo-auriculo-vertebral spectrum* commonly has malformations of the pinnae, but cleft lip and palate are relatively uncommon (7%) and severe hypertelorism is not a feature. Motohashi et al (7) reported a boy with a chromosomal abnormality [46,XY,t(1;7)(1q31;7p15)] and features similar to those found in this condition, including hypertelorism, microtia, and cleft palate. However, the child lacked cleft lip and broad/bifid nose and had additional features that included distichiasis, hypoplastic eye lids, and absent lacrimal ducts.

DiGeorge anomaly

Depending on etiology, severity, and time of embryonic insult during the fourth to seventh week of gestation, DiGeorge anomaly can be minimally expressed as the III–IV pharyngeal pouch complex in which there is absence or hypoplasia of the thymus and/or parathyroid glands (Fig. 19–23) (32). However, it may be maximally expressed with cardiovascular anomalies, especially interrupted aortic arch and truncus arteriosus, and various craniofacial anomalies (11,36). The neural crest plays a critical role in the development of the thymus and parathyroid glands, aortic arches, and conotruncal part of the heart (6,7,29,57,60). DiGeorge (16), in 1965, first called attention to the association of absence of the thymus with aplasia of the parathyroid glands and described human thymic deficiency. Good (see 55) coined the term DiGeorge syndrome. Although we and others have used the term DiGeorge anomaly (19,25,29,42,57), the condition has also been known as III–IV pharyngeal pouch syndrome (46,48,49,55), DiGeorge syndrome (1–13,18,20,28,33,35,37,38,51,62), and DiGeorge sequence. An excellent history of the syndrome has been provided by Greenberg (19).

Etiology. Clinical and genetic aspects of DiGeorge anomaly are reviewed extensively by Lammer and Opitz (29), Müller et al (38), and Belohradsky (6). Conley et al (11) reported necropsy data on 25 patients. Miller et al (36) reviewed 156 patients with idiopathic hypoparathyroidism and found 40 different kinds of branchial arch and pharyngeal pouch anomalies. Thomas et al (57) have elegantly reviewed these variations.

Most instances of DiGeorge anomaly occur sporadically, but vertical (54) and horizontal (48,51,62) transmission have been documented. Monozygotic twins (35) have also been noted. Sporadic occurrence in most cases with occasional vertical and horizontal transmission is compatible with microdeletion 22q11 (50).

Clinical and pathologic evidence indicates that DiGeorge anomaly is etiologically heterogeneous (57) and may occur as part of a broader pattern of abnormalities. Various syndromes and associations have been reported (10,15,29) besides del(22q11): dup(1q), del(5p), dup(8q), del(10p), del(17p),del(18q), Zellweger syndrome, diabetic embryopathy, fetal alcohol syndrome, retinoid embryopathy, Kallmann syndrome, holoprosencephaly, arhinencephaly/DiGeorge anomaly, CHARGE/DiGeorge anomaly, and cardiofacial syndrome/DiGeorge anomaly (1,2,6,11,13,14,17,18–30,34,40–45,50–54,56–58). The nude mouse gene, syntenic at human 17p13, may not be accidental (19).

The DiGeorge critical region (22q11.2) associated with microdeletions has a clinical spectrum of abnormalities that includes "DiGeorge anomaly," "velocardiofacial syndrome," and "conotruncal anomalies-face syndrome" (9,17,61,63). A number of candidate genes have been found in the critical region and several appear to be particularly important at this writing. Yamagishi et al (64) suggested that UFD1L haploinsufficiency contributes to the craniofacial and heart defects seen with 22q11 deletion. Baldini (3) and Srivastava and Yamagishi (53) discussed *UFD1L* and *CDC45L* and the role of the *dHAND-UFD1L* pathway in which *dHAND* normally activates *UFD1L* in neural crest-derived cells. Novelli et al (39) expressed skepticism by finding no *UFD1L* mutations in 20 affected but nondeleted patients. They indicated that the gene

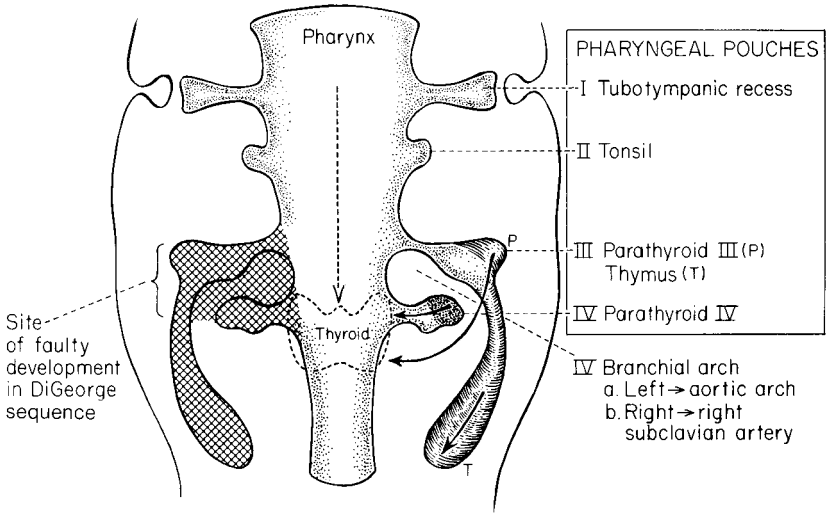

Fig. 19–23. *DiGeorge anomaly*. Schematic appearance of anterior foregut and its derivatives around fifth week of development showing site of DiGeorge defect. III–IV pharyngeal pouch complex. Thymus and inferior parathyroids develop from third pouch. Superior parathyroids develop from fourth pouch. Aortic arch from IV may also be involved. Left involvement results in type B interrupted aortic arch. Involvement of the right aortic arch results in aberrant right subclavian artery. (From DW Smith, Recognizable Patterns of Human Malformation, 3rd ed, W.B. Saunders, Philadelphia, 1982, p 470.)

responsible for the DiGeorge/velocardiofacial phenotype has not yet been isolated and that microdeletions per se might merely reflect genetic instability in the 22q11.2 region. Haplo-insufficiency of the GATA3 gene causes the condition (59a).

A second locus for DiGeorge appears to be at 10p13 (4,12,13,19,21, 27,31,51,59). We do not believe that the facies is reminiscent of velocardiofacial syndrome.

Clinical history. Infants with complete DiGeorge anomaly have a poor prognosis. Patients may have hypocalcemia with seizures, murmurs, or cardiac failure, or, after the first few weeks of life, may develop infections with purulent rhinorrhea, maculopapular rashes, failure to thrive, and development delay. Those with partial DiGeorge anomaly who survive infancy are moderately to severely mentally retarded (11,38).

Parathyroids. Hypocalcemia is a variable feature and patients with severe hypocalcemia are likely to have complete absence of the parathyroids. In most cases, one or two parathyroids or ectopic parathyroids are present (11).

Thymus. Defective cell-mediated immunity is attributable to deficiency of thymic tissue. The thymus gland may be absent (complete DiGeorge anomaly) or hypoplastic (partial DiGeorge anomaly). In the necropsy series of Conley et al (11), partial absence occurred in 58%. Three patterns were observed: cervical lobes only, median thymic tissue situated above the left innominate vein, or small lateralized accessory thymic lobules located in the neck (11). Moderate to almost normal T-cell function is found (4).

Cardiovascular anomalies. Only 5% have a normal heart. Symptomatic heart defects are common. Among 161 cases, type B interrupted aortic arch was found in 30% of clinically symptomatic cases and in 50% of necropsy cases (11,60). This may occur with or without aberrant right subclavian artery. Persistent truncus arteriosus was found in 24% (47,60). Pulmonary arteries in these patients are of variable size. Approximately 12% of cardiovascular anomalies are of other types, most commonly tetralogy of Fallot (6%) (10,36,60).

Craniofacial anomalies. Craniofacial anomalies occur in approximately 60%. The most frequent features include micrognathia, deep-set, low-set, small, posteriorly angulated ears that are sometimes pointed, anteverted nostrils, blunted nose, clefting or indentation of the nose, and hypertelorism (11). Short philtrum, cleft palate or bifid uvula, highly arched palate, choanal atresia, abnormalities of the middle ear, various eye anomalies, and central nervous system malformations have also been noted (11,32,36,38).

Other abnormalities. A variety of other abnormalities have been reported including absent thyroid lobe, accessory thyroid tissue, esophageal atresia, anomalous speech musculature, diaphragmatic defects, Meckel diverticulum, abnormal bowel rotation, imperforate anus, and hydronephrosis (11,36).

Diagnosis and differential diagnosis. DiGeorge anomaly includes patients with two of the three following findings: (1) cellular immune deficiency or demonstrated absence of all or part of the thymus gland or both, (2) symptomatic hypocalcemia or anatomic deficiency of the parathyroids or both, and (3) congenital heart defects. DiGeorge anomaly should be suspected in any neonate with interrupted aortic arch or truncus arteriosus, hypocalcemia, failure to thrive, chronic purulent rhinitis, or a mildly retarded child with manifestations of immunodeficiency (Table 19–1).

Several conditions have features in common with DiGeorge anomaly. *Oculo-auriculo-vertebral spectrum* has overlapping features with DiGeorge anomaly. However, to our knowledge, the finding of T-cell deficiency and/or hypoparathyroidism has not been reported to date. Characteristics of *trisomy 18 syndrome* include low birthweight, triangular facies, low-set pointed ears, micrognathia, congenital heart defects, renal anomalies, and central nervous system malformations. The thymus is frequently noted to be small on necropsy, and absence of the parathyroid glands has also been reported (11).

[a] Affected male sibs have been reported on three occasions (2,62) suggesting that X-linked inheritance is still a theoretical possibility.

[b] Bisdiamine, a drug initially studied as a male contraceptive and not approved for human use in the United States, is known to produce a DiGeorge-like pattern of defects in experimental animals (41,43). From MM Cohen Jr and DEC Cole, J Pediatr 115:161, 1989.

Studies of calcium metabolism, cell-mediated immunocompetence, and cardiovascular function are indicated. Immunoregulatory disturbances (hypergammaglobulinemia, high titers of specific antibody production) prevail in partial DiGeorge anomaly (38).

Oromandibular-limb hypogenesis syndromes

General aspects

Nosology. Syndromes of oromandibular-limb hypogenesis are confusing. Hall (31) called attention to the number of ambiguous and overlapping entities that exist in the literature on the subject. The problem is twofold. First, because almost all cases reported to date are seemingly sporadic, it has been extremely difficult to define syndrome boundaries among this group. Entities have been delimited on a somewhat arbitrary basis, and cases can be graded with various degrees of overlap between defined syndrome entities. Second, Hall (31) noted that the terminology used to describe these disorders shows many discrepancies, thus compounding the problem. He proposed a classification of syndromes with oromandibular-limb hypogenesis based on the presence of hypoglossia. It should be noted that mild degrees of hypoglossia are difficult to detect and may, in fact, go unnoticed.

This chapter considers six defined syndrome entities, including Moebius syndrome, hypoglossia-hypodactylia syndrome, Hanhart syndrome, glossopalatine ankylosis syndrome, limb deficiency-splenogonadal fusion syndrome, and Charlie M. syndrome. All are very uncommon except Moebius syndrome. After an extensive introductory section, each condition is discussed separately. However, this is done for convenience in documenting the vast literature on the subject. We do not recognize that all of the conditions are necessarily separate entities because of significant overlap among them. Furthermore, to speak of them as syndromes, as the literature does, may be misleading because some may represent sequences.

The etiology of this group of conditions is heterogeneous (12,14, 18,23,28,29,30,45). Because sporadicity is seemingly apparent in almost all cases and because the clinical features, especially limb anomalies, are remarkably variable, and, furthermore, because clinically graded overlap occurs between defined entities, it is not known how many entities there are or how etiologically heterogeneous or homogeneous this group is. Kaplan et al (41) considered them to be a syndrome community in which the overlapping phenotypes of the defined syndromes reflect underlying developmental relationships.

Documentation of phenotypic overlap is extensive. Spivak and Bennett (66) suggested that the glossopalatine ankylosis syndrome and the hypoglossia-hypodactylia syndrome were closely related. Cohen et al (16) reported a patient with a minute tongue, limb deficiency, and Moebius involvement; they suggested that hypoglossia-hypodactylia syndrome, Hanhart syndrome, and glossopalatine ankylosis syndrome might represent the same recurrent pattern syndrome. Bökesoy et al (9) reported a patient with features of hypoglossia-hypodactylia and glossopalatine ankylosis and called the condition Hanhart syndrome. Pauli and Greenlaw (56) and Barr (5) questioned whether Hanhart syndrome and limb deficiency-splenogonadal fusion might not be variants of the same condition. Tsingoglou and Wilkinson (75) and Watson (82) reported micrognathia and splenogonadal fusion; in the latter case, microstomia and cleft palate also occurred. Sieber (65) observed Moebius syndrome with splenogonadal fusion. Keymolen et al (41a) reported a variant with renal anomaly, micrognathia, and mild mental retardation in sibs. The association of Moebius syndrome with Poland anomaly has been documented by a number of authors (36,68).

Herrmann et al (36) analyzed 7 personally studied and 62 previously reported cases of oromandibular-limb hypogenesis. They found that severity of upper limb involvement and especially malformation of the feet, but not the presence of cranial nerve palsies, was significant in differentiating cases, and that the group of patients with cranial nerve palsies included some with limb defects similar to those observed in Hanhart syndrome and others with Poland anomaly. Finally, cases with cranial nerve palsies without limb involvement were documented. Herrmann et al (36) concluded that most reported cases of "aglossia-adactylia," "ankyloglossia superior," and Moebius syndrome represented instances of Hanhart syndrome. Second, they concluded that cases of Moebius syndrome combining a chest defect and/or symbrachydactyly represented Poland-Moebius syndrome. Finally, they noted that cranial nerve palsies obviously occurred in several etiologically distinct conditions.

Temtamy and McKusick (70) recognized three clinical entities within the Moebius syndrome category: (1) sixth and seventh cranial nerve palsy alone, (2) sixth and seventh nerve palsy with limb anomalies, and (3) sixth and seventh nerve palsy with arthrogryposis.

Etiology. Teratogenic etiology has been suspected by some authors, but reports to date have generally been anecdotal in nature. Gorlin and Pindborg (27) first suggested that cases of the hypoglossia-hypodactylia syndrome should be examined carefully for intrauterine environmental factors. Torpin (74) noted that rupture of the amnion during early pregnancy may produce membranous strands that constrict or amputate limbs and that may also lead to oral anomalies by ingestion of amnionic strands that interfere with orofacial development.

Hall (31) noted in his case that Tigan was given to the mother during the critical period of facial and limb development and cited another unpublished case in which the mother received Tigan. In the patient reported by Bökesoy et al (9), meclizine hydrochloride usage during pregnancy was noted. Putschar and Manion (59) postulated that limb deficiency-splenogonadal fusion syndrome is secondary to some environmental teratogen. Promethazine was prescribed during the sixth week of pregnancy in the case reported by Pauli and Greenlaw (56). In a case of glossopalatine ankylosis syndrome, Nevin et al (54) found that the mother had taken imipramine, diazepam, chlorpromazine, and meclizine throughout the pregnancy. Drug usage during gestation has also been recorded in other oromandibular-limb hypogenesis cases (36,66,76).

Graham et al (29) reported three cases of Moebius syndrome in which gestational hyperthermia toward the end of the first trimester or early second trimester may have been the etiology. Superneau and Wertelecki (69) reported a patient whose mother had a febrile illness during early pregnancy. They suggested similarities to the experimental effects of hyperthermia as a teratogen. In an animal model of the Moebius syndrome (47) when pregnant rats were subjected to hyperthermia (or uterine trauma), hemorrhage occurred in the distal limbs and brain stem. Human neuropathologic studies have demonstrated brain stem tegmental necrosis affecting multiple cranial nuclei (72).

In Brazil, misoprostol is used orally and vaginally as an abortifacient. Pastuszak et al (55) studied 96 infants with Moebius syndrome and concluded that attempted abortion with misoprostol was associated with an increased risk of Moebius syndrome in infants. The reader is referred to *misoprostol embryopathy*.

Bouwes-Bavinck and Weaver (12) hypothesized subclavian artery disruption sequence as a cause for Moebius syndrome. Possible causes for interruption or reduction of blood flow in the subclavian arteries and their branches include mechanical factors such as blood vessel edema, thrombi or emboli, hemorrhage, early intrauterine compression, delayed or abnormal formation of blood vessels, disruption of newly formed vessels, or premature disappearance of transient vessels (77). Uteroplacental vascular insufficiency has been postulated to cause the spectrum of oromandibular limb hypogenesis syndromes (49).

Chorionic villus sampling (CVS) has been associated with several cases of oromandibular limb hypogenesis (24,30). Firth et al (24) noted four cases in 289 CVS procedures.

David et al (18) reported a case of hypoglossia-hypodactylia with jejunal atresia in an infant of a diabetic mother.

Genetic causes have been postulated by a number of authors. However, almost all cases of oromandibular-limb hypogenesis have occurred sporadically. Genetic interpretations seem to depend on the presence of consanguinity or the rare presence of a relative of the proband with partial (never complete) manifestation of the condition or the presence of mendelian inheritance in a disorder that mimics oromandibular-limb hypogenesis syndromes but clearly differs from them.

In a case of hypoglossia-hypodactylia, Temtamy and McKusick (70) noted that the father and paternal aunt of the proband had hypodontia. They further observed in their study of several patients with the hypoglossia-hypodactylia syndrome or glossopalatine ankylosis syndrome that orofacial anomalies were observed in various relatives, but in no instance were limb abnormalities observed in a relative. They suggested either multifactorial inheritance or autosomal dominant transmission with reduced penetrance and extreme variability in expression. Since most cases are seemingly sporadic, the possibility that some examples represent autosomal dominant mutations with reduced genetic fitness could not be excluded. In Turkey, one case of hypoglossia-hypodactylia and two instances of isolated hypoglossia were each associated with parental consanguinity (76). However, the consanguinity rate is known to be high in the Turkish population and all three cases occurred sporadically within their respective families. Dellagrammaticas (21) reported two sporadic cases of hypoglossia-hypodactylia, referring to them as examples of Hanhart syndrome. Both sets of parents were Gypsies in whom the consanguinity rate is known to be high. In two published papers on Hanhart syndrome (31,32,50), distant consanguinity was noted, also suggesting autosomal recessive inheritance. However, affected sibs have never been reported.

Although autosomal dominant inheritance (25,51,79), autosomal recessive inheritance (6,42,73), affected first cousins (33), and instances of consanguinity [13,33,39 (case 3)] have been reported for some cases of the Moebius syndrome, critical review of such cases suggests strongly that they represent entities distinct from Moebius syndrome. In every instance, only the seventh cranial nerve was affected, and none of these patients had other manifestations of the Moebius syndrome (minimally sixth nerve palsy, in addition). Furthermore, patients in this genetically determined group also had a high frequency of hearing deficit and ear anomalies and were usually of normal intelligence. In the family reported by Becker-Christensen and Lund (6), only the proband had sixth and seventh nerve palsy. It is also clear that the dominantly inherited conditions described by Legum et al (45), Rubinstein et al (62), and Ziter et al (84) as Moebius syndrome represent other entities. Wishnick et al (83) reported bilateral sixth and seventh nerve palsies in six family members of two generations. However, affected individuals also had arthrogryposis and except for mild soft tissue syndactyly and talipes equinovarus, no limb defects were noted, especially reductive.

Using the original criteria of Moebius syndrome as sixth and seventh cranial nerve involvement with or without limb defects, almost all reported cases have occurred sporadically except for the dominantly inherited binary combination of abducens and facial paralysis reported by Krueger and Friedrich (43) and the mother–son involvement described by Hicks (38). Collins and Schimke (17) observed a Moebius syndrome

proband whose father had a transverse defect of one arm with absent radius and ulna just below the elbow but no cranial nerve involvement. Mitter and Chudley (53) reported a Moebius syndrome proband whose sister had isolated oligosyndactyly; the mother was noted to have bilateral facial weakness.

Pathogenesis. In the Moebius syndrome, combined palsy of the sixth and seventh cranial nerves occurs (31,67). The basic cause remains to be clarified and is probably heterogeneous. Postmortem studies have shown nuclear agenesis (36), prenatal encephalomalacic lesions with mineralized necrotic foci in brain stem nuclei (72), neuron hypoplasia (61), absence or hypoplasia of various cranial nerve trunks and nerves (2), and hypoplasia or absence of the facial muscles (57). Electromyograms and muscle biopsies have been of little value in determining etiology, although results have usually indicated a neural deficit (78). The most complete discussion of pathologic findings and theories of pathogenesis has been presented by Pitner and associates (57). Lammens et al (44) reported neuropathological findings in two presumed cases of Moebius syndrome. The first had splenogonadal fusion and the second lacked seventh nerve involvement.

In a detailed anatomic study of two infants with Hanhart syndrome, Bersu et al (8) indicated that phenotypic features probably resulted from incomplete rather than abnormal morphogenesis. They postulated that oral and limb anomalies resulted from deficient mesodermal proliferation caused by disturbances in ectoderm–mesoderm interactions beginning approximately the fourth week of intrauterine development. In glossopalatine ankylosis, the mechanism of fusion between intraoral structures such as tongue and palate is not yet clear. It is known that their epithelial coverings must come into contact, fuse, and disintegrate (64).

With regard to subclavian artery disruption as a postulated cause for Moebius syndrome, vascular compromise at specific locations around the sixth week of embryonic development could result in predictable patterns. Involvement of the subclavian artery distal to the origin of the internal thoracic artery could cause terminal transverse limb defects. Interruption of the subclavian artery proximal to the internal thoracic artery but distal to the origin of the vertebral artery could lead to Poland anomaly. Moebius involvement could result from premature regression of the primitive trigeminal arteries and/or delayed formation of, or obstruction in, the basilar and/or vertebral arteries (12). Vascular disruption was suggested by Preis et al (58) to explain the concurrent association of *OAV spectrum*, Moebius syndrome, and hypoglossia-hypodactylia.

In the limb deficiency-splenogonadal fusion syndrome, splenic and gonadal anlage may combine by adherence of the left surface of the dorsal mesogastrium (which becomes the dorsal border of the spleen following rotation) to the dorsal coelomic wall or ventral border of the developing mesonephric-gonadal structures. The presence of intraovarian splenic nodules found in some cases cannot be explained by adhesion, but by migrating splenic cells (28). Splenogonadal fusion may be of two types: the continuous variant type, in which a cord connects the spleen with the mesonephric-gonadal structures, and the discontinuous type, in which the splenogonadal fusion has no cord connected to the spleen itself (59). Fetal activity and mobility may be important in development of the two types (28).

Differential diagnosis. As we have already pointed out, there may be variable degrees of overlap between defined syndrome entities of oromandibular-limb hypogenesis. Limb defects have the same range of variability in all six syndromes, except for limb deficiency-splenogonadal fusion syndrome in which extensive lower limb defects may be found. Limb defects may be observed with isolated Poland anomaly, amnion rupture sequence, autosomal recessive acheiropody, and other syndromes with reductive limb anomalies.

Isolated hypoglossia is known to occur (19,22). Hypoglossia has also been observed in association with transposed viscera and dextrocardia (81). Hypoglossia has further been noted to occur with intraoral bands (13,23). Cleft palate has been reported in association with intraoral bands through three generations (35). Such bands have also been documented in some instances of the *popliteal pterygium syndrome*. Sato et al (63) reported a family with ankyloglossia (in which the lingual frenulum is attached to the tongue tip) associated with heterochromia irides and congenital clasped thumbs.

Superficially, syndromes of oromandibular-limb hypogenesis may be confused with *Robin sequence*, *oculo-auriculo-vertebral spectrum*, and *mandibulofacial dysostosis*.

Isolated seventh nerve palsy may result from birth trauma in some instances and has also been observed to follow autosomal dominant and autosomal recessive modes of inheritance. Familial juvenile onset of Bell's palsy (1) and familial palsy in Kawasaki disease (34) have been reported. Families with hereditary seventh nerve palsy without sixth nerve involvement with or without other cranial nerve palsies and with or without other types of anomalies (6,25,42,51,73,79) should not be confused with Moebius syndrome. Some Moebius-like cases eventuate as facioscapulohumeral dystrophy or as infantile *myotonic dystrophy*, both autosomal dominant disorders (3). Families with total external ophthalmoplegia and not abducens palsies (45) should not be confused with Moebius syndrome (4). Ziter et al (84) reported a three-generation pedigree of what they called a Moebius syndrome variant; patients had seventh nerve palsy, normal sixth nerve, finger contractures, mild mental deficiency, and a reciprocal translocation between chromosomes 1 and 13. Rubinstein et al (62) reported a patient with congenital paresis of the third, fourth, and seventh nerves, progressive peripheral neuropathy, anosmia, and hypogonadism. The *cardiofacial "syndrome"* (really an association) combines seventh nerve involvement as asymmetric crying facies with congenital heart defects, skeletal anomalies, and renal defects. Some cases of *thalidomide embryopathy* (39,52) have been noted to mimic Moebius syndrome.

Cohen (15) and Verloes and Koulischer (80) described a newly recognized oroacral syndrome consisting of absent maxillary incisors and canines together with asymmetric reduction defects of fingers and toes.

Splenogonadal fusion may occur as an isolated abnormality. When combined with extensive limb defects involving femora, fibulae, and upper limbs, there is overlap with femur-fibula-ulna dysostosis (FFU) discussed by Lenz et al (46). Splenogonadal fusion has also been noted in a case of *Roberts syndrome*.

Recurrence risk. Since syndromes of oromandibular-limb hypogenesis occur sporadically in almost all instances reported to date, recurrence risk is essentially negligible. Moebius syndrome should be separated from other syndromes of oromandibular-limb hypogenesis syndromes and should especially be separated from high-risk congenital myopathies, from seventh cranial nerve palsy without sixth nerve involvement, and from various other pseudo-Moebius syndromes (for differential diagnosis, vide supra). Several papers have dealt with recurrence risk of the Moebius syndrome (3,4,26). Baraitser (3) studied sibs and parents of 15 cases and concluded that when Moebius syndrome was accompanied by skeletal anomalies, recurrence risk was only approximately 2%, whereas bilateral facial palsy with or without abducens palsy without skeletal anomalies had a greater risk of recurrence. Defining skeletal anomalies as a feature of Moebius syndrome helped exclude high risk monogenic disorders of muscle and anterior horn cell, which facially appear Moebius-like in infancy.

Careful family history and examination are essential in Moebius syndrome patients. Although recurrence risk is negligible, rare familial full (38,43) or partial (17,53) instances have been recorded. Establishing a diagnosis of Moebius syndrome either with or without limb anomalies is important because assessment of psychomotor development tends to be erroneous. Early relative delay tends to disappear with age. Poor feeding during the first year of life, often resulting in poor growth, tends to improve. Some degree of mental deficiency occurs in only 10%–15%.

Moebius syndrome. Moebius (22,23), in attempting to classify multiple congenital cranial nerve palsies, created a division in which palsies of the sixth and seventh cranial nerves were combined. Subsequent authors have broadened this classification to include involvement of other cranial nerves (15,32). Additional abnormalities may include reductive limb anomalies, defects of the chest wall, and mental retardation (Fig. 19–24).

If the minimal criteria for Moebius syndrome include palsies of the sixth and seventh cranial nerves, then almost all examples are apparently sporadic with few exceptions (8,16,18,21). Approximately 160 cases had been published by 1970 (13) and over 300 cases have been recorded to date. The ratio of affected males to females is 1:1. Extensive reviews include those of Henderson (15) and Danis (9). Various topics have already been addressed in the first section of this review: pathogenesis (1,25,34,36); pseudo-Moebius genetic entities with autosomal dominant inheritance (11,19,29,35,38), with autosomal recessive inheritance (3,4), with affected first cousins (14), and with consanguinity [6,14,28 (case 3)]; rare truly inherited cases (16,18,20); chromosome translocations and gene mapping (37); cases with partial manifestation in a first degree relative (8,21); recurrence risk (2), and Moebius sequence with hypogenitalism, and cerebral and skeletal changes in two brothers (8a). Poland syndrome, Moebius syndrome and Klippel-Trenaunay syndrome have been found in the same kindred (18a).

Mask-like facies may be obvious in the newborn, but may often go unrecognized at this time (10,12,15). Bilateral facial paralysis usually imparts a symmetric appearance to the face, but variance in the degree of involvement on each side of the face or upper and lower portions of the face can cause significant asymmetry. Occasionally, only unilateral facial nerve palsy is present (10). Sixth nerve palsy is the most common ocular finding (31). Nearly every remaining cranial nerve can be affected in addition, but of these, the third, fifth, ninth, and twelfth nerves predominate (10,30,32).

Most patients cannot abduct either eye beyond the midline. However, unilateral palsy does occur (17). Ptosis, nystagmus, or strabismus may accompany the above findings (5,13,15). Epicanthal folds are frequent. Some patients may be unable to close their eyes either during sleep or while awake, resulting in conjunctivitis or corneal ulceration (17,26).

The nasal bridge is often high and broad, particularly during infancy and early childhood (26). The broadness of the nasal bridge extends downward in a parallel fashion to include the nasal tip (15). Thus, an upper midfacial prominence usually results.

The mouth aperture is often small. The angles of the mouth droop and may allow saliva to escape (5,26). Attempts at opening the mouth further result in little change. As the child grows older, a definite but slow improvement can be observed in the ability both to open the mouth and to feed adequately (10,15). Poor feeding during the first year of life frequently results in poor growth.

Unilateral tongue hypoplasia is frequent (10), but bilateral hypoplasia can occur (10,13,26). The degree of hypoplasia may, on occasion, be extreme (7). Muscular fasciculations of the tongue may be present (12). Poor palatal mobility, inefficient sucking and swallowing, coarse voice, and speech impairment are often present (26).

Frequently, the mandible is mildly to moderately hypoplastic (10,26), and when combined with the small mouth aperture, imparts the appearance of a lower midfacial hypoplasia. The coronoid process may be enlarged (34a). Oligodontia has been described in one case (28).

The pinnae may be normal. However, they may be large, may be deficient in cartilage, and may protrude laterally (10). Occasionally, they are hypoplastic, but most instances of severe hypoplasia probably do not represent true examples of the Moebius syndrome. Likewise, the hearing deficits that are reported occasionally with these hypoplastic ears are very infrequent findings in the Moebius syndrome.

Bilateral, unilateral, or asymmetric hypoplasia or aplasia of the pectoralis major muscle or complete Poland anomaly (33) occurs in 15%. Polythelia or athelia may be present (15). Spinal curvatures are occasionally noted but, as a rule, only in those few instances associated with arthrogryposis (13).

Limb defects occur in approximately 50%. Thirty percent constitute talipes deformities (15). The remaining 20% include primarily hypoplasia of digits, syndactyly, or more severe reduction deformities of the limbs. Clinodactyly, polydactyly, joint contractures, and congenital hip dislocation occur less frequently (15,27).

Other findings rarely may include congenital heart defects, urinary tract abnormalities, hypogenitalism, and hypogonadism (13,24,33) and premature thelarche (17). The authors have seen two examples with congenital heart defects.

Ten percent to 15% are mentally retarded (9,15). The degree of mental retardation is usually mild (15). Estimates of early psychomotor development tend to be erroneously low (5,10). The severe physical deformities often cause a relative delay in apparent psychomotor development that tends to disappear as the child grows older.

Hypoglossia-hypodactylia syndrome. In a critical review of the literature in 1971, Hall (17) was able to confirm only nine cases of the hypoglossia-hypodactylia syndrome (Fig. 19–25) including one of his own (6,11,13,17,20,21,26,30,32). Since then, many other cases have been recorded (1–4,7–9,12,14–16,18,19,22,24,25,31,33). Of six patients reported by Johnson and Robinow (19), four had hypoglossia-hypodactylia and two had Moebius syndrome. The cases reported by Temtamy and McKusick (31) had either hypoglossia-hypodactylia syndrome or glossopalatine ankylosis syndrome. The case described by Schuhl (28) is an example of Moebius syndrome. To date, approximately 30 cases have been recorded, although a few of these, as already mentioned (31), had glossopalatine ankylosis. The condition is frequently called aglossia-adactylia, a misleading term, in our opinion, because the tongue is never completely absent, and adactylia does not convey the variation in limb defects of affected individuals.

All cases of the hypoglossia-hypodactylia syndrome have been sporadic to date. Etiologic, pathogenetic, and nosologic considerations have been addressed in an earlier section.

The mandible is small and the chin recedes. Hypoglossia is variable in degree, being extreme in the cases of Rosenthal (26), Fulford et al (11), and Thornton (32), but the tongue was reduced only 25% in Hall's case (17). Mandibular incisors have been noted to be absent, with concomitant hypoplasia of the associated alveolar ridge (17,26). Marked enlargement of the sublingual muscular ridges and hypertrophy of the sublingual and submandibular glands have been described (11,26). A mild defect of the lower lip was noted by Rosenthal (26). Fusion of the anterior alveolar processes and cleft palate have been noted in several cases (4,18,25). In some patients, the size of the oral opening is markedly reduced (Fig. 19–25).

Limb anomalies are extremely variable. Any limb may be affected, and variability may be observed in the same patient as well as in different patients. For example, hemimelia of all four limbs was noted by Temtamy and McKusick (31). Involvement of both left limbs with normal right limbs was reported by Nevin et al (22). Oligodactyly and syndactyly of both hands and complete adactyly of one foot with absence of the hallux on the other foot were observed by Kelln et al (20).

Speech is surprisingly good, and patients have been of normal intelligence. Other findings have included fused labia majora (20), unilateral renal agenesis [19 (case 5)], and congenital occlusion of the superior mesenteric artery [19 (case 2)]. Because of associated abducens and oculomotor palsies, the patient reported by Ernst and Meinhold (10) represents a nosologic bridge. The patient reported by Cohen et al (5) had Moebius facies with sixth and seventh nerve palsies, limb anomalies, and severe microglossia.

Isolated hypoglossia was first reported by de Jussieu (8) in 1718. Other such cases have been described by several authors (27,33,35,36). Shah (29) tabulated 30 cases of hypoglossia and found cleft palate in 11 of these and other malformations in 24. Watkin (34) reported hypoglossia in association with transposed viscera and dextrocardia. Oulis and Thornton (23) observed a patient with severe hypoglossia, micrognathia, oligodontia, enamel hypoplasia, situs inversus, dextrocardia, and asplenia.

Hanhart syndrome. Hanhart syndrome as originally defined consisted of micrognathia and peromelia (Fig. 19–26). Using this definition, approximately 12 cases have been described (1,2,5–8,10–14). The patient reported by Bökesoy et al (3) had microglossia and glossopalatine ankylosis. The two patients reported by Dellagrammaticas et al (4) had severe microglossia and fit the original definition of the hypoglossia-hypodactylia syndrome. Using a broader definition of Hanhart syndrome that encompasses several conditions with oromandibular-limb hypogenesis, Herrmann et al (8) tabulated 31 cases from the literature and presented four of their own. To date, all cases have been sporadic. Nosologic, etiologic, and pathogenetic considerations have been addressed previously. American clinicians should carefully note that in the European literature, although four conditions are called Hanhart syndrome (9), they are nosologically unrelated and are as distinct as von Recklinghausen's neurofibromatosis and von Recklinghausen's disease of bone. None of the other three conditions named after Hanhart has oligodactyly or partial syndactyly, despite a report to the contrary [5 (case 1)].

Micrognathia has been a feature in all cases. In Case 2 of Garner and Bixler (5), a fibrous band was noted connecting the maxilla and mandible on both sides but not anteriorly. The tongue was noted to be relatively normal in size in their patient. Most authors have not commented upon tongue size except Herrmann et al (8) who specifically mentioned microglossia. In one case, the tongue was fused to the lower lip, alveolus, and the floor of the mouth. Because of the degree of micrognathia expressed in some cases of Hanhart syndrome, we feel that hypoglossia should certainly be looked for in any suspected case. Hypodontia has been reported (7,8,13). Assemany et al (1) reported Robin sequence in their case. Absence of major salivary glands has been noted (2).

Limb anomalies range from stunted digits and oligodactyly to more severe peromelia. Any limb may be affected, and variability of involvement in the same patient and in different patients is well illustrated by Hanhart (7). Coxa valga was noted in one instance (7). Imperforate anus has also been recorded (2).

Glossopalatine ankylosis syndrome. This syndrome, first described in 1887 by Illera (7) and early in the twentieth century by Kettner (9) and Kramer (10), is rare. Approximately 15 cases have been reported (1–19). To date, all cases have been sporadic. Nosologic, etiologic, and pathogenetic considerations have been previously discussed. Shah (15) published a summary of cases of intraoral attachments. In 14 cases with glossopalatine ankylosis, cleft palate was present in six and other types of malformations (e.g., limb anomalies) in four.

The tongue is usually attached to the hard palate (Fig. 19–27) (1,5), but may also be adherent to the maxillary alveolar ridge (5). Highly arched palate has been documented in some instances (3). Cleft palate has also been observed (8,18) and, in these cases, the tongue may be attached to the lower edge of the nasal septum. In glossopalatine ankylosis, palatal attachment usually occurs to the anterior portion of the tongue. The tongue tip has been noted to be mildly cleft (1). Its mobility is reduced, and its extension beyond the teeth is limited (1,3). The mandible may be hypoplastic, and the central portion of the upper lip has also been described as hypoplastic (1,3). Hypodontia principally affects the incisor teeth (1,3). Ankylosis of the temporomandibular joint has also been recorded (1). Facial paralysis has been noted in several instances (1,10,16). Limb anomalies are extremely variable and may affect both hands and feet. Oligodactyly, syndactyly, polydactyly, and more severe peromelia have been observed (1–3,8,14,16,18,19).

Fig. 19–27. *Glossopalatine ankylosis syndrome*. At arrow, see attachment between ventral tongue tip and hard palate. (From Minami K et al, J Oral Maxillofac Surg 53:588, 1995.)

Charlie M. syndrome. In 1969, Gorlin (1) observed that the Moebius syndrome category had been overworked as a repository for several different disorders and cited the Charlie M. syndrome as an example (Fig. 19–28). The condition is characterized by hypertelorism, facial paralysis in some instance, absent or conically crowned incisors, cleft palate, and variable degrees of hypodactyly of the hands and feet. We have observed several cases and, in each instance, the affected individual has represented a sporadic occurrence. Another patient was reported by Kaplan et al (2).

Limb deficiency-splenogonadal fusion syndrome. Splenogonadal fusion was first mentioned by Bostroem (5) in 1883 and described in detail by Pommer (17) in 1889. By 1985, 84 cases were on record (9), and by 1999, 150 cases were known (4). However, only 25 of these cases had associated limb defects (1–4,7,8,10–19,22) and approximately 70% of these had mandibular hypoplasia (4).

Although there is a strong male bias in ascertaining splenogonadal fusion (4,9,24), the sex ratio is misleading because of the rarity of ovarian complications in females during their lifetimes or by difficulty in examining ovaries compared to testes. Putschar and Manion (18) divided splenogonadal fusion into two types: a continuous type in which a fibrous cord-like structure connects splenic tissue between the spleen and the gonad (Fig. 19–29) and a discontinuous type in which no connection exists between the main spleen and the ectopic spleens. When splenogonadal fusion is associated with limb reduction defects, 83% of the cases are continuous (4). In all cases of splenogonadal/limb deficiency cases

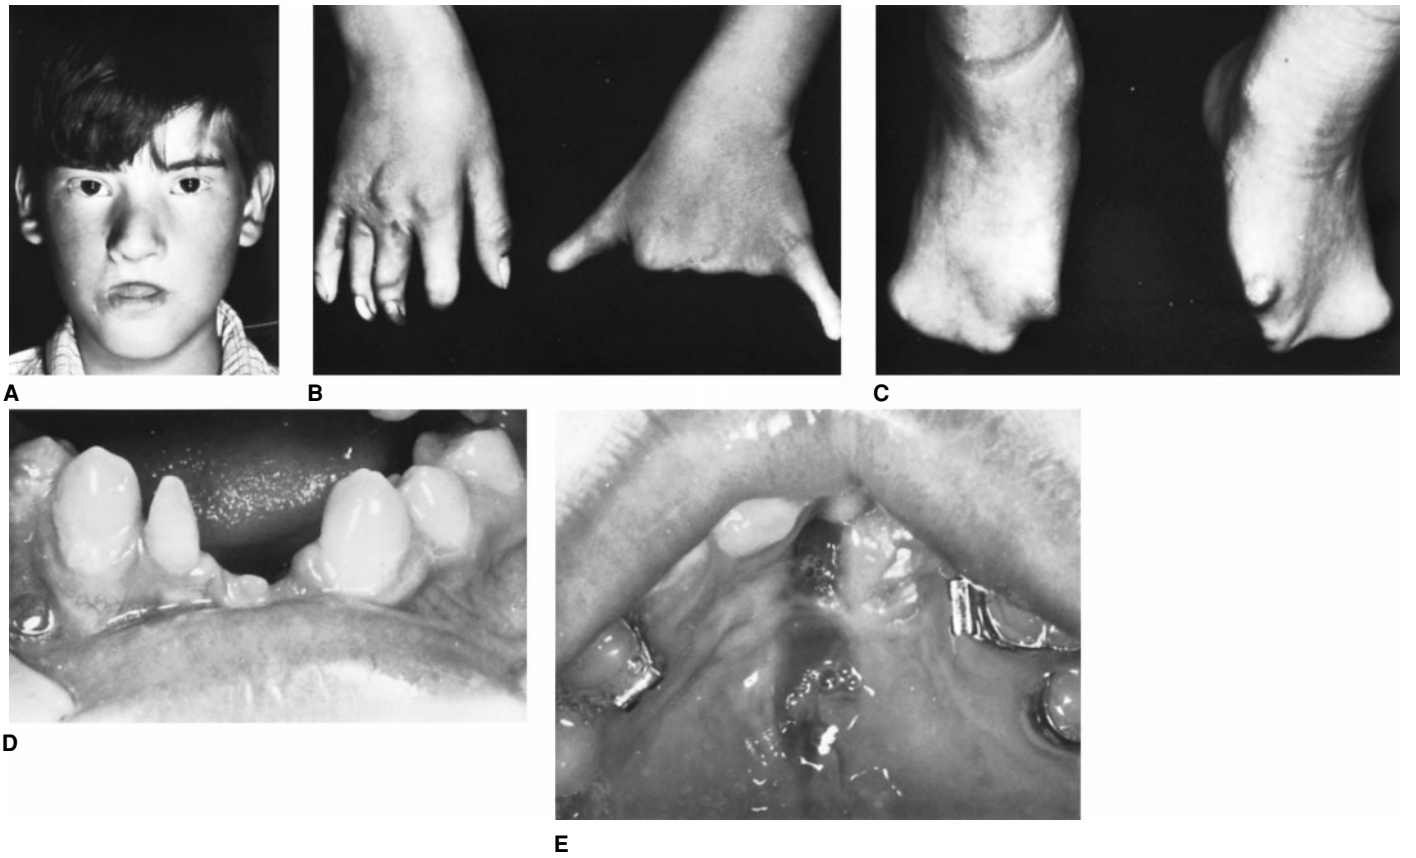

Fig. 19–28. *Charlie M. syndrome*. (A) Upslanting palpebral fissures, ocular hypertelorism, lower facial palsy. (B,C) Bizarre digital agenesis and malformations. (D) Absence of three lower incisors, conical crown form of remaining incisor. (E) Repaired cleft of anterior palate. [From RJ Gorlin, Birth Defects 5(2):65, 1969.]

analyzed by Bonneau et al (4), 70% had severe limb reduction defect (4). More complex defects involving the upper limbs, femora, and fibulae were found in 23% (4). Mandibular hypoplasia was found in 70% (4).

To date, all cases have been sporadic (1–19,22). Excellent reviews are those of Pauli and Greenlaw (15) and Bonneau et al (4). Gouw et al (9) provided an analysis of splenogonadal fusion and its associated anomalies. Nosologic (3,4,14,15,20,22,23), etiologic (18), and pathogenetic (9) concepts have been dealt with in the general section on oromandibular limb hypogenesis.

Craniofacial anomalies have been reported in some patients, but less frequently than micrognathia. Findings have included plagiocephaly (15), malformed and/or low-set ears (4,18), deviated nose (16), cleft palate or bifid uvula (4), V-shaped palate (15), microglossia (4), and unerupted teeth (15). Splenogonadal fusion has also been associated with oral anomalies in patients with normal limbs. Tsingoglou and Wilkinson (23) reported micrognathia and Watson (24) described micrognathia, microstomia, and cleft soft palate. Sieber (21) noted a patient with splenogonadal fusion and Moebius syndrome.

Limb reduction defects have great variability. Involvement appears to be more severe more frequently than in other syndromes of oromandibular-limb hypogenesis.

In males, splenogonadal fusion almost always involves the left gonad; in females, the left ovary or adnexal structure is usually involved (9). Male infertility has been noted (1). In the patients reported by Barr (3), four accessory spleens were found along the descending colon and a fifth accessory spleen was fused to the left ovary.

In males, correct preoperative diagnosis is rarely made, differential diagnosis usually including supernumerary testis, epididymitis, testicular tumor, hydrocele, and angioma or cyst of the lower spermatic cord (6,10). Splenogonadal fusion should be suspected in any patient with limb reduction defects and either a scrotal mass or left cryptorchidism. A bloody tap from a punctured scrotal mass should arouse suspicion of an aberrant spleen even more. Paratesticular spleen occasionally may produce clinical symptoms such as pain and swelling of the scrotum (18,22). In rare instances, a continuous splenic-gonadal band may cross ventral to the intestinal loops, resulting in bowel obstruction (12). In Sommer's case (22), a unique alternate drainage of considerable magnitude shunted blood directly into the inferior vena cava via the spermatic and left renal vein, bypassing the liver.

Various other anomalies have also been reported. Significantly, imperforate anus and other anorectal abnormalities have been noted (14,16,17), a finding also reported in one instance of Hanhart syndrome. Low-frequency findings have included hypoplastic lungs (4,16), abnormal lung fissures (15), agenesis of left diaphragm (4,16), congenital heart defects (3,4,16), spina bifida (22), and coccygeal defect (17). Central nervous system abnormalities have been variable and nonspecific (1,2,7,13,15,22). Polymicrogyria was described by Fritzsche (7). Pauli and Greenlaw (15) reported mild mental deficiency.

Oral-facial-digital syndromes

It is becoming increasingly apparent that striking heterogeneity exists among the oral-facial-digital (OFD) syndromes. In common to all are minor facial anomalies, oral findings (e.g., cleft or lobulated tongue, oral frenula, and/or cleft palate), and digital anomalies, including brachydactyly, syndactyly, clinodactyly, and polydactyly. Other anomalies are often present, which make it difficult to ascertain whether cases with unusual anomalies indicate variable expressivity of an OFD or represent other conditions, thus indicating heterogeneity. Often these examples are sporadic in otherwise normal families; in the few instances in which affected sibs are reported, information is often incomplete on all but the propositus. Classification of many of the new OFD syndromes is therefore tentative, and is usually based on the consistent occurrence of an unusual anomaly in all affected cases (1–4). Only in OFD I has the gene been mapped. We await further molecular mapping for true classification.

OFD type I (Papillon-Léage/Psaume syndrome). In 1954, Papillon-Léage and Psaume (25) defined a syndrome of hyperplastic frenula, multilobulated tongue, hypoplasia of nasal alar cartilages, median pseudocleft of upper lip, asymmetric cleft palate, various malformations of digits, and mild mental retardation.

Similar cases had been reported under a variety of names as early as 1860. To date, more than 250 cases have appeared in the literature. There are several comprehensive reviews (2,9,10,13,14,20,21,30). Wahrman et al (35) suggested that the frequency of the syndrome is probably approximately 1/50,000 live births.

OFD I syndrome has dominant X-linked inheritance although 75% of the cases are sporadic. It is limited to females and is lethal in male heterozygotes (6,10,14,19). It has been described in a male with XXY Klinefelter syndrome (35) and in karyotypically normal males who died soon after birth (11,12). One of the most perplexing pedigrees is that of Vaillaud et al (33) and Vissian and Vaillaud (34). In this family the disorder appears to have been transmitted through unaffected males. Several other reported "affected" males probably had Mohr syndrome (OFD II syndrome). The gene, *OFD1*, maps to Xp22.2–Xp22.3 (8,9a,10a). Discordant monozygotic twins have been noted (28), possibly because of postzygotic mutations. The gene escapes X inactivation (9a).

Facies. The facies is remarkably distinctive. Frontal bossing has been documented in 30%. Usually there is euryopia, but in approximately 35% dystopia canthorum (lateral displacement of the inner canthi) is evident (19). Some aquiline thinning of the nose, due, at least in part, to hypoplasia of alar cartilages, and a pseudocleft in the midline of the upper lip are present in approximately 45% (Fig. 19–30). The upper lip is usually short, and the nasal root is broad. One nostril may be smaller than the other, and there may be flattening of the nasal tip. Because of zygomatic hypoplasia, the midfacial region is flattened in approximately 25% (21).

A B

Fig. 19–30. *Oral-facial-digital syndrome, type I.* (A) Pseudocleft in midline of upper lip, lack of nasal alar flare. (B) Note frontal bossing, widely spaced eyes, hypoplastic alar cartilages, and downturned mouth. (A from H Reinwein et al, Humangenetik 2:165, 1966.)

Skin and skin appendages. Commonly there are evanescent milia of the face and ears (Fig. 19–31). These usually disappear before the third year of life (15). Approximately 65% have dryness, brittleness, and/or alopecia of the scalp hair (26), especially over skull prominences and following Blaschko lines (5a,16). There is marked decrease in sebaceous glands.

Dermatoglyphics have been studied (5,6,26). A preponderance of whorls has been noted.

Skeletal manifestations. Malformations of fingers, seen in 50%–70% include clinodactyly, syndactyly, and brachydactyly of digits 2–5 (Fig. 19–32A,B). Toe malformations, noted in 25%, include unilateral hallucal polysyndactyly, syndactyly, and brachydactyly (Fig. 19–32C). Bilateral polydactyly of halluces has been documented on one occasion (31). The hallux is often bent in a fibular direction, with brachydactyly and hypoplasia of the second to fifth toes. Occasionally, there is a postminimus finger or toe (6,19,26,28,30). A patient was reported with unilateral pseudoarthrosis of the tibia (23).

Fig. 19–31. *Oral-facial-digital syndrome, type I.* Milia of pinna, which ordinarily disappear by the third year of life. (From F Majewski et al, Z Kinderheilkd 112:89, 1972.)

The nasion-sella-basion (cranial base) angle is increased, being about 144(and exceeding the normal value of 131° (SD = 4.5°) by almost 3 SD (1,14,30) in approximately one-half of the patients.

Radiographic examination shows the short tubular bones of the hands and feet to be irregularly short and thick. Irregular reticular pattern of radiolucency and/or spicule-like formation are observed in metacarpals and, especially, phalanges (36). Some patients have cone-shaped epiphyses in the fingers. Irregularities of the long bones were also reported by Stapleton et al (31).

Central nervous system. Mild mental retardation is seen in approximately 40% (19,21,27,32). The intelligence quotient usually ranges from 70 to 90. Various central nervous system alterations have been described: hydrocephaly, hydranencephaly, microcephaly, porencephaly, and agenesis of corpus callosum (Fig. 19–33) (4,5,13,14,18,19,22,26–28,36). Precocious puberty has been noted in association with hypothalamic hamartoma (29). Pachygyria, heterotopic gray matter, bilateral arachnoid cysts, and Dandy-Walker cyst have been noted (18,32). These and other anomalies have been reviewed by Wood et al (36) and Baraton (3). Decreased hearing has also been noted (6).

Urinary system. Adult onset bilateral polycystic kidneys and medullary cystic renal disease, usually asymptomatic, have been reported in approximately 50% (4,5,7,19,22,27,35). In the case reported by Stapleton et al (31), the kidneys were normal at 1 year; reevaluation at 11 years demonstrated bilateral polycystic kidneys. Others have found progressive renal insufficiency (5,22). Even fetal polycystic disease has been described (21a).

Oral manifestations. The most striking oral manifestations are the clefts associated with hyperplasia of frenula (Fig. 19–34). There is often (in approximately 45% of whites) a small midline cleft in the upper lip extending through the vermilion border. Blacks apparently rarely have upper lip midline clefts (27). Upon retraction of the short upper lip, a wide, thickened, or hyperplastic reduplicated frenum is seen to be associated with the pseudocleft. This, in part, eradicates the mucobuccal fold in the area. Because of these bands, complete retraction of the lip is often not possible. Thick frenula are seen in virtually all patients (10,13,19).

The palate is cleft laterally, deep bilateral grooves extending medially from the maxillary buccal frenula, dividing the palate into an anterior segment (containing the incisors and canines) and two lateral palatal

C

Fig. 19–32. *Oral-facial-digital syndrome, type I.* (A) Asymmetric soft-tissue syndactyly, abbreviation of fingers. (B) Shortened metacarpals, malformed, abbreviated phalanges. (C) Unilateral preaxial polysyndactyly of hallux. (A from H Reinwein et al, Humangenetik 2:165, 1966. B from JA Dodge and DC Kernohan, Arch Dis Child 42:214, 1967. C from JW Curtin, Plast Reconstr Surg 34:579, 1964.)

processes. The soft palate is completely and asymmetrically cleft in at least 80% in whites and in 25% of blacks (10,21,27). In some persons, a large bony ridge extends from the alveolar crest medially to the midline in the canine–premolar area, somewhat resembling a misplaced torus.

Numerous thick fibrous bands are evident in the lower mucobuccal fold in 75%. Cleft tongue with two lobes is seen in 30%, with three or more lobes in 45%. On the ventral surface of the tongue, between the tongue halves or lobules, a small whitish to yellowish hamartomatous mass is seen in approximately 70% (19,21). This consists of fibrous connective tissue, salivary gland tissue, fat, a few striated or smooth muscle fibers, and, rarely, cartilage (21). Ankyloglossia or tongue-tie of a diffuse nature is present in at least 30% (19,21).

Malposition of the maxillary canine teeth, supernumerary maxillary deciduous canines and premolars, and infraocclusion are common. Supernumerary canines, often separated by the clefts, are noted in approximately 20%. The canine crown form is often T-shaped. Aplasia of mandibular lateral incisors occurs in approximately 50% and appears to be predicated on the effect of the fibrous bands on developing tooth germs. The mandible is small or hypoplastic with a short ramus (17).

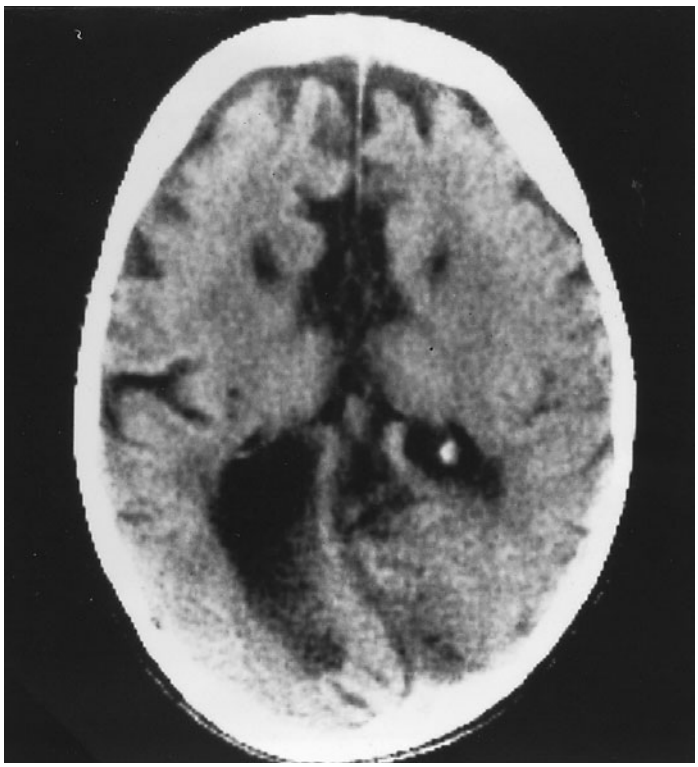

Fig. 19–33. *Oral-facial-digital syndrome, type I.* Agenesis of corpus callosum and cerebral atrophy. (From AA Connacher et al, J Med Genet 24:116, 1987.)

Differential diagnosis. Several of these components may be seen in other syndromes. For example, in *Ellis-van Creveld syndrome*, the upper or, occasionally, the lower lip may be attached to the gingiva, there being no mucobuccal fold anteriorly. Associated with this may be a mild mid-upper lip defect. Alar cartilage hypoplasia and dystopia canthorum occur in *Waardenburg syndrome*, but to a greater degree. Postaxial polydactyly of the hands and feet, unusual facial appearance (metopic prominence, upward-slanting palpebral fissures, epicanthal folds, anteverted nostrils), labiogingival frenula, highly arched palate, short stature, skin laxity, and failure to thrive occur in the *Opitz trigonocephaly (C) syndrome*. Hamartomata of the tongue may be an isolated finding (24).

Most closely related to this syndrome is *OFD II syndrome*. It has autosomal recessive inheritance. These patients also have midline cleft of the upper lip, lobate tongue with small excrescences, bilateral manual hexadactyly, and bilateral polysyndactyly of the halluces. In contrast to patients with OFD I syndrome, these patients may be male. They do not have hyperplastic frenula, the lower central incisors may be absent, and occasionally there is a hearing defect. Other oral-facial-digital syndromes can also usually be distinguished on clinical grounds. Hallucal polydactyly can be found in many syndromes: *cephalopolysyndactyly, Greig syndrome, acrocallosal syndrome, Apert syndrome, Pfeiffer syndrome, Jackson-Weiss syndrome, Saethre-Chotzen syndrome, craniofrontonasal dysplasia, Rubinstein-Taybi syndrome, femoral hypoplasia-unusual facies syndrome, del(4p) syndrome*, and *del(7p) syndrome*.

Laboratory aids. A CAT scan and/or and an MRI can be employed for brain and kidney abnormalities, pre- and postnatally (27a).

OFD type II (Mohr syndrome). In 1941, Mohr (20) described a family later expanded upon by Claussen (8). Several sibs and a cousin exhibited lobed tongue, manual polydactyly, and bilateral polysyndactyly of the halluces (Fig. 19–35). Earlier cases may have been described by Otto (21) in 1841 and Dreibholz (11) in 1873. Subsequently, a number of well-defined examples have been published (2,5,10,12–15,18). Less certain are several other cases (3,4). Although some examples previously described as Mohr syndrome have been subsequently recognized as being distinct conditions (vide infra), further heterogeneity within this group is very likely.

The syndrome clearly has autosomal recessive inheritance. Parental consanguinity has been demonstrated (8) and there have been several examples in sibs (8,21). Its frequency may be approximately 1/300,000 live births (1).

Facies. Frequently there is a midline cleft of the upper lip. Hypertelorism and micrognathia are also common (1,7,16). The ears may be lowset and/or posteriorly angulated (1). Facial milia are not present (Fig. 19–35A).

Skeletal alterations. Bony changes appear to be limited to hands and feet. Bilateral manual hexadactyly and bilateral polysyndactyly of the halluces are characteristic (1,5,10,15,18) (Fig. 19–35). The hallucal polysyndactyly in the patients described by Beaudry (4) and Mayer and Schnidder (19) was, however, unilateral. Christophorou and Nicolaidou (7) and Cordero and Holmes (9) reported duplicated thumbs in their patient. Patients described by several authors (4,8,9,18) also had one or more postminimus digits of hands and/or feet.

Bimanual hexadactyly apparently is not requisite for the diagnosis of the syndrome, since in some cases there have been five fingers with ulnar deviation of the fifth finger, 3–4 syndactyly with extra bones in the web, or hexadactyly of only one hand (8,16).

Central nervous system. Mental retardation has been reported in several cases (15,21). Various other neurologic anomalies have been described, including microcephaly (15), porencephaly (15), hydrocephalus (10,23), subarachnoid cyst and hypoplastic vermis (2,23), conductive hearing loss (16), choroid coloboma (10,19), and muscular hypotonia with poor coordination (8,15,18).

Other findings. There appears to be increased susceptibility to respiratory infection, which in several patients has resulted in death during infancy (3,8,10). Tachypnea has also been reported (8). Cryptorchidism (4,8) and inguinal hernia (15) have been noted. Complex heart malformations have been reported occasionally (9,14).

Oral manifestations. Cleft tongue is probably a constant feature of the syndrome, and several authors have spoken of general ankyloglossia (3,4) (Fig. 19–35G). In a few cases, cleft or highly arched palate (1,3,16,18) has been mentioned. However, in most patients, the palate has been intact (15,18). A small median cleft of the upper lip is a relatively common feature, but was missing in the case described by Mohr (20) and Claussen (8) (Fig. 19–35A). Multiple frenula are occasionally present (1,15,18), but far less frequent than in OFD I syndrome. Fatty hamartomas on the dorsum of the tongue have been found in several cases (3,4,8,18,19,21).

Differential diagnosis. Median cleft of the upper lip is also seen in other OFD syndromes (vide infra). There are a number of cases in which there is overlap between OFD II and OFD IV (13,24) (see OFD IV for discussion). There are also examples of overlap between OFD II and

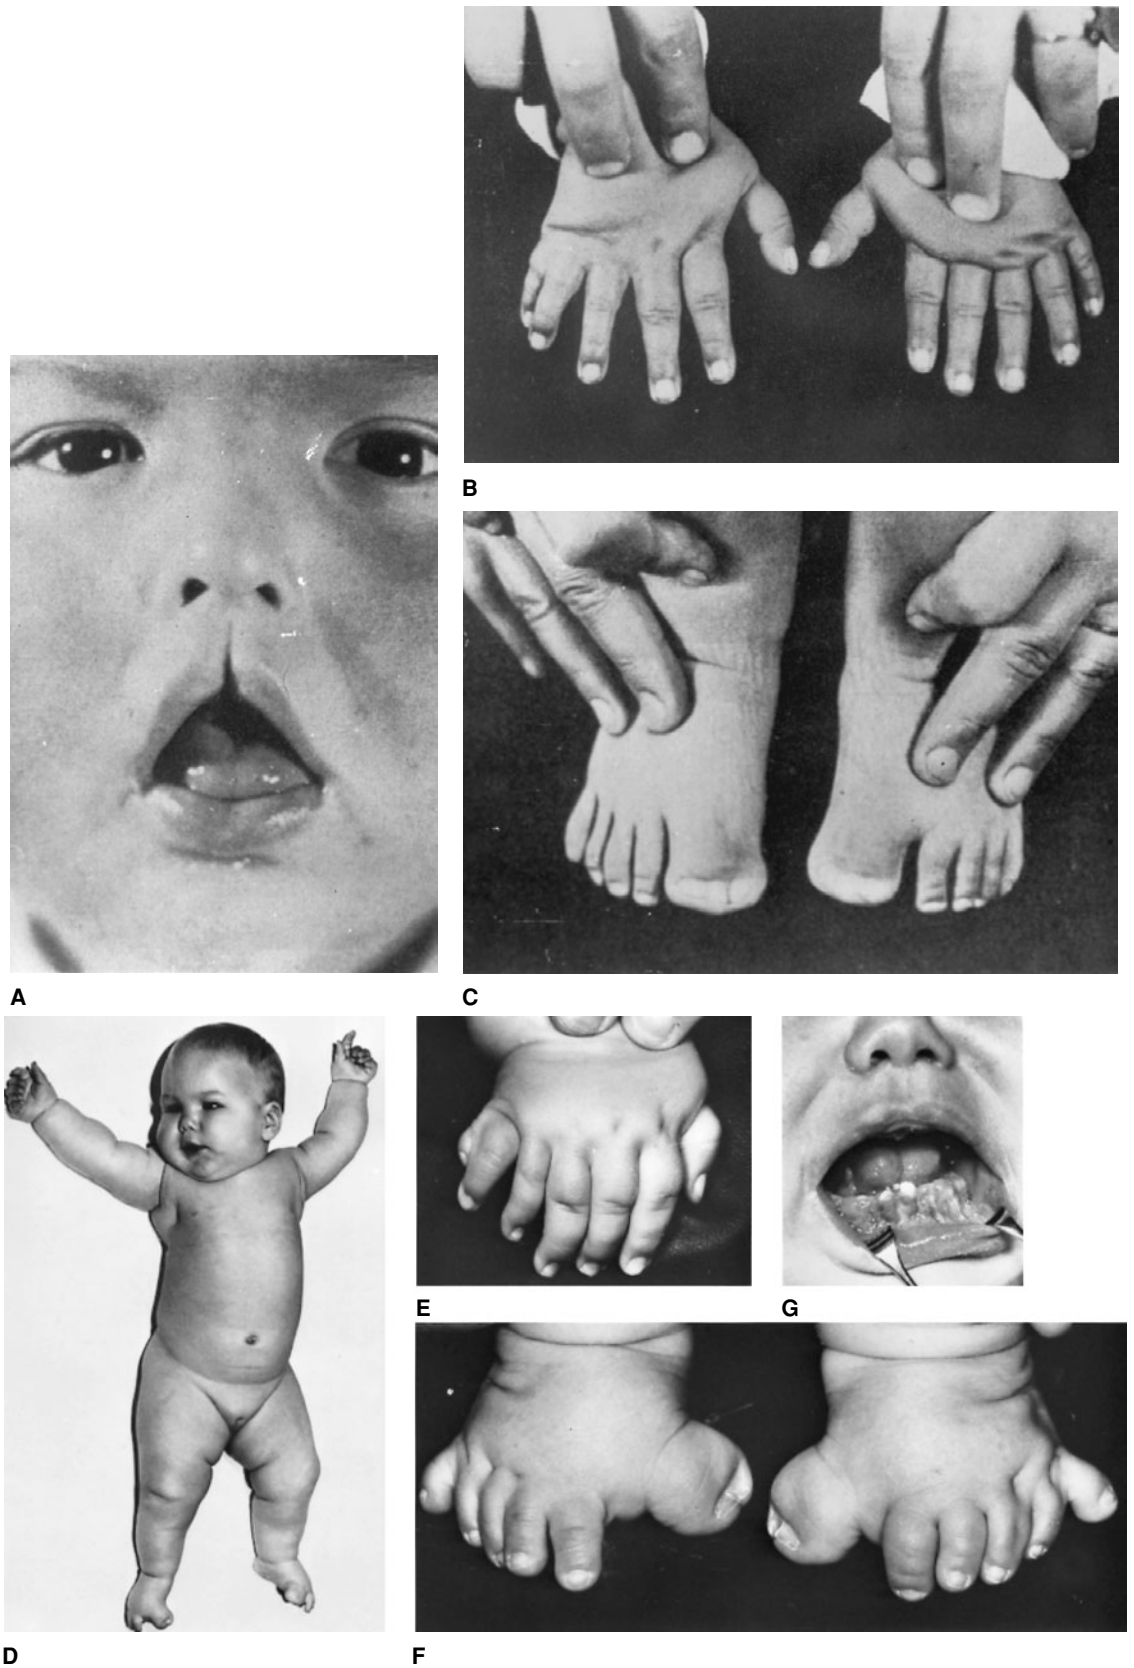

Fig. 19–35. *Oral-facial-digital syndrome, type II*. (A–C) Note median cleft of upper lip and bimanual hexadactyly. Child also had bilateral polysyndactyly of halluces. (D–G) Compare with patient in A–C. Note bilateral manual hexadactyly, polysyndactyly of halluces, defect in middle of upper lip, hamartoma of tongue. (A–C courtesy of F Burian, Prague, Czechoslovakia. B from RA Pfeiffer et al, Klin Padiatr 185:224, 1973.)

OFD VI (6). We suspect that the children reported by Lyons (17) have *Carpenter syndrome*.

Laboratory aids. Prenatal diagnosis has been accomplished (2a).

OFD type III [see-saw winking with oral-facial-digital anomalies and postaxial polydactyly of the hands and feet (Sugarman syndrome)]. Sugarman et al (2) reported female sibs with a syndrome similar to, but distinct from OFD I and II syndromes. Both sisters had lobulated, hamartomatous tongue, dental anomalies, including malocclusion and extra teeth, bifid uvula and normal palate, postaxial hexadactyly of hands and feet, pectus excavatum, short sternum, kyphosis, and profound mental retardation. In addition, the younger sister had frontal bossing, hypertelorism, down-slanting palpebral fissures, esotropia, apparently low-set ears, brachydactyly with hyperconvex nails, and continuous alternating winking of the eyelids that the authors termed *see-saw winking* (Fig. 19–36). The older sister did not exhibit this phenomenon, but did have blepharospasm. McKusick (personal communication, 1986) has seen a similar case. Smith and Gardner-Medwin (1), in 1993, reported male and female sibs with lingual hamartomas, postaxial polydactyly, mental retardation, see-saw eye movements and hypoglossia of cerebellar vermis. We cannot exclude *OFD VI* or Joubert syndrome (see *Differential diagnosis*).

Fig. 19–36. *Oral-facial-digital syndrome, type III*. See-saw winking, strabismus, pectus excavatum, short sternum, polydactyly, profound mental deficiency. (Courtesy of GI Sugarman, Los Angeles.)

Inheritance is likely autosomal recessive.

OFD type IV (oral-facial-digital syndrome with tibial dysplasia, Baraitser-Burn type). There have been 25 reported cases (1–9,11–20) of patients with oral, facial, and digital anomalies who have also had tibial dysplasia and/or mesomelia (Fig. 19–37). Sensenbrenner and Jorgenson (15) reported a case they described as having Mohr syndrome and skeletal dysplasia; Temtamy and McKusick (18) later described the same case and suggested this entity represented an overlap of Majewski and Mohr syndromes. Baraitser et al (1) also reported a case with features of both Mohr and Majewski syndromes; Burn et al (3) later described an affected sib of the proband in Baraitser's report and suggested this entity be named OFD IV.

Inheritance is probably autosomal recessive. Three reports have involved affected sibs (3,8,14); the remaining reports have been sporadic cases. Consanguinity has been noted (2,19).

Facial anomalies have included broad nasal root (2,11,14,16,18), broad nasal tip (6,8,14,15,17), hypertelorism or telecanthus (2,3,11,14,16,18), micrognathia (3,14,15,17,18), hypoplastic mandible (2,3,14), and low-set ears (3,8). Numerous oral anomalies are present, including cleft lip (6,8,11,14,18), cleft or highly arched palate (3,6,8,11,12,14,15,17), bifid uvula (17), cleft or hypoplastic maxillary and/or mandibular alveolar ridge (3,8,14,17,18), oral frenulae (7,10), and lingual hamartoma (2,3,6,12,15,17,18). Dental anomalies are also common, and generally include absent and supernumerary teeth (6,8,14–18). Goldstein and Medina (8) further described the teeth as being small, and exhibiting abnormal crown and root morphology (hypertaurodontism and talonism). Absent or hypoplastic epiglottis has been found (12,18).

Fig. 19–37. *Oral-facial-digital syndrome, type IV*. (A,B) Broad nasal root, broad nasal tip, micrognathia. (C) Short stature with short tibiae. (D) Note short tibiae with midshaft bowing, talipes equinovarus. (E,F) Brachydactyly. Extra postaxial digit surgically removed from each hand. (G) Syndactyly. Excision of postaxial digit from each foot. (A–C, E–G from GI Sugarman, J Clin Dysmorphol 1:16, 1983. D from J Burn et al, J Med Genet 21:189, 1984.)

Digital anomalies were varied, but generally present. Both pre- and postaxial polydactyly of the hands have been described (7–14); syndactyly (6,7,17), clinodactyly (2,7,8,14,16,18), and brachydactyly (7,14,16–18) can also occur. Preaxial polydactyly of the feet was described in three cases (2,14,18) and both pre- and postaxial polydactyly in five cases (2,10). One patient had six toes on each foot, but whether they were pre- or postaxial was not specified (7). Neither of the sibs reported by Goldstein and Medina (8) had polydactyly of either hands or feet, so this finding is apparently not consistent.

Talipes equinovarus has also been described (3,12,17). Mesomelia of varying degrees is present in most cases, and often the tibia is described as dysplastic. Several authors (3,7,17) described the tibia as being short with midshaft bowing. Büttner and Eysholdt (4) and Fenton and Watt-Smith (6) reported the tibia as pseudoarthrotic. Other tibial anomalies include proximal metaphyseal or epiphyseal flattening (3,8,14,17) and/or metaphyseal flaring (2,8,14). Forearms can also be short (15,16) and stature, when noted, is below the third centile (8,14,15–17).

Conductive hearing loss occurs in some patients (3,8,12,14,17). Although intellect has been reported as normal in several cases (14–16), most have been mentally retarded (2,3,6). We have also seen a child with OFD IV with retardation secondary to porencephaly.

The chest is sometimes small (17–20) and pectus carinatum or excavatum has also been reported (14,15).

Two additional cases of OFD IV may be the sibs reported by Michels et al (10). These sibs had oral, facial, and digital anomalies, and were thought to have OFD II; however, one or both sibs also had clubfeet, pectus excavatum, and short stature, which is more consistent with OFD IV. Because it was not noted whether X-rays of the long bones were made, classification of these cases as examples of OFD IV is tentative.

In conclusion, all cases of OFD IV have tibial defects in common, ranging from metaphyseal and epiphyseal abnormalities detected by X-ray (2,14) to dysplasia severe enough to necessitate amputation (16). Tibial defects may be unilateral (6) or bilateral. The presence of postaxial polydactyly and pectus excavatum in some cases also helps distinguish this condition from OFD II. However, it is likely that this group is very heterogeneous, and resolution of this question awaits description of further cases of affected siblings, and delineation of degree of intrafamilial variability (19).

OFD type V [median cleft of upper lip and postaxial polydactyly of hands and feet (Thurston syndrome)]. Thurston (7), in 1909, appears to be the first to describe a syndrome of median cleft of the vermilion of the upper lip and postaxial polydactyly of the hands and feet (Fig. 19–38). All reported patients have been from India (1–7). Inheritance is autosomal recessive.

Thurston's patients were brothers. In one brother, the extra digit was of normal morphology, but of somewhat smaller size. The extra toe was of normal size and appearance. The other brother had seven fingers on each hand. There were six toes on one side and five on the other. No other anomalies were present.

Chowdhury (2) described nine cases in one family. Two sets of second cousins sibs were affected. Consanguinity was noted. Another large kindred was reported by Chaurasia and Goswami (1). Two sibs had heptadactyly.

Khoo and Saad (4) and Sidhu and Grewal (5) reported isolated cases in Indian males. Another Indian male was noted by Gopalakrishna and Thatte (3). There was hexadactyly of one hand and heptadactyly of the other. Both feet exhibited hexadactyly. A sister had similar hand abnormalities. The upper median frenum was duplicated.

OFD type VI [polydactyly, cleft lip/palate, lingual lump, and cerebellar anomalies (Váradi syndrome)]. In 1980, Váradi et al (23) reported a syndrome of polydactyly, cleft lip/palate, and mental retardation in an inbred Gypsy family. Mattei and Aymé (14) reported a similar case, and suggested this condition should be distinguished from other OFD syndromes. There are numerous other cases in the literature (1,7–9, 11,15), some of which were reported as examples of OFD II syndrome or Joubert-Boltshauser syndrome with polydactyly. Other possible examples were reviewed by Muenke et al (15). We agree with Toriello (22) and Neri et al (18) that until there has been some molecular breakthrough that classification of this group will be unsatisfactory.

The presence of consanguinity in one family (23) and affected sibs in other families (7,8,11,14) suggest autosomal recessive inheritance.

Facial features are often described as consisting of hypertelorism (1,8,9,11,15), epicanthal folds (1,9,15), broad nasal tip (8,11,23), and cleft lip (Fig. 19–39A) (1,14,15,23). In some cases there is also a mild midline cleft of the upper lip. Microphthalmia has also been noted (8). Rotary nystagmus, oculomotor apraxia, and esotropia are common (9,15,23). Posteriorly angulated and/or apparently low-set ears were reported in several examples (8,11,13,14,23).

Fig. 19–38. *Oral-facial-digital syndrome, type V*. (A,B) Postaxial polydactyly of hands and feet. (C) Typical midline cleft of upper lip. (From CT Khoo and MN Saad, Plast Reconstr Surg 33:407, 1980.)

Both intraoral frenulae (8,11,15) and lingual or sublingual lumps (8,9,14,15,23) have been noted. The palate can be highly arched or cleft (1,8,9,11,23). Dental anomalies are generally not present, although one patient had enamel hypoplasia (23).

Postaxial polydactyly of the hands is common (Fig. 19–38B,C) (1,7–9, 11,14,15,23). Preaxial polydactyly of the hands (15) has been described. Clinodactyly and syndactyly can also occur (8,9,11,14,15,23). Most striking, however, and present in nearly all cases thus far examined, is the presence of a central Y-shaped or forked metacarpal noted on X-ray (Fig. 19–39B,C).

The feet usually have bilateral preaxial polydactyly (Fig. 19–39D) (1,8,9,11,14,15,20,23), although four patients had an accessory fifth toe as well (7,9,15). Cutaneous syndactyly has also been reported (9).

Nearly all affected children have severe mental retardation with rare exception (15); postnatal growth retardation (9,14,15,23), hypotonia and/or gait disturbance (9,15,23), and deafness (9,14,15) can also occur.

Several internal anomalies have also been described. Cardiac defects included aortic stenosis in one case (23) and common atrioventricular canal and coarctation of the aorta in the other (9). Unilateral renal agenesis was reported in one affected sib by Mattei and Aymé (14). Hypogonadism with micropenis has been reported (15,23).

A distinguishing feature of this condition seems to be various degrees of cerebellar defects ranging from absent or hypoplastic cerebellar vermis (Fig. 19–39E) to include all variants of the Dandy-Walker malformation (7,11), or evidence of cerebellar defects such as motor incoordination and delayed or absent speech (1,8,9). Recurrent episodes of tachypnea and hyperpnea are common (15). Hyperthermia has been reported (23). Hypothalamic hamartoma has also been found (vide infra).

The twins described by Hingorani et al (12) and the fetus reported by Muenke et al (16) have features that overlap those of OFD VI, hydrolethalus syndrome, and Pallister-Hall syndrome, thus raising the question of whether they are three separate entities. Hypothalamic hamartoma, supernumerary maxillary central incisor and precocious puberty was reported moreover by Stephan et al (21). Doss et al (6) describe a glial defect. Other examples of overlap cases are those of Hart et al (10), Anyane-Yeboa et al (2), Shashi et al (19), Bankier and Rose (3), and Hsieh and Hou (13a). One child reported by Váradi et al (23) also had arhinencephaly. Although Baraitser (4) considers some of these cases (7,9,11) to be examples of Joubert-Boltshauser syndrome with polydactyly, it seems more appropriate to classify these cases as examples of Váradi syndrome because of the overall phenotype (22).

Another possible example of Váradi syndrome may be the sibs reported by Hooft and Jongbloet (13). One or both had oral frenulae, ocular coloboma, microphthalmia, palatal malformations, and postaxial polydactyly. One sib had a tumor at the base of the brain, although no additional data are given regarding the nature of the tumor. We cannot classify the patients of Cleper et al (5).

Dandy-Walker malformation (hydrocephalus, incomplete cerebellar vermis, and posterior fossa cyst) may occur as an isolated finding or in association with myriad conditions, including Joubert-Boltshauser syndrome, *Coffin-Siris syndrome, Meckel syndrome, Ellis-van Creveld syndrome, cryptophthalmos syndrome* (17), and *Jones craniosynostosis/ Dandy-Walker syndrome*.

Fetal ultrasonography may possibly be used to detect the anomalies of the extremities, cleft lip and palate, and partial agenesis of the cerebellar vermis.

OFD type VII [facial asymmetry, pseudo cleft lip, lobulated tongue, and hydronephrosis (Whelan syndrome)]. Whelan et al (1) reported a mother and daughter with similar findings, which the authors suggested represented OFD I syndrome. However, some of the findings are inconsistent with that diagnosis, and this likely represents a distinct entity.

Both mother and daughter had apparent hypertelorism, with pseudocleft of the upper lip, highly arched palate, bifid tongue, and facial asymmetry. The daughter also had a low-set, posteriorly angulated ear, preauricular tags, and mucosal frenulae. Polydactyly was not present; the only digital anomaly was clinodactyly in both mother and daughter. In addition, both had bilateral hydronephrosis. The daughter was developmentally delayed, whereas the mother had low-normal intelligence. Inheritance is either X-linked or autosomal dominant.

OFD type VIII (OFD and retinal abnormalities). Edwards et al (1), in 1988, described a family with what was thought to be an X-linked form of oral-facial-digital syndrome with tongue lobulations and hamartomas, median cleft upper lip, dystopia canthorum, broad or bifid nasal tip, bilateral preaxial and postaxial polydactyly of the hands and feet, duplication of the halluces, shortened tibiae and/or radii, short stature, recurrent aspiration pneumonia, and developmental delay. There was forking of metatarsals 6–7 in one boy.

There were four affected males in three generations. Female heterozygotes had mild expression (tongue hamartoma, ankyloglossia, mild tongue clefting). Death occurred in three of the affected males during infancy, probably from aspiration pneumonia.

Gurrieri et al (2) reported brothers affected also with retinochoroideal lacunae of colobomatous type, similar to those seen in Aicardi syndrome. Sigaudy et al (5) and Stevens and Marsh (6) reported females with areas of chorioretinal atrophy. Jameison and Collins (3) described a similarly affected male. Nagai et al (4) added Dandy-Walker malformations

We cannot say that type III is not the same as type VIII.

Miscellaneous or unclassifiable syndromes

There are a plethora of syndromes that defy categorization.

Tucker et al (16) reported a patient with oral, facial, and digital anomalies. In addition to hypertelorism, micrognathia, oral frenulae, bifid tongue, and an extra finger, the deceased newborn female had posterior encephalocele, omphalocele, and talipes valgus. Autopsy revealed cerebral microgyria, partial hypoplasia of parietal lobes, and polycystic liver and kidneys. Moran-Barroso et al (11) described a male infant with myelomeningocoele, stenosis of the aqueduct of Sylvius and congenital heart anomalies.

Iaccarino et al (10) described three cases of an oral-facial-digital syndrome with cardiac, but not brain, abnormalities. The first case, in addition to midline cleft upper lip, had lobulated tongue, pseudocleft palate, and pre- and postaxial polydactyly of hands and feet, a complex cardiac defect, including common atrium, single atrioventricular valve, single ventricle, and truncus arteriosus, small epiglottis, anteriorly placed anus, and absent lobation of the left lung. Iaccarino et al (10) further reported sibs each having cardiac, oral, facial, and digital anomalies. The first sib had cleft lip, polydactyly of hands and feet, VSD, and mitral valve atresia; the second sib had preaxial polysyndactyly of the hands and feet, and complete atrioventricular canal. Whether oral, facial, and digital anomalies with cardiac defects represent yet another type of OFD syndrome remains to be seen; however, the presence of cardiac defects in both sibs reported by Iaccarino et al (10) suggests that this is a distinct possibility. A similar condition has been noted by Bonneau et al (3).

Örstavik et al (12) noted a brother and sister with hamartomas of tongue, polysyndactyly, and congenital heart defects (coarctation of aorta, subaortic stenosis, atrioventricular canal).

Toriello et al (15) reported an infant with features of frontonasal malformation, as well as polydactyly of the hands and feet, agenesis of corpus callosum, Dandy-Walker malformation, persistent fetal circulation, short limbs, and cryptorchidism. X-ray examination demonstrated narrow ribcage, elongated trunk, and long bones that were shorter than average (65%–90% for age). The tibiae were most severely affected. This case has features of both OFD IV and Váradi syndrome, and may be a unique condition.

Berberich et al (2) reported a patient with centrally notched upper lip, frenulae extending from the alveolar ridge to the buccal mucosa, lobulated tongue, partial cleft palate, thoracic dystrophy, preaxial polysyndactyly involving one thumb and both halluces, mild shortening of humeri, bowed tibiae, short penis, and imperforate anus. The condition was compatible with survival during the first year of life.

Figueroa et al (7) noted a female with cleft palate, vestibular frenulae, oligodactyly, preaxial polydactyly, radial shortening, fibular agenesis and coalescence of tarsal bones. This has been called OFD type X.

Adès et al (1) reported a fetus with occipitoschisis, polydactyly, campomelia, cleft palate, laryngeal dysplasia, ocular colobomata, hepatic fibrosis, ambiguous genitalia, cystic kidneys and brain malformations. The parents were first cousins.

Gabrielli et al (9) described a male with hypertelorism, down-slanting palpebral fissures, tongue clefts, multiple frenulae, cleft palate, bulbous nose, postaxial polydactyly of hands and feet and fusion of C_2 and C_3. There was a striking resemblance to those with terminal deletion 3p.

Richmond and Mene (13) reported female sibs with microcephaly, extra digits, natal teeth, mental retardation and hamartomata of tongue.

Chitayat et al (5) described male and female sibs with postaxial polydactyly of hands and feet, syndactyly and brachydactyly, pectus excavatum, mesomelic shortness of upper and lower limbs, see-saw winking, and a host of anomalies that spanned types II, III, IV and VI.

Fujiwara et al (8) noted a girl with tongue hamartomata, multiple frenulae, hypoplasia of ulnae, fibulae, tibiae, polysyndactyly of hands and feet, hydronephrosis, hypothalamic hamartoma, seizures and central precocious puberty. This child was found to have a GLI3 mutation.

Lukusa and Fryns (10a) described a boy with oral, facial, and digital anomalies associated with dup(7q21.2), macrocephaly, hypertelorism, small down-slanting palpebral fissures, lobulated tongue, multiple frenula, oligodontia, cutaneous syndactyly of fingers 2–3 and 3–4, fetal finger pads, and broad thumbs and halluces.

Differential diagnosis. There are a significant number of disorders that have midline defect of the upper lip ranging from isolated midline cleft to encephalocele to Ellis-van Creveld syndrome to short rib-polydactyly syndrome, Majewski type. None of these disorders should present problems in differential diagnosis of the OFD syndrome for the clinician.

Of all the disorders reported in this text, the oral-facial-digital syndromes have afforded us the least satisfaction in addressing them. Each new report describes a patient that differs in some respect from the types already described. One can easily distinguish OFD types I and V, but then one runs into problems. Types II, III, IV, and VI are not clear cut and there are some patients that seem to bridge two or more types. Type III, for example, is presumably distinguished by "see-saw" eye movements, but this has been noted in other types. Type IV has short tibiae as a hallmark but so do some miscellaneous forms of OFD. This also applies to type VI with the forked midmetacarpal. Some of the rarer types have been grouped by their association with eye findings similar to those seen in *Aicardi syndrome*. *Pallister-Hall syndrome* has overlaps. To further confound the problem, Joubert syndrome (not otherwise discussed because of lack of facial dysmorphism), an autosomal recessive syndrome, is characterized by mental retardation, cerebellar vermis agenesis or hypoplasia, episodic panting tachypnea, abnormal eye movements, hypotonia, retinal dysplasia (25%), and a host of overlapping features (occipital meningocele/encephalocele, seizures, and various digital anomalies) (4). At least one gene for Joubert syndrome maps to 9q34.3 (14).

Until we obtain help from the molecular geneticists, we are lost in this morass.

Otopalatodigital syndrome, type I

Otopalatodigital syndrome, type I (OPD I), first reported by Taybi (29) in 1962 and by Dudding et al (4) in 1967, is characterized by short stature, pugilistic facial appearance, conductive hearing loss, cleft palate, and generalized bone dysplasia. Inheritance is X-linked with variable heterozygote expression (8,9,13,16,18,24). The gene has been mapped to Xq28 (2,10,11). Verloes et al (30) has opined that OPDI and II, *frontometaphyseal dysplasia* and *Melnick-Needles syndrome* are but variants of a single disorder. This has been echoed by Superti-Furga (24a).

Craniofacial and orofacial findings. The facies in males is characteristic (4,18,19) (Fig. 19–40). An overhanging brow, prominent supraorbital ridges, and down-slanting palpebral fissures are noted. Hypertelorism and broad nasal root give the patient a pugilistic appearance. Slight notching may be noted at the junction between the medial third and lateral two-thirds of the upper eyelid margin in some affected males (6). The corners of the mouth are often down turned. Facial features in affected females are more variable and usually more mild than in affected The most constant features in affected females are overhanging brow, hyperteloric appearance, prominent lateral supraorbital ridges, depressed nasal bridge, and flat midface (6). Cleft palate has been seen in all affected males except one (20); it has not been found in affected females.

Auditory system. Mental retardation and slow speech development may be related to the conductive hearing loss that, in the few patients tested, ranged from 30 to 90 dB. However, not all patients have hearing loss (18). Abnormally shaped middle ear ossicles and small external auditory canals have been found (1–4,9,13,17,20,29).

Fig. 19–40. *Otopalatodigital syndrome, type I.* (A) Overhanging brow with prominent supraorbital ridge and wide nasal bridge resulting in pugilistic appearance. (B) An affected female. (A from BA Dudding et al, Am J Dis Child 113:214, 1967. B courtesy of HD Rott, Nürnberg, Germany.)

A B

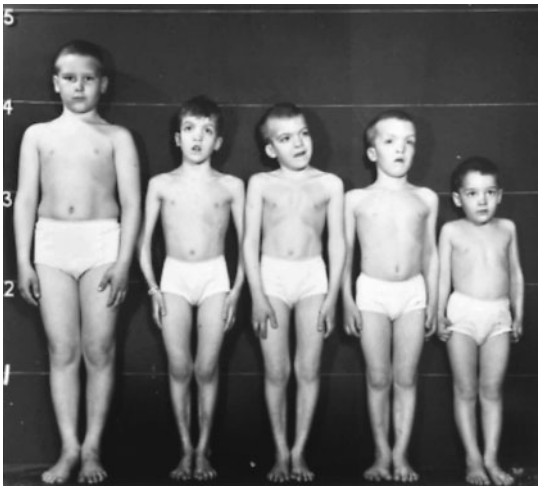

Fig. 19–41. *Otopalatodigital syndrome, type I.* Skeletal growth is retarded. Three affected sibs, ages 8, 7, and 6 years, are flanked by their two normal brothers, ages 10 and 4 years. Note subluxation of elbows of affected. (From BA Dudding et al, Am J Dis Child 113:214, 1967.)

Central nervous system. Most male patients have mild mental slowness, intelligence quotients ranging between 75 and 90. Speech development is slow. Hypoplasia of the transverse sinus and hyperplasia of the occipital sinuses have been noted (27).

Musculoskeletal system. Skeletal growth is retarded; all male patients are below the 10th centile and may be below the 3rd centile for height (6) (Fig. 19–41). The trunk is small, and there is pectus excavatum(4,25). Limited elbow extension and wrist supination have been noted in several patients, some of whom have subluxation of radial heads (4,15,24,29). Hands and feet are striking (4). Thumbs and halluces are spatulate and especially abbreviated (Fig. 19–42). Clefting between the hallux and the other toes is exaggerated. The toes and fingers are irregular in form and direction of curvature. The second and third fingers may deviate to the ulnar side, whereas the fifth finger often bends to the radial side. Affected females are not unusually short; although only mild abnormalities may be observed in the hands, the feet usually have more obvious abnormalities (6).

F

Fig. 19–44. *Otopalatodigital syndrome, type II.* (A) Hypertelorism, downslanting palpebral fissures, small mouth. (B) Posteriorly angulated ears, micrognathia. (C) Curvature of lower limbs, fanned-out toes. (D) Abnormal position of fingers. (E) Flattened face, dislocated elbows and hips, fingers held in flexed overlapping position. (F) Severely abbreviated halluces and fifth toes, and camptodactyly. (A–D from M André et al, J Pediatr 98:747, 1981. E,F from K Kozlowski, Pediatr Radiol 6:97, 1977.)

thick, the facial bones are hypoplastic, and the paranasal sinuses and mastoids are poorly pneumatized. The nasion-sella-basion angle is approximately 116 degrees (normal mean = 132 degrees), and the mandibular plane angle is increased. The mandible is small and the mandibular angle more obtuse than normal (6,15,15a,23). The clivus, or basisphenoid, lies further posteriorly than normal in relation to the cervical spine. These changes are essentially limited to affected males (Fig. 19–43A).

Iliac bones are small, with decreased flare. Coxa valga is a common finding. The lower tibia is laterally bowed. Failure of fusion of several vertebral arches is common.

Distinctive changes in hands of males include shortening of radial side of middle phalanx of fifth finger, clinodactyly, short distal phalanx of thumb (which during development has a cone-shaped epiphysis), accessory ossification center in second metacarpal, tear-drop-shaped trapezium, transverse capitate, and trapezium-scaphoid fusion (6,15, 22,26,28) (Fig. 19–43B). Females may have greater multangular-scaphoid fusion.

In affected males, radiologic abnormalities in the feet include short phalanges and metatarsals of great toes. The second and third metatarsals are long and abnormally shaped because of their fusion with the cuneiform bones (Fig. 19–43C). The fifth metatarsal may be prominent, with an extra ossification center. Tarsal fusions are common, and males usually have two ossification centers in the navicular bone.

Diagnosis. *Larsen syndrome* shares a number of features, such as cleft palate and joint dislocations, with the OPD I syndrome. However, patients with Larsen syndrome have a different facies, multiple carpal bones, a juxtacalcaneal bone, and false flexion creases of the fingers. Larsen syndrome is far more severe in its skeletal manifestations. *Acro-cranio-facial dysostosis syndrome* is also more marked in its expression. The patients reported by Salinas et al (22) have a different disorder than OPD I or OPD II. The patients described as having X-linked cleft palate in one paper (30) are examples of OPD, type I. It is difficult to classify the patients described by Jäger and Refior (14) and García-Cruz et al (7).

Otopalatodigital syndrome, type II

Otopalatodigital syndrome, type II (OPD II), first described by Fitch et al (7) in 1976, is characterized by short stature, unusual facies, cleft palate, and multiple skeletal anomalies. Skeletal manifestations are far more severe in this syndrome than they are in OPD syndrome, type I. Approximately 30 cases have been reported to date. We cannot accept the case of Holder and Winter (10) as a valid example. The patients of Stoll and Alembik (21) and Alembik et al (1) fit better Larsen syndrome. We cannot diagnose the cases of Eccles et al (5) and Preis et al (16). The cases of Gendall and Kozlowski (9) are male Melnick-Needles examples.

Death has occurred, usually because of respiratory infection, within the first 5 months of life in at least 12 cases (2,6,7,19,24); another died of similar causes at age 2 1/2 years (11). Those who survive have short stature.

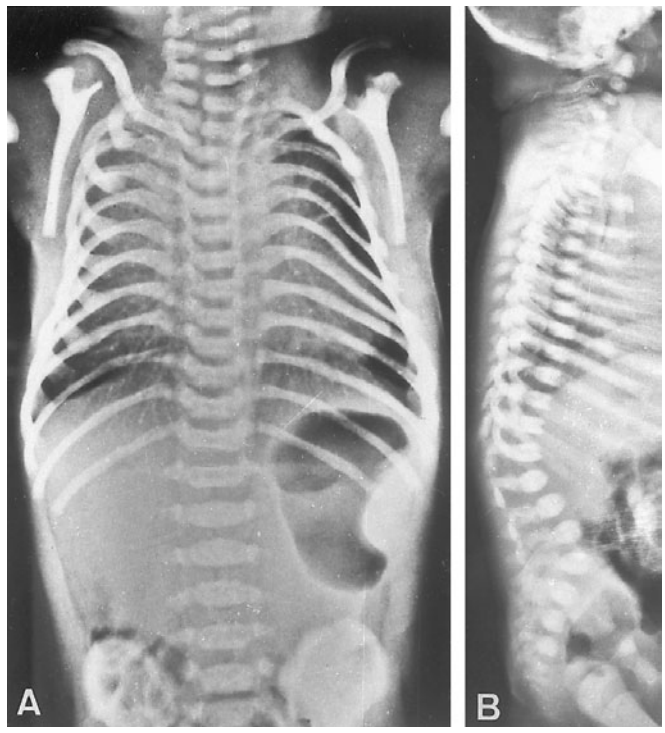
Heredity is X-linked recessive. Presumably OPD type I and II are allelic. However, Melnick-Needles syndrome should be studied for allelism (3,4a,10,18).

Craniofacial findings. Hypertelorism, frontal bossing, lateral fullness of supraorbital ridges, broad nasal bridge, stubby nose, downslanting palpebral fissures, midface hypoplasia, low-set ears, microstomia with down-turned bow of upper lip, and marked mandibular micrognathia are noted (2,4,16,19) (Fig. 19–44). Carrier females may have midfacial abnormalities (2,4,16,19,24) but many appear quite normal (14,18a). Cleft palate is found in 85% of affected males, and bifid uvula in a carrier female has been noted (7). In some instances, frank Robin sequence may be present (2).

Central nervous system. Psychomotor development and intelligence appear normal in some patients (8), whereas others are mentally retarded (11). Hydrocephalus has been noted (8,22,24). Hearing loss has been reported (2,8,12,16,19,22).

Musculoskeletal system. The anterior fontanel may be large (7). The base of the skull is sclerotic (7). Midface hypoplasia is evident. Clavicles are thin and wavy. The thorax is narrow, and there may be

Fig. 19–45. *Otopalatodigital syndrome, type II*. (A) Steeply sloping sinuous clavicles, sinuous ribs. (B) Dorsolumbar kyphosis, increased lumbar lordosis. (From M André et al, J Pediatr 98:747, 1981.)



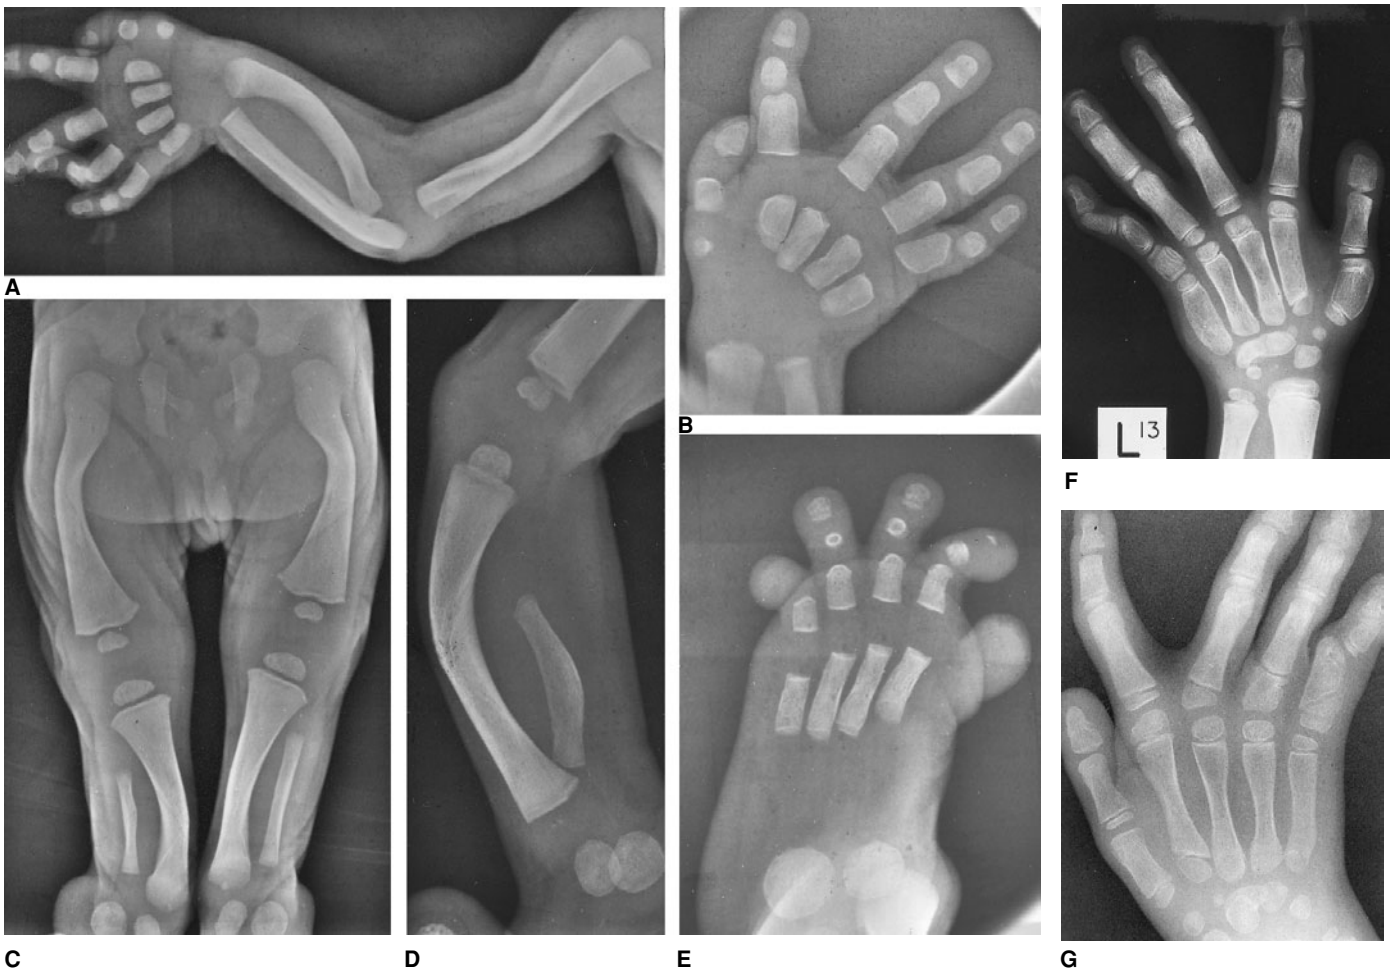


Fig. 19–46. *Otopalatodigital syndrome, type II*. Radiographs. (A) Curvature of humerus and radius, anomalies of metacarpals and phalanges. (B) Small first metacarpal, large proximal phalanges. (C) Hip dislocation, curvature of femora, hypoplastic fibulae. Advanced bone age. (D) Curvature of tibia. (E) Absence of ossification of first metatarsals and its phalanges, short fifth metatarsal. (F) Anomalies of metacarpals and phalanges. Note extra bone between proximal phalanx and metacarpal on fifth finger, enlarged epiphyses, capitate-hamate complex. (G) Compare this patient with patient in B and patient in F. Note unusual proximal phalangeal epiphyses, transverse capitate, extra bone in carpal complex. (A–E from M André et al, J Pediatr 98:747, 1981. F from K Kozlowski et al, Pediatr Radiol 6:97, 1977. G from N Fitch et al, Am J Med Genet 15:655, 1983.)

pectus excavatum. Ribs are wide posteriorly and anteriorly, but narrow in their middle portions. Vertebrae are flattened (Fig. 19–45). There may be scoliosis. The humeri, radii, femora, and tibiae are bowed; curving of long bones may disappear early in life (8). Radial heads may be dislocated. Fibulae are small or absent in 70%. Ilia are hypoplastic. Thumbs are broad and short, as are the great toes (Fig. 19–46). Fingers are held in a flexed, overlapping position. Syndactyly of the fingers and toes is variable. Tubular bones of hands and feet are deformed and bones of the wrists and ankles are hypoplastic and malformed and some may fail to ossify (Fig. 19–46). Rocker-bottom or equinovarus feet may be present (2,4,12). Carrier females may have abnormalities of the hands and feet (7,19). Ogata et al (14) found defective ossification.

Other findings. Omphalocele (17,20,24), hydronephrosis, hydroureter, and chordee (6,8,24) have been noted.

Auditory system. Hearing loss has been described (8,11,12); one patient (8) had aseptic meningitis twice during the first year of life. Bilateral conductive hearing loss was described in a carrier female (2); malformed ossicles were noted at surgery. The 2 1/2-year-old male reported by Shi (19) likely had OPD II (H Schucknecht, personal communication, 1985). Histologic studies of his temporal bone revealed malformed ossicles and abnormalities of the bony labyrinth.

Laboratory aids. Prenatal diagnosis has been done by ultrasound (17,23). Both membranous bone formation and bone remodeling are defective (18a).

Diagnosis. There is much overlap among oto-palato-digital syndrome I and II, *Larsen syndrome, atelosteogenesis I and II, boomerang dysplasia*, and the lethal male *Melnick-Needles syndrome* (3,13,18). This syndrome should be distinguished *from otopalatodigital syndrome, type I, campomelic dysplasia*, and *trisomy 18*. There is similarity to acrocoxo-melic dysplasia, an autosomal recessive disorder described by Plauchu et al (15).

Chapter 20
Orofacial Clefting Syndromes: General Aspects

Facial clefts and associated anomalies

Introduction. The first evidence of clefting is in an Egyptian mummy dating from 2400 to 1300 BC (12). A 2000-year-old ceramic statue of a king with a cleft has been reported from Colombia (22), and an African mask showing cleft lip and palate has been described (5). It is curious that in spite of the frequent occurrence of facial clefts, Greek and Roman physicians made no mention of them. A Ming dynasty painting depicts cleft lip (8) as does a twentieth century Russian work by Vrubel (7). Treatment of cleft lip was apparently first carried out by a Chinese physician in 390 AD (2).

Before cleft lip and cleft palate syndromes are considered, the embryologic, epidemiologic, and genetic aspects of isolated cleft lip and cleft palate are reviewed. Readers wishing to examine the subject in greater detail should consult Fraser (10), Millard (21), Melnick et al (20), Dronemaraju (6), and Bear (1).

Clefts of the primary and/or secondary palates are included among the more common congenital anomalies. Clinically there is great variability in degree of cleft formation. Minimal involvement includes bifid uvula, linear lip indentations with or without nostril deformity (intrauterine-healed clefts), lateral upper lip fistula, and submucous palatal cleft (3,4,9,11,13–18,23,26–29). Martin et al (19) suggested that they could detect the carriers among first degree relatives by ultrasound of the orbicularis oris.

A cleft may involve only the upper lip or may extend to involve the nostril and the hard and soft palates. An isolated palatal cleft may be limited to the uvula (bifid uvula) or may be more extensive, cleaving the soft palate or both the hard and soft palates. A combination of cleft lip and cleft palate is most common. Breakdown according to type has differed somewhat in several large surveys. Roughly, however, cleft lip with cleft palate comprises approximately 45%, isolated cleft palate approximately 30%, and cleft lip approximately 25%. The rare instance of separate clefts of the lip and palate represents a variant of cleft lip-palate (24).

Embryology. Neural crest cells play an integral part in facial morphogenesis (5,10,23,27). Just prior to the time when the neural folds fuse to form the neural tube, ectodermal cells adjacent to the neural plate migrate into the underlying regions where they act as mesenchyme (ectomesenchyme). Crest cells in the head and face form essentially all the skeletal and connective tissues of the face: bone, cartilage, fibrous connective tissue, and all dental tissues except enamel.

During the fourth week (day 25), the anterior neuropore has closed. The face, if one can call it that at this time, consists of a large frontal prominence that constitutes the upper boundary of the stomodeum (primitive mouth) and results from ectodermal proliferation ventral to the developing brain (17). The primary mouth is separated from the foregut by the buccopharyngeal membrane that undergoes selective cell death and ruptures at this time in development (18). On each side of the lower aspect of the frontonasal prominence, the nasal placodes are forming. These bilateral structures located just above the primary mouth are represented by local thickenings of the surface ectoderm. Rapid proliferation of ectomesenchyme results in nasal swellings both lateral to and medial to the nasal placodes. By means of selective cell death and proliferation of tissues, the nasal or olfactory pits are formed and extend into the primitive mouth. These are primitive nostrils (Fig. 20–1). Sulik and

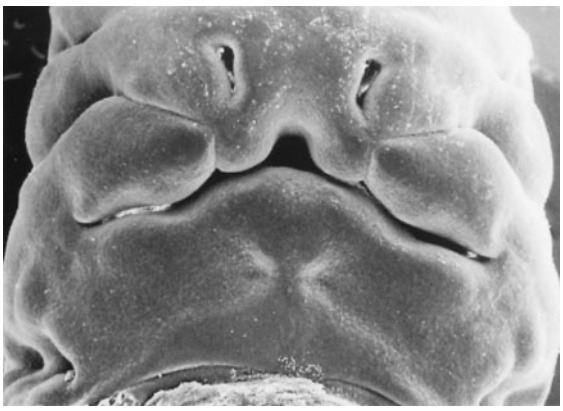
Fig. 20–1. *Facial clefts and associated anomalies*. Scanning electron microscopy of face of 5-week-old embryo. Note olfactory pits developing on lateral portions of fronto-nasal prominence. (Courtesy of K Sulik, Chapel Hill, North Carolina.)

Schoenwolf (23) have elegantly illustrated these changes by scanning electron microscopy.

Extremely active growth occurs during the fifth and sixth weeks. The maxillary swellings, which represent the upper anterior portion of the first pharyngeal arch, enlarge considerably, again through ectomesenchymal proliferations. During the sixth and seventh weeks, the medial nasal prominences merge with each other and with the bilateral maxillary processes (17). Thus, the upper lip is formed laterally by the maxillary prominences and medially by the fused medial nasal prominences (Fig. 20–2). It should be emphasized that the lateral nasal prominences play no role in formation of the upper lip but form the alae or wings of the nose. The philtral ridges have nothing to do with facial prominences. They do not appear until the third to fourth embryonal month (16).

The primary palate consists of the two merged medial nasal prominences that form the intermaxillary segment. This, in turn, consists of two portions: (*1*) a labial component that forms the philtrum of the upper lip, that is, the indented area flanked by roughly parallel ridges that run from the columella of the nose to the middle of the upper lip, and (*2*) the triangular palatal component of alveolar bone that includes the four maxillary incisor teeth. The primary palate extends posteriorly to the incisive foramen or, clinically, to the incisive papilla (22). The rare paramedian pit or fistula of the upper lip occurs at the line of fusion of the median nasal prominence and the maxillary process (2,3,8,14,15,24). The etiology of the midline sinus of the upper lip is not known (1), but likely involves entrapment of epithelium.

Fig. 20–2. *Facial clefts and associated anomalies*. Scanning electron microscopy of 6-week-old embryo. Upper lip formed from fusion between notched median nasal prominence has not yet fused with maxillary processes. (Courtesy of K Sulik, Chapel Hill, North Carolina.)



The so-called secondary palate comprises at least 90% of the hard and soft palates, that is, all except the anterior portion that holds the incisor teeth. Its development is more complicated than originally thought. The palatal shelves originate as swellings or shelf-like burgeonings of the medial surfaces of the maxillary prominences. They appear in the sixth week and grow downward, lateral to the tongue. Elevation of the palatal processes to a horizontal plane is more vigorous anteriorly, that is, in the part nearer the primary palate. Elevation begins in the seventh week (7). Final closure, by fusion, occurs somewhat later in females than in males (20) (Fig. 20–3). The soft palate and uvula are formed by merging, not fusion, of two growth centers at the caudal end of the hard palate. Good reviews of secondary palate formation are those of Greene and Pratt (6) and Ferguson (4).

What promotes the elevation has been called *intrinsic shelf force* and has a complex biochemical and physiochemical basis. The tongue appears to play little role in shelf elevation. Elevation of the shelves is associated with widening and forward growth of the mandible. Once the shelves are elevated to the horizontal plane, there is programmed cell death of the medial edge. When the shelf edges touch, the epithelium has thinned and

Fig. 20–3. *Facial clefts and associated anomalies*. (A) Scanning electron microscopy of secondary palate in 53-day-old embryo. Fusion with primary palate has occurred. (B) At 59 days, complete fusion of secondary palate has occurred. (Courtesy of L Russell, Chapel Hill, North Carolina.)

A

B

has undergone advanced stages of degeneration allowing mesenchyme from each side to join in the midline (13). Complete fusion of the palatal shelves is effected by the tenth week (20). The soft palate and uvula are formed from secondary growth centers by successive merging. In some infants, there is cystic degeneration of the epithelial remnants that produces evanescent midline palatal microcysts (Epstein's pearls).

Knowledge concerning mechanisms involved in regulation of embryonic growth is, at best, sparse. The blueprints for the rate at which facial prominences burgeon and for the direction in which they grow are in part determined by the genetic template, the DNA code located in the cell nucleus. But hereditary factors do not act alone. Growth patterns can also be influenced by environmental factors. For example, there are several mouse models for cleft lip and for cleft palate. There are both susceptible and nonsusceptible strains and a large list of teratogenic substances that produce clefting in mice. However, there is little evidence that these agents play a significant role in cleft production in humans (11), the exceptions being phenytoin, folic acid antagonists, and retinoic acid (see Chapter 2).

Various genetic and/or environmental factors may inhibit the flow of or decrease the number of neural crest cells or may affect their mass so that contact between prominences is impossible or inadequate (9,11). The epithelium covering the mesenchyme may not undergo programmed cell death so that fusion cannot take place. Exact timing and positioning play critical roles. For example, Johnston and Sulik (9) showed that if the bilaterally formed nasal placodes contact one another, there is severe to complete suppression of development of medial nasal prominences.

Altered positioning of the nasal placodes or abnormal directional growth of the facial prominences may be reasonable for cleft of the primary palate (cleft lip). This has been supported not only by animal models but by the clinical observation that parents of children with cleft lip exhibit some degree of reduction in overall midface size.

There may be many mechanisms by which a cleft of the secondary palate (cleft palate) occurs. Failure of growth of the mandible (micrognathia) may inhibit elevation of the shelves. For example, the Robin sequence is associated with U-shaped cleft palate.

Clefts of the primary and secondary palates occur together in about one-half the cases. A common mechanism of production has been sought. It has been suggested that the tongue tip becomes wedged in the labial cleft, produced by failure of fusion of the medial nasal and maxillary prominences. This, it has been argued, would not allow the tongue to drop and, consequently, would interfere with midline contact and inhibit fusion. This explanation appears to be simplistic. It would seem that reduction in size of both the labial maxillary prominences and the palatine process of the maxillary prominences is a more reasonable explanation.

Clefts of the secondary palate likely result from either hypoplasia of the shelves or delay in timing of shelf elevation. Experiments carried out on susceptible strains of mice have suggested that both mechanisms are operative, but at different times in gestation. For example, large doses of vitamin A given early in gestation inhibit palatal shelf growth whereas cortisone given later in gestation inhibits palatal shelf elevation (19).

Recent evidence for reduction of neural tube defects (anencephaly, spina bifida) by administration of dietary supplements of folic acid has caused several teams of investigators to study whether a similar reduction in cleft lip and/or cleft palate might be effected. There seems to be a 25%–50% reduction in the rate of clefting (21,25,26), but a multicenter randomized double-blind study is needed.

Cigarette smoking during pregnancy seems to be correlated with clefting (12).

Epidemiology. Cleft lip with or without cleft palate. Cleft lip with or without cleft palate [CL(P)] occurs in approximately 1/1000 white births (range 0.7–1.3), although data differ somewhat from study to study in various parts of Europe and the United States, depending on source of information (birth records, birth certificates, pregnancy follow-up data, surgical records, hospital records, multiple sources), whether the data were obtained retrospectively or prospectively, and whether stillbirths or syndromal disorders were included (1,4–6, 13,16,18,22,25,41,42,45,50,58,70,72,75,78,80,83). A good summary of these data is that of Derijcke et al (20). The problems of data gathering have been elegantly discussed by Vanderas (80) and Sayetta et al (65). Greene et al (27) has shown that birth certificate data are extremely inaccurate. Data gathered from parents may also be suspect (59).

There is marked racial predilection. The frequency of CL(P) in Native Americans appears to be the highest of any group in the world (over 3.6/1000 live births) (17,22,35,42,57). It is also high in Japanese (approximately 2.1/1000 births (13,17,22,37,42,52–54,) and Chinese (approximately 1.4/1000 births) (16a,21,31,42) and, in contrast, it is lower among blacks (approximately 0.3/1000 births) (2,15,17,19,33,

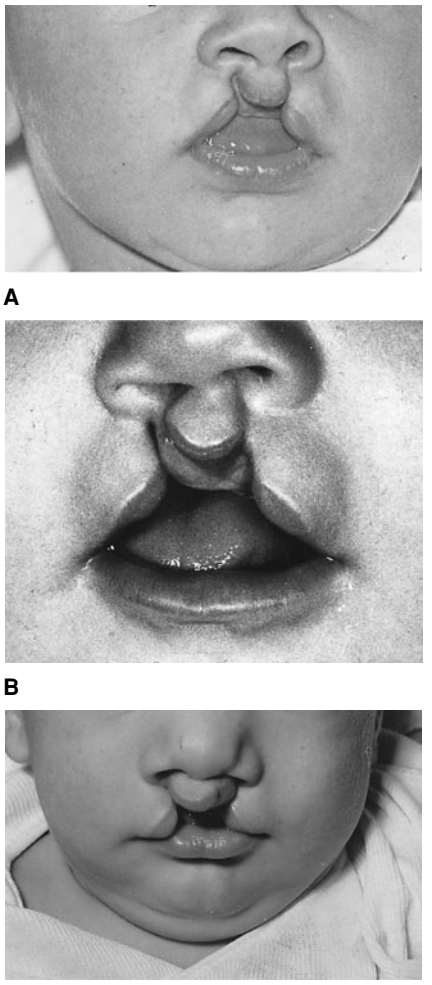

Fig. 20–5. *Facial clefts and associated anomalies*. (A–C). Bilateral cleft lip showing varying degrees of completeness. (From T Skoog, Plast Reconstr Surg 35:34, 1965.)

76,80) and Maori (12). Data from African blacks are cited by Cervenka (10). In the Philippines, the birth prevalence was 1.94 for cleft lip with or without cleft palate (51). Data from Turkey is also summarized (7).

In general, the more severe the defect, the greater the proportion of males affected [i.e., CL(P) (2M:1F) is greater than CL (1.5M:1F) and bilateral CL is greater than unilateral CL (26,58)]. However, not all races have similar sex predilections; for example, most Japanese studies have shown that females with CL outnumbered males with CL. However, males with CL(P) outnumbered females, as in whites.

Isolated CL may be unilateral (80%) or bilateral (20%) (83) (Figs. 20–4 to 20–6). However, when only cleft lip is involved, bilateral cases amount to approximately 10%; when cleft lip is combined with cleft palate, approximately 25% are bilateral (10a,18,44,45,78). When unilateral, the cleft is more common on the left side (approximately 70%), although no more extensive. Approximately 85% of cases of bilateral CL and 70% of unilateral CL are associated with cleft palate. Cleft lip is not always complete (i.e., extending into the nostril). In approximately 10%–30%, the cleft is associated with skin bridges (Simonart's bands) (67,73). Minimal involvement is manifested by linear lip indentation(s) (9,29,39) or, very rarely, lateral fistulas of the upper lip (8,30,63,77) (Fig. 20–7). Both are located at the position of fusion of the median nasal and maxillary prominences. Bilateral sinuses have been documented (61).

Isolated cleft palate. Cleft palate (CP) appears to be an entity separate from CL(P) (Fig. 20–8). Sibs of patients with CL(P) have an increased frequency of the same anomaly but not of isolated CP and vice versa (26).

The frequency of CP among whites and blacks would appear to be approximately 0.4/1000 births and is more common in females (64). Cleft palate among the Maori of New Zealand is approximately 1.9/1000 births (12). When cases of CP are broken down according to extent, a 2:1 female predilection for complete clefts of the hard and soft palate is clearly indicated, but the ratio approaches 1:1 for clefts of the soft palate only (47,55). This is consistent with the observation that the soft palate forms by merging, after closure of the hard palate.

The incidence of cleft uvula (1/80 white individuals) is much higher than that for cleft palate (1/2500 births) (16,46,69,79). Clefting of the uvula varies in degree but some clefting is present in 2%–4% (71). Total cleft of the uvula is approximately 1 in 300 (84). Like cleft of the soft palate, cleft uvula approaches a 1:1 sex ratio (14,41,47). The frequency of cleft uvula among various American Indian and Inuit groups is high, ranging from 1/9 to 1/14 individuals (11,28,34,41,68) and in Asians in 1/10 to 1/25 (41). In blacks, it is comparatively rare (1/250) (41,62,66,68).

Submucous palatal cleft refers to the condition in which there is imperfect muscle union across the velum but an intact mucosal surface (60) (Fig. 20–9A). An incidence of approximately 1/1200 to 1/2000 births has been reported (3,74,82). Over 50% occur in males, an unusual finding

Fig. 20–7. *Facial clefts and associated anomalies*. (A) Minimal cleft lip showing groove extending from vermilion to nostrils representing defect in orbicularis oris. (B) Lateral fistula of upper lip. (A from FR Heckler et al, Cleft Palate J 16:240, 1979.)

since cleft palate has a distinct female predilection. The palate is short in approximately 60% with poor mobility demonstrated in 20%. This makes velopharyngeal closure incompetent, resulting in hypernasal speech. There is frequently a notch in the bone at the posterior edge of the hard palate and bifid uvula is found in most but not all patients (40). Conversely, bifid uvula is usually accompanied by submucous cleft palate (71) and the former has been considered a marker for that condition. Rarely, the hard palate is entirely perforated (24,38,49) (Fig. 20–9B). Kono et al (38) estimated that approximately 13% of patients with clefts of the primary palate have submucous cleft palate. Rarely, the soft palate is asymmetrically

Genetics. During the early decades of the twentieth century, it became evident that recurrence risks for clefting did not correspond to any simple mendelian pattern of inheritance. Between 50% and 75% of cases are sporadic (48). This was bolstered by twin studies that indicated the relative roles of genetic and nongenetic influences in cleft production. We have tabulated twin studies in 1996 (Table 20–1). In twins with CL(P), concordance is far greater for monozygotic twins (40%) than for dizygotic twins (4.2%). In twins with isolated CP, the difference in concordance is not quite as great between the groups (MZ—35%; DZ—7.8%), suggesting a stronger genetic basis for CL(P) than for isolated CP. Heritability has been estimated at approximately 0.74 (82). Twin studies are, at best, of limited value; the concordance of 3.8% for dizygotic twins (greater than that for sibs) implies that maternal factors are operative. Microforms such as submucous palatal cleft could alter these data markedly. An unusual report is that of clefts in three of quintuplets (84). Mirror image clefts have been reported in monozygotic twins (36,38). Conjoined twins also have exhibited this phenomenon, but this example is the exception, all others having been discordant (46).

In the 1970s–1980s, enthusiasm waxed regarding multifactorial inheritance of CL(P) and CP. This view was supported by Woolf et al (81), Carter (10), Mendell et al (50), and Tolarová (75,76,78). Fraser (23–28), however, although generally supporting the multifactorial-threshold inheritance of CL(P), expressed skepticism that CP obeyed the rules and suggested that environmental factors played a major role. Bixler and coworkers (5), in a reexamination of the Danish data of Fogh-Andersen, noted that there was little support for the sex-modified threshold polygenic model for CL(P), but also found little evidence for major gene effects. They agreed that CP did not fit the polygenic threshold concept and suggested genetic heterogeneity (68). For CP, they proposed three categories: syndromal, autosomal dominant, and environmental etiologies. Czeizel (16), in his analysis of Hungarian patients, found CL(P) in agreement with polygenic multifactorial inheritance but did not find similar support for CP. Melnick et al (48), Shields et al (67), and Marazita et al (43), reassessing the Danish data, indicated that CL(P) and isolated CP data were not compatible with the multifactorial threshold model, and posed an alternate hypothesis that CL(P) and CP result from the effects of a single major gene (most likely recessive) with reduced penetrance. The same was true for studies of CL(P) families in England (44), Shanghai, China (45,49), and Madras, India (56). Chung et al (14), employing complex segregation analysis, could not distinguish between major gene versus multifactorial inheritance on Hawaiian data, but later Chung et al (15) suggested that a major gene with low penetrance fits the Danish material but that a multifactorial model best fit the Japanese data. Cephalometric evidence has been used to support the major gene hypothesis (80). Extremely well-balanced discussions of the problems are those of Melnick (47), Wyszynski et al (82), and Mitchell and Risch (52).

Table 20–1. Concordance in facial clefts—twin studies (1922–1996)

	Monozygotic twins		Dizygotic twins	
	CL(P), $n = 105$	CP, $n = 40$	CL(P), $n = 236$	CP, $n = 89$
Concordance (n)	42.0	14.0	10.0	7.0
Percent	40.0	35.0	4.2	7.8

Based on Gorlin et al (29) together with cases of Blake and Wreakes (7), Christensen and Fogh-Andersen (12), Czeizel (16), Davies and Thompson (18), Keusch et al (37), Nordström et al (57), Schweckendiek (64), Shields et al (67), Tolarová (personal communication, 1988), and other authors.

Allelic association studies (*TGFα, BCL3, RARA, TGFβ*3, and *MSX1*) abound (63a). Ardinger et al (3) and others (11,21,32,33,62,66) found association with transforming growth factor-alpha (*TGFα*), but linkage has not been found (40,63a,78a,79). *TGFα* maps to 2p13. It is a potent epithelial mitogen and plays a role in palatal development, modifying severity of the cleft (22,58). However, other studies have failed to demonstrate the association (40,65,73). A possible association has been described for a joint effect of maternal smoking and carrying the *TGFα Tag IC2* allele and the risk for cleft palate (33,65). Other candidate genes have been investigated such as retinoic acid receptor alpha and *MSX1* (11,78a,79). Epithelial growth factor receptor has been shown to be intimately involved in palate closure (51). Beiraghi et al (3a) noted a possible major gene on 4q.

Linkage studies date from the work of Eiberg et al (19) who found susceptibility to CL(P) and blood clotting factor XIIIa on chromosome 6. The same chromosome was suggested earlier (70) and later (55) as the site of a major gene. Carinci et al (9) and Scapoli et al (63) also found linkage at a 6p23 marker (D6S89). Davies et al (17) studied deletions in three unrelated patients and concluded that a major gene was located at 6p24.3. Stein et al (72) found significant linkage to the proto-oncogene, *BCL3*, at 19q13. This was supported by Amos et al (1). However, linkage was not found by Wyszynski et al (82,83), but association was noted. An MSX1 mutation has been found in a family with various combinations of cleft lip, cleft palate, and tooth agenesis (4).

Romitti et al (60) found that mothers who smoke *and* who have allelic variants of *TGFβ3* or *MSX1* have increased risk for having children with cleft palate. Mothers who drink *and* have allelic variants of *MSX1* have elevated risks for infants with cleft lip/palate. At this writing, *TGFβ3* and *MSX1* appear to be the most consistent and important (40).

Kurnit et al (39) revolutionized our thinking about the role that chance may play in the occurrence of malformations. Their model may be applicable to malformations that are presently thought to have "low risk multifactorial recurrence." They suggested that variability may be inherent in the role that chance itself plays in the process of development. Based on computer simulations, a stochastic single gene model generated a continuous liability curve resembling that obtained from a multifactorial threshold model. Outcomes were quite variable despite using identical genotypes and environments. Thus, segregation of a given malformation may be explained by a single defective gene that predisposes to, but does not necessarily result in, the malformation. Their model was successfully applied to VSD. Whether the model can be used for other malformations, such as clefting, remains to be determined.

Cleft lip and/or palate is seen in families with autosomal dominant holoprosencephaly, but a relationship with *Sonic Hedgehog* has been denied (57c).

It certainly appears that clefting is heterogeneous, the variation in liability probably being determined by a number of major genes, minor genes, environmental insults, and a developmental threshold (28). Within recent years, recurrence risk calculations have purposely excluded syndromal clefting, and lethal disorders such as trisomy 13, from the data. Recurrence risk is thereby related to both the genome and environmental exposure. We would agree that both CL(P) and CP do not fit the original multifactorial model very well. Further, CP is probably more heterogeneous than CL(P) (13).

Since one cannot at this time distinguish clearly among the mixed model, a major gene with reduced penetrance, and an admixture of sporadic cases in most instances, it seems foolish to argue heatedly about one or the other (26). Until more evidence has been presented, we can see little error being made using empiric risk data or, in fact, even mathematical model data such as that of Spence et al (69) or Bonaiti-Pellié, (8). Whereas one may fault the models, the figures derived are very close to the empiric risks found (20).

It should be pointed out that a few families appear to have X-linked inheritance of isolated cleft palate with or without ankyloglossia (4,6,30,31,41,53,59,61). Female heterozygotes have variable expression. However, there is clearly genetic heterogeneity. The German and Icelandic families map to Xq21.3–q22 (34,42) whereas a native British Columbian kindred maps to a gene at Xq13–q21.31 (30,71). One family apparently had autosomal dominant inheritance of cleft palate (35,59) and a few cleft lip-palate (74). Autosomal dominant inheritance of velopharyngeal incompetence has been observed in a large kindred by Andres et al (2), but we wonder whether that family had velocardiofacial syndrome.

Moosey et al (54) suggested that by finding the molecular aberrations at the parental TGFα genotype and factoring in parental craniofacial measurements, they were able to predict CP in 76% and CL(P) in 94% of the cases.

Recurrence risks. Data regarding recurrence risks of CL(P) and CP for an affected parent or in case of normal parents who have an affected child have been ascertained in numerous studies. In general, the data do not differ drastically from the Falconer estimation, that is, the recurrence risk being the square root of the frequency of the disorder in the population. In the case of CL(P), $\sqrt{1/900} = 1/30 = 3.3\%$ and for isolated CP $\sqrt{1/2500} = 1/50 = 2\%$. Of course, many factors can modify the data: similarly affected sib(s) or parent, racial group, sex of proband, severity of cleft, etc. These have been dealt with by an inordinate number of investigators (1–3,5–13,16–18,20,21,23–25). Tenconi et al (22) have also devised a theoretical recurrence risk.

Table 20–2. Comparative empiric risks for cleft lip–palate and cleft palate

	CL ± P		CP	
	Proband (%)		Proband (%)	
Relative	Male	Female	Male	Female
Brother	6.7	6.8	1.8	2.8
Sister	2.8	4.4	3.7	1.7
Son	6.7	2.4	11.5	6.0
Daughter	4.0	8.7	5.6	17.2

Modified from M Melnick et al, Clinical Dysmorphology of Oral-Facial Structures, John Wright, Boston, 1982.

For CL(P) and CP, if the proband has no other affected first or second degree relatives, the empiric risk is 3%–5%. However, for CL(P) if the proband has other affected first degree relatives, the risk to sibs or offspring is 10%–20% (23,25, Melnick, unpublished data, 1987). In the rare case of both parents being affected, empiric risk data range from 25% to 50% (23). For these and other situations, see Tolarová (unpublished data, 1987), Melnick et al (15), and Woolf (25) (Tables 20–2 and 20–3). Regarding sex and severity, Tolarová (24) calculated the following risk figures (%) for sibs of those with CL±P: unilateral male—2.9 ± 0.5; unilateral female—4.6 ± 0.9; bilateral male—6.0 ± 1.7; bilateral female—6.8 ± 2.4. Similar data may be found in Woolf (25). Naturally, the usual caveat applies; one must exclude cleft syndromes. The number of cleft syndromes has grown from about 75 in our second edition to over 350 in this fourth edition of our text. They have been reviewed by a number of authors (4,12,14,19).

Associated anomalies. Many investigators have tabulated the frequency and types of anomalies that accompany facial clefts (3,5,10a,11,13,14,21). For a thorough critical review of the earlier data, see Shprintzen et al (21). Data secured at birth differ from those on patients who have undergone surgery, since those with more serious defects often succumb prior to surgery. Recent studies have suggested that as high as 44%–64% of cleft patients have associated anomalies (18,21). Over 350 cleft syndromes have been reported by 2000 (4). When the data are broken down according to subtype, there is general agreement that isolated CP (13%–50%) is far more often associated with other congenital defects than either isolated CL (7%–13%) or CL(P) (2%–11%) (8,9). However, Milerad et al (15) found that patients with CL(P) (28%) had more associated anomalies than those with CP (22%). Growth retardation is more marked in those with cleft lip/palate than in controls (10,10a).

More malformations have been found in infants with bilateral CL(P) than with unilateral CL (15). The more malformations a child has, the lighter the birth weight. Clefts are more frequently found in spontaneously aborted and in stillborn infants, reflecting, in part, chromosomal aneuploidy (13). Associated anomalies are more frequently noted in patients without a family history of clefts than in patients with affected relatives. Conversely, the recurrence risk is lower in sibs of patients with, rather than without, associated malformations. Congenital velopharyngeal incompetence has been noted to be frequently associated with cervical spine anomalies (9). Congenital heart defects have been found in 3%–7% of cleft cases (21,25,26). Milerad et al (15) noted heart anomalies in 24% of their series. Tetralogy of Fallot is especially frequent. Some of these patients surely have velocardiofacial syndrome (26).

Strunz et al (23) noted an increased rate of urinary tract anomalies, especially in association with CP. Biewald et al (3) found approximately 40% of patients with facial clefts to have minor anomalies of the urinary tract. Azmy et al (1), examining 114 patients with esophageal atresia, found 5% with CL(P). Sandham (20) and Osborne et al (16), studying cervical vertebral anomalies in cleft lip/palate patients, found 15%–20% to have either posterior arch deficiency or fusion anomalies versus 7% in the normal population. Those with cleft palate had an even higher frequency of cervical anomalies (45%). Richman et al (17) described olfaction defects in approximately 50% of males with cleft palate. Mean IQ scores tend to be lower in those with clefts (22).

Dronemaraju and Bixler (6,7) noted a greater fetal mortality in sibs of probands with CL(P) than in those with isolated CL, but this has been denied by Bear (2) and Tolarová (24).

Rudman et al (19) found that children with isolated cleft lip-palate have short stature four times and growth hormone deficiency 40 times more often than those without cleft lip-palate. Short stature was also found by Shprintzen et al (21).

Skull, facial bones, and dentition. Postnatal studies of patients with facial clefts have shown that growth of the face proceeds in harmony with the deviation initially induced by the cleft. However, overall head size is slightly smaller and the length of the cranial base slightly shorter than normal in individuals with CP. Facial growth and development in those with clefts has been extensively reviewed (5,13,15).

The anomalous growth associated with CL(P) is generally considered to be limited to the middle part of the face. Bony interorbital distance is slightly increased. Approximately one-third of those with CP exhibit an anteroposterior deficiency of the middle third of the face, and over 50% with bilateral clefts manifest this alteration (1–3,8).

Nasopharyngeal widths are greater than normal in patients with clefts. The mandible is shorter in length with a shorter ramus, thus reducing posterior facial height. The mandibular plane angle is increased and the gonial angle more obtuse.

The teeth in the cleft area, most commonly the maxillary lateral incisors, are commonly missing or supernumerary and may be natal or neonatal. In general, the more severe the cleft, the more teeth are missing or eruption delayed. In patients with clefts of the lip and alveolus, a median fissural tooth is found in almost 50% in the primary dentition and in approximately 25% in the secondary dentition (6,11). Corresponding figures for a distal fissural tooth are 75% and 45%, in the primary and secondary dentitions, respectively. Agenesis of teeth in the cleft area is found in 15% in the primary and 45% in the secondary dentition, and both fissural teeth are present in approximately 35% in the primary and 15% in the secondary dentition. Hypodontia is not uncommon outside the area of clefting in children with CL(P) (10). Over 40% have missing teeth, more often in the upper jaw. Even in isolated CP, which does not involve a tooth-bearing area, hypodontia is present in approximately 35%. The teeth most commonly missing are premolars and maxillary lateral incisors. The size of the permanent teeth tends to be smaller and there is often metric asymmetry (7,11,12,17). Wisdom teeth tend to be missing (14). Natal and neonatal teeth are found in 10% of those with bilateral cleft lip/palate and in 2% of those with unilateral cleft lip/palate (4). Taurodontism may be increased (9).

An inordinate number of cephalometric studies have been carried out on the parents of children with clefts with no conclusive results. These have been reviewed by Ward et al (16). Within an affected family, Ward et al (16) described how, with discriminant function analysis, they were able to find some correlation with increased midfacial and nasal cavity widths, reduced facial height and flat facial profile.

Prenatal diagnosis. Ultrasonography has been used to detect clefting prenatally (1–8). The more severe the cleft, the more likely diagnosis will be made. With improvement of real-time ultrasound equipment on adequate examination of facial structures may be done as early as 16 weeks when formation of the palate and development of soft tissues of the face are complete. Doppler ultrasonography allows observation of fluid flow of amniotic fluid through the mouth to reveal cleft palate. Most people would not elect to have prenatal counseling for cleft lip and palate.

Robin sequence

The well-recognized combination of micrognathia, cleft palate, and glossoptosis, known as Robin sequence, was named after Pierre Robin (44) whose first report appeared in 1923. However, the condition was described earlier by St. Hilaire in 1822, Fairbairn (19) in 1846, and Shukowsky (56) in 1911. Historic development is thoroughly discussed by Grimm et al (23) and Randall et al (39).

Birth prevalence estimates have varied from 1/2000 (37) to 1/30,000; Bush and Williams (8) suggested 1/8500. Definitions of Robin sequence are variable. Our own definition is based on the triad of micrognathia, cleft palate, and glossoptosis. However, others have been advocated. For example, one definition permits the presence of submucous cleft palate (43). Another consists of micrognathia ± cleft palate ± glossoptosis. Such a view allows cleft palate or isolated micrognathia to qualify as Robin sequence as well as the binary combination of cleft palate and micrognathia. Williams et al (64) have cautioned against describing every infant with cleft palate and micrognathia as an example of Robin sequence, indicating that respiratory difficulty is an essential component of the condition. It is obvious that differences in definition result in differences in estimated birth prevalence and differences in the list of syndromes said to be associated with Robin sequence. Extensive discussions of this problem are those of Shprintzen (55) and Cohen (16).

An animal model based on intrauterine mandibular constraint resulting in failure of the tongue to descend and resultant cleft plate has been described by a number of investigators (12,37). Explaining Robin sequence on a deformational basis has been supported by several authors (13,30,37). Others have considered absent or delayed lowering of the embryonic tongue as the primary pathogenetic event. Still others have suggested that growth disturbance affecting both the maxilla and mandible can result directly in cleft palate and micrognathia. Cohen, in 1979 (14) and in 1999 (16), indicated that a unitary etiologic and pathogenetic hypothesis was unlikely, noting that clinical evidence was most consistent with etiologic and pathogenetic heterogeneity and phenotypic variability. These include malformational and deformational causes and connective tissue dysplasia.

Table 20–4 lists some representative syndromes in which Robin sequence may be a feature with variable frequency. In Stickler syndrome (50,62), Robin sequence may occur in some patients. Since abnormalities of bones and joints are characteristic, the major pleiotropic effect appears to be on connective tissue. Thus, in this condition, Robin sequence may result from intrinsic mandibular hypoplasia and failure of connective tissue penetration across the palate.

Another condition that may have Robin sequence is dup(11q) syndrome. With the hypoplastic growth that accompanies most chromosomal syndromes, there may not be significant mandibular catch-up growth in infants with dup(11q) syndrome who survive. Therefore, to include such patients in a mandibular growth study of Robin sequence would be to study "fruit" since "oranges" are being confused with "apples."

Some instances of Robin sequence have been associated with oligohydramnios. It is thought that reduced amnionic fluid results in compression of the chin against the sternum, restricting mandibular growth and impacting the tongue between the palatal shelves. Because micrognathia is based on intrauterine molding, mandibular catch-up growth is expected after birth when intrauterine deforming forces are no longer acting. However, Vegter et al (62) denied catch-up growth. Poswillo (37) produced a phenocopy of Robin sequence in rats by puncturing the amniotic sac prior to palatal closure. Some experimental animals also had anomalies of the limbs, ranging from clubfoot to ring constrictions and intrauterine amputations. Such limb abnormalities have also been observed with Robin sequence in humans.

The association of amputations and/or limb reduction defects in some human cases suggests that Robin sequence may occur on a disruptive basis. For example, an amnionic tear may cause oligohydramnios that can result in severe compressive disruption, causing limb reduction defects, and bands, causing amputations. Such primary disruption with oligohydramnios can also cause secondary deformation such as mandibular constraint, leading to Robin sequence (30a).

Finally, Robin sequence has been associated with congenital hypotonia (51). If neurogenic hypotonia occurred prior to complete closure of the palate, it is conceivable that Robin sequence might result from lack of mandibular exercise. Different etiologic and pathogenetic possibilities are summarized diagramatically in Figure 20–10. Further evidence for etiologic and pathogenetic heterogeneity was provided by Carey et al (10).

Hanson and Smith (24) found Robin sequence in specific syndromes in 25% of their patients. Another 35% had multiple anomalies, but no specific syndrome was recognized. The remaining 40% were instances of isolated Robin sequence. In the study of Williams et al (64), only 26% of children with Robin sequence had other anomalies including both recognized and unrecognized syndromes. Caouette-Laberge et al (9) found 57 of 125 patients to have an additional finding. Among 64 patients analyzed by Sheffield et al (52), 16 died and 12 of these were thought to have a syndrome. Of those that lived, 26% had an underlying syndrome, one-half of these having Stickler syndrome. There was no recurrence in sibs of those with nonsyndromal Robin sequence. Conditions associated with Robin sequence listed in Table 20–4 are derived primarily from Cohen (13–15), Hanson and Smith (24), Carey et al (10), and Shprintzen (54). The reader is referred to several articles on some of these conditions (3,22,26,35,45,53,59,60). With hindsight, it is fascinating to note that of the six patients with Robin sequence and multiple anomalies reported by Holthusen (27) in 1972, two had spondyloepiphyseal dysplasia congenita, two had Catel-Manzke syndrome, and one had unusual facies/femoral dysgenesis syndromes, and one had Robin/amelia association. It should be recognized that the list of conditions associated with Robin sequence found in Table 20–4, although representative, is not complete. Robin sequence may be found with other conditions. Since there is further ill-defined heterogeneity, the reader may expect to find Robin sequence with various other anomalies, especially involving the eye, ear, heart, and limbs.

From MM Cohen Jr, The Child with Multiple Birth Defects, Oxford University Press, New York, 1997.

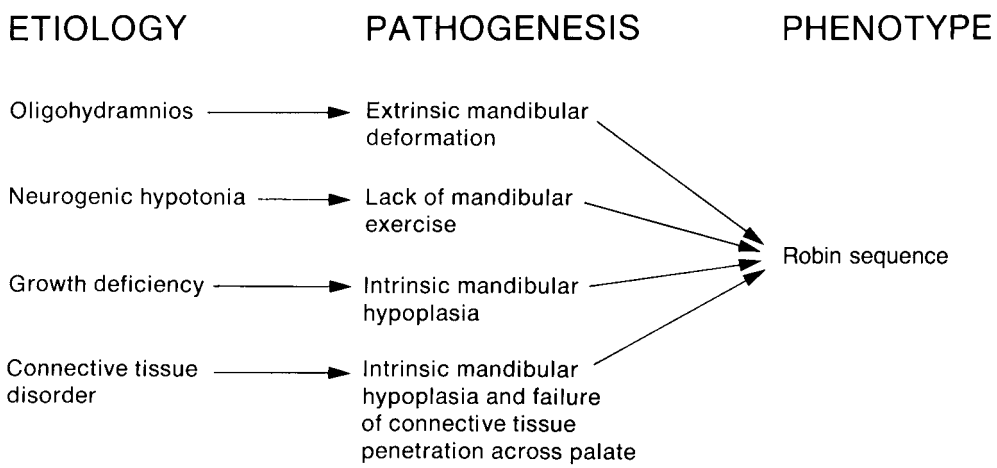

Fig. 20–10. *Robin sequence*. Etiologic heterogeneity suggests pathogenetic heterogeneity in Robin sequence. The following pathogenetic possibilities should be considered. (I) Oligohydramnios results in decreased amnionic fluid, compressing the chin against the sternum and thus restricting mandibular growth. (II) If hypotonia restricts mouth opening during early fetal life prior to complete palatal closure, Robin sequence might result from lack of mandibular exercise. (III) Growth deficiency, as observed in chromosomal syndromes such as dup(11q) syndrome, may produce Robin sequence by intrinsic mandibular hypoplasia. (IV) In a connective tissue disorder such as Stickler syndrome, Robin sequence may result from intrinsic hypoplasia and failure of connective tissue penetration across the palate. (From MM Cohen Jr, The Child with Multiple Birth Defects, Raven Press, New York, 1982.)

Genetic factors are clearly implicated in many examples of Robin sequence (11,22,33,45). The most common genetic syndrome associated with Robin sequence is *Stickler syndrome* (18a). A personal account of just such an example is highly recommended reading (36). Active detection of myopia should be sought because blindness, resulting from retinal detachment, can probably be prevented in this syndrome. The second most common is *velocardiofacial syndrome*.

Clinical manifestations. The facies is striking at birth. The mandible is small and symmetrically receded (Figs. 20–11 and 20–12). Commonly the base of the nose is flattened. The palatal cleft may be U-shaped (Fig. 20–13) (24). Rintala et al (43) and Amaratunga (2) indicated that both U- and V-shaped clefts (Fig. 20–14) were found in Robin sequence and in isolated cleft palate with equal frequency. However, on the average, the width of the cleft was greater in Robin sequence than in isolated cleft palate. We have not been impressed by the so-called U-shaped cleft being a constant feature.

Difficulty in the inspiratory phase of respiration is apparent, with periodic cyanotic attacks, labored breathing, and recession of the sternum and ribs. This becomes especially apparent when the child is in the supine position. Respiratory difficulty is usually evident at birth, although it may not be severe for the first week. Only rarely is its initiation delayed until the first month (46).

Although there is no complete agreement concerning the exact mechanism by which respiratory and feeding difficulties are produced, the classic explanation suggests that the micrognathia makes for little support of the tongue musculature (51). This allows the tongue to fall downward and backward (glossoptosis) into the lower postpharyngeal space, obstructing the epiglottis. In this position, the tongue permits egress of air but prevents inhalation, acting much as a ball valve, causing period cyanosis and sternal retraction. Feeding problems are thought to be because of inadequate control of the tongue. Nursing, even when performed in a favorable position, is an ordeal (17).

Routledge (46), however, suggested that the respiratory difficulty might be due, in large part, to impaction of the tongue tip in the palatal

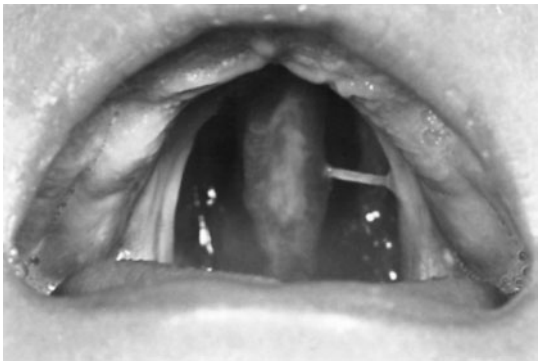

Fig. 20–13. *Robin sequence*. U-shaped cleft palate.

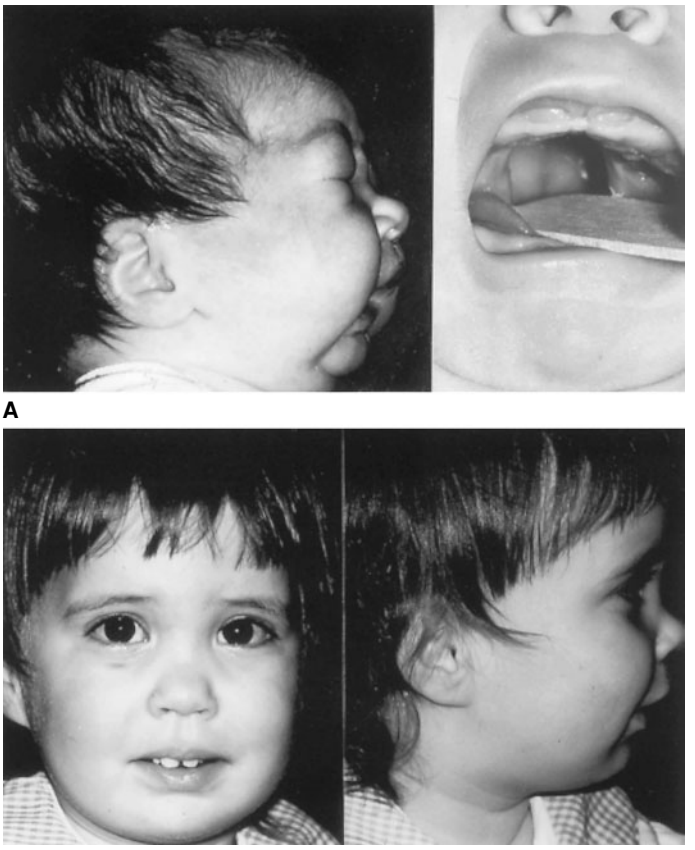

Fig. 20–15. *Robin sequence*. (A) Patient with Robin sequence showing micrognathia and U-shaped cleft palate. (B) Same patient showing mandibular catch-up growth. (From MM Cohen Jr, The Child with Multiple Birth Defects, Raven Press, New York, 1982.)

cleft, from which it is not easily disengaged. Violent muscular contractions resulting from efforts to free it cause the tongue to bulge into the nasopharynx resulting in asphyxia. Routledge realized that his theory did not explain those cases in which surgical repair of the palate failed to correct the respiratory difficulty or those cases associated with ankyloglossia, which does not permit upward movement of the tongue tip.

It has also been shown, most notably by Pruzansky and his co-workers (5,38,39) and Stellmach and Schettler (58), that mandibular catch-up growth often results in a normal profile by 4–6 years of age (Figs. 20–15 and 20–16). This was not substantiated by Laitinen and Ranta (29). Pruzansky (38) described the mandible as having a foreshortened body with a characteristic ratio of the ramus to mandibular body length.

The tongue has been stated by some investigators to be small, by others, normal, and by still others, large. Depending on particular syndromic diagnoses, all may be correct. For example, the tongue may be small in Moebius sequence but large in Beckwith-Wiedemann syndrome. It has also been suggested that there may be disproportionate growth of the tongue (46). Pruzansky and Richmond (38) concluded from cephalometric studies that micrognathia, *sui generis*, is not sufficient to produce respiratory embarrassment unless the tongue is normal in size or enlarged. Ankyloglossia is a commonly associated complication. For additional discussion of cephalometric findings, see Ranta et al (41).

Growth deficiency, which sometimes accompanies Robin sequence, may be related to severity of airflow obstruction or to the overall syndromic condition if it is caused by a chromosomal abnormality or teratogenic agent. Heaf et al (25) found that failure to thrive was significantly correlated with severity of airflow obstruction. Failure to thrive was reversed in infants managed with a nasopharyngeal airway. In a large series of patients reported by Williams et al (64), 26% died within the first 3 months. Of those who survived, 13% showed delayed language development. Other authors have indicated that as many as 25% exhibit major mental deficiency and various anomalies may be associated such as microcephaly and hydrocephaly (9).

Congenital murmurs and/or heart defects have been observed in 15%–25% of patients who die in early infancy (52). Necropsy has revealed PDA, patent foramen ovale, ASD, VSD, ventricular hypertrophy, cor triloculare, coarctation of the aorta, biventricular aorta, and dextrocardia (17,46,57). Congestive cardiac failure with signs of cor pulmonale

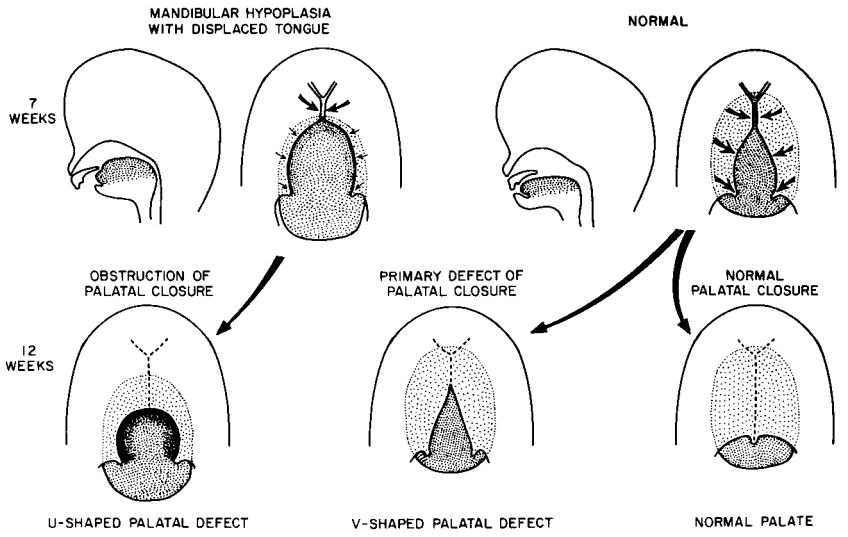

Fig. 20–14. *Robin sequence*. At left, small mandible results in posteriorly placed tongue partially interposed between palatal shelves. This prevents closure and posterior growth of soft palate, producing U-shaped cleft palate. V-shaped defect at right is frequently seen in primary defects of palatal closure not secondary to mandibular involvement. (From JW Hanson and DW Smith, J Pediatr 87:30, 1975.)

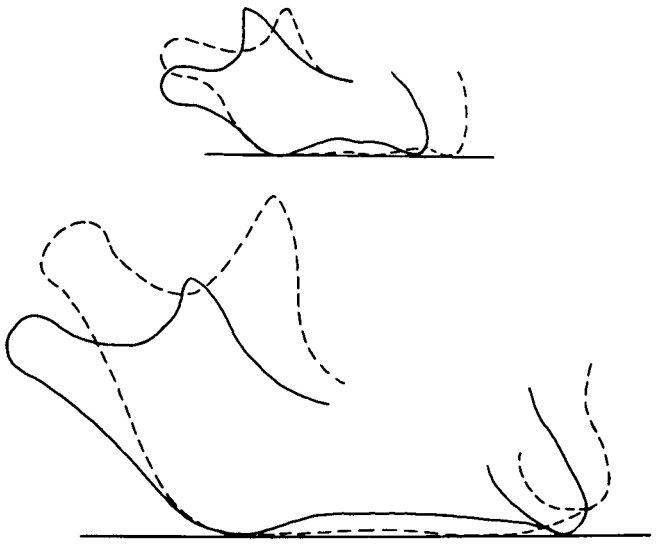

Fig. 20–16. *Robin sequence*. Superimposed tracings from normal (broken line) and Robin (solid line) mandibles. Note differences in height of ramus, length of body, gonial angle, and inclination of condyle to ramus. Note also catch-up growth. [From S Pruzansky, Birth Defects 5(2):120, 1969.]

has been recorded by a number of authors (18,28). Nasopharyngeal intubation or tracheostomy may reverse the signs of cor pulmonale.

Many striking abnormalities are features of the syndromes listed in Table 20–4. Other anomalies occur in unrecognized patterns. Ocular findings are particularly common. Smith and Stowe (57) found 13 eye anomalies in nine patients including esotropia, glaucoma, and microphthalmia. Saraux and Dhermy (48) and Ortlepp and Brandt (34) reviewed glaucoma and Robin sequence. Ear anomalies occur less frequently, but especially include low-set ears and malformed ears (23,57).

Limb anomalies may be particularly striking and occur with some frequency. Wood and Sandlin (65), in a review of eight patients with Robin sequence, found three cases with limb anomalies including syndactyly, hypoplastic digits, and Poland anomaly. Williams et al (64) noted that peripheral limb defects were particularly common. Congenital amputations, limb reduction defects, talipes equinovarus, and congenital hip dislocation have been reported as well as rib and sternal anomalies (4,7,23,31,38,46,57).

Glander and Cisneros (21) compared craniofacial measurements in velocardiofacial and Stickler patients, both groups having presented with a Robin phenotype.

Prenatal diagnosis has been carried out (27a).

Robin sequence, congenital thrombocytopenia, agenesis of the corpus callosum, distinctive facies, and developmental delay

Braddock and Carey (1) reported a combination of Robin sequence, congenital thrombocytopenia, distinctive facies, agenesis of the corpus callosum, and developmental delay in two unrelated females.

Both exhibited pre- and postnatal growth retardation, microcephaly, mental retardation, sparse curly hair, large posteriorly rotated pinnae, high forehead, broad nasal root, inverted U-shaped mouth, Robin sequence, lack of facial expression, and hypoplastic tooth enamel.

Neonatal persistent thrombocytopenia with normal number of marrow megakaryocytes in one and a decreased number in the other were found. Agenesis of the corpus callosum was noted in both.

Ventricular septal defect was found in one child, multicystic kidneys in the other.

Both had clinodactyly/camptodactyly of the fifth fingers.

Reference (Robin sequence, congenital thrombocytopenia, agenesis of the corpus callosum, distinctive facies, and developmental delay)

1. Braddock SR, Carey JC: A new syndrome: Congenital thrombocytopenia, Robin sequence, agenesis of the corpus callosum, distinctive facies, and developmental delay. Clin Dysmorphol 3:75–81, 1994.

Robin sequence, unusual facies, and digital anomalies

Chitayat et al (1) reported two half brothers with the same mother. The forehead was high and broad with widow's peak and partial bossing. The nasal bridge was broad, flat, and wrinkled. The philtrum was long. The cleft palate was U-shaped.

The fingers and toes tapered with short distal phalanges and hyperconvex nails. Clinodactyly of the fifth digit was evident bilaterally. Delayed bone age was demonstrated.

Inheritance may be X-linked recessive.

Reference (Robin sequence, unusual facies, and digital anomalies)

1. Chitayat D et al: Robin sequence with facial and digital anomalies in two half-brothers by the same mother. Am J Med Genet 40:167–172, 1991.

Robin sequence, ventricular extrasystoles with syncopal episodes, and digital hypoplasia

Stoll et al (1) described hypoplasia or absence of the distal phalanges of the toes (perodactyly), ventricular extrasystoles with syncopal episodes, and Robin sequence in six individuals in three generations.

Four of the six had bilateral terminal transverse defects of the fingers and toes. Small stature was present in four patients. All exhibited ventricular extrasystoles, occurring more often as bigemini. Five of the six had sudden syncopal episodes. Retardation of mandibular growth, and glossoptosis, a constant feature, were more striking in younger patients. Submucous cleft palate was found in five of the six with a U-shaped cleft palate presented in the sixth.

Inheritance is presumably autosomal dominant.

Wood and Sandling (3) and Williams et al (2), in reviews of patients with Robin sequence, noted hypoplastic digits as a feature but no mention was made of other findings.

References (Robin sequence, ventricular extrasystoles with syncopal episodes, and digital hypoplasia)

3. Wood VE, Sandling C: The hand in the Pierre Robin syndrome. J Hand Surg 8:273–276, 1983.

Robin sequence, short stature, vertebral anomalies, short neck, and mental retardation

Mathieu et al (1) reported a father and son with unusual facies (epicanthic folds, short nose with anteverted nostrils, thin upper lip, posteriorly

rotated pinnae), micrognathia, cleft palate, brevicollis, vertebral anomalies, and mental retardation. Stature was short (-4SD). Joints were hyperextensible. The hands appeared especially short.

Diaphragmatic hernia and ankylosis of the ankles were also documented.

Reference (Robin sequence, short stature, vertebral anomalies, short neck, and mental retardation)

1. Mathieu M et al: A familial syndrome with micrognathia, cleft palate, short neck and stature, vertebral anomalies, and mental retardation. Genet Couns 4:299–303, 1993.

Robin sequence, mental retardation, and brachydactyly

Gurrieri et al (1) reported a brother and sister with mental retardation, Robin sequence, and brachydactyly.

In addition, they had a somewhat unusual facial appearance: synophrys, short palpebral fissures, long philtrum, bowed-shaped upper lip, and severe micrognathia. In addition to the brachydactyly, there was considerable clinodactyly of the fourth and fifth fingers.

The mental retardation was mild to moderate.

Noncleft palatal anomalies

The palate may or may not be highly arched, but this can only be known by measurement of palatal height. The term *highly arched palate* is most commonly used as a subjective description. Objective measurements often belie subjective clinical impression. For example, patients with trisomy 21 syndrome are commonly described as having highly arched palates. However, in the metric study of Shapiro et al (9), palatal height tended to be in the normal range and was not markedly high. Palatal width tended to be more narrow than in normal controls, resulting in the illusion of highly arched palate (Fig. 20–17). Surprisingly, palatal length was found to be dramatically shorter than normal, and in the overwhelming majority of cases, trisomy 21 syndrome patients and normal controls could be distinguished on the basis of this measurement (Fig. 20–18).

Prominent lateral palatine ridges (Fig. 20–19) are a nonspecific feature of various conditions (Table 20–5). Two types of disorders predominate: those with neuromotor dysfunction and those with primary palatal malformation. In both types, proper tongue thrust into the palatal vault is prevented. This may occur in patients with neuromuscular dysfunction of long standing or with malformation such as Byzantine arch palate. Hanson et al (4) suggested that long-standing deficit of tongue thrust is the common pathogenetic mechanism. In the Byzantine arch palate of Apert syndrome, lateral palatal swellings are present that increase in size with age (Fig. 20–20). These swellings have been shown to contain excess mucopolysaccharide content, predominantly hyaluronic acid, and to a lesser extent, sulfated mucopolysaccharides (2,10).

Acquired palatal groove (Fig. 20–21) has been observed in infants with prolonged orotracheal intubation. The palatal groove appears to be related to the duration of intubation and to vigorous sucking during that period of time (3,8).

An unusual palatal anomaly is found in anencephaly (5–7) and holoprosencephaly (1). Although the palate is closed, deep depressions are found extending the length of the hard palate. The abnormality appears to be caused by incomplete downgrowth of the central nasal process. The appearance of such a palate in a case of cyclopia is shown in Figure 20–22.

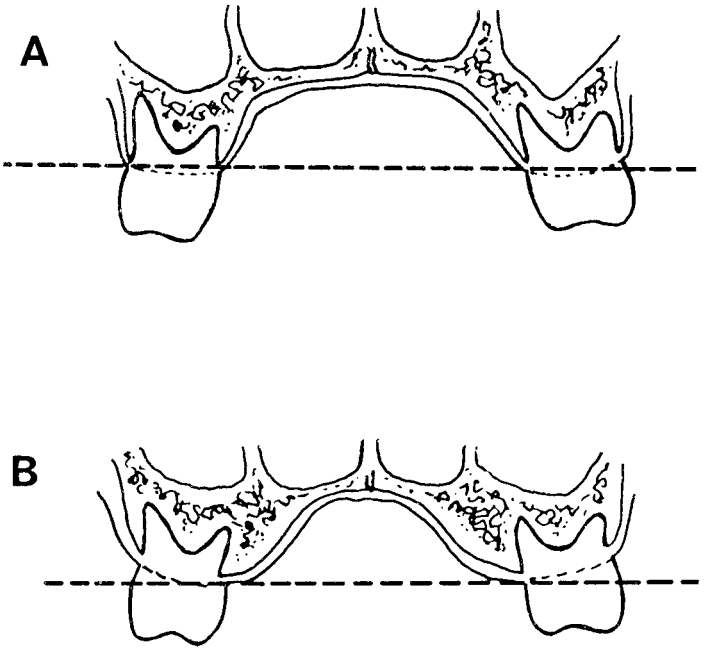

Fig. 20–17. *Noncleft palatal anomalies*. Cross-sections through palate. (A) Normal. (B) Narrow palate of trisomy 21 syndrome giving the illusion of being high. (From BL Shapiro et al, N Engl J Med 276:1460, 1967.)

Tessier clefting system

Many classifications for orofacial clefting have been used (4,6,13) and more elaborate classifications have been proposed to deal with extensive craniofacial clefting (5,7,8–10). Tessier (11), in 1976, described a classificatory system in which clefts are situated along definite axes. His system assigns numbers to various sites of clefting, depending on their relationships to the sagittal midline (Fig. 20–23). Bone and soft tissues are both involved, but rarely to the same extent. From the sagittal midline to the infraorbital foramen, abnormalities of soft tissue predominate. From the infraorbital foramen to the temporal bone, however, osseous defects are more severe than those of soft tissue, a notable exception being the ear. Clefts through the orbit use the lower eyelid as an equator. Cleft numbered lines may be either northbound (cranial) or southbound (facial). Cranial numbered lines have facial numbered counterparts, yet these numbers are different to avoid the implication that they necessarily have the same etiopathogenesis.

Table 20–5. Conditions with altered neuromuscular function or malformations associated with prominent lateral palatal ridges

Clinical sign of neuromuscular dysfunction	Condition
Hypotonia	Trisomy 21 syndrome
	Prader-Willi syndrome
	Zellweger syndrome
Hypertonia	Smith-Lemli-Opitz syndrome
	Menkes syndrome
Other	Sotos syndrome
	Fetal alcohol syndrome
Syndrome	"Abnormality proposed to interfere with palatal molding by tongue"
Apert syndrome	Extremely narrow midpalate
Glossopalatine ankylosis syndrome	Mechanically immobilized tongue
Hypoglossia–hypodactylia syndrome	Small tongue

Modified from JW Hanson et al, J Pediatr 89:990, 1976.

Fig. 20–20. *Noncleft palatal anomalies*. Palatal swellings in Apert syndrome. (A) Younger patient. (B) Older patient. Note change in size of palatal swellings with age. (From MM Cohen Jr, Craniosynostosis: Diagnosis, Evaluation, and Management, Raven Press, New York, 1986.)

In some instances, overlying soft tissue defects predict the possibility of underlying bony clefts. Features such as colobomatous notching of the upper or lower eyelid and nostril or interruption of eyelashes and eyebrows have been referred to as Tessier signs (1). Such patients should be examined radiographically to rule out possible underlying bony clefts. Several types of osseous clefting are illustrated in Figure 20–24 and clinical examples of the Tessier clefting system are shown in Figures 20–25 to 20–27.

The Tessier classification is anatomic and descriptive, thereby avoiding terms that imply, often erroneously, etiopathogenetic mechanisms. The causes of most such clefts are unknown. The overwhelming majority occur sporadically. Many cannot be explained embryologically, suggesting the possibility of disruptive factors. David et al (3) have elegantly illustrated each type and have added three dimensional reconstruction. Thorne (12) and Cohen (2) also have illustrated each type. The reader is also referred to the sections on *oblique facial clefts, lateral (transverse) facial clefts,* and *median mandibular clefts.*

Fig. 20–21. *Noncleft palatal anomalies*. Acquired palatal groove from orotracheal intubation. Infant intubated for 70 days. (From BS Saunders et al, J Pediatr 89:988, 1976.)

Lateral (transverse) facial clefts

Lateral facial cleft (macrostomia, Tessier type 7) may be an isolated phenomenon. More often, however, it occurs in association with other disorders: *mandibulofacial dysostosis, oculo-auriculo-vertebral spectrum, Nager acrofacial dysostosis, amniotic rupture sequence,* etc.

Various authors have estimated the frequency of isolated lateral facial cleft as 1/100 to 350 cases of cleft lip and/or palate, that is, approximately

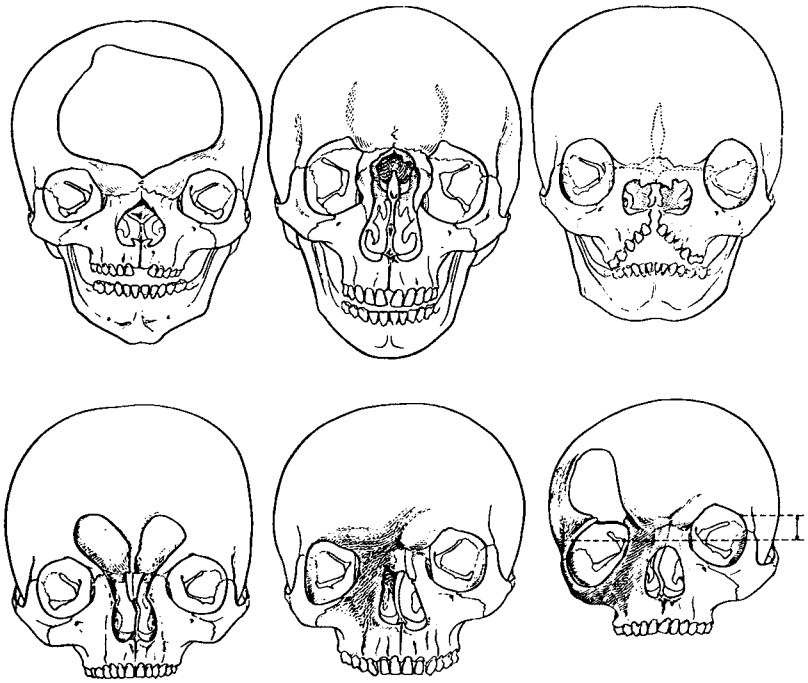

Fig. 20–24. *Tessier clefting system*. Upper left: Cleft Nos. 0, 14. Median craniofacial dysraphism involving encephalocele, hypertelorism, bifid nose, and diastema between maxillary central incisors. Upper middle: Cleft Nos. 0, 14. Median frontonasal encephalocele and dystopia canthorum. Note sparing of upper cranial region and tooth bearing part of maxilla. Upper right: Cleft Nos. 0, 14. Median craniofacial dysraphism with encephalocele or calcification of the falx cerebri or both, duplication of the crista galli, hypertelorism, bifid nose, absence of vomer, and keel-shaped maxillary dental arch. Lower left: Cleft Nos. 1, 13. Bilateral paramedian encephaloceles and hypertelorism. This case was associated with colobomatous notching of both nostrils. Lower middle: Cleft Nos. 2, 12. Unilateral involvement affecting facial component more severely than cranial component. Cleft is either through frontal process of maxilla or between maxilla and nasal bone. Note unilateral hypertelorism. Patient had cleft through medial part of the right nostril. Lower right: Cleft No. 10. Unilateral large defect of frontal bone involving supraorbital rim and orbital roof with encephalocele, unilateral hypertelorism, and dystopia with lateral rotation of the affected orbit. (From P Tessier, J Maxillofac Surg 4:69, 1976.)

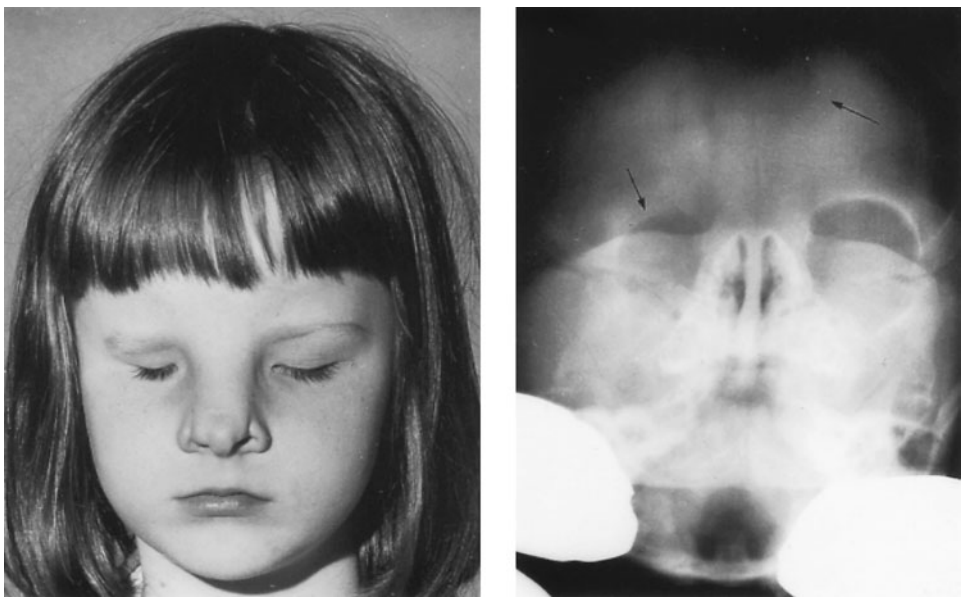
1/50,000 to 1/175,000 live births (5,6,10,18). Like oblique facial cleft, the isolated lateral cleft does not appear to have a genetic basis. It has been reported in one of monozygous twins (12). Especially bizarre are the severe cases in sibs whose father had cleft lip and cleft palate (21) and in three half sibs, each having a different father (11).

The cleft may represent failure of penetration of ectomesenchyme between developing maxillary and mandibular prominences. Multiple growth centers are involved in each facial prominence. Failures of these centers to merge could eventuate in macrostomia. However, the variable placement of the lateral cleft in relation to the ear in different cases (Figs. 20–28 and 20–29) suggests the possibility of disruptive factors in many cases.

The lateral facial cleft may be unilateral or bilateral (10%–20%), partial or rarely complete, extending from the angle of the mouth to the ear (3,13,14,19). It appears to be somewhat more common in males, and, when unilateral, is more frequent on the left side. Minimally, it may involve only a groove-like thinning of the cheek or mild lateral displacement of the commissure (16). The external defect is always accompanied by an underlying muscle defect (Fig. 20–29). The reader is referred to *Tessier clefting system* (type 7).

Associated anomalies have been reported including micrognathia (4), nasal dermoid (5), tetralogy of Fallot and intestinal anomalies (16a), and epignathus (1). Bizarre clefts of all types may be associated with *amniotic band syndrome*. Transverse facial cleft may be associated with accessory maxillae (7–9,15,20,23). Patients with *Klippel-Feil syndrome* rarely have creases running from both commissures toward the ears (2,17,24,25). We suspect the patient of Shetty et al (22) has *oculo-auriculo-vertebral spectrum*.



A B

Fig. 20–25. *Tessier clefting system*. (A,B) Cleft Nos. 0, 14. Note midline cranium bifidum, hypertelorism, unilateral microphthalmia with small orbit, and colobomatous notching of nostrils. (From HO Sedano et al, J Pediatr 76:906, 1970.)

A B C

Fig. 20–26. *Tessier clefting system*. (A–C) Cleft No. 10. Note unilateral hypertelorism with downward displacement of the orbit, interruption of eyebrow on affected side, and repaired cleft lip (CCFA #1240, female, age 14 yrs, 7 mos). [From S Pruzansky. In: JF Bosma, Symposium on Development of the Basicranium, HEW Publication No. (HIN) 76–989, Bethesda, Maryland, p 278, 1976.]

Oblique facial clefts

Oblique facial cleft (meloschisis) is exceedingly rare. Fogh-Andersen (12) reported 1 case/1300 cases of facial cleft. Gunter (13) found 4 among 900 cases of facial cleft. Wilson et al (42) estimated that they represented 0.25% of clefts. Kawamoto (16) estimated that they occur in approximately 2–5 per 100,000 births.

From the approximately 225 published examples that we have tabulated, the cleft appears to be bilateral in approximately 20% (4,5,31) and more often on the right side when unilateral (3). The cleft is nearly always associated with cleft lip and palate. Occasionally lateral facial cleft is also present (3,9,38). There is no sex predilection. All known cases are sporadic. For historic discussion, see Morian (22) and Boo-Chai (3).

Oblique facial cleft is extremely variable in degree (4). It may extend through the upper lip to the nose (as a typical cleft lip) to involve the eye (producing microphthalmia or anophthalmia), at times even reaching the brow or temple (3,11,21,23,26,30), or it may arise lateral to the philtrum and extend to the eye by skirting the nose (Figs. 20–28,20–30 and 20–31). The more severe types are, not uncommonly, incompatible with life. A three-dimensional study is that of David et al (7).

An early attempt was made by Morian (22) to classify the oblique facial cleft into two types: (1) *naso-ocular cleft*, extending from the nostril to the lower eyelid border with possible extension to the temporal region, that is, along the line of closure of the nasolacrimal groove, and (b) *oro-ocular cleft*, extending from the eye to the lip. This latter form, the more common (60%) type, was subdivided into (b_1) oromedial canthal type and (b_2) orolateral canthal type (1,3,8,17,40). Tessier (36) proposed a more elaborate surgically oriented numerical classification of rare facial clefts. Oblique facial clefts include those of types 2–6. Those that involve the nostril are called type 3; the ones that skirt the nostril are type 4, and those that extend from the oral commissure to the eye are type 5. Type 9 extends to the temporal area. These classifications are important descriptive observations that do not consider etiopathogenesis. The reader is referred to *Tessier clefting system* for further discussion.

The cleft has been stated to represent failure of penetration of ectomesenchyme between the lateral nasal and maxillary prominences with resultant failure of coverage of the nasolacrimal groove. We believe that most examples are because of tears in the ectomesenchyme related to the *amniotic rupture sequence*. This appears to be clearly evident in those cases associated with constriction rings or bands, intrauterine amputation of digits, or aplasia cutis congenita (3,5a,8,12,17–20,29,30,38). In some cases, an amniotic strand is presumably swallowed and becomes attached to the pharynx, slicing the ectomesenchyme of the facial processes. See also *tetra-amelia* for discussion of another association.

Other so-called associated anomalies may be interpreted as being secondary to the cleft, such as abnormal eyebrow and/or hairline, facial asymmetry, choanal atresia, absence of nasal ala, agenesis of lacrimal puncta with or without formation of nasolacrimal duct, bifid nasolacrimal system, eyelid colobomas as well as sundry eye anomalies (choroid coloboma, microphthalmia, rarely anophthalmia), supernumerary teeth, jaw fusion, and dental malocclusion (2,8–10,15,16,24,25,27,28,32,33,35,38,39).

Various other associated anomalies may occur including hernia (25), genitourinary abnormalities (13), talipes (13,20), cutaneous tag (6), spinal and costal defects (9), encephalocele (14,17), and hydrocephalus (22). Mental retardation is a variable finding.

There is no evidence that the cleft has single gene inheritance (41).

Median cleft of the upper lip

Most median clefts of the upper lip are not true median clefts. They represent agenesis of the primary palate associated with holoprosencephaly with or without trisomy 13.

True median cleft of the upper lip is because of failure of the lowest part of the median nasal prominences to approximate in the midline (14). It is among the rarest of facial clefts, constituting only approximately 0.2% (7). The median cleft usually involves only the vermilion of the upper lip but occasionally extends between the central incisors into the alveolar process (Fig. 20–32). Often there is duplication of the frenum of the upper lip with a small pit between the mucosal folds. The philtral columns are somewhat widened (1–6,8–14). Philtral pits have been reported in a few cases (5,13).

Median cleft of the upper lip may be associated with a number of syndromes such as the *oral-facial-digital syndromes, Ellis-van Creveld syndrome, Majewski syndrome*, and *median cleft of upper lip, double frenum, and hamartoma of columella and/or anterior alveolar ridge*.

Fogh-Andersen (7) very briefly reported male sibs with midline cleft of the upper lip and dysplastic terminal phalanges of the hands (digital amputation and syndactyly).

Lateral sinus of the upper lip

The lateral sinus of the upper lip is located along the line at the position of fusion of the median nasal and maxillary prominences, i.e., along the line of closure of the lip, and probably represents a microform of cleft lip (1–9). It may be in the vermilion and associated with minor salivary glands or even extend into a palatal cyst. Bilateral sinuses have been reported (6,8).

Median cleft of upper lip, double frenum, and hamartoma of columella and/or anterior alveolar ridge

Approximately 25 authors (1–6,8–26) have described patients with (a) median cleft of the upper lip extending through the vermilion, (b) duplication of the maxillary median frenum, (c) pedunculated skin-covered club-shaped cylindrical mass presented through one nostril, its base attached to the nasal septum or columella, and (d) a similar mass attached to the mid-anterior alveolar process (Figs. 20–33 and 20–34). Not all patients have all four components present. In rare examples, the midline cleft of the upper lip extends into the nose (24). Striking examples are those of Kernahan (9) and Guion-Almeida (4), whose patients had a skin raphé, extending from the midline cleft lip along the nasal bridge to the bregma. In both there was hypertelorism. In one (9), a skin

tag was present on the side of the nose near the glabella. No details were presented. Microscopically, it consists of skin and dermal appendages, fibrous connective tissue, adipose tissue, and striated muscle. This represents a malformation of the primary palate. In several cases, a lipoma was found in the corpus callosum (4,5,15,16,19,21,23) and in the spinal canal (18). Rarely, the nasal tip is bifid (25). Although the syndrome has been called Pai syndrome, a large number of examples had been described prior to the report of Pai et al (19) in 1987.

Midline clefts of the upper lip can be seen in other disorders such as *holoprosencephaly*, palate duplication, various *oral-facial-digital syndromes, Ellis-van Creveld syndrome, Majewski short-rib polydactyly syndrome*, and bifid nose (22).

Miscellaneous anomalies have included: mesodermal dysgenesis of the anterior eye (5,21), conjunctival lipoma (15), cartilaginous skin tag of glabella, mid-forehead, or lateral nose (8,19,23), bifid uvula (23), mental retardation and short stature (4), and clinodactyly of V (19). A similar skin tag was found in an infant who manifested no other sign of the syndrome.

The suggestion that the condition has autosomal dominant inheritance, we believe, is weak (23). The father had only a coloboma of the iris. There is a slight male sex predilection. Masuno et al (14) reported finding a translocation in a patient that involved either Xq28 or 16q11.2.

Lipoma of the corpus callosum can be found in *frontonasal malformation*.

Median mandibular cleft (Tessier type 30)

The rare anomaly is usually an isolated finding. Redard and Michel (30) reviewed early examples. The earliest may be that of Couronné (11) in 1819. Although Rey et al (31), in 1982, listed 64 examples, they included a number we cannot accept. As of 1997, perhaps 80 true cases have been reported. The disorder is not hereditary and there is no sex predilection. Its frequency is approximately 4 to 5 cases/million births (27,28).

Some examples are mild, involving only the lower lip and essentially sparing the bone (23); approximately 70% are more extensive (2) (Fig. 20–35). In approximately 35%, the tongue is significantly cleft. In nearly all cases there is ankyloglossia, the tongue tip being attached to the median cleft by a broad frenum (8,13,18,20,21). In others, there is more extensive ankyloglossia. Rarely is the tongue spared. The cleft may be very severe, bifurcating the mandible, tongue, and structures of the midneck down to the region of the hyoid bone (19) (Figs. 20–35 and 20–36). The hyoid bone and occasionally the manubrium of the sternum are absent. Some patients have a midline cervical cord (14,24). Ranta (29) described 12 cases of minimal cleft of the lower lip with cleft palate in 7, Robin sequence in 3, and/or agenesis of lower central incisor teeth in 2 patients.

We do not agree that the anomaly results from failure of merging of the paired first and second arches (22). We agree with Oostrom et al (25) that there is a single branchial arch with two mandibular swellings separated by a groove in the midline. The groove is normally erased by ectomesenchymal growth (merging). Variable hypoplasia of the mandibular prominences within the first arch makes for the variable degrees of expression of this anomaly. Giroud and Martinet (15) reported an animal model.

Various associated congenital abnormalities include symbrachydactyly and contractures of digits (5.24), cleft palate (8,9,14,24,29), congenital heart anomalies (12,24,26,33,34), and ear tags. Fujino et al (14) described a midline cervical cord; Surendran and Varghese (35) and Chidzonga and Shija (8), and Armstrong and Waterhouse (3) found midline dermoid of the neck/chin area. Constantinides and Cywes (10) noted aplasia of the epiglottis. Other miscellaneous anomalies are cited by Fujino et al (14), Rey et al (31), Oostrom et al (25), and Lu et al (19). A *Klippel-Feil anomaly* has been described (36).

Cleft tongue can be seen in association with the *oral-facial-digital syndromes*. It may be an isolated phenomenon (17). It should not be mistaken for true doubling or replication of the tongue that can be associated with cleft palate. *Frontonasal dysplasia* can be associated with cleft palate, cleft lip, and midline dermoid (4,6,7,16,32). The reader is referred also to *oral duplication and cleft* palate. Complex clefting of the lower lip was reported by Abramson (1). The oft-cited patient of Braithwaite and Watson (5) clearly has *oculo-auriculo-vertebral spectrum*.

Chapter 21
Orofacial Clefting Syndromes: Common and Well-Known Syndromes

Cerebro-costo-mandibular syndrome (rib-gap syndrome)

The syndrome originally described by Smith et al (28), in 1966, consists of both intrauterine and postnatal growth disturbance, cerebral maldevelopment or malfunction, bell-shaped thorax, variable rib-gap defects, respiratory distress, cleft palate, and micrognathia. Although approximately 55 cases have been reported, it is possible that the correct diagnosis of other examples may not have been made because of failure to perform autopsy or to take a radiograph of the chest.

The inheritance pattern is unknown (26). There is no sex predilection (24). McNicholl et al (18) and Trautman et al (32) reported affected sibs. Leroy et al (16) described the disorder in a mother and in her two children by different fathers. Merlob et al (20) reported the disorder in a father and daughter. Schrander-Stumpel et al (25) described an affected mother and daughter. Van den Ende et al (33) reported two examples of affected mother and daughter. Hennekam et al (8) noted affected sibs, one of them having only mild expression. In three cases, relatives had some stigmata (6,22). Duval et al (4) reported two female sibs with severe intrauterine growth retardation, severe microcephaly, prominent eyes, large nose, small mouth with full lips and severe micrognathia, severe brain hypoplasia, severe rib gaps, contractures of joints and hypoplasia of several bones. Kirk et al (12) described male and female sibs with severe micrognathia, cleft palate, absent olfactory tracts, and abnormal rib development. A similar case is that of Hennekam and Goldschmeding (7). Two pairs of dizygous twin sibs have been described (3). There was extremely variable expression. All other examples have been isolated. Consanguinity was noted in only one case (2). Chromosome studies have been normal (23,32). We are not certain how to classify one example (22). The child, the product of an incestuous union, exhibited cleft palate, hypoplasia of the sternum, clavicles and pubis, semirudimentary ribs, and porencephalic cyst.

Polyhydramnios has been reported in a few cases (3,6,18,20). Approximately 50% die prior to the first year of life (11,24).

Microcrania has been reported in approximately 35% (19,24,25), and mental retardation, ranging from moderate to severe, has been documented in approximately 35% of those that have survived. Normal intelligence has been described in most cases (15,17,19,23), but asphyxia, seen in a few examples, may contribute to retardation in approximately 30% of those that have survived (24).

The mandible is small in all cases, some patients requiring tracheostomy (Fig. 21–1A,B). Cleft palate (65%), short palate (15%), and glossoptosis (65%) have been noted and several infants were classified as having Robin sequence (19,23,34).

The upper thorax is very narrow (Fig. 21–1A). The constant feature is bilateral posterior rib gaps. They vary in number but are most frequent between the third and seventh thoracic segments, although all 12 levels have been affected (27). Rudimentary ribs may occur at the second level with absent twelfth ribs in approximately 70% of the cases (19,24) (Fig. 21–1C). Other lower ribs may be missing (25). The gaps represent pseudoarthroses (10,14). Follow-up reveals that the gaps are ultimately joined by bony bridges.

Respiratory distress is evident in nearly 100% in early infancy (31). The lungs are hypoplastic and with age, the chest width is greatly reduced (25).

Miscellaneous findings have included pterygium colli (5,13,20,25,26, 28) and an assortment of orthopedic anomalies: clubfoot, scoliosis (21,25), hip dislocation, stippled epiphyses (1), absence of external auditory canals (33), choanal atresia (33) and elbow dysplasia (6,13,15, 18,29,33,35). Conductive hearing loss (5,16,26,32), microstomia (20), ventricular septal defect (14), and cystic renal changes (22) have also been noted.

Prenatal diagnosis has been made (9).

Differential diagnosis would include an autosomal dominant syndrome of Robin sequence, rib dysplasia, scapular hypoplasia, and pectus excavatum (30). *Robin sequence, unusual facies, and digital anomalies* must also be excluded for pectus excavatum was also noted. Some patients with *del22q* have a similar phenotype.

EEC syndrome (ectrodactyly-ectodermal dysplasia-clefting syndrome)

The first report of the syndrome of ectrodactyly (lobster-claw anomaly) of the hands and feet, lacrimal duct anomalies with ocular complications, and cleft lip-palate was likely that of Eckholdt and Martens (19) in 1804. Another early nineteenth century description was that of Cruveilhier (17). In excess of 250 cases have been reported (42,74,76). EEC syndrome is present in 1/50,000 live births. The acronym, EEC syndrome, was coined by Rüdiger et al (79). Most reports are sporadic but the syndrome has autosomal dominant inheritance with reduced penetrance and variable expressivity (49,62,75,80,89).

Approximately 50% are sporadic examples (76). Pedigrees with skipped generations have been noted (16,21,35,96). Penetrance has been estimated as somewhat less than 80% (74). One ectrodactyly gene, *EEC1*, has been mapped to 7q11.2–q21.3 (2,24,28,29,69). A second gene, *EEC2*, maps to 19p13–q13 (59), while a third, *EEC3*, is at 3q27. The last gene is *p63*, where missense mutations are responsible for the EEC syndrome (5a). These are due to amino acid substitutions. *p63* is the homologue of the archetypal tumor suppressor gene *p53* (52,97a). However, *p63* mutations have been found in only 85% of EEC patients. Prenatal diagnosis has been accomplished (9). A comprehensive literature review is that of Roelfsma and Cobben (76).

There is marked overlap among Rapp-Hodgkin and Hay-Wells syndromes and a child with EEC syndrome (52a,53).

Birth weight may be somewhat low (10th–25th centiles) (4,10,11).

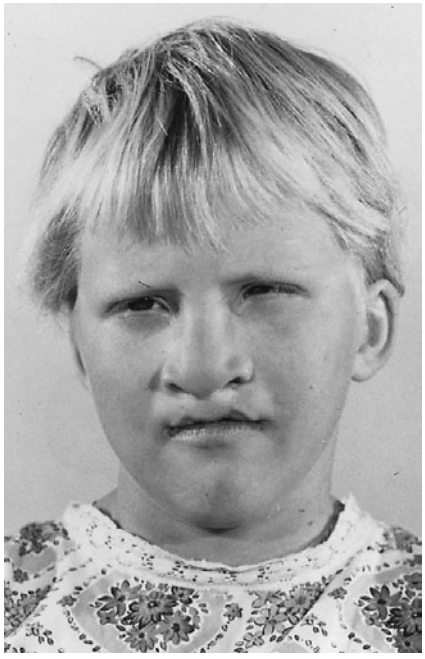
Fig. 21–2. *EEC syndrome*. Bilateral cleft lip-palate and ectrodactyly. (From RA Rüdiger et al, Am J Dis Child 120:160, 1970.)

Facies. The facies is characterized by dacryocystitis, keratoconjunctivitis, tearing, photophobia, and cleft lip. Scalp hair, lashes, and eyebrows are nearly always sparse (15,78). (Figs. 21–2 and 21–3).

Extremities. Limb anomalies affect approximately 85%–90%, with tetramelic involvement in 60%. Approximately 40% have asymmetric anomalies. The classic central ray deficit may be present in the hands with only syndactyly present in the toes (Fig. 21–4). However, some patients have been described without ectrodactyly (12,23,42,49,60,66), a single extremity may be normal (14). Occasionally, soft tissue syndactyly, especially of the toes or preaxial polydactyly or duplication of part of a digit occurs (4,7,89).

Eyes. Absent lacrimal punctas, usually bilateral and noted in approximately 90%, are associated with tearing, blepharitis, dacryocystitis, keratoconjunctivitis, and pannus with photophobia (10,11) (Fig. 21–4C).

Fig. 21–3. *EEC syndrome*. Patient has photophobia, clefting, and sparse hair.



These conditions often cause chronic corneal ulcers and scarring, which result in severe visual impairment. The irides are often blue in white patients as part of the pigment dilution. The number of Meibomian orifices is reduced (54,60,66,88).

Skin, hair, and nails. Pigmentary dilution of the skin and hair has been noted in most white patients (1,7,12,22,60), but black patients have normal pigmentation. Scalp hair, eyebrows, and lashes are silvery blond, coarse, and dry in 80%. The scalp hair is sparse in approximately 20% and slow growing (12,22,60,79,86). Light microscopic examination has shown the hair to be normal (60). Nails are dysplastic in 80% (7,11,38,71,78,86). They are also slow growing and transversely ridged or pitted. Absence or sparse sebaceous glands have been observed on skin biopsy (60,66,88). Approximately 12% have many pigmented nevi (12,22,41,60,66), and widespread comedone nevi have been described (45). Opitz (58) described a large kindred with clefting and ectrodactyly but no ectodermal defects as in the ECP (ectrodactyly-cleft palate) syndrome. Hypohidrosis is rare (10%). In one patient, the scalp was ulcerated as seen in *Hay-Wells syndrome* (82).

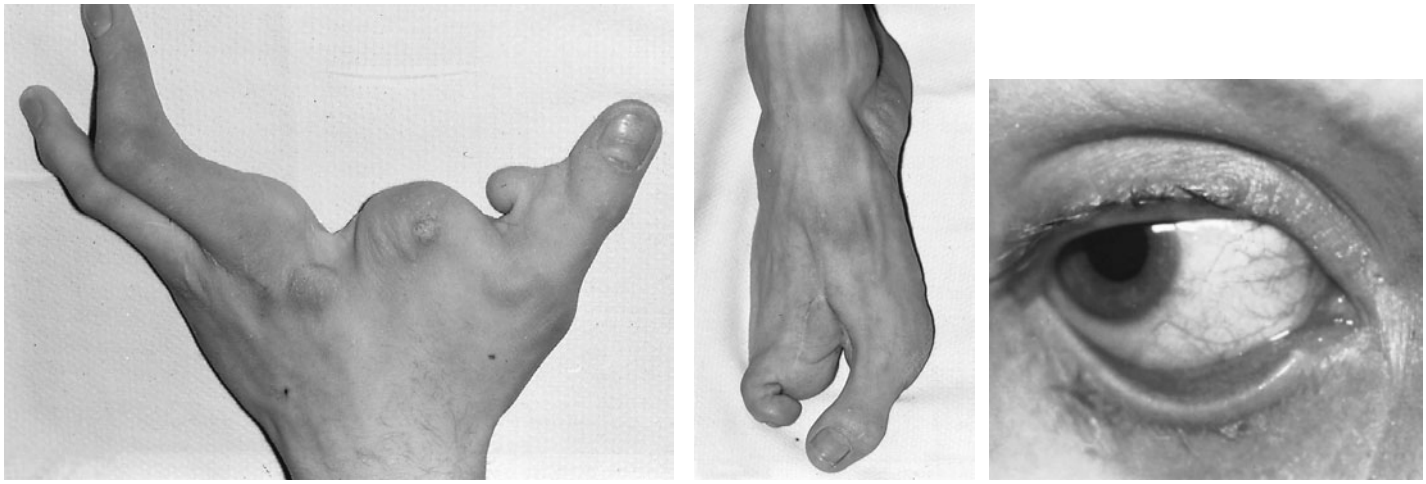
Central nervous system. Microcephaly and mental retardation have been reported in approximately 10% (1,6,7,22,60,79) but there may have been ascertainment bias. Growth hormone deficiency has been noted (40).

Genitourinary system. Kidney and ureter malformations (duplication of the kidney, collecting system and ureter, absent kidney, recurrent urinary tract infections, small dysplastic kidney, hydronephrosis, and hydroureter) have been described in at least 45% (3,8,34,38,74,86,88,96) as has hypospadias (11,55). Cryptorchidism (3,30), prune belly (34), and anal atresia (18,50) have been documented. One form may be related to having a thin atrophic bladder (48).

Endocrine system. Hypogonadotrophic hypogonadism has been reported (25,94) as well as growth hormone deficiency (40). Thymic aplasia has been described (36).

Otolaryngologic manifestations. Conductive hearing loss has been reported in approximately 30% (11,12,38,46,64,66,70,86,90). Absence of the stapes and part of the incus was found in one patient (12). Breathy voice has been observed in some patients (63). Choanal atresia has also been noted (14,91). Non-Hodgkin lymphoma was diagnosed from peritonsillar masses (56a).

Oral manifestations. Cleft lip-palate, bilateral in approximately one-half the cases, is described in 60%–75% (7,12,16,22,38,45,60,64,79,



A B C

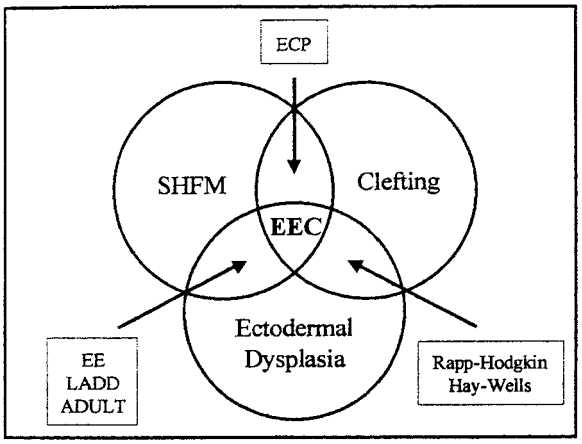
Fig. 21–4. *EEC syndrome*. (A,B) Ectrodactyly of hands and feet. (C) Absence of lacrimal point.

86,88). In possibly 10%, cleft palate without cleft lip is noted (11,63,64). Clefting is absent in other patients (15,22,49,62,65,97). Congenitally missing permanent teeth and teeth with coniform crowns (45) are common and, rarely, may be the only manifestation of the syndrome (15). The deciduous teeth are usually normal in number (68) but rarely the maxillary deciduous first molars are missing (62). Taurodontism has been noted (11). Xerostomia and enamel dysplasia may contribute to high dental caries rate. Parotid duct atresia has been documented (60,66). A deep anteroposterior furrow in the midline of the dorsum of the tongue has also been described along with candidal cheilitis and candidal perleche (60,66).

Differential diagnosis. Ectrodactyly is most commonly an isolated finding. At least three genes (100) have been mapped for isolated ectrodactyly, the most common being a deletion at 7q21.3 (33,51,72,73), but others have been located at 10q24 (26), Xq26 (27), and 3q27.

The number of ectrodactyly syndromes is legion: Wildervanck (99) described two sibs with severe sensorineural hearing impairment and ectrodactyly of the hands and feet, born to presumably normal parents; no other abnormalities were recorded. The *Patterson-Stevenson-Fontaine syndrome* (61) is characterized by ectrodactyly of the feet and craniofacial findings reminiscent of *mandibulofacial dysostosis*. Reed et al (71) described a mother and daughter with ectrodactyly, lacrimal duct obstruction, early graying of hair with pili torti, subtotal alopecia, and atrophic pigmented macules on the extensor surfaces of the body. Propping and Zerres (67) suggested an *ADULT syndrome* composed of autosomal dominant inheritance of ectrodactyly, pigment anomalies, nail dysplasia, and hypodontia. No clefting was evident. *Cleft lip-palate, hypohidrosis, thin, wiry hair, and dystrophic nails (Rapp-Hodgkin syndrome)* (84), when combined with ankyloblepharon filiform adnatum, is called *Hay-Wells syndrome*. Both (if they are indeed separate disorders) have autosomal dominant inheritance. Some authors have suggested that there is identity among these two and EEC syndrome (53) (Fig. 21–5). We suspect that some examples are EEC syndrome without ectrodactly. We also suggest that *Bowen-Armstrong syndrome* (8) *is Hay-Wells syndrome*. The *odontotrichomelic syndrome (cleft lip-palate, tetraperomelia, deformed pinnas, and ectodermal dysplasia)* (13) appears to have autosomal recessive inheritance. Patients with *craniosynostosis, severe asymmetrically malformed extremities, and cleft lip-palate (Herrmann syndrome)* resemble those with EEC syndrome. Stewart et al (83) reported cleft lip-palate with ectrodactyly and hypomelanosis of Ito which indicates mosaicism. Ohdo et al (57) reported a kindred with ectrodactyly, syndactyly, sparse thin hair, and macular dystrophy; inheritance was autosomal recessive. There is overlap with of EEC syndrome with *LADD syndrome* with which it may be identical (31,43). Ohdo et al (57) described the EEM syndrome, an autosomal recessive disorder consisting of sparse hair. ectrodactyly, and macular dystrophy. Differential diagnosis of many of these conditions has been extremely well discussed by Rodini and Richieri-Costa (74). Additional ectrodactyly syndromes has been reviewed by Schroer (81) and Buss (11). One must exclude the autosomal recessive syndrome of *cleft lip/palate, cardiac anomalies, genital anomalies and ectrodactyly*.

Fig. 21–5. *EEC syndrome*. Relationship among EEC and overlapping conditions. (From D Everman, 2001.)



The limb-mammary syndrome, an autosomal dominant syndrome mapping to 3q27, is characterized by hypoplasia of the mammary gland and nipple, variable ectrodactyly, lacrimal duct atresia, nail dysplasia, hypohidrosis, hypodontia, and cleft palate (92).

Lacrimal duct obstruction occurs in 1%–2% of the general childhood population, it has been found in approximately 10% of patients with isolated cleft lip-palate. Hoyme et al (32) described autosomal dominant ectrodactyly and absence of long bones of upper and lower extremities. Oğur and Yüksel (56) described two male sibs, the product of a consanguineous union, with tetramelic syndactyly, ectodermal dysplasia, cleft lip and palate, renal anomalies, and mental retardation. Atkin and Patil (5) reported a male infant and his maternal uncle with microphthalmia, cloudy corneae, and a CNS anomaly. The infant also had ectrodactyly, cleft lip, brain cyst, renal anomaly, hypospadias, and cryptorchidism. Conditions such as *de Lange syndrome, focal dermal hypoplasia*, and various ectodermal dysplasias with clefting by Fosko et al (20) can easily be excluded. Jones et al (37) reported ectrodactyly with aplasia cutis congenita, cleft palate and epidermolysis bullosa. Kasznicka et al (39) described ectrodactyly with abnormal pinnae and congenital

heart anomaly. Landy and Donnai (44) noted ectrodactyly with duplication of halluces, and hydrops. Van den Ende (93) reported ectrodactyly, congenital heart anomalies, and unusual facies. Viljoen and Smart (95) and Suthers and Morris (85) described ectrodactyly, microphthalmia, cleft palate, and mental retardation.

ECP syndrome (ectrodactyly-cleft palate syndrome)

In 1980, Opitz et al (2) reported an autosomal dominantly inherited syndrome of cleft palate and ectrodactyly involving the hands and feet in a large five-generation pedigree (Figs. 21–6 and 21–7). Features of the *EEC syndrome* such as cleft lip, hypotrichosis, nail dysplasia, and defects of the lacrimal canal were not observed. Other less common manifestations of the EEC syndrome such as mental retardation, microcephaly, conductive hearing loss, renal anomalies, and cryptorchidism were also not observed. The ECP syndrome is, in addition, distinct from *Patterson-Stevenson-Fontaine syndrome* consisting of ectrodactyly of the feet, micrognathia, submucous cleft palate, dysplastic ears, mental deficiency in some instances, and autosomal dominant inheritance (1). This must be differentiated from *acro-cardio-facial syndrome*.

Ectrodactyly of the feet and cleft palate (Patterson-Stevenson-Fontaine syndrome)

Patterson and Stevenson (2) in 1964 and Fontaine et al (1) in 1974 described an acrofacial dysostosis characterized by cleft palate, unusual pinnae, sensorineural hearing loss and variable oligosyndactyly of the feet. Another case from the Patterson-Stevenson family was added by Willkie and Goodacre (3).

In the kindred described by Fontaine et al (1), one of four exhibited moderate mental retardation and seizures whereas two had mild retardation. Microretrognathia has been evident in all.

Autosomal dominant inheritance is evident with variable penetrance and expression (1–3). One must exclude the *EEC syndrome*.

Cleft lip/palate, cardiac anomalies, genital anomalies, and ectrodactyly (acro-cardio-facial syndrome)

Richieri-Costa and Orquizas (3) reported a male with ectrodactyly, cleft lip/palate, VSD, micropenis, and mental retardation. Giannotti et al (1) described male and female sibs with low birthweight, cleft palate, ASD, VSD, coarctation of aorta, cryptorchidism, cleft hand, and mental retardation. They may have the same syndrome. Another example is that of Guion-Almeida et al (2).

Inheritance is probably autosomal recessive.

Cleft lip/palate, ectodermal dysplasia with [Hay-Wells (AEC) syndrome] or without [Rapp-Hodgkin syndrome] ankyloblepharon filiforme

In 1976, Hay and Wells (16) described seven patients from four families with autosomal dominant inheritance of congenital ankyloblepharon, principally involving the lateral lid margins, atresia of the lacrimal ducts or absence of lacrimal punctae, absent or dystrophic nails, coarse wiry sparse hair, pili torti, scalp infections, sparse to absent eyelashes, cleft palate, cleft lip, deficient teeth and teeth with conical crown form, maxillary hypoplasia, and mild hypohidrosis (Figs. 21–8 and 21–9). Numerous additional examples with ankyloblepharon have been published (13–15, 20,22,29,31,33,35).

The syndrome described by Rapp and Hodgkin (23) in 1968 consists of cleft lip and/or palate, sparse hair, small mouth, and hypospadias in males. Several other families (3,5,7,9,10,14–21,25,27,28,30,34,36,37,40,41), and isolated examples (11,12,18,19) have been described (Figs. 21–10 and 21–11). The condition reported by Bonafé et al (4) probably represents this syndrome.

Missense mutations have been found in the SAM protein-protein interaction domain of the *p63* gene on 3q27 (19a). A family seen by R. Gorlin maps to a 3′ splice site exon located between the DNA binding site and the SAM. This family greatly resembled that of Hay and Wells (16).

We do not believe that the former group is clearly separable from so-called *Rapp-Hodgkin syndrome*. Clinical findings in both groups of patients are roughly comparable (8). Only ankyloblepharon filiforme separates them. Autosomal dominant inheritance with variable expressivity is evident (25), but there may be genetic heterogeneity. We await molecular evidence. There have been a few cases of affected sibs with presumably normal parents (7,21,32,41).

Clinical findings. Stature, although often cited as short, has seldom been documented (37,40).

A B

Fig. 21–8. *Hay-Wells syndrome*. (A,B) Frontal and lateral facial views of 38-year-old male patient showing lack of scalp hair, eyebrows, and lashes, midfacial hypoplasia, dysmorphic left pinna. Patient has cleft palate. (From RJ Hay and RS Wells, Br J Dermatol 94:277, 1976.)

Craniofacial findings. High forehead, midface hypoplasia, narrow nose, short philtrum, thin vermilion, and small mouth characterize the face. There is midfacial hypoplasia (15). Approximately 50% have cleft lip and palate and 50% have cleft palate. The teeth are usually deficient in number, and the incisors have conical crown form (12). Ear canals may be atretic (12,27,35,37).

Skin. Scalp and body hair is generally sparse as are eyebrows and eyelashes. The hair is generally slow growing, blond, and wiry. However, it may be abundant and uncombable (36). Microscopic study reveals pili torti and/or pili canaliculi (34). Nails are typically narrow, dystrophic, and brittle. There is hypohidrosis but never to the degree seen in hypohidrotic ectodermal dysplasia (10,27,30). There are reduced numbers of sweat pores (10). Scalp dermatitis, especially in infants, is seen in 15%–50% (10%) and appears to be more common in those with ankyloblepharon. Mild 3–4 syndactyly has been described (12). The breasts may not develop in females (38).

The hair is triangular or ellipsoidal in cross-section. SEM has demonstrated canal-like grooves along the axis (5,7,12,27,32) (Fig. 21–12).

Ocular system. Approximately 30% have ankyloblepharon filiforme. These patients have been classified as having Hay-Wells (AEC) syndrome. Agenesis or atresia of lacrimal punctae has been noted (3,12,14,16,23,30,35–37,40), resulting in blepharitis and photophobia.

Fig. 21–9. *Hay-Wells syndrome*. Congenitally absent fingernails. (From RJ Hay and RS Wells, Br J Dermatol 94:277, 1976.)

Genitourinary system. Hypospadias has been noted in most males (4,7,12,23,37,39).

Other. Thymic aplasia has been noted (6).

Diagnosis. Ankyloblepharon may be a dominantly inherited isolated finding, or found in binary combination with cleft lip and/or cleft palate in *popliteal pterygium syndrome*, in *van der Woude syndrome*, and in CHANDS (curly hair and nail dysplasia) and with trisomy 18 (2).

Seres-Santamaria et al (31) reported male and female sibs with coarse wiry hair, ankyloblepharon, cleft palate, dystrophic nails, soft tissue syngnathia, and pits of the lower lip. This bridges *van der Woude syndrome*.

Rosselli and Gulienetti (26) described what is probably a unique syndrome. Their cases 2 and 3 had wooly hair, cleft lip and palate, dystrophic nails, subungual keratoses, dystrophic facial skin, a papulofollicular dermatosis of the trunk, and hypoplasia or aplasia of the thumbs and popliteal pterygia.

Abramovits-Ackerman et al (1), in 1992, reported 20 patients from 7 families with an autosomal recessive syndrome of pili torti, scalp follicular plugging, scalp keloids (15%), keratosis pilaris, xerosis, eczema, palmoplantar keratoderma, mild syndactyly of fingers (65%), nail dysplasia, typical facies (unfortunately not illustrated), anteverted pinnae (75%), malar hypoplasia, and cleft lip/palate (35%). They stated that dental anomalies were found in all patients, but they were neither illustrated nor described.

There is probably etiologic heterogeneity and molecular studies should solve this dilemma. Some studies may represent the EEC syndrome without ectrodactyly that maps to 7q21.21. Watson and Hardwick (41) described a girl with bilateral cleft lip-palate, hypoplastic pinnae, total anodontia, and dystrophic nails. A sib who died soon after birth had cleft lip-palate and congenital heart anomalies. The mother and a sister exhibited oligodontia. The parents were consanguineous. Shelley and Shelley (32) described sibs with uncombable sparse blond hair, scarring alopecia of the scalp at the occiput, absence of tears, sparse eyelashes, cup-shaped pinnae, dysplastic ridged nails, and short palate with bifid uvula or cleft palate. The nose was narrow. The incisors were anomalous. One sib had clubfoot and another mesodermal dysgenesis of the anterior segment of both eyes. Their father had syndactyly of the right index and middle fingers without a nail on the middle finger. The child described by Crawford et al (10) had hypoplastic nasal alae, absent lacrimal

A B

Fig. 21–10. *Rapp-Hodgkin syndrome*. (A) Sparse wiry hair, absent lashes and lacrimal puncta, ectropion of lower lids, hypoplasia of nasal alae, abnormal pinnae, bilateral cleft lip-palate. (B) Boy has cleft palate and blond, wiry hair. [A from RL Summitt and RL Hiatt, Birth Defects 7(8):121, 1971. B courtesy of C Salinas, Charleston, South Carolina.]

puncta, epiphora, photophobia, cleft soft palate, sparse eyebrows, coarse kinky scalp hair, dysplastic nails, reduced sweat pores, hypoplastic dermal ridges, and oligodontia. Moynahan (21) reported sibs with what he called XTE (*X*eroderma, *T*alipes, and *E*namel defect) syndrome. The parents were consanguineous. The syndrome consisted of cleft palate, hypohidrosis, dry skin, dry coarse hair, nail deformities, evanescent cutaneous bullae, absence of eyelashes, small lacrimal puncta, talipes, and defective enamel. We believe that these patients can be classified in this group.

It is interesting to note that the mother in one family had the syndrome although her child appeared to have EEC syndrome (20). Filiform adhesions were found between the eyelids. There is obvious overlap with the disorder reported by Zlotogora et al (43), but mental retardation was found. We are not convinced that the condition described by Richieri-Costa et al (24) is different from the syndrome in spite of alleged autosomal recessive inheritance. Mild syndactyly (2–3 and 3–4) was evident. We, too, believe that *Bowen-Armstrong syndrome* is the same as Hay-Wells (AEC) syndrome (42). Hay-Wells syndrome and CHAND syndrome seem to overlap as does limb-mammary syndrome.

Bowen-Armstrong syndrome (cleft lip-palate, ectodermal dysplasia, and mental retardation)

Bowen and Armstrong (1) described three female sibs with mild to moderate mental retardation, ectodermal dysplasia, and cleft lip and/or palate. It is uncertain whether these children had incomplete expression of the *EEC syndrome*, had the *AEC (Hay-Wells) syndrome*, or represented a unique disorder (2).

The hair was sparse and fair, with the brows and lashes absent (Fig. 21–13A). One child had congenital skin defects on the buttocks (Fig. 21–13B). Mottled brown pigmentation subsequently appeared on

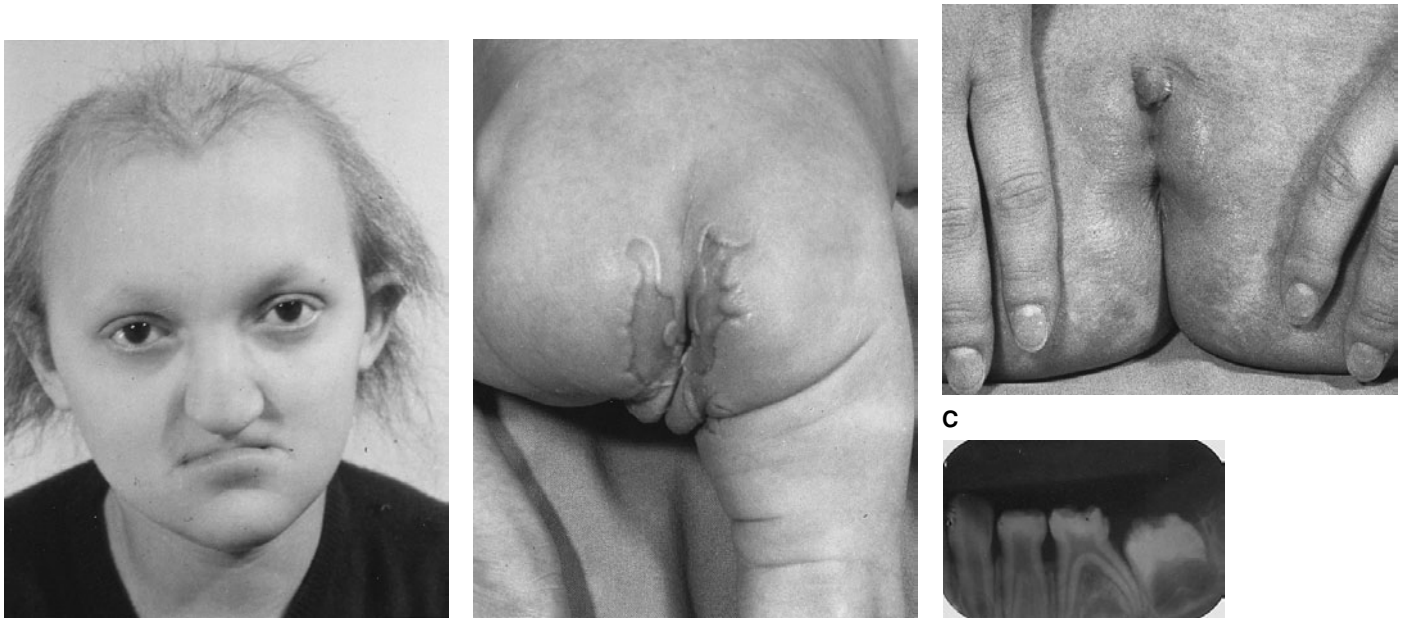

Fig. 21–13. *Bowen-Armstrong syndrome*. (A) Note unusual facies, wiry, scaly hair, sparse eyebrows and lashes. (B) Congenital skin defects on buttocks. (C) Absence of labia and vaginal introitus and mottled pigmentation of area. (D) Thin dysplastic enamel. (From P Bowen and HB Armstrong, Clin Genet 9:35, 1976.)

the genital area, axillae, and buttocks (Fig. 21–13C). Blepharitis and photophobia were present in one child and ankyloblepharon filiforme adnatum in two of the sibs. The extremities exhibited variable soft tissue syndactyly of the feet. There was some degree of bony syndactyly. The nails were somewhat hypoplastic. Genital anomalies included hypoplasia of the labia minora with absence of vaginal opening. Dental abnormalities were absence of primary and secondary maxillary incisors and canines and enamel hypoplasia (Fig. 21–13D).

Filiform adhesions of the eyelids and cleft lip-palate

The association of cleft lip with or without cleft palate and congenital filiform fusion of the eyelids (ankyloblepharon filiforme adnatum) appears to be inherited as an autosomal dominant trait with extremely variable expressivity (1–23). In several families, there were relatives with facial clefting but no eyelid anomalies (6,12,14,20,21). There has been one association with isolated cleft palate (5). The disorder may be more common in India. Syngnathia was noted in two patients (16,22).

Multiple connective tissue bands, 0.3 to 5.0 mm in width, extend from the white line of one lid to that of the other lid, posterior to the cilia and anterior to the meibomian orifices (Fig. 21–14). No associated anomalies are found in the eyeballs. The filiform adhesions may be an isolated finding or in combination with the *cleft lip-palate and paramedian lower lip pits*, in the *popliteal pterygium syndrome* and in the *Hay-Wells (AEC) syndrome*. They have been found in patients with trisomy 18 (3,7) and in CHANDS, an autosomal recessive disorder of curly hair, ankyloblepharon, nail dysplasia, and ataxia (4). Associated anomalies that appear to be aleatory are spina bifida, superior adherence of pinna, and syndactyly of fourth and fifth toes. Imperforate anus has been described in several patients. (2,5,10,11).

The orofacial findings have been attributed to defects in inductive influences or terminal differentiation in cephalic neural crest cells (23).

Larsen syndrome

Recognized as an entity in 1950 by Larsen et al (25), the syndrome consists of flattened facies, multiple congenital joint dislocations, clubfoot deformities, and, frequently, cleft palate. Earlier cases date back to Drehmann (10) and many others (21,33,34,49). Among the Buang of New Guinea, there are examples (31). At least 150 patients have been reported to date. The frequency has been estimated to be approximately 1 per 100,000 births (2).

The syndrome is heterogeneous. Examples of Larsen syndrome have been reported in affected sibs with normal parents (3,5,38,44,49,59), but many more have been found in two or more generations (12,14,26, 34,40,46,47,51,56,60,62). Differentiation of the autosomal recessive form from the autosomal dominant form is not possible in the individual case. In general, among "recessive cases," increased parental consanguinity has not been found (13) with rare exception (23), although a recessive form has been seen with high frequency (38 cases) in the island of La Réunion in the Indian Ocean (4,27). Fourteen of the 38 patients died in childhood from dislocation of the cervical spine, tracheomalacia, congenital heart disease, or severe respiratory infections. All were short (−5 SD). Larsen syndrome has been shown not to be a collagen disorder (4). Petrella et al (42) reported what appeared to be sibs with the recessive form. One of them subsequently had an affected child, thus raising the possibility of gonadal mosaicism. Strisciuglio et al (55) suggested that the recessive form is more often associated with cardiac and respiratory complications than the dominant form, but this has never been confirmed. Short stature was also emphasized by Topley et al (59) in the recessive form. Le Marec et al (29) opined that cervical malformations were more common in the recessive form.

The gene for the dominant form has been mapped to 3p21.1–p14.1 (63).

Facies. The facies is typically flattened and there is depressed nasal bridge. The eyes appear widely spaced. Frontal bossing may be marked (Figs. 21–15 and 21–16A).

Skeletal system. Bony alterations include bilateral anterior dislocation of the radial head (70%), bilateral anterior dislocation of the tibia on the femur (80%), hip dislocation (80%), and talipes equinovarus or equinovalgus (85%). The patella is often dislocated laterally. Joint dislocations become less frequent with age. Adult height is reduced, the patient usually being less than 152 cm tall (Fig. 21–16). The fingers are long and cylindric (pseudoclubbing) with extra creases in approximately 75% (Fig. 21–17). The thumb is spatulate. Mild thoracolumbar scoliosis is absent at birth but becomes evident during infancy (11,12,21,24,26,28,34,45,52,60). Pectus excavatum is present in 10% (9).

Radiographic changes include dislocations, as previously noted. The distal phalanges are abbreviated. The metacarpals and metatarsals are relatively shortened. Bone age is retarded. When the carpal bones appear, they are irregular. There are from one to four supernumerary carpal bones in 75% (Fig. 21–18A). Abnormal segmentation and/or hypoplasia of

cervical and thoracic vertebrae are common (2,12,21,24–26,29,35,36,40, 52,56,58,60). This may be associated with marked cervical kyphosis (19,58). In some cases, cervical vertebral instability has led to quadriplegia or death (35,39). The vertebral bodies may be flattened (24,26,56). A juxtacalcaneal accessory bone is present within the first four years of life in approximately 40% (25,48,56). It coalesces with the calcaneus by 5–8 years of age forming a bifid calcaneus that is evident in lateral view (Fig. 21–18B). Additional centers of ossification may be seen at the elbow (13,19,39,49,54). The proximal tibial epiphysis is often cone-shaped during development. Approximately 60% of the La Réunion group exhibited proximal radioulnar synostosis (27).

Cardiovascular anomalies. ASD and VSD as well as aortic dilatation and valvular anomalies are seen in approximately 10% (9,22,33, 45,55,57).

Central nervous system. Mental retardation has been noted in approximately 15% (9,47). Sensorineural, mixed, and conduction hearing loss has been described in 20% (16,44,50,62), the last because of deformity or dislocation of the malleus, incus, or stapes footplate (18,20,30).

Oral manifestations. Oral changes are essentially limited to cleft palate, which occurs in approximately 30% (9,54). This may be limited to the soft palate or uvula. Some patients have laryngotracheomalacia (11,26,46). Collapse of the flabby laryngeal cartilages may lead to death. Others may have laryngeal stenosis (8,17,58). Cephalometric study has been reported (61).

Differential diagnosis. *Otopalatodigital syndrome* is most often mistaken for Larsen syndrome. In contrast, these patients exhibit a pugilistic facies, hearing loss, paddle-shaped metatarsal bones, no juxtacalcaneal bone, and no supernumerary carpal bones. Differential diagnosis also includes arthrogryposis, *fetal akinesia sequence, monosomy 21, Ehlers-Danlos syndrome, types VII and XI, COFS syndrome, cleft palate, short stature, depressed nasal bridge, and sensorineural hearing loss* (19), *spondyloepimetaphyseal dysplasia, Desbuquois syndrome, SPONASTRIME dysplasia,* and lethal Larsen-like syndrome (6,7,37,64).

Multiple congenital dislocations may occur as an isolated finding (15).

Schröder (48) reported a syndrome in five sibs. There were bizarre pinnae, bilateral luxation of the radius, radiohumeral ankylosis, dislocation of hips, shoulders, and knees, genua valga, and camptodactyly. Matsoukas et al (32) described an autosomal dominantly inherited syndrome of joint dislocations (hips, elbows, wrist), short stature, mental retardation (IQ-65), and various ocular anomalies (myopia, microphthalmia, corneal sclerosis).

Pavone (41) described a patient with multiple dislocations, unusual facies, and decreased production of procollagen.

Fig. 21–17. *Larsen syndrome*. Note extra flexion creases of fingers, spatulate thumb.

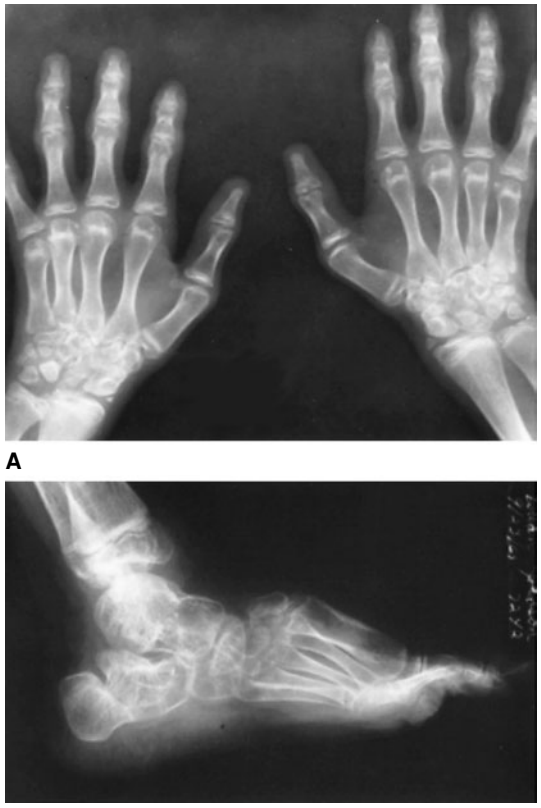

Fig. 21–18. *Larsen syndrome*. (A) The carpal bones, late to appear, are supernumerary. (B) Juxtacalcaneal bone fuses with calcaneus just prior to puberty. Also note unusual relationship of metatarsals to tarsal bones.

Anderson et al (1) reported sibs with what we suspect is SEM dysplasia.

Phoake et al (43) noted a patient with multiple joint dislocations, metaphyseal dysplasia, deficient calcification of the skull vault, growth retardation, natal tooth, lymphedema, and unusual facies. The child died during the neonatal period.

Steel et al (53) reported a syndrome of dislocated hips and radial heads, carpal coalition, scoliosis, cavus feet, and short stature. Three of 23 Puerto Rican patients had an affected sib but inheritance was not clearly recessive.

Meckel syndrome (Gruber syndrome, dysencephalia splanchnocystica)

Meckel (25), in 1882, delineated a lethal syndrome of microcephaly, encephalocele, microphthalmia, congenital heart defects, postaxial polydactyly, polycystic kidneys, and clefts of the lip and/or palate. The condition has been forgotten, and periodically rediscovered. We refer the reader to several comprehensive historical reviews of cases published prior to 1970 (8,15,24,26,28,31).

Inheritance is autosomal recessive (15,21,42). Parental consanguinity has been noted in approximately 30% of cases. The gene has been mapped to 17q21–q24 (32) in Finnish families. A second gene has been identified at 11q13 in Middle Eastern and African families (40,56). There may be a third gene responsible (33). Nelson et al (29) reported postaxial polydactyly as an expression of the carrier state, but we are dubious. Estimates of frequency in various parts of the world range between 1 in 1500 to 1 in 50,000 births (21,42,44,52,55). In Finland, birth prevalence is 1 in 9000 births (18a). Perhaps 300 cases have been reported to date.

Breech presentation occurs in approximately half of the cases. Oligohydramnios has been noted in over 60%. The thorax is short and bell-shaped and the abdomen bulges. The syndrome is lethal, death usually occurring at birth or in the first few hours of life. The placenta is grossly enlarged in approximately 25%.

It should be emphasized that there is extreme variability from case to case and from affected sib to affected sib (6,10). There appears to be no obligatory feature of the syndrome (19).

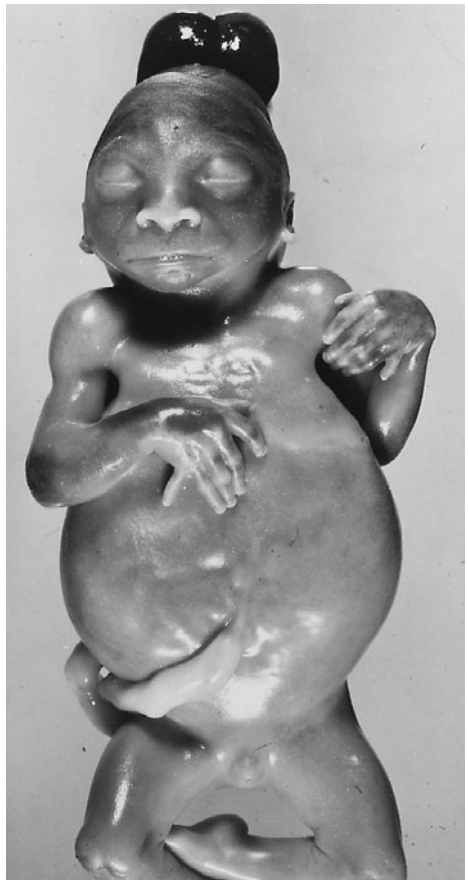
Craniofacial findings. Microcephaly, sloping forehead, sunken eyes, occasional Potter facies, large low-set dysmorphic pinnae, macrostomia, clefting, and micrognathia present a striking appearance (Figs. 21–19 and 21–20).

Ocular findings. Various eye anomalies, seen in approximately 30%, include sclerocornea, microcornea, partial aniridia, cataract, anophthalmia, microphthalmia, iris coloboma, retinal dysplasia, and hypoplasia of optic nerves (22,26).

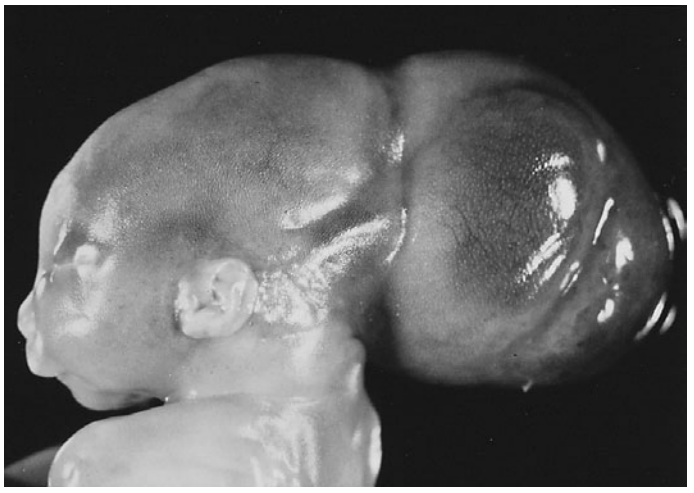
Central nervous system. Microcephaly/anencephaly (50%–65%), absent olfactory bulbs (80%), and double occipital encephalocele (65%–90%) are striking (Figs. 21–19 and 21–20) (50). The larger encephalocele occurs rather high in the occipital bone. The smaller is low in the basal occipital bone resulting in a cleft in the occipital foramen magnum and extending onto the first vertebral arches (cerebellar encephalocele) (34). It is covered by a focal depression of skin. It has been estimated that Meckel syndrome may account for 5% of neural tube defects. Microgyria or polygyria, heterotopias, fusion of frontal lobes, agenesis or hypoplasia of the optic tracts, olfactory lobes, corpus callosum and septum pellucidum, cerebellum and brain stem, Dandy-Walker malformation, neurorosettes, and internal hydrocephalus have been found in 15%–20% (1,14,35,51,53). Cervical rachischisis occurs in approximately 5% (18,27). Craniosynostosis is a rare finding. Hydrocephalus is seen in 10%–20% (50).

Kidney, liver, pancreas, and lungs. Huge cystic and dysplastic kidneys (10–20 times larger than normal) are a constant feature (38). The spherical cysts, ranging in size from 1 to 10 mm, are smallest in the subcapsular area and largest near the renal pelvis. Glomeruli are grossly deficient in numbers, interstitial fibrosis is marked, and the finding of cartilage is frequent (4). The renal pelves, calices, ureters, and urinary bladder are often hypoplastic (2,3,7,12,20,27,37,39,41) (Fig. 21–21). Urethral atresia and/or obstructive uropathy have been described in a few patients (13,41,54).

Fig. 21–19. *Meckel syndrome*. Male fetus at 23 weeks gestation. Note occipital encephalocele, microcephaly, polydactyly, enlarged abdomen due to polycystic kidneys. (From NC Nevin et al, Clin Genet 15:1, 1979.)



A



B

Fig. 21–21. *Meckel syndrome*. (A) Huge multicystic dysplastic kidneys. Note tiny ureters and hypoplastic bladder. (B) Multicystic dysplastic kidney. (A from P Moerman et al, Hum Genet 62:240, 1982. B from U Friedrich et al, Clin Genet 15:278, 1979.)

The liver exhibits macroscopic cysts in 15% with fibrotic changes in the portal areas due to hamartomatous proliferation and dilatation of bile ducts in nearly all patients (4). The pancreas is fibrotic and the ducts dilated in 30% (3,7,20,37,38). The lungs are uniformly hypoplastic.

Musculoskeletal findings. The most common skeletal alteration is bilateral postaxial polydactyly (55%–80%) (18). Rarely, there is preaxial polydactyly (23,53,54). The hands are more often involved than the feet. There may be six or more digits (Figs. 21–19 and 21–22). There are usually six metacarpal bones or, if five, the middle one is often bifurcated. Talipes equinovarus, probably due to oligohydramnios, has been noted in 30%–50%. The tibiae may be short and angulated and the upper extremities are shortened in approximately 15% (7,15,17,23,27,36,41,45,47). The cranial base is malformed, as noted earlier (18). The lumbar vertebral bodies may also be cleft (18).

Genital anomalies. Hypoplastic penis and cryptorchidism in males are almost constant features and may lead to erroneous gender assignment (38) (Fig. 21–23). Males often have Müllerian duct remnants (20%) and epididymal cysts (40%) (37). Septate vagina and hypoplastic or bicornuate uterus in females have been observed in 20%–25% (3,7,27,30,41,46). On occasion, ambiguous external genitalia have been noted (31).

Other findings. Malrotation of the intestines, situs inversus, and a wide array of congenital/cardiac anomalies (VSD, ASD, common atrium, absent mitral valve, preductal coarctation, persistence of left superior vena cava) have been found in 30% (7,20,27,41).

Oral manifestations. Cleft lip (20%) and/or, more often, cleft palate (45%) and various malformations of the tongue (ankyloglossia, bifid tongue, anterior marginal hamartomas) have been noted (8,27,39). The larynx is frequently hypoplastic (41).

Differential diagnosis. Marked variability makes for difficulty in diagnosis. Meckel syndrome may be confused with *trisomy 13* and occasionally severe *Smith-Lemli-Opitz syndrome, C syndrome,* and *hydrolethalus syndrome* (19). Although not obligatory, the triad of occipital encephalocele, postaxial polydactyly, and polycystic kidneys is persuasive

Fig. 21–22. *Meckel syndrome*. Polydactyly, syndactyly, abbreviation of hallux, talipes. [From JM Opitz and JJ Howe, Birth Defects 5(2):167, 1969.]

in making a diagnosis of Meckel syndrome. Seller (46) indicated that the triad is present in 60%–70% of the cases. In approximately 15%, there is binary combination of either encephalocele or polydactyly with polycystic kidneys. Among the remainder, there is only a single component present. In studies of affected sibs, approximately 50% have identical anomalies whereas the other half do not. The *short rib-polydactyly syndromes* (Majewski type, Saldino-Noonan type, Naumoff type, etc.) can easily be separated from Meckel syndrome.

The so-called cerebro-reno-digital (Meckel-like) syndrome with Dandy-Walker malformation of Genuardi et al (11), we view as an example of Meckel syndrome. A number of cases with Dandy-Walker malformation have been considered to be other syndromes. These have been elegantly reviewed by Al-Gazali et al (1). We cannot accept these as representing other than the variable expression of Meckel syndrome.

Laboratory aids. Chromosome studies will exclude *trisomy 13*. Prenatal diagnosis may be made by ultrasonography (oligohydramnios, microcephaly, anencephaly, occipital encephalocele, internal hydrocephalus, large kidneys, empty bladder, reduced femur length). Ultrasonography should be employed from the 11th to 12th weeks of pregnancy serially (10,34,48). Amniotic fluid α-fetoprotein levels are elevated in approximately 70% (open CNS lesions, cystic kidneys) at around week 17–18 of pregnancy. Various other backup tests may be employed: study of amniotic fluid for acetylcholinesterase levels, elevated pregnancy specific β_1-glycoprotein, positive β-trace protein, human chorionic gonadotropin levels, and amniotic cell culture (5,9,16,30, 39,45).

Fig. 21–23. *Meckel symdrome*. Hypoplastic penis, hypospadias. [From JM Opitz and JJ Howe, Birth Defects 5(2):167, 1969.]

Hydrolethalus syndrome

Salonen et al (15), in 1981, reported 28 patients from 18 families in Finland with a lethal syndrome characterized by polyhydramnios, variable degrees of hydrocephalus, crossed polydactyly, talipes, congenital heart anomalies (most frequently VSD and common arteriovenous canal), and severe micrognathia. Salonen and Herva (14) estimated a frequency of approximately 1 per 20,000 births. Approximately 70 patients have been described to date (2,8,19). A mild example was reported (3). Nearly all have been aborted or stillborn.

Preterm delivery is common. Polyhydramnios is present in over 90% (14).

Inheritance is clearly autosomal recessive (2,8). The gene maps to 11q23–q25 (20). To date, almost all certain reports emanate from Finland (13). It is possible that the patient described by Fitch and Pinsky (5) may have the disorder, but one cannot exclude *Meckel syndrome* or, more likely *Smith-Lemli-Opitz syndrome*. The sibs reported by Adetoro et al (1) appear to have some new form of short rib-polydactyly syndrome. We believe that the child reported by Bachman et al (4) has *pseudotrisomy 13 syndrome*.

Fig. 21–24. *Hydrolethalus syndrome*. Small wide set eyes, malformed nose, midline cleft of upper lip, micrognathia. (From R Salonen, The Meckel and Hydrolethalus Syndromes. Diagnostic, Genetic, and Epidemiologic Studies. Academic Dissertation, Med. Fac. of Helsinki, 1986.)

The face is rather striking. The nasal root is wide. The neck is broad. The eyes are deeply set (95%) and occasionally may be microphthalmic. The tongue is occasionally malformed, small, or absent. Approximately 40% have cleft palate. An equal number have smaller clefts of the mid-upper and lower lip. Cleft lip-palate has been noted in 50% (2,3,7). Micrognathia is marked in nearly all examples (Fig. 21–24).

In addition to hydrocephalus (85%), various other brain abnormalities found in approximately 25% include widely separated hemispheres and agenesis of the corpus callosum and septum pellucidum and, occasionally, the pituitary gland (Fig. 21–25) (10). Dandy-Walker anomaly has been described (11,12,18,19).

The larynx, trachea, and/or bronchi are stenotic or, less often, dilated in 60%. There is reduced lobation of the lungs in 60%. Various other abnormalities include incomplete rotation of the gut (25%), accessory spleens (15%), cryptorchidism (75%), and bicornuate or duplicated uterus (50%). Congenital heart anomalies are seen in 50%.

Radiographically, there is obvious hydrocephalus with a midline defect in the occipital bone posterior to the foramen magnum. Non-fusion of one of the dorsal arches of the first few cervical vertebrae has been noted. This "keyhole" defect seen in 75% in the base of the skull has been termed occipitoschisis (9,16,17). Approximately 20% have short limbs. Among those with polydactyly (80%), the extra digits are postaxial in the hands (50%) and preaxial in the feet, a characteristic hallux duplex (40%). Rarely, there are postaxial toes. The upper limbs are short in approximately 15%. The tibiae exhibit proximal hypoplasia. The feet are clubbed in 50%. Prenatal diagnosis by ultrasound is possible (6).

In hydrolethalus syndrome, in contrast to the *Meckel syndrome*, one finds hydrocephaly rather than microcephaly and/or occipital encephalocele. The polydactyly is crossed. The kidneys and liver are normal, the

Fig. 21–25. *Hydrolethalus syndrome*. (A,B). Hydrocephalus, small mandible, short lower limbs, and polydactyly. (From R Salonen, The Meckel and Hydrolethalus Syndromes. Diagnostic, Genetic, and Epidemiologic Studies. Academic Dissertation, Med. Fac. of Helsinki, 1986.)

tibiae exhibit proximal hypoplasia, and there is polyhydramnios rather than oligohydramnios. Macrocephaly, hallucal duplication, and postaxial polydactyly of the hands are seen in the *acrocallosal syndrome* but hydrocephalus does not occur. Hydrocephalus, cerebellar hypoplasia, cardiac and genital anomalies, cleft palate, and polydactyly are seen in severe *Smith-Lemli-Opitz syndrome*, and hydrocephalus and agenesis of midline structures are found in *Walker-Warburg syndrome*. Other disorders such as *pseudotrisomy 13 syndrome* and *oral-facial- digital syndromes* IV and VI *must be excluded*. Excellent discussions of differential diagnosis are those of Krassikoff et al (10) and Morava et al (11).

Branchio-oculo-facial (BOF) syndrome

A syndrome of cervical aplasia cutis congenita, cervical thymus, pseudocleft of the upper lip or cleft lip-palate, congenital nasolacrimal duct obstruction, and conductive hearing loss has been reported by a number of authors (1–9,11–23). The earliest example appears to be that of Harrison (9) in 1957. Fujimoto et al (4), in 1987, coined the term

branchio-oculo-facial syndrome. The reader is referred to a detailed review of 43 cases of the syndrome by Lin et al (14) in 1995.

Autosomal dominant inheritance has been demonstrated (2,7,11). The parents of two sibs were normal in two reports, suggesting gonadal mosaicism (6, C. Oley, personal communication). The gene does not map to the branchio-oto-renal area (14a).

Prenatal growth retardation has been noted in 45% whereas postnatal growth is slowed in 40% (14,16).

Craniofacial findings. The scalp hair begins to gray in late adolescence in 25% although it may begin as early as the age of ten (7), and there may be subcutaneous scalp cysts in 10% (7). A white forelock may be evident (17). The lack of hair pigment has been demonstrated microscopically (18). The nose may be broad and misshapen with a wide bridge and an indented or flattened nasal tip (7,20). The philtrum is often short (6,8,11,16) and prominent with thick fibrous vertical ridges producing a pseudocleft seen in 40%. Another 40% have cleft lip and/or palate (2,3,5,13,17–22). Paramedian upper lip pits, seen in 20%, correspond to the fusion sites of the median nasal and maxillary prominences (2,7) (Fig. 21–26). Approximately 15% have small sites of aplasia of the skin of the scalp above the ear (9,13,14,16,17,22). The mastoid bones may be hypoplastic (16) (Fig. 21–26).

Ocular system. Various eye anomalies have included unilateral microphthalmia (30%), anophthalmia (10%), myopia (30%), cataracts (25%), strabismus (30%), ptosis (30%), colobomas of iris, choroid, retina, and optic nerve (45%), orbital cysts (6), and upslanting palpebral fissures (50%). Nasolacrimal duct, seen in approximately 75%, results in dacryocystitis, which, in turn, eventuates in thickened lower eyelids (22).

Auditory system. The pinnae are almost always posteriorly angulated with a hypoplastic helix, prominent anthelix, and upturned lobules (5,7–9,11,16). Microtia is noted in 20% (16). Pre- and post-auricular and/or lobular pits have been documented in 25% (7,12,14,21). Conductive hearing loss of mild to moderate degree has been reported in 40% (7–9,11,16).

Neck. Bilateral cervical aplasia cutis congenita with thinned epidermis and underlying cervical thymus extending along the sternocleidomastoid muscle is a constant feature (Fig. 21–26A–C and Fig. 26–27A).

Skin. Small sites of aplasia cutis congenita may be seen over the sternum (14,16).

Microscopically, a ciliated epithelium representing the pharyngeal epithelium of the third pouch is located between the thymus and the skin (1,2,4,13,21,22) (Fig. 21–27B,C).

Extremities. Fifth finger clinodactyly has been seen in 20%.

Central nervous system. Developmental delay or mental retardation has been noted in 40% with microcephaly in 10%. Agenesis of the cerebellar vermis has been observed (15).

Renal system. Unilateral renal agenesis or renal multicystic dysplasia is found in 35% (12,13,21,22).

Diagnosis. Microscopic differential diagnosis of the neck lesions would include thymic cyst, ectopic hamartomatous thymoma, and benign lymphoepithelial tumor of the skin (2,5). Hing et al (10) reported an infant with holoprosencephaly and branchial cleft fistulae.

Femoral hypoplasia-unusual facies syndrome (femoral facial syndrome)

Daentl et al (7), in 1975, defined the femoral hypoplasia-unusual facies syndrome. However, a number of other authors reported earlier examples (1,2,10,20,26). Approximately 35% of those with the syndrome are examples of *diabetic embryopathy*. (15,19,27,28), thus making the syndrome analogous to caudal regression (sacral agenesis) with which one can also find cleft lip and/or cleft palate (4,10). However, 65% of the cases result from other causes. Although the condition has been reported in two generations (21), its inheritance pattern, if any, would more likely be multifactorial than autosomal dominant (22). We cannot accept the example of Robinow et al (28). At least 60 examples have been documented.

The facies is characterized by upward slanting palpebral fissures (35%), short pointed nose with hypoplastic alae (65%), mildly dysmorphic pinnae (45%), long flat philtrum, thin vermilion of upper lip (65%), and micrognathia (80%) (6,8,9,11,14,17,30,34). The pinnae may be deformed or low-set and overfolded (3,12,13,27). The ear canals may be narrowed . Cleft palate is common (80%); cleft lip-palate is rare (18,33) (Fig. 21–28).

Stature is markedly reduced due to abbreviation of the lower extremities (Figs. 21–29 and 21–30A). Arrest of femoral growth has been noted on ultrasound between 24 and 32 weeks of gestation with normal subsequent growth (31). The upper extremities and shoulder girdle

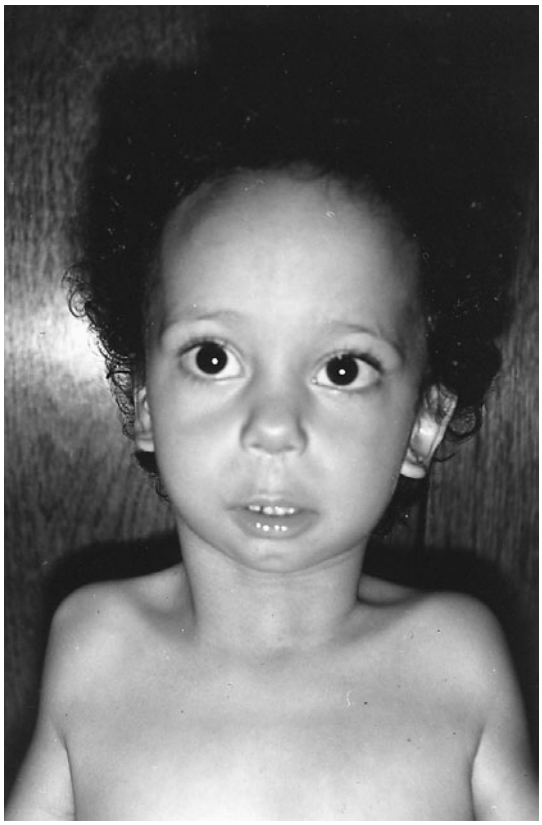

Fig. 21–28. *Femoral hypoplasia-unusual facies syndrome*. Note shortened nose, long philtrum, and micrognathia. (From RB Goldberg et al, Cleft Palate J 15:386, 1978.)

are affected in 75%. The humerus may be mildly shortened and there is limited motion of the shoulders and elbows. Sprengel deformity is rather frequent (1,12). Absent fibula has been reported (30). Syndactyly of toes and broad or bifid halluces have been noted as well as polydactyly (3,12,13,27). Inguinal hernia is common. Cardiac anomalies, documented in 20%, include VSD, pulmonary stenosis, and persistent truncus arteriosus.

Genitourinary anomalies have been noted in 60% (absent or hypoplastic labia, cryptorchidism, hypoplastic penis, macrophallus, polycystic kidneys, absent kidney, abnormal collecting system) (5,7,13,15,16,18,30) (Fig. 21–30A).

Radiographic changes are usually asymmetric. The femora, fibulae, and acetabulae range from being hypoplastic to aplastic (Fig. 21–30B). Vertebral anomalies, seen in 35%, include scoliosis, hemivertebrae, anterior synostosis of lumbar vertebrae, spina bifida occulta, and malsegmentation of the sacrum. The ribs may taper, and some may be fused or missing. Pelvic anomalies include small iliac wings and hypoplastic or absent acetabuli. Derangement of elbow joints (radiohumeral synostosis: radioulnar synostosis) and talipes are frequent. The great toes may be bifid and, rarely, there is polydactyly or agenesis of a toe (3,12,13,27,30). It should be noted that preaxial polydactyly is increased in the offspring of diabetic mothers (24).

Long bone histology has shown disorganization of the growth plate with vacuolization and binucleation of chondrocytes (32).

Fryns syndrome (cleft palate, diaphragmatic hernia, coarse facies, and acral aplasia)

Fryns (11), in 1979, described an essentially lethal syndrome of diaphragmatic hernia, coarse facies, acral hypoplasia, and cleft palate. The infant reported by Fitch et al (10) in 1978 appears to have had the disorder. Inheritance is clearly autosomal recessive (1,2,20,23,24,30,31). Duplication of 1q24–q31.2 has been described, but its significance has yet to be determined (5). Aymé et al (1) estimated the prevalence as 0.7/10,000 births. It is seen in 4%–10% of infants with congenital diaphragmatic hernia (9). Approximately 50 cases have been reported (1–5,7,10–18,20–27, 30,37). The syndrome has been noted in MZ twins with variable expression (34a).

Polyhydramnios developing in the second trimester has been present in approximately 60% of the cases (1,2). Death often occurs at approximately 30 weeks gestation. Birth length, weight, and OFC tend to be normal. Of the 15% that survive, there are less diaphragmatic hernia, better lung development, and absence of complex heart anomalies (13,15). Neurologic impairment is, however, common (27,34).

Craniofacial findings. The face is coarse and hirsute with narrow palpebral fissures, broad flat nasal bridge, large upturned nose, large dysplastic pinnae with hypoplastic attached lobes, short upper lip, macrostomia, microretrognathia, and short broad neck (12) (Fig. 21–31). Dandy-Walker malformation and agenesis of the corpus callosum have been noted in 70% (26). Arhinencephaly and agenesis of olfactory bulbs have been described (1). The corneae are cloudy in approximately 15%, and retinal dysplasia has been noted (1). Scalp defects have been reported (14).

Chest and abdomen. Diaphragmatic defects are found in 90% (1,35,36). They are often large, allowing herniation of the abdominal contents into the thoracic cavity. They are usually unilateral (85%) and left-sided (70%). Fryns et al (11) suggested that the diaphragmatic hernia was secondary to the primary defect in lung development. Rarely, there is no diaphragmatic hernia (2,7,17,20,31,36). The thorax is narrow with hypoplastic widely spaced nipples in approximately 50% (26). Digestive tract anomalies, secondary to the diaphragmatic defect, are found in 60%. They include intestinal malrotation, anomalous attachment of the gut, omphalocele, duodenal atresia, and esophageal atresia. The lungs are usually hypoplastic and abnormally lobulated. The anus may be imperforate, atretic, or especially anteriorly displaced. Agangliosis of the bowel and bladder has been found (2).

Genitourinary findings. Various renal abnormalities (renal agenesis, cystic kidney, hydronephrosis, ureteral cysts, misplaced megaureters, duplicate and atretic ureters) have been reported in 55%. Genital anomalies, noted in 60%, consist of bicornuate uterus, hypoplastic upper vagina, hypoplastic ovaries, cryptorchidism, and saddle scrotum (1,2,11,16,20,23,24,31).

Cardiovascular system. Assorted cardiac defects (VSD, ASD, overriding aorta) were noted in 85% (26).

Musculoskeletal system. Distal limb hypoplasia (brachytelephalangy) with nail deficiency is found in 75%. The terminal digits may be broad. Camptodactyly of the fifth finger is frequent. Other fingers may be axially deviated. Other skeletal changes are minimal, consisting of broad medial ends of the clavicles (2), delayed ossification of basiocciput and cervical vertebrae (18).

Oral findings. Isolated cleft palate has been present in 30% (1,2,24,31), and cleft lip with cleft palate has been found in 25% (1–3, 20,23,32). Macrostomia is a constant feature. Natal teeth have been described (21).

Differential diagnosis. Prenatal diagnosis has been made at 19–20 weeks by ultrasonographic demonstration of diaphragmatic hernia and elevated alphafetoprotein levels (1,2,4,13,15,21,24,25).

Diaphragmatic hernia is ordinarily considered to be a multifactorial trait with a 3:1 male predilection occurring in 1 in 2000 births. In a study of associations among 143 cases of diaphragmatic hernia, David and Illingworth (8) noted two patients with cleft palate and micrognathia (Robin sequence) and three with cleft lip in association with diaphragmatic hernia. Crane (6) reported a different, probably X-linked lethal syndrome of cleft lip-palate, polyhydramnios, diaphragmatic hernia, and various urogenital anomalies. Lowry and MacLean (19) described a female child with cleft palate, proptosis of eyeballs, divergent squint, glaucoma, multiple congenital heart defects, mental retardation, diaphragmatic eventration, and craniosynostosis (*Lowry-MacLean syndrome*). Saal et al (29) reported monozygotic twins with cleft palate, agenesis of hemidiaphragm, and ambiguous genitalia but no distal limb anomalies.

Also to be excluded are *trisomy 18* and *Zellweger syndrome*. There appears to be considerable overlap with *Rüdiger syndrome* and *Pallister-Killian syndrome* (22,28,33). Diaphragmatic defects are also seen in *de Lange syndrome*.

Roberts-SC phocomelia syndrome

The syndrome of cleft lip-palate and tetraphocomelia was discovered independently by a number of authors. The first classic description was that by Roberts (39) in 1919. However, there were earlier and later scattered reports until 1966 (6,12,14,22,24,33,43,46,48,52,54). The condition was largely forgotten until Appelt et al (1), in 1966, rediscovered it. Meanwhile, Herrmann et al (17), in 1969, reported the pseudothalidomide or SC syndrome, believing it to be a separate entity. Several authors (8,13,16,32,41,56) provided convincing evidence that the two disorders represent extreme ends of a phenotypic spectrum of a single syndrome. Very mild expression has been documented (32,34,36,44). A single complementation group has been demonstrated regardless of severity (32a).

Inheritance is autosomal recessive. Parental consanguinity and occurrence in sibs have been reported in approximately 50% of the cases (50). It has been described in identical twins (9). Over 100 cases have been reported (50). The reader is referred to the comprehensive review of Van den Berg and Francke (50) for analysis of each case and proposal of a rating system.

Prenatal growth retardation is a constant feature—full-term infants weighing less than the 3rd centile. Postnatal growth retardation can range from mild to very severe (20,32,40,41,47). Those with most severe growth retardation have the most severe limb reduction and craniofacial malformations. The minority who reach adulthood have been mildly growth retarded. Life expectancy is often short. At least 20% are stillborn.

Facies. Approximately 80% have microcephaly. Among those that die within the first month of life, there is hypertelorism (90%) and exophthalmos because of shallow orbits (70%). The nasal bridge is wide (80%) and the nostrils are small (30%) (Figs. 21–32 and 21–33). The pinnae are low-set, posteriorly angulated, dysmorphic, and lobeless (Fig. 21–34).

Facial clefts are present in 80%. In a few severe examples, the clefts are combined with encephalocele (7,8,32,51). Most are bilateral cleft lip-palate whereas isolated cleft palate occurs in only 10% (9,12, 13,17,21,35,37) (Figs. 21–32A).

In those that survive early infancy, the scalp hair is often sparse and silvery blond (13,15,28,37), but it may be dark initially (2). The nasal bridge is narrow. Hypoplastic alar cartilages producing thin nares and a pointed tip are more often found in milder cases.

Also, in milder cases, there are superficial capillary hemangiomas on the lip, nose, forehead, and ears in 85% (2,4,8,15,17,19,25,29,55,56). Cataracts and corneal opacities resulting in blindness have been observed more in those that survive infancy, but can be found in both groups (8,25,56).

Fig. 21–32. *Roberts-pseudothalidomide syndrome*. (A) Ocular hypertelorism, reduction in digits, clitoral enlargement, bizarre pinnae. (B) Thin, pinched nose, abnormal pinnae, convergent strabismus, symmetric reduction of arms and legs with decreased number of fingers. [A from J Appelt, Padiatr Padol 2:119, 1966. B from J Herrmann et al, Birth Defects 5(3):81, 1969.]

A B

Fig. 21–33. *Roberts-pseudothalidomide syndrome*. (A,B) Compare with other cases. (From BD Hall and MH Greenberg, Am J Dis Child 123:602, 1972.)

Musculoskeletal system. The skull tends to be microbrachycephalic. There are asymmetric reduction anomalies of variable degree in the tubular bones of all extremities (90%), ranging from complete absence of arms and legs with rudimentary digits to mild reduction (Figs. 21–32 and 21–33). Only rarely is there symmetry. In general, the humerus is proportionately shorter than the femur. The radius is shorter than the ulna. The upper extremities are more often involved than the lower extremities. In several cases, the lower limbs are not affected (4,17,19,29,45). The hands may be radially clubbed and single palmar creases are common. The length and number of digits is reduced in 80%, more frequently in the hands (75%) (thumb, fifth finger) than in the feet (25%). The index fingers may be clinodactylous. Rarely polydactyly of toes (8) has been reported. Various joints, especially the knees, ankles, wrists, and elbows, exhibit flexion contractures in 50% (Fig. 21–33). Talipes and soft tissue syndactyly (40%) are common. The bones of the arm or leg are fused in approximately 10%. Tetra-amelia has been reported in association with splenogonadal fusion (5).

Radiographically, Wormian bones may be seen in the lambdoidal sutures. There are more severe skeletal anomalies among those that die in early infancy. Absence or severe hypoplasia of the radius, ulna, tibia, fibula, or femur is seen. The thumb phalanges and first and fifth metacarpals are hypoplastic or missing. The carpal bones are irregular and reduced in number. Humeroradial or humeroulnar synostosis, talipes, calcaneovalgus, and absence or posterior displacement and/or bilateral deformity of the fibulae are commonly reported (4,9,19) (Fig. 21–35). Less frequently, shortened or curved humerus and tibia, fusion of the fourth and fifth metacarpals, and femorotibial synostosis have been described in approximately 10% (2,17,29,38). The ribs are occasionally reduced in number (9).

Central nervous system. Among those that survive, approximately 50% are mentally retarded. Miscellaneous findings include hydrocephalus (8), calcification of basal ganglia (20), seizures (17), encephalocele (8,31,32,51), absent olfactory lobes (31), and cranial nerve paralysis (34).

Urogenital findings. Various findings include enlarged penis (4,8, 12,31,39,52) or clitoris (1,31,39,43,55), ambiguous genitalia (31), hypospadias (53), enlarged or cleft labia minora (1), septate vagina (8), and bicornuate uterus (8). Cryptorchidism is a frequent feature in males.

Polycystic kidney, hydronephrosis, ureteral stenosis, and horseshoe kidney have been described (8,31,53).

Cardiac anomalies. Miscellaneous anomalies include VSD (21, 28,53), ASD (6), and PDA (8,53,55).

Miscellaneous findings. Thrombocytopenia has been reported in a few cases (4,53). Melanoma (34) and splenogonadal fusion (5) have also been noted.

Differential diagnosis. Reduction anomalies occur in a number of disorders: *thalidomide embryopathy*, DK-phocomelia (encephalocele and urogenital anomalies), Holt-Oram syndrome, thrombocyte aplasia radius (TAR) syndrome, VACTERL association, Fanconi anemia, *Baller-Gerold syndrome, trisomy 18, Nager syndrome*, etc. (37). Urban et al (49) pointed out the overlap with TAR syndrome. A case having some similarities was reported by Ladda et al (26), which we suspect is a mild form of Roberts-pseudothalidomide syndrome. This is discussed further under *Herrmann syndrome*. An X-linked lethal disorder (tetra-amelia, hydrocephalus, facial clefts, eye anomalies) has some overlap (57). Schinzel phocomelia is a recessive syndrome characterized by phocomelia, diaphragmatic hernia, agenesis of uterus and vagina, and hypoplasia of sacrum and pelvic bones (42).

Laboratory aids. Approximately 80% of the patients exhibit a striking chromosomal change involving the heterochromatic C-banding regions of most chromosomes (2,8,9,11,20,28,30,31,38,49,55,56) regardless of the degree of severity. The heterochromatic regions around the centromeres, especially of chromosome 1,9, and 16, have a puffed appearance. The heterochromatin of the long arms of the Y chromosome and the short arms of acrocentric chromosomes are often widely separated in metaphase spreads (30). Chromatid repulsion or, more accurately, constitutive heterochromatic repulsion has been demonstrated (32), the chromosomes looking like railroad tracks because of absence of centromeric constriction (Fig. 21–36). Fibroblasts exhibit unusual growth characteristics. Their mitotic processes are also altered (48). Prenatal diagnosis has been accomplished by ultrasound and by heterochromatic repulsion (10,40,41,45,51). Heterozygotes may occasionally show heterochromatic repulsion (32,35).

Van der Woude syndrome (cleft lip-palate and paramedian sinuses of the lower lip)

The first report of congenital sinuses of the lower lip in combination with cleft lip and/or cleft palate appears to be that of Demarquay in 1845 (5). It was reported independently by Murray in 1860 (16). Over 900 cases have been published (3). The syndrome occurs in roughly 2% of patients with facial clefts (3,22,29) or roughly 1:35,000 to 1:100,000 in the white population (2,4,22). Numerous authors (4,8,10,13,19,39,42) have carried out extensive reviews and analyses of published cases. The most complete survey is that of Burdick et al (3).

The syndrome has autosomal dominant inheritance with variable expressivity. Penetrance ranges between 0.89 and 0.99 (2,3,11,33). The estimate of 80% penetrance (4) is too low, probably because of failure to include submucous cleft palate in the calculations. Between 30% and 50% represent new mutations (29). The mutation rate has been calculated to be 1.8×10^{-5} (3). After a deletion was demonstrated at 1q32–q41 (1,26,30), linkage to the renin gene was found (17,25,27). Sertié et al (32) suggested that mutation at 17p11.2 enhances the expression of cleft palate at the van der Woude locus.

Manifestations of the syndrome in other than the oral or facial areas are unusual.

Oral manifestations. Usually bilateral, often symmetrically placed depressions are observed on the vermilion portion of the lower lip, one on each side of the midline (Fig. 21–37A,B). The dimples are usually circular

but they may be transverse slits or sulci (22). On occasion, they may be located at the apex of nipple-like elevation (36). Rarely, the elevations may fuse in the midline, producing a snoutlike structure. The depressions represent blind sinuses that descend through the orbicularis oris muscle to a depth of 1 mm to 2.5 cm and communicate with the underlying minor salivary glands through their excretory ducts. The sinuses often transport a viscid saliva to the surface, either spontaneously or on pressure.

They may be so small as barely to permit a hair probe, or they may be as wide as 3 cm or more. Nipple-like processes occasionally occur without demonstrable fistulas (40). Although usually bilateral and symmetrically placed, an asymmetric single pit (37,40,41), a central single pit (21,40), or bilateral asymmetric pits (21) may occur. The appearance of the pits may be remarkably subtle (15).

Microforms exist such as transverse mucosal ridges of the lower lip and bilateral somewhat conical elevations of the lower lip mucosa (22). The latter are associated with cleft palate but not with cleft lip (24).

Sicher and Pohl (34) and Warbrick et al (41) suggested that the congenital fistulas arise from arrested development, that is, persistence of a median and/or lateral sulcus or sulci that normally are evanescent structures. These median and lateral grooves appear in the 5–6 mm embryo and disappear at the 10–16 mm stage (Fig. 21–37C). It should be pointed out that the grooves disappear at approximately the same time that fusion occurs between several facial prominences. This probably accounts for the simultaneous occurrence of sinuses and facial cleft. Although surveys have differed considerably because of various biases (4,11,22,33,38,42), roughly 33% have pits without clefts, 33% have pits with cleft lip-palate, and 33% have pits with cleft palate or submucous cleft palate. The combination of pits with cleft lip alone is very rare. Conversely, approximately 10% of those with the syndrome do not exhibit lip pits. Burdick (2) calculated that the risk of inheriting a cleft from an affected parent is approximately 20%; the risk of inheriting lip pits only or being nonpenetrant is approximately 25%.

Adhesions between maxilla and mandible (syngnathia) have been noted (14,18). Absence of maxillary and mandibular second premolars has been described as part of the syndrome in 10%–20% of cases (23,28). Natal teeth have been found in monozygous twins (9).

Extremities. Talipes equinovarus (10,37) and 3–4 syndactyly of the fingers (16) have been reported

Other findings. Ankyloblepharon has been described in association with the condition (14,18). These patients, however, may have had mild expression of the *popliteal pterygium syndrome*. Accessory nipples, congenital heart defects (20), Hirschsprung disease (7,31), trichorrhexis nodosa (35), and amniotic band limb deficiency defects (12) have also been reported. These latter findings are likely due to chance.

Diagnosis. Because of variable expressivity, affected family members may exhibit clefts without pits. This may greatly complicate genetic counseling as the chances for transmitting cleft lip or palate vary depending on whether the anomaly is associated with lip pits (50%) or is an isolated phenomenon (2%–5%). Lip pits may also occur in *popliteal pterygium syndrome* and with *aganglionic megacolon and cleft lip and/or palate* and in *Kabuki syndrome*. The type of pits under discussion should not be confused with commissural lip pits at the corners of the mouth that are seen in 10%–20% of the population.

Prenatal diagnosis has been made using embryoscopy (6).

Velocardiofacial syndrome (Shprintzen syndrome, del22q11, Sedlacková syndrome)

In 1978, Shprintzen et al (66) reported a syndrome of typical facies, prominent nose, retruded mandible, cardiovascular anomalies, cleft palate, and learning disabilities subsequently known as *velocardiofacial (VCF) syndrome*. Since then, Shprintzen and colleagues have made numerous contributions to our understanding of this syndrome (1,2,6, 7,24,25,32,33,38,40,43,50,51,53,56,62,67,68,79,80,87). Stern et al (69), Strong (73), Kinouchi et al (35), Kimura et al (34), and Matsuoka et al (44) probably described the same entity, the Japanese preferring the term *conotruncal anomaly face*. Sedlacková and co-workers (16,64,78) included several examples of the syndrome under the title of *velofacial hypoplasia* as early as 1955. Some examples of *asymmetric crying facies (Cayler syndrome)* appear to be VCF syndrome (15,22,71). Velocardiofacial syndrome is not rare, comprising approximately 8% of patients seen in a cleft palate clinic, and appearing to be second only to *Stickler syndrome* as a cause (15%) of *Robin sequence* (67). Over 700 cases have been described (24,45).

Inheritance is autosomal dominant with variable expressivity (47, 67,79). A hemizygous microdeletion shared with *DiGeorge sequence* has been found with high resolution banding and FISH techniques at chromosome 22q11.2 in approximately 85% of the cases of velocardiofacial syndrome (6,7,14,33,37–39,44,51,62,81,82). Among patients with velopharyngeal insufficiency of unknown cause, Zori et al (88) noted that 37% had the deletion. The gene responsible for the cardiovascular aspects is *TBX1* (48). The phenotype in adults has been described (8). The deletion appears to be somewhat more frequently of maternal origin (10,51,63). Among 558 patients with interstitial deletion of 22q11, approximately 28% had inherited deletions predominantly (75%) from the female parent (4,5,60). The frequency of the deletion has been estimated to be 1/5000 live births. Imprinting plays no role in the etiology of VCF syndrome (51). No correlation has been found between the presence or size of the deletion and the phenotype (7). Phenotypic discordance has been reported in monozygous twins (27,86). An acronym for this combination called CATCH 22 (23,30) sounds denigratory and should be discouraged. Overlap with der(22) syndrome has been reported (20). Der(22) is rare, consisting of mental retardation, preauricular skin tags or pits, and conotruncal heart anomalies.

Facies. Approximately 40% are microcephalic. One patient had holoprosencephaly (84). Scalp hair is abundant in over 50%. The face is long with vertical maxillary excess (85%), malar flatness (70%), and mandibular retrusion (80%) (2,40,53). Approximately 15% exhibit *Robin sequence*. Conversely, approximately 15% of infants with Robin sequence have velocardiofacial syndrome. The nose is prominent with squared nasal root, hypoplastic alae nasi, and narrow nasal passages in 75% (2,40). The tip may be dimpled (29). The philtrum is long and the upper lip is thin. The mouth is often held open (Figs. 21–38 and 21–39). It is not rare for the face to be somewhat asymmetric. The adenoids are hypoplastic in almost 85% (80). There is resemblance to the Cycladic face depicted in Greek statues from about 3000 B.C.

Eyes. Narrow palpebral fissures with blue suborbital coloring or "allergic shiners" occur in 35%–50% (24). Tortuous retinal vessels, posterior embryotoxon, small optic discs or bilateral cataracts have been seen in possibly 70% (3,18,43,79). Ocular coloboma has been documented in a few cases (3,24). One of these patients (24) did not have a molecular deletion and perhaps did not have VCF syndrome.

Fig. 21–38. *Velocardiofacial syndrome*. Two affected patients to the right contrasting sharply with their 6-year-old normal sister. Note narrow receding forehead, broad and prominent nasal bridge, upslanting short palpebral fissures, and epicanthal folds. (From P Meinecke et al, Eur J Pediatr 145:539, 1986.)

Ears. Small auricles and minor thickening of the helical rims have been seen in approximately 48% (Fig. 21–39B) (personal communication, Reyes and LeBlanc, 1997). Intermittent conductive hearing loss, noted in 75%, is probably secondary to frequent bouts of serous otitis media and cleft palate. Marked reduction in size of the nasopharyngeal lumen of the Eustachian tube has been noted. Sensorineural hearing loss has also been found in 8% (67, personal communication, Reyes and LeBlanc, 1997).

Cardiovascular aspects. Multiple, largely conotruncal, cardiac anomalies are present in 75%–80%, especially VSD (65%), right-sided aortic arch (35%), tetralogy of Fallot (20%), and aberrant left subclavian artery (20%) (31,40,65,84,87). McDonald-McGinn et al (45) found tetralogy of Fallot to be the most common finding in their series of 250 patients. Conversely, however, among patients with conotruncal anomalies, approximately 8% had 22q11 deletions (75). The combination of pulmonary atresia/VSD has been noted (63). Among patients with interrupted aortic arch type B (between left carotid and left subclavian arteries), 9 of 11 had the deletion (58). Aortic valve disease is not uncommonly found. Of interest and diagnostic significance, right-sided aortic arch was seen in 30% of patients with VSD, in 80% of those with tetralogy of Fallot, and in nearly 50% of patients with otherwise normal hearts. Approximately 10% die from congenital heart anomalies in early infancy (60). MacKenzie et al (42), Goldberg et al (24), Finkelstein et al (17), and D'Antonio and Marsh (9) noted enlargement, medial displacement, and tortuosity of the internal carotid arteries in the posterior pharyngeal wall in approximately 25% (Fig. 21–40). The carotids straighten out with age (30a). Goldmuntz et al (26) and Mehraein et al (46) found that approximately 20%–30% of "nonsyndromal" patients with conotruncal defects had the deletion. Takahashi et al (75) arrived at a figure of approximately 8% for a corresponding group. Transposition of the great arteries was associated with the deletion in 12% of 32 patients (47).

A number of patients have exhibited Raynaud's phenomenon.

Mental status. Learning disability to some degree is experienced by virtually all patients, although mild mental retardation is found in approximately 45% (36,74,74a,82). Severe retardation is rare in the syndrome. Language development is often slow (21). Speech is hypernasal, because of dysfunction of the velopharyngeal mechanism (Le Blanc, personal communication, 1997). The voice is hoarse and high-pitched. In secondary school age children, IQ scores ranged from 69 to 87 on verbal scale and 55 to 78 on performance scale (25,74). Mathematical concepts were poorly understood (52).

Fig. 21–40. *Velocardiofacial syndrome*. (A,B) Carotid arteriograms showing tortuous right internal carotid artery and smaller than usual left internal carotid artery. (Courtesy of K MacKenzie, Toronto, Ontario, Canada.)

At all ages, the children tended to have bland affect (25). Social interaction was poor with respect to quality and quantity. The children were described as demonstrating extremes of behavior, being disinhibited, impulsive, and very affectionate or serious and shy. Reading comprehension, auditory processing deficit, mathematics, and comprehension of abstract concepts are especially poor (36). Most patients develop a spectrum of psychiatric disorders that include bipolar spectrum disorders and attention deficit disorder with hyperactivity. Those younger than 18 years old were affected with bipolar disorder. Older patients manifested paranoid and grandiose delusions (7). A suggestion has been made that a gene for schizophrenia at 22q11.2 may be deleted (26,32,56,68). Demyelination/gliosis, cerebellar atrophy, cerebellar hypoplasia, and cysts have been described (1,12,41,50). Neural tube defect is apparently increased (54,55).

Musculoskeletal findings. Hypotonia in infancy and childhood is frequent (40). Approximately 35%–50% are below the 3rd centile in height (24,40,79). Approximately 25% have umbilical or inguinal hernia and 15% have scoliosis (24,40,79). Talipes is found in 10% (40). The hands and fingers appear slender and tapered in approximately 60% (24). The digits may be hyperextensible. Radiographically, there is platybasia in 75%. Chiari I malformation is seen in 20%, occipitalization of the atlas in 15%, and velar paralysis in 25% (30b). Skeletal anomalies principally involving the extremities, ribs, and/or vertebrae have been noted in approximately 35% (49).

Anogenital and renal anomalies. Hypospadias has been noted in approximately 10% of males (24,40). Anal anomalies have also been reported (82,83). Silent renal anomalies have been found in 35% (60).

Immunologic and endocrine findings. Failure to thrive in infancy is seen in approximately 25%. Absent or small thymus (10%), tonsils (50%), and adenoids (85%), T-lymphocyte dysfunction, and hypocalcemia in infancy, noted in approximately 15%, indicate an association with the *DiGeorge sequence* (57,70,80). Ryan et al (60) found hypocalcemia in 60%. Autoimmune diseases (juvenile rheumatoid arthritis, Hashimoto thyroiditis) appear to be increased (13). Devriendt et al (12a) suggested that the annual incidence of velocardiofacial/DiGeorge syndrome was 1 per 4000.

Oral manifestations. In one study, cleft palate (35%), submucous cleft palate (33%), and occult submucous cleft palate or velar paresis (33%) resulting in hypernasal speech were found in nearly all patients, but this surely reflected ascertainment bias (24). In a more unbiased study, 10% had cleft palate whereas 35% had velopharyngeal insufficiency (60). McDonald-McGinn et al (45) found 27% with velopharyngeal incompetence. Lipson et al (40) and others (45) found that 2%–5% had cleft lip. Class I malocclusion is a common finding. The pharynx is hypotonic (Fig. 21–41). Obstructive sleep apnea has been found in approximately one-half of the neonates. Adenoidectomy and tonsillectomy must be avoided in these patients (17).

Diagnosis. *CHARGE association* must be excluded. Facial paresis may be in CHARGE association. Approximately 8% of patients with DiGeorge syndrome have unilateral facial nerve paralysis (82). There is some overlap with the *Ritscher-Schinzel (3C syndrome)* (12). The same deletion has been identified in some examples of *asymmetric crying facies* and anterior laryngeal webs (19,72) and *Kenny-Caffey syndrome* (61). The initial belief that the autosomal dominant form of *Opitz BBB/G syndrome* maps to the same area has been disputed (85). Bilateral cleft lip-palate with median facial dysplasia seems to have 22q11.2 deletion (62a), a group we have obviously missed because of phenotypic bias.

Prenatal diagnosis of 22q11 deletions has been made in fetuses with conotruncal anomalies (14,59).

Velo-facio-skeletal syndrome

Teebi et al (1), in 1995, described a mother and daughter with short stature, unusual face, nasal speech, and skeletal anomalies.

The facies was characterized by elongated face, mild hypertelorism, broad high nasal bridge, and high arched palate. Both had nasal speech, but no mention was made of velopharyngeal insufficiency.

The hands and feet were short with prominent finger pads and hyperextensible finger joints. Mesomelic brachymelia was noted. Stature was small.

There was some facial resemblance to *velocardiofacial syndrome*, but no deletion at 22q11 was found on FISH study.

Chapter 22
Orofacial Clefting Syndromes: Other Syndromes

Aase-Smith syndrome I

Aase and Smith (1) in 1968 and Patton et al (3) in 1985 reported two generation inheritance of hydrocephalus, severe contractures of joints, dysmorphic pinnae, and cleft palate (Fig. 22–1). In each case, the parent was less severely affected (Fig. 22–2).

All extremities, including the fingers, were contracted (Fig. 22–3). There were thoracic scoliosis and dislocated hips (1). Talipes was seen in the other family (3).

The facies was normal, but the pinnae were dysmorphic in the patients of Aase and Smith (1). However, in those of Patton et al (3), there were broad forehead, short palpebral fissures, and broad nasal bridge. Cleft palate was found in most cases (1,3).

Dermal ridge patterning of palms and fingertips was hypoplastic.

Autopsy showed Dandy-Walker formation in the infants but not in the affected parent. A neuroblastoma was found in the adrenal in one case (1). A possible additional example is that of Potter and Parrish (4).

Dandy-Walker malformation may be an isolated finding or seen in combination with many disorders such as Joubert syndrome, *Walker-Warburg syndrome*, the *oral-facial-digital syndromes*, and, rarely, *Ellis-van Creveld syndrome*.

There is, at times, overlap with *Gordon syndrome*.

Fig. 22–1. *Aase-Smith syndrome I*. Hydrocephalus, cleft palate, malformed pinnae, joint contractures, hip dislocation. (From JM Aase and DW Smith, J Pediatr 73:606, 1968.)

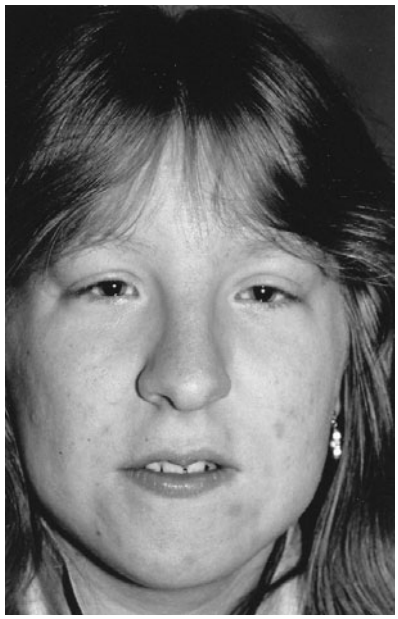

Fig. 22–2. *Aase-Smith syndrome I*. Mother of similarly affected child. Note broad forehead, broad nasal bridge, and short palpebral fissures. (From MA Patton et al, Clin Genet 28:521, 1985.)

Aase-Smith syndrome II (Blackfan-Diamond syndrome)

Aase and Smith (1) reported male sibs with congenital hypoplastic anemia, triphalangeal thumbs, hypoplastic radii, and cleft lip (Fig. 22–4). One sib had narrow shoulders. Murphy and Lubin (11) described a male child with cleft lip-palate, congenital erythroid hypoplasia, and triphalangeal thumbs. Also noted were somatic and mental retardation, narrow shoulders, abnormal pigmentation of the skin, and short webbed neck. There was a family history of a similar thumb anomaly. Muis et al (10) reported a male infant with cleft lip-palate, congenital hypoplastic anemia, and triphalangeal thumbs. Others (9,12–16) have reported similar examples but without cleft lip and/or palate. RJ Gorlin has seen a child with cleft palate, strabismus, and Blackfan-Diamond syndrome. Approximately 10% of patients with Blackfan-Diamond syndrome have CL(P). K. Gripp et al (5a) noted microtia. Hasan and Inoue (7) described a child with cleft palate, microtia, and Blackfan-Diamond anemia. Cousins with cleft palate and microtia were noted by Gripp et al (5). Halal et al (6a) misdiagnosed a case as Nager syndrome.

We consider the combination of anomalies described by Aase and Smith to be Blackfan-Diamond syndrome (3,4). All of the anomalies reported by Aase and Smith have been described as part of the syndrome. These have been well tabulated by Alter (2) and Ball et al (3). Included are short stature, congenital hypoplastic anemia, triphalangeal or bifid or absent thumbs, hypoplastic thenar eminences, webbed neck, flat nasal bridge, narrow shoulders, cleft lip and/or palate, macrocytosis, elevated HbF, and erythrocytic adenosine deaminase. The gene has been mapped to 19q13 (6).

Although most examples are sporadic, some examples appear to autosomal dominant or recessive (8). Others present as a contiguous gene syndrome mapping to 19q13.2 (14).

Ablepharon-macrostomia syndrome

In 1977, McCarthy and West (7) reported a syndrome in two unrelated male children. Hornblass and Reifler (4) Price et al (9), Markouizos et at (6), and Stevens (personal communication, 2000) described the same condition. Common features were triangular facies, hypertelorism, late development of sparse thin hair, absence of upper and lower eyelids, eyebrows, and eyelashes, and internal strabismus. The pinnae were low-set and rudimentary in form with collapsed canals and associated hearing loss. The nose was small with some degree of coloboma formation of the mid-alae producing triangular nostrils. The zygomatic arches were flattened and the labial commissures were not adequately fused, producing macrostomia and thin vermilion (4) (Fig. 22–5A,B). The zygomatic arches may, in part, be missing (5).

The skin was dry and coarse with excess skin folds, especially over the hands and feet, buttocks, popliteal fossae, and neck. There was webbing between the proximal phalanges of the fingers and limitation of finger extension because of tight skin over the interphalangeal joints. The nipples were absent or hypoplastic (Fig. 22–5C).

Suggestion has been made that the gene maps to 18q (8). However, we suspect that the description better fits Barber-Say syndrome (vide infra). Affected sibs were described by Cruz et al (2,3) and Ferraz et al (3a). The father had a coloboma of his upper eyelid (3a).

The genitalia were ambiguous with posteriorly displaced micropenis, cryptorchidism, and absent scrotum (Fig. 22–5D). There was umbilical hernia or omphalocele in two of three cases.

The *Barber-Say syndrome* of hypertrichosis, atrophic skin, ectropion, and macrostomia has some resemblance to ablepharon-macrostomia. We suspect that the cases of Caesarino et al (1) and Pellegrino et al (8) have Barber-Say syndrome.

Hirschsprung disease and cleft lip and/or palate (Goldberg-Shprintzen syndrome)

Goldberg and Shprintzen (5) described sibs with unusual facies, microcephaly, neonatal hypotonia, short stature, aganglionic megacolon of the short type, and submucous cleft palate. Sibs were also reported by Kumasaka and Clarren (9) and Yomo et al (16). One of the latter had cleft lip-palate, the other cleft palate. At least 20 patients have been described (1–7,9,11,17,18). A less likely example is that of Brunoni et al (3). Consanguinity was documented by Hurst et al (7) and Brooks et al (2), and autosomal recessive inheritance is possible. Possible localization to 2q22–q23 has been suggested.

The facies was characterized by microcephaly, fine scalp hair, hypertelorism, narrow palpebral fissures, synophrys, thick eyebrows, thick curly eye lashes, prominent nose with broad nasal bridge, large ears with indented lobes, maxillary hypoplasia, microstomia, and pointed chin (Fig. 22–6). Ptosis was noted in a few patients (7,16). Iris coloboma has been reported in 30% (7). Submucous cleft palate was noted by Goldberg and Shprintzen (5).

All have been mentally retarded (IQ 25–60). Abnormal cranial computed tomography (CT) scan has been noted in most patients (agenesis of corpus callosum, atrophy of white matter, enlarged ventricles), abnormal electroencephalographic findings in a few patients (7,11,17), agenesis of the corpus callosum, and congenital heart disease (ASD, VSD, PDA) in 30% (6,11,17).

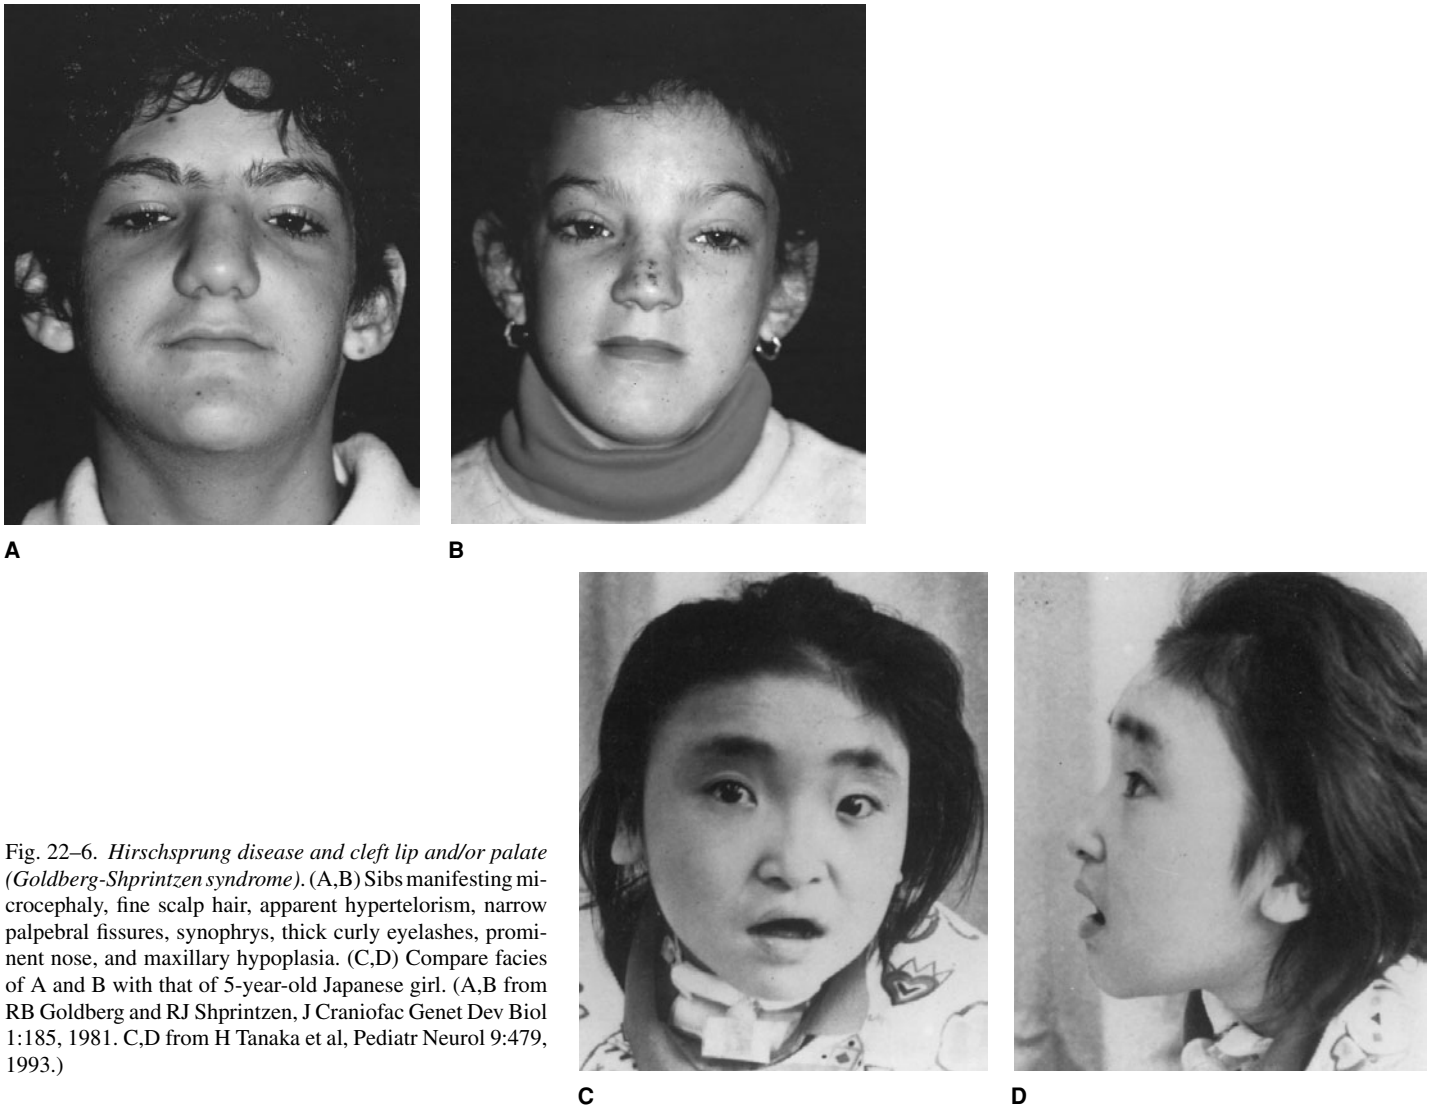

Fig. 22–6. *Hirschsprung disease and cleft lip and/or palate (Goldberg-Shprintzen syndrome).* (A,B) Sibs manifesting microcephaly, fine scalp hair, apparent hypertelorism, narrow palpebral fissures, synophrys, thick curly eyelashes, prominent nose, and maxillary hypoplasia. (C,D) Compare facies of A and B with that of 5-year-old Japanese girl. (A,B from RB Goldberg and RJ Shprintzen, J Craniofac Genet Dev Biol 1:185, 1981. C,D from H Tanaka et al, Pediatr Neurol 9:479, 1993.)

Aganglionic megacolon has also been seen with submucous *cleft palate and paramedian pits of the lower lip* (16), with bilateral cleft lip-palate (15), with cleft palate and hearing loss (1), *Aarskog syndrome*, and *Waardenburg syndrome*. The report of Hirschsprung anomaly with bicolored irides is probably Waardenburg syndrome (10). It is also seen in approximately 6% of those with trisomy 21. There is increased frequency in severe *Smith-Lemli-Opitz syndrome, Nager syndrome*, *Bardet-Biedl syndrome, cartilage-hair hypoplasia, multiple endocrine neoplasia, types 2A and 2B, Aarskog syndrome, rubella embryopathy*, Kaufman-McKusick syndrome, and primary hypoventilation syndrome.

Hirschsprung disease is heterogeneous. At least four genes have been mapped, one at 10q11.2 and the others at 13q22, 19p13.3, and 5p13.1 (12,14).

Baraitser syndrome and cleft lip-palate

Baraitser syndrome is a presumed autosomal recessive pattern of anomalies defined on the basis of a 5 1/2-year old female of normal karyotype and an 18-week-old male fetus (1). There was one normal sib. Both parents were normal and consanguinity was denied.

The 5 1/2-year old proband manifested craniosynostosis involving the coronal suture, mental retardation, seizures, choroidal colobomas, mild hypertelorism, beaked nose, cleft lip-palate, protuberant ears, mild mesomelic shortening of the upper and lower extremities, short broad fingers, and cystic dysplastic kidneys.

A second case was diagnosed prenatally by fetoscopy at 16 weeks. The presence of cleft lip was indicative with high probability of the full syndrome. The pregnancy was terminated and postmortem examination at 18 weeks showed cleft lip-palate, small posterior fontanel, and findings consistent with choroidal coloboma.

Reference (Baraitser syndrome and cleft lip-palate)

Bencze syndrome (facial asymmetry, strabismus, and submucous cleft palate)

The Bencze syndrome (1,2) consists of mild facial asymmetry, esotropia, amblyopia, and submucous cleft palate. The syndrome has autosomal dominant inheritance with variable expression. On the hypoplastic side, the palpebral fissure is usually upslanting (Fig. 22–7). Other body proportions are symmetric.

Blepharo-cheilo-dontic (BCD) syndrome

Blepharo-cheilo-dontic (BCD) syndrome was first brought to our attention by Piper (14) in 1957. From reading his publication one can tell relatively little about the child he illustrated. However, one can see euryblepharon, ectropion of lower eyelids and bilaterally cleft lip-palate. Gorlin et al (7), in a 1996 review, suggested the term "blepharo-cheilo-dontic syndrome."

Allanson and McGillivray (1) were probably the first to report a large, four-generation family with euryblepharon, ectropion of lower eyelids, bilateral cleft lip-palate, and conically-shaped anterior teeth. Eyebrows, eyelashes and scalp hair were sparse. Among the 20 affected members, approximately 25% had cleft lip and/or palate, 40% had ectropion and approximately 50% had teeth with conical crown form. Several other large kindreds and numerous isolated examples have been published (6–8,10,11).

Inheritance is autosomal dominant with full penetrance and variable expressivity (1,6,7,10,11).

Ophthalmologic findings. The upper eyelid may be the site of a double row of eyelashes (distichiasis); the lower eyelid exhibits ectropion (Fig. 22–8A). The palpebral fissures are wider than normal (euryblepharon). As a result, the eyes often cannot be closed (lagophthalmia). Ankyloblepharon has also been noted (8).

Euryblepharon is bilaterally symmetrical and is often accompanied by epiphora and conjunctivitis. It has been present in approximately 70% of the patients. Approximately 60% manifest distichiasis, an accessory row of lashes that may consist of only a few cilia running along the inner part of the intermarginal strip, occupying the site of the orifices of the Meibomian glands. The lashes are usually small, soft, and fine. Ectropion, an outward turning of the lower eyelid, was seen in approximately 40%. Lagophthalmia, a condition in which the eye cannot be entirely closed, has been described in association with euryblepharon (16,19) and has been documented in approximately 25%.

Cutaneous findings. Some patients have sparse scalp hair, eyebrows, and eyelashes (1,8). The nails have been hypoplastic in a few patients (10).

Oral findings. The oral changes consist of cleft lip-palate, usually bilateral (Fig. 22–8A). Although most patients have come to attention because of this, not all have this anomaly. Falace and Hall (6) found only 15% with cleft lip or palate, whereas Anderson and McGillivray (1) noted 25% with clefts. All the patients of Korula et al (10) had bilateral cleft lip-palate whereas one of our 8 patients did not have a cleft (7).

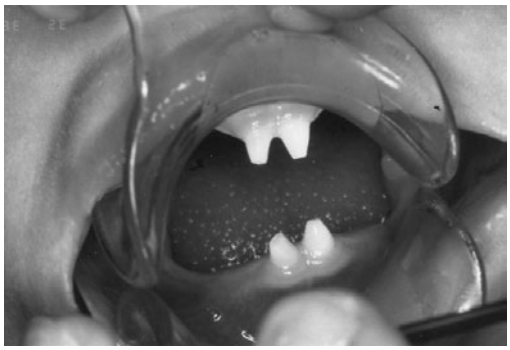
B

Fig. 22–7. *Bencze syndrome*. (A) Primary telecanthus, strabismus, malocclusion. (B) Aunt of proband showing facial asymmetry and upslanting palpebral fissure on hypoplastic side. (From D Kurnit et al, Clin Genet 16:301, 1979.)

A



B

Fig. 22–8. *Blepharo-cheilo-dontic (BCD) syndrome*. (A) Ectropion of lower eyelids, bilateral cleft lip-palate, lagophthalmia, euryblepharon. (B) Oligodontia. Note reduced crown form. (From RJ Gorlin et al, Am J Med Genet 65:109, 1996.)

Reduction in the number of teeth and anterior teeth with conical crown form is a common finding (Fig. 22–8B). Falace and Hall (6), noting these changes in 75%, Anderson and McGillivray (1) in 50%, Korula et al (10) in 12%, and Gorlin et al (7) in over 80%.

Other findings. A miscellaneous group of findings include: umbilical hernia (8), sinus of frontotemporal area (8), small head circumference (8), imperforate anus (1,8), nasolacrimal obstruction (8), syndactyly of first two fingers (11), pili torti (11), and dermoid of lateral eyelids (10).

Differential diagnosis. Several of the changes described here have been reported as isolated findings or in other combinations. Hence, we cannot judge in many cases whether one is dealing with the syndrome. For example, Becker (3) and Weve (20) reported severe euryblepharon with ectropion of lower eyelids. Duke-Elder (5) noted a combination of euryblepharon, ectropion of lower eyelids, and lagophthalmia. Ectropion of the lower eyelid may be a solitary finding or it may be seen in *postaxial acrofacial dysostosis*. Distichiasis, often inherited as an isolated autosomal dominant trait (4,12), may be associated with ectropion, and can be found with lymphedema and/or spinal extradural cysts (15,17,18). Picó (13) found 13 of 20 affected in 3 generations with distichiasis and/or ectropion.

Patients with CL(P) exhibit agenesis of teeth more often than do normal individuals. The differential diagnosis of syndromes having oligodontia and/or microdontia is legion and does not warrant discussion here. Distichiasis has been reported in combination with cleft palate in a child with Robin sequence, but there is no evidence that this child had blepharo-cheilo-dontic syndrome (2). Neither did the patient described by Jester (9) with lymphedema, distichiasis and cleft palate. A male patient with some overlapping findings was seen in Gentofte Hospital, Gentofte, Denmark in 1973 by M. Warburg. Findings included repaired bilateral cleft lip-palate, euryblepharon, lagophthalmia, and ectropion of lower eyelids. However, his other findings have not been noted in any other patient with blepharo-cheilo-dontic syndrome. These include colobomas of choroid and optic nerve, mild microphthalmia, atrial septal defect, sensorineural hearing loss, short stature, and hypogonadism (micropenis). His appearance was illustrated in the 1976 edition of *Syndromes of the Head and Neck*.

Catel-Manzke syndrome (palatodigital syndrome)

Catel (3), in 1961, and Manzke (13), in 1966, reported the same patient with cleft palate, micrognathia, and bilateral clinodactyly (radial angulation) of the index finger (Fig. 22–9). Approximately 25 cases (1-19,21) have been documented to date, all but five (5,9,12) in males. RJ Gorlin and MM Cohen, Jr. have each seen a case of the syndrome in a female patient. Although there has been some familial aggregation (2,8,17), in our view X-linked recessive inheritance is not tenable and recurrence risk is low. We cannot accept the case of Petit et al (14) as an example of the syndrome.

A

B

C

Fig. 22–9. *Catel-Manzke syndrome*. (A) Note marked clinodactyly of index finger. (B) Note separate bone at base of proximal phalanx of index finger. (C) Same anomaly in older patient, but fusion has taken place. (A courtesy of E Brude, Eur J Pediatr 142:222, 1984. B,C from W Holthusen, Ann Radiol 15:253, 1972.)

The cranium may be globular in shape with shallow orbits. Dysmorphic ears have been noted in 35%. Approximately 90% have cleft palate and small mandible and have been classified as examples of Robin sequence. One child had cleft lip-palate (16). The neck has been noted to be short in approximately 40%.

Postnatal growth delay has been found in at least 65% (20).

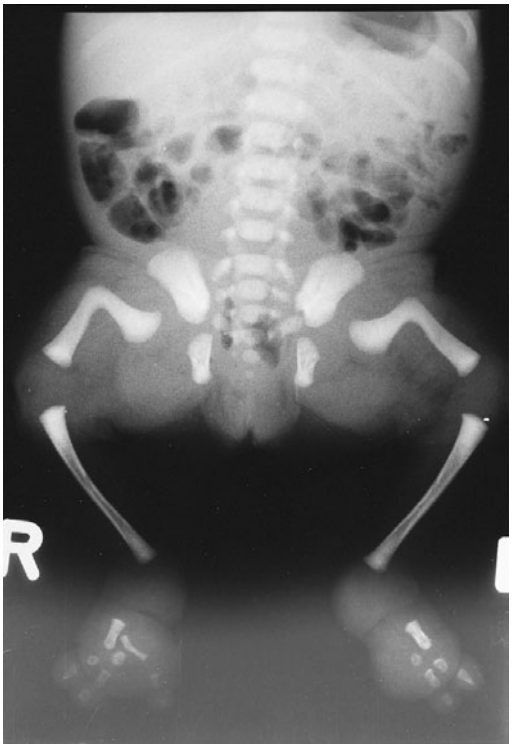
In addition to hyperphalangy of the index finger, other anomalies of the extremities have included short fingers and toes (50%), clinodactyly of 5th fingers (35%), single palmar creases (40%), and talipes equinovarus (15%). Other skeletal defects have been pectus excavatum (20%), joint laxity (25%), and vertebral/rib anomalies (20%) (7,10,19).

Cardiac septal defects (ASD, VSD), overriding aorta, aortic coarctation and dextrocardia have been found in 50% (7,8,15,17,18).

Radiographically, the clinodactyly is seen to result from an accessory bone, irregular in form, located between the shortened second metacarpal and the corresponding shortened proximal phalanx of the index finger.

A

B



C

D

Fig. 22–10. *Cleft lip-palate, agenesis of fibula and ulna, bowing of femora, and contractures (Fuhrmann syndrome).* (A,B) Dysplastic digits with nail aplasia. (C) Bent femora, unusual shape of ilia, absence of femora, oligodactyly. (D) Talipes, asymmetric oligodactyly. (From W Fuhrmann et al, Eur J Pediatr 133:123, 1980.)

With time, the supernumerary bone fuses with both the radially deviated proximal phalanx and the metacarpal (10) (Fig. 22–9A,B). Miscellaneous bony anomalies have included bifurcated first metacarpal (10) and multiple vertebral anomalies (17).

Having the same digital anomalies but a different phenotype (bushy eyebrows, prominent eyes, hallux valgus, bronchomalacia, and no cleft palate) is a child reported by Chitayat et al (4). Several other disorders having hyperphalangy of the index fingers (of a different kind) clearly represent other conditions. Devriendt et al (4a) described severe short stature, severe mental retardation, unusual facies, and an additional phalanx in the index fingers with short second metacarpal. Hyperphalangism may occur as an isolated finding (21) and as part of *Desbuquois syndrome*. The patient described by Wilson et al (20) was short, retarded and had iris coloboma. Two other patients are worthy of mention: Camera and Costa (2a) noted unilateral index finger involvement, VSD, and hearing loss while Temtamy et al (18a) found hyperphalangism of digits I–III, preaxial polydactyly, deafness, and talon cusps of the maxillary central incisors.

Cleft lip-palate, agenesis of fibula and ulna, bowing of femora, and contractures (Fuhrmann syndrome)

Pfeiffer et al (3), in 1998, described two sibs of Turkish origin. The parents were consanguineous. They cited the report of Fuhrmann et al (1) of three somewhat similarly affected sibs. Lipson et al (2) also described affected sibs. Inheritance is autosomal recessive.

Cleft lip and palate were noted only in the sibs reported by Pfeiffer et al (3). The cranium bulged. The neck was short. Communicating hydrocephalus, absence of cerebellar vermis, and Arnold-Chiari anomaly were reported (3).

Radiographically, the fibula was aplastic in all cases and the ulna was aplastic or hypoplastic. The radius was present. There was oligodactyly in one set of sibs (3), polydactyly in another set (1), and aplasia of nails. The humerus and tibia were normal, but the femur was markedly bowed and the pelvis abnormally shaped. All joints were somewhat contracted (Fig. 22–10).

Cleft lip-palate, pili torti, malformed ears, partial syndactyly of fingers and toes, and mental retardation (Zlotogora-Oğur syndrome)

In 1987, Zlotogora et al (12) and, in 1988, Oğur and Yüksul (5) reported sibs with a syndrome of cleft lip-palate, sparse hair with pili torti, partial syndactyly of fingers and toes, and mental retardation. Subsequently, approximately a dozen additional examples have been reported (1,2,6,7,9–11) (Fig. 22–11).

Inheritance is autosomal recessive. Mutations of PVRL1 which encodes a cell-cell adhesion molecule are responsible (8a). The gene maps to 11q23 and is allelic to *Margarita Island ectodermal dysplasia*.

The hair is sparse and abnormal in quality (kinky hair, pili torti). Hair loss occurs as the patient ages (1). The eyebrows are sparse, especially laterally. The skin of the palms and soles becomes hyperkeratotic. The nails may be dysplastic. Hypohidrosis is mild. Nipples may be hypoplastic (5,7,10).

Various tooth anomalies have been described: hypodontia, microdontia, and delayed eruption.

Cleft lip-palate has been present in most of the affected. The pinnae may be outstanding and/or dysmorphic. Hearing loss has been described in a few patients (5,7).

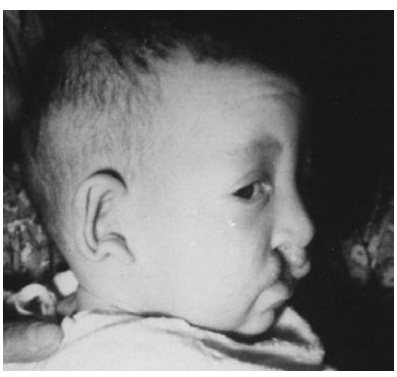
Mental retardation has been variable.

Partial syndactyly of fingers 2-3-4 and toes 2–3 is frequent. Rarely toes 4–5 are fused (9).

Various genitourinary anomalies have been reported (5,7,11).

There is some overlap with *AEC, EEC, Rapp-Hodgkin* and *Bowen-Armstrong syndromes*. The female child reported by Freihofer et al (3)

A



B

Fig. 22–11. *Cleft lip and palate, pili torti, malformed ears, partial syndactyly of fingers and toes, and mental retardation (Zlotogora-Oğur syndrome).* (A,B) Note high forehead, sparse hair, dysmorphic pinnae, bilateral cleft lip, partial soft tissue syndactyly of fingers 3–4, and transverse palmar crease. (From J Zlotogora et al, J Med Genet 24:291, 1987.)

was much more severely affected than those with Zlotogora-Oğur syndrome. We view cases 2 and 3 of Rosselli and Gulienetti (8) as a unique entity.

The girl described by Martinez et al (4) had cleft lip-palate, anodontia of deciduous dentition, oligodontia of permanent dentition, pili torti, long eyelashes, hypertelorism, prominent eyes, lagophthalmos, midface hypoplasia, syndactyly, and other findings. This is *BCD syndrome*.

Cleft lip-palate, ectodermal dysplasia, marked syndactyly, and mental retardation

Freihofer et al (1) reported a mentally retarded female with cleft lip-palate, severe cutaneous and osseous syndactyly, and ectodermal dysplasia.

The parents were consanguineous.

Short stature, head circumference below the 10th centile, and mental retardation were noted. The child was subsequently found to be congenitally hypothyroid. Eyebrows and eyelashes were ample. The scalp hair was thin and barely pigmented. Frontal bossing, high hairline, lagophthalmos, broad nasal base, hypoplastic maxilla, marked oligodontia, and bilateral cleft lip-palate were evident.

Marked cutaneous and osseous syndactyly with fused nails of fingers 2–4, broad metacarpals 3–5, and syndactyly of hypoplastic toes and absent distal phalanges were noted. The first metatarsals were broad.

There is considerable overlap with the autosomal recessive Zlotogora-Oğur syndrome (*cleft lip and palate, pili torti, malformed ears, partial syndactyly of fingers and toes, and mental retardation*) and the somewhat similar disorder reported by Martinez (2), which we have diagnosed as having *blepharo-cheilo-dontic syndrome*. However, the degree of syndactyly was much more severe.

The syndrome also has overlap with *cleft palate, congenital hypothyroidism, curly hair, and choanal atresia*.

Cleft lip-palate, prominent eyes, and congenital heart disease

Dinno (1), in 1987, described three generations with cleft lip-palate, large ears, prominent eyes, high forehead, hypertelorism, and a beak-shaped nose with a short philtrum (Fig. 22–12).

Possibly the same condition was described by Kumar et al (2).

2. Kumar D et al: A distinct syndrome of familial cleft lip and palate with prominent eyes and characteristic facies in two unrelated families. Clin Dysmorphol 5:295–301, 1996.

Prominent eyes, deglutition dysfunction, choanal stenosis, and cleft palate

Ørstavik et al (1), in 1998, reported a brother and sister with unusual facies and deglutition dysfunction. The unusual appearance was because of exophthalmos secondary to shallow orbits. There was nasal deviation and choanal stenosis. The ear lobules were prominent. The male sib had interjaw alveolar synechiae, ankylosis of the temporomandibular joint, and hypoplastic malar area. A sister had cleft palate (Fig. 22–13).

Both had severe deglutition dysfunction. The girl developed thoracolumbar kyphoscoliosis. Intelligence was normal.

Inheritance may be autosomal recessive or, less likely, an example of parental gonadal mosaicism.

One must exclude *cleft lip-palate, prominent eyes, and congenital heart anomalies* and *Cole-Carpenter syndrome*.

Cleft lip-palate, abnormal ears, congenital heart defect, and skeletal anomalies

The sibs described by Verloove-Vanhorick et al (1) had bilateral short femur and humerus, absence of one metacarpal and one metatarsal with partial soft syndactyly of fingers and toes, four lumbar vertebrae, tapering of proximal femur with absence of femoral head, and absence of calcaneus.

There were bilateral cleft lip-palate, micrognathia, and malformed pinnae with absent external meatus (Fig. 22–14). Internal anomalies included cryptorchidism, persistent truncus arteriosus, bilobed lungs, and parathyroid aplasia.

This lethal condition possibly had autosomal recessive inheritance.

Fig. 22–15. *Cleft lip-palate, microcephaly, and hypoplasia of radius and thumb (Juberg-Hayward syndrome).* (A,B) Sibs with cleft lip, hypertelorism, epicanthal folds, broad nasal bridge, and hypoplastic columella. (C) Severe hypoplasia of thumbs. (From RC Juberg and JR Hayward, J Pediatr 74:755, 1969.)

Cleft lip-palate, microcephaly, and hypoplasia of radius and thumb (Juberg-Hayward syndrome, orocraniodigital syndrome)

Juberg and Hayward (1), in 1969, reported three of six sibs with cleft lip-palate, mild microcephaly, hypertelorism, hypoplastic and distally positioned thumbs, limited extensions of the elbows because of anterior displacement of the radial head, and short stature (Fig. 22–15). Birthweight was low. Nevin et al (5), Kingston et al (4), and Kantaputra and Mongkolchaisup (2) described isolated examples. The child reported by Nevin et al (5) was found to have absence of the pituitary fossa and flattened vertebral bodies. There were no hormone deficiencies. Kingston et al (4) noted isolated growth hormone deficiency, micropenis, and bilateral thumb aplasia in their patient. Kato (3) tabulated several case reports, some of which may represent the condition. Verloes et al (9) described three isolated examples. Cleft lip-palate, upslanting eyebrows, hypertelorism, and anomalies of the extremities (luxation of radial head, hypoplasia/aplasia of the thumb), and horseshoe kidneys were noted as well as ptosis, anterior anal displacement, and mental retardation. Perçin et al (6) described a family with microcephaly, cleft lip-palate, digital anomalies, and congenital heart anomalies. The authors made comparison to Juberg-Hayward syndrome, but we cannot see the similarity. Silengo and Tornetta (8) described additional vertebral anomalies. The reader is referred to a recent survey (3). Overlap with *Malpuech syndrome* is discussed (7).

Cleft lip-palate, microcephaly, mental retardation, and holoprosencephaly

Martin et al (3) reported three generations of a large kindred in which there was variable expression of cleft lip and/or cleft palate, microcephaly, mental retardation, hypotelorism, downslanting palpebral fissures, large pinnae, skeletal anomalies including scoliosis and talipes, and chronic constipation. One of the affected clearly had the premaxillary agenesis form of holoprosencephaly. Two others had agenesis of maxillary central and lateral incisors. Three affected males lived past 20 years of age whereas three affected females died early in infancy.

Martin et al (4) separated this disorder from familial isolated holoprosencephaly (1,2) because of the skeletal anomalies found in this family. See *holoprosencephaly* for more extensive discussion.

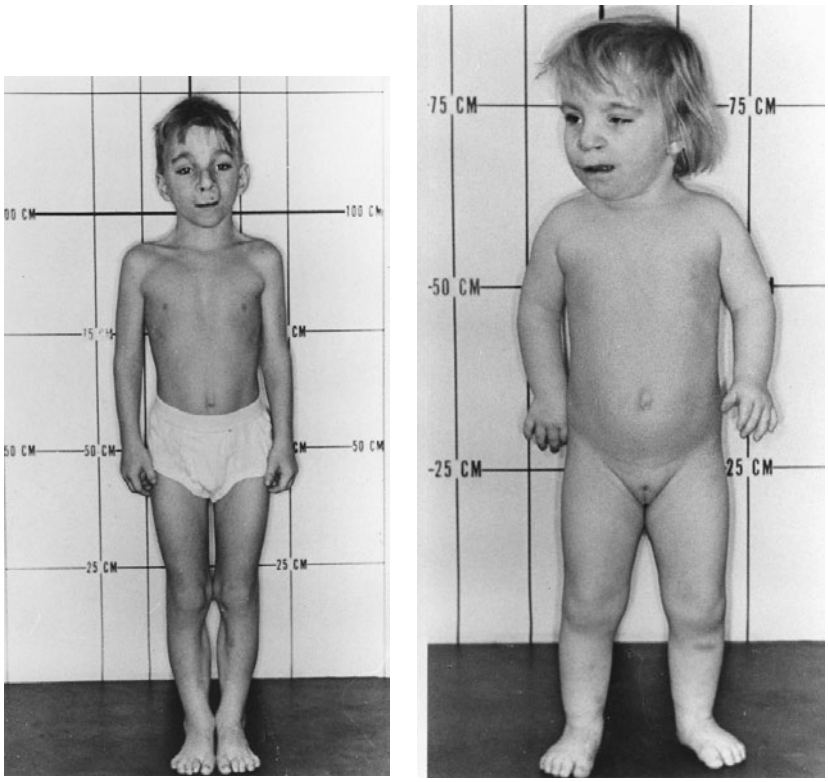
Cleft lip-palate, posterior keratoconus, short stature, mental retardation, and genitourinary anomalies

Young et al (8) described two sibs with keratoconus posticus circumscriptus, retinal colobomas, short stature, moderate mental retardation, vertebral segmentation and fusion anomalies, tight heel cords, and cleft lip-palate. The nose was prominent. The neck was mildly webbed with low posterior hairline (Figs. 22–16 and 22–17). Extension at the elbows



A B

Fig. 22–16. *Cleft lip-palate, posterior keratoconus, short stature, mental retardation, and genitourinary anomalies*. (A,B) Mentally retarded brother and sister with cleft lip-palate, short stature, mild neck webbing, small hands and feet. (Courtesy of ID Young, Leicester, England.)

was mildly limited. Haney and Falls (3) and Streeten et al (6) described somewhat similarly affected sibs.

It may be argued that posterior keratoconus is a mild form of the Peters anomaly (developmental defect of Descemet membrane and deep stromal layers of the cornea with or without iris-cornea adhesions) that has also been reported with cleft lip-palate (1,2,4,5,7). (See sections on *coloboma, hearing loss, hematuria, and cleft lip-palate* and *Peters plus syndrome* for overlap.)

Toriello-Carey syndrome

In 1988, Toriello and Carey (10) noted four children, three of whom were sibs, with postnatal growth retardation, agenesis of corpus callosum, hypotonia, short palpebral fissures, micrognathia, and congenital heart anomalies. Subsequently, others (1–9) confirmed the syndrome, approximately 15 examples having been documented.

About 70% died within 3 months of birth. All exhibited hypotonia and 30% had seizures.

Craniofacial findings include hypertelorism (100%), small palpebral fissures (90%), small nose (100%), depressed nasal root (100%), low-set malformed pinnae (85%), and micrognathia (100%). Cleft palate or submucous cleft palate was noted in 70%. Laryngeal hypoplasia was seen in all that survived early infancy. Excess skin was seen at the nape in 70% (Fig. 22–18A,B).

Congenital heart anomalies were noted in 90% (4).

A B C

Fig. 22–18. *Toriello-Carey syndrome*. (A,B) Macrocephaly, short nose, telecanthus, micrognathia, microtia, excess nuchal skin. (C) Hypoplastic nails. (From P Czarnecki et al, Am J Med Genet 65:291, 1996.)

Various other anomalies have included: cryptorchidism (60%), Hirschsprung anomaly (25%), abnormal number of ribs (50%), and esophageal reflux (35%) and digital anomalies (Fig. 22–18C). Anteriorly-placed anus and talipes were noted in one case (1).

Autosomal recessive inheritance was originally suggested because of occurrence in two pairs of sibs and parental consanguinity (8). However, there have been twelve males and two females affected and the question of X-linked recessive inheritance has been raised (1,3,4,8,11). The females are less severely affected and are still alive whereas the males have all died.

Cleft lip-palate, preaxial and postaxial polydactyly of hands and feet, congenital heart defect, and genitourinary anomalies

Töllner et al (1), in 1981, reported a child with bilateral cleft lip-palate, preaxial and postaxial polydactyly of the hands and feet, internal hydrocephalus, ependymal cysts of the lateral ventricle, complex malformations of the heart and great vessels, horseshoe kidney, and micropenis (Figs. 22–19 to 22–22). The karyotype was normal.

Cleft lip-palate, urogenital anomalies, caudal appendage, somatic and mental retardation (Malpuech syndrome)

Malpuech et al (4) reported six sibs in a highly inbred Gypsy family with cleft lip-palate, somatic retardation (−3 to −5 SD), moderate mental retardation, and various urogenital anomalies. There was marked hypertelorism (Fig. 22–23). The urogenital abnormalities consisted of unilateral aplasia or bilateral hypoplasia of the kidney, ectopia or malrotation of the kidney, vesicoureteral reflex, bladder diverticulosis, micropenis, shawl scrotum, penoscrotal hypospadias, and ectopic testes. Three of the sibs were stillborn. Their cousin and seven other second or third degree relatives were similarly affected. Additional examples appear to be those of Chinen and Naritomi (1), Guion-Almeida (3), and Crisponi et al (2). Overlap with *Juberg-Hayward syndrome* is noted (5).

The patient of Chinen and Naritomi (1) had congenital heart anomaly (VSD), cryptorchidism, hypoplastic scrotum, and periarticular skin dimples. Wormian bones were noted. The three patients of Guion-Almeida (3) also had pre- and postnatal growth failures, omphalocele, mixed hearing loss, aniridia, corneal leukoma, and caudal appendage. The sibs noted by Crisponi et al (2) had micropenis, shawl scrotum, caudal appendage, umbilical hernia, and sensorineural hearing loss.

Inheritance is autosomal recessive. Resemblance to *del4p* has been suggested (6). It is possible that the patient reported by van Langen and Hennekam (7) actually had Malpuech syndrome.

Cleft palate, absent tibiae, preaxial polydactyly of the feet, and congenital heart defect

Ho et al (1) reported a child with lower legs symmetrically curved so that the feet were oriented cranially with the plantar surfaces facing dorsally.

A B

Fig. 22–21. *Cleft lip-palate, preaxial and postaxial polydactyly of hands and feet, congenital heart defect, and genitourinary anomalies*. (A,B) Octodactyly of feet. (From U Töllner et al, Eur J Pediatr 136:207, 1981.)

D

Fig. 22–24. *Cleft palate, absent tibiae, preaxial polydactyly of the feet, and congenital heart defect*. Small mandible, ulnar deviation of fingers, bowing of lower extremities, polydactyly. (From CK Ho et al, Am J Dis Child 129:714, 1975.)

There was preaxial polydactyly of the halluces. The fingers were long with ulnar deviation. The child also had cleft palate, micrognathia, VSD, and bilateral single palmar creases (Fig. 22–24). Radiographically, wormian bones, absent tibias, and fibulas curved at midshaft were evident (Fig. 22–25). The authors cited several reports of agenesis of the tibia with preaxial polydactyly but indicated that none was truly similar to their case.

There are several autosomal dominant tibial hemimelia syndromes: Werner 2 syndrome, tibial hemimelia-ectrodactyly syndrome, tibial hemimelia-diplopodia syndrome, and tibial hemimelia-micromelia-trigonomacrocephaly syndrome, among others (2). There are also several autosomal recessive tibial hemimelia syndromes: tibial hemimelia with normal upper limbs, tibial hemimelia and ectrodactyly, and tibial hemimelia with sensorineural hearing loss (2). Richieri-Costa (2) described a child with tibial hemimelia and cleft lip-palate.

Cleft palate, craniofacial sclerosis, and musculoskeletal abnormalities

Currarino and Friedman (1) reported a family having variable expression of a syndrome of abnormal facies, cleft palate, and various musculoskeletal abnormalities.

The facies in the boy was characterized by large calvaria with biparietal bossing, thick arched eyebrows, synophrys, long upper lip with Cupid's bow form, cleft palate, and thick dental arches. There was delayed shedding of deciduous teeth. A speech defect and conductive hearing loss were noted.

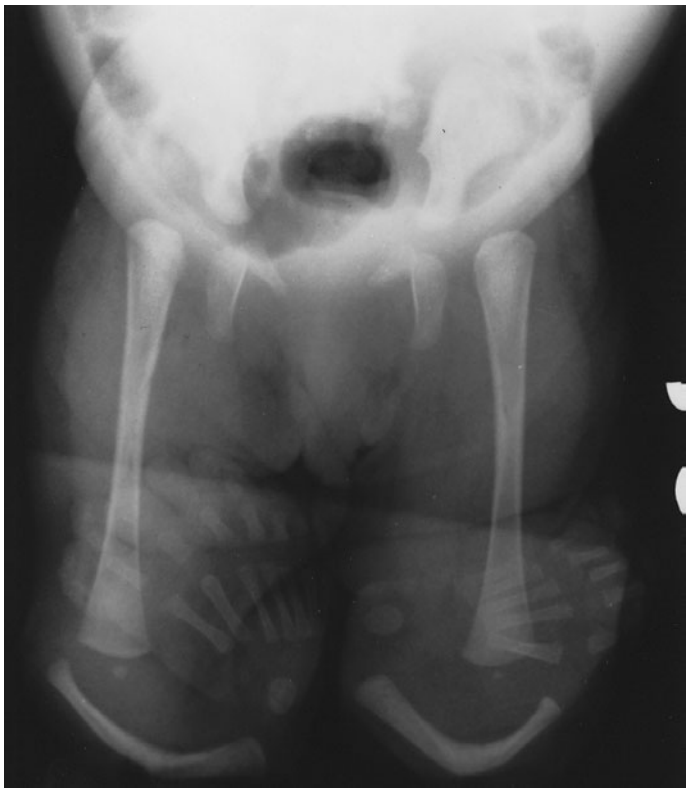

Fig. 22–25. *Cleft palate, absent tibiae, preaxial polydactyly of the feet, and congenital heart defect*. Absent tibiae, dislocated and bowed fibulae, dislocated hips, polydactyly. (From CK Ho et al, Am J Dis Child 129:714, 1975.)

Musculoskeletal changes include short stature, inguinal hernia, digital anomalies, progressive lumbar lordosis, dislocation of radial heads, and hallux valgus (Fig. 22–26).

Radiographically, enlarged calvaria, vertical clivus, cervical kyphosis, severe lumbar lordosis, and delta phalanx of middle phalanges of the index fingers and proximal phalanges of halluces were found.

The mother exhibited osteopathia striata, enlarged head, highly arched eyebrows, and Cupid's bow mouth. Another child who died during infancy had enlarged head, cleft palate, large soft pinnae, omphalocele, and hypospadias.

Although the mother has findings compatible with *cleft palate, osteopathia striata, cranial sclerosis, and hearing loss*, the findings in her children are too severe for that diagnosis to be considered.

Cleft palate, dwarfism, trichodysplasia, and unusual facies

Jorgenson and Bick (1) described two brothers with an apparently new malformation syndrome. At birth, both were below the third centile for length, weight, and head circumference. The elder was still dwarfed when examined at age three. Both had sparse, coarse, and brittle hair. Light and scanning electron microscopy of the hair showed fractures, thin shafts, and a decreased number of cuticles. The palpebral fissures were narrow (below the third centile by measurement), and the elder had bilateral entropion of the lashes. Both had prominent pinnae, micrognathia, and cleft palate. The older had telecanthus, abnormally shaped incisors, bilateral inguinal herniae, and bilateral clinodactyly of the fifth fingers. The younger had bilateral single palmar flexion creases. Sensory, motor, and cerebellar functions appeared normal in each, although the older used only 10 words at age three. Skeletal radiographs were unremarkable.

Parental consanguinity was denied, although both parents were from a small village near Sabinas, Mexico. Autosomal recessive inheritance is likely. The possibility of this being a trichothiodystrophy exists because cleft lip-palate has been reported (2).

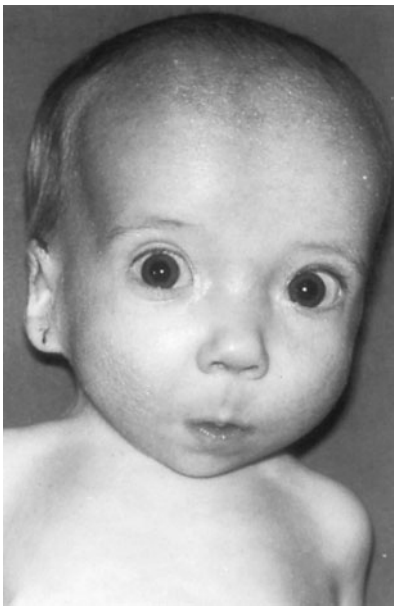

Fig. 22–27. *Cleft palate, dysmorphic facies, and digital defects*. Child has cleft palate, micrognathia, and rhizomelic dwarfism. [From J Martsolf et al, Syndrome Ident 5(1):14, 1977.]

Cleft palate, dysmorphic facies, and digital defects

Martsolf et al (1), in 1977, reported a male infant with a rhizomelic dwarfism, polydactyly, and Robin sequence. Length at birth was below the third centile.

At 18 months, he had a prominent, square forehead, the anterior fontanel was still widely patent with apparent hypertelorism and marked micrognathia (Fig. 22–27).

The thumbs were broad with varus deflexion, and there was hypoplasia of the third and fifth middle phalanges and absence of the middle phalanx of the index fingers (Fig. 22–28). The halluces were broad with valgus deflexion and there was bilateral postaxial hexadactyly of the feet (Fig. 22–29). Radiographic studies showed reversal of normal curvature of the spine, increased sacral angle, abnormal acetabula, short tubular bones, and tibial bowing.

Fig. 22–28. *Cleft palate, dysmorphic facies, and digital defects*. Broad thumb with varus deflection. Index finger is short because of agenesis of middle phalanx. Note single palmar flexion crease. [From J Martsolf et al, Syndrome Ident 5(1):14, 1977.]

Fig. 22–29. *Cleft palate, dysmorphic facies, and digital defects*. Postaxial hexadactyly. [From J Martsolf et al, Syndrome Ident 5(1):14, 1977.]

We were not able to place this in any of the *oral-facial-digital syndromes*.

Reference (Cleft palate, dysmorphic facies, and digital defects)

1. Martsolf JT et al: Case report 56: Skeletal dysplasia, Robin anomalad, and polydactyly. Syndrome Ident 5(1):14–18, 1977.

Cleft palate, ectodermal dysplasia, growth failure, and apparent pancreatic insufficiency

Donlan (1) described a brother and sister with V-shaped cleft palate, relative micrognathia, growth failure, eczema, and apparent pancreatic insufficiency (Fig. 22–30). There was diarrhea with absence of stool trypsin. The skin appeared thin and there was a deficiency of teeth and enamel hypoplasia. Inheritance is probably autosomal recessive. In spite of overlap of signs and symptoms, there was no facial resemblance to *Johanson-Blizzard syndrome*.

Reference (Cleft palate, ectodermal dysplasia, growth failure, and apparent pancreatic insufficiency)

1. Donlan MA: Growth failure, cleft palate, ectodermal dysplasia and apparent pancreatic insufficiency—a new syndrome. Birth Defects 13(3B):230–231, 1977.

Cleft palate, eye coloboma, short stature, hypospadias, and mixed hearing loss (Abruzzo-Erickson syndrome)

In 1977, Abruzzo and Erickson (1) described a syndrome of cleft palate, coloboma of the eye, hypospadias, short stature, radial synostosis, and mixed hearing loss in two male sibs and their mother's brother.

Three affected males with minor stigmata in carrier females suggests X-linked inheritance.

Stature was below the 3rd centile in all three. Adult height in the maternal uncle was 5 feet.

The face tended to be flat with the pinnae long and soft. Cleft palate was present in both sibs and a submucous cleft palate was evident in the uncle. Sensorineural hearing loss was noted at 20 years in the uncle. It was progressive and severe at 34 years. Both sibs had 10–25 dB sensorineural loss and a greater conductive loss attributed to many middle ear infections

A B

Fig. 22–30. *Cleft palate, ectodermal dysplasia, growth failure, and apparent pancreatic insufficiency*. (A,B) Sibs affected with cleft palate, short stature, mild micrognathia, diarrhea with absence of stool trypsin. Teeth were deficient in number and enamel. [From MA Donlan, Birth Defects 13(3B):230, 1977.]

secondary to cleft palate. Colobomas of the iris, choroid, and retina were found in both sibs.

Radial synostosis was noted in the uncle and in one sib. There was wide spacing between the second and third metacarpals and some ulnar deviation of index fingers.

Hypospadias of varying degree was present in all three affected individuals. Cryptorchidism was noted in the uncle. A horseshoe kidney was found in one sib.

Several of the stigmata are found in *CHARGE association* (3–5). Abruzzo and Erickson (2) have argued convincingly that because their patients did not have choanal atresia, retarded development, or genital hypoplasia, they did not have familial CHARGE association.

Cleft palate, hypotonia, and mental retardation

Davis and Lafer (1) reported a brother and sister with cleft palate, mental retardation, hypotonia, failure to thrive, frontal bossing, and epicanthal folds. The male sib had hypospadias, cryptorchidism, and inguinal hernias.

Reference (Cleft palate, hypotonia, and mental retardation)

Cleft palate, microcephaly, large ears, and short stature (Say syndrome)

Say et al (5) reported a dominantly inherited syndrome of cleft palate associated with microcephaly, large pinnae, and short stature affecting four members of a family (Fig. 22–31). The mother and her sister had distally tapering fingers with hypoplastic distal phalanges of the second and fourth digits bilaterally, ulnar deviation of the middle fingers, low-set thumbs, and bilateral acromial dimples.

The proband also had ptosis, hypospadias, delayed bone age, and developmental delay. A patient seen by Abu-Libdeh et al (1) had sparse scalp hair, delayed bone age, and proximal renal tubular acidosis with cystic dysplasia of the kidneys in addition to the cardinal features. Ashton-Prolla and Félix (2), Guion-Almeida et al (3), and Pagnan et al (4) have reported similar findings. In all, approximately eight cases have been tabulated to date.

Cleft palate, microcephaly, mental retardation, and musculoskeletal mass deficiency (Weaver-Williams syndrome)

Weaver and Williams (1) described male and female sibs with mental retardation, microcephaly, unusual facies, and cleft palate. Autosomal recessive inheritance is possible.

There was marked deficiency in muscle mass (Fig. 22–32A,B). Weight was −4 SD. Height was less significantly reduced. Head circumference was −5 SD, but because the facial bones were small, it did not appear severe. There was midface hypoplasia and the mouth was small and downturned. The neck was long and was held in an extended position (Fig. 22–32C,D). The incisors had a somewhat conical crown form.

Both sibs manifested moderate to severe mental retardation with incomprehensible speech.

The limbs were extremely thin. The fingers exhibited clinodactyly.

Radiographically, there was generalized bone hypoplasia with increased tubulation, tall narrow vertebral bones, downward sloping ribs, short ulnas and fibulas, and delayed bone age (Fig. 22–33).

Reference [Cleft palate, microcephaly, mental retardation, and musculoskeletal mass deficiency (Weaver-Williams syndrome)]

Cleft lip-palate, hypospadias, and inguinal hernia

RJ Gorlin has seen two male siblings with the following findings: large anterior fontanel, patent posterior fontanel, superficial capillary angioma of forehead, mild hypertelorism, absent eyebrows, small palpebral fissures, cleft lip and palate in one sib, cleft palate in the second, broad nasal base, hypospadias, large inguinal hernia, and atrial septal defect in both. One sib died at the age of 4 months and the other at 2 weeks from infection. Only one of the sibs had the following: two-vessel cord, metatarsus adductus, digitalized thumbs, proximally placed thumbs, bilateral coloboma of iris, unilateral ear tags, and double urinary collecting system. We were unable to find any additional examples of this syndrome in the literature.

Cleft palate, stapes fixation, and oligodontia

Gorlin et al (1) described two sisters, the offspring of a consanguineous marriage, who had stapes fixation, cleft palate, and oligodontia (1). Neither girl had ever had more than three or four deciduous teeth, and those had conical crown form. No permanent teeth were ever present, and alveolar ridges were absent.

There was coalition of all cuneiform bones, as well as coalition of the navicular and talus, the talus and calcaneus, and the first cuneiform with the first metatarsal. The talus was malformed, having a superior and medial hump. The carpal navicular was sharply wedge-shaped, lacking its normal convexity (Fig. 22–34).

Cleft palate, unusual facies, conductive hearing loss, and male pseudohermaphroditism

Ieshima et al (1) described male and female sibs with cleft of the soft palate, intrauterine growth retardation and failure to thrive, severe mental retardation, microcephaly, hypotonia, repeated respiratory infections, conductive hearing loss, and pulmonary hypertension with PDA.

A B

Fig. 22–35. *Cleft palate, unusual facies, conduction hearing loss, and male pseudohermaphroditism.* (A,B). One of two sibs having hypertelorism, arched eyebrows, broad flat nasal bridge, profound hearing loss, severe psychomotor retardation, cleft palate, and short neck. (From A Ieshima et al, Clin Genet 30:136, 1986.)

The facies was characterized by asymmetry, arched eyebrows, hypertelorism, broad nasal bridge, small nose, anteverted nostrils, microtia, and micrognathia (Fig. 22–35).

The male had hypospadias, micropenis, cryptorchidism, and shawl scrotum (Fig. 22–36).

Inheritance is probably autosomal recessive.

Reference (Cleft palate, unusual facies, conductive hearing loss, and male pseudohermaphroditism)

1. Ieshima A et al: Peculiar facies, deafness, cleft palate, male pseudohermaphroditism, and growth and psychomotor retardation: A new autosomal recessive syndrome? Clin Genet 30:136–141, 1986.

Cleft palate, unusual facies, mental retardation, and limb abnormalities

Palant et al (1) described two sisters with mild microcephaly, short stature, severe mental retardation, almond-shaped upslanting deep-set eyes, bulbous nasal tip, cleft palate, clinodactyly of toes, and firm nonbony prominence of the anteromedial aspect of the wrists. The syndrome possibly has autosomal recessive inheritance (Fig. 22–37).

Fig. 22–36. *Cleft palate, unusual facies, conduction hearing loss, and male pseudohermaphroditism.* Male pseudohermaphroditism (hypospadias, micropenis, cryptorchidism, small scrotum). (Courtesy of A Ieshima, Yonago, Japan.)

Cleft palate, ventricular septal defect, persistent truncus arteriosus, and intrauterine death

Lowry and Miller (1) noted sibs with cleft palate, persistent truncus arteriosus, and abnormal right pulmonary artery. The left pulmonary artery came off the truncus. Presumably the syndrome has autosomal recessive inheritance.

Reference (Cleft palate, ventricular septal defect, persistent truncus arteriosus, and intrauterine death)

1. Lowry RB, Miller JR: Cleft palate and congenital heart disease. Lancet 1:1302–1303, 1971.

Cleft uvula, conductive hearing loss, nephrosis, congenital urinary tract, and digital anomalies

The syndrome was found by Braun and Bayer (2) in five of seven boys and in none of five girls in a sibship. Inheritance appears to be X-linked or, less likely, autosomal recessive.

The hearing defect proved to be a conductive deficit in all but one child who had mixed hearing loss. The digital anomaly consisted of shortening and broadening of the distal portion of the thumbs and great toes. Radiographic examination revealed that the distal phalanges were rudimentary with bifid ends. The urinary tract anomalies present in two children were bandlike constrictions of the ureter and duplication of the renal pelvis and ureter. The nephrosis appeared in infancy.

The uvula was bifid in two of five affected males. This appears to be statistically significant, since the prevalence of bifid uvula in whites is approximately 1 in 100.

Four male sibs were reported by Bakarat et al (1) with nephrosis, sensorineural hearing loss, and hypoparathyroidism. However, this appears to be a different disorder.

2. Braun FC Jr, Bayer JF: Familial nephrosis associated with deafness and congenital urinary tract anomalies in siblings. J Pediatr 60:33–41, 1962.

Cleft uvula, preaxial and postaxial polysyndactyly, and somatic and motor retardation

Engelhard and Yatziv (1) reported a male with short stature, microcephaly, psychomotor retardation, eyelid ptosis, stenosis of lacrimal points, asymmetric manual preaxial and postaxial polysyndactyly, brachyphalangy, and kyphosis (Fig. 22–38). The uvula was bifid. The mandibular incisors were fused.

The parents were cousins. The authors considered acropectorovertebral (F) syndrome (2) in differential diagnosis.

Fig. 22–39. *Congenital myopathy, malignant hyperthermia, and cleft palate*. (A,B) Two children of Lumbee Indian extraction exhibiting congenital myopathy, malignant hyperthermia, scoliosis, and cleft palate. Note eyelid ptosis and facial resemblance of child shown in B to that of Noonan syndrome. (From CR Stewart et al: Pediatr Neurol 4:371, 1988.)

Congenital myopathy, malignant hyperthermia, and cleft palate

Stewart et al (8) reported six children of similar ethnic origin (Lumbee Indians of south central North Carolina) with congenital myopathy, malignant hyperthermia, skeletal anomalies, and cleft palate (Fig. 22–39). Affected sibs suggest autosomal recessive inheritance.

The facies was characterized by myotonia and eyelid ptosis. The mouth appeared small.

Musculoskeletal anomalies consisted of short stature, generalized weakness, myotonia, congenital kyphoscoliosis, and talipes. Tendon reflexes were hypoactive to absent. Plantar responses were flexor. The hyperthermia makes anesthesia hazardous.

This disorder has marked overlap with King syndrome (short stature, motor delay, slowly progressive myopathy, downslanting palpebral fissures, posteriorly rotated pinnae, mandibular hypoplasia, scoliosis, pectus carinatum, cryptorchidism, and susceptibility to malignant hyperthermia), a sporadic disorder (3,4,6,7). Cleft palate is not a frequent component of King syndrome. King syndrome, in turn, has been alleged to be a subset of *Noonan syndrome* (1), but we remain skeptical of creating a separate nosologic status although we recognize the hazard that hyperthermia creates for anesthesia.

Malignant hyperthermia appears to be a genetic heterogeneity, one gene was mapped to 19q13, another to 17q and a third to neither (2,5).

Crane-Heise syndrome (cleft lip-palate, agenesis of clavicles and cervical vertebrae, and talipes equinovarus)

Crane and Heise (2) described three sibs having disproportionately large head, small face, hypertelorism, low-set dysmorphic pinnae, depressed nasal bridge with upturned nares, micrognathia, cleft lip and/or cleft palate, and short neck (Fig. 22–40).

In addition, they had intrauterine growth retardation, partial soft tissue syndactyly of the second to fourth fingers and toes, talipes equinovarus, short penis, and cryptorchidism. Radiographic studies revealed poorly mineralized calvaria, apparently absent cervical vertebrae and clavicles, small scapulae, and dislocated radial heads (Fig. 22–41).

Agenesis of the corpus callosum was noted in one sib and single palmar creases in two sibs. This apparently lethal syndrome probably has autosomal recessive inheritance.

Several other patients have been described as resembling Crane-Heise syndrome. Barnicoat et al (1) described a male fetus, the product of consanguineous parents. The child had all of the anomalies save that of cranial bone defects. Another is a male, reported by Weaver and Johnson (3), currently approximately 18 years of age. His parents are not consanguineous. Findings included deficient mineralization, disproportionately large head, hypoplastic clavicles, cleft lip-palate, downslanting palpebral fissures, hypertelorism, unusual pinnae, talipes equinovarus, radial head dislocation, genital hypoplasia, cryptorchidism, and severe growth retardation. Intelligence is almost normal.

We do not see any resemblance to *aminopterin embryopathy*.

Genito-palato-cardiac syndrome (Gardner-Silengo-Wachtel syndrome)

Greenberg et al (5) coined the term genito-palato-cardiac syndrome to describe a disorder of cleft palate, male pseudohermaphroditism (46,XY gonadal dysgenesis), and conotruncal anomalies. They cited a number of earlier cases (1,3,4,6–9) as examples of the disorder. Inheritance is probably autosomal recessive (1).

There has been debate as to whether this is a disorder separate from severe *Smith-Lemli-Opitz* syndrome, (3). Opitz and Lowry (6) have reserved judgment. Determination of 7-dehydrocholesterol levels should settle the debate.

Most of the infants succumbed during the neonatal period.

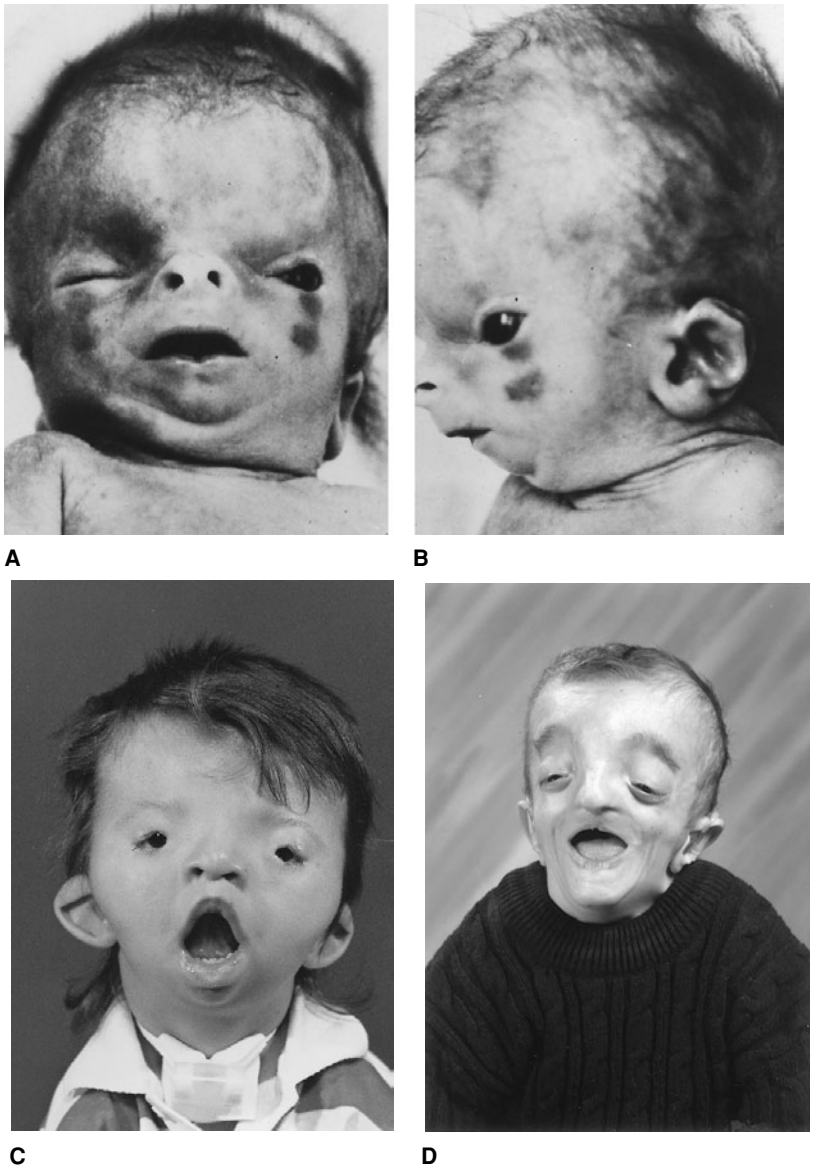

Fig. 22–40. *Crane-Heise syndrome*. (A,B) Postmortem view of one of three sibs showing large head, depressed nasal bridge with anteverted nares, apparent hypertelorism, hypoplastic helices, and short neck. (C) Five-year-old. (D) Fourteen-year-old. Note similarity in facial phenotype. (A,B from JP Crane and RL Heise, Pediatrics 68:235, 1981. C courtesy of M Lubinsky and A Denny, Milwaukee, Wisconsin. D courtesy of B Guzzo, Evansville, Indiana.)

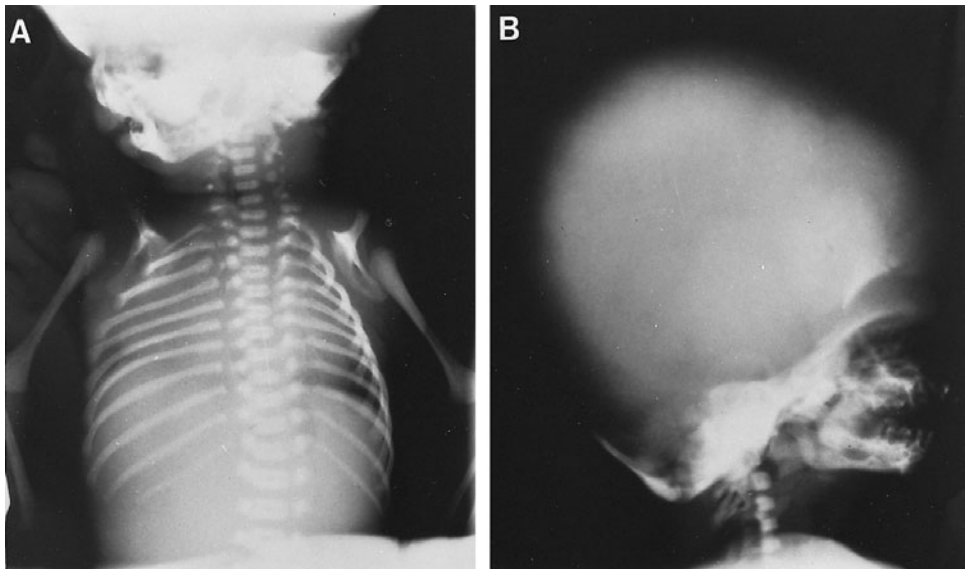

Fig. 22–41. *Crane-Heise syndrome*. (A,B) Note hypoplasia of cervical vertebrae, absent clavicles, small scapulae, markedly deficient mineralization of calvaria. (From JP Crane and RL Heise, Pediatrics 68:235, 1981.)

Hydrocephalus was found in two cases (5,9). A few manifest downslanting palpebral fissures. The pinnae were low set in nearly all cases. Cleft palate (1,2,4,5,8,9) or cleft lip (5) and micrognathia were virtually constant findings.

Musculoskeletal defects included flexion deformities of thumb and great toes (5), camptodactyly (7), dysplastic ribs (7), postaxial polydactyly (2), prominent heels (2), and clubfeet (7,9). Congenital heart defects such as double outlet right ventricle and/or VSD, right aortic arch, transposition of great vessels, and tetralogy of Fallot were documented (1,2,5).

Although the phenotypic sex is nearly always female, the chromosomal sex is 46,XY. Thus, there is sex reversal. Hypospadias was found in one infant with a male phenotype (5). The genitalia have usually been normal female with rare exception, when gonadal dysgenesis has been found (2,8). Miscellaneous abnormalities have included cystic kidneys (5), dysgenesis of urinary bladder (5), agenesis of gall bladder (5), and intestinal malrotation (5).

Cleft palate, camptodactyly, and clubfoot (distal arthrogryposis, type 3; Gordon syndrome)

Gordon et al (6) first recognized the syndrome of camptodactyly, talipes, and cleft palate. Several additional families have been described (8,10,11,13,14,16). The classification of the distal arthrogryposes by Hall et al (9) was updated by Bamshad et al (2) in 1996, and Gordon syndrome was classified as type 3. The patient reported by Bijlsma (3) also had spasticity and mental retardation and cannot be accepted as a valid example of this disorder. The patients reported by McCormack et al (12), Sack (15), Gripp et al (7), Bocian et al (4), Boles (5), and Sweet and Seaver (17) probably have Gordon syndrome, and perhaps even the patient described by Al-Chamdi et al (1).

There is autosomal dominant inheritance with variable expressivity and incomplete penetrance, possibly being more reduced in females.

The camptodactyly affects only the PIP joints, sparing the thumbs. Cleft palate occurs in approximately 20%. Other patients have exhibited submucous cleft palate or bifid uvula.

Additional components of the syndrome appear to be short stature, hip dislocation, various vertebral abnormalities (lumbar lordosis, kyphoscoliosis), and short neck with mild pterygia. Some patients have ptosis of eyelids, epicanthal folds, and nevus flammeus of the face (9,13,14,16). Cryptorchidism may be part of the syndrome (5,14).

One must exclude Tel Hashomer syndrome (11).

Distal arthrogryposis, unusual facies, cleft lip with/without cleft palate, short stature, hydronephrosis, and normal intelligence

Sonoda and Kouno (1) reported two brothers with joint contractures of the distal limbs, an unusual facies characterized by marked hypertelorism, and blepharophimosis, one with cleft lip, the other with cleft lip and palate, short stature, hydronephrosis, undescended testes, and normal intelligence. Although the authors suggested that they represented a form of *oto-palato-digital syndrome*, we disagree, and further suggest that it represents a new entity.

Cleft palate, micrognathia, talipes equinovarus, atrial septal defect, and persistence of left superior vena cava

Gorlin et al (1,2) presented a kindred exhibiting cleft palate, micrognathia, talipes equinovarus, atrial septal defect, persistence of the left superior vena cava, a cardiac conduction anomaly, and death in infancy. The occurrence of the syndrome in several male children of sisters suggests X-linked recessive inheritance.

It is possible that other examples have been reported. Smith and Stowe (4), in their survey of 39 patients with Robin sequence, noted that 5 died of congenital heart anomaly and that 3 had clubfeet. No mention was made of the sex of the affected. Sachtleben (3) described a male infant with ASD of the primum type, cleft palate, inguinal hernia, and talipes equinovarus. He further noted two brothers with this combination.

Kabuki (Niikawa-Kuroki) syndrome

In 1981, Niikawa et al (34) and Kuroki et al (24) independently reported a syndrome characterized by mild to moderate mental retardation, postnatal progressive growth retardation, and strikingly unusual facies reminiscent of the make-up used in Kabuki theatre (15). An estimate of frequency is 1 per 32,000–50,000 liveborn (11,35). Approximately 200 examples have been reported, approximately one-third in non-Japanese (1,48). There is currently favor for the term "Kabuki syndrome."

Almost all cases reported to date have been isolated examples. However, it has been described in two generations (6a,14,18,21,43,45). The majority of reported patients have been Japanese. There is no sex predilection (42). We suspect that the condition is just more difficult to diagnose in non-Japanese (2,4,13,14,19,21,23,31,33,37,39,42,48).

Craniofacial findings. Perhaps 30% have some degree of microcephaly (15,39). The palpebral fissures are long (100%) with eversion of the lateral third of the lower eyelid (90%). (Fig. 22–42A–C). Ptosis has been noted in 35%. The eyebrows are arched (80%) and tend to be diminished laterally. The lashes are heavy and long. The sclerae are blue in 30%. Strabismus and epicanthal folds are present in 50%–60% (20a). Nocturnal lagophthalmos is noted in 50% (H. Toriello, personal communication, 2000). The pinnae are large, outstanding, and poorly folded in 80%. The nose is broad with a depressed tip (80%) and/or short septum (90%) (Fig. 22–42A,B). The teeth are widely spaced in 65%. Cleft lip and/or cleft palate or submucous cleft palate have been found in 40% (3,26,48). The philtrum is prominent and broad. The occipital hairline is often low. One-third have retrognathia. There is often an exaggerated depression below the midpoint of the lower lip. Lower paramedian lip pits have been reported (7,9,22,29) but were shown to be unrelated to the van der Woude mutation (29). Hypodontia, missing mandibular incisors, and incisors with conical crown form or screw-driver shape have been noted in a patient (27,30a,32).

The ears are large and outstanding with prominent lobules in 85%. The anthelix tends to be hypoplastic. Approximately 25% have a pretragal pit. Otitis media is extremely frequent during childhood (60%), and there is hearing loss in 40% (20,35,41–44). The ossicles may rarely be severely malformed (37), and Mondini dysplasia of the cochlea has been found in at least 30% (16a,39).

Skeletal system. Frequent anomalies include short stature (80%), short fifth fingers (80%), scoliosis (30%), congenital sagitally-cleft vertebrae (35%), dislocation of hip (20%), various rib anomalies (20%), and spina bifida occulta (15%) (11,34). Hypermobile joints (75%) may be more common in non-Japanese (13,17,31,38,39). Hypoplastic clavicles have been noted (10).

Neurologic findings. Microcephaly is documented in 25%. Mental retardation has been found in over 90% (26,48). Approximately 30% exhibit hypotonia, 75% have joint laxity, and 75% have feeding problems (6a,42). Seizures are seen in 50% (20,48). Mirror image movements of the extremities may be seen (46). A subarachnoid cyst has been noted (6). Poor feeding in infancy is noted in 40% (20,48).

Cardiovascular system. Congenital heart abnormalities have been reported in approximately 55%: ASD, VSD, single ventricle with common atrium, PDA, and juxtaductal coarctation of the aorta (6b,7,16, 20,24,36).

Integumentary system. There is persistence of fetal fingertip pads in approximately 80% (2,4,48) (Fig. 22–42D). Dermatological findings include increased ulnar loops and hypothenar loop patterns (70%) and absent digital triradius *c* and/or *d* (11,21). Trichorrhexis nodosa and hypoplastic nails have been reported (6a,27).

Anogenital and endocrine findings. Early breast development in females and/or elevated gonadotropin levels have been described in 35% (3,9,25,45) (Fig. 22–42E). Approximately 15% have imperforate anus, anal stenosis, or anovestibular fistulae (3,22,30,35). Turner syndrome or ovarian dysfunction has been noted in two cases (37,47), male pseudohermaphroditism in another (12). The mother of a patient was a Turner mosaic (46). Hypospadias has also been reported (13) in 15%. Neonatal hypoglycemia has been described in 40% (1,3,35,48). Growth hormone deficiency has also been described (10a,40).

Immunodeficiency. There have been isolated reports of immunodeficiency (1,5,8). Approximately 60% have increased infections in childhood (48).

Miscellaneous. Extrahepatic biliary atresia has been found in two patients (7,30b,42a,45a). Neonatal sclerosing cholangitis and dysplastic kidneys have also been described (8). Diaphragmatic defects apparently are more frequent in non-Asians (6c,39,43,45a).

Diagnosis. A Kabuki-like syndrome has been found in association with pseudodicentric chromosome 13(28).

Cleft palate-lateral synechiae syndrome

Unilateral or bilateral bands may extend from the edges of a palatal cleft to the lateral margins of the tongue or oral floor (Fig. 22–43). Several authors have reported autosomal dominant inheritance with variable expressivity for this syndrome (1–5). RJ Gorlin has seen the disorder in two generations. Also see *syngnathia and cleft palate*.

Preus et al (7) emphasized the variable expression of the disorder. Nakata et al (6) reported three cases, two being sibs whose parents were normal and nonconsanguineous. In addition to the usual findings, they noted short stature, microcephaly, long upslanting palpebral fissures, and prominent pinnae. Mild mental retardation was documented in two patients (3,6). L Sadler (personal communication, 1999) found that VSD was an associated finding. Fernandez et al (2a) noted recto-vaginal fistula. Although the sibs described by Nakata et al (6) may represent a new syndrome, the variable expressivity of the syndrome and the possibility of gonadal mosaicism do not make this likely. Dinardo et al (2) used the term "cleft palate lateral synechia syndrome," but they referred to a child with *syngnathia and cleft palate*.

Posterior palatal synechiae and cleft palate

The buccopharyngeal membrane is an evanescent structure that undergoes dissolution in the 4th embryonal week. It separates the primitive mouth from the oral pharynx. In a few cases, there has been membranous extension of the cleft palate to the base of the tongue (1,2,3,5–9,11) (Fig. 22–44). All examples have been isolated. It has been suggested that this represents persistence of the buccopharyngeal membrane. We are skeptical, given that the tongue develops behind the buccopharyngeal membrane. Cases of subglossopalatal membrane and cleft palate (8,10–13) appear to be more legitimate examples of persistence of the membrane. Associated anomalies included ankylosis of the distal interphalangeal joints of the fifth fingers, absence of the distal phalanx of the fifth toes (10), toenail hypoplasia, umbilical hernia, and hypospadias (13). Seghers (11), Flannery (6), and RJ Gorlin have seen associated rib and vertebral changes similar to those in *cerebro-costo-mandibular syndrome*. Complete failure of development of the mandible has been associated with cleft palate and persistence of the buccopharyngeal membrane (4). We do not know how to classify the patient described by Wassermann (12).

One must exclude *Holzgreve-Wagner-Rehder* syndrome (bilateral renal agenesis, buccopharyngeal membrane, cleft palate, congenital heart anomalies, mesoaxial hexadactyly, and bifid metacarpal) as a single entity. Several examples have been reported (2, 8,10).

Lethal omphalocele and cleft palate

Czeisel (1) reported three female sibs with cleft palate and omphalocele. One sib had a bicornuate uterus, another internal hydrocephalus, and the third a hypoplastic uterus. The parents were nonconsanguineous. All three children died in infancy presumably from pneumonia.

Lymphedema of pubertal onset and cleft palate

Figueroa et al (3) reported the association of lymphedema of pubertal onset (Meige type) with cleft palate. Inheritance is probably autosomal dominant with variable expressivity (2,4,6,7,12). The lymphedema is largely limited to the legs (Fig. 22–45). The arms, hands, and feet may also be involved. Among the latter group, the genitalia and intestines are more commonly affected. The etiology is thought to be hypoplasia or late development of the superficial lymphatic channels that inhibits effective drainage of a body part. There are many syndromes that involve lymphedema (microcephaly, distichiasis, yellow nails, ptosis, partial lower eyelid ectropion, spinal extradural cysts, vertebral anomalies, *Noonan syndrome, Turner syndrome*, etc.) (8,10,11). The patients reported by Jester (7) and Bartley and Jackson (2) also had distichiasis of the upper eyelids. *Hennekam syndrome*, which should be excluded, has autosomal recessive inheritance. Irons et al (5) described an autosomal recessive syndrome in sibs with lymphedema, hydroceles, atrial septal defect, and facial changes (epicanthic folds, wide nasal bridge). Anderson et al (1) reported associated lymphangiosarcoma.

The lymphedema-distichiasis gene, *MFH1*, maps to 16q24.3 (9) as does the gene for distichiasis-lymphedema-cleft palate (1a,2a).

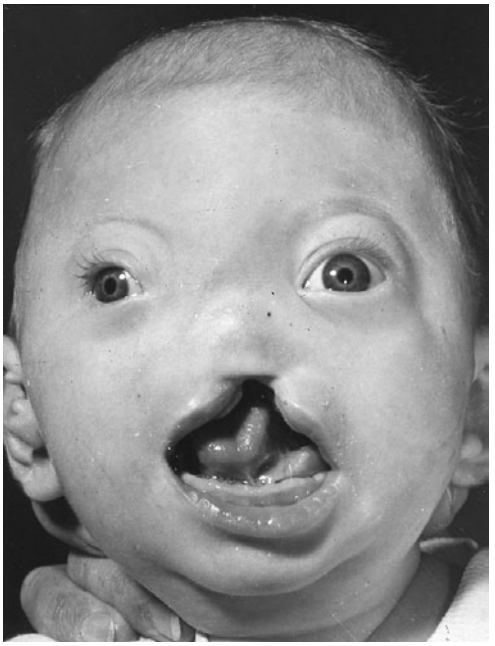

Fig. 22–46. *Median cleft upper lip, hypertelorism, and holoprosencephaly*. Median cleft upper lip and palate. (From WE Bell and WM Van Allen, Neurology 9:694, 1959.)

Median cleft upper lip, hypertelorism, and holoprosencephaly

Bell and Van Allen (1) described an infant with marked hypertelorism and unusual median cleft lip with cleft palate. There were microcephaly, agenesis of the corpus callosum, and ear tags (Fig. 22–46).

In what may be a second example, Ohtsuka (4) reported an 11-year-old female with hypertelorism and similar facial abnormalities. The child had seizures since birth and unilateral microphthalmos. Hydranencephaly and holoprosencephaly were demonstrated. Cleft palate was also present. Arthrogryposis was probably secondary to central nervous system alterations. Bony abnormalities included lumbar scoliosis, bilateral dislocation of hips, underdeveloped pelvic bones, and slender femora.

Both were isolated cases but consanguinity was documented by Ohtsuka (4). Hypertelorism is also known to be associated with semilobar holoprosencephaly with *del(18q)* and with *frontonasal malformation*. See *holoprosencephaly* for more detail. The combination of holoprosencephaly and hypertelorism has been described by Hartsfield et al (2) and Moore et al (3).

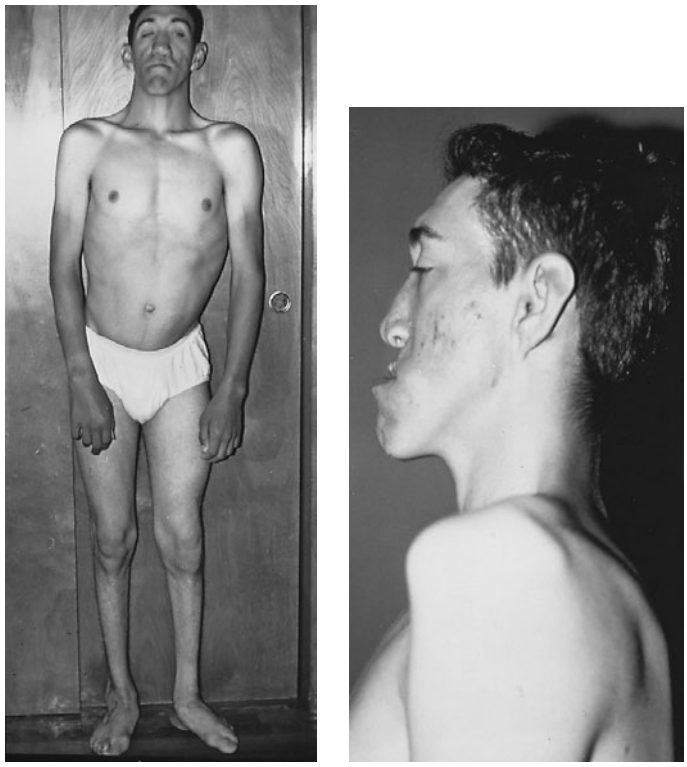
Median cleft upper lip, mental retardation, and pugilistic facies (W syndrome)

Pallister et al (4) described a mother and three children. The mother was reported by Bottani and Schinzel (1). The disorder may have X-linked dominant inheritance (2).



A B

Fig. 22–47. *Median cleft upper lip, mental retardation, and pugilistic facies (W syndrome)*. (A,B) Note frontal prominence, internal strabismus, flattened nasal bridge, midline notch of upper lip. Compare with Fig. 22–48. Although facies are similar, this probably is not the same disorder. The latter appears to have *cleft lip-palate, mental retardation, and holoprosencephaly syndrome*. [From PD Pallister et al, Birth Defects 10(7):51, 1974.]

The facies was characterized by high broad forehead, anterior cowlick, hypertelorism, downward slanting palpebral fissures, and alternating internal strabismus (Figs. 22–47 and 22–48). The nasal bridge was flattened. The upper lip had a midline notch because of a bifid frenum (Fig. 22–49). The hard palate exhibited anterior palatal cleft, and all probably had submucous cleft palate. The upper central incisors were missing.

Mental retardation, seizures, and mild spasticity were noted in a few individuals.

Musculoskeletal anomalies consisted of hernias, cubitus valgus with subluxation of the proximal radioulnar joints, lateral bowing of the radii, short ulnae, mild clinodactyly and camptodactyly of the fourth and fifth fingers, and pes cavus.

All had acne.

The syndrome should be differentiated from *otopalatodigital syndrome, Type I*, autosomal dominant *holoprosencephaly*, and *cleft lip-palate, microcephaly, mental retardation, and holoprosencephaly* (3).

Michels syndrome (oculopalatoskeletal syndrome; blepharophimosis-ptosis, inverse epicanthus, anterior segment anomalies, craniosynostosis, and cleft lip-palate)

Michels et al (5), in 1978, described four sibs, three brothers and a sister, with anterior chamber eye anomalies, other craniofacial anomalies, and skeletal defects. Added information was supplied by de la Paz et al (3). Other examples are those of Guion-Almeida and Rodini (4), Cunniff and Jones (2), and possibly those of Al Gazali et al (1). Inheritance is clearly autosomal recessive (1–6).

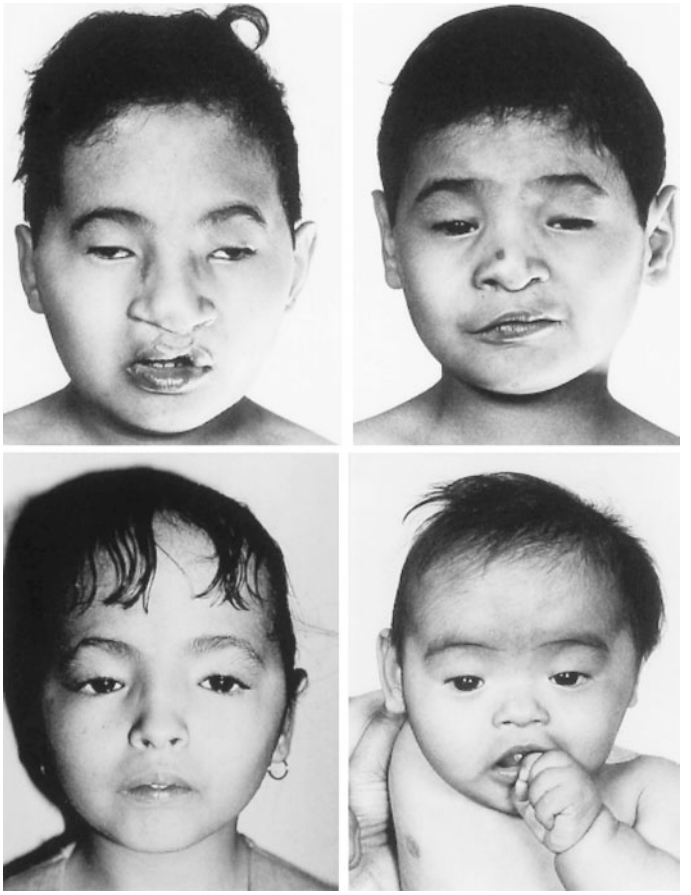
Height was generally below the 3rd centile as was head circumference (5). In some there was prenatal growth retardation (1,5). Mild mental retardation has been evident (3,5).

Eye anomalies seen in all affected included blepharoptosis, blepharophimosis, and inverse epicanthus. Mild hypertelorism, limited upward gaze, and corneal stromal opacities were noted in 65% (Figs. 22–50 and 22–51). The eyebrows were highly arched in 50%. Craniosynostosis of the lambdoidal sutures was observed in 60% (2–5). Cleft lip and palate were found in approximately 50% (2–5). Conductive hearing loss was noted in 80% (3,4).

Short clinodactylous fifth finger was present in most patients. Less common anomalies included radioulnar synostosis (3,5), arachnodactyly (1), long bowed fibulae (5), and talipes (5).

Fig. 22–49. *Median cleft upper lip, mental retardation, and pugilistic facies (W syndrome).* Midline cleft of upper lip, deep anterior palatal groove. [From PD Pallister et al, Birth Defects 10(7):51, 1974.]

Fig. 22–50. *Michels syndrome*. Blepharoptosis, blepharophimosis, and epicanthus inversus. Note repaired cleft lip in upper two patients. (From VV Michels et al, J Pediatr 93:444, 1978.)



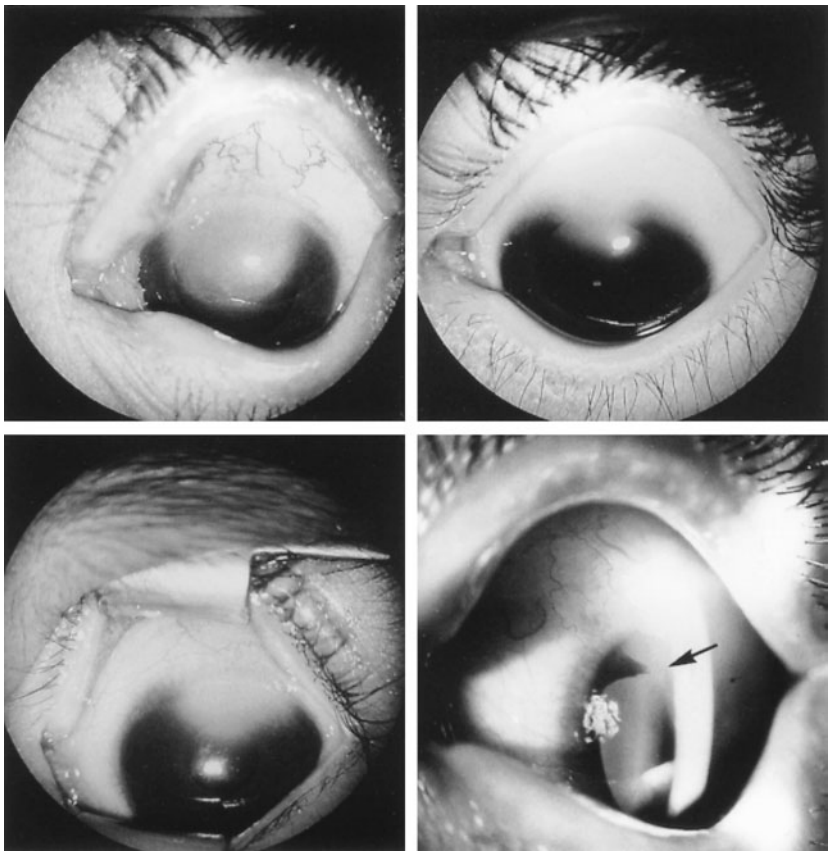


Fig. 22–51. *Michels syndrome*. Corneal opacities. Arrows point to iris adhesion in lower right. (From VV Michels et al, J Pediatr 93:444, 1978.)

An umbilical depression was noted in 70% (4,5).

The triad of *blepharophimosis, blepharoptosis, and inverse epicanthus* is a well-recognized autosomal dominant syndrome (eye triad) that has been mapped to 3q22.3. Also to be excluded are *Peters Plus syndrome* characterized by anterior segment eye anomalies, cleft lip and palate, and mental retardation but no anomalies of the skeleton other than short stature and brachydactyly.

Al Gazali et al (1) noted that the eye triad was absent in their patients. Some skeletal anomalies and congenital heart anomalies were found. They suggested that it may represent a different entity.

Microcephaly and cleft palate

Halal (1) reported cleft palate and microcephaly in two sisters and their mother. The facies was somewhat unusual. There was mild hypotelorism and maxillary hypoplasia.

Abnormal retinal pigmentation with normal electroretinogram (ERG) findings was demonstrated. The microcephaly was at approximately the third centile. Mental retardation was mild. The mother had euthyroid goiter and bilateral camptodactyly at the DIP joints of fingers 2 to 5.

A similar combination of autosomal dominantly inherited cleft palate and microcephaly was reported by Say et al, but the patients also had short stature and large pinnae (see *Cleft palate, microcephaly, large ears, and short stature*). Microcephaly, mental retardation, persistent primary vitreous, and short stature have been reported as a recessive syndrome by Frydman (see *Oculo-palato-cerebral dwarfism*).

Reference (Microcephaly and cleft palate)

1. Halal F: Dominantly inherited syndrome of microcephaly and cleft palate. Am J Med Genet 15:135–140, 1983.

Oculo-palato-cerebral dwarfism

Frydman et al (1), in 1985, described a syndrome in three children of consanguineous parents. The syndrome consisted of cleft palate, microcephaly, mental retardation, spasticity, short stature, asthma, and persistent hypertrophic primary vitreous of the eye. Inheritance appears to be autosomal recessive.

Gestational hypertension was noted with all three sibs. Birthweight was approximately −2 SD. Stature fell to −2.5 to −4 SD. Hypotonia was noted in the neonatal period.

The facies was characterized by coarse hair, full cheeks, and deeply set eyes (Figs. 22–52 and 22–53). Hands and feet were small. The joints were mildly hypermobile. The skin was soft with a doughlike texture. The veins were visible beneath the skin.

Leukocoria became evident during the first month of life. Primary persistent hyperplastic primary vitreous and microphthalmia were evident.

Mental retardation ranged from mild to severe with microcephaly −3 to 5.5 SD. Spasticity ranged from a moderate degree to complete

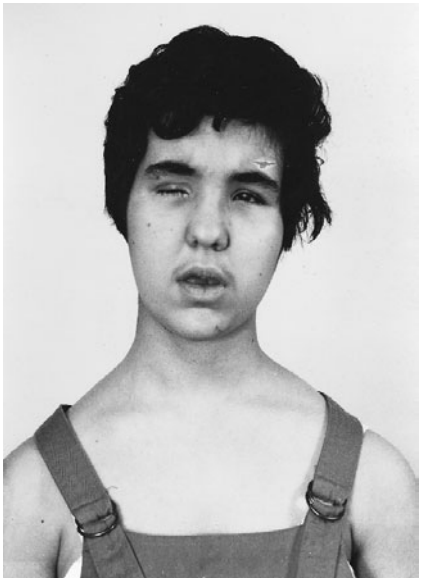

Fig. 22–52. *Oculo-palato-cerebral dwarfism*. Fifteen-year-old with microcephaly, mild mental retardation, hypotonia, cleft palate, short stature, long thin neck, and sloping shoulders. Patient had persistent hypertrophic primary vitreous, microphthalmia, mild hearing loss, small hands and feet, ankle spasticity, and asthma. (From M Frydman et al, Clin Genet 27:414, 1985.)

quadriplegia. Hearing loss was mild. All patients had severe asthma, pneumonitis, otitis media, pectus excavatum, and cleft palate.

A combination of microcephaly and cleft palate is seen in the syndromes described by Halal (see *microcephaly and cleft palate*) and by Say et al (see *Cleft palate, microcephaly, large ears, and short stature*).

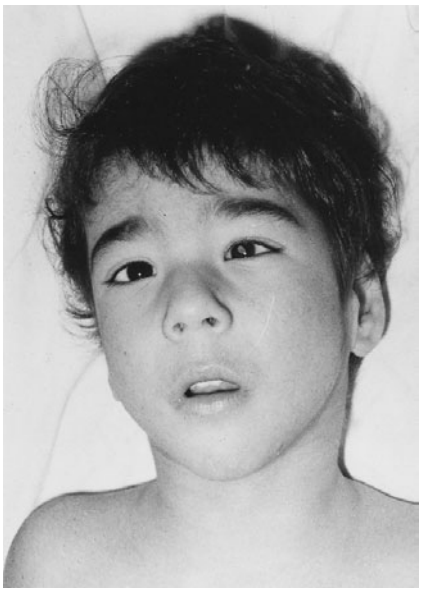
Fig. 22–53. *Oculo-palato-cerebral dwarfism*. Sib having similar features: short stature, severe mental retardation, cleft palate, microphthalmia, persistent hypertrophic primary vitreous of left eye, quadriplegia, and asthma. (From M Frydman et al, Clin Genet 27:414, 1985.)



Odontotrichomelic syndrome (tetramelic deficiency, ectodermal dysplasia, and deformed pinnae)

Freire-Maia, Pinheiro, and co-workers (1–4,7) described a form of ectodermal dysplasia with tetramelic deficiency in four of eight Brazilian sibs. The parents were normal and apparently not consanguineous but were from a highly inbred region. Rather extensive bone deficiencies involved all extremities. Various skeletal abnormalities were reported. There was marked reduction in the amount of scalp and body hair, eyebrows, and lashes. The ears were large, thin, outstanding, and deformed. Oligodontia and conical crown form were noted. The nipples and areolas were hypoplastic, and hypogonadism was found, as well as mild mental retardation. Two of four affected sibs died in infancy. Cleft lip occurred in only one boy (Fig. 22–54). Some of these patients resemble those with *EEC syndrome* (6).

Herrmann et al (5) described a mentally retarded Amerindian boy with some of the stigmata seen in the syndrome noted above. However, their case probably represents another syndrome discussed under *Herrmann syndrome*.

Oligodactyly and cleft palate

Robinow et al (2), in 1986, reported a mother and son with cleft palate, microretrognathia, and anomalies of the hands and feet. The first ray in the hands was hypoplastic and the fifth ray was absent. The fourth metacarpal was somewhat broadened. In the feet of the boy, the fifth rays were hypoplastic (Figs. 22–55 and 22–56). The mother had no abnormality of the toes. We are not aware of similar cases. Meinecke and Wiedemann (1) suggested that the syndrome represents incomplete expression of *postaxial acrofacial dysostosis*. Both Robinow et al (3) and RJ Gorlin express skepticism.

Recurrent brachial plexus and neuropathy, characteristic facies, and cleft palate

Jacob et al (12) were probably the first to recognize the syndrome of recurrent brachial neuropathy (AD neuralgic amyotrophy), characteristic facies, and cleft palate. There have been a considerable number of other reports (1–8,11,12). Most patients with neuralgic amyotrophy do not have characteristic facies and cleft palate. Inheritance is autosomal dominant with variable expressivity and nearly complete penetrance. The gene has been mapped to 17q24–q25 (14,18). Heterogeneity has been alleged (10,19). Its frequency has been estimated as 1 per 60,000 in the general population (3).

The face is somewhat narrow and often there is mild facial asymmetry. The eyes appear deeply set and hypoteloric. There are epicanthal folds and mild upslanting of the palpebral fissures (Fig. 22–57). A number of patients have cleft palate or bifid uvula (1,2,4,6,7,9,12,13,16). Some patients experience hoarseness, implying involvement of the recurrent laryngeal nerve (9,12,15).

Usually beginning in the 4th to 8th year of life, the patient experiences sudden attacks of pain in the shoulder that radiate to the arms and hands. A few days after the pain subsides, paresthesia, weakness, and, later, atrophy of the upper extremities occur. Some patients exhibit wrist drop, whereas others cannot lift the arm above the horizontal level. Reflexes are reduced and there may be some transient sensory loss over the forearms and hands. Attacks may be more common during pregnancy, or following parturition, infectious disorders, or strenuous exercise. Recurrences occur at intervals of months or years. Electromyographic studies have shown partial denervation of several muscles of the upper extremities corresponding to a lesion of the brachial plexus. Stature is often small. Limitation of extension at the elbow and winging of the scapulae have also been noted. Rarely, other peripheral nerves or lower cranial nerves are involved. In most cases, there is complete resolution, but long-standing residual weakness and atrophy may occur.

The facies is remarkably similar to that described by Schilbach and Rott (17) in a dominantly inherited syndrome of *submucous cleft palate, hypotelorism, and hypospadias*. However, in that family, no brachial neuropathy was mentioned.

The disorder is not genetically related to hereditary neuropathy with liability to pressure palsies which has been mapped to 17p11.2 (5,19).

Ring-shaped skin creases and cleft palate

Kunze and Riehm (8) reported two families each with autosomal dominant transmission of ring-shaped creases (Fig. 22–58) which gradually improve with age (5,9,13). In one family, a son had cleft palate and in the other family, a daughter had cleft palate. Cleft palate has been described in other reports (4,7,15). However, most patients with ring-shaped skin creases have not had cleft palate (9,13). We view the term "Michelin tire baby" as pejorative (3). An early report is that of Ross (13). The creases are associated with lipomatosus nevus or smooth muscle hamartoma (5,6,10,11,14–16). We cannot accept the case of Burgdorf et al (2).

There has been evidence of autosomal dominant inheritance (1,7–9). However, there is surely etiologic heterogeneity.

In addition to cleft palate, facial anomalies have included microcephaly, high forehead, microphthalmia and microcornea, broad nasal bridge, hypotelorism, microstomia and dysmorphic pinnae, and microtia with stenotic canals (4,5,7,8). A similar example is that of Case 1 of Cohen et al (3). Macrostomia was noted in Case 2 of Cohen (3).

Miscellaneous abnormalities include lax joints (16), hirsutism (10, 12,16), seizures (16), mental retardation (4,5,16), obesity (5,8), retinopathy (12), neuroblastoma (8), ureterocele (8), and mastocytosis (11).

Rüdiger syndrome

Rüdiger et al (1) described a lethal, probably autosomal recessive, syndrome in sibs, the infants succumbing within the first year of life. The disorder is characterized by somatic retardation, flexion contractures of hands with thick, single palmar creases, small fingers and nails, and ureterovesical stenosis. The male sib had micropenis and inguinal hernias; the female sib had bicornuate uterus and cystic ovaries. Arches were noted on2all fingers. The facies was coarse with prominent forehead, flat nasal bridge, stubby nose, and prominent upper lip. The soft palate was cleft (Fig. 22–59).

Short stature and cleft palate

Gareis and Smith (1) reported a kindred in which several affected members had short stature below the third centile because of relative shortness of the extremities. All affected males and approximately half the affected females had cleft palate or submucous cleft palate and bifid uvula. Micrognathia was present in approximately half those affected. The condition is dominantly inherited, possibly X-linked.

A B

Fig. 22–59. *Rüdiger syndrome*. (A) Coarse facies, finger contractures. (B) Small middle phalanges and small triangular terminal phalanges. (From RA Rüdiger et al, J Pediatr 79:977, 1971.)

Submucosal cleft palate, hypotelorism, and hypospadias

Schilbach and Rott (1) described 10 affected individuals in 5 generations of a family. All exhibited hypotelorism and submucosal cleft palate. In addition, the facies was characterized by epicanthic folds, blepharophimosis, and upslanting palpebral fissures (Fig. 22–60). Males exhibited hypospadias of variable degrees.

There was very mild cutaneous syndactyly of the third and fourth fingers and the second and third toes. In the hands, the syndactyly correlated with an abnormally low ridge count of digital triradii *b* and *c*.

The face is similar to that seen in *recurrent brachial plexus neuropathy*.

Inheritance is clearly autosomal dominant.

Reference (Submucosal cleft palate, hypotelorism, and hypospadias)

Cleft lip-palate, mental and growth retardation, sensorineural hearing loss, and postaxial polydactyly

RJ Gorlin and J Cervenka have seen a family in 1985 with autosomal dominant inheritance of cleft lip-palate, micrognathia, sensorineural hearing loss, mental and somatic retardation, and postaxial polydactyly.

Cleft lip-palate, sensorineural hearing loss, sacral lipomas, and aberrant fingerlike appendages—*disorganization* homologue?

Lowry and Yong (4) observed two male Chinese sibs with cleft lip and palate, profound sensorineural hearing loss, and sacral lipomas. In one child, there was connection of the lipoma with the spinal cord. An anterior sacral meningocoele was found. The other child had two separate aberrant fingerlike appendages of the heel and thigh and a dislocated hip. Both suffered from functional constipation and lower limb asymmetry. Intelligence and growth were normal (Fig. 22–61).

A B

Fig. 22–60. *Submucosal cleft palate, hypotelorism, and hypospadias*. (A,B) Affected sibs with blepharophimosis, upslanting palpebral fissures, and hypotrichosis. (From U Schilbach and H-D Rott, Am J Med Genet 31:863–870, 1988.)

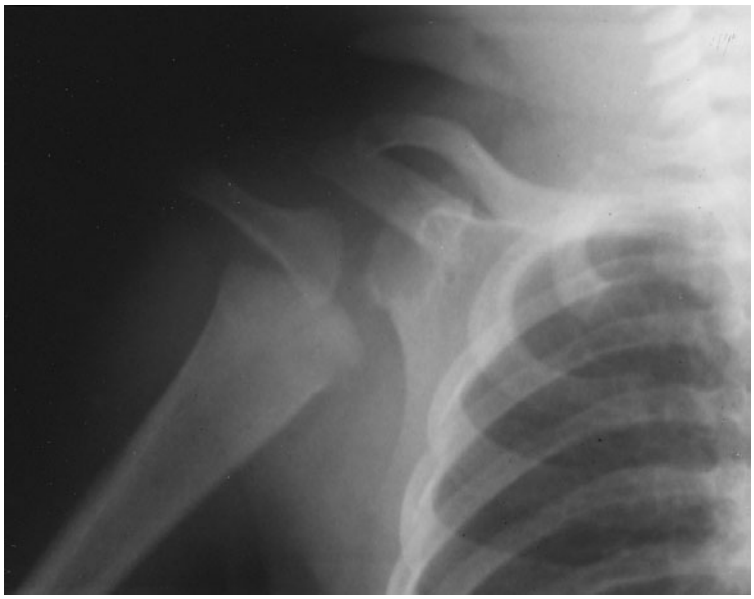
C



D

Fig. 22–61. *Cleft lip-palate, sensorineural hearing loss, sacral lipomas, and aberrant fingerlike appendages—disorganization homologue*? (A) Sacral lipoma. (B) Digit-like appendages of thigh and foot. (C) Close-up view of pedal growth. (D) Radiograph of boy with extra bone of shoulder. (A–C courtesy of RB Lowry, Calgary, Alberta. D courtesy of J Murray, Iowa City, Iowa.)

Nasal bone and cartilage were poorly developed, resulting in a flattened facial profile. A small area of cutis aplasia congenita was evident in the scalp on one boy. An accessory calcaneus was present on the lateral heel of the same sib and a rotational anomaly of the penis in the other.

Van Langen and Hennekam (9) described a male child of consanguineous parents with cleft lip-palate, hypertelorism, natal teeth, digit-like appendage of the chest wall, prominent coccyx, profound sensorineural hearing loss, ptosis, divergent strabismus, abnormal EEG, and global retardation. *Malpuech syndrome* should also be considered.

One of us (RJG) has seen a similarly affected boy at the University of Iowa Medical Center (Fig. 22–61).

All reported patients are males. Inheritance may be autosomal or X-linked recessive.

Winter and Donnai (12) noted a possible relationship to the mouse mutant "disorganization" (Ds). A number of other "disorganization" homologues have been noted, but we cannot find much common thread to bind them to the syndrome considered here (1–3,5–8,10,11). Each appeared to be unique. Especially bizarre was one child with three facial appendages (1).

Macrosomia, microphthalmia, plus or minus cleft palate, and early infant death

Teebi et al (1) described a consanguineous Kuwaiti family with 5 of 10 siblings exhibiting early macrosomia, wide anterior fontanel, bilateral severe microphthalmia, protuberant abdomen, and respiratory infections leading to early infant death. Three of the five had cleft palate.

Inheritance appears to be autosomal recessive.

To be excluded is *macrosomia, obesity, macrocephaly, and ocular abnormalities (MOMO) syndrome*.

Reference (Macrosomia, microphthalmia, plus or minus cleft palate, and early infant death)

1. Teebi AS et al: Macrosomia, microphthalmia, cleft palate and early infant death: A new autosomal recessive syndrome. Clin Genet 36:174–177, 1989.

Cleft lip-palate and X-linked mental retardation

Siderius et al (4), in 1999, described a three-generation family with a form of X-linked mental retardation. Three affected males exhibited mild to borderline mental retardation and cleft lip-palate, some unilateral, some bilateral. The face was long, and the nasal tip was broad but may have been secondary to the cleft. A somewhat similar syndrome in which there was X-linked mental retardation with variable stature, head circumference, and testicular volume has been linked to Xq12–q21. Two of this kindred had cleft lip-palate (1). A still further X-linked syndrome incorporates mental retardation with short stature, small hands and feet, seizures, glaucoma, and cleft palate. Linkage was established to Xq28 (2). The X-linked cerebropalatocardiac syndrome has microcephaly, short stature, cleft palate, cupped ears, bulbous nose, short philtrum, and tented upper lip (3).

Cleft lip-palate, ectrodactyly, holoprosencephaly, and hypertelorism

Hartsfield et al (1) in 1984, Young et al (3) in 1992, and Imaizumi et al (2) in 1988 reported examples of association of holoprosencephaly, ectrodactyly, hypertelorism, cleft lip-palate, and dysmorphic pinnae.

One patient had craniosynostosis (1). In the only child who survived there was mental retardation (2).

References (Cleft lip-palate, ectrodactyly, holoprosencephaly, and hypertelorism)

Cleft palate, micrognathia, ptosis, facial weakness, hypotonia, and lateral ophthalmoplegia (Carey-Fineman-Ziter syndrome)

In 1982, Carey et al (2) described a brother and sister with hypotonia, bilateral ptosis, lateral ophthalmoplegia, downslanting palpebral fissures, and Robin sequence. Additional examples were provided by Schimke et al (5), Baraitser and Reardon (1), and Ryan et al (4).

Normal intelligence, feeding and swallowing problems, facial weakness, bilateral ptosis, downslanting palpebral fissures, external ophthalmoplegia, triangular nose, long philtrum, micrognathia, and small tongue have been essentially constant features (Fig. 22–62). More than one-third die in infancy, and more than one-third exhibit mental retardation.

Hypotonia and weakness, hypoplastic pectoral muscles, scoliosis, generalized-poor muscle mass, brachydactyly, poor flexion creases, talipes and wrist dimples have been noted in most.

Miscellaneous findings have included: talipes (1,4,5), scoliosis (2,4), cleft palate (2,5), microcephaly (2,5), and short stature (1,2,5).

Inheritance may possibly be autosomal recessive (2,4), but caution is needed in counseling.

It is possible that the syndrome may be a form of *Moebius syndrome* (3).

Cleft palate, multiple epiphyseal dysplasia (Ribbing), and micrognathia

Lowry et al (1), in 1996, reported two unrelated patients with cleft palate and micrognathia (Robin sequence) with short extremities because of multiple epiphyseal dysplasia of the Ribbing type.

Facial changes that were minimal included mild hypertelorism, mild upslanting palpebral fissures, and broad nasal tip.

There was delay in appearance of epiphyses of the long bones. Later the epiphyses appeared fragmented and, finally, very flat. The fibulae were short and the radial heads dislocated. Marked genu valgum and scoliosis developed.

Cleft palate, unusual facies, generalized hypotonia, and congenital hydronephrosis

Okamoto et al (1), in 1997, described two unrelated Japanese patients with severe growth failure, severe mental retardation, generalized floppiness, unusual facies characterized by microcephaly, midface hypoplasia, synophrys, long eyelashes, prominent eyes, epicanthic folds, apparently low-set pinnae with long ear lobes, flat nasal bridge, short upturned nose, long philtrum, open mouth, and webbed neck. Both had cleft palate and generalized hypertrichosis. The joints were hypermobile. Cardiac anomalies included VSD, ASD, and endocardial cushion defect. Both exhibited congenital hydronephrosis.

Reference (Cleft palate, unusual facies, generalized hypotonia, and congenital hydronephrosis)

1. Okamoto N et al: New MCA/MR syndrome with generalized hypotonia, congenital hydronephrosis, and characteristic face. Am J Med Genet 68:347–349, 1997.

Oto-facio-cervical syndrome

A family with abnormalities of the external ear, face, and neck was described by Fára et al (2) in 1967. The father and four of seven children were affected. A sporadic case was reported by Dallapiccola and Mingarelli (1). Another possible example is that of Allanson (personal communication, 1989). We suspect that the patient of Pennie and Marres (4) also had the syndrome.

Autosomal dominant inheritance is evident.

The face is long and of an inverted triangular shape, with a relatively broad forehead and narrow mandible (Fig. 22–63). In most cases, lateral cervical fistulas are also present either unilaterally or bilaterally. Lacrimal duct atresia has also been seen. The auricles are prominent with large conchae. Preauricular fistulas are present just in front of the helix. The sporadic case of Allanson had a right-sided preauricular fistula and a tag anterior to the left ear. Audiometric testing of four affected family members showed bilateral conductive hearing loss of 60–70 dB, more marked in low and high frequencies with 40–50 dB loss in middle frequencies (2). Sensorineural hearing loss has also been seen (1).

The neck appears long with weak musculature, and the shoulders and clavicles sloped downward markedly. The scapulae are located more laterally than normal and showed mild winging. A Sprengel shoulder was noted in the sporadic patient of Allanson, that of Dallapiccola and Mingarelli (1), and in the patient of Pennie and Marres (4). All affected persons have been short in stature.

Unilateral renal agenesis was found in one family member.

There was mild to moderate hyporeflexia, more marked in the arms than the legs. Mild intellectual deficit was noted in the family members.

Radiographs were similar in all affected members of the family. The skull showed narrowing in the middle third of the face, the sella turcica was deep with a slanting clivus, and there was a marked difference in the level of the orbital roof and the cribriform plate (Fig. 22–63G). The temporal pyramids were asymmetric with poor mastoid pneumatization. The clavicles slanted obliquely downward (Fig. 22–63H). Radiographs of the carpal bones showed moderately retarded bone age in three children in the affected family.

In the isolated patient there was spina bifida occulta of the fifth lumbar and first sacral vertebrae.

The combination of the characteristic facies, sloping shoulders, auricular abnormalities, and hearing loss appears unique. There is marked overlap, however, between this syndrome and the *branchio-oto-renal syndrome* (3). The latter syndrome lacks anomalies of the shoulder and short stature, whereas renal anomalies are much more common. Although the family of Fára et al did not have preauricular tags or lacrimal duct stenosis, the sporadic patient of Allanson had both a preauricular tag and lacrimal duct stenosis, increasing the overlap between these two conditions.

Midline malformations, limb abnormalities, and hypopituitarism (Dincsoy syndrome)

In 1995, Dincsoy and colleagues (1) reported male and female Saudi Arabian sibs, born to first cousin parents. The sibs exhibited midline anomalies that included cleft lip and palate, flat nose, ocular hypotelorism, and dysgenesis of the corpus callosum and/or Dandy-Walker anomaly. Skeletal changes included short limbs and unusual radiolucent anterior tibial notch and digital anomalies such as overlapping fingers and camptodactyly.

In addition, the patients had hypopituitarism and secondary ambiguous genitalia that included perineal hypospadias and cryptorchidism.

Inheritance is probably autosomal recessive.

One must exclude *hydrolethalus syndrome* and *pseudotrisomy 13 syndrome*. Neither sib exhibited preaxial or postaxial polydactyly (although that is not an absolute requirement). The radiolucent notch in the midshaft of the tibia is seen in neither of those syndromes.

Tetra-amelia with pulmonary hypoplasia

Rosenak et al (1) described a Muslim Arab family with autosomal recessive inheritance of symmetric tetra-amelia and pulmonary hypoplasia. One had cleft lip. Death occurred soon after birth. Zlotogora et al (2) added two Palestinian families with the same combination of findings. An enlarged head (hydrocephalus?) was described.

Inheritance is autosomal recessive (1,2).

The reader should also see *amelia* and *cleft lip-palate* and *unusual facies, tetra-amelia, hypotrichosis, and developmental retardation*.

Robin sequence, cleft mandible, pre- and postaxial hand anomalies, and clubfoot (Richieri-Costa and Pereira syndrome)

Richieri-Costa and Pereira (3), in 1992, described five unrelated female Brazilian children with short stature, Robin sequence, agenesis of mandibular incisors, pre- and postaxial hand anomalies, and talipes. Two additional male examples were presented by Richieri-Costa and Pereira (4) in 1993. Another was added in 1998 (2). A non-Brazilian infant was described (6).

Inheritance is clearly autosomal recessive. Parental consanguinity was noted in five of eight families. All affected male patients died.

Birth weight and length were generally unremarkable, but subsequent growth showed the children to be below the 3rd centile for height, weight, and OFC. Intelligence was normal.

Craniofacial findings. Mild ocular hypertelorism, outstanding low-set pinnae, retromicrognathia, microstomia, cleft lower alveolar ridge with ankyloglossia in some, and variable degrees of cleft palate are characteristic (Fig. 22–64). The lower central and lateral incisors were absent and radiographs showed a cleft through the midline of the mandible (Fig. 22–64D). In some cases, the mandible is so small that a tracheostomy must be done. Laryngeal malformations include: short round larynx, absent or reduced epiglottis, hypertrophic aryepiglottic folds, and a fold in the posterior larynx above the glottis (5).

Musculoskeletal system. There was radial deviation of the hands. The thumbs were hypoplastic and the fifth fingers were clinodactylous. Clubfoot and short lower extremities were evident. The halluces were short and, in the rare case, duplicated (1) (Fig. 22–65A,B).

Radiographs showed hypoplastic radii and first rays. Metacarpals 4–5 were fused proximally. The middle phalanx of the fifth fingers were hypoplastic, carpal bone age was delayed, and carpal coalition was common. The distal tibiae were hypoplastic, the fibulae had proximal and lateral displacement, and there was talipes (Fig. 22–65C,D).

Diagnosis. The clinical picture clearly distinguished this condition from all other cleft syndromes.

Cleft lip-palate, congenital contractures, ectodermal dysplasia, and psychomotor and growth retardation

Ladda et al (1) reported two brothers with congenital contractures of all major joints as well as the fingers and toes (Fig. 22–66).

Hair was brittle and thin with little pigmentation. Brachycephaly, deep-set eyes, blepharophimosis, ptosis, and microretrognathia were evident. One brother had cleft lip-palate, the other had cleft palate. Oligodontia and conical crown form were documented.

Both growth and marked mental retardation were described in the brother that lived. The other died soon after birth.

Inheritance may be X-linked or autosomal recessive.

Reference (Cleft lip-palate, congenital contractures, ectodermal dysplasia, and psychomotor and growth retardation)

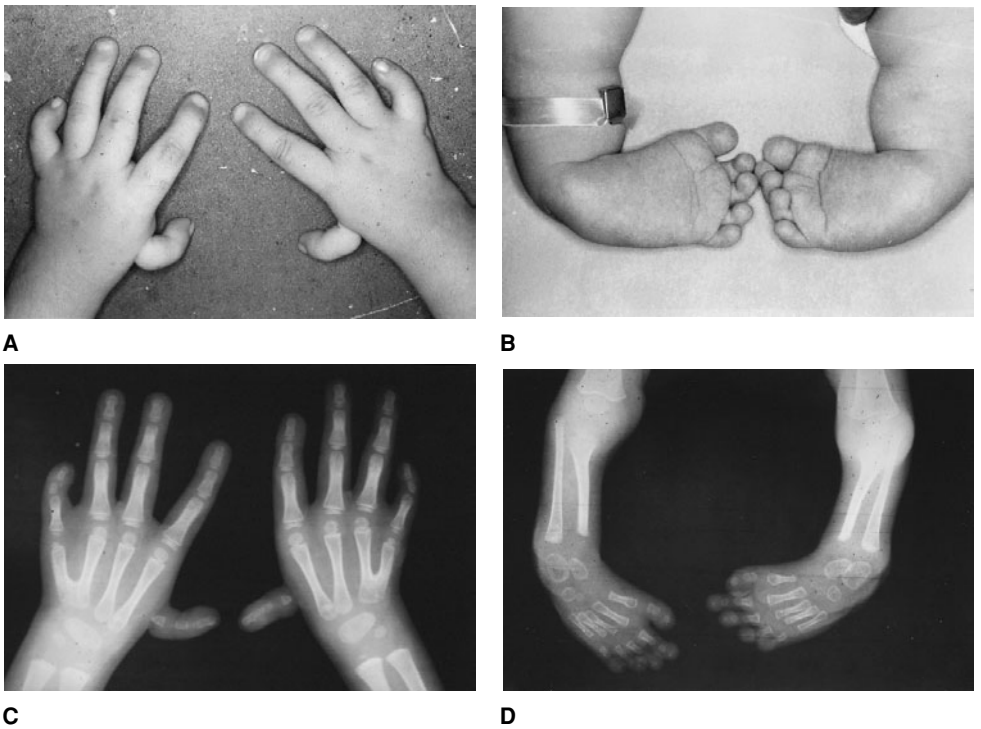
Cleft lip-palate, microbrachycephaly, eye anomalies, short stature, and mental retardation

Richieri-Costa and Guion-Almeida (2), in 1992, reported three Brazilian brothers with a unique syndrome of microbrachycephaly,



A B C D

Fig. 22–65. *Robin sequence, cleft mandible, pre- and postaxial hand anomalies, and clubfoot (Richieri-Costa and Pereira syndrome).* (A) Hypoplastic displaced thumb, short middle phalanx of fifth finger. (B) Club feet. (C) Radiograph showing hypoplastic thumbs and first metacarpals, fused metacarpals IV–V. (D) Radiograph showing club feet, abbreviated tibiae, and proximal and lateral fibulae. (From A Richieri-Costa and SCS Pereira, Am J Med Genet 42:681, 1992.)

A B

Fig. 22–66. *Cleft lip-palate, congenital contractures, ectodermal dysplasia, and psychomotor and growth retardation*. (A) Note cleft and sparse hair growth. (B) Congenital contractures of fingers. (From RL Ladda et al, Am J Med Genet 47:550, 1993.)

prominent supraorbital ridges, deep-set eyes, asymmetric palpebral fissures, palpebral ptosis, coloboma of iris and retina, nystagmus, strabismus, malar hypoplasia, cleft lip-palate, short stature, and mental retardation (Fig. 22–67). There was no parental consanguinity. Another probable example was that of Natacci et al (1).

One must rule out *Michels syndrome* (cleft lip-palate, blepharophimosis, ptosis, corneal stromal opacities, sensorineural hearing loss, radioulnar synostosis).

Cleft palate, abnormal pinnae, short stature, and monodactylous tetraectrodactyly

Richieri-Costa and de Miranda (3) described a male child, the offspring of unrelated parents.

Height was below the 3rd centile as was birthweight.

The face was normal except for small low-set outstanding pinnae. Cleft palate was noted. The teeth, hair, and eyes were normal (Fig. 22–68).

The hands and feet exhibited bilateral symmetrical monodactylous ectrodactyly.

Differential diagnosis includes *ectrodactyly-cleft palate syndrome* (2). There is neither short stature nor ear anomalies in that disorder.

A somewhat similar example was described by Herrmann et al (1) in association with *alcohol embryopathy*.

Unusual facies, blepharophimosis, and contractural arachnodactyly (van den Ende-Gupta syndrome)

van den Ende et al (3), in 1992, Gupta et al (1), in 1995, and Phadke et al (2), in 1998, reported patients with blepharophimosis, arachnodactyly, and camptodactyly (Fig. 22–69).

Inheritance appears to be clearly autosomal recessive.

The facies is characterized by blepharophimosis, triangular face, malar hypoplasia with downslanting eyebrows and possibly upslanting palpebral fissures. The pinnae have been prominent, and the nose narrow and beaked. Lips are everted. Cleft palate and velopharyngeal insufficiency have been reported (1,3).

The hands and feet are long, and arachnodactyly, camptodactyly, and valgus deformity of the hallux have been constant findings. The elbow is deformed with posterior dislocation of the head of the radius. Radiographically, the ribs are slender. Intelligence has been normal.

Marden-Walker syndrome can be excluded by absence of microcephaly, mental retardation, hypotonia, and joint limitation.

Cleft lip, microbrachycephaly, long thin face, ptosis, hypotelorism, lumbosacral/pelvic anomalies, and mental retardation

Richieri-Costa et al (1), in 1992, noted two sisters with a strikingly similar facial phenotype: microbrachycephaly, hypoplastic supraorbital ridges, long thin face, ptosis, hypotelorism, strabismus, midface hypoplasia, dysmorphic pinnae, and cleft lip. The bitemporal distance was reduced. The chin was large and prominent, and the mandibular angle was obtuse (Fig. 22–70).

Both sisters exhibited large fontanelles with delayed closure, pectus excavatum, wrinkled skin, lymphedema, abnormally modeled lumbosacral and pelvic bones, lumbar lordosis, brachydactyly, and short flat feet. Clasped thumbs were noted at birth.

Low birthweight, short adult stature, and moderate mental retardation were evident.

Radiologic studies showed hypoplastic distal epiphyses of radius and ulna, capitate/hamate coalition, short hypoplastic metacarpals 4–5, hypoplastic phalanges, hallux valgus, scoliosis, broad pelvis, vertically-shaped pubic and ischial bones, and shallow acetabulae.

The parents were not consanguineous. Inheritance is probably autosomal recessive.

The facies is very similar to that of *facio-cardio-renal syndrome*.

Cleft palate, sickle-shaped scapulae, and talipes equinovarus

Bezirdjian and Szucs (1) documented a female with micrognathia, cleft palate, and an unusual sickle shaped deformity of both scapulae (Fig. 22–71). She also had bilateral club foot deformity.

Reference (Cleft palate, sickle-shaped scapulae, and talipes equinovarus)

1. Bezirdjian DR, Szucs R: Sickle-shaped scapulae in a patient with the Pierre Robin syndrome. Br J Radiol 62:171–173, 1989.

Unusual smiling face, cleft palate, and absence of middle ear space

Morris (1) described a mother and daughter with craniofacial anomalies and hearing loss. Both exhibited a striking appearance: a smiling face with lateral creases extending from the corners of the mouth to a point midway between the tragus and mouth. The daughter had submucous cleft palate, lacrimal duct stenosis, and a 40 dB conductive hearing loss. CT scan of the temporal bone showed normal ossicles, inner ear structures, and external auditory canals, but the mastoid air cells were poorly developed with abnormal soft tissue filling both the air cells and the middle ear space. On surgery, there was a thick vascular scar-like tissue in place of the middle ear cleft. External ear length was at the lower end of normal (5th centile). The mother had exhibited a repaired cleft of the soft palate, lacrimal duct stenosis, and mixed hearing loss.

The etiology is unknown. Failure of expansion of the distal portion of the first pharyngeal pouch that forms the tympanic cavity and mastoid air cells could have resulted in lack of middle ear space. The unusual appearance of the smiling face is apparently because of the lateral cleft-like extensions of the smile and may be caused by mandibular deficiency, facial muscle hypoplasia, or abnormal facial muscle insertion. The last possibility would suggest abnormal insertion of the zygomaticus major muscle into the orbicularis auris muscle.

Vance and Brei (2) also reported a case of a male with bilateral cheek dimples, the facial creases becoming more evident upon smiling or crying, lacrimal duct stenosis, and bilateral conductive hearing loss. Also noted were epicanthal folds, mild ptosis, upturned nose, high-arched palate, micrognathia, laryngomalacia, and pectus excavatum.

Wiedemann et al (3) described a 6-year-old girl that they labeled *Wildervanck syndrome* (Fig. 22–72). There was bony malformation at the atlantoccipital junction and block formation of cervical vertebrae 2–4 and synostosis of the spinous processes to C-6. The soft palate was immobile. The same facies was present as that seen in the above-mentioned cases, and there was conductive hearing impairment.

Coloboma, hearing loss, hematuria, and cleft lip-palate

Collum (4) and Kingston et al (8) described a three-generation family in which colobomata of iris and choroid were segregating, sometimes accompanied by clefting and mental retardation. The family was updated by Ravine et al (13). Autosomal dominant inheritance with wide variation is obvious. No chromosomal localization is known. Most family members have required remedial teaching, and one male was institutionalized. It has remained uncertain whether the learning difficulties have been primary or secondary.

Craniofacial findings. Six patients had cleft lip with or without cleft palate. The range of expression was wide.

Ocular system. The most common finding was coloboma of the chorioretina and, to a lesser extent, coloboma of the iris, optic pits, and colobomatous microphthalmia. Presenile cataracts and retinal detachment were also found as complication of the colobomata. Impairment of extraocular movements was also prevalent. Three members had anomalous branching of retinal vessels.

Auditory system. The most common hearing loss was mid-frequency sensorineural, but in some patients with clefting, there was superimposed conductive hearing loss because of recurrent otitis media.

Hematuria. Seven members had hematuria without renal impairment.

Other findings. An anencephalic child with cleft lip and palate was born within the family, but this may have been aleatory.

Differential diagnosis. Hussels (6) described an adult female with uveal coloboma, clefting, and deafness, and microphthalmia in her son. Wenstrom et al (16) reported familial coloboma including microphthalmia, cataracts, hearing loss, and mild mental retardation. Other entities to be excluded are *Waardenburg syndrome*, *CHIME syndrome*, ocular-renal syndrome caused by PAX2 mutations (12,15), and the case report by Richieri-Costa and Guion-Almeida (14).

Atkin and Patil (3) reported a child and his maternal uncle with cleft lip-palate, microphthalmia, cloudy cornea, congenital heart defect, hemivertebrae, ureteral anomalies, hypospadias, cryptorchidism, and ectrodactyly. Pinsky et al (11) reported three sisters with microphthalmia, cloudy cornea, cleft lip, variable anomalies of the pinnae, mental retardation, and spasticity. Their mother had microphthalmia. Ho et al (5) noted the association of various forms of ocular coloboma with congenital heart anomalies, mental retardation, skeletal defects, and cleft palate. *Pilotto syndrome* consists of brachycephaly, cleft lip-palate, high nasal bridge, mildly dysmorphic pinnae, congenital heart defect, vertebral anomalies, short stature, and mental retardation (10). A similarly affected child was noted by Pena (9). The latter patient had microphthalmia, coloboma of the optic discs and choroid, and scoliosis. S Kapur (personal communication, 1989) described male and female sibs with cleft lip-palate, bulbous nasal tip, microphthalmia, iris coloboma, cataract, ASD, VSD, tetralogy of Fallot, displaced kidneys, hypoplastic thumbs, finger contractures, anal stenosis, and severe mental retardation.

The association of clefting with eye colobomas is also found in *Abruzzo-Erickson syndrome, Baraitser syndrome*, and *Michels syndrome*. Female sibs with cleft lip-palate, corneal opacities, optic nerve coloboma, profound psychomotor retardation, and congenital heart defects were reported by Anyane-Yeboa et al (1). James et al (6) noted the association of cleft lip and/or palate with uveal colobomas. The eye coloboma/cleft lip-palate association overlaps with *CHARGE* association (2).

Agenesis of the corpus callosum, profound mental retardation, oculocutaneous albinism, combined immunodeficiency, and cleft palate

Vici et al (3), in 1988, reported two brothers with agenesis of the corpus callosum with profound developmental delay, seizures, bilateral cataract, oculocutaneous albinism, combined immunodeficiency, and cleft lip-palate. They died at 2–3 years. A male and female sib with similar findings, but without cleft palate, were described by del Campo et al (1). In addition, there was marked hypoplasia of the cerebellar vermis and neuronal white matter heterotopia as well as polymicrogyria and pachygyria.

Inheritance is probably autosomal recessive (1).

While there is some overlap with Chediak-Higashi syndrome and Griscelli syndrome, the autosomal recessive disorder considered here appears to be distinct. Toriello and Carey (2) reported four children, three of whom were sibs, with cleft palate, agenesis of the corpus callosum, and unusual facies.

Anophthalmia, heminasal a/hypoplasia, atypical facial clefting, growth and mental retardation, and agenesis of corpus callosum

Guion-Almeida and Richieri-Costa (1), in 1999, noted four unrelated children with growth and mental retardation, agenesis of corpus callosum, prominent forehead, facial asymmetry, anophthalmia, heminasal a/hypoplasia, preauricular skin tags, dysmorphic pinnae and atypical facial clefting.

To be excluded are *oculoauriculofrontonasal spectrum, heminasal aplasia*, and *oculo-auriculo-vertebral spectrum*.

Reference (Anophthalmia, heminasal a/hypoplasia, atypical facial clefting, growth and mental retardation, and agenesis of corpus callosum)

2. Spear GS et al: Bilateral pulmonary agenesis and microphthalmia. Am J Med Genet (Suppl) 3:379–382, 1987.

Cleft lip and cone-rod dystrophy

Ausems et al (1) reported three sibs, the product of a consanguineous marriage, with cleft lip. Two developed a progressive retinopathy identified as cone-rod dystrophy.

Inheritance appears to be autosomal recessive.

Impaired color vision (because of cone dystrophy) followed by night blindness and peripheral field diminution (because of rod dystrophy) leads to early vision loss. It is usually found in otherwise normal individuals but other findings have been reported: hereditary ataxia, alopecia, mental retardation with hypogonadism and sensorineural hearing loss (4) and renal dysfunction and sensorineural hearing loss (2).

Inheritance has been autosomal dominant in some kindred, autosomal recessive in others, and X-linked recessive in still others (3).

Cleft lip-palate and "anophthalmia plus"

Fryns et al (1) described a female fetus with bilateral anophthalmia, bilateral cleft lip-palate, microtia with mild bilateral lateral facial clefting, myelomeningocoele, and uterus unicornis. A second child, a male, had bilateral anophthalmia and a lobeless ear.

Inheritance may possibly be autosomal recessive.

Reference (Cleft lip-palate and "anophthalmia plus")

1. Fryns J-P et al: Apparently new "anophthalmia-plus" syndrome in sibs. Am J Med Genet 58:113–114, 1995.

Cleft lip-palate and XY gonadal dysgenesis (Brosnan syndrome)

Brosnan et al, in 1980, reported two female sibs with 46,XY gonadal dysgenesis, short stature, narrow forehead with metopic ridge, broad squashed nose, pretragal pits, narrow external ear canals, overfolded helices, cleft lip-palate, enamel dysplasia, punched-out scalp defects, broad hands and feet with spatulate thumbs and halluces, VSD, umbilical hernia, and mild mental retardation.

Both had streak gonads, 46,XY chromosome constitution, and small bicornuate uterus.

Follow-up was carried out by Schimke and Ardinger (2).

Cleft lip-palate, agenesis of corpus callosum, microcephaly, seizures, psychomotor retardation, and preaxial polydactyly

Several patients have been described with microcephaly, agenesis or hypoplasia of the corpus callosum, mental retardation, seizures or infantile spasm, and cortical atrophy. At least three patients had cleft lip-palate (1–3). One had inguinal hernia (2).

Two had preaxial polydactyly; another had exophthalmos. Such conditions as *acrocallosal syndrome; cleft lip and palate, prominent eyes, and congenital heart disease; Lin-Gettig syndrome* and *Lowry-MacLean syndrome* must be excluded.

Cleft lip-palate, antecubital pterygia, and the nail-patella syndrome

Cleft lip-palate may be associated with antecubital pterygia as part of the nail-patella syndrome. This combination has been documented in two cases (1,4).

The nail-patella syndrome is an autosomal dominant condition characterized by patellar a/hypoplasia, finger nail dysplasia (especially of the thumbs and index fingers), arthrodysplasia of elbows, iliac horns, and nephropathy (5). The usual elbow alterations involve subluxation or luxation of the radial and/or ulnar heads with limitation of pronation, supination, and extension. However, it has been reported with antecubital pterygia (2–4).

Cleft lip-palate, blepharoptosis, oligodontia, and ectrodactyly

Rodini and Richieri-Costa (1) reported the female offspring of consanguineous parents. The father has cleft lip-palate. His daughter presented with ectrodactyly of the feet, syndactyly of toes, bilateral ptosis, cleft lip-palate, and oligodontia.

We suspect that in spite of the parental consanguinity that this case may be incomplete expression of the *EEC syndrome*, which often has variable expression.

Reference (Cleft lip-palate, blepharoptosis, oligodontia, and ectrodactyly)

1. Rodini ESO, Richieri-Costa A: Autosomal recessive, blepharoptosis, cleft lip/palate, dental anomalies and ectrodactyly. Am J Med Genet 42:340–342, 1992.

Cleft lip-palate, facial, eye, heart, and intestinal anomalies (Kapur-Toriello syndrome)

Kapur and Toriello (2) reported a brother and sister with cleft lip-palate, nose with bulbous tip and columella below nares, microphthalmia (one with cataract and colobomata of iris and retina), and low-set pinnae with atretic canal and ear tags.

Congenital heart anomalies (ASD, VSD, tetralogy of Fallot), hypoplastic thumbs, finger contractures, hypoplastic labia in the female, small penis in the male, rectal stenosis, and malrotation of the intestine were also observed. Growth and development were significantly retarded.

Similar cases were described by Zelante et al (3) and Graham et al (1).

Inheritance may be autosomal recessive.

References [Cleft lip-palate, facial, eye, heart, and intestinal anomalies (Kapur-Toriello syndrome)]

1. Graham GE et al: A fourth patient with the Kapur-Toriello syndrome: Nesidioblastosis, digital hypoplasia and late parental age as novel findings. Am J Hum Genet 67:Abst 685, 2000.

Cleft lip-palate, leptomeningeal angiomatosis, absent olfactory tracts, Dandy-Walker malformation, and congenital heart anomalies

Hurst et al (1) described a stillborn male with an unusual combination of cleft lip-palate, broad nasal root, downslanting palpebral fissures, small posteriorly rotated pinnae, congenital heart anomalies (small atria, hypoplastic left ventricle, atretic aorta and aortic valve), leptomeningeal angiomatosis, absent olfactory tracts, thin corpus callosum, absent septum pellucidum, and hypoplasia of the cerebellar vermis.

Reference (Cleft lip-palate, leptomeningeal angiomatosis, absent olfactory tracts, Dandy-Walker malformation, and congenital heart anomalies)

1. Hurst JA et al: Leptomeningeal angiomatosis, absent olfactory tracts, hypoplasia of cerebellar vermis, cleft lip and palate, and congenital heart disease in a stillborn infant. Clin Dysmorphol 1:168–171, 1992.

Cleft lip-palate, microcephaly, cardiac malformations, and digital anomalies

Perçin et al (1) reported two sibs with atrial septal defect in one, tetralogy of Fallot in the other, small middle phalanges of fingers II and V, and long, broad halluces. Cone-shaped epiphyses were noted on X-ray examination.

One had cleft lip-palate, the other occult cleft lip.

There is some similarity to *Juberg-Hayward syndrome*.

Reference (Cleft lip-palate, microcephaly, cardiac malformations, and digital anomalies)

1. Perçin EF et al: A new syndrome with cardiac malformations, cleft lip-palate, microcephaly, and digital anomalies. Clin Genet 48:264–267, 1995.

Cleft lip-palate, pigmentary retinopathy, and cholestasis

Hardikar et al (2), in 1992, reported two unrelated children with a syndrome of cleft lip-palate, pigmentary retinopathy, multisystem obstruction with cholestasis and pulmonary outflow murmur. Another example is that of Cools and Jaeken (1).

The facies is characterized by long narrow palpebral fissures, depressed nasal tip, preauricular dimples, and moderate psychomotor development. The patient of Hardikar et al (1) manifest a stenotic hepatic duct responsible for the obstruction. This could not be demonstrated in the case of Cools and Jaeken (2). A jejunal web or rotation anomaly of the gut was present in all three patients as was hydronephrosis. Congenital heart anomalies were found in two of the three patients. There is some resemblance to *Kabuki syndrome*.

Various disorders were excluded such as *Alagille syndrome*, Norwegian cholestasis, congenital hepatic fibrosis, and Caroli disease.

References (Cleft lip-palate, pigmentary retinopathy, and cholestasis)

1. Hardikar W et al: Multisystem obstruction with cholestasis, pigmentary retinopathy, and cleft palate. A new syndrome? Am J Med Genet 44:13–17, 1992.

Cleft lip-palate, scoliosis, congenital heart disease, and mental retardation (Pilotto syndrome)

Pilotto et al (2) reported a syndrome of bilateral cleft lip-palate, microbrachycephaly, facial asymmetry, high nasal bridge, dysmorphic pinnae, short neck, retarded bone age, kyphoscoliosis with vertebral body defects, 13 pairs of ribs, pseudoepiphyses of metacarpals, and skeletal anomalies, congenital heart anomalies (PDA, ASD), genital hypoplasia, and growth and mental retardation. Additional possible examples were recorded by Pena (1) and Strømme et al (3).

Inheritance is unknown. Pilotto et al (2) noted two other sibs who died in infancy with malformations (scoliosis, congenital heart anomaly).

References [Cleft lip-palate, scoliosis, congenital heart disease, and mental retardation (Pilotto syndrome)]

1. Pena SDJ: Cleft lip and palate, congenital heart disease, scoliosis, short neck and mental retardation: The Pilotto syndrome. Birth Defects 18(3B):183–186, 1982.

3. Strømme P et al: Cleft lip and palate, scoliosis, skeletal and cardiac malformations and other dysmorphic features in a child. Scand J Plast Reconstr Hand Surg 27:71–74, 1993.

Cleft lip-palate, severe psychomotor retardation, characteristic facies, hypospadias, and limb contractures

Wolff et al (1) described severely mentally retarded male sibs, one of whom had seizures. Both had a facies marked by low hair line, hypertelorism, bulbous nose, upslanting palpebral fissures, large pinnae, micro/retrognathia, and thick lips. One had cleft lip-palate, the other convergent strabismus and abnormal nasal septum.

Both exhibited hypospadias; one had cryptorchidism, the other inguinal hernia.

Both had delayed skeletal maturation, large hands, progressive postnatal limb contractures, hypoplasia of the terminal phalanges, talipes, and camptodactyly. One had scoliosis and clinodactyly, the other rough skin.

There is some overlap with the *branchio-skeleto-genital syndrome, acro-fronto-facio-nasal dysostosis* and *Opitz (BBB/G) syndrome*.

Inheritance is either autosomal or X-linked recessive.

Reference (Cleft lip-palate, severe psychomotor retardation, characteristic facies, hypospadias, and limb contractures)

1. Wolff G et al: Two brothers with characteristic facial appearance, severe psychomotor retardation, hypospadias, contractures, and other symptoms: A new recessive syndrome? J Med Genet 31:65–67, 1994.

Cleft lip-palate, unusual facies, intestinal malrotation, and congenital heart anomalies

McPherson and Clemens (1) reported male and female sibs with bilateral cleft lip-palate, hypertelorism, flat profile and occiput, malrotation of intestine, and complex congenital heart anomalies leading to death. The female had bifid thumbs; and the male was large for gestational age and had a bilobed tongue. The neck appeared short and broad in the male and with nuchal edema in the female sib. Visceromegaly and glial heterotopias were found in the male infant. Three male sibs were added by Nevins et al (2). They manifested similar anomalies but did not have bifid tongue, malrotation of the intestine, or bifid thumbs.

Excluded were *Simpson-Golabi-Behmel syndrome* and *Fryns syndrome*.

Inheritance is probably autosomal recessive.

References (Cleft lip-palate, unusual facies, intestinal malrotation, and congenital heart anomalies)

1. McPherson E, Clemens M: Cleft lip and palate, characteristic facial appearance, malrotation of the intestine, and lethal congenital heart disease in two sibs. A new autosomal recessive condition? Am J Med Genet 62:58–60, 1996.
2. Nevin NC et al: Cleft lip and palate, hypertelorism, brachycephaly, flat facial profile, and congenital heart disease in three brothers. Am J Med Genet 73:412–415, 1997.

Cleft palate, atresia of the auditory meati, and limb reduction defects

Glass et al (1), in 1994, reported male and female sibs with common anomalies of cleft palate, auditory meatal atresia, and limb reduction in spite of marked dissimilarity in other abnormalities.

Inheritance may be autosomal recessive. One child had macrocephaly, porencephaly, spastic tetraplegia, seizures, and severe mental retardation. Preauricular tag, slit-like auditory meati, cleft palate were also found. The other sib had cleft palate, bilateral ear tags, narrow meati, lack of one arm, absence of proximal humerus of the other arm with humero-radio-ulnar synostosis at the elbow. The third digit had camptodactyly.

There was no evidence of *Delleman syndrome*. Teratogen exposure was excluded.

Reference (Cleft palate, atresia of the auditory meati, and limb reduction defects)

1. Glass IA et al: Ear anomalies, clefting, and limb reduction defects: A new autosomal recessive condition? Clin Dysmorphol 3:150–156, 1994.

Cleft palate, congenital hypothyroidism, curly hair, and choanal atresia

Bamforth et al (1) reported two brothers with congenital hypothyroidism, sparse curly/spiky hair, low-set dysmorphic pinnae, micrognathia, and cleft palate. Choanal atresia and bifid epiglottis were found as well as developmental delay. A similarly affected female was described by Buntincx et al (2). Bilateral choanal atresia was found. The eyelashes were long. The scalp hair extended low in the forehead. Late polyhydramnios was noted in all cases (1,2).

Inheritance may be autosomal recessive.

It may be the same as *hypothyroidism and hypohidrotic ectodermal dysplasia* (3–5). Zadik et al (6) reported a female with congenital hypothyroidism, dermoid cysts of the upper eyelids, convergent strabismus, oligodontia, and cleft palate.

ANOTHER syndrome should be excluded.

References (Cleft palate, congenital hypothyroidism, curly hair, and choanal atresia)

Cleft palate, craniosynostosis, joint contractures, anomalous pinnae, and scoliosis

Iida et al (1) described a female infant with coronal synostosis, trismus, outstanding pinnae with flat helices, flat nasal root, and finger contractures. The palate was widely cleft and there was scoliosis.

There was some resemblance to *Antley-Bixler syndrome*, but the child had no radiohumeral synostosis, choanal atresia, congenital heart or urogenital anomalies.

Reference (Cleft palate, craniosynostosis, joint contractures, anomalous pinnae, and scoliosis)

1. Iida A et al: Craniosynostosis with joint contractures, ear deformity, cleft palate, scoliosis, and other features. Cleft Palate Craniofac J 32:489–491, 1995.

Cleft palate, microphthalmia, dextrocardia, choreoathetosis, and mental retardation

Aughton (1) and Nachlieli and Gershoni-Baruch (2) reported male infants born to consanguineous Arab parents. The infants had sloping foreheads, anophthalmia/microphthalmia, small deep-set palpebral fissures, prominent nasal root and nasal bridge, and large pinnae. One had cleft palate (2).

Both had dextrocardia, one had vertebral rib defects and supernumerary ribs. One had mental retardation, choreoathetosis, and seizures (2). Both had folding of the plantae pedis.

Inheritance appears to be autosomal recessive.

Other conditions to be excluded are *cerebro-oculo-facial (COFS) syndrome*, Waardenburg microphthalmia syndrome (3), and *Lenz microphthalmia syndrome*.

References (Cleft palate, microphthalmia, dextrocardia, choreoathetosis, and mental retardation)

1. Aughton DJ: New syndrome? Clinical anophthalmia, dextrocardia, and skeletal anomalies in an infant born to consanguineous parents. Am J Med Genet 37:178–181, 1990.

3. Traboulsi EI et al: Waardenburg's recessive anophthalmia syndrome. Ophthalmol Paediatr Genet 1:13–18, 1983.

Cleft palate, Potter sequence, congenital heart anomalies, and mesoaxial polydactyly (Holzgreve-Wagner-Rehder syndrome)

Cleft palate, persistent buccopharyngeal membrane, mesoaxial hexadactyly, and congenital heart anomalies was discussed as a syndrome by Holzgreve et al (2) in 1984. To date there have been only isolated examples (1–3).

Craniofacial findings. Marked acrocephaly without craniosynostosis has been present. Posterior cleft palate with glossoptosis and persistent buccopharyngeal membrane are constant features (1–3).

Respiratory and cardiovascular systems. The lungs are hypoplastic. Congenital heart and great vessel anomalies have included VSD, hypoplastic left heart, aortic arch hypoplasia, and single umbilical artery.

Musculoskeletal findings. Mesoaxial hexadactyly, postaxial polydactyly, Y-shaped fusion of metacarpals 4–5, ossification defects of ribs and sacral vertebral defects have been noted. The fifth finger may be abbreviated. Eleven ribs have been documented. The lower limbs have been fixed.

Renal anomalies. All have bilateral renal agenesis with associated Potter sequence.

Differential diagnosis. One must exclude the various *oral-facial-digital syndromes* and Kaufman syndrome (polydactyly, hematocolpos, cardiopathy, *Thomas syndrome, Gillessen-Kaesbach syndrome*, and *Pallister-Hall syndrome*. Potter sequence is associated with a veritable host of other anomalies in single gene disorders and in *amnion rupture sequence* (see Chapter 1). Thomas et al (4) and Zlotogora et al (5) described sibs with hypoplastic left heart, ASD, renal hypoplasia/agenesis, and cleft lip-palate but no anomalies of the extremities.

References [Cleft palate, Potter sequence, congenital heart anomalies, and mesoaxial polydactyly (Holzgreve-Wagner-Rehder syndrome)]

4. Thomas IT et al: Holzgreve syndrome: Recurrence in sibs. Am J Med Genet 45:767–769, 1993.
5. Zlotogora J et al: Thomas syndrome: Potter sequence with cleft lip/plate and cardiac anomalies. Am J Med Genet 62:224–226, 1996.

Cleft lip-palate, Potter sequence, and cardiac abnormalities (Thomas syndrome)

Thomas et al (3), in 1993, and Zlotogora et al (4), in 1996, both reported sibs with Potter sequence, cleft lip or cleft palate and congenital heart anomalies. Sibs reported earlier by Curry (2) probably had the same syndrome. Additional affected sibs were described by Briscioli et al (1).

Inheritance is clearly autosomal recessive.

Several had intrauterine growth retardation (4).

Kidney abnormalities ranged from hypoplasia (3,4) to cystic dysplasia (2,4) to agenesis (1,4). All infants exhibited Potter sequence.

Cleft palate (2,3) and cleft lip with cleft palate (1,4) were found.

Congenital heart anomalies included VSD, mitral valve atresia, aortic valve atresia, PDA, tetralogy of Fallot, coarctation of aorta, and bicuspid pulmonary valve.

Holzgreve-Wagner-Rehder syndrome is similar but does not have extremity anomalies and all examples have been isolated. *Gillessen-Kaesbach syndrome* is characterized by Potter sequence, microbrachycephaly, and brachymelia.

References [Cleft lip-palate, Potter sequence, and cardiac abnormalities (Thomas syndrome)]

Cleft palate, radial and patellar aplasia/hypoplasia, and short stature (RAPADILINO syndrome)

Kääriänen et al (2) reported a syndrome, employing the acronym RAPADILINO: *R*A (*ra*dial anomalies), *P*A (absent/hypoplastic *pa*tellae), *D*I (*di*arrhea, *di*slocated joints), *L*I (*li*ttle size, *li*mb malformations), *N*O (long thin *no*se, *no*rmal intelligence).

Their four patients exhibited radial aplasia or hypoplasia, absence of thumbs, absent or hypoplastic patellae, dislocation of joints, diarrhea in infancy, long slender nose, and small chin.

Intelligence was normal. The voice was high-pitched. Two of the four patients had cleft palate.

Vargas et al (4) described an isolated male with similar phenotype. In addition, there was partial anal stenosis. The ulnae were short and bowed. An ASD was also described. Kant et al (3) reported a male who, in addition, had a poikilodermatous skin rash, somewhat resembling that seen in *Rothmund-Thompson syndrome*.

Inheritance may be autosomal recessive.

One must exclude TAR syndrome, VATER association, Fanconi anemia, and *Aase-Smith syndrome II*.

Cleft palate, whistling face, distal arthrogryposis, and mental retardation

Illum et al (2), Schrander-Stumpel et al (4) and Di Rocco et al (1), and others (3,5) described patients with Robin sequence, distal arthrogryposis type IID or E, severe encephalopathy, mental retardation, hypotonia, seizures, postnatal growth retardation, and a face characterized by small mandible and a somewhat whistling face appearance. Polyhydramnios was noted in several cases (2,4). Death occurred relatively early. Calcium deposits were found throughout the brain.

Inheritance may possibly be autosomal recessive (2).

References (Cleft palate, whistling face, distal arthrogryposis, and mental retardation)

Distal arthrogryposis, unusual facies, cleft lip with/without cleft palate, short stature, hydronephrosis, and normal intelligence

Sonoda and Kouno (1) reported two brothers with joint contractures of the distal limbs, an unusual facies characterized by marked hypertelorism, and blepharophimosis, one with cleft lip, the other with cleft lip and palate, short stature, hydronephrosis, undescended testes, and normal intelligence. Although the authors suggested that they represented a form of oto-palato-digital syndrome, we disagree, and further suggest that it represents a new entity.

Reference (Distal arthrogryposis, unusual facies, cleft lip with/without cleft palate, short stature, hydronephrosis, and normal intelligence)

1. Sonoda T, Kouno K: Two brothers with distal arthrogryposis, peculiar facial appearance, cleft palate, short stature, hydronephrosis, retentio testis, and normal intelligence: A new type of distal arthrogryposis? Am J Med Genet 91:280–285, 2000.

Microcephaly, preauricular skin tags, cleft palate, camptodactyly, and distal limb anomalies

Guion-Almeida et al (1), in 1999, reported two unrelated children born to nonconsanguineous parents. The children had microcephaly, growth and mental retardation, telecanthus, hypoplastic tragus, short nose, preauricular skin tags/pits, short neck, micrognathia, camptodactyly, long thin fingers, and foot abnormalities.

Both children exhibited hypotonia; one had seizures. There were abnormal palmar creases.

Differential diagnosis would include *Toriello-Carey syndrome, cerebro-facio-articular syndrome*, and *oculo-auriculo-vertebral spectrum*.

Reference (Microcephaly, preauricular skin tags, cleft palate, camptodactyly, and distal limb anomalies)

1. Guion-Almeida ML et al: Multiple congenital anomalies syndrome: Growth and mental retardation, microcephaly, preauricular skin tags, cleft palate, camptodactyly, and distal limb anomalies. Report on two unrelated Brazilian patients. Am J Med Genet 87:72–77, 1999.

Chapter 23
Orofacial Clefting Syndromes: Associations

Aicardi syndrome and cleft lip-palate

Aicardi syndrome consists of seizures, callosal agenesis, severe mental retardation, delayed development, and ocular abnormalities (chorioretinal lacunae, microphthalmia) occurring in retarded females. It is believed to be caused by an X-linked dominant gene that is lethal in the hemizygous male. The gene maps to Xp22.3 (1). Death usually occurs during the first decade of life. The syndrome has been reported in association with porencephaly, corticoheterotopias, Arnold-Chiari malformation, papilloma of the choroid plexus, lissencephaly, ventricular cyst, polygyria, microgyria, arhinencephaly, and Dandy–Walker malformation. It has been estimated that cleft lip-palate (1–6) is found in about 3% of the cases. *Holoprosencephaly* (5) has also been described

Anencephaly and/or cleft lip-palate

Anencephaly, a disorder due to failure of closure of the anterior neuropore and resultant lack of brain development, is characterized by absence of cranial vault and brain, hypoplastic and/or deformed pituitary gland, and absent hypothalamus. Associated are protruding eyeballs and tongue, aquiline nose, malformations of the cranial base, short neck, and changes secondary to lack of neural connections between the pituitary and the generally absent hypothalamus, such as hypoplasia of the adrenal glands and gonads (4). The protruding tongue may be due to an abnormally small oral cavity. The mandible is relatively large. A general account of *anencephaly* appears in chapter 16. The reader is referred to the comprehensive work of Lemire et al (18) for detailed information.

The association of clefting and anencephaly is certainly higher than chance would dictate. Khoury et al (16) found a relationship with neural tube defects and CL(P) especially significant. Heintel (13) stated that every anencephalic had submucous cleft palate. Although this may be an exaggeration, palatal form is certainly bizarre with a pronounced midline palatal raphe, suggesting to us altered temporal fusion of the palatal shelves with the nasal septum. Similar palatal changes are seen in holoprosencephaly (see Fig. 20–22). Among 114 infants with isolated cleft palate, MacMahon and McKeown (19) found one anencephalic, but three with this condition were noted among 105 infants with cleft lip and palate among 34 Japanese anencephalics. A number of authors (9,10,24) have also noted the association. Conversely, several investigators examining infants with anencephaly have found cleft lip-palate (2,3, 5,6,14,26) or cleft palate or uvula (1,11,14,15,22,26). However, since no systematic large survey has been done, clefting has ranged from 2% to 20% (7,8,14,18,21,25,26). Gleeson and Stovin (12) described an anencephalic child with cleft palate, Klippel-Feil-like anomaly, and neuroenteric cyst. Rejjal and Abu-Osba (23) reported discordant anencephaly with cleft lip-palate in a triplet pregnancy. Medeira et al (20) noted anencephaly, spina bifida, limb anomalies, and cleft lip-palate.

Lateral nasal proboscis and its associations

Lateral nasal proboscis is characterized by a tubular proboscis-like structure (similar to that seen in the midline above the eye in cyclopia), usually 2–4 cm in length and 0.5–1.0 cm in width extending from an area just lateral to the glabella or nasal root (2,5,6,8) (Fig. 23–1). Ocular hypertelorism may be present (7,11). It usually is accompanied by agenesis of one-half of the nose (vide supra). Rarely, the proboscis is located in the midline. A bizarre example associated with holoprosencephaly and oblique facial cleft was located above the eyebrow lateral to the eye (1). In a few cases, there has been normal nose formation (4,13). Bilateral proboscides have also been described (12).

The proboscis is usually blind-ended, rarely solid. It represents the missing nostril and lateral half of the nose. The lacrimal duct, nasal bone, vomer, maxillary sinus, cribriform plate, and ethmoid cells are often missing on the involved side and there may be unilateral choanal atresia. In several cases, colobomas of the iris and upper and lower eyelids were found (3,9). The olfactory bulb is usually rudimentary on the involved side (13). An intraorbital cyst has been found (10,14).

The frequency has been estimated to be less than 1 in 100,000 live-born infants. There is no sex or racial predilection.

Embryologically, as indicated earlier, the external nose is derived from the medial and lateral nasal prominences. The median nasal prominence gives rise to half of the septum and the medial crus of the lower lateral cartilage. Each lateral nasal prominence forms the nasal bone, the lateral crus of the lower lateral cartilage, the upper lateral cartilage and the anterior end of the lower turbinal complex. The lateral nasal proboscis arises from defective formation of the lateral nasal prominence sometime during the 4th–5th week of embryonal life.

Boo-Chai (3) classified proboscis lateralis into four groups: (*1*) proboscis with normal nose, (*2*) proboscis with nasal defect, (*3*) proboscis with nasal defect plus defects of eye and adnexa, and (*4*) proboscis with nasal defect plus abnormality of eye and adnexa plus cleft lip or palate.

Duane anomaly and cleft palate

The Duane retraction syndrome is a congenital eye movement disorder characterized by marked limitation of abduction, limitation of adduction, palpebral fissure narrowing, and globe retraction on attempted adduction. The anomaly may be unilateral or bilateral. The sixth nerve nucleus or nuclei have been found to be hypoplastic, the lateral rectus fibrotic, and the medial rectus hypertrophic.

Occasionally, Duane anomaly is associated with cleft palate. Although some patients clearly have *Klippel–Feil anomaly* or *Wildervanck syndrome* (Klippel–Feil anomaly plus), others have only the binary combination (1,2). Kirkham (3), describing patients with Duane anomaly, cleft palate, and profound hearing loss, suggested that the patients had incomplete expression of the wider spectrum. The Okihiro syndrome consists of Duane anomaly, hypoplasia of the thenar eminence, and sensorineural hearing loss (4). Gorlin et al (4) have reviewed the general problem.

Retinoblastoma and cleft palate

Bonaïti-Pellié et al (1) reported two sibs with cleft palate and retinoblastoma. Their mother had retinoblastoma but no cleft palate. The children also had severe micrognathia. Jensen and Miller (2) noted a child with Robin sequence and retinoblastoma; and Walker (3) described identical twins, one having cleft palate and the other retinoblastoma.

Cleft larynx, laryngeal web, and cleft palate

Cleft lip–palate is rarely associated with cleft larynx with or without extension into the trachea and/or esophagus (3,6–8,10). It presents with stridor, respiratory distress, or choking during feeding. Several patients have had multiple malformations (malformed pinnae, hypertelorism, tracheoesophageal fistula, congenital heart anomalies, urogenital anomalies).

Many have succumbed in early infancy. Some surely represent examples of the *G syndrome* (10). Laryngeal cleft is also seen in *Pallister–Hall syndrome*. Lim et al (8) and Tyler (11) listed other associated anomalies.

Laryngeal webs, most often (75%) glottic, may rarely be found with cleft lip–palate or submucous palatal cleft (1,2,4,5). The clinical manifestations are hoarseness, dyspnea, and inspiratory stridor. Excellent reviews of the early and recent literature have been published (9,10).

Both combinations are usually sporadic. Cleft larynx is probably a developmental field defect, occurring with separation of the larynx and esophagus and closure of the larynx.

Oral duplication and cleft palate

The occurrence of supernumerary mouth and/or jaws is rare indeed. Although these cases have differed enough from one another to make each one relatively unique, for purposes of general discussion, we will briefly consider four forms: (*1*) single mouth with duplication of maxillary arch, (*2*) supernumerary mouth laterally placed with rudimentary mandible, (*3*) single mouth with replication of mandibular segments, and (*4*) true facial duplication (diprosopus) with or without anencephaly. Duplication, in most cases, probably arises from forking of the notochord, partial doubling of the prosencephalon or olfactory placodes, or duplication of growth centers around the stomodeal plate (40).

Our interest here will largely be limited to the first and last forms. Reduplication of the mouth and mandible alone is quite rare (1,16,29) as is duplication of the upper lip and maxilla (17). We suspect that the mildest form is doubling of the pituitary gland (27a). The child reported by Avery and Hayward (3) had hypertelorism and a single mouth with two palates, each of which was cleft. There were two arcades of maxillary teeth and a bilaterally grooved or bifid or trifid tongue. We believe that the third lobe represents the tuberculum impar (Fig. 23–2). She was also moderately mentally retarded and had tetralogy of Fallot. Many similarly affected children have been described (8,10,18,20,26,27,32,33,35,38–41). Two pituitary glands have been found in several of these children (5,32,36). Two of the children had hamartomatous tissue hanging from the palate. An unusual variant of the condition was reported by Fish (22). This child also had a nasal dermoid, a median cleft of the upper lip, and a fleshy hamartomatous mass (fat, cartilage, nevus cells) on the chin. Similar cases but without cleft palate have been described (14,23,36). Some have encephaloceles (6).

A child with two mouths, one of which had cleft palate, was documented by Bacsich et al (5). We are also aware of several examples of children with an extra tongue. The children have other stigmata which would classify them in the *oculo-auriculo-vertebral spectrum*. Some of these infants had cleft palate.

Calomeni and Jordan (12) described a male with large lower lip, doubling of tongue, cleft palate, incomplete fusion of mandibular symphysis, nasal dermoid, hirsutism, fusion defects of cervical spine, and anomalous aorta. Bartholdson et al (7) reported a male with two tongues, cleft palate, and mild ocular hypertelorism. Variants have been reported by Britto et al (8a), Chen and Noordhoff (16a), and Tharanon et al (36a).

Diprosopus is the most extreme form of facial doubling. There may be two lateral eyes, a median eye, and doubling of the hypophysis, mouth, and nose. Clefting of the lip or palate is common (37). There have been several examples, some of which have been anencephalic (2,4,9,11,15,19, 21,24,28,30,34), not all of which have cleft palate (31).

Lateral facial clefts with maxillary duplication are discussed elsewhere in this text (13,25).

Thoracopagous twins and cleft lip-palate

Knowledge of conjoined twins dates back to the Neolithic period (31). There are early reports from the sixteenth century (4,6). The four basic types of conjoined twins are: (*1*) thoracopagus (73%), exhibiting various degrees of thoracic fusion, (*2*) pygopagus (19%), generally fused at the level of the sacral spine, (*3*) ischiopagus (6%), in which each twin has a single leg and a common fused leg, and (*4*) craniopagus (2%), exhibiting fusion of the skulls (26).

Investigators agree that conjoined twins result from incomplete separation of a single fertilized ovum, prior to the end of the third week (21,22,34). The degree and site of incomplete splitting determine the type of conjoined twins. It has been suggested that a defect in the primitive streak, aging of the ovum, and environmental factors may play a causative role. Experimental manipulation of the primitive streak in amphibian and chick embryos has induced complete and incomplete twinning (34).

Epidemiologic studies, based on data from the Birth Defects Monitoring Program of the CDC, indicated that 81 sets of conjoined twins were found among 7,903,000 births from 1970 to 1977, representing an incidence of roughly 1 per 100,000 births. The International Clearing House for Birth Defects Monitoring Systems (13), in 1991, found 1.3 per 100,000 births. Similar findings were presented by Machin (17). Thoracoomphalopagus represented 28%, followed by thoracopagus 18%, omphalopagus 10%, parasitic twins 10%, and craniopagus 6%. There was an approximately 3F:2M sex predilection. The birth prevalence among nonwhites (16/million) is greater than among whites (9/million). No maternal age effect is found. Conjoined twins have higher rates of malformation than monozygotic separate twins. About 80% are malformed in areas other than at the union and 20% are discordant (19). Among the 81 cases, six presented orofacial clefts, five being cleft lip–palate and one isolated cleft palate (8). The six cases of clefts all occurred in thoracopagous twins, representing 7% of all cases or 13% of thoracopagus cases. Other studies have shown similar data (1,13,21,22). Thoracopagous twins thus have a higher rate of facial clefting than that expected by chance (8,10,13). Mirror image cleft lip has been reported in several instances (9,15,18–22,28) (Fig. 23–3). Discordance for cleft lip in thoracopagous twins has also been found (4a,21,22,24,26,27). Cleft palate (3,7) and cleft lip and palate (11,12) have been reported in cephalothoracopagus. Ayer and Mariappa (2) observed unilateral cleft lip and palate in both thoracopagous twins and bilateral cleft lip and palate in both faces of a diprosopic child. Similar cases were documented by Latteier and Anderson (16), Ueo et al (29), and Pavone et al (23). Ivy (14) and Vestergaard (30) described a two-headed fetus, one with cleft lip–palate and the other normal. Buchta (5) described anencephaly in thoracopagous twins with facial clefting. Cleft palate has been reported in craniopagus (31,33). Rowlatt (25) noted a double tongue and a single pituitary fossa containing two pituitary glands in thoracocephalopagous twins.

Oral teratoma, encephalomeningocele, and cleft palate

Epignathus is a term used to describe a congenital teratoma protruding from the mouth of an infant (1–9,16,18,19,25,26,34,35). It has been shown that these growths usually develop in the area of Rathke's pouch and project and fill the pharynx or oral cavity between the palatal shelves (8,34) (Fig. 23–4). Among 81 cases of teratomas seen in infancy and childhood, cleft palate was found in 1.2% (15). In general, oral teratomas constitute no more than a few percent of all teratomas (3,22). Affected infants rarely survive the neonatal period. The mass interferes with swallowing in the fetus, thereby causing polyhydramnios in the mother (6).

Erich (8), reviewing 22 cases of oral teratomas, noted that 11 were attached to the sphenoid bone, six to the lateral wall of the epipharynx near the opening of the eustachian tube, two to the soft palate, and one to the hard palate. They may even be attached to the lower jaw (13,29). The size of the teratoma varies from several centimeters to huge parasitic masses. The smaller and simpler cases are compatible with life and, as a rule, arise further back in the oral cavity (2,18). The larger examples often cause deformity of the mandible due to mechanical interference in growth (18). A teratoma of the tongue associated with cleft was reported by Grier and MacNerland (11). Congenital oral teratomas are far more common in females (6F:1M) and are benign.

Fig. 23–4. *Oral teratoma and cleft palate*. (Courtesy of CO Dummett, Los Angeles, California.)

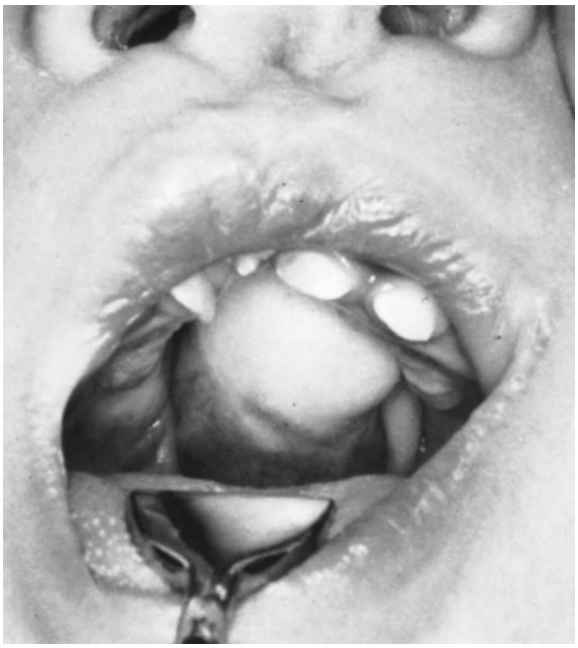

Fig. 23–5. *Encephalomeningocele and cleft palate*. Repaired cleft lip, unrepaired cleft palate.

The cleft, in most cases, has involved both hard and soft palates, but in others only the soft palate is cleft (2,18,25). The cleft may be submucosal (34). Hirshowitz et al (14) reported a case of congenital intraoral teratoma with bifid nose. The teratoma was attached to the area normally occupied by the maxillary central incisors.

Histologically, the teratomas can be solid and/or cystic. They consist of tissues derived from the three germ layers, including skin and adnexa, mucous and nonmucous secreting glands, muscle, cartilage, lymphoid tissue, nervous tissue, and bone. Some are covered with hair (1,2,5,25,35). Wynn et al (35) found a perfectly formed finger with bones, joints, and nail inside the mass. Malignant changes have not been observed in these tumors.

Cleft lip and/or palate has also been described in association with glioma or encephalomeningocele which herniates through the sphenoid bone to present in the mouth (7,10,17,20,21,26,29,32,33,36) (Fig. 23–5). The encephalocele may also present as a bulge on the frontal bone (20) and may be associated with ocular hypertelorism.

The cleft can involve both lip and palate (9,20,26,29) or only the palate (10,21,28,30,36).

Naidich et al (24), in a survey of 30 cases of basal (sphenoidal, sphenoethmoidal, ethmoidal) encephaloceles, noted that in addition to optic nerve dysplasia (rarely microphthalmia) (40%) and callosal agenesis (rarely lipoma) (40%), about 50% were associated with median cleft of the upper lip. Conversely, Grogono's (12) analysis of 50 patients with callosal agenesis showed one (2%) with median cleft upper lip. Carpenter and Druckemiller (4), surveying 45 patients with callosal agenesis, also found midline cleft upper lip, cleft lip, and cleft palate. It would, thus, appear that midline cleft of the upper lip in the presence of hypertelorism should suggest further examination of the child for midline dysraphic anomalies such as basal encephalocele, callosal agenesis, or optic nerve dysplasia (28).

Histologically, these masses are composed of glial tissue or choroid plexus (10,36) or even melanocytes (10).

Hypogonadotropic hypogonadism and cleft lip and/or palate (includes Kallmann syndrome)

Cleft lip and/or cleft palate have been reported in both males and females with low urinary gonadotropin levels due to defective release of hypothalamic gonadotropin-releasing hormone. This results in low levels of LH

and FSH, which in males, for example, normally simulate testosterone production and spermatogenesis, respectively (16). Such individuals have normal sexual differentiation, but females manifest oligomenorrhea, poor breast development, and scanty axillary and pubic hair while males have infantile testes with cryptorchidism, aspermia, and absent Leydig cells. About 60% of males have gynecomastia and eunuchoid habitus, and about. Forty percent exhibit anosmia (Kallmann syndrome, olfactogenital dysplasia) (1,3,7–10,12,13,17); others do not (14,15). The anosmia results from absence of olfactory tracts and bulbs (5). Conversely, it has been estimated that about 15% of patients with Kallmann syndrome have clefts. About 20% have sensorineural hearing loss (2). Kallmann syndrome has several patterns of transmission: autosomal dominant, autosomal recessive, and X- linked (17), the last being the most frequent form. It has been estimated that there are 5M:1F. The X-linked form has been mapped to Xp22.3 (6,11). The gene is involved in neuronal cell migration, there being a common developmental pathway for olfactory neurons and those synthesizing gonadotropin-releasing hormone. Some carrier females exhibit anosmia (4,12). See *holoprosencephaly* for related material.

Hypophyseal short stature and cleft lip-palate

Francés et al (2) and other (3,5–10) described cleft lip and/or palate associated with either panhypopituitarism or isolated growth hormone deficiency. A converse study was done in which 200 children with isolated clefts of the lip, palate, or both were examined. Among those that were short, about 30% showed partial or complete growth hormone deficiency. However, normal values were found by Köster et al (4) in an unselected group of 200 patients with clefts. The second patient reported by Francés et al (2) appeared to have some degree of the premaxillary agenesis form of holoprosencephaly.

The patient described by Zuppinger et al (11) also exhibited colobomata of the choroid and optic nerve with resultant retinal detachment. Brewer (1) described bilateral cleft lip and agenesis of the pituitary gland. Also see *hypogonadotropic hypogonadism and cleft lip and/or cleft palate* and *holoprosencephaly*.

Growth hormone deficiency may be found in association with a number of congenital malformations: *anencephaly, holoprosencephaly, frontonasal malformation, Rieger syndrome*, microcephaly, *single central incisor, EEC syndrome*, and septo-optic dysplasia.

Amelia and cleft lip-palate

Centa and Rovei (2) described amelia, micrognathia, and cleft palate in a child described as having the Robin sequence. Holthusen (6) reported a less severely affected child. The arms, femurs, and fibulas were absent. Perhaps this case should be classified with absent femurs and cleft palate. Frantz and O'Rahilly (3) noted the association between amelia and cleft lip and cleft palate. Thomas and Donnai (10), Yim and Ebbin (11), and Froster et al (4) reported brachial amelia with cleft lip–palate and forebrain anomalies (encephalocele, hydrocephaly, holoprosencephaly) (Fig. 23–6).

Zimmer et al (12), Gershoni-Baruch et al (5), and Kosaki et al (7) described tetra-amelia, lung abnormalities, hydrocephalus, midfacial clefts, absence of ears and nose, and anal atresia as an X-linked recessive syndrome affecting seven male children in an Arab-Muslim family. This has been termed "Zimmer phocomelia"(7). There is evidence of sex reversal (11). Rosenak et al (9) also reported male and female sibs with tetra-amelia, lung hypo–aplasia, and anomalies of the pulmonary arteries. Başaran et al (1) noted male sibs with tetra-amelia, cleft lip–palate, lung agenesis, and cardiovascular malformations. The tetraphocomelic infant with neural tube defects and facial clefts had an unidentified condition (9).

One must exclude *odontotrichomelic syndrome* and the *Ohdo syndrome (unusual facies, tetra-amelia, congenital hypothyroidism, and severe mental retardation)*. Michaud et al (8) reported autosomal recessive amelia unassociated with other anomalies.

Cleft lip-palate and congenital heart defects

Clefting can be associated with a wide spectrum of congenital heart defects. Boeson et al (2) noted 11 cases of cleft lip and/or cleft palate among 516 patients with congenital heart anomalies. The cardiac defects were of various types, the most common being ASD and VSD. Rabl and Schulz (8) noted the association of cleft lip–palate with pulmonary valvular atresia and septal defect in twins. They also described two sibs with clefts. Geis et al (4) found that 6% of their cleft lip–palate population had congenital heart defects of various forms. Baetz-Greenwalt et al (1) found 14% of infants with hypoplastic right-sided heart to have cleft palate.

Pradat (7), in examination of 2618 infants with major heart malformations, noted that 73 had facial clefts. No specific heart anomalies were associated.

Shah et al (10), in an extensive review of congenital cardiac malformations in children with facial clefts, found no consistent pattern of heart anomalies. Among 32 children with cleft lip or cleft palate who died, cardiac anomalies were present in 66%. Seventeen had cleft palate, six had Robin sequence, four had tetralogy of Fallot, four had tricuspid stenosis, three had coarctation of the aorta, and three had ASD of the secundum type. There were no cases of transposition of the great vessels or examples of a single ventricle among the group. Similar observations were made by Okada et al (6), who also noted that the Robin sequence was associated with coarctation of the aorta and tetralogy of Fallot. It is quite possible that some had *velocardiofacial syndrome* (9).

An equally diverse group with congenital heart anomalies and hypoplastic, aplastic, or triploid thumbs is described in Holt-Oram syndrome (3,5). The reader is also referred to *cleft lip-palate and extrathoracic ectopia of the heart*. Shamberger and Welch (11) described tetralogy of Fallot, omphalocele and cleft palate.

Enlarged parietal foramina and cleft lip and/or palate

Enlarged parietal bone defects (Catlin marks, cranium bifidum), usually bilateral, frequently represent an isolated autosomal dominant trait. They may be associated with clefting of the lip or palate with a possibly greater-than-chance frequency.

The nature of these cranial defects has been discussed by numerous authors (7–11). The fenestrae are usually symptom free, but occasionally there is associated headache (10). The frequency of the parietal bone defects would appear to be less than 1 in 25,000 individuals. Over 300 cases have been described. Miscellaneous other malformations may be associated with enlarged parietal fenestrae. Cases in which clefting has been noted are those of Irvine and Taylor (5), James (6), and Hollender (4). In the case of Hässler (3), a maternal uncle had cleft lip. Parietal foramina may be seen in *cleidocranial dysplasia* (1,2), probably in *FG syndrome* and *Rubinstein-Taybi syndrome*, and in *enlarged parietal foramina, craniofacial anomalies, mental retardation, and multiple exostoses (Potocki–Shaffer syndrome, del11p11.2p12 syndrome)*. Functional haploinsufficiency of the human homeobox gene *ALX4* causes defects in skull ossification (7a,13). Haploinsufficiency of *MSX2* also causes parietal foramina (12).

Extrathoracic ectopia of the heart and cleft lip-palate

Millhouse and Joos (18) tabulated reported cases of extrathoracic ectopia of the heart and found cleft lip and/or cleft palate in 21 of 27 cases (Fig. 23–7). Our independent tally does not confirm their data; but among the 100 cases that we reviewed, there is surely a high correlation between ectopia of the heart and cleft lip–palate (4,5,9,12,14,15,16,19,20,24,26) or cleft palate (2,6,13). Many examples clearly represent the amniotic band sequence following early rupture of the chorion or yolk sac (1,3,6–8, 10,11,21,23). See *amnion rupture sequence* for detailed discussion. In one case there was cleft mandible (9). Cleft sternum, which may represent the same anomaly, has been described with cleft lip (9). Cleft of the upper sternum may be seen with facial hemangiomas and supraumbilical raphe.

Ectopia cordis may be cervical (9%); thoracic (40%); thoracoabdominal (Cantrell syndrome) (38%); or abdominal (11%). Cantrell syndrome is a midline developmental field defect of sternal clefts, anterior diaphragmatic deficiency, ectopia cordis, ventral wall deficiencies, congenital heart anomalies, and pericardial defects (14). Somewhat different values were tabulated by Shao-Tsu (22). Diagnosis can be made by ultrasound (17,25).

Sprengel shoulder and cleft palate (Hodgson-Chiu syndrome)

Hodgson and Chin (1) reported apparent autosomal dominant inheritance of elevated scapula (Sprengel deformity) with cleft palate. One member had Klippel–Feil syndrome. Probably this family represents variable expression of the latter syndrome rather than being a separate entity. Another familial example is that of Monier et al (2).

Syngnathia and cleft palate

A combination of cleft palate and soft tissues or bony adhesions between the upper and lower jaws has been reported (3,9,12,14,22,26,28–31) (Fig. 23–8). Other infants with syngnathia have not had cleft palate. Presumably, the primary defect is fusion between gingivae or alveolar processes that in turn prevents the tongue from dropping and prevents closure of the palatal shelves. It may also be related to the small size of the mandible (micrognathia). In cases of firm bony fusion, the temporomandibular joint is usually ankylosed because movement is necessary during the developmental period (28). Bony union (1,13,14,26) is much rarer than fibrous union (3,9,23).

Since not all cases have been well documented, it is difficult to know how many are legitimate cases. Nearly all have been isolated examples. Gassner (12) described the occurrence in mother and child, while Sternberg et al (28) reported the combination in sibs with consanguineous parents. The surviving child also had CLP. Von Domarus and Scheunemann (32) described sibs with congenital temporomandibular ankylosis. In a few cases, there has been congenital fusion of the jaws but no associated anomalies (17–19,27). Shah (25) reviewed cases of interjaw fusion. Some examples may represent some variant of *oculo-auriculo-vertebral spectrum* (2,4,7).

Dawson et al (8) has attempted to classify syngnathia into (a) type 1-simple syngnathia and (b) type 2-complex syngnathia which they further divide into those with aglossia and those with agenesis or hypogenesis of the mandible. We suspect that this is oversimplification of a very heterogeneous group of conditions.

Syngnathia also occurs with *popliteal pterygium syndrome* (30), *Van der Woude syndrome* (30), and *glossopalatine ankylosis* (6,11,24).The reader is also referred to buccopharyngeal membrane persistence (15). Absence of the soft palate is seen in *agnathia* (5,21). Fusion between the coronoid process of the mandible and the zygoma may occur (16,20). The patient of Dobrow (10) had bilateral iris colobomas and microphthalmia in addition to syngnathia.

Triophthalmia and facial clefting

Tayel et al (4), in 1998, reported a Libyan male infant with dolichocephaly, porencephaly, facial asymmetry, micrognathia, cleft lip-palate, and VSD. The child had an additional eye unilaterally lateral to one of the eyes (1).

Several genes involved in eye development have been identified. The *PAX6* gene appears to play a major role. Nerve growth factor and TGFβ also play a role. Retinoic acid and its receptors in high concentration can induce duplication of eye components in animals (2,3).

Aplasia of the trochlea and cleft palate

Mead and Martin (1) described cleft palate in a patient who also had aplasia of the trochlea. Conceivably the association is one of chance. However, because of the rarity of aplasia of the trochlea, the finding may be significant.

Cleft lip-palate and supernumerary nostrils

Patients with as many as four asymmetric nostrils have been reported among those with cleft lip-palate. The extra nostrils connect to the ipsilateral nasal cavity. Presumably this results from an accessory olfactory pit or pits (4,5,8,9). Asymmetric eyelids were noted as well (9). There have been several examples of supernumerary nostrils unassociated with cleft lip and/or palate (1–3,6,7).

Chapter 24
Syndromes with Unusual Facies: Well-Known Syndromes

Frontonasal malformation (frontonasal dysplasia, median cleft face syndrome)

Frontonasal malformation, probably first described by Hoppe (31) in 1859, consists of hypertelorism, broad nasal root, lack of nasal tip, widow's peak, and anterior cranium bifidum occultum. Associated defects may include midline clefting of nose and/or upper lip, rarely, the palate, and defects of the alae nasi (Figs. 24–1 to 24–5).

The term *median cleft face syndrome* was introduced by DeMyer (12) in 1967 to describe the disorder; Rohasco and Massa (53), in 1968, proposed *frontonasal syndrome*, and Sedano et al (56), in 1970, employed the term *frontonasal dysplasia*. Since then, the term frontonasal malformation (FNM) has been suggested (55,61) based on the premise that the observed pattern of anomalies constitutes a single developmental field defect (55). If the nasal capsule fails to develop properly, the primitive brain vesicle fills the space normally occupied by the capsule, thus producing anterior cranium bifidum occultum, a morphokinetic arrest in the positioning of the eyes, and lack of formation of the nasal tip. The widow's peak scalp-hair anomaly results from ocular hypertelorism, since the two fields of hair-growth suppression are also farther apart than usual (9,57).

Experimental models have been produced by various teratogenic agents in animals. Burck and Sadler (4) concluded that cell death in the frontonasal process midline mesenchyme and in the neural epithelium and/or increased facial width were underlying factors in diazo-oxo-norleucine-induced median cleft face in mice. Darab et al (10), studying methotrexate-induced median cleft face in mice, implicated damage to blood vessels in the frontonasal process (dilated and congested blood vessels) and to distension of the developing brain. Interestingly, the number of instances of twinning is greater in families with frontonasal malformation than in the general population (56). We have no explanation for this phenomenon.

Most cases of frontonasal malformation are sporadic (12,56), although it has been found in identical twins (A Perez Aytes et al, personal communication, 1989) and in a mother and two of her children (22). However, most reports citing familial aggregation likely represent other entities that have frontonasal malformation as a component manifestation; indeed, there are several case reports that do not represent examples of FNM (2,3,5,14–18,20,38,44,56,61,63).

Toriello (61) described a distinct subgroup associated with a severe form of frontonasal malformation. This syndrome includes epibulbar dermoids, agenesis of the corpus callosum, Dandy-Walker malformation, tibial aplasia, and bilateral polydactyly of halluces. The facies is shown in Fig. 24–2A; the halluces in Fig. 24–5. This combination in part or in full has been reported by several other authors (5,14–16,20,42,56,61,64,65). Warkany et al (65) described two half-sisters with this combination, and parental consanguinity (15) has been reported.

The *oculoauriculofrontonasal syndrome* [5,16(case 2),25,28,29,42, 43,46] includes manifestations of the oculo-auriculo-vertebral sequence, including epibulbar dermoids and preauricular tags, and FNM. *Fronto-facio-nasal dyplasia* (23,50,67) includes variable combinations of cerebral, ocular, nasal, and other defects, and may itself be heterogeneous. For example, Temple et al (60) described five children with iris coloboma, mental retardation, and other anomalies in some, whereas Reardon et al (50) described children with coloboma, marked alar deficiency, and

Fig. 24–4. *Frontonasal malformation*. (A) Hypertelorism, bifid nose. (B) Colobomas of nostrils, wide nasal bridge, anophthalmia on right, microphthalmia on left. When the eyes are involved, this is called *fronto-facio-nasal* type. (A from W DeMyer, Neurology 17:961, 1967.)

normal cognitive development. For a review, see Toriello et al (62). DeMoor et al (11), Meinecke and Blunck (42), and Meguid (41) described children with FNM, heart defects, and other anomalies. All cases were sporadic. Guion-Almeida and Richieri-Costa (27) and Masuno et al (40) reported children with FNM, macroblepharon, eyelid colobomas, macrostomia, ear anomalies, submucous cleft palate, mental retardation, and Dandy–Walker anomaly, which they believe represented a provisionally unique syndrome. The heterogeneity of FNM is consistent with DeMyer's (12) observation that when extracephalic anomalies occur or when hypertelorism is severe, mental deficiency appears to be increased.

A B

Fig. 24–5. *Frontonasal malformation*. (A,B) Shortening of right tibia, preaxial polydactyly. (From WC Edwards et al, Am J Ophthalmol 72:202, 1971.)

Conversely, when extracephalic anomalies are absent and hypertelorism is mild, the probability of mental deficiency is low.

There have been a few reports of chromosomal anomalies in those with FNM. Chen et al (7) described FNM in an individual with *dup(2q) syndrome*. Fryns et al (24) noted a child with FNM and an apparently balanced translocation t(15;22)(q22;q13) (although this individual may have had craniofrontonasal syndrome), and Stevens and Qumsiyeh (58) reported a complex translocation involving chromosomes 3,7, and 11. Stratton and Payne (58a) and Kirkpatrick and Pauli (36) reported deletion of 22q11.

Facies. The clinical appearance of the face has been classified on a somewhat different basis by DeMyer (12) and Sedano et al (56). Facies can be graded from mild to severe (Figs. 24–1 to 24–5), although it should be recognized that the variability seen in FNM simply constitutes a continuum of the basic developmental defect.

Eyes. Hypertelorism is a constant feature. Secondary telecanthus may be observed in severe examples. Roarty et al (51) found that patients with moderate to severe FNM had refractive errors and/or strabismus. The presence of epibulbar dermoids (9,14), congenital cataracts (56), iris colobomas (36,60), upper eyelid colobomas (16,20,57), and symblepharon has been described, but this should suggest that this could represent a multiple anomaly syndrome of which FNM is but one manifestation.

Nose. In severe cases, the nose may be flattened with widely spaced nostrils and broad nasal root. In other cases, clefting of the nose or notching or clefting of the nasal alae may be seen. When notching occurs bilaterally, the nose appears square (Fig. 24–2A). Nasal tags have also been noted (53).

Ears. Preauricular tags (4), low-set ears, absent tragus, and conductive hearing loss (55) have been reported, although here again the presence of these anomalies could suggest the presence of a syndromic cause of FNM and observed anomaly.

Central nervous system. Mental deficiency has been found occasionally (14,20,64). Although Hori (32) described two hypophyses, this case is likely an example of facial duplication.

Radiographic findings. Anterior cranium bifidum (33) and hypoplastic frontal sinuses are seen (34). Other findings include absence of corpus callosum (1,3,12,16,20,32,58,59,63,65), but in some of these cases, one of the above-described syndromes may be present. Approximately 50% of those with more severe facial phenotype, on MRI and CT examination, have dense calcification of the falx and interhemispheric lipoma (42). The latter is sometimes mistaken for callosal agenesis (46). Hydrocephaly (56), occipital encephalocele (45), early occlusive anterior and middle cerebral artery disease (RJ Gorlin and MM Cohen Jr, personal observation, 1990), as well as mild (pseudohemispheric) holoprosencephaly (54) have been documented.

Other findings. Clinodactyly (12,66), brachydactyly (RJ Gorlin and MM Cohen Jr, personal observation, 1990), parietal foramina (45), micropenis (20), cryptorchidism (12,56), tetralogy of Fallot (11,27), and other anomalies (12,52,56) have been documented. The presence of other findings should prompt a search for other manifestations indicative of an underlying syndrome.

Oral manifestations. Median cleft of the upper lip was present, especially in the more severe type, as noted above (56). Rarely, cleft lip and/or palate is observed (32,56).

Differential diagnosis. The same facial phenotype may be observed with large anterior encephalocele, hamartoma, frontal lipoma, frontal teratoma, and intracranial cyst (28,30,39). Bifid nose may occur without hypertelorism, and familial instances are known (19,66). Since epibulbar dermoids, and sometimes upper eyelid colobomas and preauricular tags, may occur in association with frontonasal malformation, differentiation from *oculo-auriculo-vertebral spectrum* should be kept in mind. *Fronto-facio-nasal dyplasia* should be considered in differential diagnosis because of clinical similarities in facial appearance (see above). This condition apparently has autosomal recessive inheritance. Keith and Macomber (35) described a case of "hypertelorism" occurring in two sisters that we cannot classify among known conditions. Fragoso et al (18) reported a patient who, in addition to frontonasal malformation, exhibited fusion of the second and third cervical vertebrae and pedal postaxial polydactyly. It was labeled frontonasal malformation in combination with Klippel-Feil anomaly. The patient was female and may represent an example of *craniofrontonasal syndrome*, although craniosynostosis was not mentioned. Various conditions recently isolated from the frontonasal malformation pool should be excluded such as autosomal dominant *Greig cephalopolysyndactyly (13), Opitz BBB/G syndrome, Sener syndrome, acro-fronto-facio-nasal dysostosis, Teebi hypertelorism syndrome, Aarskog syndrome, Waardenburg syndrome, craniofrontonasal syndrome*, and *Pai syndrome* (28). *Cerebro-fronto-facial syndrome* is discussed in Chapter 25.

Laboratory aids. Frontonasal malformation has been diagnosed prenatally (21).

Craniofrontonasal syndrome

A subpopulation of frontonasal malformation patients was identified by Cohen in 1979 (1) as representing a heritable condition which he called *craniofrontonasal dysplasia*. An earlier series of patients was reported in 1977 by Reich et al (29). The syndrome consists of frontonasal malformation, craniosynostosis (especially including the coronal suture), and various skeletal and soft tissue abnormalities. To date over 100 cases have been identified (1–15,19,22–39,41,43). The mothers and daughters reported by McCowatt Montford (17), Ogilvie and Posel (22), and Friede (8) probably had the disorder, although craniosynostosis was not specifically mentioned. The patients with pre- and postaxial polydactyly, hypertelorism, and coronal synostosis reported by Kwee and Lindhout (16) probably have Greig cephalopolysyndactyly syndrome in which craniosynostosis can occur, albeit with low frequency. The female patient reported by Fragoso et al (7) with frontonasal dysplasia and Klippel–Feil anomaly probably had craniofrontonasal dysplasia; however, craniostenosis was not mentioned. The family with three affected males and three affected females reported by Morris et al (20) may represent some other condition. In this family, short stature, delayed bone age, shawl scrotum, and hypospadias were prominent features in affected males, and only one of three affected females had craniosynostosis. Natarajan et al (21) described affected male sibs with normal parents; the presence of multiple joint contractures and generalized hirsutism in these males suggests that they have some other condition. The reader is referred to several reviews (9,34,42).

X-linked dominant inheritance has been observed through three generations (9,15,27,32,37,38) but, uniquely, females are affected much more frequently and usually more severely than males (9,36), who usually have only hypertelorism and exotropia and are probably underascertained. The gene has been mapped to Xp22 (6,27a). However, there have been a few males with more severe manifestations than their female relatives (4,12) and a few markedly affected male examples (2,4,12). Most affected males represent new mutations. Metabolic interference analogous to the T-semilethal allele of the mouse T locus has been proposed (27,32–38).

Craniofacial features. Craniofacial features include brachycephaly, unilateral or bilateral coronal synostosis (50%), frontal bossing, hypertelorism (95%), and broad nasal bridge with broad bifid nasal tip (55%). An increased bony interorbital distance noted radiographically is essential to diagnose the "carrier male." Widow's peak, strabismus, and downslanting palpebral fissures have been frequently reported. The orbits are asymmetric in 50%. Abnormal ocular movements and/or squint are common (23). Unilateral or bilateral cleft lip has been

A B

Fig. 24–6. *Craniofrontonasal syndrome*. (A) Facial asymmetry, hypertelorism, exotropia, downslanting palpebral fissures, bifid nasal tip, and repaired bilateral cleft lip. (B) More mildly affected sister of A showing exotropia, hypertelorism, and hypermobility of shoulder girdle. (From E Grutzner and RJ Gorlin, Oral Surg Oral Med Oral Pathol 65:436, 1988.)

observed in a few cases (6). Other findings have included highly arched palate, malocclusion, and pterygium colli (1,5–9,15,18,20,22–27,32–38) (Figs. 24–6 and 24–7).

Limbs. Longitudinally split nails have been observed in 40% (Fig. 24–8). Other findings have included hyperextensible joints (which require supportive measures), broad great toes, partial soft tissue syndactyly, short fifth fingers, clinodactyly, gap between the first and second toes, long fingers and toes, and single transverse palmar creases (1,5–9, 15,23–27,35,38). The lower limbs are asymmetrically short in 15% (34).

Other findings. The hair is thick, wiry or curly in 30%, with this manifestation developing during childhood. There is unilateral breast hypoplasia in 50%. High and prominent scapulae, small or absent clavicles (25%), scoliosis, vertebral anomalies, pectus excavatum, axillary pterygia (10%), and other minor skeletal defects have been recorded (23,34).

Intelligence. Although normal intelligence has usually been found, mental deficiency has been noted in a few females (9,15).

Fig. 24–7. *Craniofrontonasal syndrome*. (A) Similar facies in unrelated patient. (B) Male hemizygote. Note only hypertelorism, mild downslanting palpebral fissures, and repaired cleft lip. (From E Grutzner and RJ Gorlin, Oral Surg Oral Med Oral Pathol 65:436, 1988.)

A B

Fig. 24–8. *Craniofrontonasal syndrome*. Vertical striping of nail. (From E Grutzner and RJ Gorlin, Oral Surg Oral Med Oral Pathol 65:436, 1988.)

Differential diagnosis. *Frontonasal dysplasia, fronto-facio-nasal dysplasia, Greig cephalopolysyndactyly syndrome*, and other craniosynostosis syndromes must be excluded. *Brachycephalofrontonasal dysplasia* (*Teebi hypertelorism syndrome*) has some resemblance to craniofrontonasal dysplasia but without bifid nose, craniosynostosis, pterygium colli, rounded sloping shoulders, or nail abnormalities. Some patients have shawl scrotum (40). This may be the same disorder as that described by Morris et al (20) as their two male patients also had shawl scrotum.

Teebi hypertelorism syndrome (brachycephalofrontonasal dysplasia)

Teebi (4), in 1987, described an apparently new autosomal dominantly inherited syndrome with features of craniofrontal dysplasia but with normal or slightly broad nasal tip and without evidence of craniosynostosis or nail abnormalities. The face was round with prominent forehead, widow's peak, pronounced hypertelorism, mild downslanting palpebral fissures, very heavy and broad eyebrows, ptosis of lids, broad and/or depressed nasal bridge, short nose, fleshy ear lobules and/or prominent anthelix, hypoplastic maxilla, long deep philtrum, dental malocclusion, horizontal thin upper lip and/or pouty lower lip, and prominent lower jaw (Fig. 24–9). Additional cases have since been described (2,3,5,6). It may be the same as the disorder reported by Morris et al (1).

The hands are small and broad with mild interdigital webbing and clinodactyly of the fifth fingers. All of the males had a shawl scrotum. Growth and cognitive development are normal. Heart defects are an occasional manifestation (2,5,6). Differential diagnosis includes *Aarskog syndrome* and *Opitz BBB/G syndromes*, as well as *craniofrontonasal syndrome*.

Acro-fronto-facio-nasal dysostosis

Richieri-Costa et al (2), in 1985, described two sibs born to first cousins and, in 1992, a second pair of sibs (4). In addition to bilateral cleft lip–palate, they shared severe mental retardation, hypertelorism, widow's peak, S-shaped palpebral fissures, ptosis, long eyelashes and eyebrows, broad notched nasal tip, macrostomia, anteverted pinnae, occasional postaxial polysyndactyly of hands, hypoplasia of distal phalanges of digits 1 and 5, PIP or DIP camptodactyly of some or all digits, short legs, and talipes equinovarus (Fig. 24–10). Radiographic changes included brachycephaly, vertical clivus, capitate-hamate fusion, abnormal ossification of patellae, curved or hypoplastic fibulae, brachymetacarpalia, and iliac hypoplasia (Figs. 24–10 to 24–13).

In 1989, Richieri-Costa et al (3) reported a more severe type of acro-fronto-facio-nasal dysostosis associated with microbrachycephaly, wide forehead, marked hypertelorism, broad nose with midline groove, soft tissue syndactyly of fingers 3–4, and hypospadias. Naguib (1) described an earlier example of this type. Affected sibs and parental consanguinity suggest autosomal recessive inheritance. Teebi (5) suggested the more severe form be termed the Naguib–Richieri-Costa syndrome.

Fronto-facio-nasal dysplasia (cleft lip-palate, blepharophimosis, lagophthalmos, and hypertelorism) (Gollop syndrome)

Two sibs with consanguineous parents were described by Gollop (2) in 1981. The sibs had cleft lip–palate, blepharophimosis, lagophthalmos, primary telecanthus, S-shaped palpebral fissures, and eyelid colobomas (Fig. 24–14). Gollop et al (3) and others (5,8) provided additional documentation.

Inheritance is autosomal recessive. Variability of expression is wide.

The most constant features include defects of the eyes (blepharophimosis, lagophthalmos, hypertelorism, S-shaped palpebral fissures, colobomata of eyelids, absent eyelashes). The midface is hypoplastic and there is cleft lip–palate. Defects are found in the alae nasi and the nasal tip is bifid or grooved.

Less common findings include microphthalmia and iris colobomata. The corpus callosum has been absent in one of two cases.

Several examples are possible but not typical (1,4,6,7).

Blepharonasofacial syndrome

Pashayan et al (3) and Putterman et al (4), in 1973, described autosomal dominant inheritance of a syndrome of telecanthus and lateral displacement and stenosis of lacrimal puncta, bulky nose with broad nasal bridge, masklike face, midfacial hypoplasia, longitudinal cheek furrows, and trapezoidal upper lip (Fig. 24–15). Joints were hyperextensible. All patients exhibited a positive Babinski reflex, poor coordination, torsion dystonia, mild soft-tissue syndactyly of the fingers, and mental retardation.

Allanson (1) described a mother and son with expressionless facies, telecanthus with blepharophimosis, lacrimal duct anomalies, broad nasal root, bulky nasal shape, hypoplastic alae and deficient cartilage, thickened facial skin, dysmorphic pinnae, and mild interdigital webbing. The mother had cleft palate, hoarse voice, oligodontia, and optic atrophy. Upswept frontal hair was evident in both.

Sommer et al (5), in 1983, described a mother and daughter with telecanthus, blepharophimosis, anomalous lacrimal apparatus, broad nasal root with underdeveloped alae nasi, and hypoplastic nasal root. There was sensorineural hearing loss and camptodactyly of fingers. A relationship to *Klein–Waardenburg syndrome* was raised, and a *PAX3* mutation was found (2).

Cerebro-facio-articular (Van Maldergem) syndrome must be excluded.

X-linked mental retardation syndrome associated with α-thalassemia (ATR-X syndrome, cerebro-facio-genital syndrome)

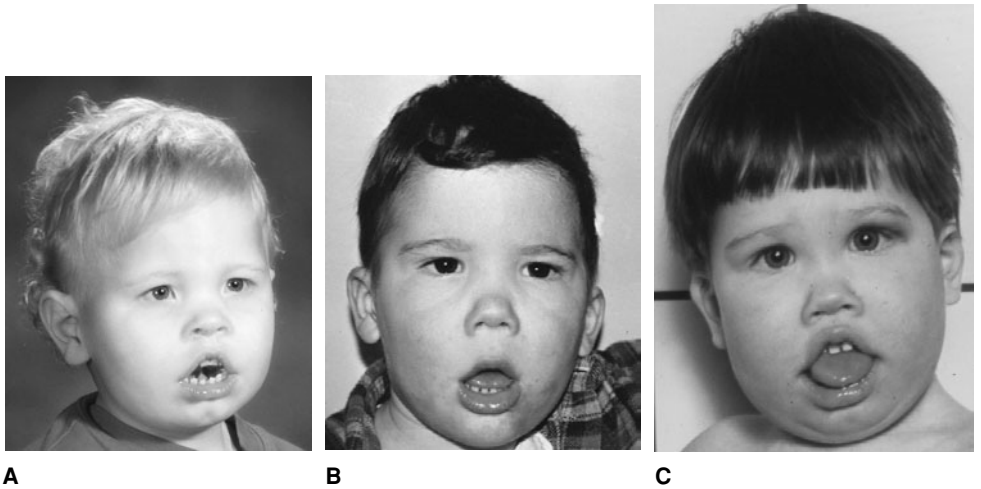
An X-linked syndrome (ATR-X) comprising severe mental retardation, characteristic facies, genital abnormalities, and mild hemoglobin H (HbH) disease was first described by Weatherall et al (30) in 1981 and further defined in the same family by Wilkie et al (34) in 1990. Since then approximately 100 cases have been reported (1–27,30,32–34). For excellent reviews, see Wilkie et al (32) and Gibbons et al (9). RE Stevenson (personal communication, 1998) suggested the name *cerebro-facio-genital syndrome* because α-thalassemia is not a constant feature.

HbH disease occurs when a greater than 50% reduction in synthesis of α globin chains of adult hemoglobin results in the accumulation of excess β globin chains. The latter form β_4 tetramers. Gibbons et al (8) and Houdayer et al (13) found that the gene maps to Xq13.3(ATR-X). The syndrome appears due to mutations in XNP which is a zinc-finger helicase-2 regulator involved in transcription (10,22,27). Skewed inactivation occurs in ATR-X so that carrier females show no expression of the condition (11,26). Mutations cause diverse changes in methylation (11a,11b,11c). Mosaicism has been noted (1a). The disorder appears to be allelic with *Juberg-Marsidi syndrome* and Carpenter–Waziri syndrome (vide infra).

The patients described by Chudley and colleagues (2,3) and Adès et al (1) have similar phenotype despite absence of HbH disease (27). There was, however, neither microcephaly nor HbH disease (Fig. 24–16C). In spite of remarkable clinical similarity, the condition does not map to Xq33.3 (26a).

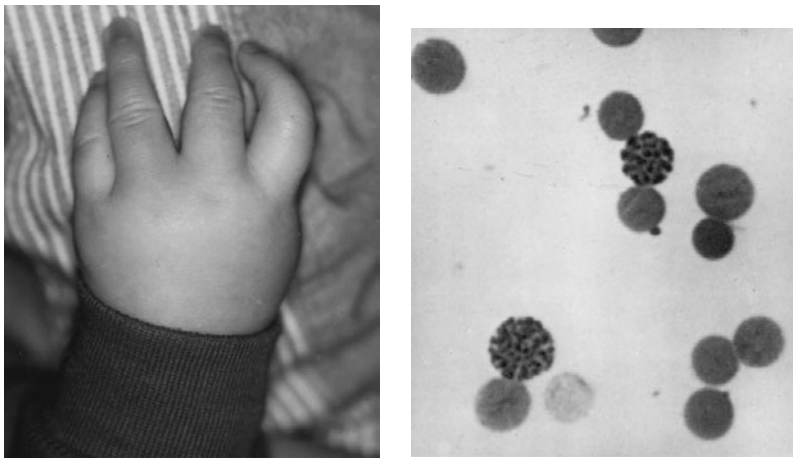
Clinical considerations. Hypotonia and feeding difficulty become apparent within the first few days of life. Birthweight is normal. All developmental milestones are subsequently delayed. Severe to profound mental retardation is a constant feature. Drooling is common. Walking is especially retarded and may not be achieved even by adulthood. Speech is absent in 90%. Even when speech is achieved, it is limited to a few words, and comprehension is poor. Self-biting and/or hitting has been noted in 50%. No more than partial bowel or bladder control is ever attained. Seizures occur in approximately 35%. Most patients (90%) are hypotonic from birth, while others develop spasticity in time. Cerebral atrophy is evident on CT scan in approximately 35%. Apneic spells are noted in 60%. Short stature is evident in 65% (11b).

Facies. Characteristic facies is marked by microcephaly, upswept frontal hairline, telecanthus (30%), epicanthic folds (85%), flat nasal bridge (70%), midface hypoplasia (85%), small triangular nose with anteverted nostrils with columella and septum above the alae (85%), and carp-shaped mouth with full drooping lip (95%) (Fig. 24–16). The tongue is often enlarged and may protrude. Malocclusion is common, and the incisors are widely spaced (70%). The pinnae are mildly dysmorphic (75%).



A B C

Fig. 24–16. *ATR-X (*A,B*). Chudley-Lowry syndrome* (C). Face marked by telecanthus, epicanthic folds, markedly flat nasal bridge, midface hypoplasia, and small triangular nose with anteverted nostrils. The columella and septum are above alae. The mouth is usually held open and the lip droops. (A courtesy of D Elliott-Pearson, Wallace, Idaho. B from D Lacombe et al, Arch Fr Pediatr 50:723, 1993. C from AE Chudley et al, Am J Med Genet 31:74, 1988.)



A B

Fig. 24–17. *ATR-X syndrome*. (A) Tapering fingers. (B) Blood stained with brilliant cresyl blue exhibits coarse hemoglobin granulations. (Courtesy of RJ Gibbons, London, England.)

Initially round, the facies tends to coarsen with age. Head circumference is less than the third centile in approximately 70% (9).

Genital anomalies. Testicular abnormalities, seen in 90%, range from small, high-lying (15%) testes to cryptorchidism (70%) to severe dysgenesis. The scrotum may be hypoplastic or shawllike (20%), and the penis small with deficient foreskin (15%). In 20%, hypospadias has been noted (5). Occasionally a male will have female or ambiguous genitalia (19,24).

Skeletal abnormalities. A wide range of relatively minor anomalies has been reported which include delayed bone age (60%), tapering digits (15%), clinodactyly (25%), brachydactyly (10%), overlapping digits (30%), syndactyly (30%), kyphoscoliosis (40%), coxa valga (35%), and talipes equinovarus (40%) (Fig. 24–17A). Short stature has been noted in approximately 50%.

Other findings. Regurgitation of food (55%), constipation (30%), and respiratory infections (40%) are relatively common. Hearing loss has been noted in a few cases.

Differential diagnosis. There is a superficial resemblance to various disorders such as *Coffin–Lowry syndrome, tetrasomy 12p, Smith-Magenis syndrome, Angelman syndrome, FG syndrome*, and *Smith-Fineman–Myers syndrome* (26a). Coarse facial appearance may bring lysosomal storage disorders to mind. There has been evidence that ATR-X syndrome is related to *Juberg–Marsidi syndrome* (25) and Carpenter–Waziri syndrome (1b). They map to the same region (Xq12–q21) and have been shown to be allelic (28).

There is another α-thalassemia/mental retardation syndrome due to contiguous deletion of 16p13.3(ATR-16). Physical anomalies are mild (tall forehead, hypertelorism, downslanting palpebral fissures, ptosis, broad flat nasal bridge, anteverted nares, macrodontia, small chin, and talipes equinovarus (6,18,30,31). Mild to moderate mental retardation has been demonstrated. Some have hypodontia, seizures, incoordination and speech delay, and some males have cryptorchidism. Nipples may be accessory or highly placed.

Laboratory findings. Hemoglobin H inclusions can be demonstrated in hemizygotes after incubation of red cells from fresh whole blood with 1% brilliant cresyl blue in isotonic saline at room temperature for 4 hours or overnight. The proportion of cells in which the coarse hemoglobin granulations are found ranges from 0.01%–40% (Fig. 24–17B). Repeated analyses may be required to demonstrate the changes (19). We were initially fooled by failure to demonstrate HbH in two families in spite of typical clinical findings. Villard et al (27), in fact, have demonstrated that one does not need α-thalassemia to manifest the ATR-X phenotype. Villard et al (29a) reported a relatively inexpensive molecular first screen approach. Detected electrophoretically, HbH has ranged from 0–6.7% and is correlated with the proportion of cells in which HbH inclusions can be found. Normal hemoglobin levels in red cell indices do not exclude the condition, nor does the inability to show HbH electrophoretically, which occurs when the proportion of HbH positive cells falls below 3% (34). In female heterozygotes one can see the rare HbH inclusions as one would expect by lyonization (8).

Opitz oculo-genito-laryngeal syndrome (Opitz BBB/G compound syndrome)

In 1965, Opitz et al (40) briefly reported a syndrome consisting of hypertelorism, hypospadias, and other anomalies. Four years later, Opitz et al (42), described the BBB syndrome and the G syndrome, considering them to be different disorders. The initials were those of the names of the reported families. Subsequent publications (1,12,21,30,43,57), noting similarities and differences between both disorders, proposed various names: hypertelorism-hypospadias, telecanthus-hypospadias, and Opitz syndrome for the BBB syndrome and hypospadias-dysphagia, Opitz–Frias syndrome, and Opitz G syndrome for the G syndrome. Cappa et al (6) suggested the eponym Opitz syndrome to unify both entities.

Recent molecular studies have, however, demonstrated that there is genetic heterogeneity, with one locus mapping to Xp22.3, another to Xq22 (5a) and still another mapping to 22q11.2 (48). A few patients with clinical findings consistent with Opitz BBB/G syndrome have had

Fig. 24–18. *Opitz oculo-genito-laryngeal syndrome*. Widely-spaced eyes. [From JM Opitz et al, Birth Defects 5(2):86, 1969.]

chromosome 22q11.2 deletions (9,19,33,34). There are several examples of male-to-male transmission (7,16,17,21,54,55,60). A pericentric inversion of the X chromosome was reported by Verloes et al (58). The X-linked gene has been identified as the *MID1* gene, which is responsible for midline development (14,46). The gene product, midin, interacts with an X-chromosomal gene mapping to the linkage interval of FG syndrome (55a). Robin et al (49) concluded that posterior pharyngeal clefts and anteverted nostrils were seen in the X-linked form but not in the autosomal dominant form. Otherwise there was so much overlap that they could not be separated. Imperforate anus and dysphagia occurred more often in the X-linked form. Females with the X-linked form were not necessarily hyperteloric. Fryns et al (20a), however, suggested that there is a distinct facies in the X-linked form: prominent bossed forehead, hypertelorism, deep nasal bridge, anteverted nostrils, long philtrum, thin upper lip with downturned corners, and transverse crease below lower lip. The gene is rarely nonpenetrant (49,54).

Facies. Various degrees of hypertelorism/telecanthus are observed in 90% as well as slight upslanting or downslanting of the palpebral fissures, epicanthic folds, and strabismus (8,10,11,21,23,32,38,40,41,48,51,60), (Figs. 24–18 and 24–19). Some patients have exhibited relative entropion of the lower eyelid. The nasal bridge is flattened in the autosomal dominant form (Fig. 24–19), and the nostrils anteverted and philtrum flat and inapparent in the X-linked form (49). Usually there is mild micrognathia (13). Cephalometric analysis was carried out by Brooks et al (5). The pinnae may exhibit mild posterior rotation and occasionally abnormal modeling, primarily affecting the helix (10,13,18,35,43). Cranial asymmetry occurs in 20% (8,45) and brachycephaly, prominent forehead, open fontanels (13,18,31,36,44), prominent metopic suture, widow's peak, and low-set anterior and posterior scalp line have been observed occasionally (12,17,21,23,32). Prominence of occipital and parietal eminences can occur (12,21,41). Patients can present normal intelligence or mild to moderate mental deficiency (6,33,35,38,42,56).

Genitourinary system. Hypospadias occurs in most affected males with either genotype (49) (Fig. 24–20). The degree of hypospadias varies from a mild coronal to a scrotal type with an associated ventral urethral groove (15,23). In mild cases, the scrotum appears normal; in severe examples, the scrotum is cleft and chordee may be so severe as to draw the tip of the glans to the anterior edge of the anus (Fig. 24–21). Cryptorchidism, renal anomalies, ureteral stenosis, ureteral reflux, and inguinal hernia have been noted (6,8,12,21,23,35,38,41,42,49).

Imperforate or ectopic anus with rectourethral fistula has been reported (12,17,42,44,55) and may be associated more often with the X-linked

A B

Fig. 24–19. *Opitz oculo-genito-laryngeal syndrome*. (A) Hypertelorism, narrow palpebral fissures, anteverted nostrils. (B) Patient of one of the authors. [A from JM Opitz et al, Birth Defects 5(2):95, 1969.]

form (49). Affected females have normal genitalia, but splayed posterior labia majora, anteriorly placed anus, and imperforate anus have also been rarely noted (39).

Respiratory system. Minor respiratory anomalies might be present in patients. In most infants, respiration usually begins spontaneously at birth, and generally the Apgar scores are normal (12). Laryngotracheal clefting may be limited to those with the X-linked form (11,49,50), although other respiratory difficulties can occur in both types. In some infants, stridorous respiration and a hoarse cry may be noted even before the first feeding. In severe cases, the infant sucks eagerly but seems to have difficulty in swallowing, manifested by choking, coughing, and resultant cyanosis (26,36). This may be followed by respiratory distress, increase in stridor, apparent aspiration pneumonia (12), patchy atelectasis and emphysema, and, in chronic cases, bronchiectasis and anesthetic risk (4). Cinefluoroscopic studies have shown apparent neuromuscular dysfunction of the swallowing mechanism, with up to half of each mouthful entering the tracheobronchial tree with gastroesophageal reflux (10) (Fig. 24–22). It is noteworthy that cinefluoroscopic studies can miss the presence of a laryngotracheal-esophageal cleft (3). Malformation of the upper gastrointestinal tract or respiratory tract (59,60) occurs in up to 40%. Hypoplasia of vocal cords has been found at autopsy (13).

Fig. 24–20. *Opitz oculo-genito-laryngeal syndrome*. Hypospadias. [From JM Opitz et al, Birth Defects 5(2):86, 1969.]

Esophageal dysmotility is present in approximately 70% (60). In one family, this was associated with complex malformations: short trachea with high carina and supraclavicular tracheal bifurcation, severe hypoplasia of a lung, epiglottis, vocal cords, and larynx, with absence of the dorsal portions of the larynx and first tracheal rings and a single cavity extending from the epiglottis and hypopharynx superiorly to the trachea and inferiorly to the esophagus (32). Hypoplasia of the epiglottis has also been noted (16,52).

Cardiovascular findings. Congenital heart defects (CA, PDA, ASD) had been estimated to occur in 20%–25% of patients (27,38,45,60), but in a recent review, Robin et al (49) found only 5% had a heart defect.

Other findings. Diastasis recti, multiple lipomas, and slight hyperextensibility of joints have been observed (8,17,41,51). Cutaneous syndactyly of toes 2, 3, and 4 has been noted (21). Distally placed axial triradii, increased number of arches, and bridged palmar creases also have been reported (21,40,54). Unlobed lungs as well as bifid renal pelvis with double ureter, Meckel diverticulum, and absence of the gallbladder and duodenal stricture have been seen (29). Fetal hydrops has been reported prenatally in a patient subsequently diagnosed as Opitz G syndrome (44). Agenesis of the corpus callosum is a relatively infrequent finding (33,37). Other brain anomalies in a few patients include cerebellar vermis hypoplasia, cortical atrophy, wide cavum septum pellucidum, and Dandy-Walker malformation (24,33). Posterior scalp defects were described in one child (20); the authors made the point that this was evidence for defective midline development. Given that the gene responsible for the X-linked form is involved in midline development, it is not surprising that a wide spectrum of midline anomalies could be found associated in low frequencies in at least the X-linked form. Platelet dysfunction has been mentioned once (28).

Oral manifestations. Cleft lip–palate and micrognathia have been observed in 25%–35% (6,8,12,21,23,35,38,41,45,49,51,53,55,56,60). Fused and supernumerary teeth and malocclusion may occur (8,35,38, 41,51,53). Additional oral manifestations include broad or bifid uvula and ankyloglossia, bifid tongue, or shortened lingual frenulum (2,13,17, 18,22). Brooks et al (5) concluded that affected males are more likely than affected females to have oral anomalies.

Differential diagnosis. Hypertelorism and hypospadias may each be observed as isolated anomalies or in association with various other malformation syndromes. Reed et al (47) erroneously reported three brothers with the *branchio-skeleto-genital syndrome* as examples of the type I syndrome. There is overlap with *FG syndrome*.

A B

Fig. 24–21. *Opitz oculo-genito-laryngeal syndrome*. (A) Cleft scrotum with anterior displacement, severe chordee deformity of hypoplastic phallus. (B) Hypospadias, chordee. [A from JM Opitz et al, Birth Defects 5(2):95, 1969.]

Laboratory aids. Cinefluoroscopic study of swallowing should be carried out to determine LTE defects. The disorder has been diagnosed prenatally by ultrasound (25). Linkage studies should be available.

Robinow syndrome (fetal face syndrome)

Robinow et al (34), in 1969, reported a syndrome consisting primarily of characteristic facies, mesomelic brachymelia of arms, short fingers, and hypoplastic genitalia. Since then, over 80 patients have been described (1–7,9–26,28–36,39–43,45,47–55). Several cited cases are uncertain [8,27,37(case 1)].

In some families (34,42,47), the syndrome has autosomal dominant inheritance, and there is increased paternal age (33). However, affected sibs with normal parents (15,32,35,40,43,51,52) indicate an autosomal recessive type. Perhaps this is more common in Turkey (1b). Afzal et al (1,1a) and van Bokhoven et al (47a) found that the recessive form results from mutation of *ROR2 tyrosine kinase* gene located at 9q22. We assume that this is the same as in the brachydactyly B reported by Schwalbe et al (40a). Although the dominant and recessive forms have phenotypic overlap, the recessive type is more severe. Both share the typical facies, short stature, hypoplastic genitalia, and normal intelligence, but in the recessive form short stature and brachymelia appear to be more marked and there are numerous rib and vertebral anomalies and radial head dislocation (35%) (4,31). However, the ability to separate the forms has been denied by Butler and Wadlington (9), who suggested that in an isolated case a recurrence risk of 25% should be given. Robinow and Markert (33) aver that in approximately 20%, separation into dominant and recessive forms cannot be made. Robinow syndrome has been seen in identical twins (38).

Birthweight and birth length are somewhat greater in the dominant type. Death occurred before 3 years in approximately 10% with the recessive form (28,32,49,54); cause of death was pulmonary or cardiac disease.

Face. The face resembles that of a fetus at 8 weeks: disproportionately large neurocranium, dolichocephaly, bulging forehead, hypertelorism, wide palpebral fissures, S-shaped lower eyelids (which can make the eyes look exophthalmic), and short broad and upturned nose with anteverted nostrils. There is a long philtrum with a broad horizontal upper lip

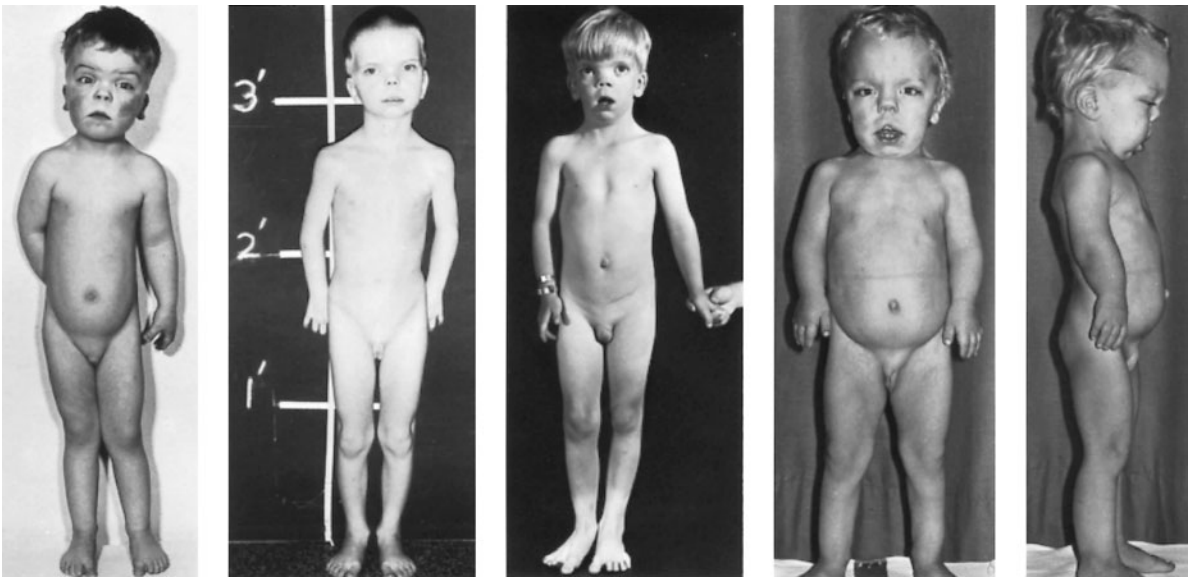

Fig. 24–23. *Robinow syndrome*. (A) Flattened facies, micropenis. (B) *Dominant form*. Short stature, mesomelia, and micropenis. (C) Compare with boy seen in A. (D,E) *Recessive form*. Note short philtrum and tented upper lip. (A from RA Pfeiffer and H Müller, Padiatr Padol 6:262, 1971. B courtesy of M Robinow, Yellow Springs, Ohio. C courtesy of HN Needleman, Boston, Massachusetts. D,E from RE Seel et al, Monatsschr Kinderheilkd 122:663, 1974.)

in the dominant form (Fig. 24–23A-C and 24–24). A short philtrum is seen in the recessive form with an inverted V-shaped or tented upper lip (Fig. 24–23D,E). In both forms, there are frequent overfolding of the helices and a small chin (Fig. 24–25). Cephalometric study has been carried out by Israel and Johnson (18).

Central nervous system. Intelligence is usually normal but developmental delay and mental retardation have been found in approximately 20%. Severe mental retardation was noted in the sibs reported by Baxovà et al (7). The macrocephaly is not associated with hydrocephaly nor is there any dramatic change in the slope of head circumference with age.

Musculoskeletal alterations. Stature is −1.5 SD in the dominant form and −4.9 SD in the recessive form. A few authors (9,42) described adults with the dominant type having normal height, although it may be possible that the diagnosis is incorrect in these cases. An alternative diagnosis could be *Teebi hypertelorism syndrome*. Kawai et al (20) reported a child with Robinow syndrome and growth hormone deficiency. However, neither photographs nor measurements were provided, thus making the diagnosis suspect. Forearm brachymelia is found to some degree in nearly all patients (21,23,42,49) making the height/span ratio excessive. Limitation of extension and supination or pronation at the elbows has been noted (21,51). Robinow and Markert (33) found radius/humerus length to be −3.6 SD in the dominant form in contrast with −10.6 SD in the recessive form.

Fig. 24–24. *Robinow syndrome*. (A) Close-up of face showing fetal proportions. (B,C) Sister of boy seen in A. Note S-shaped lower eyelids, ocular hypertelorism, and midface hypoplasia. (Courtesy of M Robinow, Yellow Springs, Ohio.)

Fig. 24–25. *Robinow syndrome*. Ear with overfolded helix.

Hemivertebrae and/or fused vertebrae (65%), progressive scoliosis (50%), and displaced and/or fused and abnormal numbers of ribs (35%) are found in the recessive form (Fig. 24–26). In 10% of those with the dominant form, there is a single butterfly vertebra. Short radius and short ulna are also found. The phalanges are short, and the terminal phalanx of the thumbs and halluces may be bifid (14,17–21,29) (Fig. 24–27). Some patients have a split hand anomaly (5). Small hands with clinodactyly and brachymesophalangy of fifth fingers are noted in over 85%. An increase in bone sclerosis has been reported (21,42). Delayed bone age is evident in 35%. A characteristic metacarpophalangeal pattern profile has been demonstrated (10). Dysplastic nails occur in approximately 50% (9). Radial head dislocation is almost never seen in the dominant form but is usual in the recessive form. Inguinal hernia has been reported (42). The umbilicus may be highly placed (13).

Genitourinary system. In spite of the genital malformations frequently present, sex can be properly assigned in the newborn period. Unnecessary delay in evaluating ambiguous external genitalia should be avoided since sex determination can be made by examination alone regardless of the malformation. Micropenis, a very common feature, is usually apparent at birth (34) (Fig. 24–28). Computerized tomography and magnetic resonance imaging of the genitalia has been done on three boys with Robinow syndrome (54). This demonstrated abnormal insertion of the penile crura onto the medial aspect of the ischial tuberosity. This results in a penis which appears shorter than average. Cryptorchidism has been found in 65% (9,17,34,42) and absent penis or epididymal or vasal abnormalities (12,45,46) have also been observed. Lee et al (24) evaluated testicular function and pubertal development in four males with the syndrome and found partial primary hypogonadism, normal pubertal virilization with persistence of micropenis, and normal 5a-reductase and androgen receptor activity in genital skin fibroblasts. Schönau et al (39) reported androgen receptor deficiency. The clitoris and labia minor are hypoplastic in affected females (30,34). Vaginal atresia and hematocolpos have been found (6). Inverted nipples were present in one female (25). Bilateral renal duplication and bilateral hydronephrosis have been described (47,52).

Oral manifestations. The maxillary arch is trapezoidal, and the teeth are almost always crowded. An upper lip with inverted V-shape has been described in the recessive form (7,33,34). There is gingival enlargement in 65% (9,21,23,29,34). Cleft lip and cleft palate (26,27) are found in 10% and bifid or hypoplastic uvula (21,42) in 20%. The palate is short (18). Minor clefting of the lower lip has been noted (34) as has ankyloglossia (18).

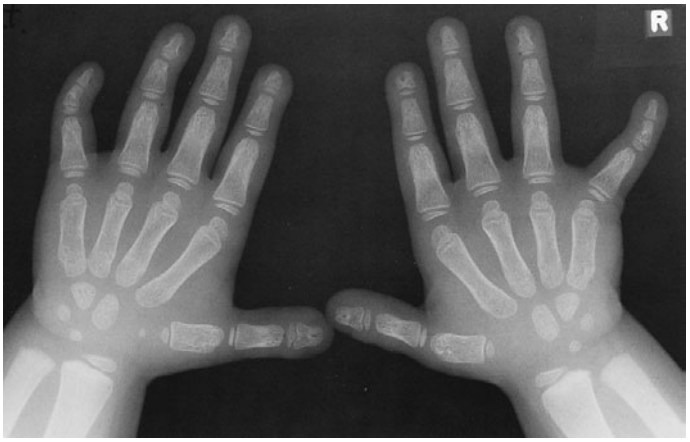
A



B

Fig. 24–27. *Robinow syndrome*. (A,B) Note shortened terminal phalanx of second digit and middle phalanx of fifth digit. Also note bifid terminal phalanges of thumb and right second digit.

Other. Congenital heart disease is present in 16%, with the defects causing right ventricular obstruction in over 50% of those with CHD (2,3,32,53). Guillen-Navarro et al (16) reported on a girl with developmental dysplasia of gray and white matter noted on MRI.

Differential diagnosis. The combination is so striking and characteristic that no other conditions with the possible exception of *Aarskog syndrome, acrodysostosis*, and *pseudohypoparathyroidism* with severe facial and acral involvement need be considered. Sabry et al (37) described sibs and an isolated case with a presumed diagnosis of Robinow syndrome; the sibs were thought by Van Steensel (48) to have a different condition. Baxovà et al (8a) described a child with rhizomelic dwarfism with superficial resemblance to Robinow syndrome. Turnpenny and Thwaites (46) described a girl with rhizomelia and facial anomalies, whom they believed had a Robinow-syndrome-like phenotype (46). Teebi et al (44) described a mother and daughter with facial and skeletal anomalies and noted similarities to those with Robinow syndrome. Differential diagnosis has been discussed extensively by Giedion et al (14).

Greig cephalopolysyndactyly syndrome

The combination of frontal bossing, scaphocephaly, hypertelorism, broad thumbs and halluces, pre- and postaxial polydactyly of hands and feet, and variable syndactyly of fingers and toes was probably first described by Greig (12) in 1926. Over 50 patients have been described subsequently (1,2,4–11,13–26,31) under a variety of terms, including frontodigital syndrome (20), Hootnick-Holmes syndrome (13), and unacceptable ones: Noack-type acrocephalopolysyndactyly (8), frontonasal dysplasia (19), median cleft face syndrome (14), and acrofacial dysostosis (16). Greig cephalopolysyndactyly syndrome is the most commonly used designation and appears to be most appropriate. Just using the designation cephalopolysyndactyly is too nonspecific. Furthermore, the term "Greig syndrome," used in the past to refer to hypertelorism, describes a symptom complex known to be etiologically and pathogenetically heterogeneous. Hence, the term "Greig syndrome" bears no relationship to Greig cephalopolysyndactyly syndrome and should be abandoned.

Autosomal dominant inheritance with markedly variable expressivity has been demonstrated in several families. Several families were reported with translocations or deletions involving 7p13 (17,23,28,33). Subsequently, the responsible gene has been mapped to 7p13 (3,30,32), and has been identified as the *GLI3* gene, which is a zinc finger transcription factor and homologous to *Cubitus interruptus* in the fruit fly (15,29,32). Haploinsufficiency as well as point mutations of this gene causes Greig cephalopolysyndactyly, postaxial polydactyly type A, and PIV syndrome (polydactyly, imperforate anus, and vertebral anomalies). An animal model has been suggested (34). Deletions that encompass neighboring genes cause a syndrome indistinguishable from *acrocallosal syndrome* (LG Biesecker, personal communication, 2000).

Facies. Approximately 50% manifest frontal bossing, increased head circumference, and broad forehead. Broad nasal bridge is seen in 85% (Fig. 24–29A). In children, the sutures may be broad and close late. The facies is not always striking. Hypertelorism is less common than the

Fig. 24–29. *Greig cephalopolysyndactyly syndrome*. (A) Note broad forehead, broad nasal bridge, and apparent hypertelorism. (B) Deviated and duplicated thumbs with 2–4 soft tissue syndactyly. Postaxial digit removed earlier. (C) Preaxial duplication or triplication and syndactyly.(From D Hootnick and LB Holmes, Clin Genet 3:128, 1972.)

B

C

literature would suggest (1,5,6,21). Craniosynostosis has been reported on occasion (13,19). The patient of Töllner et al (27), in spite of having cleft lip–palate, may have the syndrome.

Extremities. Broad thumbs (60%) and broad halluces (40%) are rather frequent. Soft tissue syndactyly of fingers (70%) and toes (95%) is variable in degree. Although postaxial polydactyly of the hands is common (65%), postaxial polydactyly of the feet is relatively infrequent (10%). Preaxial polysyndactyly of the thumbs varies from broad terminal phalanx (common) to bifid distal phalanx to complete duplication (rare) (26). Preaxial duplication of the thumbs always seems associated with bifid hallux (Fig. 24–29B). In the feet, the most common anomaly is preaxial polydactyly (75%). In some patients who clinically do not appear to have polydactyly, radiographs will demonstrate duplication of phalanges (1). Syndactyly, nearly a constant feature in the feet, may be present in the absence of polydactyly (Fig. 24–29C). It is unilateral in 40%. The halluces and thumbs may be medially deviated. Radiographic changes in the halluces are bifid terminal phalanges (30%) and duplication of both phalanges (55%). The first metacarpal is duplicated in approximately 15%. Bony fusion of the third to fifth distal phalanges of the hands has been reported (7,8,28). Bone age has been somewhat advanced (21,27,28). Characteristic dermatoglyphic changes have been reported. Several digital triradii are missing. Whorl patterns are present on the thumbs with the loops extending beyond the end of the thumb (14). A t′ axial triradius is often seen.

Muscular system. Inguinal and, rarely, umbilical hernia have been noted.

Central nervous system. Intelligence is normal with rare exception (8,13). Agenesis of the corpus callosum (13) and hydrocephaly (2,13) have been reported.

Differential diagnosis. The *acrocallosal syndrome* markedly overlaps with Greig cephalopolysyndactyly syndrome but differs in that agenesis of the corpus callosum and severe mental retardation are rare in Greig cephalosyndactyly syndrome. Furthermore, the latter clearly has autosomal dominant inheritance. *Acrocallosal syndrome* probably has autosomal recessive inheritance. *Craniofrontonasal syndrome* has a somewhat similar facies. The *OFD syndromes* (cleft palate, tongue hamartoma, polysyndactyly) have similar hands and feet. *Pallister-Hall syndrome* also has some phenotypic overlap with Greig cephalopolysyndactyly syndrome but is clinically distinct.

Acrocallosal syndrome

The acrocallosal syndrome, first reported by Schinzel (24) in 1979, is characterized by post- and/or preaxial polydactyly and syndactyly of fingers or toes, severe mental retardation, agenesis or hypoplasia of the corpus callosum, and growth retardation. Schinzel et al (25-28), in a series of papers, developed and expanded the phenotype. Over 30 cases have been reported (1-4,10,13,15-29). A good survey is that of Casamassima et al (3). The patient reported by Guion-Almeida and Richieri-Costa (10a) does not have the syndrome.

There has been no sex predilection. The disorder has been described in siblings and in cousins (2,4,5,10,26,27). All other cases have been sporadic. Parental consanguinity has been demonstrated (6,21,22,29,33), thus autosomal recessive inheritance has been suggested. Bonatz et al (1) described a child with a diagnosis of acrocallosal syndrome whose father had Greig syndrome. Sporadic *GLI3* deletions encompassing neighboring regions of 7p13 cause a phenotype indistinguishable from acrocallosal syndrome (LG Biesecker, personal communication, 2000). Perhaps the child in the report of Bonatz (1) had a severe form of Greig syndrome. Pfeiffer et al (20) described a child with inverted tandem duplicated 12p11.2-13.3, who they believed had acrocallosal syndrome. They suggested a common cause of the phenotypes of acrocallosal syndrome,

A B

Fig. 24–30. *Acrocallosal syndrome*. (A,B) Unrelated patients exhibiting large head, prominent forehead, broad nasal bridge. (From A Schinzel and N Schmidt, Am J Med Genet 6:241, 1980.)

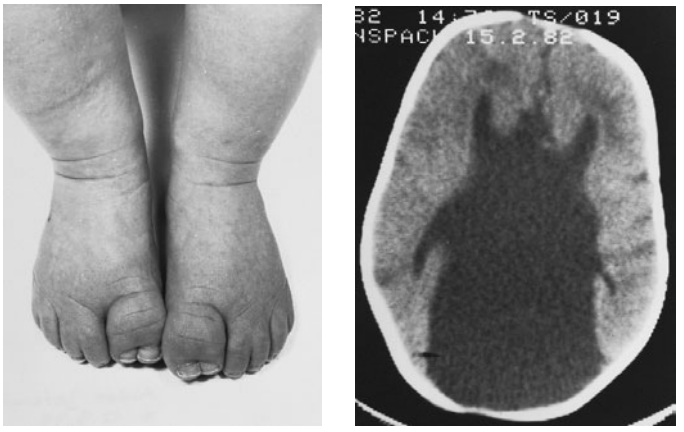
duplication 12p, and Pallister-Killian (tetrasomy 12p mosaicism) syndrome.

Craniofacial findings. Macrocephaly with bulging and high broad forehead, prominent occiput, large fontanel, hypertelorism, downslanting palpebral fissures, ptosis, epicanthal folds, convergent strabismus, hypoplastic midface, posteriorly rotated and somewhat dysmorphic pinnae, short nose, and protruding lips constitute the facies (Fig. 24–30). Cleft lip and palate has been found in approximately 15%.

Growth. Birthweight and length are usually normal; high birthweight has been reported in some patients (4,5,13,18,19). However, postnatal growth retardation, even in some of the infants with high birthweight, is fairly common (3,5,13,15,18,23,24,26–28,33).

Musculoskeletal findings. Duplicated halluces (65%), postaxial polydactyly of toes (40%), fully formed postaxial polydactyly of fingers (70%), bifid terminal phalanges of thumbs (20%), inguinal (55%) or umbilical (20%) hernia, and epigastric (15%) hernia have been found. Partial syndactyly of the toes occurred in approximately 65% (Fig. 24–31A).

Fig. 24–31. *Acrocallosal syndrome*. (A) Duplication, syndactyly, and fusion of nails, and halluces. (B) Agenesis of corpus callosum. (A from A Schinzel and N Schmidt, Am J Med Genet 6:241, 1980. B from A Schinzel and U Kaufmann, Clin Genet 30:399, 1986.)



A B

Central nervous system. Severe mental retardation is an almost constant finding, although there have been reports of children with a clinical diagnosis of acrocallosal syndrome who have had normal cognitive development (8,9,11). Since the child in the report of Guzzetta et al (11) also had trigonocephaly, it could be argued that this is a distinct, yet pathogenetically related condition. Total or partial agenesis of the corpus callosum are constant findings (Fig. 24–31B). Approximately 75% exhibit seizures. Congenital cysts of the brain (including interhemispheric, arachnoid, and supratentorial) (21,25–27,30), Dandy-Walker anomaly (18), and central diffuse cerebral cortical atrophy (10,13,22) have been demonstrated. Three children with anencephaly have been described (4,6,17).

Other findings. Miscellaneous findings include: cryptorchidism (20%) (29), micropenis and hypospadias (10,22), diaphragmatic eventration (4), sensorineural hearing loss (4), broad nasal bridge, and prominent occiput.

Differential diagnosis. Greig cephalopolysyndactyly syndrome overlaps considerably, but in that disorder there are few reports of agenesis of the corpus callosum or mental retardation (14). Moreover, postaxial manual digits are only minimally found. In contrast to acrocallosal syndrome, inheritance is clearly autosomal dominant. Agenesis of the corpus callosum is a field defect and is found in a host of chromosomal and single gene disorders listed extensively by Temtamy and Meguid (29). Among these are the *FG syndrome, Aicardi syndrome, Neu-Laxova syndrome, cerebro-oculo-facial-skeletal syndrome, Opitz BBB/G syndrome, hydrolethalus syndrome* and several of the *oral-facial-digital syndromes*. It should be noted that there is a severe form of frontonasal malformation in which duplication of halluces and agenesis of the corpus callosum are found. This has been called *Toriello syndrome*.

Branchio-skeleto-genital syndrome (Elsahy-Waters syndrome)

Elsahy and Waters (1) described three male sibs who exhibited seizures, moderate mental retardation (IQ 45–60), pectus excavatum, and penoscrotal hypospadias. Family 1, in the article by Reed et al (2), also had the syndrome. The detailed account of the oral and dental findings presented by Wedgwood et al (4) represent the same family reported by Elsahy and Waters (1). A very doubtful example was reported by Shafai et al (3).

The facies was characterized by brachycephaly, frontal bossing, marked midfacial hypoplasia, hypertelorism, divergent strabismus, nystagmus, and mild ptosis. The nasal bridge was broad with a wide nasal tip and flared alae. There was relative mandibular prognathism and facial acne (Fig. 24–32).

Radiographic study showed brachycephaly, mild microcephaly, extensive development of the mastoids, hypertelorism, short cranial base, bony projections above the external occipital protuberance (2), and fusion of the second and third cervical vertebrae in two brothers. Schmorl nodules were evident in the vertebral bodies (Fig. 24–33).

Hypospadias involving the glans, penile shaft, and proximal scrotum were present in all three sibs but to various degrees (Fig. 24–34).

Oral manifestations included multiple dentigerous cysts, cleft uvula or cleft soft palate, and teeth having dysplastic dentin with partial obliteration of pulp chambers resembling that seen in radicular dentin dysplasia (5) (Fig. 24–35). The dental anomalies were also described by Wedgwood et al (4).

Nasopalpebral lipoma-coloboma syndrome (Penchaszadeh syndrome)

Penchaszadeh et al (2), in 1982, reported an apparently unique autosomal dominantly inherited syndrome in eight members of a Venezuelan kindred. A Turkish family of seven affected members was described by Akarsu and Sayli (1) and Sevin et al (3).

The facies is striking. It is characterized by congenital symmetrical round to ovoid lipomas of the upper eyelids. More extensive, less circumscribed lipomas of the nasopalpebral regions may cover the root of the nose and extend symmetrically toward the inner canthi that are laterally displaced, covering the medial part of the irides. There are bilateral symmetrical colobomas of both upper and lower eyelids at the junction of the inner and middle third of the lids. The eyelashes are long and curly lateral to the lid defect but absent medially. The upper and, less often, lower lacrimal puncta are malpositioned or occasionally absent with resultant epiphora. Divergent strabismus is marked in all patients. The conjunctivae are hyperemic and several patients have corneal opacities, probably secondary to exposure (Fig. 24–36).

Broad forehead, widow's peak, medial outflaring of the eyebrows, and short philtrum add to the unusual appearance. Midface hypoplasia which was present in the Venezuelan family was not present in the Turkish family. Radiographic studies reveal normal bony interorbital distances (3).

Noonan syndrome

Noonan syndrome is characterized by short stature, various congenital heart defects, broad or webbed neck, chest deformity, hypertelorism with characteristic facial appearance and, in some cases, mild mental deficiency. Described by Noonan and Ehmke (102) in 1963, the syndrome was first reported by Kobylinski in 1883 (83). Over 400 cases have been recorded and a number of excellent reviews are available (4,28,34, 39,46,94,101,102,104,105,109,125,140a). Birth prevalence is estimated to be between 1/1000 and 1/2500 (97).

Etiology and pathogenesis. Although most of the early cases appear to be sporadic, recent surveys indicate transmission from parent to child in 30%–75% (4,28,94,97,105,109,128). Autosomal dominant inheritance with highly variable expression is evident (141). Improved recognition of the adult phenotype may further reduce the frequency of sporadic cases. Maternal transmission of the gene is three times more common than paternal transmission, most likely because of associated cryptorchidism and reduced male fertility (4,34). The gene has been mapped to 12q24 (85), although it has not yet been isolated (22,76). There is evidence of a recessive form (140b).

Several pathogenetic hypotheses have been proposed. Sanchez-Cascos (122) noted that the abnormalities of the head, neck, and heart that occur in Noonan syndrome could be produced by altered embryonic branchial arch structures. Another hypothesis implicates lymphedema. Intrauterine cystic hygroma resulting in pterygium colli and disruption of tissue migration and organ placement could possibly explain hypertelorism, downslanting palpebral fissures, low-set posteriorly angulated ears, prominent trapezius, widely spaced nipples, cryptorchidism, and abnormal dermatoglyphics. Clark (32) proposed that lymphatic obstruction might reduce right-sided cardiac blood flow and cause pulmonic stenosis.

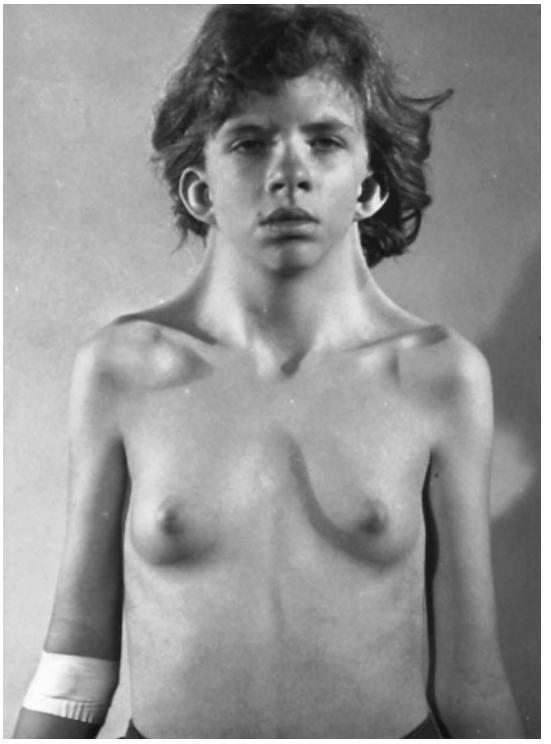

Fig. 24–37. *Noonan syndrome*. Pterygium colli and prominent ears. Note normal breast development.

Craniofacial features. Facial characteristics change with age (5,125). In the newborn, features include tall forehead, hypertelorism (75%), downslanting palpebral fissures (40%–95%), epicanthal folds, depressed nasal root with upturned nasal tip, deeply grooved philtrum with high, wide peaks of the vermilion border (95%), highly arched palate (45%), micrognathia (25%), low-set and posteriorly angulated ears with thick helices (90%), and excessive nuchal skin with low posterior hairline (55%). During infancy, the head is relatively large with a turricephalic configuration. Hypertelorism, prominent eyes, and thick hooded eyelids are characteristic. The nasal bridge is low and the nose has a wide base with bulbous tip. During childhood, the face may appear coarse or myopathic. Facial contour becomes more triangular with age. During adolescence and young adulthood, the eyes become less prominent, and the nose has a thin, high bridge and a wide base. The neck appears longer with accentuated webbing or prominent trapezius (90%). In older adults, the nasolabial folds are prominent, the anterior hairline is high, and the skin appears wrinkled and transparent (4,5,7) (Figs. 24–37 and 24–38). An extensive photoanthropometric study of the face has been reported (127).

Features present regardless of age include blue-green irides, halo iris, arched eyebrows, and low-set posteriorly angulated ears with thick helices (4,27,125). The hair may be wispy during infancy and curly or woolly in older childhood and adolescence. Loose anagen hair has been described in two children (139). Malocclusion occurs in 35% (4,5). Allanson (5) discussed the changing facies of Noonan syndrome with age.

Ocular anomalies. Ocular anomalies are fairly common. One study of 58 patients (86) reported strabismus in 48%, refractive errors in 61%, amblyopia in 33%, and nystagmus in 9%. Anterior segment changes (prominent corneal nerves, anterior stromal dystrophy, cataracts, and panuveitis) were found in 63% (84). Coloboma (9,84) and spontaneous corneal rupture (9,11) are rare complications; however, some of those with coloboma may have a distinct condition.

Cardiovascular anomalies. Congenital heart defects occur in approximately 65%. The most common anomaly is dysplastic and/or stenotic pulmonary valve (50%) (76). In addition, some degree of hypertrophic cardiomyopathy, both obstructive and nonobstructive, occurs in 20%–33% (23,24,75,100,103). Other common cardiac anomalies include atrial septal or ventricular septal defects and tetralogy of Fallot. Less common defects are atrioventricular septal defect, aortic stenosis, coarctation of the aorta (42,44,66,153), bicuspid aortic valve (23), double chambered right ventricle (108), mitral valve anomalies (89), Ebstein anomaly, total anomalous pulmonary venous return, restrictive cardiomyopathy (145), and dilated cardiomyopathy (129,152). ECG commonly demonstrates a wide QRS complex, left axis deviation, giant Q waves, and the left precordial leads have a negative pattern (122).

Growth and skeletal findings. Polyhydramnios occurs in 33% (125). Average birth length is 47 cm and birthweight is usually normal (40%) but may be increased by subcutaneous edema. Childhood growth tends to parallel the third percentile (60%), usually with normal growth velocity. The growth spurt during puberty is frequently reduced or absent (136). Delay in osseous maturation has been recorded in approximately 20%. Growth hormone levels have been normal with a slight rise in somatomedin in some patients (48). Growth curves specifically for Noonan syndrome are available (115,148). Average adult height in males is 162.5 cm and in females is 152.7 cm (115). Recent studies have described the use of growth hormone in children with Noonan syndrome (3,43,137) with promising results.

Characteristic are pectus carinatum superiorly and pectus excavatum inferiorly (70%–95%) due to precocious closure of sternal sutures. The thorax is broad. During childhood, the upper chest appears to lengthen; the nipples appear low set, and axillary webbing, which persists into adulthood, is present. Common features include rounded shoulders, cubitus valgus (50%), clinobrachydactyly and blunt fingertips (30%), and vertebral and sternal anomalies (25%). Other described skeletal anomalies include talipes equinovarus (12%), joint contractures (4%), radioulnar synostosis (2%). Joint hyperextensibility occurs in 30% (125).

Abdominal organ anomalies. Renal anomalies are fairly common, and include dilation of renal pelvis (most common), duplex systems (60),

A B C

Fig. 24–38. *Noonan syndrome*. (A–C) Similar facies showing ptosis, widespread eyes, pterygium colli, and dysmorphic pinnae. [C from F Char et al, Birth Defects 8(5):110, 1972.]

minor rotational anomalies, distal ureteric stenosis, and renal hypoplasia/aplasia. Splenomegaly is common (53%), as is hepatomegaly (26%). Other reported abdominal anomalies include choledochal cyst and midgut rotation (60).

Central nervous system. Failure to thrive in infancy occurs in 40%. Feeding difficulties occur in 77% (124a,125), and range from mild characterized by poor suck to severe characterized by the necessity for tube feeding. Other abnormalities include psychomotor delay (25%), learning disability with specific visual-constructional problems and verbal-performance discrepancy (36,95,122a) (15%), and language delay (20%), which may be secondary to perceptual motor disabilities, articulation abnormalities (70%), or recurrent convulsions (125). The hearing loss is usually a mild conductive loss (40%–50%) secondary to recurrent otitis media, but congenital conductive, sensorineural (3%), or mixed hearing loss has also been described (38). Qui et al (114) found progressive high tone loss in 50% of 20 individuals with Noonan syndrome. Naficy et al (98) described temporal bone anomalies in patients with Noonan syndrome. Mild mental retardation, found more often in males (115), may occur in up to 35%. However, IQ has ranged from 64 to 127 (4,94,95,105,109,125).

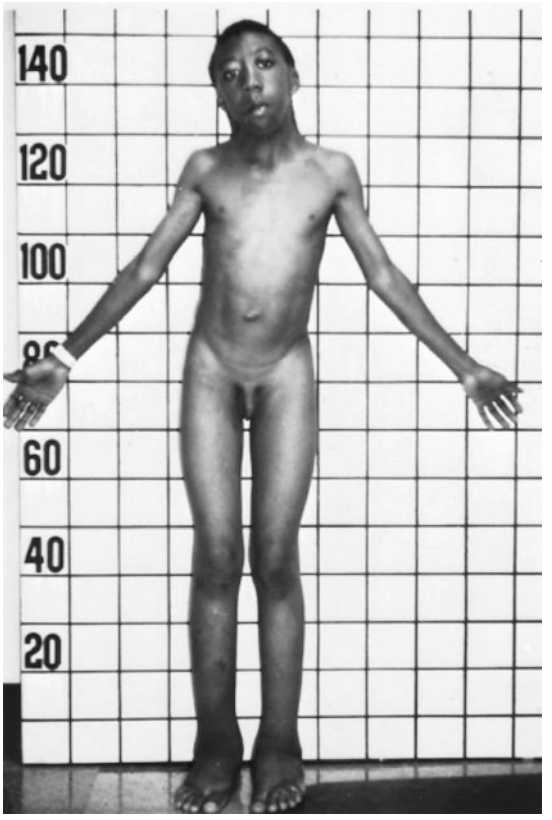
Cerebrovascular anomalies have been described in a few (14,65,69, 70,118,122,135). Hydrocephalus is not often reported in Noonan syndrome (68), although two Noonan-phenotype affected individuals in the same family were described by Henn et al (67). Fryns (56) noted that in their experience 5% (3/62) of patients had hydrocephalus, which was causally heterogeneous.

Genitourinary system. In males, pubertal development varies from normal virilization with subsequent fertility to delay but normal pubertal development to inadequate sexual development associated with early cryptorchidism (60%) and later deficiency in spermatogenesis (49). Most females are fertile, and puberty may be either normal or delayed (4,49).

Skin. A number of skin manifestations have been reported including café-au-lait spots (10%), pigmented nevi (25%), and lentigines (2%) (39) (also see Differential diagnosis). Keratosis pilaris atrophicans faciei has been noted in several instances (110). RJG has seen several children with multiple subcutaneous granular cell schwannomas. This has been discussed under *LEOPARD syndrome*. Other examples have been reported (86a,120a).

Lymphatics. Hypoplasia or aplasia of the lymphatic channels (20%) may result in generalized lymphedema, peripheral lymphedema, pulmonary lymphangiectasia, chylothorax, intestinal lymphangiectasia, hydrops fetalis, and cystic hygroma (1,17,61,121,149) (Fig. 24–39). A rare complication is lymphangioma (21,52).

Fig. 24–39. *Noonan syndrome*. Note lymphangiectatic edema of feet and ankles. (Courtesy of RL Summitt, Memphis, Tennessee.)



Hematologic abnormalities. Bleeding abnormalities (126,150) are found in 50%–65% and include (most commonly) factor XI deficiency (40,82,90,126), factor XII deficiency (50,90), factor VIII deficiency (126,130), von Willebrand disease, and platelet dysfunction, which may be associated with trimethylaminuria (73,147) or acyclooxygenase deficiency (55). Low frequency abnormalities such as congenital bone marrow hypoplasia (53), congenital hypoplastic anemia (84), and pancytopenia (120) have been reported. A low frequency association with myeloproliferative disorders has been noted. These include acute lymphoblastic anemia (10,77,111) and chronic myelomonocytic leukemia (12,57). The exact frequency of hematologic malignancy in Noonan syndrome is unknown but considered low.

Malignant hyperthermia. Malignant hyperthermia has been reported in a number of cases (74,81,117,132). Some authors have designated this as King syndrome, but we feel separate nosologic status is unnecessary as long as the possibility of malignant hyperthermia is recognized. However, some examples of King symptoms are associated with congenital myopathies (30).

Behavior phenotype. A behavioral profile for Noonan syndrome was suggested by Wood et al (151). Over 50% in this study were stubborn, clumsy, affected by mood disorders and faddy eating. Although autism has been reported in a few individuals (59), the association is not common.

Other findings. Various low frequency abnormalities have included autoimmune thyroiditis (29,143), pheochromocytoma (18), malignant schwannoma (78),vaginal rhabdomyosarcoma (80), neuroblastoma (37,87,88a), lateral meningocele (72), xanthomas of the skin and oral mucous membranes, polydactyly (62), Moyamoya disease (58), and constrictive pericarditis (107). Several have found central giant cell lesions of the jaws consistent with cherubism (1a,20,30,47,71,134,144; L Kaplan, personal communication, 1987; C Hall, personal communication, 1988).

Differential diagnosis. Differential diagnosis includes *Turner syndrome, Aarskog syndrome* (51), *Gorlin syndrome* (35,54,63), *Williams syndrome* (25,36), *Baraitser-Winter syndrome* (16,142), *fetal alcohol syndrome* (64,131), and *primidone embryopathy* (96). There is also overlap with several cardiocutaneous syndromes including *LEOPARD syndrome*, Watson syndrome (6,57) [which has been shown to probably be allelic with the NF1 gene on chromosome 17 (5)], and, especially, neurofibromatosis (8,72,93,94,106,112,113). Opitz and Weaver (106) enumerated four possible interpretations of the Noonan-neurofibromatosis association: (a) chance concurrence of Noonan syndrome and neurofibromatosis, (b) neurofibromatosis/Noonan syndrome as an unusual variant of Noonan syndrome, (c) neurofibromatosis/Noonan syndrome as an unusual type of neurofibromatosis, and (d) neurofibromatosis/Noonan syndrome as a newly recognized entity (5). Carey (26) and Meinecke (92) reviewed the evidence that cases of NF–Noonan syndrome (NF–NS) have been shown to have the phenotype based on all four of these mechanisms. Colley et al (33) described a family in which the genes for NF and NS were co-segregating independently. Khalifa and Graham (79) surely were describing Noonan syndrome. Ahlbon et al (2) described a family with NS and café-au-lait spots in which there was no linkage to NF1, supporting hypothesis (a); Stern et al (133) and Colley et al (33) also described families in which the manifestations of Noonan occasionally occurred in individuals with NF thus supporting hypothesis (c). Finally, Bahuau et al (13) described a novel nonsense mutation of the NF gene in a family with NF–NS. A similar relationship exists for Noonan syndrome-LEOPARD syndrome-cherubism-polyarticular pigmented villonodular synovitis. We suspect that this represents a contiguous gene syndrome. Cherubism may occur as an autosomal dominant disorder, in combination with neurofibromatosis or in the *Ramon syndrome* with juvenile rheumatoid arthritis (polyarticular pigmented villonodular synovitis). The gene for cherubism has been mapped to 4p16.3 (88b,137a). *Noonanoid syndrome* has giant cell granulomas (20,140).

Cardio-facio-cutaneous syndrome includes mental deficiency, growth retardation, cardiac anomalies, a Noonanoid facial appearance, and abnormalities of the hair and skin. Facial features were coarse. Sparse hair broke easily, leaving patches of alopecia, and skin abnormalities varied from follicular hyperkeratosis to an ichthyosis hystrixlike picture (116). As indicated elsewhere, there is good evidence to suggest that cardio-facio-cutaneous syndrome maps to the same region as Noonan syndrome (55,86,88,99). Possibly the children reported by Baraitser and Patton (15) have the same syndrome. Maximilian et al (91) described three sibs with a Noonan-like phenotype but with the additional manifestation of mental retardation. The parents were normal. Tonoki et al (138) described a boy with a phenotype vaguely reminiscent of Noonan syndrome and deletion 12q12-q13.12. Wilson et al (146) described a child with a Noonan syndrome phenotype, DiGeorge anomaly and deletion 22q11; others have not found this deletion in patients with Noonan syndrome (43,119). However, chromosome studies with particular attention paid to the 22q11 region may be worthwhile in a child with suspected Noonan syndrome and unusual manifestations. A unique patient with polycystic brain disease and Noonanoid appearance is called *Sener syndrome* (124). Fryns and Aftimos (56a) and others (40a) reported patients with webbed neck, unusual facies, inverted nipples, and pachygyria of frontal lobes. This condition is now called *cerebro-fronto-facial syndrome*.

Laboratory aids. If posterior cervical cystic hygromas are present on ultrasound and polyhydramnios and normal karyotype are present, a tentative diagnosis of Noonan syndrome is indicated (19). Those fetuses with nonseptate cystic hygroma with regression prior to mid second trimester have a more favorable prognosis than those with later regression (45).

Trichorhinophalangeal syndrome, type I

The disorder was described initially by Klingmüller (49) in 1956, although it was mentioned even earlier (85). The name trichorhinophalangeal syndrome was first applied by Giedion (26,27). The condition is characterized by cone-shaped epiphyses, sparse fine hair, bulbous nose with lack of alar flare, and variable growth retardation. The majority of reported kindreds are consistent with autosomal dominant inheritance (2,4,16,18,19,21,22,24,25,29,30,32,33,39,53–57,63,69,74,88–90). Monozygotic twins have been reported (66). A few affected sibs with normal parents (42,45,86) may represent gonadal mosaicism. Translocation involving 8q24 has been found (61,77). The parental origin of the deletion is probably not significant (65). TRP syndrome, type I, is due to a deletion of band 8q24.11 or a point mutation. The gene is a zinc finger transcription factor (62a). The more severe type II (Langer–Giedion) syndrome is due to a larger deletion which also includes the EXT1 gene for multiple exostoses (9,40). Type III refers to those with a phenotype like type II but without exostoses or mental retardation (43,46,57,64,67,81). In contrast to TRP I, growth retardation and brachydactyly are more severe. On radiographic exam, the metacarpals had bulbous ends. Patients with this condition who have been karyotyped did not have a detectable deletion of chromosome 9 (43,65). We view type III as a severe form of type I, probably due to a different mutation, and not worthy of separation.

Facies. The nose is pear-shaped (51,53–55,59,60,68) and the alae are retropositioned. The philtrum is elongated (41,70) and the lips are thin (32,59). There may be a small protuberance below the lower lip (32,42,68,70). Cephalometric analysis (42,58) has documented a shortened posterior facial height associated with short mandibular ramus and reduced and superiorly deflected posterior cranial base. The lower border of the mandible is more steeply inclined, and the gonial angle is more obtuse than normal. Ears are often large and outstanding (12,16,19, 32,51,76, 87,89) (Fig. 24–40A,B).

Hair and nails. Scalp hair may be sparse from birth (38,69,89) and is especially scant in the frontotemporal areas, simulating male pattern baldness. Its texture is fine and brittle, and growth is slow (7,41,68,71,85). Scalp hair is more like vellus than terminal hair. In some patients, hair falls out during the mid-second decade of life (3,41,47,85); male (30) and female (84) patients may become almost totally bald prematurely. Electron microscopy has shown an elliptical rather than cross-sectional pattern, although the authors were not certain whether this finding was typical for trichorhinophalangeal syndrome (6). Lalevic-Vasic et al (53) also described an oval pattern, as well as folded cuticle cells and clear rhexis. Eyebrows are thick medially and sparse laterally (18,30,32,46, 48–50,67–70). Eyelashes and pubic and axillary hair may be scant (25,47). Nails may be thin (26,38,89). Koilonychia (32,69,70) and leukonychia (32,69,70,85) have been described. The diameter of the hair shaft is markedly decreased (72) and there may be abnormalities of the cuticle cells (72). Van Neste and Dumortier (86) reported that hair diameter was thinner than normal, but that the cuticular pattern was normal;

they also reported that hair follicles had a relatively hypoplastic papilla when inserted into a well-developed hair matrix.

Musculoskeletal system. Height is below the third centile in 40% and seldom above the twenty-fifth centile (26, 30, 42, 71, 86). Bone age is often several years behind chronologic age.

Characteristically, there is swelling of the proximal interphalangeal joints, resulting in clinobrachydactyly (70,89) (Fig. 24–40C). Burgess (10) suggests that ulnar deviation of the index and middle fingers at the PIP and radial deviation of the fourth and fifth fingers at the PIP are characteristic of trichorhinophalangeal syndrome. The distal phalanges in both thumbs and halluces are usually short (38,69,70). Toes as well as fingers may be abbreviated. Pes planus has been noted in several cases (26,48). Limitation of movement and bone pain can occur in the hips (26, 30,41,47,50,51,68) and hands (51,67,83). Joint hypermobility at the elbows (12) and fingers (38,52,67) has been noted. On occasion, severe arthritic involvement has been found (BD Hall, personal communication, 1984).

Radiographically, the mandibular condyles may be flattened (59). Cone-shaped epiphyses (type 12) are most frequently present in the middle and less often the proximal phalanges of the second, third, and fourth fingers (28,70) and there are eburnated epiphyses of the distal phalanges in fingers 2, 4, and 5 (Fig. 24–40D). The fifth fingers as well as both phalanges of the thumbs may be similarly affected. Metacarpals, especially the fourth and fifth, are shortened (19) in approximately 50% (30). Multiple cone-shaped epiphyses may also be noted in the toes (10,54). Scoliosis and lordosis have been described by several authors (10,16,26,32,38,42). The scapulae are often winged (63). Up to 50% have Legg-Perthes-like changes in the hips (4,12,15,16,25,41,62,63,67,70,83), although in contrast to Perthes disease, there is more severe joint involvement, increased age of presentation, and increased number with hinge abduction and pain in adolescence. Degenerative arthritis can also occur in the spine, hips, knees, elbows, and sacroiliac joints (12). The ulnae may be short. Schlessinger and Poznanski (80) documented flattened distal femoral epiphyses. Pectus carinatum has been found in 40% (12,16). Knee and wrist dislocations can occur (73). Basilar impression and syringomyelia occurred in one patient (17). Pattern profile analysis of the hands without typical cone deformity in clinically normal individuals at risk for the syndrome has been reported (16). Findings suggested that these individuals indeed had the disorder, and that the condition has wide variation in expression; however, none had affected children. Frias et al (20) described a woman who had no clinical signs of the disorder, yet her mother was affected; her son had marked changes in the capital femoral epiphyses but normal radiographs of the hands. Metacarpophalangeal pattern profiles resemble those of TRP type II (14,78).

Other findings. Frequent upper respiratory tract infections have been described (26,38,49,67,79) but are not well documented. Melanocytic nevi may occur (7,75). Giedion et al (30) and others (42,56) suggested possible increased frequency of congenital heart defects and renal disorders. Renal disease was present in the patient described by Yanez (91). Floppy mitral valve has been described by several authors (21,30,45). Polycystic ovaries are an occasional manifestation (7). Intelligence is normal (18,31,35,41,42,52,60,71), although mild mental retardation or learning disability has been described (32,63). Severe mental retardation was found by Yamamoto et al (90) and Hamers et al (34) in patients with significant interstitial deletions around 8q24.12.

Oral manifestations. Malocclusion (19,68) and supernumerary teeth (26,38,52,67,76,85) have been documented.

Differential diagnosis. Cruz and Francés (13) described a mother and daughter with abnormalities similar to those observed in the trichorhinophalangeal syndrome but without characteristic nasal alterations. The disorder described by Bellini and Bardara (3) represents a different entity, with cone-shaped epiphyses (not type 12) and involvement of the epiphyses of both knees.

Cone-shaped epiphyses in the hand may occur as an isolated finding in approximately 1% of children in southwest Ohio and in almost 9% in Guatemala (37). They may be associated with a plethora of disorders, among which are *de Lange syndrome*, *cleidocranial dysplasia*, asphyxiating thoracic dystrophy, *Ellis–van Creveld syndrome, cartilage-hair hypoplasia* and *pseudohypoparathyroidism*. Herman et al (36) described a family with facial features of trichorhinophalangeal syndrome but with the radiographic features of metachondromatosis.

Absence of exostoses should distinguish this disorder from *trichorhinophalangeal syndrome, type II* (Table 24–1). However, Jorgenson et al (44) discussed the great variation that may exist in both of these conditions and emphasized that there may be phenotypic overlap between the two syndromes. This presumably reflects the extent of chromosome deletion. Autosomal dominant cartilaginous exostoses exists without unusual facies, hair abnormalities, or cone epiphyses.

Short stature, sparse hair, and short fingers may also be observed in *cartilage-hair hypoplasia*. Carrington et al (11) described a girl with TRP initially diagnosed as having ectodermal dysplasia. H. Toriello (personal communication, 1998) has seen similar patients.

Table 24–1. Comparison of features in TRP I and TRP II and additional features of TRP II

Features	TRP I	TRP II
Features in common		
Recurrent respiratory infections	+	+
Sparse scalp hair	+	+
Large, laterally protruding ears	+	+
Bulbous nose with tented alae	+	+
Prominent elongated philtrum	+	+
Thin upper lip	+	+
Apparent mandibular micrognathia	+	+
Clinobrachydactyly	+	±
Cone-shaped epiphyses (Type 12) of the hands	+	+
Winged scapulae	+	+
Short stature	+	+
Additional features of the Langer–Giedion syndrome		
Multiple exostoses	−	+
Redundant and/or loose skin in infancy and early childhood	−	+
Laxity or hypermobility at joints	−	+
Microcephaly	−	+
Mental retardation	−	+
Significantly delayed onset of speech	−	+
Skin nevi	−	+

(Modified after BD Hall et al, Birth Defects 10(12): 147, 1974.)

Laboratory aids. Using high resolution G-banding, a number of investigators (8,9,23,31,34) have found a microdeletion of 8q23q24, while others (5,24,64) did not. Sánchez et al (77) described a boy with presumed trichorhinophalangeal syndrome, type I, who was severely mentally retarded and who, by age 9, had no exostoses; his karyotype showed a complex, apparently balanced translocation involving break points in bands 3q13, 8p22, 8q13, 11p12, and 11q21.

Trichorhinophalangeal syndrome, type II (Langer-Giedion syndrome)

Langer (28) and Giedion (19), in 1969, first described this disorder with multiple exostoses and many features of trichorhinophalangeal (TRP) syndrome, type I. In the same year, Gorlin et al (20) reported an example among a group of TRP I cases. The condition was thus termed the "Langer-Giedion syndrome" by Hall et al (23). However, an earlier description was made by Alé and Caló (1). Most examples have been sporadic. However, father-to-son transmission and mother-to-daughter transmission have been documented (27, L Kinross, personal communication, 1999), and it has been seen in monozygotic twins (23,26). Over 30 cases published prior to 1983 have been reviewed in detail by Langer et al (29). Approximately 100 examples have been published to date.

Cases with del(8)(q24.11–q24.13) have been reported by a number of authors (3,4,6–8,14,15,17,24,29,34,37,40,41,43,45,46) while others have found normal karyotypes (19,21,29,41). Molecular study, however, shows loss of genetic material in those with "normal karyotypes" (32). Bühler et al (6–8) have concluded that TRP types I and II differ only in the size of the deletion, TRP type I having the smaller. TRP II is a contiguous gene deletion (31,32), which includes the *EXT1* gene for multiple exostoses (8,24,31,32). Genetic heterogeneity has been suggested (9). There is a no sex predilection (L Kinross, personal communication, 1999).

Craniofacial findings. The craniofacial appearance has some resemblance to that in *trichorhinophalangeal syndrome, type I*, but the nose tends to be less bulbous and the philtral area more prominent. Scalp hair is sparse, The forehead is prominent. Mild microcephaly has been a feature in approximately 60% (18,29,44,45). The eyebrows are broad and the eyes deeply set. Exotropia or exophoria has been documented in approximately 40% (23,29) (Fig. 24–41A–D). The pinnae are large and outstanding. The philtrum is long and the vermilion of the upper lips is thin.

Central nervous system. Mild to moderate mental retardation has been noted in 75% (20,23,27,29,41,45). Severe mental retardation has rarely been reported (17,18,44). Approximately 25% are normal or in the dull normal range (22,29), and some have attention deficit disorder. Delayed onset of speech (20,23,45) and, less often, moderate hearing deficit, both sensorineural and conductive, have been noted, although the frequencies affected, age of onset, and degree of severity have not been well documented (23,27,29,42). Seizures and hypotonia are more common than in the general population.

Skeletal system. In addition to skeletal abnormalities similar to those found in trichorhinophalangeal syndrome, type, I, multiple exostoses are found in 98% and are characteristic (5,17,43) (Figs. 24–41E,F and 24–42). They are usually present by the third or fourth year of life, although they may be found as early as birth. The exostoses increase in size and number until skeletal maturity. They occur in the long and short tubular bones of the limbs, primarily at the metaphyses (16,18,23,25) but may also be seen in the ribs, scapulae, and vertebrae. They may cause pain or functional problem due to pressure or interference. Cone-shaped epiphyses (Giedion, type 12) are seen in 92% in both the proximal and middle phalanges of the second to fifth fingers and in both proximal and distal phalanges of the thumb. Approximately 40% have one or more shortened metacarpal bones. The ribs may be narrowed posteriorly (6,17,20,27), and the scapulae may be winged (17). Growth retardation, postnatal in onset (2,23,29), is a constant finding, and seems to antedate multiple exostoses. Laxity or hypermobility of joints, including pes planus and calcaneovalgus foot deformities, has been observed in 65% (23,27,29). The metacarpal phalangeal pattern profile differs mildly from that of type I (11). Fractures, due to osteoporosis, have been noted in 30%. Tibial hemimelia has been described (39).

Skin and hair. During infancy and early childhood, the skin is loose or redundant in 75% (16,17,23,29). Multiple nevi are found on the face and extremities in over 50% (23,29,43). Scalp hair is sparse, but the eyebrows are full (29). Brittle nails are found in 70% (29).

Other findings. Recurrent respiratory tract and middle ear infections during infancy and childhood are found in 60% (20,23,29,43). Feeding problems during infancy and early childhood are noted in over 90% (29). This seems related to uncoordinated swallowing causing choking. Some have cyclic vomiting and/or reflux. Fryns (13) and Partington et al (34) reported hydrometrocolpos and hematometra in females. Ureteral reflux has also been documented (29,34,43,45). Miscellaneous findings have been meticulously documented by Langer et al (29). More recently, prune belly and persistent cloaca have been found (36).

Oral manifestations. Micrognathia and retrognathia (20,29) have been reported and the mandibular angle may be more obtuse than normal (23); however, measurements have not been made to confirm these subjective observations. Supernumerary central incisors (17) as well as congenitally missing teeth (17) have been noted. Malocclusion is common. Submucous cleft palate has been reported (33).

Differential diagnosis. The differential diagnosis includes *trichorhinophalangeal syndrome, type I*, although given that both TRP I and II are caused by deletions of 8q24–11, it may be argued that distinction between the two is no longer valid (see Table 24–1). Cone-shaped epiphyses occur in the general population as an isolated finding. They may also be associated with *de Lange syndrome, cleidocranial dysplasia, asphyxiating thoracic dystrophy, Ellis–van Creveld syndrome, cartilage-hair hypoplasia*, and *pseudohypoparathyroidism*. Multiple cartilaginous exostoses in the absence of other abnormalities constitute a well-established autosomal dominant entity. Three loci are involved: 8q24.1, 11p11–p13, and 19p (35).

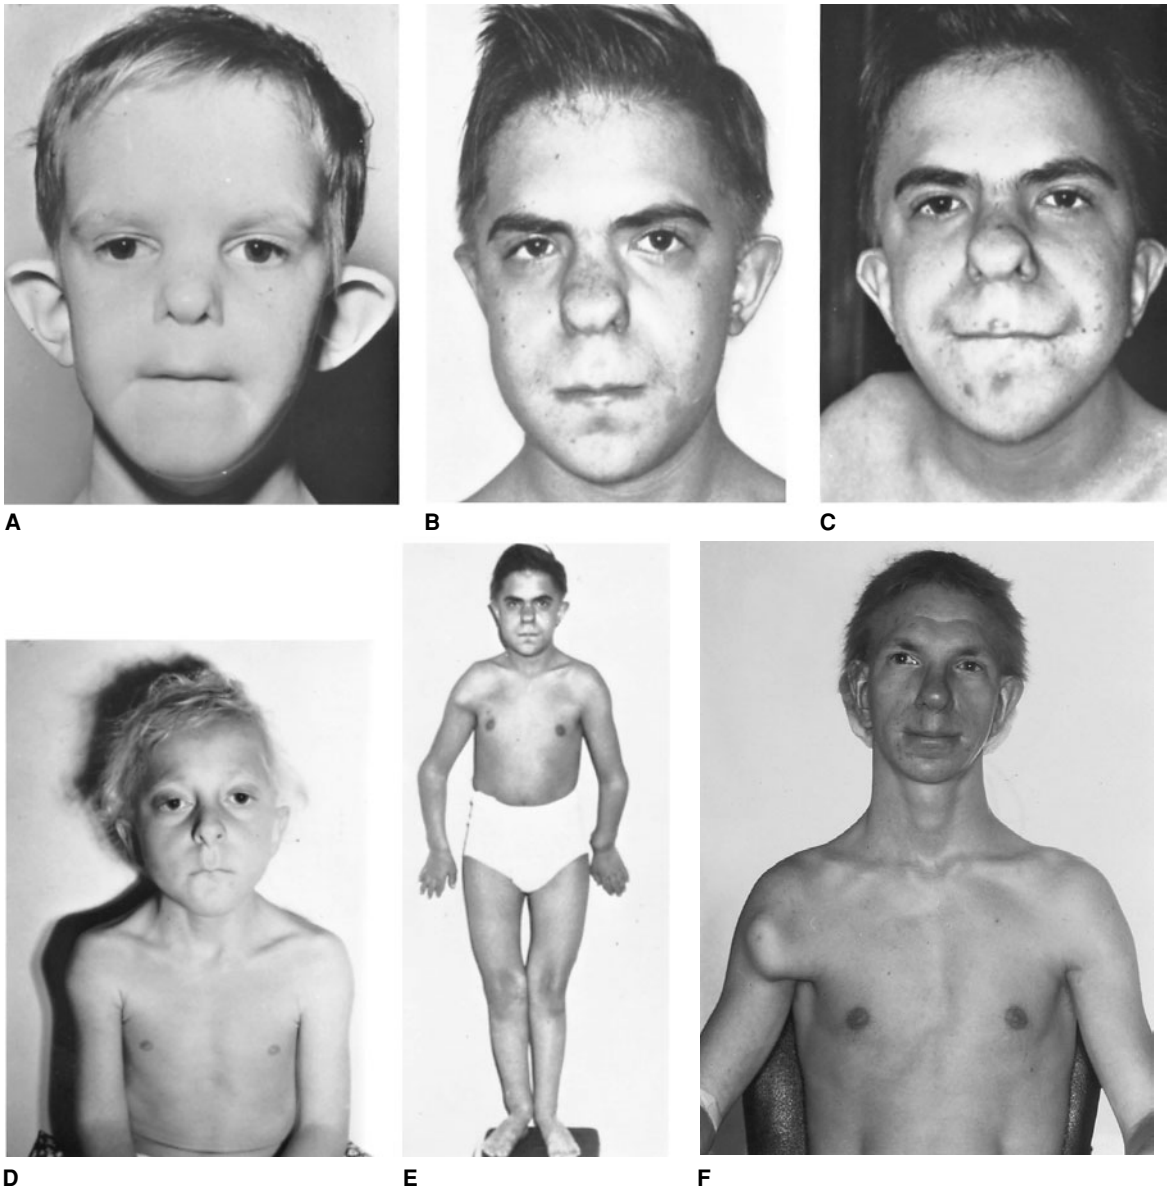

Fig. 24–41. *Trichorhinophalangeal syndrome*, *type II*. (A–D) Compare facies of four children with the disorder. All have mild microcephaly, outstanding ears. (E,F) Multiple exostoses become evident by the fourth year of life. [A–C,E from BD Hall et al, Birth Defects 10(12):147, 1974. D from RJ Gorlin et al, Am J Dis Child 118:595, 1969.]

Shabtai et al (38) reported a mother and two sons with features of trichorhinophalangeal syndrome, type II. They lacked mental retardation, microcephaly, and cone-shaped epiphyses but had a paracentric inversion of chromosome 8, inv8(q11.23;q21.1).

Deletions in 8q have been reported in patients without the trichorhinophalangeal syndrome, type II phenotype (10). At age 5 1/2 years the patient reported by Dallapiccola et al (10) still had no exostoses (12).

Lü et al (30) described an error in maternal gametogenesis in deletion of 8q23–24.1.

Laboratory aids. Karyotype analysis should be carried out to demonstrate the del(8)(q24.11–q24.13) abnormality.

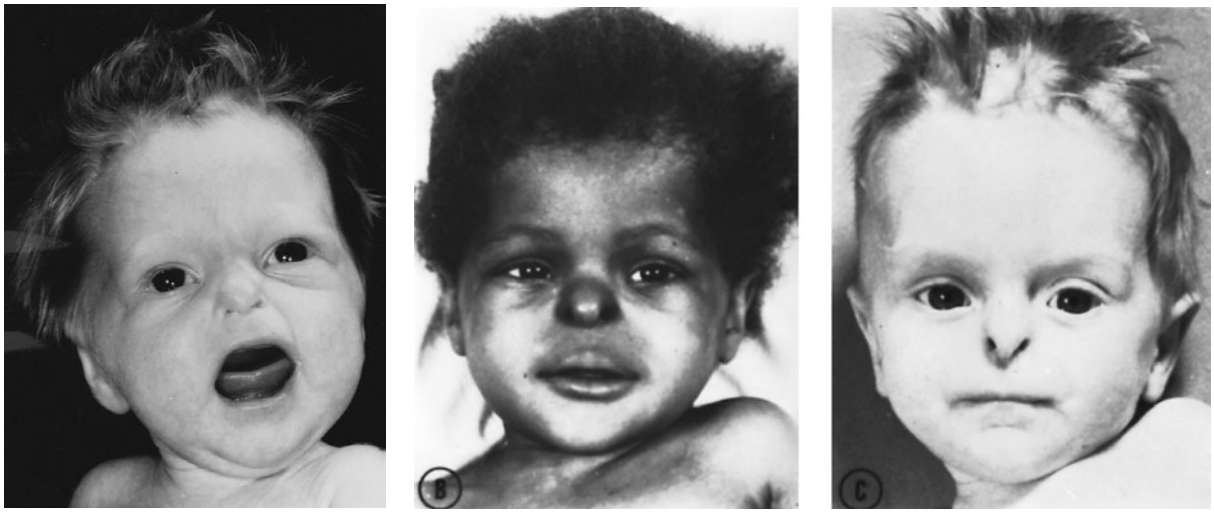
Johanson-Blizzard syndrome

Johanson and Blizzard (12), in 1971, reported three unrelated children with characteristic facies, severe mental and somatic retardation, sensorineural hearing loss, and malabsorption due to pancreatic insufficiency. The patients described in 1967 by Morris and Fischer (19) and Townes (29), in 1972, clearly had the same disorder. Approximately 30 patients have been reported (11,14). We have classified a case as probable (15) and another as an unlikely (8) example. Parental consanguinity (3,16,26,27) and affected sibs (5,10,17,24) have been reported, indicating autosomal recessive inheritance.



A B C

Fig. 24–43. *Johanson–Blizzard syndrome*. (A–C) Children exhibiting similar facies characterized by hypoplasia of nasal alae. They also have hypotonia, genital anomalies, and trypsinogen deficiency. (A from M Baraitser and SV Hodgson, J Med Genet 19:302, 1981. B and C from A Johanson and R Blizzard, J Pediatr 79:982, 1971.)

Birthweight has been low in approximately one-third of the cases (18). There is failure to thrive; somatic retardation is usually severe. At least 70% remain well below the third centile for height, weight, and head circumference with true microcephaly in 35%. Generalized edema (anasarca) due to protein loss is evident from birth. Death often occurs in childhood with malabsorption being the primary cause (31).

Facies. Aplastic nasal alae producing a beaklike nose is the most striking and constant feature of the syndrome. Aplasia of lacrimal puncta or cutaneolacrimal fistula is often noted (5,19,26). The anterior fontanel is open (19). Midline skin dimples and/or defects are noted in 90% over the anterior and posterior fontanels (7,11,12,18,26). The scalp hair is often blond, sparse, dry, and coarse. The hair in the frontal area has a marked upsweep and there is extension of the lateral hairline onto the forehead (Fig. 24–43).

A radiocephalometric study has been carried out on two patients (20). While microcephaly has been present in 35%, this was not borne out in patients studied by Motohashi et al (20) or by Sismanis et al (27). Facial, skeletal, and cranial base measurements were reduced, especially the length of the maxilla. CT of the temporal bone demonstrated cystic dilatation of the cochlea and vestibulum (2), although this is not a consistent finding (27).

Musculoskeletal. Severe hypotonia with hyperextensibility of joints is noted in 80% (12,18,19,26). Pitting edema of the hands and feet due to protein loss may be striking (19,23). Bone age is delayed in approximately 80% (20,27,29).

Genitourinary and gastrointestinal. Single urogenital orifice with infantile ovaries and double or septate vagina, clitoromegaly, micropenis, cryptorchidism, or urethrovaginal fistulae are noted in 30% and imperforate or anteriorly placed anus in approximately 50% (3,5,7,10,12,15–17, 27,30). Kristjansson et al (14) have suggested that some examples of genital hypoplasia are secondary to hypopituitarism. Pancreatic insufficiency, failure to thrive, and malabsorption have been constant features (18). Juvenile onset diabetes mellitus may be a not uncommon complication (21,31).

Central nervous system. Bilateral sensorineural hearing loss has been noted in approximately 60% (5,7,11,14,17,18,26). Speech is rudimentary both from hearing loss and psychomotor retardation. Approximately 60% of patients are mentally retarded (IQ 35–50), but intelligence may be normal (17,24) or only mildly delayed (5,11,20,29). The presence of hypothyroidism is independent of the presence of MR (6). Swanenburg-DeVeye et al (28) described a child with high intelligence. There is also some evidence that females have a better prognosis (25).

Thyroid. Hypothyroidism has been found in approximately 30% (7,11,17,18,32). The reader is also referred to several possible examples of hypothyroidism (4,5,12,22).

Skin. Nipples and areolae may be hypoplastic.

Heart. ASD, VSD, and situs inversus have been reported in 15% of the cases (10,11).

Oral manifestations. There is severe microdontia in both dentitions and, not uncommonly, the permanent dentition may be entirely absent except for the first permanent molars (32). The roots of the deciduous teeth are short, irregular, and deformed. The crowns of the few secondary teeth are frequently reduced in form, incisors being conical, maxillary molars having only three cusps. The tooth pulps are large. Permanent first molars are somewhat taurodont (22,24).

Pathology. Pancreatic changes include dramatic fatty replacement with a paucity of acini but without concomitant hypoglycemia (7,18). Jones et al (13) evaluated the nature of the pancreatic dysfunction and found reduction of secretion of trypsin, colipase, and lipase and postulated that there was primary acinar cell failure with preserved ductal function. The brain exhibits abnormal gyral formation and cortical neuronal disorganization (3,4).

Differential diagnosis. Johanson-Blizzard syndrome shares proteolytic deficiency features with other disorders: cystic fibrosis, Schwachman syndrome, *cartilage-hair hypoplasia*, trypsinogen deficiency disease, Donlan syndrome, and intestinal enterokinase deficiency. Their differentiation and the use of electrophoretic studies of pancreatic enzymes have been discussed at length by Townes (29).

While the signs and symptoms manifested by the sisters described by Reichart et al (24) are similar to those of Johanson–Blizzard syndrome, they probably represent another disorder. Guzman and Carranza (9) reported sibs, one with Donlan syndrome and one with Johanson-Blizzard syndrome and suggested these conditions are variable expression of the same entity.

Several other syndromes are characterized by varying degrees of hypoplasia of nasal alae: *trichorhinophalangeal syndrome*, *oculodentoosseous dysplasia*, *craniocarpotarsal dysplasia*, and *Roberts*

syndrome. Aplasia cutis congenita usually occurs as an isolated finding but may be seen with trisomy 13, focal dermal hypoplasia, Sakati syndrome, etc. Aplasia cutis congenita of the scalp is associated with a plethora of disorders.

Laboratory aids. Iron deficiency, low hemoglobin, fat, foul, bulky stools, hypocalcemia, and low total serum proteins are evident in early infancy (32). There is a combined proteolytic, lipolytic, and amylolytic defect manifested by complete absence of trypsin, chymotrypsin, amylase, carboxypeptidase, and lipase activities. Activation studies have proven negative. Fat and nitrogen balance studies confirm the enzyme deficiencies.

Binder anomaly (maxillonasal dysplasia)

In 1962, Binder (3) reported a condition which he called maxillonasal dysostosis. He thought the condition was a form of arhinencephaly, which it is not. Noyes (22) reported an example as early as 1939 and Zuckerkandl (44), in 1882, described a similar malformation. The condition has also been called facies scaphoidea and congenitally flat nose syndrome (12).

Fifty patients were reported by Holmström (12) and well over 200 examples have been described, including several large series of cases or reviews (2,5–21,23–27,30,31–35,40–44). We believe the condition is rather common. We do not regard it as a true syndrome, agreeing with Toriello (41) that it is a nonspecific abnormality of the nasomaxillary complex, possibly related in many cases to prenatal deficiency of vitamin K (15,16). Several cases that we have seen, when sufficiently studied, were identified as being examples of chondrodysplasia punctata. The basic significance of Binder anomaly is as a surgical entity, not as a genetic, nosologic, or syndrome entity. It is neither a dysplasia nor a syndrome. Although most cases involve only the nasomaxillary complex, a variety of other anomalies have been recorded including, especially, cervical vertebral anomalies, but also various other skeletal defects, cardiac anomalies, orofacial clefting, strabismus, mental retardation, and other abnormalities (5,9,12,23,41). Many of these cases likely have a syndrome of which Binder anomaly is a component manifestation. Others have mild chondrodysplasia punctata (5,21,28,38) or, possibly, Warfarin embryopathy.

Almost all cases are sporadic (26). Affected parent and child have been noted thrice (12,21,26) and affected sibs have been observed on four occasions (12). Consanguinity has been recorded in a few instances (5,40). Holmström (12) suggested that 16% of his sample exhibited "hereditary factors." We interpret reported familial examples to result from complex genetic factors (oligofactorial inheritance) similar to those involved in producing malocclusion. Although Binder anomaly is believed to be common, it is often unrecognized in some ethnic groups, such as the Japanese (39).

Facies. The nasofrontal angle is absent and the nose is hypoplastic with flattened alae and nasal tip (Figs. 24–44 and 24–45). The profile does not change with time (37). There is a palpable depression in the anterior nasal floor and localized maxillary hypoplasia in the alar base region (12). The nostrils are half-moon shaped when viewed from below (Fig. 24–45A). The nasal mucosa has been described as atrophic, but the sense of smell is normal (3). The philtral crests may be bow shaped, rising vertically to the columella without convergence.

Radiographically, aplasia or hypoplasia of the anterior nasal spine, thinness of the labial plate of alveolar bone over the upper incisors, and an increase in the nasomaxillary angle have been observed (5,8,13,17,19,26) (Fig. 24–46). The frontal sinuses are often hypoplastic or absent (3,5). Cephalometric studies have shown increased gonial angle and proclination of the incisors (5,8,24). There are decreased anterior cranial base measurements and a smaller maxilla vertically and anteroposteriorly, although Eliasson et al (7) have suggested that less than half have maxillary retrognathia. The cervical spine is anomalous in 40%–60% (29). The atlas and axis are most frequently involved. Various anomalies include short posterior arch, block vertebrae, separate odontoid, spina bifida occulta,

A B

Fig. 24–44. *Binder anomaly*. (A,B) Typical facies, frontal and lateral views. (Courtesy of M Olow-Nordenram, Linköping, Sweden.)

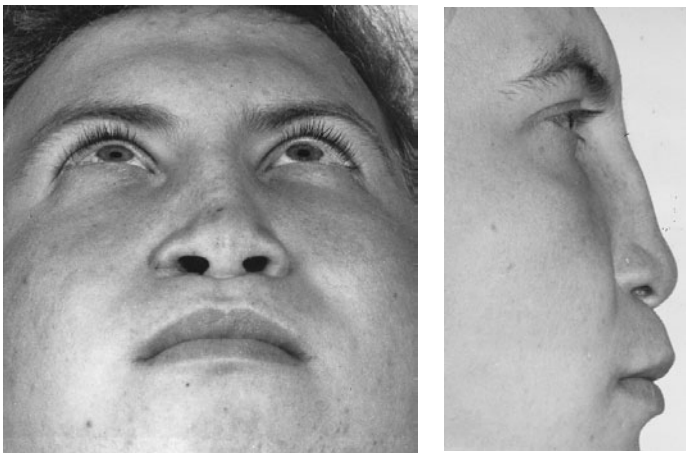
and persistence of chorda dorsalis (15%) either isolated or in various combinations. Calcifications extending from the anterior arch of the atlas have been noted as well as mild scoliosis and/or kyphosis (5,23).

Other findings. Strabismus has been found occasionally as well as mild mental retardation (5,8,14), but they probably have no statistical significance. Nonspecific congenital heart defects have been found in 5% (12,14). Hearing loss occurs in approximately 5% (8,14). George et al (9) described a girl with arteriovenous malformation of the toes. Bütow et al (4) described a boy (Case 12) with growth hormone deficiency, deafness, glaucoma, and Binder phenotype, a probable example of a Stickler-like syndrome. Minor finger anomalies have been reported (29).

Oral manifestations. The upper lip has a convex contour with poorly developed philtrum. The premaxillary area is hypoplastic, with flattening of the maxillary base and sagittal shortening of the dental arch. The mandible is of normal width, but the gonial angle is increased and the chin is flattened (5,8,24). Because of maxillary shortening, all patients have a relative mandibular prognathism with reverse overbite (class III malocclusion) (Fig. 24–47). Rarely there is cleft lip (5,12) or cleft palate (8,12,14).

Differential diagnosis. Although the facies may appear "arhinencephaloid," no brain abnormalities have been observed in this condition.

Fig. 24–45. *Binder anomaly*. (A,B) Flattened nose with depressed subnasal or alar base area and hypoplasia of premaxillary area of upper jaw. Upper lip has convex contour; nostrils are half-moon shaped. (Courtesy of H Holmstrom, Göteborg, Sweden.)



A B

Fig. 24–46. *Binder anomaly*. Radiograph showing aplasia of anterior spine, thinness of labial plate of alveolar bone over upper incisors, and increase in naxomaxillary angle. (Courtesy of M Olow-Nordenram, Linköping, Sweden.)

The sense of smell is completely normal. Absent frontal sinuses and relative mandibular prognathism can be associated with a host of conditions and may be seen in otherwise normal individuals. Nasal hypoplasia occurs in *pseudohypoparathyroidism, acrodysostosis, Stickler syndrome, Marshall syndrome, OSMED*, and *Warfarin* or *phenytoin embryopathy*. Toriello (personal communication, 1998) recently saw a patient with a "Binder face" but with other anomalies consistent with *Keutel syndrome*. It is possible that the Binder anomaly and Keutel syndrome are allelic (21a).

Lenz microphthalmia syndrome

In 1955, Lenz (13) described a syndrome consisting of microphthalmia, skeletal anomalies of the hands and clavicles, renal anomalies, genital abnormalities, and defects of the dentition. Several other kindreds have been reported (2–9,12,15,18). Four cases in a family described by Hoefnagel et al (10) possibly represent the same syndrome. We are less certain about the family reported by Cuendet (4) and that of James et al (11).

X-linked recessive transmission seems apparent. Minor malformations have been noted in heterozygous carriers in some instances (9,13). Krishnamurthy (12) described fairly significant manifestations (microphthalmia, strabismus, coloboma, and skeletal anomalies) in two sisters, therefore suggesting manifestations in carrier females could be severe. Female carriers have also been noted to have an increased abortion rate, suggesting that many cases may only appear to be sporadic (5,13). Linkage studies have shown that the gene is located in the Xq27–q28 region (6a).

Facies. The forehead is high. Unilateral or bilateral eye defects ranging from colobomatous (usually) microphthalmia to clinical anophthalmia have been observed (2–13,15). Upward slanting of palpebral fissures may be present (9). Microcornea (9), strabismus (13), nystagmus (8,9), epicanthal folds (8), and blepharoptosis (2,5,7,8,10,21) as well as other defects have been reported in over 80%. Krishnamurthy et al (12) described pathologic findings in an enucleated eye from one affected boy. The ears are asymmetric, dysplastic, hypoplastic, or protuberant in 80% (2–13,15,21) (Fig. 24–48). Micrognathia has also been noted (9). Craniosynostosis occurred in one patient (6).

Central nervous system. Mental retardation and microcephaly have been reported in over 90% (2–9,15,18,21). MRI evaluation has demonstrated agenesis of the corpus callosum and dilatation of the ventral horns (17).

Musculoskeletal system. Camptodactyly of the fifth fingers (9,13, 18), clinodactyly of the second fingers (9), hypoplastic thumb (21), duplication of the thumb (13,21), symphalangism of the thumb (12), cutaneous syndactyly of the third and fourth toes, clinodactyly of toes (20), wide gap between first and second toes, pseudoclubbing of the toes, flat foot, calcaneovalgus deformity (9,15), and varus deformity (10) have been observed in approximately 60%.

Short stature (1–5,7,8,12–15), cylindrical thorax with sloping shoulders and clavicular defects (5,9,12,13,15,18), kyphosis (5), low scapulae, notching of the vertebral bodies, mild cubitus valgus, limited extension in both hip joints, and mild genua valga with internally rotated knees and prominent fibulae (9) have been reported (Figs. 24–49 24–50).

Fig. 24–48. *Lenz microphthalmia syndrome*. Eye defects range from microphthalmia to clinical anophthalmia and may be unilateral or bilateral. Note outstanding ears. [From J Herrmann and JM Opitz, Birth Defects 5(2):138, 1969.]

Genitourinary system. Unilateral renal agenesis (13), bilateral renal agenesis (10), renal dysgenesis, hydroureters (9), cryptorchidism (9,13,15,18), and hypospadias (5) were described in approximately 50%.

Other findings. Congenital heart defect (13), atresia of the ileum (10), umbilical hernia, unusual dermatoglyphics (9), defective speech (9,10), and hirsutism of lower back (5,9,18) have been noted.

Oral manifestations. Highly arched palate, cleft palate (2,4,7,9), crooked anterior teeth (9,13), and agenesis of the permanent maxillary lateral incisors (9,18,19) have been reported in approximately 65%.

Fig. 24–49. *Lenz microphthalmia syndrome*. Patients are short with cylindric thorax and internally rotated knees. [From J Herrmann and JM Opitz, Birth Defects 5(2):138, 1969.]

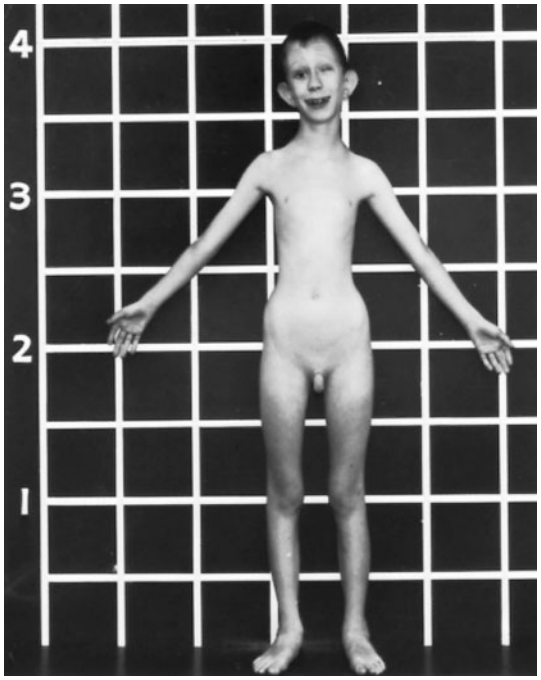

Fig. 24–50. *Lenz microphthalmia syndrome*. Radiograph showing cylindric thorax, sloping shoulders, and clavicular defects. (From JM Opitz, Birth Defects 5(2):138, 1969.)

Differential diagnosis. Isolated bilateral anophthalmia is inherited as an autosomal recessive trait. Microphthalmia may be inherited as an autosomal dominant, autosomal recessive, or X-linked recessive trait. Microphthalmia may also occur as an integral part of several different disorders (14). There is some overlap with the *Nance-Horan syndrome* (22) and an X-linked syndrome consisting of microcephaly, microphthalmia, corneal opacities, hypospadias, cryptorchidism, and dental anomalies (20). Similar changes are also seen in *dup(10q) syndrome*.

Laboratory aids. Ultrasound studies are indicated in affected individuals.

Cryptophthalmos syndrome (Fraser syndrome)

The cryptophthalmos syndrome is characterized by cryptophthalmos, syndactyly, abnormal genitalia, and other variable defects such as nasal colobomas, malformed ears, cleft lip–palate, renal agenesis, and mental deficiency. The syndrome was first described by Zehender (67), in 1872, although it has been suggested that Pliny the Elder may have reported it in the first century AD (21). Over 150 cases have been described (1–5,7–11,12–38,43–45,47,49–57,59–63,66,67). The most extensive review is that of Thomas et al (55). Several other reviews are also available (18,21,27,30,35,44,47,51,53). Histopathologic documentation of the ocular manifestations is especially well reviewed by François (18), and detailed postmortem studies have been reported (4,38,45,47,55).

The syndrome has autosomal recessive inheritance. Among 86 cases, 48 were familial and 38 were sporadic. Consanguinity has been reported in 6 of 42 families in which published pedigree data are available (55). Winter (65) and Darling and Gossier (12) suggested that Fraser syndrome could be homologous to one of the mouse bleb mutants. Because the syndrome is variably expressed, including some infants without cryptophthalmos (6,33,43) and some cases of isolated cryptophthalmos occurring as a separate entity, Thomas et al (55) proposed diagnostic criteria of the syndrome (Table 24–2). Cases were diagnosed on the basis of at least two major criteria and one minor criterion or on the basis of one major criterion and at least four minor criteria. The frequencies of individual syndrome manifestations are listed in Table 24–3. Gattuso et al (21) surveyed 68 cases. Figures differ somewhat from those of Thomas et al (55).

Approximately 50% survive for a year or more, 25% are stillborn, and 20% die within the first year of life with most deaths occurring within the first week of life. Death is usually associated with renal agenesis and laryngeal stenosis (4,21).

Craniofacial features. The face is asymmetric in approximately 10% (21). The eyebrows may be completely or partially missing (66). The globes can be seen and felt beneath the skin covering, which extends from the forehead over the eyes. Cryptophthalmos is found in 85%, and in approximately 72% of these there is bilateral involvement (55) (Fig. 24–51A–D). With unilateral cryptophthalmos, the opposite eye may exhibit upper lid coloboma, microphthalmia, epibulbar dermoid, or supernumerary eyebrows (55,63). The conjunctival sac is partially or completely obliterated, and lashes, meibomian glands, and lacrimal glands are absent. The cornea is differentiated from the sclera. The lens may be absent, hypoplastic, or calcified and displaced. Orbicularis and levator palpebrae muscles are, however, normal (68). Exposure to strong light may induce reflex wrinkling of the skin because of contraction of the orbicularis muscles (21). Surgical correction of the lid defect has been described (5,13,54,63); however, prognosis for vision is considered poor (21), although ERG and flash-VEP studies done in one child were normal (28). Rarely there is Potter facies (21). Pankau et al (46) reported a child with normal eyelids but anophthalmia. The diagnosis of Fraser syndrome may be questionable.

The hairline is bizarre in at least 25%, extending over the entire temple area and tapering to a point on the skin of the forehead overlying the eyes.

Nasal abnormalities are seen in approximately 85%. Most frequently the nose is broad with a low nasal bridge. Colobomas of the alae nasi, either unilateral or bilateral, may be observed, and midline grooving of the nasal tip has been noted (2,24,25,53,55,57,60,68). Choanal atresia is an occasional finding (19,28,49,66).

Cleft lip and/or cleft palate and ankyloglossia have been found in approximately 10% (21). Malocclusion and, on occasion, hypoplastic teeth have been reported (2,18,25,30,51,68). Laryngeal atresia or hypoplasia, as well as laryngeal cysts, laryngomalacia, or subglottic diverticulum occur in approximately 80% (2,32,49,55,60), and lung hyperplasia has been documented (36,52).

Table 24–2. Diagnostic criteria for the cryptophthalmos syndrome

Major
Cryptophthalmos
Syndactyly
Abnormal genitalia
Sibling with cryptophthalmos syndrome
Minor
Congenital malformation of nose
Congenital malformation of ears
Congenital malformation of larynx
Cleft lip and/or palate
Skeletal defects
Umbilical hernia
Renal agenesis
Mental Retardation

(From IT Thomas et al, Am J Med Genet 25:85, 1986.)

Table 24–3. Frequency of individual manifestations in cryptophthalmos syndrome

Features	Percent	(Sample size)
Craniofacial		
Cryptophthalmos	85	(93)
Abnormal nose	84	(62)
Abnormal ears	83	(64)

Skeletal defects	70	(33)
Umbilical hernia	28	(60)

(From IT Thomas et al, Am J Med Genet 25:85, 1986.)

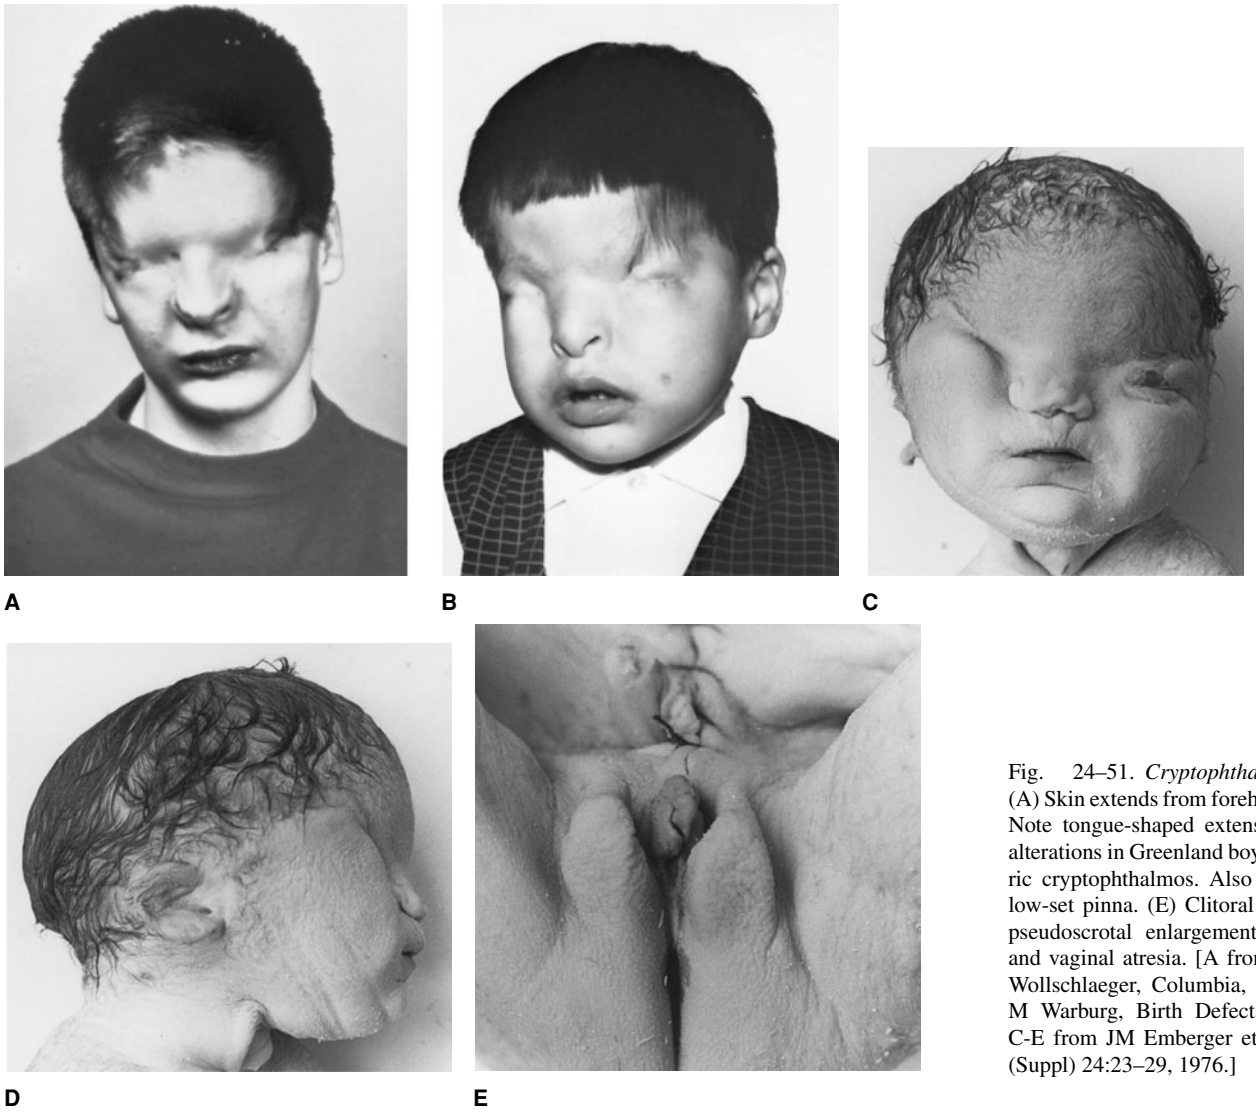

Fig. 24–51. *Cryptophthalmos syndrome*. (A) Skin extends from forehead covering eyes. Note tongue-shaped extensions. (B) Similar alterations in Greenland boy. (C,D) Asymmetric cryptophthalmos. Also note dysmorphic, low-set pinna. (E) Clitoral enlargement with pseudoscrotal enlargement of labia majora and vaginal atresia. [A from CH Ide and PB Wollschlaeger, Columbia, Missouri. B from M Warburg, Birth Defects 7(3):136, 1971. C-E from JM Emberger et al, J Genet Hum (Suppl) 24:23–29, 1976.]

The ears are abnormal in approximately 85% (32). They may be malformed and/or low set (30%), small (10%), or with fusion of the superior margin of the helix to the scalp (6%) with stenotic external ear canals (6%–15%) or with some combination of these (21,24,30,44,55,60) (Fig. 24–51D). Conductive hearing deficit is common and malformed ossicles have been noted (21,30).

Urogenital anomalies. Abnormal genitalia found in approximately 80% include cryptorchidism (7%), hypospadias, chordee, hypoplastic penis (20%), large clitoris (20%), large labia majora, vaginal atresia (15%), bicornuate or rudimentary uterus (20%), and ambiguous external genitalia (5,10,15,21,30,31,37,38,44,55,56,59,61,68) (Fig. 24–51E).

Endocrine studies in one girl with primary amenorrhea were normal (9). Greenberg et al (23) reported gonadal dysgenesis and gonadoblastoma. Renal agenesis occurs in 85% and may be either unilateral (37%) or bilateral (47%) (2,3,11,15,17,18,30,37,38,43,44,55). Abnormalities of the ureter and/or bladder are found in 10%–15% (21). Anterior urethral structure has also been documented (1).

Extremities. Marked soft-tissue syndactyly has been observed in 60%–75% (21,30,53,54,62,67,68). In most cases, both fingers and toes are involved, although in some instances, either fingers or toes alone may be affected (Fig. 24–52).

Central nervous system. Mental deficiency is observed in approximately 80% of those patients whose intelligence has been documented. Malformations of the central nervous system occur in approximately 20% and may include encephalocele (10%) or occasional anomalies such as Dandy–Walker cyst or absent left ventricle. Some patients have calcification of the falx cerebri (18,22,29,30,37,53,55,67,68).

Other abnormalities. Skeletal defects occurring in approximately 70% include small orbits, skull asymmetry, abnormal facial bones and sinuses, deformed optic foramen, absent sphenoid wing, parietal lucent defects, and diastasis of the symphysis pubis (29,30,38,44,55,59,60,67). Other low frequency skeletal anomalies have been summarized by Thomas et al (55).

Omphalocele or umbilical hernia has been noted in 10% (21,67). Low insertion of the umbilicus has been described, and may not be rare (57). Congenital heart defects have been recorded in approximately 5%. Anal anomalies, thymic aplasia or hypoplasia, intestinal hypoplasia, intestinal malrotation, and other less commonly occurring anomalies are listed elsewhere (21,32,55,66).

Differential diagnosis. Isolated cryptophthalmos may be either unilateral or bilateral and may, on occasion, have midline nasal grooving. Approximately two-thirds of these cases are sporadic, one-third occurring as an autosomal dominant trait (48,55). Brownstein et al (6) reported a patient with bilateral corneal and lenticular opacities, malformed nose, anomalous ears, bilateral renal agenesis, and cryptorchidism. Mena (42) described siblings with fused eyelids, subglottic stenosis, digital anomalies (but not syndactyly), and ovarian cysts. Marles et al (39) described unilateral upper eyelid coloboma, abnormal anterior hairline, and anal anomalies. Turner (58) and Winter et al (64) described a syndrome

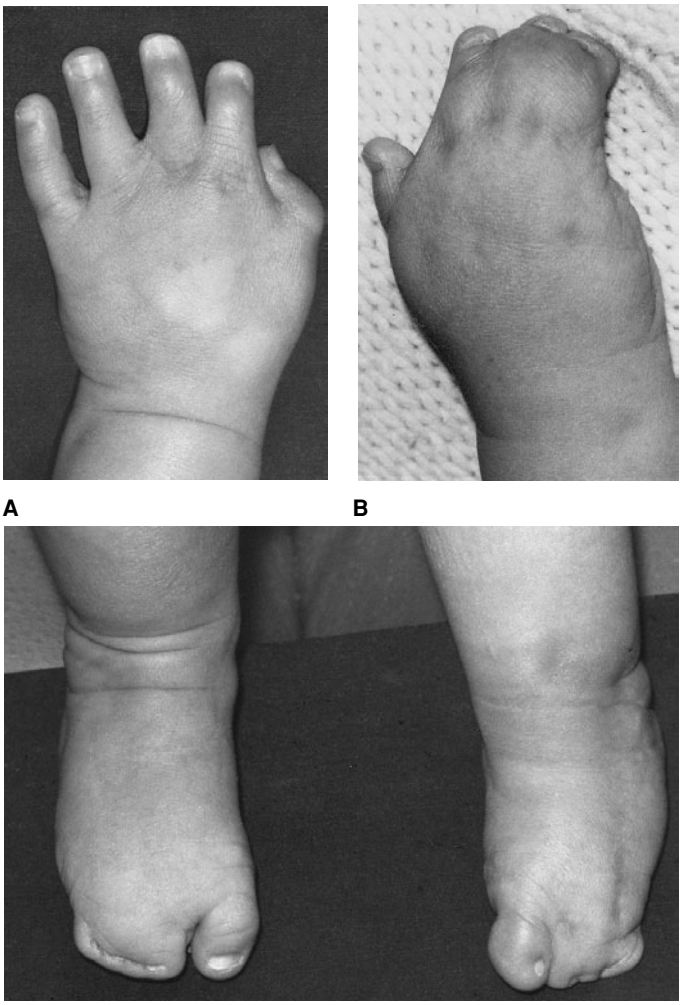

Fig. 24–52. *Cryptophthalmos syndrome*. (A,B) Varying degrees of syndactyly. Note similarity of changes in B to Apert syndrome. (C) Marked syndactyly of toes, somewhat resembling that seen in Apert syndrome. [From N Dinno et al, Birth Defects 12(6):109, 1976.]

characterized by renal agenesis, genital abnormalities, anomalous ears with stenotic ear canals, ossicle defects, and, in some instances, an abnormal nose with grooving of the nasal tip. Martínez-Frías et al (40) described a child with sclerocornea, syndactyly, and ambiguous genitalia. In their review of mouse bleb mutants, Darling and Gossier (12) suggested that there may be several nonallelic genes which could lead to a similar phenotype. This may be the explanation for some of the above-mentioned conditions. The cryptophthalmos syndrome should easily be distinguished from *ablepharon-macrostomia syndrome* (41).

Laboratory aids. Prenatal diagnosis has been made using fetoscopy and ultrasound (4,16,21,50).

Nasal alar colobomas, mirror hands and feet, and talipes (Laurin-Sandrow syndrome)

In 1964, Laurin et al (7) first described mirror image duplication of the ulna and fibula with absence of the tibia and radius, talipes equinovarus, and dislocated knees. No mention was made of unusual facies, but examination of the photograph shows a distinctly unusual nose. Sandrow et al (12), in 1970, documented a father and daughter with mirror hands and feet and unusual face. Several other examples have confirmed the syndrome (2,3,4a,6,8,9). There have been other cases (1,11) in which the nose appears normal. The mandibular condyle is enlarged (4a).

The occurrence of syndrome in parent (milder) and child in several cases (1,8,12) indicates autosomal dominant inheritance with variable expression. All other examples have been sporadic. A gene for mirror image polydactyly has been mapped to 14q13 (10).

The face is distinctively characterized by upturned nose, hypoplasia of the nasal alae with coloboma, and short grooved columella (Fig. 24–53A).

The arms and legs exhibit absent or hypoplastic radius and tibia (which may not be symmetrical) and duplication (dimelia) of the ulna and fibula. Supernumerary digits with complete syndactyly are arranged in mirror form (mirror hands and feet). The hands have mitten or rosebud form. The feet may show a median fused wide hallux. Duplication of carpal and tarsal bones in combination with talipes equinovarus and dislocated knees are usually noted (Fig. 24–53B,C).

Mirror imaging seems to depend on the gene, *Sonic Hedgehog*, which induces and regulates FGF4 in the apical ectodermal ridge, creating a positive feedback loop between the apical ectodermal ridge and the zone of proliferating activity in the limb bud. Possibly the inductive interactions of these factors indicate expression of a homeobox D gene or bone morphogenetic protein 2 or 4. Probing discussions of various possibilities are those of Hersh et al (3) and Kim et al (5). Mirror imaging can accomplished experimentally by implanting the zone of proliferating activity beneath the apical ectodermal ridge. Retinoic acid will do the same thing. We suspect that there are examples of the syndrome that have been classified as Werner syndrome 2 (4).

Fig. 24–53. *Nasal alar colobomas, mirror hands and feet, and talipes*. (A) Unusual facies marked by short nose, hypoplasia of nasal alae, and defective columella. (B) Mirror duplication of hands and extensive syndactyly leads to rosebud appearance. (C) Similar mirror duplication in feet. Note deep skin dimple, and talipes equinovarus. Romberg syndrome (progressive hemifacial atrophy)

Romberg syndrome consists of slowly progressive atrophy of the soft tissues of essentially half the face accompanied most frequently by contralateral Jacksonian epilepsy, trigeminal neuralgia, and changes in the eyes and hair. Romberg (52) is usually credited for delineation of the disorder, but Parry (47) discussed the disorders as early as 1825. The condition has been called progressive facial hemiatrophy (1,3,4,6,16,18, 28,32,35,37,39,40,43,46,49,56,61,70,71,72), hemifacial atrophy (6,14, 17,19,20,26,29,38,41,48,64), and Parry-Romberg syndrome (12,25,27, 30,34,55). Comprehensive surveys have been carried out by a number of authors (3,6,11,15,34–36,39,42,50,63,68,69). Over 1000 examples have been reported (48). Surgical aspects are particularly well covered by Rees (50) and Saccomanno et al (55). Classification is discussed by Roddi et al (51).

Nearly all cases have been sporadic, but several familial instances have been recorded (22,29,69). Familial aspects have been particularly well reviewed by Lewkonia and Lowry (34); however, discordant monozygotic twins have also been described (31) casting doubt on a single autosomal dominant gene as the cause. Theories of pathogenesis have been numerous (3,69), most emphasis being placed on alterations in the peripheral trophic sympathetic system (24,70). Up to a third of affected individuals have had a history of prior trauma or surgery (13,28,37). Moss and Crikelair (40) carried out unilateral cervical sympathectomy in rats and produced a condition that resembled hemifacial atrophy in the human. Studies have also investigated the role of autoantibodies or antibodies to infectious agents with mixed results (1,2,18,25). The presence of multiple aneurysms in one child suggested a neural crest migration disorder to the authors (56), although this hypothesis has been disputed (9). Thus it is likely that this condition is heterogeneous, with a genetic cause in some, but attributable to environmental factors such as trauma, infection, or autoimmunity as other causes (31). Pensler et al (48) opined etiology in chronic cell-mediated vascular injury.

Face, skin, and hair. In advanced cases, the face is quite distinct (Fig. 24–54). The ear may become misshapen and smaller than normal or, because of lack of supporting tissues, may project from the head (26). Basilar kyphosis, an alteration in the basal skull angle, has been described (14). An extensive cephalometric study was carried out by Berkman (6). Early facial change, usually appearing during the first decade (average-9 years) (Fig. 24–54), involves the paramedian area of the face and slowly spreads, resulting in atrophy of underlying muscle, bone, and cartilage. First to be involved is usually the area covered by the temporal or buccinator muscles. The process extends to involve the brow, angle of the mouth, neck, or even half the body (3,69) (Fig. 24–55). There is a marked predilection for left-sided involvement of the face. The overlying skin often becomes darkly pigmented. The condition slowly progresses for several years (about 9 years) and then usually becomes stationary for life (14,26,57). In those with skeletal involvement, onset is at an earlier age (5 years vs. 15 years).

Fig. 24–55. *Romberg syndrome*. Involvement of half of body. (From AJ Barsky et al, Principles and Practice of Surgery, 2nd ed. McGraw-Hill, New York, 1964.)

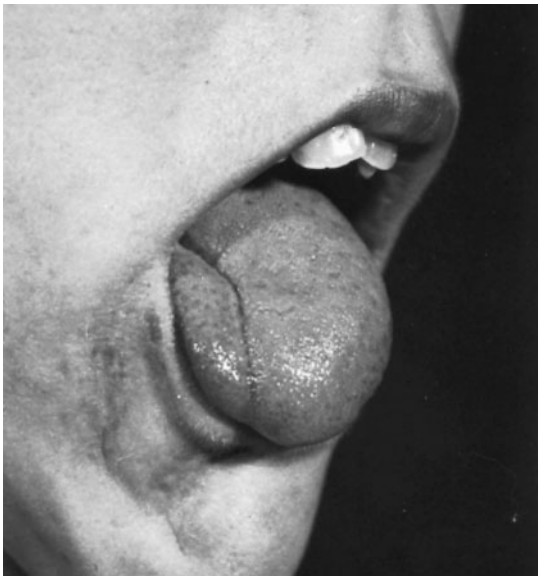

Fig. 24–56. *Romberg syndrome*. Atrophy of right side of tongue.

There has been a long-standing debate about the relationship between progressive hemifacial atrophy and scleroderma, several authors stoutly defending the position that the coup-de-sabre form of scleroderma is only a special type of progressive hemifacial atrophy (3,33,65,68,70). Others indicate that the two conditions may occur simultaneously (44). Lewkonia and Lowry (34) suggested that progressive hemifacial atrophy be considered an anatomically limited form of linear scleroderma without extensive limb or trunk involvement, although some patients diagnosed with Romberg syndrome had multiple sites of localized scleroderma on the body, or atrophy or neural involvement of the arm, chest, and/or back (30,48). There is therefore some support for the hypothesis that these conditions form a spectrum (38). It should be pointed out that, in some instances, the skin is spared while only fat and subcutaneous tissue disappears. Occasionally, vitiligo accompanies the disorder (13,58).

Changes in the hair may precede those of the skin (3,70,71). The scalp on the affected side may exhibit circumscribed but complete alopecia limited to the paramedian area, eyelashes, and median portion of the eyebrows (70). Poliosis, or blanching of the hair, has also been noted (69).

Ocular manifestations. Ocular manifestations are particularly well documented by Muchnick et al (41) and occur in 35%. Loss of periorbital fat results in enophthalmos in 80% (45,68) or, rarely, upper eyelid retraction (23) in those with involvement of the first trigeminal division. Underlying bone may disappear causing the outer canthus to be displaced downward. Muscular paralysis has been noted by several authors (20,22), as well as lagophthalmos and ptosis (3,20,70). Horner syndrome, heterochromia iridis, upper eyelid coloboma, and dilated and fixed pupil have also been reported. More rarely, posterior segment involvement can occur, and includes uveal coloboma, chorioretinal atrophy, and retinal pigmentary changes (43). Common inflammatory processes involving the eyes include neuroparalytic keratitis, iritis, iridocyclitis, choroiditis, papillitis, and cataract (22,24,69). In some instances, ocular findings may affect the eye on the contralateral side (22). Duane anomaly was described in one child (60). Vision may be mildly impaired or blindness can occur (39).

Oral manifestations. Atrophy of half of the upper lip and tongue are characteristic (46) (Fig. 24–56). Maxillary teeth on the involved side are exposed. Spontaneous fracture on the affected side of the mandible has also been noted (7,20,65,71). Other dental anomalies include delayed tooth eruption, abnormal root morphology, and, in rare cases, root resorption (19).

Radiographically, the body and ramus of the mandible are shorter on the involved side, and delayed development of the mandibular angle may be observed, resulting in malocclusion. Teeth on the affected side occasionally are delayed in eruption or have atrophic roots (21,26,53,54,62).

Central nervous system. The most common neurologic finding is epilepsy, often of the sensory Jacksonian type, which frequently appears late (3,4,9,17,49,69,71). However, trigeminal neuralgia and/or facial paresthesia may appear early, preceding other neurologic changes. Migraine has also been an occasional finding (17,69,71,72). MRI imaging has demonstrated intracranial calcifications, cerebral atrophy, porencephaly, and agenesis of the right caudate nucleus (10,12,16, 21,27,32,38,66,67) especially in those with neurologic signs or symptoms. Abnormalities of cerebral vasculature were found in one patient (72), and cerebral aneurysms were described in two (56,64).

Differential diagnosis. Asymmetric facial deformities have a diversity of manifestations and causes and these have been discussed by Souyris et al (62). Congenital facial hypoplasia can be diagnosed by its presence at birth and diminution of tooth size on the affected side following eruption (5,8,54). Scleroderma (60), fat necrosis, and *oculo-auriculo-vertebral spectrum* should also be considered.

Leprechaunism (Donohue) and pseudoleprechaunism (Patterson-David) syndromes

Although the first description of this condition is attributed to Donohue (13) in 1948, Baumeister (4) suggests that Janssen and deLange first described this as familial congenital hypertrichosis totalis. The syndrome consists of failure to thrive, unusual facies, facial hirsutism, sexual precocity, retarded bone age, and insulin resistance with glucose intolerance and hyperinsulinemia. The term "leprechaunism" was introduced by Donohue and Uchida (14) in 1954.

The disorder has autosomal recessive inheritance, but there has been a 2:1 female predilection (6). Affected sibs (12,39,40) and increased (30%) parental consanguinity (6,8,11,12,14,27,39,41) have been noted. Approximately 50 examples have been reported (6,17).

The basic defect is a mutation in the insulin receptor gene which maps to 19p13.2–13.3. (2,25,26,30,36,38). Human insulin receptor is

Fig. 24–57. *Leprechaunism*. Note hirsutism, large hands, feet, and penis.

composed of two extracellular alpha subunits which bind insulin and two beta subunits which span the plasma membrane (18,22). The receptor is encoded by a single gene. A great variety of mutations have been identified, with single base pair changes, deletions, and alternative splicing of mRNA. It is theorized that insulin receptor defects may also impair the function of other receptors, thus accounting for the varied aspects of the phenotype. Wertheimer et al (47) showed that homozygous deletion of the insulin receptor gene results in leprechaunism. Elsas et al (17) opined that two different recessive mutations impair high-affinity insulin receptor binding and that leprechaunism represents a compound heterozygote for these mutations: Most patients have a nonsense and missense mutation, although patients with nonsense mutations of both alleles have also been described (30,32). Target cell resistance to insulin varies according to age of onset. In leprechaunism, there is severe insulin resistance that results in small babies with almost an entire absence of subcutaneous fat and poor muscular development, poor early growth, and early death (37). Intravenous insulinlike growth factor I did not improve hyperglycemia or produce an anabolic effect (3).

Gestation tends to be short. Nearly all infants have been marasmic, and over 60% have died at less than 2 years of age (6,7,15,23,40).

Facies. The face is gaunt, with large ears and lips. The eyes appear widely spaced (43). Facial hirsutism may be marked (14,27,31,39–42) (Fig. 24–57).

Musculoskeletal changes. Muscle mass is severely wasted. The abdomen is distended. Bone age is usually retarded (1). The hands and feet appear disproportionately large (11,14,19,39,41) (Fig. 24–57).

Skin. Acanthosis nigricans has been observed in most cases (15,19,31,39,40). Hirsutism is usually marked. Periorificial skin rugosities, prominent nipples, and dysplastic nails have been noted (40,43).

Endocrine changes. The breasts and clitoris or penis have been enlarged in over 50% and 75%, respectively (6). There have been cystic alterations in the ovaries or testes (1,7,14,19,23,27,40). Bilateral granulosa cell tumors of the ovaries were reported by Brisigotti et al (5). Rogers (38a) described basophilic hyperplasia of the pituitary gland. Pancreatic islet cell hyperplasia (nesidioblastosis) with low fasting blood sugar level is common (1,14,19,21,40,41,44).

Oral manifestations. Large mouth, thick lips, and gingival hypertrophy are present at birth (12,15,39,40). Roth's (40) patient at age 5 had a dental age of 14 years. Whether other children had advanced dental age is not known.

Other findings. Hepatic cholestasis and fibrosis with excessive deposits of iron in the liver are frequent findings. There is paucity of lymphatic tissue (tonsils, thymus, mesenteric nodes, Peyer patches). The gut is often dilated. Microscopic foci of nephrocalcinosis have been noted in several cases (33). Electron microscopy on a renal biopsy specimen in one patient demonstrated renal and glomerular enlargement, as well as glomerular changes similar to that of patients with diabetic nephropathy (16).

Differential diagnosis. It is possible that the condition has been overdiagnosed, since many marasmic infants or those with emotional deprivation may develop a similar phenotype (25). There is clinical resemblance between leprechaunism and lipoatrophic diabetes. These similarities may possibly be explained by shared mechanisms involving both insulin and insulinlike growth factor cell receptors (37).

The Patterson-David syndrome has been confused with leprechaunism. The patients of both Patterson (34,35) and David (9,10) presented large redundant loose folds of skin of the hands and feet since birth, marked generalized bronzed hyperpigmentation, hirsutism largely confined to the limbs, severe mental retardation, bony deformities, and skeletal dysplasia (Fig. 24–58). The bony alterations are characterized by profound disorder of endochondral ossification with marked retardation of skeletal maturation (9,10). The ends of long bones are swollen, especially those of the knees, ankles, and wrists (Fig. 24–59). Similar changes can be observed in hands and feet. The thickening and deformity affect other bones, the calvaria, maxilla, ethmoids, and mandibular condyles. The occipital bone may exhibit a defect. The vertebral bodies are deformed as well as ribs, clavicles, and scapulae. Kyphoscoliosis, genua valga, and valgus deformities of the ankles are common features. The skeletal changes increase in severity with age (9,10). David's (9,10) patient had premature adrenarche.

Laboratory aids. Biochemical evidence for insulin resistance includes markedly elevated plasma insulin, impaired glucose homeostasis, absence of anti-insulin receptor antibodies, and altered insulin receptor binding and/or response to insulin by patients' cells (12,15,17, 24,28,29,37,39,40,45,46). The patient reported by Roth et al (40) was further seen at age 8 by Frindik et al (20) and was found to have markedly elevated urinary levels of epidermal growth factor.

Leprechaunism-like syndrome

Al-Gazali et al (1) noted a leprechaunism-like syndrome in five of eight offspring of a Yemeni couple.

All exhibited insulin resistance with paradoxical hypoglycemia, only mild growth retardation, somewhat coarse facial features, acanthosis nigricans, enlarged genitalia, and prolonged survival.

The facies was characterized by hypertelorism, depressed nasal bridge, flared alae nasi, thick lips, large pinnae, and enlarged gingivae. The abdomen was distended, the nipples prominent, and the genitalia enlarged. The acanthosis nigricans involved the neck, armpits, and groin. There was generalized hirsutism. No reduction in subcutaneous tissues was noted.

The hands and feet were enlarged. The kidneys and ovaries were larger than normal on ultrasound. Echocardiography demonstrated enlarged myocardium.

In leprechaunism, many mutations have been demonstrated in the insulin receptor gene, resulting in a decrease in the number of insulin receptors in target cells or in defects in insulin receptor function. In the leprechaunism-like syndrome described above, a novel mutation involving the insulin receptor gene (Ile119→Met) was described by Hone et al (2).

Lipoatrophic diabetes (Berardinelli syndrome, Seip syndrome, generalized lipodystrophy)

The syndrome consists of generalized disappearance of body fat, increased rate of skeletal growth, acanthosis nigricans, enlarged external genitalia, hepatomegaly, and insulin-resistant diabetes. Although Berardinelli (3) and Seip (32) are usually credited with first delineating the disorder, Miescher (26), in 1921, clearly described the condition in sibs. Approximately 120 cases have been reported (12). For a historic review, see Seip and co-workers (32–34). A good review is that of Garg (12) in 2000.

The syndrome has autosomal recessive inheritance. Parental consanguinity has been noted in approximately 25% (2,11,33). A gene has been mapped to 9q34 (13). However, there is genetic heterogeneity. The sublethal nature of the gene is suggested by the frequent history of miscarriage or death of affected children within the neonatal period.

The disorder is due to disturbed insulin binding to membrane receptors, but possibly is of secondary origin, that is, due to a disruption caused by a circulating factor (27,37). The best evidence suggests that the mechanism is via a defect in the tyrosine kinase of the beta subunit of the insulin receptor (23). A mouse model was created by Shimomura et al (36). Reversal was obtained with leptin.

A generalized loss of all subcutaneous fat causes the muscles to appear enlarged and the veins to stand out prominently. This is usually evident at birth (33). There is also absence of mesenteric and perinephric fat (33).

A B

Fig. 24–60. *Lipoatrophic diabetes*. (A,B) Absence of subcutaneous fat, especially buccal fat pad, produces gaunt appearance.

Females have a definitely masculinized body build. Skeletal growth is often accelerated during the first 10 years of life, during which time patients achieve 90% of their growth. Adult stature is anywhere from above to below the predicted height (34). Other skeletal changes include cystic changes or sclerotic foci, enlarged epiphyses, or thickened calvarium (9,43). The phenotype is further altered by the enlarged joints of the hands and feet. There is a bizarre fat distribution, almost all disappearing from the subcutaneous and intraabdominal regions, bone marrow, and parathyroid glands.

Long-term prognosis is rather poor, due to diabetes with its complications or hypertrophic cardiomyopathy (34). Most do not survive beyond the fourth decade.

Facies. The facies is quite distinctive. Loss of subcutaneous adipose tissue, especially the buccal fat pad, causes the cheeks to have a gaunt appearance (Fig. 24–60). This, combined with large ears, hypertelorism, and hirsutism, is characteristic.

Viscera. Hepatomegaly with abdominal prominence may be pronounced in infancy; liver biopsies, taken later in life, have shown fatty infiltration with moderate early fibrosis and increased glycogen deposits. The fatty infiltration is secondary to hypertriglyceridemia and to lack of functional peripheral fat storage depots.

Cardiac murmurs and hypertrophic cardiomyopathy are not uncommon (4,32–34). Peripheral pulmonary artery stenosis has been documented (39). In most patients, the kidneys are enlarged without apparent histologic cause.

Nervous system. Mental retardation of variable degree has been noted in approximately 50% (5,32–34). Dilated brain ventricles and cisterns (43) were noted. Appetite can be voracious in early adulthood (12).

Musculoskeletal alterations. Muscular prominence, due in part to lack of subcutaneous fat, may be absolute, as some patients exhibit increased urinary creatinine levels (Fig. 24–61). Advanced bone age is a

Fig. 24–61. *Lipoatrophic diabetes*. (A,B) Marked muscular prominence, due in part to lack of subcutaneous fat. Also note evidence of axillary acanthosis nigricans in female. Hirsutism may be marked in some patients. (From M Seip, Acta Paediatr Scand 48:555, 1959.)

A B

Fig. 24–62. Lipoatrophic diabetes. Acanthosis nigricans. (Courtesy of W Reed, Burbank, California.)

common feature during the first 4 years of life, and several patients have exhibited increased bone density (33,40,43). These strongly suggest an androgen excess. An increase in subcutaneous fat may occasionally be noted after puberty. Cystic radiolucencies of bone filled with red marrow have been found in a few families at adolescence (5,10,15,40,43). Umbilical hernia is a consistent finding (12).

Genital organs. Enlarged penis or clitoris and polycystic ovaries are common features (3,16,33,35). Oligomenorrhea is frequent.

Skin. Hirsutism of face, neck, arms, and legs may be present at birth and increases with age. With the onset of the lipodystrophy, the scalp hair may become excessively curly and thick, the hair growing nearly to the eyebrows.

Acanthosis nigricans is a prominent feature in almost all patients, appearing usually by age 8 years. It is especially common in the axillae, groin, neck, and on the wrists and ankles. It tends to diminish with increasing age and may disappear after puberty (Fig. 24–62). The skin is also dry and coarse with hyperkeratotic epidermal papillomatosis. Hyperhidrosis is common (34). Subcutaneous angiomatosis has been reported (5).

Oral manifestations. Enlarged tonsils and adenoids are common in the congenital type (33).

Differential diagnosis. The *Dunnigan syndrome* (familial partial lipodystrophy) exhibits many overlapping features (acanthosis nigricans, decreased subcutaneous fat with onset at puberty, enlarged clitoris, insulin-resistant diabetes, autosomal dominant inheritance). The fat accumulates under the chin giving a Cushingoid appearance. The gene has been mapped to 1q21–q22 (1,17,29). The nuclear envelope protein lamin A/C is involved (11,20,35). The mutations are in the globular C-terminal domain of lamin (37a).

The Rabson–Mendelhall syndrome includes thickened nails, pineal hyperplasia, precocious puberty, premature eruption of teeth, open bite and macrodontia of the upper central incisors with palatal cusps arising from the cingulum, and enlargement of the filiform and fungiform papillae of the tongue (2,6,25,30,44).

In the so-called partial or acquired lipodystrophy, there is symmetric disappearance of facial fat, the patient appearing gaunt and cadaverous (Voltaire-like) (19). Fat may also disappear from the arms, chest, abdomen, and hips. The characteristic adiposity of pelvis and legs is seen only in postpubertal females. We are not convinced that there is other than relative adiposity of the buttocks. Onset is usually noted between 5 and 15 years of age, but older examples have been noted (31). The wasting time ranges between 1.5 and 6 years. Renal problems (mesangiocapillary glomerulonephritis progressing to chronic sclerosing glomerulonephritis) have been noted in 25%–50% about 5–20 years after the appearance of the lipodystrophy (36). The ratio of females to males is 4:1. The disorder is sporadic. It is more common than lipoatrophic diabetes. A deficiency in the third component of complement (C3) and C3 activating factor is probably responsible for the disorder (19,24,44).

There are two X-linked dominant, lethal in the male, forms of partial lipodystrophy with onset at puberty. In the Kobberling variety, the fat loss is confined to the limbs, sparing the face and trunk. In the other, the trunk is also affected but the vulva is spared, giving the appearance of labial hypertrophy. Diabetes mellitus, tubero-eruptive xanthomata, insulin-resistant diabetes mellitus, hyperlipoproteinemia type V, and acanthosis nigricans frequently accompany the disorders (18,19,22).

Lawrence (21) reported a sporadically acquired lipoatrophic diabetes of adolescence or early adult life. There is female preponderance. Hepatosplenomegaly with cirrhosis, acanthosis nigricans, hyperlipidemia, and insulin-resistant diabetes mellitus were also found.

Many features of congenital lipodystrophy have been noted in *leprechaunism*: liver enlargement, lipodystrophy, enlarged clitoris or penis, neurologic damage, hirsutism, and insulin resistance. These are all evident at, or shortly following, birth. It is conceivable that leprechaunism represents a lethal form of lipoatrophic diabetes.

The so-called *SHORT syndrome* manifests partial lipodystrophy. Barraquer–Simons syndrome has postnatal onset lipodystrophy, as well as sensorineural deafness (38).

The diencephalic syndrome caused by a tumor in the region of the anterior hypothalamus is manifested by profound emaciation with accelerating early growth, increased motor activity, and euphoria (8). The affected infants are normal at birth but become symptomatic with age. Progressive emaciation leads to a loss of subcutaneous fat but without the muscularity of lipodystrophic patients. The hands and feet are often large. Hepatomegaly, genital enlargement, and hyperlipemia have not been reported.

Progeria and *Werner syndrome* patients also exhibit loss of body fat and an increased incidence of diabetes mellitus.

Laboratory aids. Lipoatrophic diabetes is clearly distinct from the common form of diabetes mellitus. The diabetes, which is insulin resistant and nonketotic, appears after the onset of the lipodystrophy, usually between 6 and 20 years of age. Normal glucose tolerance is observed during the first few years of life. Hyperglucagonemia has been found and may contribute to the insulin resistance.

Hyperlipemia, especially of the triglyceride fraction, is a constant feature. It usually precedes the onset of hyperglycemia. The serum of these patients is intermittently turbid or milky, with increased triglycerides, and contains very low density lipoprotein. In addition, there is slow turnover of 14C-labeled triglycerides and cholesterol and slow clearance of ingested triglycerides with failure of adipocytes to incorporate triglyceride fatty acids from the blood.

SHORT syndrome (unusual facies, lipoatrophy, short stature, and Rieger anomaly)

Gorlin et al (5) and Sensenbrenner et al (12) reported male sibs and a female singleton, respectively, with a striking phenotype. Gorlin et al (5) suggested the acronym SHORT (Short stature, *H*yperextensibility of joints/hernia, *O*cular depression, *R*ieger anomaly, *T*eething delay). Approximately 20 examples have been reported (1–3,5,7,9,11–16).

Inheritance is probably autosomal dominant (1,2,13), but affected sibs (5,14) have been documented.

The lower face, upper limbs, and buttocks appear thin due to lipoatrophy (Fig. 24–63). The eyes are deep set, and Rieger anomaly is usually present (Fig. 24–64). The pinnae are somewhat outstanding. The nasal alae are hypoplastic with wide nasal bridge. Stature is reduced. There is poor weight gain and frequent illness during infancy. Joints are hyperextensible, and there may be inguinal hernia. Speech is delayed in spite of normal intelligence. Sensorineural hearing loss has been documented (2,3,11,15). Dental eruption is delayed. Dimples on the chin and buttocks have been reported in several cases (1,5,9,16). Diabetes mellitus has been documented in several examples (1,11,16).

Radiologic changes include large epiphyses, gracile diaphyses, and cone-shaped epiphyses (6).

Kupchik et al (8) reported a mother and daughter with Rieger anomaly, short stature, mental retardation, microcephaly, small pinnae, short nose with depressed bridge, and small hands. This combination was termed the GMS syndrome (*G*oniodysgenesis, *M*ental retardation, *S*hort stature syndrome). *DeHauwere syndrome* exhibits Rieger anomaly, hypertelorism, short stature, and mental deficiency (3).

McAlister et al (10) described a girl with short stature, lack of subcutaneous fat, wrinkled skin, macroepiphyses, lax joints, club feet, and osteoporosis. The parents were consanguineous. The child did not appear to have *OSMED*.

Coffin-Lowry syndrome

Coffin et al (4), in 1966, and Lowry et al (22), in 1971, independently reported patients with mental and somatic retardation, characteristic facies, large soft hands with distally tapering fingers, and various skeletal

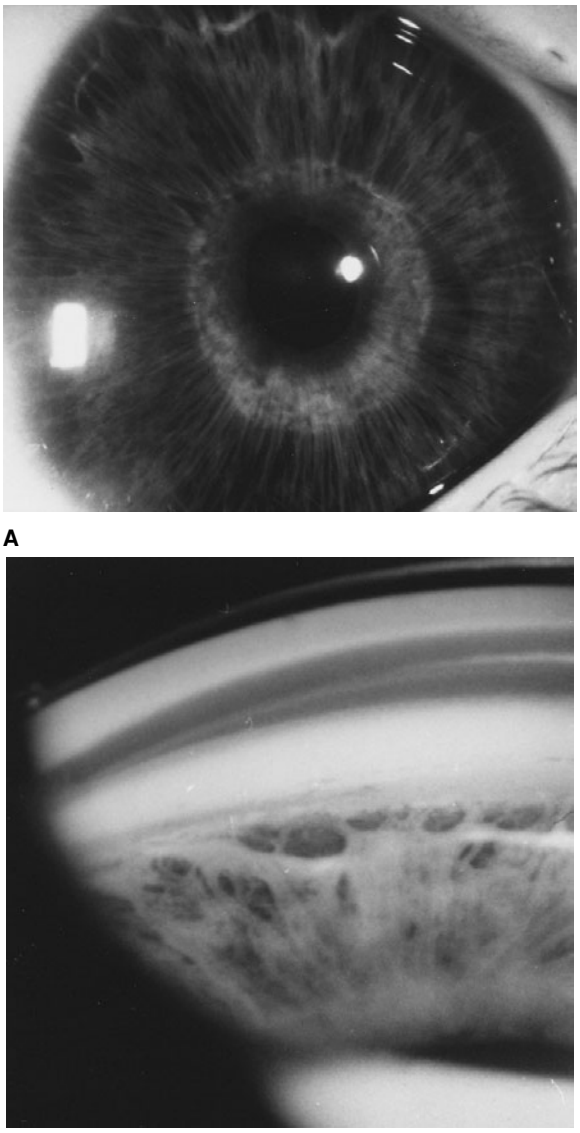

Fig. 24–64. *SHORT syndrome*. (A) Diffuse iris stromal atrophy. (B) Gonioscopic view showing iris strands adherent to Schwalbe's line. (From M Brodsky et al, Arch Ophthalmol 114:1146, 1996.)

anomalies. However, it was Temtamy et al (37), in 1975, who recognized the unity of the reports and coined the name Coffin-Lowry syndrome. An early report is that of Martinelli and Campailla (25).

The disorder has X-linked inheritance. Female heterozygotes commonly express the condition to a less severe degree, although there can be marked variable expression among female heterozygotes (31). Over 60 cases have been reported (9,42). The gene locus is on the short arm of the X chromosome at Xp22.2 (2,3,10,30), RSK2, a growth factor regulating serine-threonine protein kinase (18,24,38). There is considerable allelic heterogeneity and a high rate of new mutations (17).

Facies. Characteristic facial changes become more marked with age but are apparent by the second year of life. Hair is straight and coarse in males. The forehead is prominent and broad and the occiput is somewhat flat. There are prominent supraorbital ridges, hypertelorism, downslanting narrow palpebral fissures, heavy arched eyebrows, ptotic upper eyelids, and somewhat hypoplastic midfacial development with relative mandibular prognathism. The nose is large with a broad base and flared alae. The nostrils are anteverted and the pinnae are prominent. The philtrum appears somewhat elongated and the nasal septum is

Fig. 24–65. *Coffin-Lowry syndrome*. (A,B) Twenty-three- and ten-year-old affected males. Note facial similarities: marked hypertelorism, prominent supraorbital ridges and outer margins, short upturned nostrils, open mouth with pouty lower lip, thick bulging chin, and enlarged protuberant ears. Facial features are more coarse in the older affected male. All males had straight coarse hair. (From SA Temtamy et al, J Pediatr 86:724, 1975.)

wide. The lips are thick and pouting and the mouth is usually held open (Figs. 24–65 and 24–66).

Musculoskeletal findings. Although usually normal at birth, height and weight become reduced below the third percentile in hemizygotes and in 50% of heterozygotes. There is delayed ambulation and a clumsy broad-based gait. At birth, hypotonia and/or loose ligaments with pes planus and inguinal hernia may be noted. The hands are extremely large and soft with distal tapering fingers in both sexes (Fig. 24–67A). This is the most striking feature at birth (40,41). The nails are short and broad. The finger joints are hyperextensible. Radiographically, the calvaria is thickened, especially the frontal tables, in 60%. The anterior fontanel is large and suture closure is markedly delayed (40). Pectus carinatum or excavatum found in 80% of hemizygotes and in 30% of heterozygotes is associated with thoracolumbar kyphosis/scoliosis. Commonly there is dysplasia of the vertebral bodies at the thoracolumbar junction. Calcification of the ligamenta flava has been described (16,27). The sternum is short and often bifid. Bone age is retarded in both sexes. Pseudoepiphyses

Fig. 24–66. *Coffin-Lowry syndrome*. Female heterozygote exhibiting many of same features.

A B

Fig. 24–67. *Coffin-Lowry syndrome*. (A) Hands are spade-like; digits are thick at base and taper distally. (B) Flexion crease in hypothenar area at arrow. (A from SA Temtamy et al, J Pediatr 86:724, 1975.)

at the base of each metacarpal may be seen in males during childhood. The distal phalanges are hypoplastic and tufted and have been described as drumstick shaped (29). The middle phalanges are poorly modeled. The iliac wings may be narrowed. Female heterozygotes tend to be obese. Distal muscle atrophy is not uncommon.

Central nervous system. Intelligence quotients in males have ranged from 5 to 50 but speech is severely retarded. Sensorineural deafness has been reported in several kindred (11,14,34). It is rarely of late onset. Female carriers have varied in intelligence from normal (20%) to 60 IQ. Another 20% of heterozygotes are severely retarded (42). Internal communicating hydrocephaly or ventricular dilatation has been noted (4,12,15,22,37) in hemizygotes and over 40% exhibit severe generalized seizures (8). Agenesis of the corpus callosum is an ocasional finding (28,35). Sensorineural deafness has been described (15,34). Psychotic behavior may also be an occasional manifestation (5,34). Crow et al (6) and Carabella et al (3a) described cataplexy in affected males; Fryns and Smeets (7) reported cataplexy in 3 of 22 boys. Others (29) have also noted this phenomenon.

Cardiovascular system. Various heart anomalies have been described (4,15,20,32,37).

Skin. The skin appears loose and easily stretched. Cutis marmorata, dependent acrocyanosis, and varicose veins are frequent. There is a flexion crease in the hypothenar area of the palms (Fig. 24–67B).

Oral manifestations. The lips are large, thick, and pouting. The tongue may have a deep midline furrow (15). Torus palatinus has been stated to be more common (37) but we have not found this to be true. The lower permanent incisors are frequently absent or have reduced crown form in 80% of affected males and in 20% of females (Fig. 24–68).

Fig. 24–68. *Coffin-Lowry syndrome*. Reduced crown form of lower anterior incisors.

Malocclusion with overjet and/or overbite appears to be a nearly constant feature. Early tooth loss due to periodontal disease has been noted.

Pathology. Ultrastructural studies of conjunctiva and skin have exhibited changes suggestive of a lysosomal storage disease but this needs confirmation (1). Lacombe et al (21) reported hyperprolinemia in a mother and child.

Differential diagnosis. During infancy, several children have presented with a diagnosis of possible hypothyroidism. With age, diagnosis becomes easier but coarseness of features may suggest a mucopolysaccharidosis or oligosaccharidosis. There is some phenotypic overlap with *ATR-X syndrome, Williams syndrome, Sotos syndrome, FG syndrome*, and *fragile X syndrome* (31). Atkin-Flaitz syndrome shares some similarities as well, including short stature, telecanthus/hypertelorism, coarse facial features, everted lower lip, and dental anomalies (19). Macrocephaly and obesity should distinguish the Atkin–Flaitz syndrome, however. Proud et al (33) described mental retardation, agenesis of the corpus callosum, acquired microcephaly, limb contractures, scoliosis, tapered digits, renal dysplasia, cryptorchidism, and hypospadias in males in three generations. The facial features in these boys resembled those of the Coffin–Lowry syndrome; however, the gene mapped to Xp11.3–21.3, thus indicating distinction from the Coffin–Lowry syndrome. The patient reported by MacDermott et al (23) surely has Coffin-Lowry syndrome.

Laboratory aids. Dermatoglyphic changes include a characteristic horizontal hypothenar crease in both sexes (4,13,32,37) (Fig. 24–67B). The "atd" angle is increased and transverse palmar creases and Sydney lines are frequent. The finger tip ridge counts are decreased. Increased cd and reduced bc triradii distances appear significant (36). Abnormal proteodermatan sulfate storage has been found (1,39). Rapid immunoblot and kinase assays have been reported (26).

Williams syndrome (Williams-Beuren syndrome)

The syndrome of characteristic facial appearance, mental retardation, growth deficiency, cardiovascular anomalies, and infantile hypercalcemia (Figs. 24–69 to 24–72) was described in 1952 by Fanconi and coworkers (29). Important early papers are those of Williams et al (109) and Beuren and associates (6–8). A good historical account has been presented by Myers and Willis (81). Several important clinical reviews are available (15,25a,27,41,53,54,61,69,77,97,117a). Profound study of a single patient over many years (13) and a parental perspective (1) should interest the clinician (13). The frequency of the syndrome has been estimated to be 1 in 10,000 to 1 in 20,000 births (42,83).

Naming the syndrome has been problematic. The disorder has been known in the past as the idiopathic hypercalcemia-supravalvular aortic stenosis syndrome in spite of the fact that both features may be absent (54). The term "elfin face" syndrome presents the problem of naming a disorder after a mythical being. The currently accepted designation, Williams syndrome, or, less often, the Williams–Beuren syndrome, ignores the historical precedent mentioned earlier.

Delineating the phenotypic spectrum of abnormalities has been difficult because it is a contiguous gene syndrome (vide infra). The problem is further compounded by ascertainment on the basis of cardiovascular anomalies in some reports (7) and on the basis of facial features in others (54).

The syndrome arises because of a deletion that includes the elastin (ELN) gene at 7q11.23 in 90%–95% of all clinically typical cases (28,95a). The deletion usually spans more than 1–1.2 megabases and appears responsible for the vascular and connective tissue changes seen in the syndrome. The narrowing of large elastic arteries compromises blood flow. Using FISH techniques, over 95% exhibit deletion of the ELN gene (11,68,76,84,96,113). A gene-dosage PCR method for the deletions of the elastin gene has been described (24). Deletions can be maternal (40%) or paternal (60%). It has been asserted that if the deletion is maternal, there is more severe growth retardation and more severe microcephaly (91) and, in fact, the opposite has been found (118). Imprinting plays no role. Other genes whose functions may be deleted are the protein kinase, *LIM-kinase 1* (76,109) and replication factor C (*RFC2*) (95). Deletion of the *RFC2* gene may be responsible for the deficient growth and development (95). Although other genes such as "frizzled"and "syntaxin" may be deleted (87,119), they do not play any significant role in the phenotype (12). Deletion of the *LIM-kinase 1* gene may result in impaired visual/spatial perception (32,71). Dutly and Schinzel (26) showed that during gametogenesis the deletion results from unequal crossing over of homologous chromosomes 7. Phosphoserine phosphatase is decreased in lymphoblasts and fibroblasts, but this finding may not be significant (51). Although the syndrome appears to be autosomal dominant, parent-to-child transmission is truly rare because most affected adults do not reproduce (42,79,105).

Several authors have reported familial examples of the Williams syndrome (42,88,94,122), but the overwhelming number of reported cases are sporadic. The affected second cousins reported by White et al (122) do not represent a familial occurrence as elastin deletions arose de novo in each affected child.

Concordant monozygotic twins (16,80,86,91,124) are convincing. Jones and Smith (54), Martin et al (72), and Morris et al (77) found no evidence for a paternal age effect. However, Greenberg and Lewis (41) found paternal age increased.

Natural history has been particularly well documented by Morris et al (77), who tabulated data on 109 subjects. Features of infancy, childhood, and adulthood are listed together with their respective frequencies in Tables 24–4, 24–5, and 24–6. Pagon et al (89) studied physical, neurodevelopmental, and behavioral characteristics during late childhood and adolescence.

Facial features. Facial features are distinctive and remain in evidence into old age. Cephalometric study has been reported by Mass and Belostoky (73), and photoanthropometric study by Hovis and Butler (49). Approximately 35% have microcephaly (93). The combination of flat midface, depressed nasal bridge, anteverted nostrils, long philtrum, thick

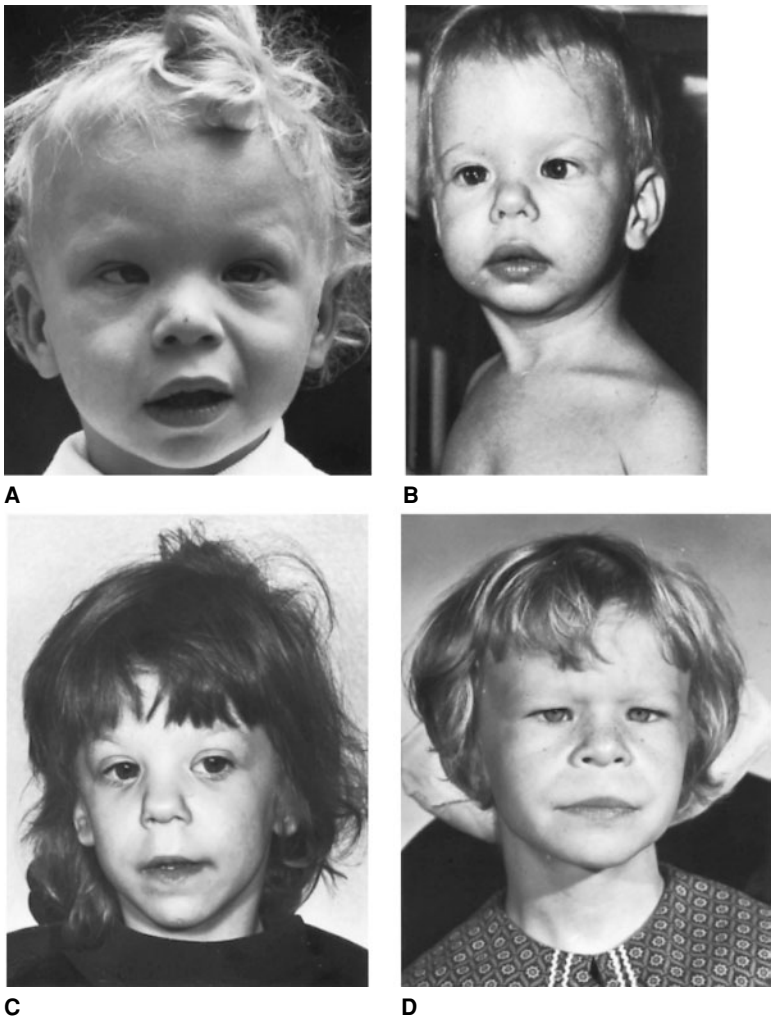

Fig. 24–69. *Williams syndrome*. (A–D) Compare facies for anteverted nostrils, long philtrum, mild midface hypoplasia, epicanthic folds, strabismus. (A from A Dupont, Dan Med Bull 17:33, 1970. B from F Roy et al, J Pediatr Ophthalmol 8:188, 1971.)

lips, wide intercommissural distance, and open mouth is characteristic (Fig. 24–69). The hair may become prematurely gray. Ocular findings may include medial eyebrow flaring (80%), short palpebral fissures (50%), hypotelorism (50%), epicanthic folds (50%), periorbital fullness, and strabismus (50%). Approximately 40% have esotropia (125). Hypermetropia has been noted in 75%. Approximately 50%–75% of blue- or hazel-eyed Williams patients have a stellate or lacy iris pattern versus 10% of the normal population (125) (Fig. 24–70). Blue eyes (77%) and green eyes (7%) are most frequently noted (7,8,29,41,46,54,104,121). Uncommonly, corneal and/or lenticular opacities (104) and ptosis of eyelids (personal observation) may be observed. Hypermetrous discs (55%) and retinal vascular tortuosity (22%) have been documented (41,48,125). In some cases, the ears are prominent. The thyroid cartilage becomes more pronounced with age (11,41).

Skeletal changes. Intrauterine growth retardation has been documented in 35% of female infants and in 22% of male babies. Until about 10 years of age, growth is at the third centile (90). Mean birth weights are lower than average (41,72). The pubertal growth spurt occurs about 1–2 years earlier than normal (10y-females, 13y-males) and menarche is

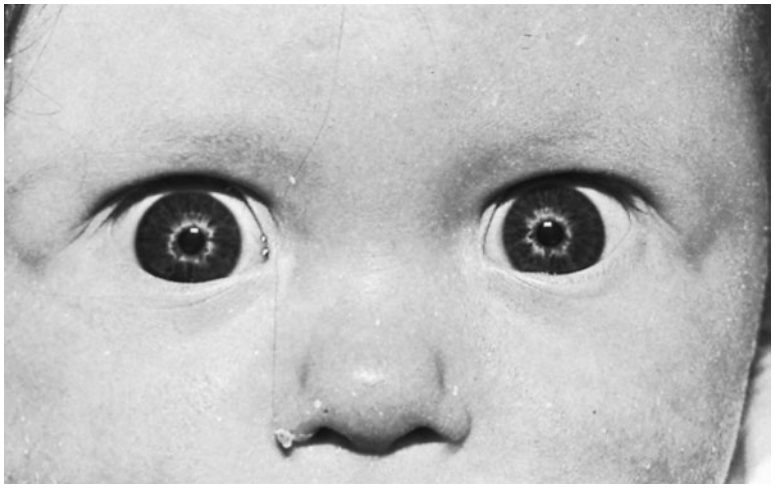

Fig. 24–70. *Williams syndrome*. Stellate iris pattern. (From FO Jensen and AC Begg, N Z Med J 68:364, 1968.)

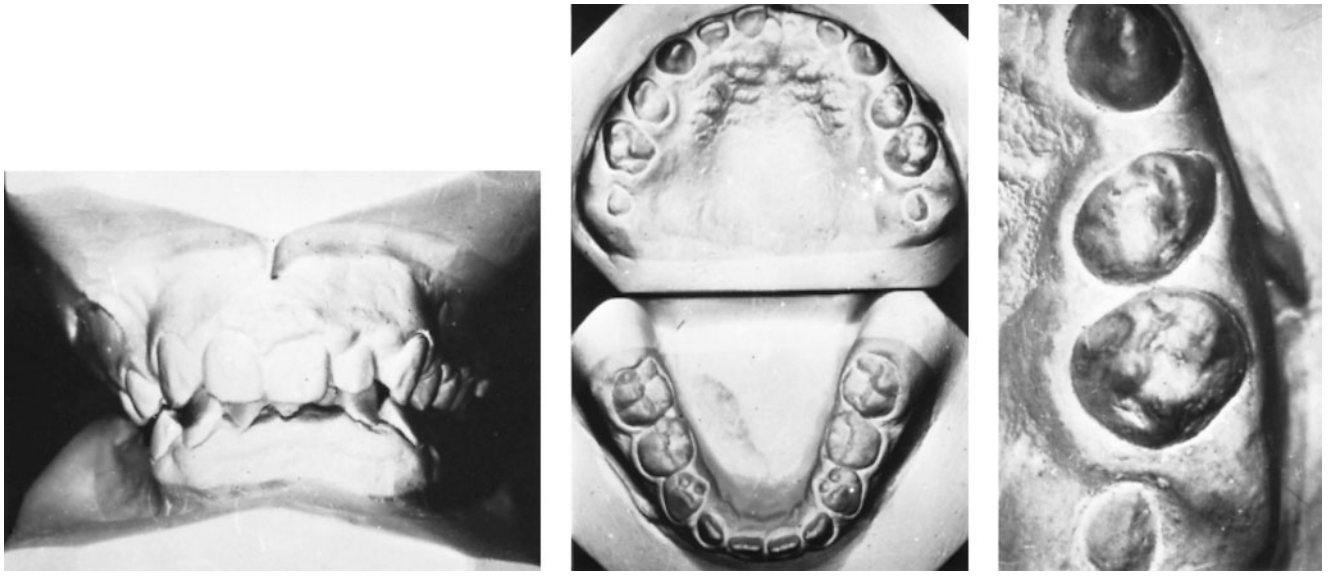


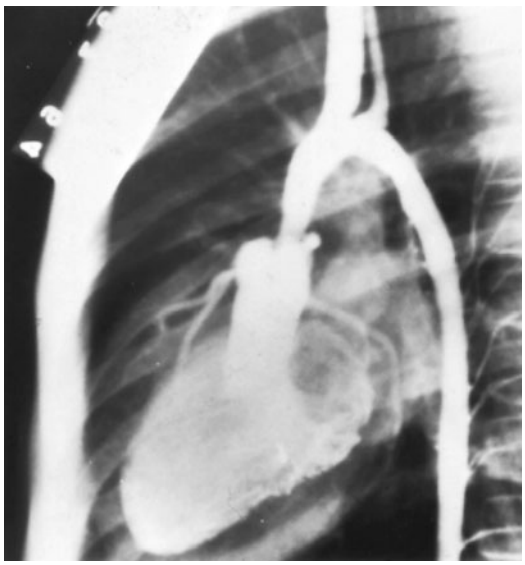
A B C

Fig. 24–71. *Williams syndrome*. (A) Upper dental arch completely overlaps lower arch. (B) Note expanded upper arch, hypoplastic upper second deciduous molar on right. (C) Detail showing bud-shaped maxillary teeth. (From AJ Beuren et al, Am J Cardiol 13:471, 1964.)

usually earlier than normal (90). Mean adult height is 165 cm in males and 153 cm in females (third centile) (94b). Mean male adult head circumference is 54.8 cm, and mean female adult head circumference is 52.8 cm (72). The elbows are often held flexed (117). Limitation of supination due to radioulnar synostosis has been reported in 8%–26% (19,92). Joint contractures, especially of the hips, heel cords, and hamstrings are very common (57,77). MCPP index is nonspecific.

The hypercalcemic phase may result in widespread osteosclerotic changes that regress in time. Craniosynostosis (secondary to microcephaly) is uncommon. Increased density of the metaphyses, epiphyses, and skull base may be present in some instances (29,58). Other findings may include pectus excavatum (40%), kyphoscoliosis (20%), minor structural and postural curvatures (55%), hallux valgus (75%), and fifth finger clinodactyly (40%) (54,72). The shoulders slope, and there is exaggerated lumbar lordosis.

Fig. 24–72. *Williams syndrome*. Note area of stenosis and hypoplasia of entire aorta distal to obstruction. (From K Jue et al, J Pediatr 67:1130, 1965.)



Central nervous system and performance. Mild microcephaly, which is most striking in bifrontal diameter, is found in 35%. Other characteristic features include mental retardation (95%), mild neurologic dysfunction (50%), and unusual personality (65%). Attention deficit disorder and restlessness are common (97). Infantile spasms are rare (112). Intelligence quotients have varied from 20 to 106 with an average IQ of 58 (37,38). There is poor visual-motor integration, the patients having problems with integration of parts into a complete picture. Developmental delay and neurologic dysfunction are highly distinctive and can be diagnostic (5,25,69,75,89,96a,114). In childhood, most patients have an echolalic, loquacious, unreserved, friendly pattern of speech that has been described as a "cocktail party manner" (54). There is a relatively better command of verbal and language skills (54,69). Vocabulary is usually excellent (39). Many play musical instruments and rarely forget a name (64). Disordered syntax, overuse of clichés, and tangential reasoning have been noted. The ability to read, to tell time, or to make change is relatively poor (2,64). In a few, impulsivity and destructive behavior predominate (54). Frank autism has also been observed (102). The loquacity is significantly less in those with more severe retardation (11).

Major motor development is relatively spared (69,72), but visual-motor integration is usually impaired to an extent that is out of proportion to

the global deficit (5,69). Hyperacusis, that is, hypersensitivity to sound without physical findings, is found in 95% (1,37,60,72,83,115).

Neurologic examination is usually abnormal with infantile hypotonia progressing over time to hypertonia and hyperreflexia. Gait abnormalities are also common (17). Cases of Chiari malformation type I, producing both acute and chronic neurologic problems have been reported (98).

Cardiovascular system. Supravalvular aortic stenosis (Fig. 24–72) and pulmonary artery stenosis are the most common findings, although various other cardiovascular defects have been recorded. Approximately 75% have clinical heart disease. When studied echocardiographically, all have supravalvular aortic narrowing (43). Among patients with cardiac changes, approximately 60% have supravalvular aortic stenosis. Other changes include aortic hypoplasia (40%), coarctation or interruption of aorta, left coronary artery stenosis (21), renal artery stenosis, peripheral pulmonary stenosis (80%), various peripheral artery stenoses (carotid, innominate, subclavian, celiac, and mesenteric), atrial septal defect, ventricular septal defect, anomalous pulmonary venous return, arteriovenous fistula (lung), rarely valvular aortic stenosis or subaortic stenosis, and aplasia of the portal vein (18,29,43,44,54,65,67,70,82,100,101,120,121). Approximately 10%–15% have mitral valve prolapse or bicuspid aortic valve (43,70). This has been stated to increase to 50% of adults (77), but most series do not show this. Some Williams syndrome patients have no cardiovascular anomalies but are easily diagnosed by characteristic facial appearance and performance (54). Stroke due to stenoses of cerebral arteries appears to be increased (57,126).

Longitudinal studies indicate that supravalvular aortic stenosis tends to progress with age; pulmonary artery stenosis improves (50). Coronary artery stenosis can lead to myocardial infarction and sudden death and probably contributes to the increased risk of death at cardiac catheterization (10,21,106,111). Up to half of individuals develop systemic hypertension, which occasionally is due to renal artery stenosis (23,43,67,72,94,106,124).

Genitourinary and endocrine abnormalities. Limited information about reproductive function is available. Delayed acquisition of urinary continence is common and approximately 10% have associated multiple bladder diverticulae (3,77,107). Nephrocalcinosis can be a complication of hypercalcemia but may not be visualized by standard radiographic technique (23,29,72,99). Ultrasonography or computerized tomography are likely to be more helpful. Renal calculi and urethral stenosis have also been recorded (72,77). Renal insufficiency, cystic dysplasia, and criteria for investigation have been discussed by Biesecker et al (9). Pober et al (99) described marked asymmetry in kidney size, small kidneys, and solitary kidney. Mild renal artery stenosis was found

in four of nine patients with persistent hypertension, and was unrelated to renal artery status in two of the nine patients. Renal artery narrowing was found in 44%, and renal anomalies, ranging from bladder diverticula to unilateral renal agenesis, in 18% by Pankau et al (94). A duplicated kidney was noted in 7%.

Onset of puberty and menarche are early (19a,108). Approximately 25% have hypothyroidism or compensated hypothyroidism (B Pober, personal communication, 2000).

Oral manifestations. Thick lips, wide intercommissural distance, and long philtrum are characteristic. The voice is often hoarse or brassy (7,8,37,54,59). The maxillary arch has been described as being too broad for the mandibular arch. Hypodontia, microdontia, small slender roots, and dens invaginatus have been reported (7,8,33,123). Hypoplastic bud-shaped maxillary deciduous second molars and mandibular permanent first molars (Fig. 24–71) have been noted by some authors (7,8). In a series of 45 patients studied metrically, microdontia, hypodontia, anterior crossbite, increased interdental spacing, and persistent tongue thrust were noted in at least 35% (45). Mild micrognathia, widened mandibular angle, osteosclerotic changes in the lamina dura (particularly in the premolar-molar region), delayed mineralization of teeth, folding and thickening of the buccal mucous membranes, and prominent and accessory labial frenula have also been noted (7,8,58).

Other findings. Hypoplastic, deeply set nails are found in 65% (54). Other findings include inguinal hernia (38%), umbilical hernia (14%), and rectal prolapse (12%) (54,72). Contractures (50%) and prematurely gray hair (60%) have been recorded (77). Chronic constipation has been documented in adults (78).

Hypercalcemia. Hypercalcemia has not been documented in most cases (54) but has been a feature in approximately 15% of infants (56; C Morris, personal communication, 1998). When present, it usually disappears during the second year of life but can recur later in life. Prolonged symptomatic hypercalcemia has been rarely observed (103). Retrospective interviewing may reveal a history of failure to thrive, hypotonia, anorexia, constipation, or renal impairment (59).

From the earliest descriptions, a disorder of vitamin D has been repeatedly implicated in some way (4,36,110). Forfar and associates (31) advanced the postulate that Williams syndrome infants are abnormally sensitive to vitamin D in utero or in early infancy. Similar craniofacial, dental, and cardiovascular anomalies were noted in newborn rabbits born to mothers who had received prodigious amounts of vitamin D (34,35). Although there has been an enormous number of papers written about vitamin D dysmetabolism in this syndrome, there is no compelling evidence that it is disturbed (62).

In contrast, there seems to be general agreement that the response of serum calcium to a calcium-loading test is abnormal, even in individuals with no history, clinical or radiographic findings, or laboratory evidence of hypercalcemia (22). Although both control of endogenous parathyroid hormone and response to exogenous parathormone are not abnormal, endogenous response of calcitonin to a calcium load is strikingly deficient (22).

Differential diagnosis and laboratory aids. Supravalvular aortic stenosis and peripheral pulmonary artery stenosis without the Williams phenotype have autosomal dominant inheritance (30,34,52,55,63,66, 74,106). These patients have 30Kb deletions or point mutations in exons 3, 16, 21, 25, and 26 of the elastin gene (85). Peripheral pulmonary stenosis may also be found in *thalidomide embryopathy*, *rubella embryopathy*, *Down syndrome*, and *Alagille syndrome*. Other causes of hypercalcemia, such as familial hypocalciuric hypercalcemia (47), hyperparathyroidism, and vitamin D intoxication can usually be distinguished by history and routine laboratory tests. Martin et al (72) distinguished benign infantile hypercalcemia (Lightwood syndrome) from severe Fanconi-type hypercalcemia (what we now classify as Williams syndrome) on the basis of absence of associated anomalies, normal development, and lack of hypercalcemia symptoms. Ultrasonography is a valuable tool for noninvasive detection of subtle cardiovascular and renal abnormalities. Cross-sectional echocardiography or MRI scan is helpful for diagnosing supravalvular aortic stenosis (116).

Low MSAFP levels have been noted in mothers of affected children (20). Mutations in the elastin gene in exons 30 and 32 cause autosomal dominant *cutis laxa*.

Chapter 25
Syndromes with Unusual Facies: Other Syndromes

Coffin-Siris syndrome (absent fifth finger- and toenails, unusual facies, and mental deficiency)

In 1970, Coffin and Siris (8) reported three children with coarse facial features, low birthweight, retarded somatic and mental growth, and hypoplastic to absent fifth finger- and toenails. Over 40 cases (1–3,7,10, 12,14–20,22–25,27,33–35,37) have been documented, although included are many cases which are doubtful or more consistent with a milder form described by Senior (30), Mace and Gotlin (21), Verloes et al (36), Ounap et al (26) and Bonioli et al (4). Rabe et al (28) also described sisters who have a similar phenotype but had hyperphosphatasia. Although most have been isolated examples, affected sibs (1,7,14,17,23) have been described; however, Levy and Baraitser (19) are doubtful about some of these cases, and suggest a 10% recurrence risk be given. About 85% are females, possibly implying lethality in males. Mild expression in a parent has also been noted (8,17,33,37). Perhaps some examples really have *fetal hydantoin syndrome, dup(9p) syndrome*, or some other condition. Burlina et al (6) described partial biotinidase deficiency in a child they had diagnosed as having Coffin-Siris syndrome: Bonneau et al (5) were unable to confirm this finding in a patient of theirs with Coffin-Siris syndrome. Therefore this is unlikely to be a helpful diagnostic aid. McPherson et al (24) described a child with an apparently balanced translocation with breakpoints 1q21.3 and 7q34, thus providing clues to possible gene location. McGhee et al (23a) also found a candidate region at 7q32→q34.

Half have low birthweight (19). Feeding problems and recurrent respiratory infections are common during infancy. Redundant gastric mucosa at the antrum has been reported (3). Craniofacial findings include microcephaly (65%), coarse facial features (100%), transient facial hypertrichosis, sparse scalp hair (80%), bushy eyebrows, flat nasal root, bulbous upturned nose, thick lips, and wide mouth. Those with Senior syndrome (brachymorphism-onychodysplasia-dysphalangism) (4,21,26,30,36) have a less coarse facial appearance, particularly because the lips are not as thick or full.

Mental deficiency (100%), hypotonia (100%), postnatal growth deficiency (85%), and short stature are consistent. Also found are hypoplastic to absent fifth finger- and toenails and terminal phalanges with less severe involvement of other digits (100%), lumbosacral hirsutism (85%), lax joints, dislocation of radial heads, coxa valga, retarded bone age, and small to absent patellae (Fig. 25–1). Radiographs of the hands and feet consistently demonstrate absent or hypoplastic distal and middle phalanges, particularly of the fifth digits. Various low frequency anomalies have included eyelid ptosis, strabismus, cleft palate, choanal atresia, herniae, cutis marmorata, single transverse palmar crease (10,12,19,33,34), and various congenital heart anomalies (30%). There appears to be a characteristic hand profile (1). Central nervous system anomalies include Dandy–Walker malformation (8,33), partial agenesis of corpus callosum, and agenesis of anterior commissure (9,33). Swillen et al (32) reported data on mental development, language, behavior, and social skills in children with Coffin-Siris syndrome. In general, most had moderate mental retardation, severely delayed speech with first words appearing at 3–5 years; increased frequency of aggressive behavior, pervasive developmental disorder, or unusual fears also were noted. Coffin and Siris (8a) added aplasia of the uterus. Good reviews are those of Levy and Baraitser (19) and Rabe et al (28).

Absent corpus callosum, coloboma, and craniofacial anomalies

Three sibs whose parents were first cousins. were reported by Temtamy et al (1). Facial phenotype included macrodolichocephaly, apparently low-set, simple ears, hypertelorism, beaked nose, micrognathia, and dental anomalies (malposition, hypoplasia). Additional manifestations included ocular colobomas (iris, choroid, and retina), agenesis of the corpus callosum, mild mental retardation, brachydactyly, genua valgga, and talipes equinovarus. Connective tissue defects were also noted: aortic dilatation, aortic regurgitation, and joint hyperextensibility. Inheritance is autosomal recessive.

Ruvalcaba syndrome

In 1971, Ruvalcaba et al (6) described male sibs and first cousins with severe mental and somatic retardation, microcephaly, hypoplastic skin, hypoplastic genitalia, delayed adolescence, cryptorchidism, and unusual facies characterized by downslanted palpebral fissures, small narrow beaked nose with hypoplastic alae, microstomia, narrow maxilla, and crowded teeth (Fig. 25–2). Other cases have been reported (2,7). We

Fig. 25–2. *Ruvalcaba syndrome*. Downslanting palpebral fissures, small narrow nose. (From R Ruvalcaba et al, J Pediatr 79:450, 1971.)

suspect marked heterogeneity. In spite of normal karyotype, the patient of Bialer et al (1) facially resembles del(2q) syndrome. The cases of Hunter et al (4) have since been termed the Hunter–McAlpine syndrome, which is associated with deletion 17q (8). The family described by Sugio and Kajii (7) was later suggested to have *tricho-rhino-phalangeal syndrome III* instead (5).

Musculoskeletal anomalies include short stature, narrow trunk, pectus carinatum, kyphoscoliosis and/or scoliosis with osteochondritis of spine, limitation of elbow extension, prominent elbows, short limbs, short hands and feet, short metapodial bones and phalanges, broad hips, and inguinal hernia.

At least 50% of the patients had pubertal delay and renal anomalies (1).

Schinzel-Giedion syndrome

In 1978, Schinzel and Giedion (22) described a syndrome of midface retraction, hirsutism, multiple skeletal anomalies, mental retardation, and seizures. Over 20 patients have been reported (1–23). The disorder has occurred in sibs (1,4,22). Autosomal recessive inheritance is probable, although an autosomal dominant mutation with somatic mosaicism accounting for the recurrences is also possible.

Over 95% of patients have exhibited severe somatic and mental retardation, spasticity, and seizures (2). Subependymal pseudocytes have been noted (14), and neurodegenerative changes have been documented (23). Death has usually occurred before 2 years, often of pneumonia. Recurrent apneic spells are common.

In infancy, the face is coarse with frontal bossing, hypertrichosis, and midface retraction. The skull sutures are widely patent and there is ocular hypertelorism or telecanthus. The nose is short, saddled, and upturned. Choanal stenosis has been noted in 30%. The ears may be low set and the teeth delayed in eruption. Facial hemangioma may be present (3). The neck is short and the skin is redundant (Figs. 25–3 and 25–4). In older children the face is "coarse," hirsutism decreased, and midface retraction less striking.

Dermatologic anomalies include hypoplastic dermal ridges, hypoplastic nipples, transverse palmar creases, and hyperconvex nails (50%) (Fig. 25–5).

Genitourinary anomalies, noted in 90%, include congenital hydronephrosis, hypospadias, short penis, and deep interlabial sulcus. Congenital megacalyces were present in one child (10), and duplicated vagina with bifid uterus in another (12).

Heart defects, often ASD, have been reported in 50%.

Sacrococcygeal embryonic tumors (teratoma, neuroectodermal tumor) may be a component manifestation (4,15,19,20).

Skeletal anomalies, seen in 90% or more, include orbital hypertelorism, short steep skull base, wide occipital synchondrosis, undermineralization of the skull, multiple Wormian bones, broad ribs, mild mesomelic brachymelia, bowed tibiae, long clavicles, hypoplasia of distal phalanges, short first metacarpals, thick diaphyses of long bones, hypoplasia of pubic bones, and talipes (24).

Fig. 25–3. *Schinzel-Giedion syndrome*. Note high bulging forehead, depressed nasal bridge with short root, protrusion of eyes, short neck, and hypertrichosis. (From A Schinzel and A Giedion, Am J Med Genet 1:361, 1978.)

CT scans of the brain have revealed ventricular dilatation (1,11,15), hypoplastic corpus callosum (17,19), periventricular leukomalacia (8), or brain atrophy and arachnoid cysts (21). Infrequently reported anomalies include microcornea (18), optic atrophy (6), or hypothyroidism and diabetes insipidus (21).

Congenital hydronephrosis is extremely rare and has been seen in few syndromes: *Johanson–Blizzard syndrome, trisomies 13 and 18, triploidy, Turner syndrome*, and *urofacial syndrome*. The facies is reminiscent of infants with a storage disease.

Growth retardation, alopecia, pseudoanodontia, and optic atrophy (GAPO syndrome)

Andersen and Pindborg (1), in 1947, were the first to publish a case of what Tipton and Gorlin (18) chose to term the GAPO (*G*rowth retardation, *A*lopecia, *P*seudoanodontia, *O*ptic atrophy) syndrome. A Brazilian patient who was described in 1977 (4) as an example of Rothmund–Thomson syndrome, was republished in 1982 under a corrected title (19). To date, over 20 patients have been described (1–4,6,10–15,19,20).

Inheritance is clearly autosomal recessive, there being affected sibs and parental consanguinity (8a).

Birthweight is normal, but birth length is somewhat reduced. Growth retardation becomes quite evident at the sixth month checkup. Body build is proportional, although some have described their patients as appearing rhizomelic (2,15). Bone age is severely retarded (2). A muscular habitus is common. Umbilical hernia is apparently a constant feature.

Scalp hair is present at birth, but, after the first years of life, the hair is completely lost and never regrows (Fig. 25–6). The jaw bones are crowded with both dentitions, neither of which erupts (Fig. 25–7). Frontal bossing, high forehead, dilated scalp veins due to absent or occluded transverse and sigmoid sinuses (3,6,8,11), mild midfacial hypoplasia, and delayed closure of the anterior fontanel are common. Craniosynostosis was found in one case (1). The facial differences include periorbital fullness or puffy eyelids, anteverted wide nostrils, long philtrum, and thick, full lips. Optic atrophy is variable in onset (1,3–5,7,8) and found in about 30% (3,8a). It may be attributable to increased intraocular pressure (3). Keratoconus and glaucoma (11,12) have also been reported. Eyelashes are white (15). Ears are large.

Other changes include mild pectus excavatum, scythelike lower ribs, hypoplastic middle and distal phalanges, hypogonadism, nephrocalcinosis (1,7), and polycystic kidneys (1,10).

Skin biopsies done in several patients (13,20) show deposition of an anomalous hyaline substance in the dermis which appears over time. Autopsy studies showed interstitial fibrosis of most visceral organs. Electron microscope studies of gingiva have also shown excessive

A B

Fig. 25–6. *Growth retardation, alopecia, pseudoanodontia, and optic atrophy (GAPO syndrome)*. (A) Note 26-year-old female with alopecia. Patient had optic atrophy. (B) Compare facies with that in A. (A from TH Andersen and JJ Pindborg, Odont T 55:484, 1947.)

collagen fiber deposition (10). Differential diagnosis of disorders with severe alopecia is elegantly discussed by Feinstein et al (3).

Brachymetapody, anodontia, hypotrichosis, and albinoid trait (Tuomaala-Haapanen syndrome)

Tuomaala and Haapanen (1) reported three sibs affected with short stature and shortening of all digits other than thumbs and halluces due to brachymetapody. Hypoplastic maxilla, anodontia, generalized hypotrichosis, hypoplastic breasts and genitalia, convergent strabismus, distichiasis, hypoplastic tarsus, cataracts, myopia, irregular nystagmus, and albinoid skin were found (Fig. 25–8). The syndrome presumably has autosomal recessive inheritance.

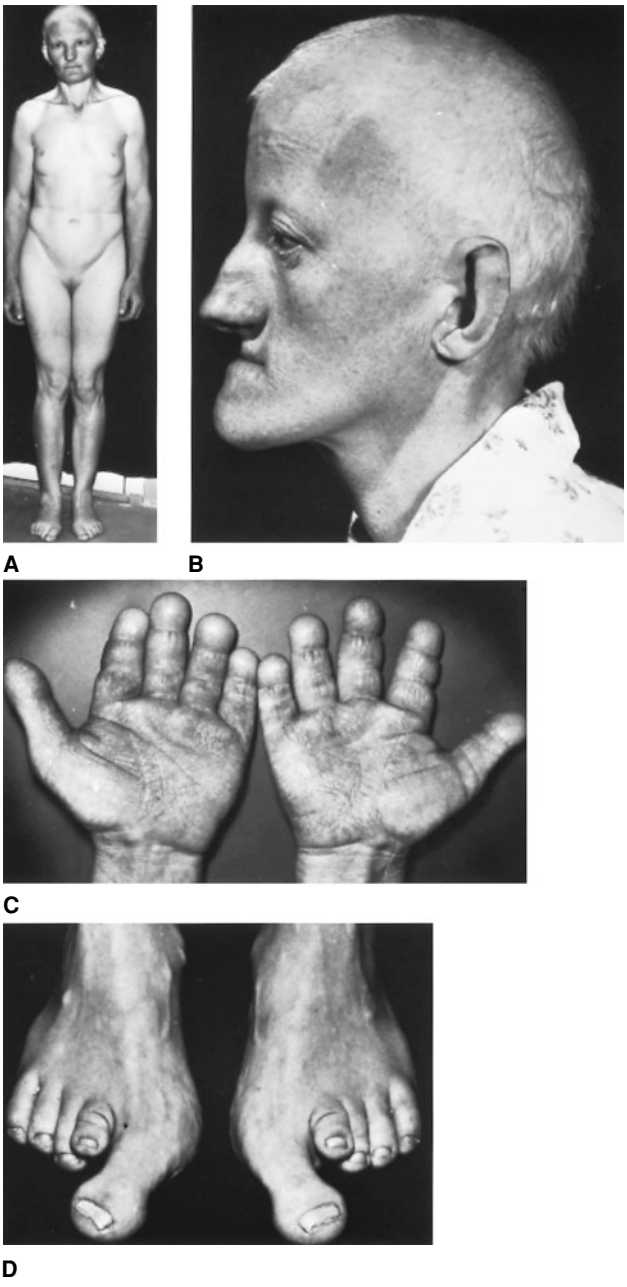

Fig. 25–8. *Brachymetapody, anodontia, hypotrichosis, and albinoid trait (Tuomaala-Haapanen syndrome).* (A) Albinoid skin, hypoplastic breasts, generalized hypotrichosis. (B) Sunken midface with loss of vertical height due to anodontia. (C,D) Shortening of all digits except thumbs and halluces. (From P Tuomaala and E Haapanen, Acta Ophthalmol 46:365, 1968.)

Broad terminal phalanges and facial abnormalities (Keipert syndrome, nasodigitoacoustic syndrome)

Male sibs with severe sensorineural hearing loss, unusual facies, and broad terminal phalanges were described by Keipert et al in 1973 (2). Balci and Dagli (1) also reported male sibs. Autosomal or X-linked recessive inheritance is likely.

The facies was marked by a large nose with a high bridge, large rounded columella, and prominent nasal alae. The upper lip protruded, with a cupid's bow configuration overlapping the rather straight lower lip laterally (Fig. 25–9A,B). The distal phalanges of the thumbs, the first, second, and third fingers, and all the toes were remarkably broad. The fifth fingers were short and clinodactylous. The toes were rotated medially (Fig. 25–9C,D). Radiographically, one sib had bifid terminal phalanges in both index fingers. In the halluces of both patients, the proximal phalanges were short and the terminal phalanges were short with large, rounded epiphyses. Mild sensorineural hearing loss and hoarse voice were present in the patients of Balci and Dagli (1); voice quality was not noted in the cases of Keipert (2).

Cardio-facio-cutaneous syndrome (CFC syndrome)

In 1986, Reynolds et al (29) described eight patients having a characteristic facial appearance, ectodermal abnormalities, growth failure, mental retardation, and variable cardiac defects. About 55 bona fide patients have been reported (1,2,4,7,10a,12,17,20,23,27,28,30–32,34,36,37), as have many doubtful cases (3,8,9,13,16,18,19,21,33,34). Some of these doubtful cases likely have Noonan syndrome, and contribute to the argument that Noonan and CFC syndromes are allelic (vide infra). Neri et al (24,26) presented a convincing argument for separation of these conditions, and suggested the following diagnostic criteria for CFC syndrome: (a) Noonan-like face, (b) mental retardation, usually severe, (c) hyperkeratotic skin lesions, (d) sparse, curly hair and absent eyebrows, (e) heart defects, and (f) sporadic occurrence.

Inheritance is unknown, with legitimate cases being sporadic occurrences. Fathers have been older (6). Legius et al (15) found allelism with Noonan syndrome at 12q24. Further, Rauen et al (27a) mapped the gene at 12q21.2. However, most patients had no deletion of 12q (38), and we suspect that the phenotypes of these patients more closely resemble *Noonan syndrome*. About 60 examples have been described. The reported familial cases (8,10,14,16,27) almost certainly have a different condition.

Craniofacial findings. The cranial vault is high and somewhat boxy. The face is characterized by high forehead with bitemporal constriction, hypoplasia of supraorbital ridges, sparse or absent eyebrows, ptosis, downslanting palpebral fissures, low nasal bridge, upturned nose, and posteriorly angulated pinnae with prominent helices. Scalp hair is sparse, friable, and unusually curly; the eyebrows are hypoplastic or absent (Fig. 25–10). The irides are rarely the blue or blue-green seen in Noonan syndrome.

Submucous cleft palate is common (5,7). The face is reminiscent of that seen in Noonan syndrome, but hypertelorism does not occur in CFC.

Growth and development. Postnatal growth retardation is present in 75%, but prenatal growth is usually normal or slightly elevated. Relative macrocephaly is present in 70%. Hydrocephalus is noted in 30%. Feeding problems are encountered in 35%. In contrast to Noonan syndrome, neurologic manifestations include moderate to severe mental retardation (95%), hypotonia (30%), markedly delayed or absent speech, autistic-like behavior, seizures, and abnormal EEGs (5,11,25,28,29).

Eyes. Ptosis (50%), nystagmus (30%),and strabismus (40%) are striking (30,37).

Skin. Skin changes vary from dry patchy hyperkeratosis to a severe generalized ichthyosislike condition, with the distribution occurring preferentially over the extensor surfaces of the limbs. Keratosis pilaris is seen in 10%. Hypopigmentation, hyperpigmentation, and hemangiomata have also been described (17).

Fig. 25–9. *Broad terminal phalanges and facial abnormalities (Keipert syndrome)*. (A,B) Nine-month- and three-year-old sibs exhibiting large nose with high bridge, large rounded columella, and prominent alae. Upper lip protrudes with cupid's bow configuration. (C) Terminal phalanges are short and broad. Fifth fingers are short and clinodactylous. (D) Toes short and broad, especially hallux. (From JA Keipert et al, Aust Paediatr J 9:10, 1973.)

Fig. 25–10. *Cardio-facio-cutaneous syndrome*. (A,B) High forehead, bitemporal constriction, sparse, friable, curly hair, hypoplasia of supraorbital ridges, low nasal bridge, dysmorphic pinnae, short neck. Patients had dry hyperkeratotic skin over extensor surface of limbs, pulmonary stenosis, and atrial septal defect. (C) Compare facies of patient seen by RJ Gorlin. (A from JF Reynolds et al, Am J Med Genet 25:413, 1986. B from G Raymond and L Holmes, Dev Med Child Neurol 35: 727, 1993.)

Musculoskeletal findings. The chest is deformed in 70%.

Heart. The most common cardiac anomalies are pulmonic stenosis (40%), ASD (30%), cardiomyopathy (25%), and VSD (10%), although other cardiac defects have also been described (31,36).

Other. Acute lymphoblastic leukemia has been reported (33a). *Noonan syndrome, neurofibromatosis/Noonan phenotype, Costello syndrome,* and *cranio-facio-cardio-skeletal syndrome* must be excluded.

Coarse face, mental retardation, sensorineural hearing loss, and skeletal abnormalities (Fountain syndrome)

Fountain (1), in 1974, briefly described four sibs. Two exhibited generalized facial edema with massive swelling of the upper and lower lips. All were mentally retarded with profound congenital sensorineural hearing loss. One sib died in early infancy but had profound hearing loss, mental retardation, and spina bifida. Three sibs had granulomatous swelling of the lips (Fig. 25–11). Three of four showed gross thickening of the calvaria (Fig. 25–12). In 1986, Fryns et al (3) confirmed the syndrome by reporting sibs with hearing loss, mental retardation, seizures, and round and coarse face with mild swelling of subcutaneous tissues, particularly those of the cheeks and lips. The hands and feet were short and plump with

Fig. 25–11. *Coarse face, mental retardation, sensorineural hearing loss, and skeletal abnormalities (Fountain syndrome).* (A,B) Affected sibs exhibiting coarse facies and skin granulomata. (From RB Fountain, Proc R Soc Med 67:878, 1974.)

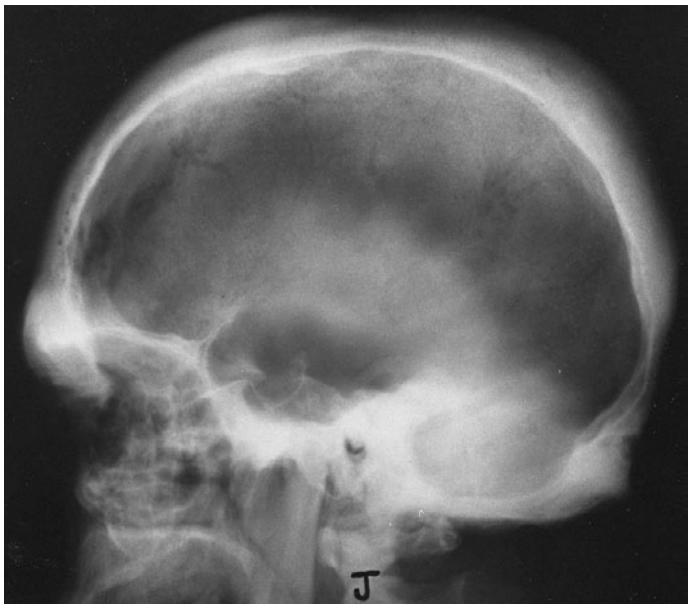

Fig. 25–12. *Coarse face, mental retardation, sensorineural hearing loss, and skeletal abnormalities (Fountain syndrome)*. Radiograph showing marked thickening of calvaria. (From RB Fountain, Proc R Soc Med 67:878, 1974.)

broad and short terminal phalanges (2). Short stature may occur. Manifestations present in only one or two patients each include high palate, ear pits, blindness, omphalocele, and scoliosis. The phenotype is fairly indistinct in infancy and early childhood but becomes more apparent with age. Behavior is described as extremely friendly (4).

Radiographically, there was marked thickening of the calvaria and thickened cortices of the bones of the hands and feet. Tomography of the temporal bones showed absence of cochlear windings.

Inheritance is presumably autosomal recessive.

There is some physical similarity to *mannosidosis* and *aspartylglycosaminuria*, but biochemical studies have been normal.

Cranio-facio-cardio-skeletal dysplasia

Cantú et al (1) reported four unrelated females with short stature (below the third centile), delayed psychomotor development (60–70 IQ), macrodolichocephaly (above 90th centile) with prominent forehead, scanty thin and hypopigmented hair, coarse facies, hypertelorism with flat nasal bridge, exophthalmos, short nose with anteverted nares, long philtrum, low-set ears, short neck, short wide thorax, prominent abdomen, cubitus valgus, cutis laxa with joint hyperelasticity, and wrinkled palms and soles (Fig. 25–13).

The ribs were slender but wider in the middle. The long bones were also slender and the vertebral bodies somewhat small.

Fig. 25–13. *Cranio-facio-cardio-skeletal dysplasia*. Child with short stature and delayed psychomotor development. Note macrodolichocephaly with prominent forehead, scanty hair, hypertelorism, flat nasal bridge, exophthalmus, short nose with anteverted nostrils, long philtrum, and short neck. The abdomen was prominent and there was cubitus valgus. (From JM Cantú et al, Clin Genet 22:172, 1982.)

Familial osteodysplasia (Anderson syndrome)

Under this unfortunately nonspecific title, Anderson et al (1) reported four sibs with an apparently unique disorder. The parents were consanguineous. Inheritance is autosomal recessive.

The facies was characterized by prominent brows, flat nasal bridge, marked midface hypoplasia with relative mandibular prognathism, pointed chin, and large ear lobes (Fig. 25–14A–D). The feet were described as paddle shaped.

Radiographically, thinning of calvaria, pointed mastoids and spinous processes of the cervical vertebrae, kyphoscoliosis, abnormal ribs, cortical thickening of femoral shafts, and thinning of the superior pubic rami were noted. The mandible had a widened angle, increased body length, reduced ramus height, and severely decreased bigonial width (2) (Fig. 25–14E–G).

We have termed the naming of the disorder "unfortunate" because there are many different "osteodysplasias" and, in particular, Melnick-Needles syndrome has been called "familial osteodysplastia." The confusion has been compounded by Schendel and Delaire (3), who employed the same term to report an autosomal dominant condition in which craniosynostosis is a variable feature but which, in our opinion, has little in common with the Anderson syndrome.

Flexion and extension deformities of the hands and unusual facies (Emery-Nelson syndrome)

Mild mental and somatic retardation, increased US/LS ratio, deformities of the first three metacarpophalangeal joints of both thumbs, clawed toes, and an unusual facies (long philtrum, flat midface) were described in a mother and daughter by Emery and Nelson (1) (Fig. 25–15). RJ Gorlin has seen the same anomalies in a mother and her two sons.

Hemimaxillofacial dysplasia (segmental odontomaxillary dysplasia)

In 1987, Miles et al (2) reported a disorder in two patients consisting of unilateral enlargement of maxillary alveolar bone and gingiva associated with hypoplastic teeth, and facial asymmetry.

One patient had hypertrichosis and missing maxillary premolars on the affected side (Figs. 25–16 to 25–18). Since then, several other patients have been described (1,2,4,5). Whereas this sporadically occurring disorder is presumed to be present at birth, age of diagnosis is often not until midchildhood. Asymmetry was nonprogressive, and noncranial abnormalities were noted. Enamel defects of primary molars and/or absent permanent teeth on the affected side were a constant finding. The right side is involved more often (1), and facial hypertrichosis is present in approximately 25%.

In a review of the radiographic and biopsy material of eight cases, Danforth et al (1) suggested that this condition be termed "segmental odontomaxillary dysplasia." This was based on the absence of facial hypertrichosis in the patients. However, examination of their material clearly shows that it is the same condition as hemimaxillofacial dysplasia because facial hypertrichosis is not an obligatory abnormality. While the term is descriptive, it does not convey the facial asymmetry that allows early recognition by the pediatrician.

An excellent review is that of Prusack et al (6).

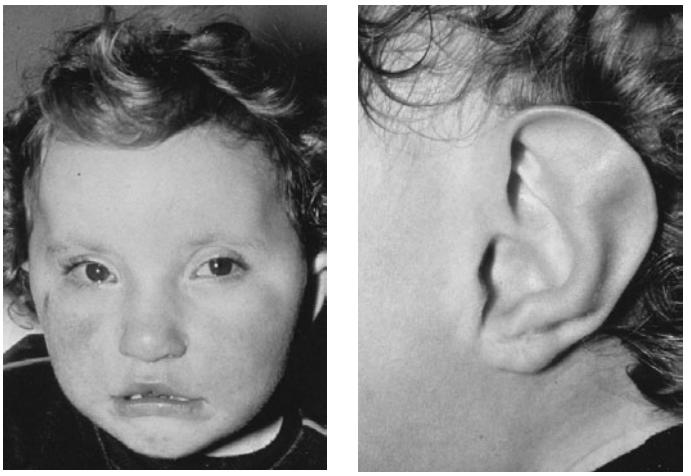
Oto-onycho-peroneal syndrome

Pfeiffer (3) described two male sibs with minor craniofacial malformations, multiple contractures, dysplastic pinnae, hypoplasia of nails, and hypoplasia of fibulae. The craniofacies was characterized by dolichocephaly, flaring of temporal regions, flat facial contour, upward slanting palpebral fissures, large low-set posteriorly angulated pinnae with unfolded helix, prominent anthelix and superior crus, and hypoplastic lobule (Fig. 25–19).

The thumb, index, and middle fingers were stiff with flattened knuckle creases and absent to rudimentary nails. The hallux and second toes were similarly affected (Fig. 25–20). The thighs were short with abnormally shaped lower limbs. Pes calcaneovalgus was evident. The fibulae were hypoplastic to absent. Radiographic examination revealed hypoplasia of malar bones and lateral clavicles. The metaphyses of the long bones were somewhat widened. The terminal phalanges of the thumbs and halluces were abbreviated. Carpal and tarsal synostosis was evident. DeVriendt et al (1) reported two affected sibs.

The condition appears similar to that reported by Leiba et al (2), although the skeletal changes are somewhat different. Leiba et al (2) described a male with mild mental retardation, short stature, ptosis of eyelids, downslanting palpebral fissures and agenesis or hypoplasia of nails and terminal phalanges. The parents were consanguineous. Eyelashes were on the medial half of the lids and there were bilateral colobomas of the retina. The pinnae were dysmorphic with prominent anthelix. The halluces were broad with absence of toenails. The thumbs were not broad but had dysplastic nails like those of the index fingers. The phallus was enlarged and there was hypospadias.

The sisters reported by DeVriendt et al (1) had abnormalities of the clavicle and scapula and small corneae with unusual pigmentation of the fundus.



A B

Fig. 25–19. *Oto-onycho-peroneal syndrome*. (A) Mildly abnormal facies characterized by flaring of temporal regions, flat facial contour, upward-slanting palpebral fissures. (B) Pinna with unfolded helix, prominent anthelix and superior crus, hypoplastic lobules. (Courtesy of R Pfeiffer, Erlangen, Germany.)

Inheritance is autosomal recessive.

Short stature, characteristic facies, mental retardation, skeletal anomalies, and macrodontia (KBG syndrome)

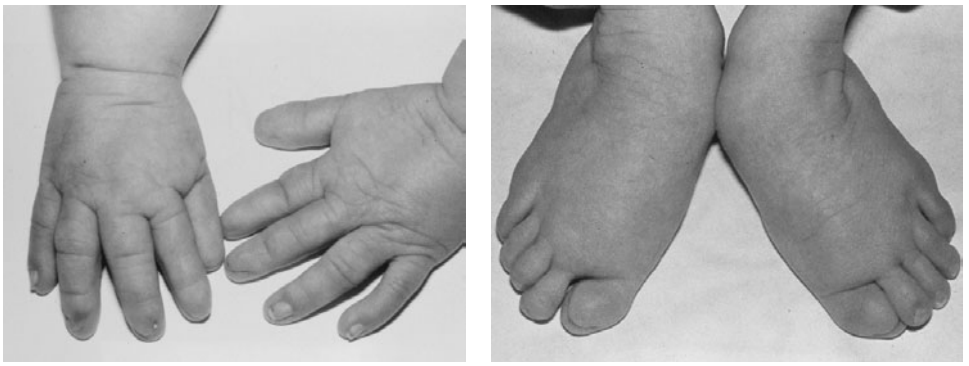
In 1975, Herrmann et al (3) described an autosomal dominantly inherited syndrome of mild mental retardation, short stature, characteristic facies, macrodontia, and various skeletal anomalies. Similarly affected individuals were described by several authors (1,2,4–6,8,9), and Soekarman et al (7) provided follow-up data on the boys reported by Parloir et al (4).

Height is below the third centile. Intelligence quotients have ranged between 40 and 65. Several patients have a speech defect.

The craniofacial appearance is characterized by brachycephaly, wide biparietal diameter, round face, wide bushy eyebrows with synophrys, long palpebral fissures, anteverted nostrils in some instances, outstanding pinnae, widely arched maxilla with short alveolar ridge (Figs. 25–21 and 25–22), thin upper lip, and outstanding pinnae. Several patients have manifested oligodontiala. The central and lateral incisors are enlarged. Their incisal edges have supernumerary mamelons, some as many as five (Fig. 25–23). The philtrum tends to be long. The vermilion of the lips is thin and lip shape is that of a hunter's bow. Seizures have been present in some, more so in childhood than in adulthood (7). One child had conductive hearing loss and pulmonary artery stenosis (5); another had a VSD (1).

Skeletal changes include those previously described as well as Wormian bones, cervical ribs, various vertebral anomalies (anterior notching, hypoplasia of upper and lower plates, open neural arches, block vertebrae), pectus excavatum, short tubular hand bones, short femoral neck, and delayed bone age (Fig. 25–24). Cerebellar vermis hypoplasia may be a relatively common component manifestation (9).

Dermatoglyphic findings consist of single palmar crease and distal axial triradius.



A B

Fig. 25–20. *Oto-onycho-peroneal syndrome*. (A,B) Hands and feet showing absent to rudimentary nails of middle and index fingers and thumb; similar changes in toes. Knuckle creases flattened. (Courtesy of R Pfeiffer, Erlangen, Germany.)

Differential diagnosis includes *Kabuki syndrome*, which also comprises long palpebral fissures, and minor nasal and ear anomalies. However, those with Kabuki syndrome do not have prominent incisors and do have fetal pads on the fingers.

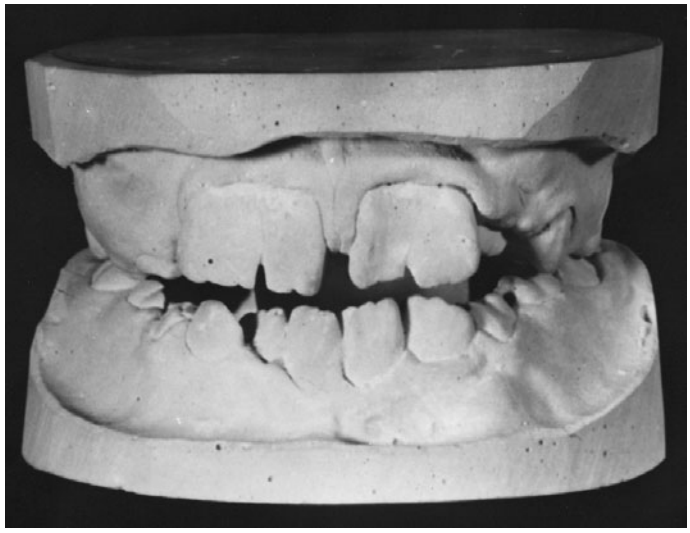

Fig. 25–23. *Short stature, characteristic facies, mental retardation, skeletal anomalies, and macrodontia (KBG syndrome).* Cast of teeth showing macrodontia. [From J Herrmann et al, Birth Defects 11(5):7, 1975.]

Unusual facies, abnormal scalp hair, and diarrhea

Stankler et al (1) reported two sibs with low birthweight, unusual facies characterized by prominent eyes with flat supraorbital ridges, broad flat nose, large mouth, cleft uvula (in one), and large low-set simple pinnae. The buttocks were excoriated before the onset of diarrhea. The skin had a rubbery feel. The scalp hair was woolly and easily removed. The hair shafts exhibited budding. Persistent diarrhea began in the third week and failure to thrive became evident. Galactosuria without galactosemia, hepatic cirrhosis, renal cortical microcysts, and islet cell hyperplasia were noted on autopsy.

Fig. 25–24. *Short stature, characteristic facies, mental retardation, skeletal anomalies, and macrodontia (KBG syndrome).* Block vertebrae of lower spine. [From J Herrmann et al, Birth Defects 11(5):7, 1975.]

Unusual facies, tetra-amelia, hypotrichosis, and developmental retardation

Ohdo et al (1) reported siblings (one liveborn, one an aborted fetus) affected with tetra-amelia, hypotrichosis, upslanting palpebral fissures, absent lacrimal openings with hypoplastic ducts and sacs opening toward the exterior, prominent bulbous nose, large downturned mouth, preauricular pits, and developmental retardation (Fig. 25–25). Hyperthermia and constipation occurred in later life. The child in the original report died at age 8 years, 7 months. He was profoundly retarded (2).

Inheritance is probably autosomal recessive.

References (Unusual facies, tetra-amelia, hypotrichosis, and developmental retardation)

Patulous lips, ptosis, patent ductus arteriosus, and phalangeal anomalies (Char syndrome)

Char (1) reported autosomal dominant inheritance of a syndrome characterized by broad forehead and slightly wide-set eyes with ptosis of the lids and internal strabismus. The eyebrows flare and the midface is somewhat flat. The nose was short with somewhat anteverted nostrils and flat nasal bridge. The pinnae appeared normal, but were low set and posteriorly rotated. The mouth was large with extremely patulous lips and very short philtrum (Figs. 25–26 and 25–27). Only two phalanges were in each fifth finger of the proband. Intelligence was low normal. Patent ductus arteriosus was found in several members of the kindred.

The syndrome has been mapped to 6p12–p21 (4). The gene, *TFAP2B*, is a transcription factor expressed in neural crest cells (4a).

Temple (7) confirmed the syndrome. In one of her patients, a 40–50 dB hearing loss was found in both ears. Height was reduced. Others have added examples (5–7). Another patient with only patent ductus and short nose has been described (2). With age, the lips become less patulous. Interstitial polydactyly of the toes and polythelia have been reported, possibly adventitious findings (9).

Patent ductus may be seen as an isolated finding, as an isolated autosomal dominantly inherited anomaly (8) in *Robinow syndrome,* in *Gorlin–Chaudhry–Moss syndrome*, and as a dominant syndrome with bicuspid aortic valve and fifth metacarpal hypoplasia and brachydactyly (3).

We are skeptical of the family reported by Sweeney et al (6a).

Unusual facies, mental retardation, short stature, hemolytic anemia, and delayed puberty

Hurst et al (2), in 1987, described male and female sibs exhibiting short stature, hypertonia, and moderate retardation with significant delay in speech and language development. In 1973, Beutler et al (1) described a similar phenotype in a male patient.

The facies was characterized by midface hypoplasia, ptosis, epicanthic folds, small mandible, cup-shaped pinnae, short neck, posterior hairline, and delayed puberty (Fig. 25–28). The male had a small penis.

Fig. 25–26. *Patulous lips, ptosis, patent ductus arteriosus, and phalangeal anomalies (Char syndrome)*. (A,B) Child has broad forehead, extremely short philtrum with patulous lips, internal strabismus, and short nose. Mother has similar appearance. (Courtesy of CI Scott, Wilmington, Delaware.)

Unusual facies, osteosarcoma, and malformation syndrome

In 1979, Schuman and Burton (1) described two unrelated females with frontal bossing, highly arched palate, low-set ears, small auditory canals, prominent beaked nose, malocclusion, and micrognathia. One had exotropia and bilateral cataracts; the other had severe myopia. One had sensorineural hearing loss, and the other had conductive hearing loss. Both had repeated urinary infections, one having deformed ureterovesical junctions and the other having duplicated right kidney and ureter. Each had osteosarcoma of an extremity.

Unusual facies, short stature, and mental deficiency (Smith-Fineman-Myers syndrome)

Smith et al (3) and others (1,2,4,5) reported a syndrome of unusual facial appearance, short stature, and mental retardation. Inheritance is probably X-linked recessive, since all affected were males, and learning disabilities affected the sister of one boy (1).

Microdolichocephaly was combined with decreased frontonasal angle, flat philtrum, prominent maxillary central incisors, and micrognathia (Fig. 25–29). Hypertelorism and downslanting palpebral fissures are occasional manifestations. Short stature, usually of prenatal onset, seizures, hypertonia, hyperreflexia, and severe mental retardation with marked delay in speech acquisition occur. Other findings have included seizures, asplenia, optic nerve hypoplasia, chest deformity, mild foot deformities, hyperconvex nails, and bridged palmar creases.

Fig. 25–29. *Unusual facies, short stature, and mental deficiency*. Microdolichocephaly, flat philtrum, prominent central maxillary incisor. (From RD Smith et al, Am J Med Genet 7:5, 1980.)

Differential diagnosis includes *Coffin–Lowry syndrome, FG syndrome*, and *alpha-thalassemia mental retardation syndrome*.

Urofacial syndrome (Ochoa syndrome)

Elejalde (2), in 1979, described a syndrome of hydronephrosis, hydroureter, megalocystis, and unusual facies in seven children from three families. Ochoa and Gorlin (4), in 1987, found 36 examples in 22 families from around Medellin, Colombia. A few other isolated cases have been described (5,6) in children of Arabic origin. RJG has recently seen an example of Scandinavian origin. Ochoa (3), in 1992, increased the number to 50 patients from 32 families.

Inheritance clearly is autosomal recessive (3). The gene has been mapped to 10q23–q24 (7–9). There appears to be genetic homogeneity (1,8).

Facial expression is that of crying while the patient is smiling (Fig. 25–30). Obstructive abnormalities of the urinary tract due to occult neuropathic bladder results in mucosal hypertrophy, trabeculation, and diverticula of the bladder, hydroureter and hydronephrosis (Fig. 25–31). Enuresis, urinary tract infection, hypertension, and uremia are seen at various stages of the disorder. Many die in adolescence in their early twenties due to renal failure if not diagnosed or treated. All affected males have cryptorchidism. About 65% experience moderate to severe constipation.

Aqueductal stenosis resulting in hydrocephalus has been found (6).

FACES syndrome

Friedman and Goodman (1), in 1984, described a new syndrome with unique *F*acies, *A*norexia, *C*achexia, and *E*ye and *S*kin lesions, employing the acronym *FACES syndrome* as an acronym. Affected were two sisters and their mother. They stemmed from a consanguineous union of Yemenite Jewish ancestry. The mode of inheritance has not been established.

The facies was characterized by mild eyelid ptosis, xanthelasma, and a nose with anteverted nostrils with bifid tip (Fig. 25–32A,B). The two daughters also exhibited nasal speech (apparently associated with a short palate) and retinitis pigmentosa. Most striking was severe muscle wasting and cachexia, the individuals appearing almost cadaverous (Fig. 25–32C). They exhibited numerous lentigines and café-au-lait spots (Fig. 25–32D). The daughters had pectus excavatum and asymmetry of the chest. All exhibited genu varum and pes planus. One daughter had papillary carcinoma of the thyroid while diffuse enlargement of the thyroid was noted in the other. Mild soft-tissue syndactyly was found in digits 2–4 of the hands and in digits 3–4 of the feet (Fig. 25–32E,F).

Reference (FACES syndrome)

Unusual facies, cataract, short stature, joint contractures, and spondyloepimetaphyseal dysplasia

Borochowitz (1) described female sibs of Moroccan Jewish ancestry with unusual facies, cataract, short stature, inguinal hernia, joint contractures, and spondyloepimetaphyseal dysplasia. The parents were consanguineous. Inheritance is probably autosomal recessive.

Both had reduced height, weight, and head circumference. Intelligence was normal. Ambulation was difficult due to severe knee and hip joint contractures. The facies was old appearing with a large nose and mouth and a pointed chin. Radiographic changes included spondyloepimetaphyseal dysplasia and marked precocious calcification of costochondral cartilages.

A somewhat similar disorder was reported by Kozlowski et al (2). The female child had cataract, outstanding ears, scant subcutis, lordosis, and genu valgum. The patient also had hypoplasia of the labia majora and mental retardation.

Widow's peak, ptosis, and skeletal abnormalities (Kapur syndrome)

Kapur et al (1) described a large family with unusual facies and skeletal abnormalities. The patients had widow's peak, ptosis of eyelids, apparently low-set angulated pinnae, difficulty in supination of

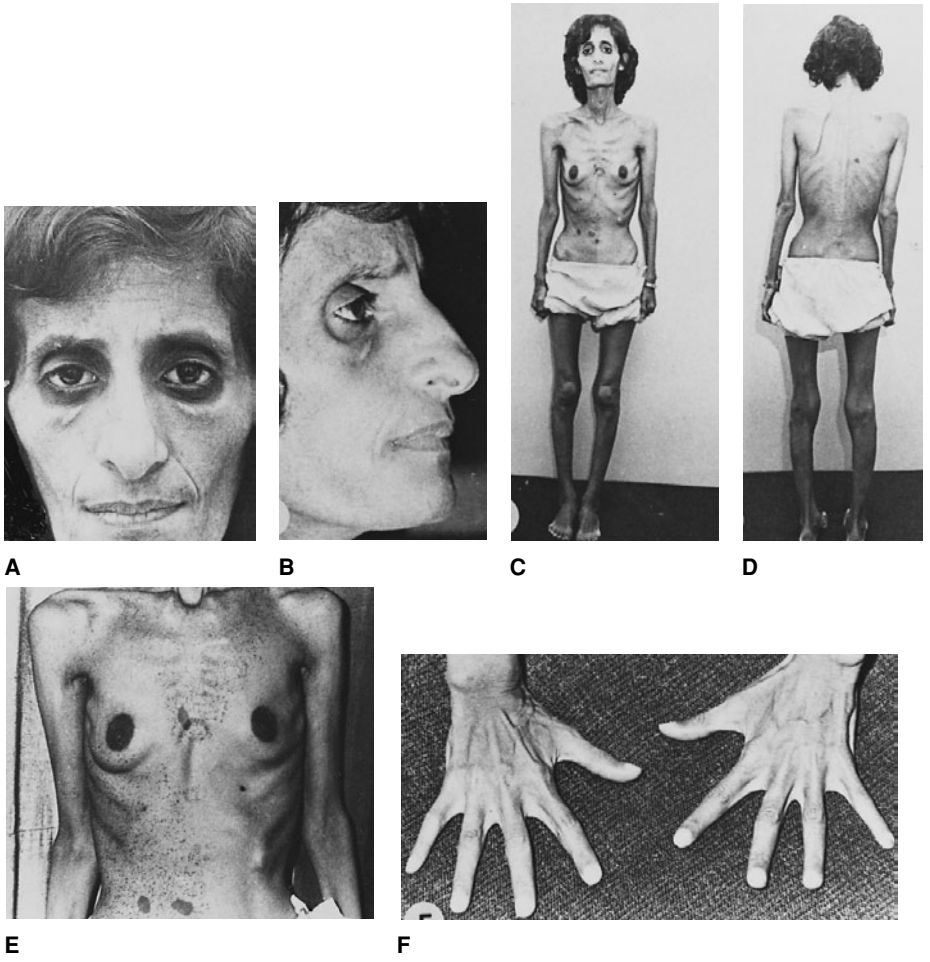

Fig. 25–32. *FACES syndrome*. (A,B) Mild ptosis, xanthelasma. (C,D) Extreme cachexia, genu varum. (E) Multiple lentigines and café-au-lait spots. (F) Mild soft tissue syndactyly. (From E Friedman and RM Goodman, J Craniofac Genet Dev Biol 4:227, 1984.)

forearms, recurrent dislocation of the patella, and pain in various joints (Fig. 25–33).

Affected males were relatively short (162–171 cm). The patella dislocated early in life was followed later by pain in the knees. Inability to supinate the forearm or touch the shoulder was noted in affected adult males. With age, the elbow, shoulder, wrist, hip, and interphalangeal joints showed progressive pain and radiologic changes of arthritis. There was flattening of the femoral condyles. At the elbow, the capitulum of the humerus was tilted with its medial edge placed proximally at the elbow. At the wrist, there was a V-shaped angulation of radius and ulna. A lateral view of the foot showed subluxation of the navicular and cuboid on the talus and calcaneus.

Inheritance appears to be X-linked dominant. Affected females had a less marked facies but exhibited ptosis and widow's peak.

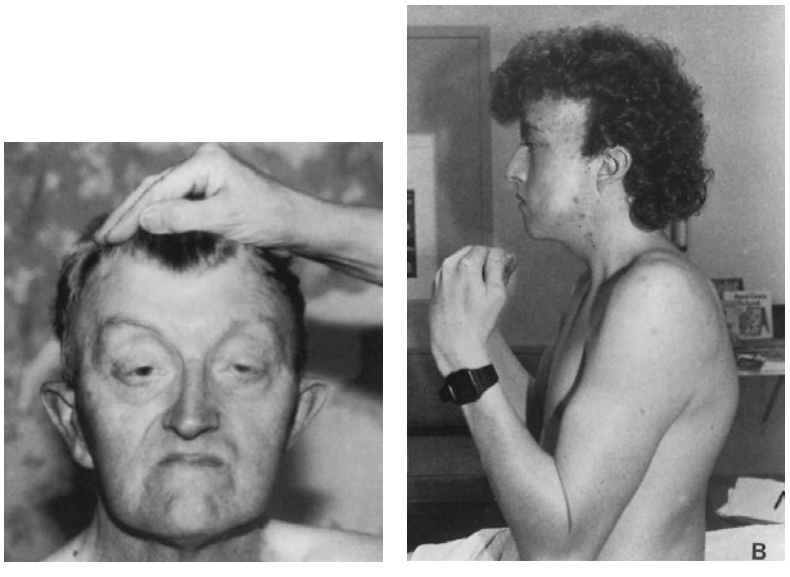

Fig. 25–33. *Widow's peak, ptosis, and skeletal abnormalities (Kapur syndrome)*. (A) Note widow's peak and ptosis. (B) Inability to touch shoulders with fingers. (From S Kapur et al, Am J Med Genet 33:357, 1989.)

Andersen syndrome (unusual facies, potassium-sensitive periodic paralysis, ventricular arrhythmia)

Andersen et al (1), in 1971, described a syndrome characterized by somewhat unusual facies, low-set pinnae, hypertelorism, broad nasal root, mandibular hypoplasia, cleft palate, scaphocephaly, clinodactyly, short stature, extra systoles, and attacks of muscular weakness (Fig. 25–34). Tawil et al (4) proposed a clinical triad including the facies, cardiac arrhythmia, and potassium-sensitive periodic paralysis. Sansone et al (3) described 11 patients from five kindred. Canún et al (2) added another family.

Inheritance is autosomal dominant. The genetic defect is not linked to any other form of sensitive periodic paralysis nor is it related to that of the long QT syndrome.

Cerebral anomalies, cardiac defects, and facial anomalies

Thakker and Donnai (1) described sibs with multiple major anomalies and facial anomalies characterized by long downslanting palpebral fissures, hypertelorism, short nose with a bulbous tip, microstomia with downturned corners, and posteriorly rotated ears (Fig. 25–35). Major malformations included brain anomalies (dilated ventricles in one, agenesis of the corpus callosum in the other), cardiac defects, short esophagus in one, anal atresia in the other, and vertebral anomalies. Muscle biopsy was consistent with atrophy.

Fig. 25–34. *Andersen syndrome*. (A,B) Scaphocephaly, low-set pinnae, hypertelorism, broad nasal root, and micrognathia. (From ED Andersen, Acta Paediatr Scand 60:559, 1971.)

Cerebro-facio-articular (Van Maldergem) syndrome

Van Maldergem et al (1), in 1992, reported a female child followed for 10 years. From two prior marriages, the mother had four boys and a girl, three of whom were mentally retarded but not dysmorphic. Zampino et al (2) described another example and used the term *cerebro-facio-articular syndrome*.

Generalized hypotonia was found at birth. In addition to microcephaly, the forehead was large with a low hairline, broad and prominent nasal bridge and large bulbous nose, telecanthus with epicanthic folds, downslanting short palpebral fissures, macrostomia with trapezoidal upper lip and full lower lip, and dysmorphic pinnae.

Camptodactyly of fingers 2 and 5 and axial clinodactyly of all fingers were noted. Genua recurvatum and laxity of fifth metacarpals were seen.

Intelligence quotient of 50 was determined.

Differential diagnosis included *blepharo-naso-facial syndrome*.

References [Cerebro-facio-articular (Van Maldergem) syndrome]

Coarse facies, acne conglobata, thick skin, gingival enlargement, osteoporosis, and mitral valve prolapse (Borrone dermato-cardio-skeletal syndrome)

Borrone et al (1), in 1993, noted two brothers with coarse facies, thick skin, acne conglobata, gingival enlargement, osteolysis, camptodactyly, and mitral valve prolapse.

The disorder was progressive and involved the skin, heart, bones, and joints. Before the end of the first year, thoracolumbar gibbus was noted. The vertebrae had reduced sagittal diameter and exhibited anterior beaking. Scheuermann osteochondritic changes were seen in late adolescence. In early childhood, there was delayed tooth eruption due to gingival enlargement. Intelligence was normal. The facies became progressively coarse with severe acne beginning in puberty. Inguinal hernias were noted. One brother died at age 24 from heart failure. Mitral valve prolapse was found.

Radiographs of the hands at 3 years resembled those of dysostosis multiplex but changes decreased with age. There was mild generalized osteoporosis.

Biochemical studies excluded lysosomal storage diseases.

Inheritance is either autosomal or X-linked recessive.

Reference [Coarse facies, acne conglobata, thick skin, gingival enlargement, osteoporosis, and mitral valve prolapse (Borrone dermato-cardio-skeletal syndrome)]

1. Borrone C et al: New multisystemic disorder involving heart valves, skin, bone, and joints in two brothers. Am J Med Genet 46:228–234, 1993.

Coarse facies, mental retardation, microcephaly, epilepsy, and skeletal anomalies

Battaglia et al (1) noted male and female sibs with mental retardation, microcephaly, seizures, skeletal anomalies, hirsutism, and coarse facies. Both had short stature and hypotonia.

Fig. 25–35. *Cerebral anomalies, cardiac defects and facial anomalies*. Hypertelorism, short nose with bulbous tip, microstomia with downturned corners, and very short webbed neck. (From Y Thakker and D Donnai, J Med Genet 28:633, 1991.)

The facies was characterized by prominent brows, broad nose, short philtrum, large open mouth, and thick lower lip.

Musculoskeletal anomalies included dorsolumbar scoliosis, stooped posture, and retarded bone age.

Reference (Coarse facies, mental retardation, microcephaly, epilepsy, and skeletal anomalies)

1. Battaglia A et al: New autosomal recessive syndrome of mental retardation, coarse facies, microcephaly, epilepsy, and skeletal anomalies. Clin Dysmorphol 5:41–47, 1996.

Unusual facies, atrophic skin, and hirsutism (Barber-Say syndrome)

Barber et al (1), in 1982, reported a syndrome consisting of growth retardation, characteristic facies, atrophic skin, and hypertrichosis. Although Cesarino et al (2) stated that their patient had ablepharon-macrostomia, we believe that the child had Barber–Say syndrome. Additional examples are those of David et al (4), Martínez Santana et al (5), and Mazzanti et al (6). A mildly affected boy was reported by Sod et al (7). Janssen and de Lange (4a) appear to have reported the syndrome in 1945.

Although there was parental consanguinity in one case (5), all examples have been isolated, save that of Dinulos and Pagon (4).

Face. The face is characterized by shallow orbits, telecanthus, sparse eyebrows and lashes, partial agenesis of eyelids, strabismus, ectropion of lower eyelids, hypoplastic nasal alae, large bulbous nasal tip, narrow vermilion of upper lip, and macrostomia (Fig. 25–36). Due to exposure, opacification of the cornea has been noted in one case (2). The pinnae, low and posteriorly rotated, have a prominent anthelix and absent tragus and lobule. The ear canals are tortuous but there is no hearing loss (1–3,5).

Skin. Hypertrichosis, especially over the forehead, back, and neck, has been a constant feature (2,3). General laxity of skin and atrophy produce an older appearance. A deficiency of fingerprints has been noted (5).

Growth and body build. Growth retardation has been observed in all patients. The shoulders slope and the nipples have been hypoplastic in all examples.

Intelligence. Moderate mental retardation has been found in two cases (1,2) and normal intelligence in two others (3,5).

Miscellaneous findings. Cryptorchidism was noted in one case (3).

Oral findings. All examples have some degree of macrostomia. A natal tooth has been reported in one case (2).

Differential diagnosis. Although there is slight overlap of signs with *ablepharon-macrostomia*, the syndromes are clearly different.

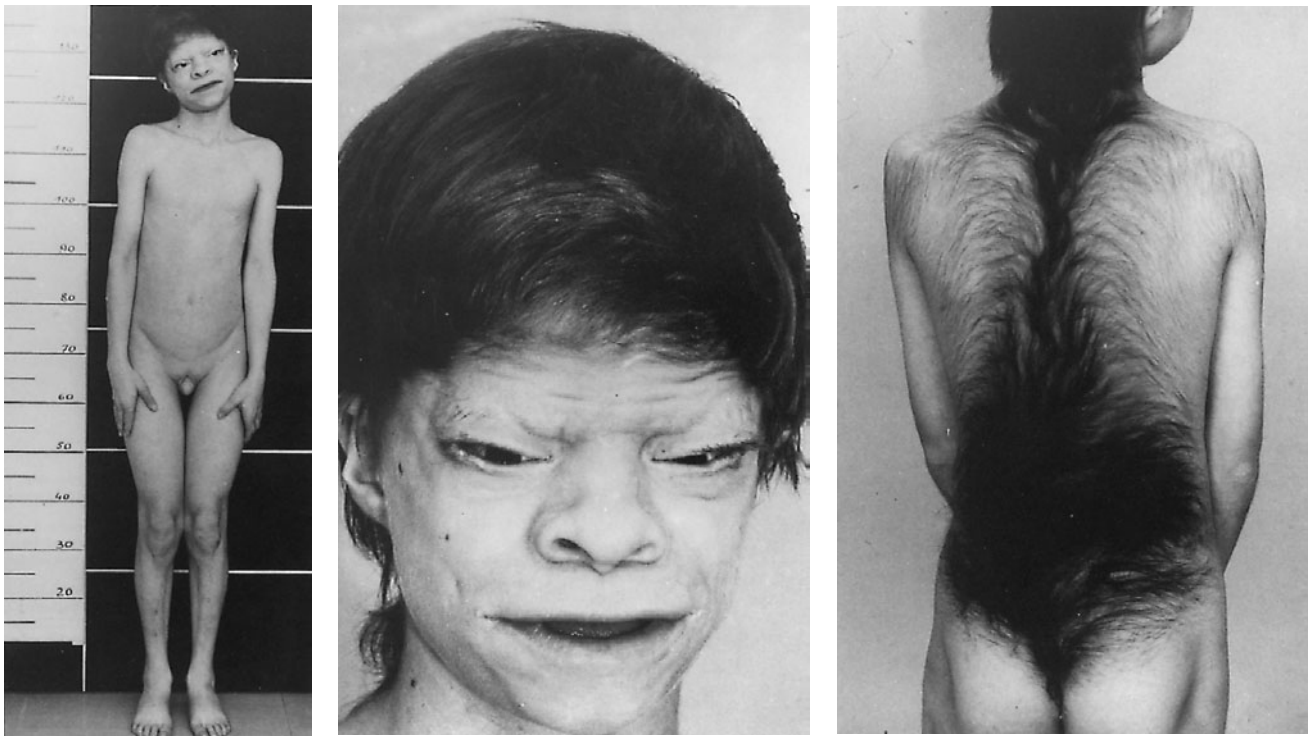
Cranio-cerebello-cardiac (3C) syndrome (Ritscher-Schinzel syndrome)

In 1987, Ritscher et al (13) reported two sisters with cerebellar vermis hypoplasia (Dandy-Walker malformation) with postnatal growth retardation, unusual facies, and atrioventricular septal defects of the heart. About 20 examples have been described to date (1–18).

Affected sibs (8,11) and parental consanguinity (11) suggest autosomal recessive inheritance, but most examples have been sporadic. The gene apparently maps to the 22q11 area (1,8).

Weight and length tend to be below the 10th centile with the OFC above the 75th centile. Postnatal growth has been retarded in most patients. One patient is described with growth hormone deficiency (17).

Craniofacial findings. The skull is macrocephalic in 20% and dolichocephalic with a very prominent forehead and occiput in at least 50%. About 50% have hydrocephaly or enlarged ventricles. Scalp hair and eyebrows tend to be thin and sparse. Ocular hypertelorism (80%),



A B C

Fig. 25–36. *Barber-Say syndrome*. (A) Eleven-year-old with atrophy of thoracic skin, hypoplastic nipples, bilateral cryptorchidism. (B) Hypertrichosis, ectropion, bulbous nose, macrostomia, thin lips, unusual pinna. (C) Hypertrichosis of back. (From A David et al, Am J Med Genet 39:112, 1991.)

downslanting palpebral fissures (75%), and flat nasal bridge (50%) are evident (Fig. 25–37A,B). Bilateral colobomata have been noted in 30% (2,8,11,16). The philtrum tends to be long and somewhat hypoplastic. The pinnae are large and posteriorly rotated. Radiographically, the anterior fontanel is always large and somewhat ragged. Parietal foramina has been seen (13). Cleft palate has been noted in 35% (3,5,10,13,16).

Central nervous system. Hypotonia, gross motor delay, and speech retardation are constant features. Vermis hypoplasia, enlarged fourth ventricle, and enlarged cysterna magna (Dandy–Walker malformation), and hydrocephalus are noted in 75% (Fig. 25–37C).

Musculoskeletal system. The hands are short with somewhat redundant skin and short terminal phalanges. There is usually clinodactyly of the fifth fingers. The nails are small. The muscles are poorly developed.

Radiographic changes. The anterior fontanel is large and late-closing with ragged edges. Some patients have hydrocephalus. The brain appears large. About 50% have aplasia of the vermis (Dandy–Walker malformation). Some patients have only 11 pairs of ribs (13,16).

Cardiovascular system. Two different types of cardiac anomalies occur: (a) endocardial cushion defects ranging from anomalies of the mitral or tricuspid valves to complete AV canal and (b) conotruncal anomalies. These have included ASD (11,13), VSD (3,11,13,16), tetralogy of Fallot (2,10), and AV valvular defects (5,13). An excellent review is that of Lurie and Ferencz (7).

Anogenital malformations. Some authors have documented gaping vulva and hypospadias (5). Anal atresia and misplaced anus have been described (11).

Diagnosis. There are many syndromes with vermis hypoplasia (15). One must exclude such conditions as *Coffin-Siris syndrome* with short fifth finger and congenital heart disease. However, the facies in that condition tends to be coarse with prominent eyebrows, thick lips, and hirsutism. Dandy–Walker malformation may be seen in association with Joubert–Boltshauser syndrome, *Meckel syndrome, Aase–Smith syndrome*, and a host of other conditions.

Laboratory findings. Immunodeficiency has been described (6).

Hunter-MacDonald syndrome

Hunter and MacDonald (2), in 1989, described a man with unusual facies, multiple epiphyseal dysplasia, hearing loss, and congenital heart anomaly. Ardinger et al (1) reported a three-generation family with the same disorder.

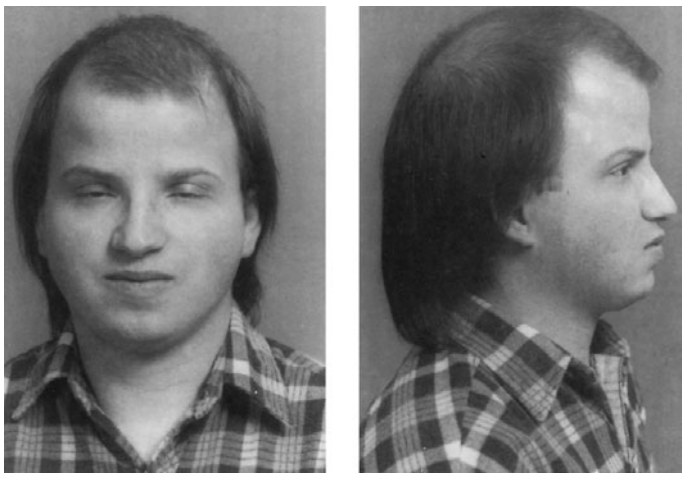

Fig. 25–38. *Hunter-MacDonald syndrome*. (A,B) Premature hair loss, bitemporal grooving, flared alae, midface hypoplasia, short philtrum. [From AGW Hunter and I MacDonald, Dysmorphol Clin Genet 3(1):8, 1989.]

Stature is proportionately short. Adult height ranges between 4′11″ and 5′2″. There is a tall forehead, bitemporal narrowing, ptosis, premature hair loss, thin upper lip, short philtrum, and long neck (Fig. 25–38).

Skeletal anomalies include pectus carinatum, hyperextensible joints with subluxation of thumbs and elbows, metatarsus adductus, and skewed fingers. Radiographic changes comprise pseudoepiphyses of middle phalanges, delayed bone age, small, flat, distal radial epiphyses, and constriction of distal shafts of humeri.

Heart anomalies consisted of mitral valve prolapse, bicuspid aortic valve, mild mitral and aortic regurgitation, and pulmonic valve stenosis.

The hearing loss is low-frequency sensorineural in one family (1) and conductive in another (2).

Hypertelorism, malar hypoplasia, low-set ears, and joint anomalies

Seaver and Cassidy (1) described a mother and son with multiple minor facial anomalies, curly hair, and mild delay; cubitus valgus, and hyperextensible joints were present in the mother, and umbilical hernia, diastasis recti, shawl scrotum, and cryptorchidism in the son. Facial features resemble those in *Noonan syndrome* and include hypertelorism, ptosis, downslanting palpebral fissures, epicanthal folds, broad nasal bridge, malar hypoplasia, smooth philtrum, thin upper lip, apparently low-set, posteriorly angulated ears, and low posterior hairline. Similarities to *Aarskog syndrome* and *Teebi hypertelorism syndrome* are also present.

Reference (Hypertelorism, malar hypoplasia, low-set ears, and joint anomalies)

1. Seaver LH, Cassidy SB: New syndrome: Mother and son with hypertelorism, downslanting palpebral fissures, malar hypoplasia, and apparently low-set ears associated with joint and scrotal anomalies. Am J Med Genet 41:405–409, 1991.

Lumbar malsegmentation, short stature, and facial anomalies

Liepala and Kaitila (1) reported two male sibs with the combination of short stature of prenatal onset, webbed neck, micrognathia, apparently low-set ears, highly arched palate, pectus excavatum, and on spine radiographs, platyspondyly and vertebral malsegmentation were noted. Cognition was not impaired. Inheritance is most likely autosomal recessive.

Reference (Lumbar malsegmentation, short stature, and facial anomalies)

1. Leipala JA, Kaitila I: Apparently new syndrome of short stature, lumbar malsegmentation, and minor facial anomalies in two brothers. Am J Med Genet 52:103–107, 1994.

Macrocephaly, facial abnormalities, disproportionate tall stature, and mental retardation

Bakker and Hennekam, 1997, reported two brothers with macrocephaly, high and narrow forehead, frontal upsweep of hairline, hypotelorism, tall stature, short limbs, mild hypermobility, and developmental delay. The father was similarly affected.

Reference (Macrocephaly, facial abnormalities, disproportionate tall stature, and mental retardation)

1. Bakker HD, Hennekam RCM: Macrocephaly, facial abnormalities, disproportionate tall stature, and mental retardation—a sib observation. Am J Med Genet 70:312–314, 1997.

Macrocephaly, rhizomelia, and conductive hearing loss

Bagatelle and Cassidy (1) described a boy with macrocephaly, apparent rhizomelia, conductive deafness, sparse hair, hypertelorism, downslanting palpebral fissures, depressed nasal bridge, and short nose with anteverted nares. The anterior fontanel was large and late to close. The child's smile was described as a wrinkling of the forehead, eyes, and nose but without upward curve of the lips. Skeletal survey was essentially normal. Toriello (personal communication, 1998) has also seen a child with similar manifestations.

Reference (Macrocephaly, rhizomelia, and conductive hearing loss)

1. Bagatelle R, Cassidy SB: New syndrome of macrocephaly, hypertelorism, short limbs, hearing loss, and developmental delay. Am J Med Genet 55:367–371, 1995.

"Long thumb" brachydactyly, maxillary hypoplasia, mental retardation, and unusual facies

Halal et al (2) described a metaphyseal dysplasia with associated short stature, nasal beaking, absent nasal alae, maxillary hypoplasia, and brachydactyly in a four-generation family. The brachydactyly was of the "long thumb" variety. Hollister and Hollister (3) also described autosomal dominant inheritance of "long thumb" brachydactyly, skeletal anomalies, and cardiac conduction defects. Stratton et al (4) reported a mentally retarded male with marfanoid habitus, "long thumb" brachydactyly, mesomelia, aortic dilatation, mitral valve prolapse, and very unusual face. Fryer (1) described a retarded female with a similar face and mitral valve prolapse (Fig. 25–39).

While there are clinical overlaps among these various families, we await their separation. One of us (RJG) has seen a similarly affected mother and son. *Velocardiofacial syndrome* must be excluded.

Fig. 25–39. *"Long thumb" brachydactyly, maxillary hypoplasia, mental retardation, and unusual facies*. Wide nasal bridge without alar flare. (From A Fryer, Am J Med Genet 51:277, 1994.

Lateral meningocele (Lehman) syndrome

Lateral meningocele syndrome was first described by Lehman et al (3) in 1977. It consists of multiple bilateral meningoceles in the thoracolumbar area, unusual facies, and skeletal changes (1–4).

Inheritance is uncertain. A possibly affected parent and child were reported by Lehman et al (3). All other cases have been sporadic (1,2,4).

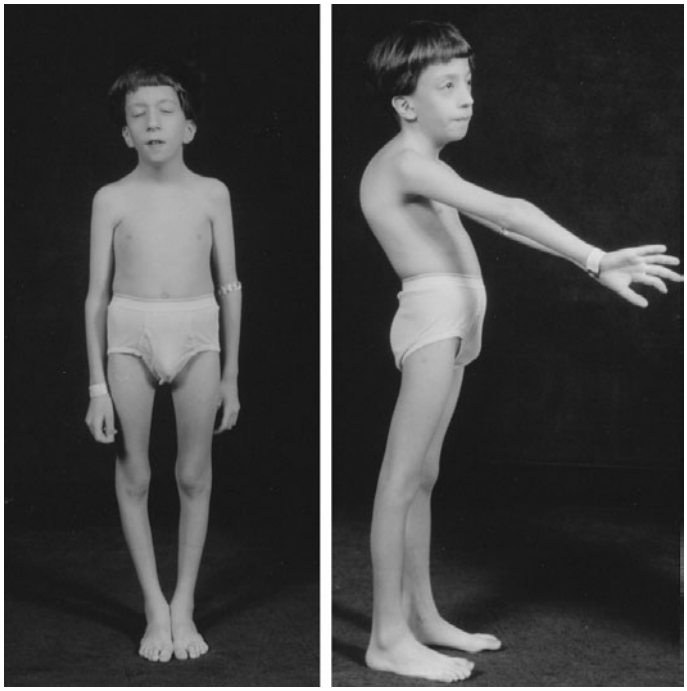
The facies is characterized by hypertelorism, malar hypoplasia, downslanting palpebral fissures, ptosis, proptosis, low-set posteriorly rotated pinnae, and small lower jaw. The neck may be somewhat short or webbed (Fig. 25–40A,B).

Hypotonia and developmental delay have been variable features.

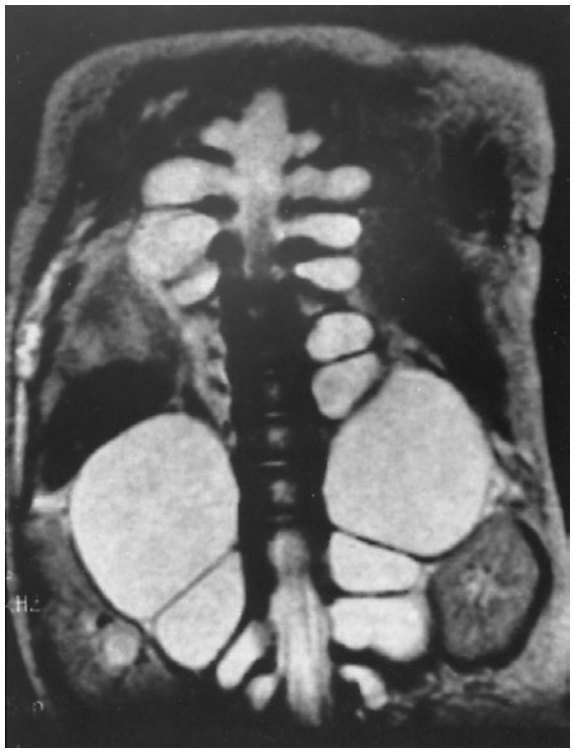
Lateral meningoceles are protrusions of the dura and arachnoid through inter- and intravertebral foramina, probably secondary to dural ectasia. They present as widening of the neural canal, thinning of the bony cortex of the vertebral body and pedicles, dilation of the neural foramina, and protrusion of the dura outside of the neural canal (5). Lateral meningoceles found in the syndrome have been in the thoracolumbar area. They are easily seen in MRI or CT scans (Fig. 25–40C).

Skeletal changes include prominent metopic suture, thickened calvaria, wormian bones, and possibly enlarged sella and flattened mandibular angle. Pectus excavatum or carinatum and scoliosis have been reported.

Miscellaneous findings include cryptorchidism, keloids, and short umbilical cord.



A B



C

Fig. 25–40. *Lateral meningocele (Lehman) syndrome*. (A,B) Note slender build, marked thoracic kyphosis, exaggerated lumbar lordosis, long fingers. (C) Coronal T2 weighted image of thoracolumbar spine showing multiple bilateral meningoceles, widened spinal canal, enlarged neural foramina, lateral displacement. (From KW Gripp et al, Am J Med Genet 70:229, 1997.)

Dural ectasia, some as severe as meningoceles, may be seen in over 60% of patients with *Marfan syndrome*. Again, over 60% of thoracic lateral meningoceles have been associated with *neurofibromatosis, type 1* (5).

Mandibular condyle hypoplasia and prominent constricted pinnae (question mark ear, congenital auricular cleft)

Uuspää (7), in 1978, described a mother and two sons with prominent constricted ears and hypoplastic mandibles. Jampol et al (4), in 1998, reported a five-generation family with prominent ears constricted between lower and middle thirds with disjunction of the lobule, malformed mandibular condyles, microstomia, and temporomandibular joint abnormalities (Fig. 25–41). Range of motion was reduced. Hearing was not affected. Storm et al (5), in 1998, described a four-generation family with prominent malformed ears and mandibular condylar hypoplasia, micrognathia, and microstomia. Similar examples are those of Brodovsky and Westreich (2), Uysal et al (8), and Takato et al (6). The pinna anomaly is the same as "question mark" ear or congenital auricular cleft (3) of which there are about 15 published examples (1). Priolo et al (4a) suggested that hypotonia is a component.

Inheritance is autosomal dominant.

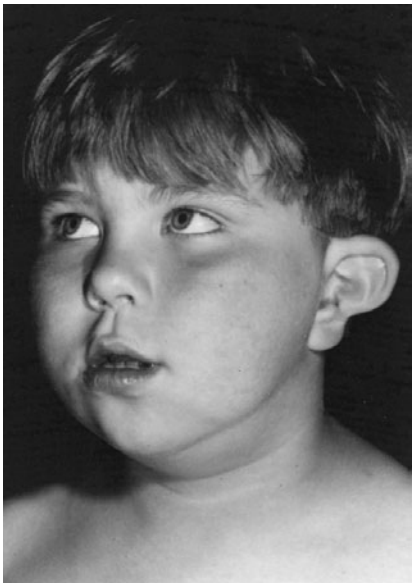
Mental and somatic retardation, generalized muscular hypertrophy, joint limitations, unusual facies, and mixed hearing loss (Myhre syndrome, GOMBO syndrome)

Myhre et al (3), in 1981, described a syndrome of growth and mental deficiency, unusual facies, generalized muscular dystrophy, joint limitation, skeletal deformities, and mixed hearing loss in two unrelated males. Other examples were reported by Soljak et al (4), Garcia-Cruz et al (2), and, possibly, Verloes et al (1,5).



A

B

Fig. 25–41. *Mandibular condyle hypoplasia and prominent constricted pinnae (question mark ear, congenital auricular cleft).* (A) Prominent malformed pinna ("question mark" ear). (B) Condylar head shows flattening of superior surface. Glenoid fossa is significantly anterior to and separated from external auditory canal. (From M Jampol et al, Am J Med Genet 75:449, 1998.)

Six of seven patients are males, raising the question of X-linked recessive inheritance, with rare manifesting heterozygotes. Verloes et al (6), however, demonstrated that it is due to a cryptic translocation involving the short arm of chromosome 3 and the long arm of chromosome 22.

There was both prenatal and postnatal growth deficiency. The muscles were enlarged and there was decreased joint mobility (Fig. 25–42A,B). The midface was hypoplastic with relative mandibular prognathism. Blepharophimosis and short philtrum were evident. One patient had cleft lip–palate (3). Hypospadias and cryptorchidism were noted.

Mixed hearing loss ranging from moderate to severe has been reported (1,2).

Radiographically, the calvaria was thickened (Fig. 25–42C). The iliac wings were hypoplastic (champagne-glass configuration), the ribs broad. The long and short tubular bones were somewhat abbreviated (Fig. 25–42D). and the vertebrae were large and somewhat flattened with large short pedicles (Fig. 25–42E).

Microcephaly, distal lymphedema, and choreoretinal dysplasia with distinctive facies

Microcephaly in combination with choreoretinopathy was first reported by Alzial et al (1), in 1980. Microcephaly, in combination with distal lymphedema, was reported by Leung (10), in 1985, and Crowe and Dickerman (3), in 1986, and others (8,16). The triad of findings was reported by Angle et al (2), in 1994. The combination was also reported by Limwongse et al (11), in 1999, who reexamined individuals from the kindred described by Crowe and Dickerman (3). Other kindred have been reported (4,5,7,9,12,14–19).

The microcephaly is quite significant (−6 SD) (Fig. 25–43A). Intelligence ranges from normal to mildly retarded, in spite of the severe microcephaly. The facies is characterized by downslanting palpebral fissures, epicanthic folds, prominent pinnae, broad nasal bridge with a broad and large nasal tip and anteverted nares, prominent philtrum, prominent full lips, and pointed chin. Short stature may be found (16).

The lymphedema is restricted to the dorsal surfaces of the hands and feet. The lymphedema is nonpitting and firm to the touch. The digits appear somewhat shortened with persisting volar and plantar pads. There may be fingernail and toenail dysplasia (Fig. 25–43B).

Eye changes consist of large areas of reticulated choreoretinal atrophy in superior and inferior fundus. Mottled pigmentation is seen in the area of atrophy. Atrophic yellow spots occur in the inferior portion of the fundi. Mild optic atrophy may be noted.

Inheritance is autosomal dominant.

Familial microcephaly is usually autosomal recessive, but dominant examples have been cited. Perhaps some of these cases may represent the syndrome (6,13).

Various lymphedemas are discussed in *Hennekam syndrome*.

Microcephaly, growth retardation, and facial anomalies

Partington and Anderson (1) described two sibs and a third unrelated child with the combination of pre- and postnatal growth retardation (average birthweight 2.6 kg), microcephaly, global developmental delay, thick curly hair, and minor facial anomalies. The facial appearance consisted of thick eyebrows with synophrys and short beaked nose with long columella. The personality was described as friendly.

Inheritance may be autosomal recessive.

Reference (Microcephaly, growth retardation, and facial anomalies)

Microcephaly, mental retardation, Hirschsprung disease, and characteristic facies (Mowat-Wilson syndrome)

Mowat et al (3) reported six children with short stature, microcephaly, and marked mental retardation. Four had Hirschsprung disease and a distinct facies (Fig. 25–44). We suspect that this syndrome is identical to *Goldberg-Shprintzen syndrome*.

The facies was characterized by deep-set, large eyes, broad nasal bridge, rounded nasal tip, prominent columella, open mouth, prominent chin, and large uplifted ear lobes.

Postnatal short stature, slender tapered fingers, and bilateral calcaneovalgus were noted in all.

All exhibited severe developmental delay with absent or minimal speech and delayed gross motor skills, but a common feature was a happy smiling affect. Four developed seizures.

Five had Hirschsprung disease (most with short segment), and one has chronic constipation.

Three had congenital heart anomalies (pulmonary atresia, tetralogy of Fallot, patent ductus, peripheral pulmonary stenosis), and three had renal structural anomalies (duplex kidney, hydronephrosis, reflux).

Several other patients have had similar phenotype (1,2,4).

Inheritance has still not been determined. All have been isolated examples. Deletion at 2q22–q23 has been found.

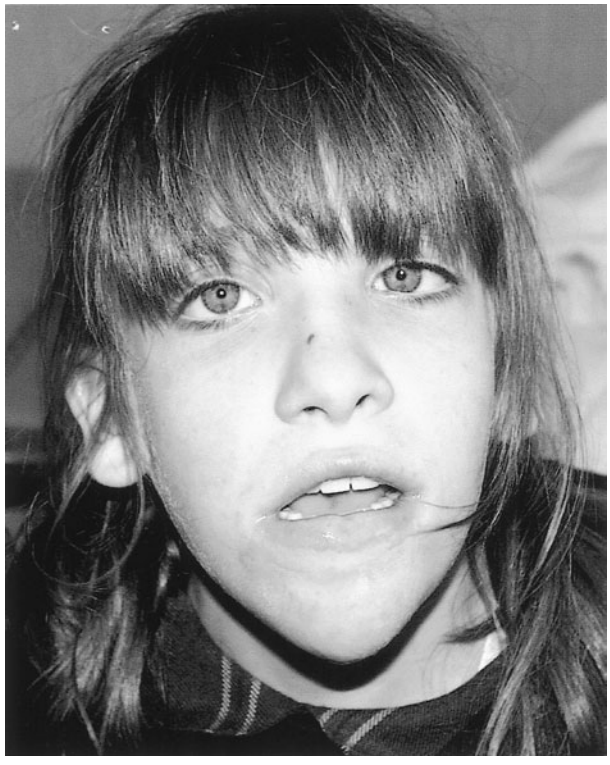

Fig. 25–45. *Nasal hypoplasia, sparse hair, truncal obesity, genital hypoplasia, and severe mental retardation*. Unusual facies characterized by ptosis, epicanthic folds, nasal hypoplasia, sparse scalp hair and eyebrows, long philtrum, and thin upper lip. (From JP Fryns et al, J Med Genet 29:676, 1992.)

Nasal hypoplasia, sparse hair, truncal obesity, genital hypoplasia, and severe mental retardation

Fryns et al (1) observed a female with unusual facies characterized by ptosis, nasal hypoplasia, epicanthic folds, and sparse scalp hair and eyebrows. The philtrum was long and the upper lip was thin (Fig. 25–45).

She was severely retarded with generalized hypotonia. In addition to truncal obesity, there were small hands and feet, puffy hands, syndactyly of toes 2–3, and hypoplastic labia majora and minora.

Pallister-Hall syndrome

In 1980, Hall, Pallister, and others (15) described a syndrome of hypothalamic hamartoblastoma, craniofacial anomalies, postaxial polydactyly, cardiac and renal defects, and endocrine dysfunction. To date, over 60 have been reported (1,2,6,7,12–19,23,29–36). Many cases have been sporadic, although there are several reports of autosomal dominant inheritance (14,19,24,28,31,32,34). Variable expressivity is common. The causative gene, mapped to 7p13, has recently been identified as the *GLI3* gene, the zinc finger transcription factor, which also causes Greig cephalopolysyndactyly syndrome, postaxial polydactyly type A and the PIV syndrome (polydactyly, imperforate anus, and vertebral anomalies) (19–21). It has been suggested by Biesecker and Graham (1) that frameshift mutations of *GLI3* cause PHS, whereas large deletions resulting in haploinsufficiency of *GLI3* cause Greig syndrome (19–21). However, Wild et al (38) have also described point mutations in individuals with Greig syndrome, so the reason for the different phenotypes has yet to be sorted out. There is no genotype-phenotype correlation (28a).

Table 25–1. *Pallister-Hall syndrome*: Clinical and pathological findings

Finding	%
Central nervous system	
Hypothalamic hamartoma	85
Holoprosencephaly	10
Hydrocephalus	25
Short/absent olfactory tracts	40
Craniofacial anomalies	
Flat nasal bridge	60
Short nose	60
Ear anomalies	90
Microglossia/micrognathia	25
Buccal frenula	50
Palatal anomalies	50
Bifid epiglottis-cleft larynx	50
Limb anomalies	
Postaxial polydactyly/oligodactyly	60
Nail dysplasia/hypoplasia	65
Short limbs	40
Syndactyly	50
Adducted forefoot	40
Pathological findings	
Renal ectopia/dysplasia	55
Congenital heart defects[a]	40
Imperforate/anteriorly placed anus	50
Lung segmentation anomalies	45
Endocrine findings[b]	
Adrenal hypoplasia/dysplasia causing hypoadrenalism	55
Pituitary aplasia/dysplasia causing panhypopituitarism	70
Testicular hypoplasia/cryptorchidism with micropenis in males	50
Thyroid aplasia/dysplasia hypothyroidism	65
Cryptorchidism	30

[a] PDA, VSD, endocardial cushion defect, mitral and aortic valve defects, and proximal aortic coarctation

[b] Endocrine findings reflect premorbid endocrinologic studies, and autopsy cases may be underreported.

Based on LG Biesecker et al, Am J Med Genet 65:76, 1996.

Diagnostic criteria were suggested by Biesecker et al (3), and include both hypothalamic hamartoma with characteristic MRI findings and central polydactyly.

Most patients were at or below the tenth centile for length and weight. Because the first reported children died during infancy, the condition was initially considered to be lethal. Over time, individuals with milder manifestations were described, and the prognosis can be quite good. Cheng et al (5) described an isolated example of hamartoblastoma and polysyndactyly in an asymptomatic adult. Biesecker and Graham (1) provide a good review of the evolution of the understanding of the phenotype. The major cause of death in the neonatal period is hypoadrenalism (13,18). Pulmonary anomalies undoubtedly contribute to neonatal respiratory distress. Clinical and pathologic findings on 13 examples are summarized in Table 25–1.

Craniofacial anomalies. Short midface, short nose with flat nasal bridge, anteverted nostrils, and asymmetric cranium with large fontanels are common. The ears are frequently low-set and posteriorly angulated. They protrude with small or absent lobules (7,13,15,17,18) (Fig. 25–46A,B).

Oral anomalies include micrognathia, microglossia, and multiple frenula between the alveolar ridge and buccal mucosa. Natal teeth, cysts of the gingiva, cleft palate, and cleft uvula have also been noted in some patients. Mandibular ridges are often hypoplastic. Two children with choanal atresia have been described (29,33).

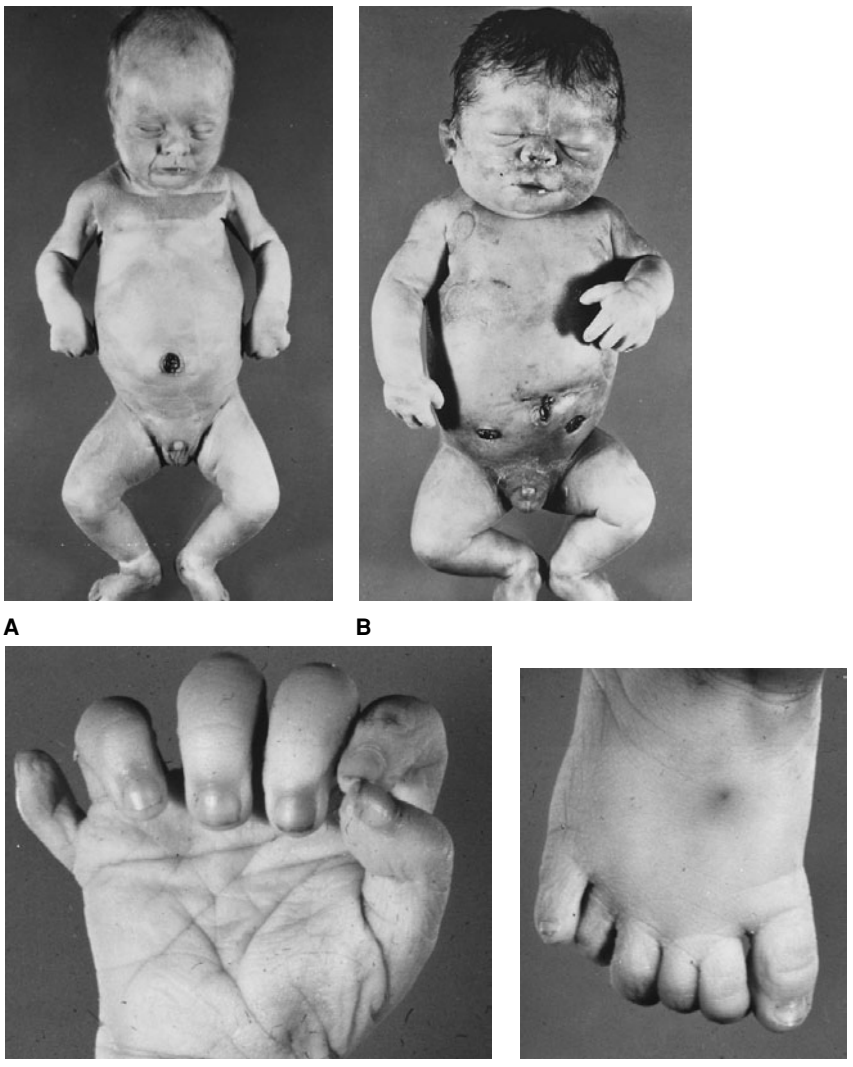

Fig. 25–46. *Pallister-Hall syndrome*. (A,B) Short midface, anteverted nostrils, long philtrum, short hands, microphallus, underdeveloped scrotum. (C) Postaxial polydactyly of hand. (D) Postaxial polydactyly of foot. (From JG Hall et al, Am J Med Genet 4:47, 1980.)

Limb abnormalities. Postaxial polydactyly, syndactyly, and nail dysplasia, involving both toes and fingers, are observed in most patients (Fig. 25–46C,D). The marked polydactyly, central or postaxial, is associated with short dysplastic fourth metacarpals, and small underdeveloped fourth fingers. Occasionally, a bifid third metacarpal is seen (Fig. 25–47). In the feet, the fourth and fifth digits are similarly involved. Subluxation of the radial head has been found in approximately half the patients (7,13,15,17,18,26) and mesomelic shortness of the long bones has been described as well (36). Encha-Razavi et al (8) described sibs with micromelia and short ribs, one of whom had hypothalamic hamartoma; it is uncertain whether they truly had Pallister–Hall syndrome.

Congenital heart defects. A wide variety of congenital heart defects has been reported in some, including PDA, VSD, endocardial cushion defect, mitral and aortic valve defects, and proximal aortic coarctation (13,15,17). As more cases were described, it has become evident that cardiac defects are less frequent than originally thought (1).

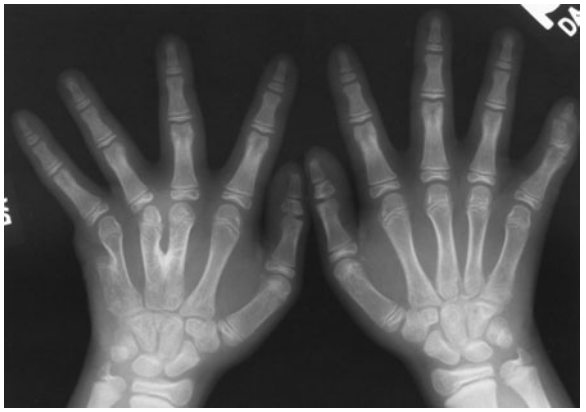
Central nervous system. The most striking and unique abnormality is congenital hypothalamic tumor, which replaces the hypothalamus and nuclei and consists of normal neuronal elements in abnormal mixture (2,32) (Fig. 25–48). The tumor probably arises from the embryonic hypothalamic plate. While undifferentiated elements may be observed, mature neural tissue has been reported (18,32) lending credence to the hypothesis that such tumors retain the ability to mature over time (2,13). However, not all affected individuals have hypothalamic hamartomas (9,34).

Since facial anomalies are associated with hypothalamic hamartoblastoma, embryonic disruption by the tumor may upset stereotactic relationships, thereby altering migration of embryonic structures. This results in craniofacial anomalies. Variation in timing and degree of hamartoblastomatous disruption could result in a range of phenotypic expression. Early insult resulted in holoprosencephaly, noted in three cases (2,18). Disruption during the fifth week could lead to the milder craniofacial anomalies usually found in the Pallister–Hall syndrome. Instances of hypothalamic hamartoma and precocious puberty without facial anomalies (18) might represent a disruptive insult that occurred even later. Since solitary central maxillary incisor may be the mildest manifestation of holoprosencephaly, its association with precocious puberty and hypothalamic hamartoma (27) helps to bridge the gap between very early hypothalamic tumors with severe craniofacial anomalies and late hypothalamic tumors without associated anomalies. Hypothalamic hamartoblastoma and its associated disruptive craniofacial features may occur alone (10,18,25,27) or together with other embryonically noncontiguous anomalies making up a true malformation syndrome like the Pallister–Hall syndrome.

Lungs. Laryngeal cleft, aplastic, hypoplastic, or bifid epiglottis; dysplastic tracheal cartilages; and absence or hypoplasia of the lung and/or abnormal lung lobulation occur (1,7,13,15,17,18).

Endocrine findings. Severe multiple endocrine dysfunction usually includes hypopituitarism, hypothyroidism, hypoglycemia, and hypoadrenalism (13,15,30). These are not always present.

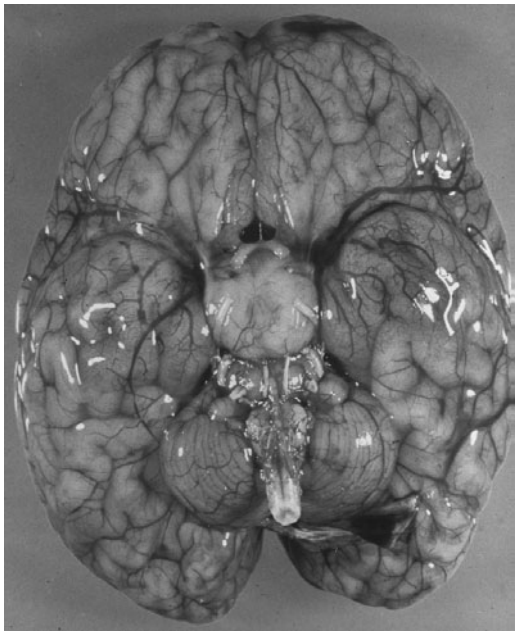
A



B

Fig. 25–47. *Pallister-Hall syndrome*. (A) Various bony anomalies of hands: fused metacarpals, hypoplastic metacarpals, fused proximal phalanges, agenesis of distal phalanges. (B) Asymmetric hand malformations: unilateral central or insertional polysyndactyly and contralateral postaxial polydactyly. (A from JG Hall et al, Am J Med Genet 4:47, 1980. B from LG Biesecker and JM Graham, Jr, J Med Genet 33:585, 1996.)

Fig. 25–48. *Pallister-Hall syndrome*. Hypothalamic hamartoblastoma. (From SK Clarren et al, Am J Med Genet 7:75, 1980.)



Other findings. Various genitourinary anomalies have been reported including absent, hypoplastic, dysplastic, or ectopic kidneys. Micropenis and cryptorchidism have also been noted. The anus is frequently imperforate or anteriorly placed. Squires et al (32) described a patient with vaginal atresia, and Unsinn et al (35) described a patient with hydrocolpos. Several patients have had narrow cervical vertebrae (7,13,15,17,18); others have laryngotracheal cleft or bifid epiglottis (26a).

Differential diagnosis. Natal teeth, multiple frenula, nail dysplasia, congenital heart defects, and postaxial polydactyly are observed in *Ellis-van Creveld syndrome*. Multiple frenula are also found in *Opitz trigonocephaly (C) syndrome*. Kaufman–McKusick syndrome, consisting of hydrometrocolpos, postaxial polydacytly, and congenital heart defect (11,23), should also be excluded. Marcuse et al (25), in a review of hypothalamic hamartoma unassociated with the syndrome, noted one patient with cleft palate and another with tetralogy of Fallot. Hennekam et al (16) reported congenital hypothalamic hamartoma, frontonasal malformation, frontal midline lipoma, and complex congenital heart defect. Gitlin and Behar (10) reported a patient with a large hypothalamic hamartoblastoma, agenesis of the corpus callosum, absent olfactory tracts and bulbs, and bilateral nasal proboscides. Verloes et al (37) described hypothalamic hamartoblastoma with holoprosencephaly, macrophthalmia, pulmonary malformations, radial hypoplasia, and Müllerian regression. Winter et al (39) reported a solitary central maxillary incisor with precocious puberty and hypothalamic hamartoma. The combination of holoprosencephaly and polydactyly may be seen in *pseudo-trisomy 13 syndrome* and *Meckel syndrome*. There is some overlap with the *oral-facial-digital syndromes* and *Smith-Lemli-Opitz syndrome*, although cholesterol levels are normal in Pallister–Hall syndrome (4). Kuller et al (22) described sibs with the presumptive diagnosis of Pallister-Hall syndrome; the younger was subsequently found to have an unbalanced translocation (46 XY, −7, +der(7),t(3;7)(p25.3;q36)pat).

Laboratory aids. Neuroradiological detection of hypothalamic hamartoblastoma can be difficult. Magnetic resonance imaging is the procedure of choice for evaluating suprasellar tumors but may be difficult to obtain in infants (18). Low maternal estriols prior to birth and large fontanels suggest endocrine hypofunction and should prompt immediate evaluation for hypoadrenalism and hypothyroidism.

Prenatal diagnosis may be possible by (*a*) measurement of maternal estriol levels, which are decreased in the presence of hypoplastic, fetal adrenals, (*b*) prenatal ultrasound for detection of renal, adrenal, and brain abnormalities, or presence of polydactyly, (*c*) measurement of disaccharidoses in amniotic fluid that may be decreased with imperforate anus (13,15) and (*d*) linkage analysis, and eventually direct mutation analysis.

Enlarged parietal foramina, craniofacial anomalies, mental retardation, and multiple exostoses (Potocki-Shaffer syndrome, del11p11.2-p12 syndrome)

Gustavson et al (2), in 1984, reported two cases of what was described as 11p13 deletion. The female exhibited bilateral aniridia, persistent urogenital sinus, enlarged clitoris, and ovotestes. Intelligence was normal. The face was characterized by short somewhat everted upper lip exposing the maxillary incisor teeth (Fig. 25–49). An unrelated male had large fontanels, large pinnae, small penis, hypoplastic scrotum, and diaphragmatic hernia. Lorenz et al (5) reported a male with brachyturricephaly, biparietal foramina, multiple exostoses of metaphyses, micropenis, and mental retardation. Shaffer et al (10), in 1993, described interstitial deletion 11p11.12-p12 in a family in which two sibs and a maternal uncle exhibited Wormian bones, biparietal foramina, brachymicrocephaly, mental retardation, unusual facies, epicanthic folds, esotropia, micropenis, cryptorchidism, and multiple exostoses (Fig. 25–50). Potocki and Shaffer (7) and Potocki et al (8) and others (1,3–5) expanded the phenotype.

The syndrome has been shown to be a contiguous gene deletion involving the *EXT2* (multiple exostoses gene) at 11p11.2-p12 (1,4,7). The *EXT2* gene defines a family of putative tumor suppressor genes (10). Loss of functional mutations in the *ALX* homeobox gene has been shown to be responsible for the syndrome (5a,11,12). Wilkie showed that haploinsufficiency of *MSX2* causes parietal foramina.

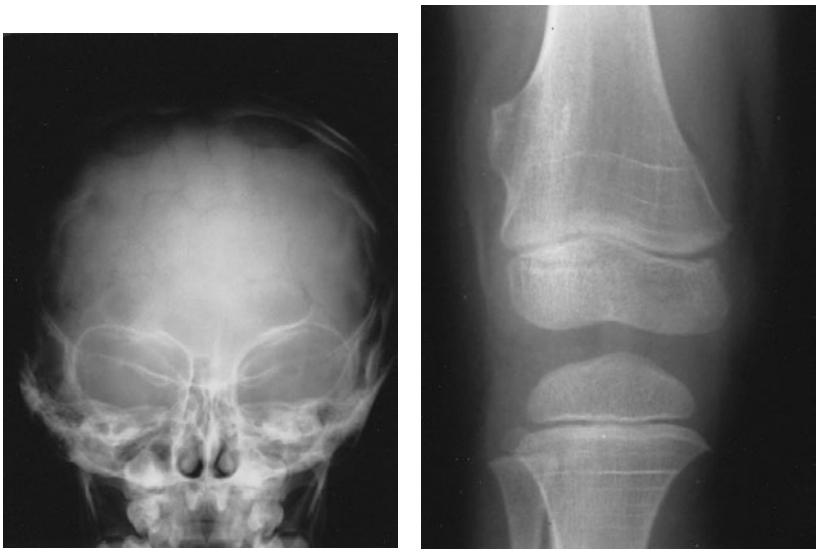
Overlapping is the *WAGR syndrome* (Wilms tumor, aniridia, genital abnormalities, and mental retardation). A patient with WAGR and multiple exostoses and parietal ramus has been noted by McGaughran et al (6). We reject the pejorative term, DEFECT11 (8a).

Craniofacial findings. Large anterior fontanel, biparietal foramina, epicanthic folds, esotropia, downturned upper lip, and short underdeveloped philtrum have been noted in virtually all affected.

Central nervous system. Developmental delay and mental retardation have been constant features. Seizures have been noted by Shaffer et al (9).

Fig. 25–49. *Enlarged parietal foramina, craniofacial anomalies, mental retardation, and multiple exostoses (Potocki-Shaffer syndrome, del11p11.2-p12 syndrome).* (A,B) Short, somewhat everted upper lip exposing upper incisors. Downslanting corners of mouth. (From LG Shaffer et al, Am J Med Genet 45:581, 1993.)

A **B**



A B

Fig. 25–50. *Enlarged parietal foramina, craniofacial anomalies, mental retardation, and multiple exostoses (Potocki-Shaffer syndrome, del11p11.2p12 syndrome.)* (A) Biparietal foramina. (B) Exostoses of metaphysis. (From LG Shaffer et al, Am J Med Genet 45:581, 1993.)

Skeletal findings. Multiple cartilaginous exostoses have been noted in all patients.

Discussion. Hereditary multiple exostoses may be a solitary finding. They have autosomal dominant inheritance. Three loci have been identified: 8q24(*EXT1*), 11p12(*EXT2*), and 19p(*EXT3*) (3). *EXT1* deletions have been identified with *Langer–Giedion syndrome*. *EXT* deletions have been seen only with multiple exostoses. Enlarged parietal foramina have been seen with cleft lip and/or palate in a syndrome.

The parietal defects are much larger in those with the deletion than in those with *MSX2* haploinsufficiency. Wu et al (12) demonstrated haploinsufficiency of *ALX4* to be responsible for parietal foramina.

The facies resembles that of *Char syndrome*.

Speech delay, facial asymmetry, and strabismus

Mehes et al (1), in 1993, described a mother and two children with markedly delayed speech development (speech appeared at approximately 4 years), strabismus, and transverse ear crease. Facial asymmetry, hypertelorism, and highly arched palate were additional manifestations.

Autosomal dominant inheritance was proposed.

Reference (Speech delay, facial asymmetry, and strabismus)

Unusual facies, agonadism, and mental retardation

Kennerknecht et al (1), in 1995, described two sisters with agonadism, mental retardation, short stature, and unusual facies.

The parents were Turkish first cousins. Autosomal recessive inheritance appears likely. The karyotype was 46,XY.

Both exhibited short stature, central obesity, inverted nipples, and global developmental retardation. Bone age was severely retarded. Mild thoracolumbar scoliosis was evident as was dysplasia of the hips.

Characterizing the facies were low-set hairline, hypotelorism, sunken eyes, long eyelashes, broad nasal bridge, retracted nostrils, thin upper lip, and dysmorphic pinnae. Hypodontia was noted but not demonstrated in the photographs.

The external genitalia were female, but agonadism, blind-ended vagina, hypoplastic uterus, and rudimentary Müllerian structures were found.

Reference (Unusual facies, agonadism, and mental retardation)

1. Kennerknecht I et al: Agonadism in two sisters with XY gonosomal constitution, mental retardation, short stature, severely retarded bone age, and multiple extragenital malformations. Am J Med Genet 59:62–67, 1995.

Unusual facies and congenital hip dislocation

Collins et al (1) reported a mother and three daughters with unusual facies (hypertelorism, epicanthic folds, puffiness around eyes, flat midface, and downslanting mouth), ASD, short stature, and congenital hip dislocation.

In addition, all three girls had clinodactyly and hyperextensible joints, features seen in the father. A picture of the father resembles that of *trichorhino-phalangeal syndrome*.

Reference (Unusual facies and congenital hip dislocation)

1. Collins AL et al: A mother and three daughters with congenital dislocation of the hip and a characteristic facial appearance: A new syndrome? Clin Dysmorphol 4:277–282, 1995.

Unusual facies, hyperphalangism, hallux valgus, and bronchomalacia

Chitayat et al (1) reported a male infant with widow's peak, bushy eyebrows, synophrys, prominent eyes, hypertelorism, depressed nasal bridge and short pointed nose with anteverted nostrils, long philtrum, and full lips.

Hyperphalangism (resembling *Catel-Manzke syndrome*, only more extensive, involving digits 2 and 3) and hallux valgus were evident.

Congenital bronchomalacia and mild hypospadias were also noted.

Reference (Unusual facies, hyperphalangism, hallux valgus, and bronchomalacia)

1. Chitayat D et al: Hyperphalangism, facial anomalies, hallux valgus, and bronchomalacia: A new syndrome. Am J Med Genet 45:1–4, 1993.

Unusual facies, hirsutism, skeletal dysplasia, mental retardation, and uric acid metabolic disorder

Wiedemann et al (1) described a patient, the son of nonconsanguineous parents. He had strikingly generalized hirsutism, but especially marked on chin, neck, shoulders, and back, which turned somewhat gray early in life. Brachycephaly, long neck with downsloping shoulders, narrow thorax, prominent elbow joints, coxa valga with subluxation of hip joints, goutlike changes in the fingers, and pes excavatum with claw toes became evident (Fig. 25–51A).

From an early age, he had a deep voice. There were delayed milestones. Moderate mental retardation was established.

Facial appearance was characterized by relatively prominent nose with blunt nasal tip, malformed pinnae, and micrognathia (Fig. 25–51B).

Elevated levels of uric acid were found in the plasma. Hypoexcretion of uric acid in the urine was suggested.

Reference (Unusual facies, hirsutism, skeletal dysplasia, mental retardation, and uric acid metabolic disorder)

1. Wiedemann H-R et al: Hirsutism-skeletal dysplasia-mental retardation syndrome with abnormal face and a uric acid metabolism disorder. Am J Med Genet 46:403–409, 1993.

Unusual facies, short stature, myopia, and mental retardation

Achermann et al (l), in 1999, described two brothers with short stature, microcephaly, myopia, retarded osseous maturation, and severe developmental delay. Facies was characterized by temporal narrowing, periorbital fullness, convergent squint, full cheeks during infancy, and wide mouth and protruding lower lip (Fig. 25–52).

A B

Fig. 25–51. *Unusual facies, hirsutism, skeletal dysplasia, mental retardation, and uric acid metabolic disorder*. (A) Fifteen-year-old male with narrow shoulders and marked hirsutism. (B) Face at 11 years showing relatively prominent nose with blunt tip and small mandible. (From H-R Wiedemann et al, Am J Med Genet 46:403, 1993.)

Inheritance may be autosomal or X-linked recessive.

Reference (Unusual facies, short stature, myopia, and mental retardation)

1. Achermann S et al: Short stature, myopia, severe developmental delay, and peculiar facial appearance in two brothers: A new syndrome? Am J Med Genet 86:486–491, 1999.

Unusual facies, hypertrichosis, and retinopathy

Pivnick et al (1) reported a boy with congenital hypertrichosis, pigmentary retinopathy, sunken cheeks, wide nasal bridge, and large downturned mouth. There was decreased fat over the buttocks, but not elsewhere. Development was delayed (Fig. 25–53).

Reference (Unusual facies, hypertrichosis, and retinopathy)

1. Pivnick EK et al: Hypertrichosis, pigmentary retinopathy, and facial anomalies: A new syndrome? Am J Med Genet 62:386–390, 1996.

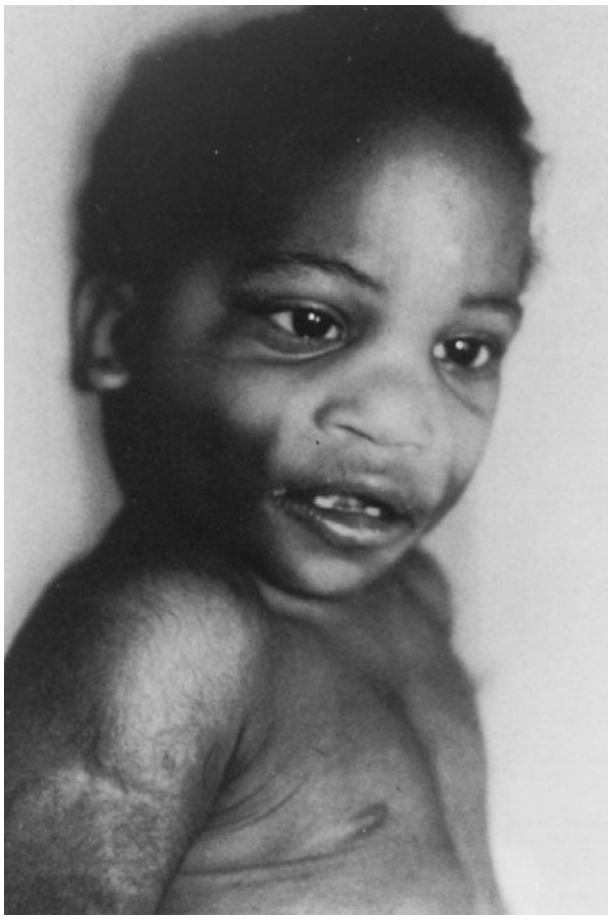
A B

Fig. 25–52. *Unusual facies, short stature, myopia, and mental retardation*. (A,B). Siblings with unusual facies, severe developmental delay, myopia and convergent squint. Note wide mouth, prominent lips, periorbital fullness. (From S Achermann et al, Am J Med Genet 86:486, 1999.)

Unusual facies, hypotonia, mental retardation, and radioulnar synostosis

Der Kaloustian et al (1) reported male and female sibs with unusual facies, generalized hypotonia, developmental retardation, and radioulnar synostosis.

Fig. 25–53. *Unusual facies, hypertrichosis, and retinopathy*. Boy with congenital hypertrichosis. Note wide nasal bridge and large downturned mouth. (From EK Pivnick et al, Am J Med Genet 62:386, 1996.)



Both exhibited dolichocephaly, long face, macrocephaly, esotropia or exotropia, prominent nose with high nasal bridge, outstanding simplified pinnae, pectus excavatum, generalized hypotonia, and type 2 radioulnar synostosis. This form is characterized by fusion just distal to the proximal radial epiphysis in association with congenital dislocation of the radial head (Fig. 25–54). One child also had unilateral polycystic kidney.

Inheritance is probably autosomal recessive.

Reference (Unusual facies, hypotonia, mental retardation, and radioulnar synostosis)

1. Der Kaloustian VM et al: Unilateral radio-ulnar synostosis, generalized hypotonia, developmental retardation, and a characteristic appearance in sibs: A new syndrome. Am J Med Genet 43:942–945, 1992.

Unusual facies, abnormal hair, camptodactyly, and caudal appendage (Teebi-Shaltout syndrome)

Teebi and Shaltout (2), in 1989, reported a kindred with unusual facies characterized by scaphocephaly with prominent occiput and bitemporal depression, thin, curly, sparse, slow-growing hair, hypertelorism, ptosis and blepharophimosis, bulbous nose with hypoplastic alae nasi, small pinnae, microstomia, camptodactyly, and caudal appendage (Fig. 25–55A). Froster et al (1) reported four affected siblings with microphthalmia, bulbous nose, hypoplastic alae nasi, microstomia, small pinnae, and mild cutis laxa.

Camptodactyly, ulnar deviation of hands, abnormal skin creases, cutis laxa, and caudal appendix were found in both families (Fig. 25–55B,C). Froster et al (1) also noted unilateral microphthalmia, cleft palate, hydronephrosis, and diastasis recti.

Multiple sibs in one family and consanguinity in both families clearly suggest autosomal recessive inheritance (1,2).

Unusual facies, elevated IgE level, and leukocyte dysfunction (Job syndrome, hyperimmunoglobulin E syndrome)

There are many syndromes in which there is defective neutrophil and monocyte chemotaxis (11,21). The most common of these syndromes was called Job syndrome by Davis et al (7) because of Job's affliction with "sore boils." About 250 patients have been described. Extensive reviews are those of Donabedian and Gallin (8), Belohradsky et al (1), Leung and Geha (18), and Grimbacher et al (12). There is no sex or race predilection. It has been estimated that Job syndrome constitutes about 1% of those with a primary immune defect (1). The classic triad of abscesses, pneumonia, and elevated IgE is seen in 75% of all patients and in 85% of those over 8 years (9).

Eczematous dermatitis, usually presenting during the first few weeks of life, often involves more than 50% of the body. There is a predilection for flexural surfaces such as popliteal and antecubital fossae and neck. From there on, nearly all patients exhibit increased susceptibility to recurrent pyogenic infections. There are abundant furuncles and carbuncles of the chest, back, and axillae. However, "cold" abscesses are found in only 30% and cellulitis occurs in only 10%.

Sinopulmonary infections include otitis media (45%), otitis externa (10%), sinusitis (15%), tonsillitis (12%), mastoiditis (5%), pneumonia (70%), lung abscess (40%), and empyema (10%) (14,19). Gingivitis, periodontitis, aphthae, and oral abscesses have been noted in 70% (4,15). There is failure to shed deciduous teeth in 75%, owing to lack of root resorption (12, 19a). Conjunctivitis and/or corneal ulceration occur in 20%. Bones, joints, and viscera are involved in less than 5% of the cases. *Staphylococcus aureus* has been isolated in 90%. Oral and vaginal candidosis and candidal nail dystrophy are evident in about 40%. Perforation of the gut occurs rarely (5).

Joints are hyperextensible (70%) and recurrent fractures are noted in 50% (12).

Quie and Cates (20) first noted the coarse facies characterized by prominent forehead, deep-set eyes, hypoplastic midface, broad nasal bridge, prominent nose, thick pinnae, and prominent lower lip (2). It has been estimated that the facies is seen in 50%–60% (Fig. 25–56) and may be present at birth (17). Craniosynostosis has been occasionally reported (6,16,23), and these cases are discussed further in chapter 15 under *hyper-IgE syndrome*. Grimbacher et al (12) have suggested autosomal dominant inheritance with variable expressivity. The gene has been mapped to chromosome 4 (13).

The chemotactic defect, present at about 50% of the mean normal range, is variable and often intermittent. Most patients have a low grade eosinophilia (about 10%) (8). Serum IgE levels are at least 10 times normal, that is, greater than 2000 IU/ml, in some patients being as high as 100-fold normal values (1,3,10,22,24). Erythrocyte sedimentation rates are elevated in all patients. IgE levels tend to decline with time (12).

Fig. 25–56. *Unusual facies, elevated IgE levels, and leukocyte dysfunction (Job syndrome)*. Patient has coarse facies typical of patients with Job syndrome. The midface is hypoplastic and there is hypertelorism. (Courtesy of PG Quie, Minneapolis, Minnesota.)

Unusual facies, microcephaly, normal intelligence, immunodeficiency, and lymphoreticular malignancy

Seemanová et al (1) described a disorder in nine patients characterized by microcephaly with normal intelligence, cellular and humoral immune defects, increased risk for lymphoreticular malignancy, and a facies similar to that of primordial dwarfism.

Inheritance is clearly autosomal recessive.

Reference (Unusual facies, microcephaly, normal intelligence, immunodeficiency, and lymphoreticular malignancy)

1. Seemanová E et al: Familial microcephaly with normal intelligence, immunodeficiency, and risk for lymphoreticular malignancies: A new autosomal recessive disorder. Am J Med Genet 20:639–648, 1985.

Unusual facies and familial intestinal malrotation

Stalker and Chitayat (1) reported a brother and sister with boxy head, high forehead, frontal bossing, long palpebral fissures, epicanthic folds, and micrognathia.

Both had congenital midgut volvulus.

Inheritance, if any, may be autosomal recessive.

Reference (Unusual facies and familial intestinal malrotation)

1. Stalker HJ, Chitayat D: Familial intestinal malrotation with midgut volvulus and facial anomalies: A disorder involving a gene controlling the normal gut rotation. Am J Med Genet 44:46–47, 1992.

Unusual facies, cerebellar hypoplasia, and heart and lung abnormalities

Seller et al (1) described three female sibs with unusual facies characterized by high forehead, low posteriorly rotated pinnae, prominent upper lip, and micrognathia.

All had cerebellar hypoplasia and contractures (flexed fingers, talipes). Two have ASD and two had deficient lobulation of lungs

Inheritance is likely autosomal recessive.

Reference (Unusual facies, cerebellar hypoplasia, and heart and lung abnormalities)

1. Seller MJ et al: Cerebellar hypoplasia, facial dysmorphism, and internal abnormalities. A new recessive syndrome? Clin Dysmorphol 7:41–44, 1994.

Unusual facies, congenital hypothyroidism, and severe mental retardation (Young-Simpson syndrome)

Young and Simpson (6), in 1987, reported a syndrome of unusual facies, congenital hypothyroidism, asphyxia, hypotonia, and severe global and growth retardation. Similar examples have subsequently been described (1–5). The craniofacies was characterized by microcephaly, blepharophimosis, bulbous nose, long philtrum, thin upper lip, downturned mouth, low-set posteriorly rotated pinnae, and micrognathia (Fig. 25–57). All males have had cryptorchidism. Less constant features have been congenital heart anomaly (ASD, VSD, AV canal, PDA) (1,4–6), and postaxial polydactyly of hands and feet (2). Cleft palate was found by Fryns and Moerman (3).

Polyhydramnios has been noted in a few cases (3,4).

Although autosomal recessive inheritance was proposed on the basis of parental consanguinity (1), all examples have been sporadic.

Digital fibromas, metacarpal and metatarsal disorganization, and facial pigmentary dysplasia (digito-cutaneous dysplasia, terminal osseous dysplasia, and pigmentary defects)

Bloem et al (2), in 1974, described a syndrome consisting of recurring digital fibromas of infancy in a female infant. There were wide linear pigmented marks over the temporal regions and abundance of the vermilion of the lower lip. Two editors (RJG, RCMH) had an occasion in Amsterdam in 1995 to see this affected woman and her more severely affected child. In addition to multiple digital fibromas, the hands and feet were dysplastic (Fig. 25–58A–C). Toriello (personal communication, 1995) indicated that she had seen a similar example in a female patient. Horii et al (5), in 1998, and Dabney et al (4) described females with skeletal changes in the hands and feet including digital fibromas, joint contractures, brachymesophalangy with cone-shaped epiphyses, variable brachydactyly and deformity of the metacarpals and metatarsals, unusual brachydactyly, hypertelorism, and midface hypoplasia with punched out pigmentary anomalies of the face and scalp. A similar case was shown to one of the authors (RJG) in 1992. A large kindred was reported by Zhang et al (6,7) and the clinical features reviewed by Bacino et al (1) who demonstrated the cutaneous and bony changes (Figs. 25–58A–C and 25–59). Bacino et al (1) suggested the term "terminal osseous dysplasia with pigmentary defects." We prefer *digito-cutaneous dysplasia*.

Facial abnormalities included upslanting palpebral fissures, primary telecanthus with epicanthic folds, depressed nasal tip, and small fibrous tumor of left eyelid. There were also patchy brownish facial discolorations (Fig. 25–58D). Multiple oral frenula were reported in three of nine patients.

The condition clearly has X-linked dominant inheritance, lethal in the male. It has been mapped to Xq28 (1,6).

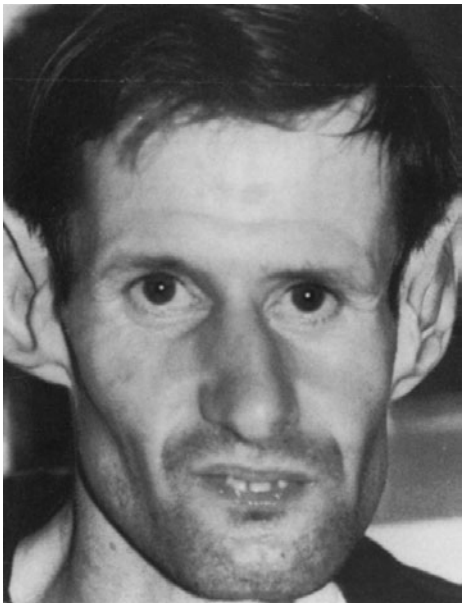
Unusual facies, arachnodactyly, hypogenitalism, and failure to thrive

Harrod et al (2) reported two brothers with small size at birth, microcephaly, mental retardation, long thin face, unusually large anteverted pinnae, long thin nose, hypotelorism, small mouth, and pointed chin

A



B

Fig. 25–60. *Unusual facies, arachnodactyly, hypogenitalism and failure to thrive*. (A) Child with microcephaly, mental retardation, long thin face, large ears. (B) Microcephaly, long thin face, unusually large anteverted pinnae, long thin nose, hypotelorism, small mouth, and pointed chin in male with severe mental retardation. Note resemblance to that of fragile X syndrome. [A from MJ Harrod et al, Birth Defects 13(3B):111, 1977. B from SB Jurenka and MI Van Allen, Am J Med Genet 61:168, 1996.]

(Fig. 25–60). The facies resembled that of typical *fragile X syndrome*. Both exhibited pectus, arachnodactyly, hypospadias, cryptorchidism, and aberrant subclavian artery. Malrotation of the bowel and pyloric stenosis as well as multiple microcysts of the renal cortex were found in one brother. An additional example of an affected male was reported by Jurenka and Van Allen (3). In addition, their patient had scoliosis, cataracts, megacolon, and varicose veins.

Inheritance may be X-linked recessive.

A similar phenotype was reported in *unusual facies, arachnodactyly, and mental retardation* by de Die-Smulders et al (1). One must exclude other X-linked mental retardation syndromes such as Allan–Harndon–Dudley syndrome (4) and others cited by Stevenson et al (5).

Unusual facies, hypopituitarism, distal arthrogryposis, and mental retardation

Chitayat et al (1) described a brother and sister with unusual facial features, mental retardation, hypopituitarism, and distal arthrogryposis.

The head was somewhat square with a small anterior fontanel and ridging of the coronal, sagittal, and metopic sutures. There was frontal bossing, high narrow forehead, prominent supraorbital ridges, small upturned nose with depressed bridge, small mouth, prominent pinnae, and small mandible.

Seizures and severe developmental delay were noted in both sibs. Partial growth hormone deficiency was ascertained. Low serum gonadotropin and testosterone concentrations combined with microphallus, cryptorchidism, and small adrenals suggested hypopituitarism. Further findings indicated hypothalamic origin.

The distal arthrogryposis resembled the hand changes seen in *trisomy 18*.

Reference (Unusual facies, hypopituitarism, distal arthrogryposis, and mental retardation)

Unusual facies and microcephaly with normal intelligence

Teebi et al (1) reported a large highly inbred kindred of Palestinian Arabs with eight affected.

All were microcephalic but with normal intelligence.

There were low receding forehead, prominent eyes, upslanting palpebral fissures, epicanthic folds, long straight nose with high nasal bridge, widely spaced teeth, and receding chin.

Inheritance is autosomal recessive.

Reference (Unusual facies and microcephaly with normal intelligence)

1. Teebi AS et al: Autosomal recessive microcephaly with normal intelligence. Am J Med Genet 26:355–359, 1987.

Unusual facies and partial alopecia

Feinstein et al (1) and Straussberg et al (2) reported a male patient and his female first cousin from a highly inbred family of Oriental Jews. They exhibited partial alopecia (sparse light scalp hair, eyebrows, eyelashes), smooth skin, and an unusual facies characterized by long philtrum, thick earlobes, and microcephaly. Both had a harsh deep voice and very similar personality (mischievous, hyperactive, affable, etc.).

Inheritance may be autosomal recessive.

References (Unusual facies and partial alopecia)

Unusual facies, hooked clavicles, supernumerary ribs, widened metaphyses, and square-shaped vertebral bodies

Kozlowski et al (1) noted dizygotic twins with long narrow head, midface hypoplasia, hypertelorism, small upturned nose, downslanting palpebral fissures, small chin, large hands and feet, and long slender fingers.

Radiographic changes included large anterior fontanel, hypertelorism, 13 pairs of ribs, hypoplastic hooked clavicles, widened metaphyses, and square-shaped vertebral bodies.

Inheritance may be autosomal recessive.

Reference (Unusual facies, hooked clavicles, supernumerary ribs, widened metaphyses, and square-shaped vertebral bodies)

1. Kozlowski K et al: Unusual facies, hooked clavicles, 13 pairs of ribs, widened metaphyses, square shaped vertebral bodies and communicating hydrocephalus. Pediatr Radiol 22:328–330, 1992.

Unusual facies, lipodystrophy, and joint contractures (Werner-like syndrome)

Hoepffner et al (1) described a Werner syndrome-like disorder in three male siblings (Fig. 25–61). They had been described earlier by Mensing et al (2). Sclerodermatous alterations of the skin, sharp facies, and joint contractures were noted. One had insulin-resistant diabetes mellitus. Impaired function of three related peptide growth factors was found at the post-receptor level. The related peptides were insulin, insulinlike growth factor, and epidermal growth factor.

Various syndromes of insulin-resistant diabetes mellitus must be excluded: *leprechaunism*, severe insulin resistance A–E, *lipodystrophic diabetes*, and Rabson–Mendenhall syndrome. *Werner syndrome* was excluded because the patients' fibroblasts had normal life and redoubling spans. We believe the sibs have *mandibuloacral dysplasia*.

References [Unusual facies, lipodystrophy, and joint contractures (Werner-like syndrome)]

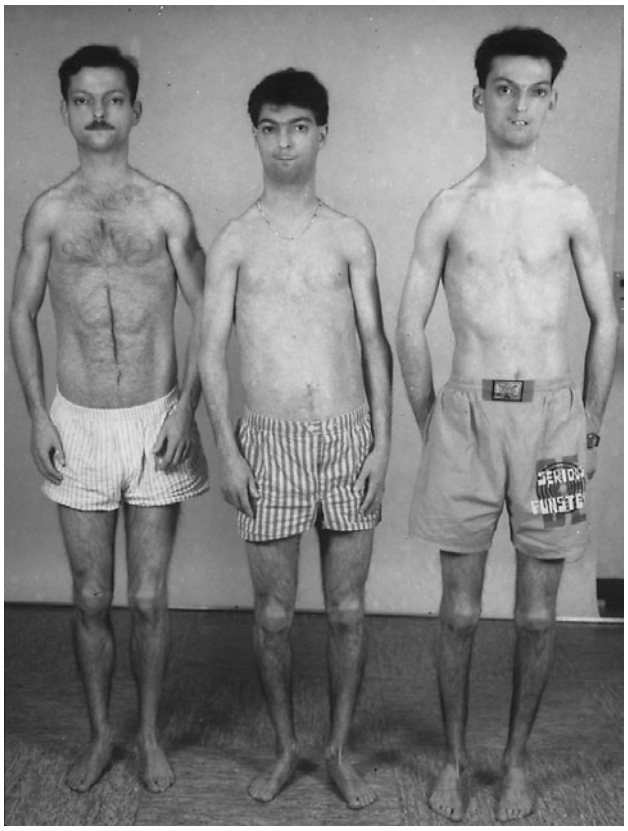

Fig. 25–61. *Unusual facies, lipodystrophy, and joint contractures (Werner-like syndrome)*. Note small mandible, long neck, sloping shoulders, genu varum. We suspect that these brothers have *mandibuloacral dysplasia*. (From HJ Hoepffner et al, Hum Genet 83:209, 1989.)

Unusual facies, lymphedema, intestinal lymphangiectasia, and mental retardation (Hennekam syndrome)

Hennekam et al (5), in 1988, described three sibs and their cousin with mental retardation, lymphedematous facies, marked edema of the lower extremities, and gastrointestinal lymphangiectasia. Gabrielli et al (4) confirmed the syndrome. About 25 examples have since been reported (1,2,13).

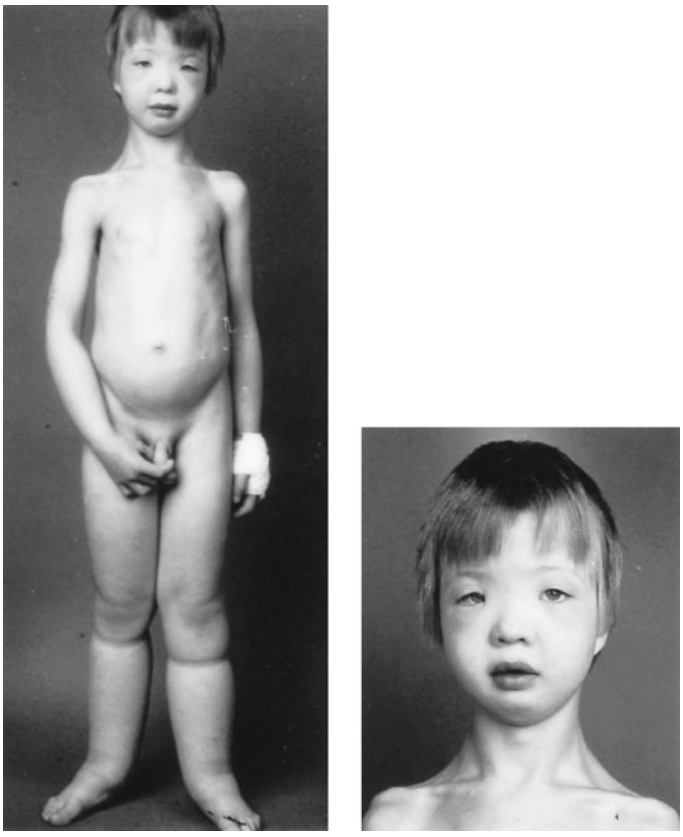
Inheritance is autosomal recessive, there being multiple sibs (4) and parental consanguinity in 25% (2,4). The gene is probably involved in lymphangiogenesis.

The facies appears Oriental due to periorbital edema. Hypertelorism, frontal upsweep, heavy eyebrows, epicanthic folds, and depressed nasal bridge give the face a flat appearance. Some had dysmorphic pinnae, microstomia, narrow palate, retrognathia, and unusual teeth: oligodontia and incisors with conical crown form (Fig. 25–62).

Lymphedema, present before birth, causes the characteristic facies. After birth, the swelling progresses and causes asymmetric massive enlargement of the lower extremities and genitalia. Lymph may ooze from the swollen area and become infected, resulting in erysipelas. Intestinal lymphangiectasia of the small bowel was demonstrated in all affected, causing protein-losing enteropathy and attendant complications, such as mild growth retardation (1,5).

Talipes equinovarus and cryptorchidism were noted as well as mild cutaneous syndactyly of fingers 2–5 (4). The distal thumbs were hypoplastic. MRI showed focal parietal pachygyria (4). Bone age may be retarded (13). Coronal craniosynostosis has been reported as well as ectopic kidney (2). Other findings include rectal prolapse and VSD (1) and ectopic pelvic kidney (2). Death rarely occurs during the first year of life (11).

Mental retardation was mild to moderate in nearly all affected. Most have exhibited seizures. Sensorineural and conductive hearing loss have been described (1).



A B

Fig. 25–62. *Unusual facies, lymphedema, intestinal lymphangiectasia, and mental retardation*. (A) This boy shows congenital generalized edema especially of the lower extremities. (B) Hypertelorism, periorbital edema, epicanthal folds, and depressed nasal bridge impart a flat appearance to the face. (Courtesy of RCM Hennekam, Amsterdam, The Netherlands.)

There is some overlap with the autosomal recessive disorder described by Mücke et al (8). Unrelated is the syndrome in two brothers reported by Irons et al (7). This involved lymphedema of the lower limbs, atrial septal defect, and a somewhat unusual facies (upslanting palpebral fissures, prominent forehead, flat nasal bridge). An affected sister had severe hydrops fetalis, omphalocele, ASD, round face, wide nasal bridge, and horizontal chin cleft. The two boys had speech delay.

Among the other cases of congenital lymphedema, there are Nonne–Milroy syndrome, *Turner syndrome, Noonan syndrome*, distichiasis and lymphedema (9,10), microcephaly and lymphedema (3), lymphedema of legs and conjunctivae (12), and cerebellar hypoplasia and lymphedema (6). Distichiasis-lymphedema-cleft palate maps to 16q24.3 (1a). Mutations in *FOXC2(MFH-1)*, a forkhead family transcription factor, are responsible for the condition (3a).

Unusual facies, ectodermal dysplasia, and polycystic brain (dilated Virchow-Robin spaces) (Sener syndrome)

Sener (2) reported a 9-year-old girl with progressive learning difficulties. Lynch et al (1) described two additional examples.

The facies somewhat resembled that of *Noonan syndrome* (Fig. 25–63A). The maxilla was prominent. A broad nasal bridge, hypertelorism, and low hairline somewhat resemble mild *frontonasal malformation*. Dystrophic nails, hypodontia, and multiple buccal frenula were evident. Ophthalmologic examination revealed irregular retinal pigment epithelium and prominent excavation of the optic discs. Inguinal hernia was also documented.

CT and MRI studies of the brain showed numerous small hypodense lesions scattered throughout the cerebral hemispheres, predominantly within the white matter (Fig. 25–63B). The authors suggested that they may have been derived from the normal perivascular spaces of Virchow–Robin.

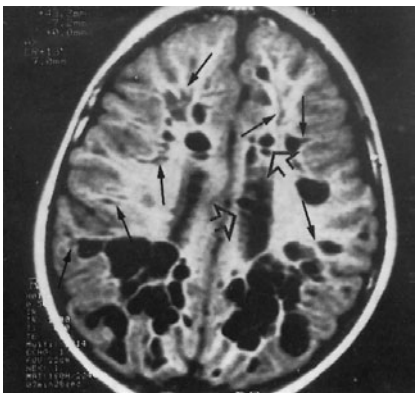
Unusual facies, mental retardation, and intrauterine and postnatal growth retardation (Pitt-Rogers-Danks syndrome, microdeletion 4p16)

Pitt et al (10), in 1984, reported two sibs and two isolated children with intrauterine and postnatal growth retardation and unusual facies. An additional nine cases were reported by a number of authors (1,2,4,6–9,12). In 1996, the syndrome was found to be due to a microdeletion of 4p16 by FISH technique (2,5,6).

Microcephaly is a constant feature as are intrauterine growth retardation, mental retardation (IQ 35–49), and short stature. About 50% have seizures and hyperactivity.

The forehead is high, and usually there is moderate telecanthus. The eyes appear prominent due to maxillary hypoplasia. The nose is usually beaked with a prominent glabella. The columella is low, the philtrum

A



B

Fig. 25–63. *Unusual facies, ectodermal dysplasia, and polycystic brain (dilated Virchow-Robin spaces) (Sener syndrome).* (A) Facies somewhat resembling that of Noonan syndrome. (B) Numerous small hypodense lesions scattered throughout cerebral hemisphere. Arrows point to larger Virchow-Robin spaces. (From RN Sener, Pediatr Radiol 24:116, 1994.)

short, and the mouth always wide. The pinnae are simplified and often outstanding. The corners of the mouth are downturned (Fig. 25–64).

The joints are hyperextensible. Extra palmar or digital creases are very common. Some patients have had a wide space between the hallux and the second toe (6).

There is some resemblance to del(4p) (Wolf–Hirschhorn) syndrome (2,5,6) and overlapping deletions have been demonstrated (11). Pitt–Rogers–Danks syndrome lies just outside the critical region for del(4p) syndrome. It should be pointed out that not all patients with a Pitt–Rogers–Danks phenotype exhibit the microdeletion (4,5,12). In one case, dup(11q) was noted (3).

Partington et al (9) noted overgrowth and mental retardation in duplication of the 4p16.3 area. There were macrocephaly, bushy eyebrows and synophrys, prominent supraorbital ridges, and short nose and philtrum. Height was increased and the hands were enlarged.

Unusual facies, macrocephaly, aplasia of corpus callosum, seizures, hypertrichosis, claw hands, and overlapping fingers

Müller et al (1) described female and male sibs with a distinct syndrome of macrocephaly.

Both sibs exhibited macrocephaly, aplasia of the corpus callosum, septum pellucidum cyst, cavum vergae, hypertrichosis with synophrys, dysplastic pinnae, overlapping digits, transverse palmar creases, widespaced nipples, lack of sucking, swallowing, and vomiting reflexes, hypertonia of limbs, and tonic seizures.

Inheritance is probably autosomal recessive.

Various syndromes such as *Toriello–Carey, Lin–Gettig*, and *FG* were excluded.

Unusual facies, microcephaly, abnormal gyri, contractural arachnodactyly, and glomerulopathy (Galloway-Mowat syndrome)

Galloway and Mowat (2), in 1968, described a syndrome in sibs which consisted of microcephaly, developmental delay, abnormal gyri, glomerulopathy, and contractural arachnodactyly. Other examples have been noted (1,3–5).

Receding forehead, large pinnae, and micrognathia are striking.

Onset of proteinuria often occurs in the first 3 months of life. Various renal changes lead to the development of nephrotic syndrome with marked proteinuria and microscopic hematuria.

Unusual facies, microcephaly, and large ears (Lambotte syndrome)

Verloes et al (2) described four Moroccan Arabic sibs (one had been described earlier in abstract form by Lambotte et al). The sublethal condition included mental retardation, intrauterine growth retardation, hypotonia, microcephaly, hypertelorism, large floppy pinnae, hooked nose, flat face, narrow mouth, small chin, severe neurologic impairment, delayed bone age, wide anterior fontanel, and 13 ribs. Herens et al (1) noted that a subtle translocation which results in 2q trisomy/4p monosomy is responsible for the phenotype.

Multicentric osteolysis with arthritis, short stature, and unusual facies

There are several disorders of multicentric osteolysis which have recessive inheritance. The syndromes of Torg, Thieffry-Kohler, Winchester, and François principally affect the carpal, tarsal, and interphalangeal joints. There is progressive bone loss. The crippling arthritic deformities mimic severe juvenile rheumatoid arthritis. Al-Mayouf et al (2) and Al Aqeel et al (1) collectively described twelve patients from seven unrelated Saudi Arabian families. Similarly affected patients have been reported by others (3–7).

All patients had nodulosis and distal arthropathy. Ten patients presented with deformed hands, and approximately half exhibited pain in the hands.

Radiographically, osteopenia and undertubulation of bones affecting the distal areas more than the proximal areas and the upper limbs more severely than the lower limbs were apparent in all patients. Osteolysis was also seen in carpal and tarsal bones. Other common findings were sclerotic cranial sutures, brachycephaly, and broad medial clavicles. Stature is short. Involvement of the extremities begins in the first few months of life and eventuates in a crippling ankylosis.

Facial changes include high forehead, proptosis, narrow high nasal bridge, flat nasofrontal angle, short nose with bulbous tip, flat philtrum, and micrognathia.

Large painful fibrocollagenous palmar and plantar pads are evident as well as mild hirsutism of the body.

Normal intelligence and normal renal function mark this form of multicentric osteolysis. A dominantly-inherited form with nephropathy has been described (8).

Unusual facies, mental retardation, early balding, patellar subluxation, acromicria, and hypogonadism

Scholte et al (1) noted an isolated male with unusual facies, mental retardation, hypogonadism, small hands, and subluxation of the kneecaps.

His facies was characterized by a narrow cranium, pronounced frontal balding, pale blue irides, upslanting palpebral fissures, thin nose with bulbous tip, and short philtrum with thin upper vermilion. The frontal balding began at puberty.

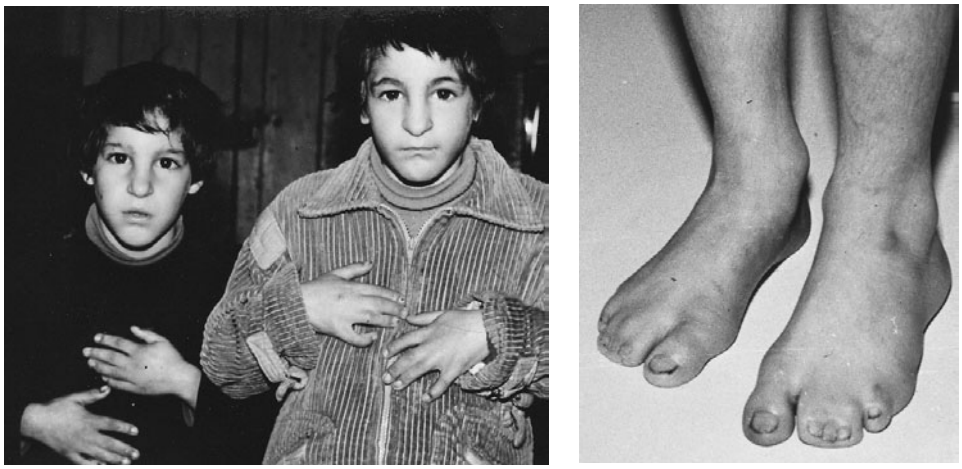
The hands and feet are small. In addition, there is kypholordosis. Flexion of the metacarpophalangeal joints is limited. The proximal interphalangeal joints are hyperextensible. The knee caps frequently subluxate. Pes cavus is evident.

Intelligence is severely retarded. Speech was never attained.

The penis and testes are small.

Reference (Unusual facies, mental retardation, early balding, patellar subluxation, acromicria, and hypogonadism)

1. Scholte FA et al: Unknown syndrome: Mental retardation with dysmorphic features, early balding, patella luxations, acromicria and hypogonadism. J Med Genet 28:140–142, 1991.



A B

Fig. 25–65. *Unusual facies, microcephaly, syndactyly, and growth and mental retardation*. (A) In addition to microcephaly and moderate mental retardation, the sibs have similar facies. Note broad nasal root, lack of alar flare, and syndactyly. (B) Both brothers had syndactyly of fingers 3–4 and toes 2–3–4. (From G Filippi, Am J Med Genet 22:821, 1985.)

Unusual facies, microcephaly, syndactyly, and growth and mental retardation (Filippi syndrome, craniodigital syndrome of Filippi)

Filippi (1), in 1985, reported two male and one female sib with unusual facies, retarded somatic development, severe mental retardation with inability to speak, and syndactyly of the fingers and toes. Additional examples have been described (3,5,8,10). Possible examples are those of Fryer (2) and Orrico and Hayek (6). All had low birthweight. Nearly all have retarded stature (9).

The facies was characterized by microcephaly, high forehead, prominent broad nasal root and diminished alar flare, long philtrum, and thin vermilion. Optic atrophy has also been noted (10) (Fig. 25–65A)

Bilateral syndactyly of fingers 2–3 or 3–4 and toes 2–4 or 2–3, 4–5 is a constant feature. There was clinodactyly of the fifth fingers, single palmar crease, and long great toes (Fig. 25–65B).

Cryptorchidism was a constant feature. Other features have included delayed bone age (1,8), cleft palate (8), and dislocated elbow (3).

Inheritance is clearly autosomal recessive (3,5,10).

Differential diagnosis would include *craniodigital syndrome, blepharo-naso-facial syndrome, Chitayat syndrome* (normal mental development), Kelly syndrome (microcephaly, normal birthweight, digital anomalies, mental retardation) (4), Zerres syndrome (postnatal short stature, microcephaly, dysmorphic face, syndactyly of hands and feet, and mental retardation (11), and Pfeiffer–Kapferer syndrome (synostosis of metacarpals and metatarsals 4–5, sensorineural hearing loss, hypospadias, and mental retardation) (7). Woods et al (10) reported three sibs, offspring of consanguineous Pakistani parents. Growth and head circumference were grossly retarded. Other findings included brachyclinodactyly of fifth toes, 3–4 syndactyly of fingers, single palmar creases, restricted elbow extension, mild spastic paraplegia, and dystonic movements.

Unusual facies, short stature, enamel hypoplasia, stiff joints, and high-pitched voice

Pfeiffer et al (1) reported male and female sibs with short stature, unusual facies, lack of enamel, stiff joints, and high- pitched voice. Gait was stiff and movements slow, characterized as "puppetlike." Intelligence was normal.

The facies was characterized by narrow palpebral fissures, epicanthic folds, and cup-shaped pinnae.

Inheritance is probably autosomal recessive.

Reference (Unusual facies, short stature, enamel hypoplasia, stiff joints, and high-pitched voice)

1. Pfeiffer RA et al: A syndrome of short stature, amimic facies, enamel hypoplasia, slowly progressive stiffness of the joints, and high-pitched voice in two siblings. J Pediatr 91:955–957, 1977.

Unusual facies, short webbed neck, mental retardation, and short stature

There are a number of autosomal recessive Noonan-like syndromes which have various degrees of overlap which we cannot easily separate into distinct conditions. Neuhauser and Opitz (4), in 1975, described three sibs with dysmorphic facies, mental retardation, and congenital heart anomalies that they termed McDonough syndrome. Garcia-Segredo et al (2), in 1984, added two cases. Siblings described by Maximilian et al (3) also exhibited a Noonan-like phenotype.

Al-Gazali et al (1), in 1996, noted four sibs with consanguineous parents who, in addition, had webbed neck and somewhat eczematous skin and dystrophic nail changes. The face was long and the forehead high with hypoplastic supraorbital ridges. The eyebrows were highly arched

with downslanting palpebral fissures. The nose was large. The neck was short and webbed, the chest resembling that of *Noonan syndrome* with pectus excavatum or carinatum and widely spaced nipples. Umbilical hernia was commonly noted. The abdomen was distended. Congenital heart anomalies (ASD, VSD) were found in two of the four children.

Unusual facies, arachnodactyly, and mental retardation

In 1993, de Die-Smulders et al (1) reported two unrelated females with mental retardation, absent speech, microcephaly, long face with flat upper jaw, hypertelorism, divergent strabismus, thin upper lip, and hyperextensible finger joints (Fig. 25–66). Another example was reported by Van Buggenhout et al (3). A similar phenotype was observed in *unusual facies, arachnodactyly, hypogenitalism, and failure to thrive* by Harrod et al (2).

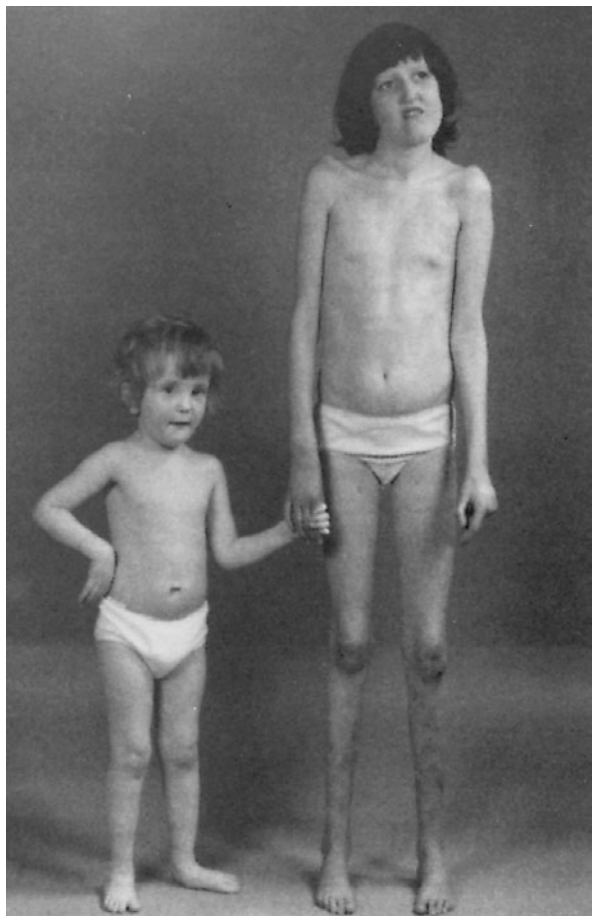

Fig. 25–66. *Unusual facies, arachnodactyly, and mental retardation.* Unrelated females with absent speech, mental retardation, microcephaly, long face with flat upper jaw, thin upper lip, and hyperextensible finger joints. [From C de Die-Smulders et al, Genet Couns 4(2): 165, 1993.]

Unusual facies, preauricular pits, fifth finger clinodactyly, and tetralogy of Fallot (Jones-Waldman syndrome)

Jones and Waldman (1) noted six related individuals.

All had low birthweight but normal postnatal growth.

Frequent facial features included broad forehead, proptosis in infancy, prominent nasal tip, and preauricular pits.

The hands had short or clinodactylous fifth fingers and thenar crease hypoplasia. Two of the four males had cryptorchidism. Three had tetralogy of Fallot.

Schuler et al (2) described a male child with tetralogy of Fallot, somewhat prominent eyes, wide nasal bridge, thin vermilion of upper lip, and cleft palate. We are not convinced that this child had the same condition as that described by Jones and Waldman (1).

Unusual facies, uncombable hair, mental retardation, postaxial polydactyly, phalangeal hypoplasia, and 2–3 toe syndactyly

Kozlowski and Krajewski (1), in 1997, described a syndrome comprising unusual facies, uncombable hair, mental retardation, postaxial manual polydactyly, phalangeal hypoplasia, and 2–3 toe syndactyly.

Height, weight, and head circumference were all below the third centile. The facies was characterized by frontal bossing, hypotelorism, narrow mildly upslanting palpebral fissures, prominent nasal root with narrow bridge, thin lips, micrognathia, outstanding pinnae with prominent anthelix and poorly folded helix, underdeveloped lobule and antitragus. Conductive hearing loss was noted. I.Q. was between 60 and 70. The hair was uncombable. The neck exhibited decreased mobility. There was pectus carinatum, widely spaced nipples, inguinal hernia, dysplastic scrotum, cryptorchidism, and small bowed penis.

The hands were small with short fingers and clinodactyly V. Talipes equinovarus and syndactyly of toes 2–3 were noted. The hallux was large and broad. Radiographically, the phalanges were short, especially the middle phalanges of the hand. The ribs were thin, curved in the posterior part, and obliquely positioned. The sternal ends of the clavicles were widened. The proximal femoral epiphyses were large, the knee epiphyses flattened, and the distal tibia epiphyses wedge shaped. A similarly affected brother died at 4 months. Inheritance is presumably X-linked or autosomal recessive.

Reference (Unusual facies, uncombable hair, mental retardation, postaxial polydactyly, phalangeal hypoplasia, and 2–3 toe syndactyly)

1. Kozlowski K, Krajewska M: Mental retardation, postaxial polydactyly, phalangeal hypoplasia, 2–3 toe syndactyly, unusual face, uncombable hair: New syndrome? Am J Med Genet 68:142–146, 1997.

Unusual facies, trigonobrachycephaly, and hand and foot anomalies

Male and female Kuwaiti sibs with trigonobrachycephaly, narrow forehead, upslanting palpebral fissures, thin eyebrows, long eyelashes, broad nasal root, bulbous nose with mildly bifid tip, thick nasal septum, short philtrum, macrostomia, thin vermilion, and small chin were noted by Teebi et al (1). One had cleft palate.

Other findings included bulbous fingertips, fifth finger clinodactyly, short stature, hypotonia, pectus excavatum, and severe psychomotor retardation.

Inheritance is autosomal recessive.

Reference (Unusual facies, trigonobrachycephaly, and hand and foot anomalies)

1. Teebi AS: Trigonobrachycephaly, bulbous bifid nose, macrostomia, acral anomalies, and hypotonia in sibs: New syndrome. Am J Med Genet 38:529–531, 1991.

Unusual facies, osteochondrodysplasia, and short stature, Brussels type

Mievis et al (1) reported two brothers with extreme intrauterine and postnatal growth retardation, short stature, osteochondrodysplasia, and unusual facies.

The facies is characterized by a relatively large head, small triangular face, frontal bossing, broad forehead with prominent veins, deep-set eyes, narrow palpebral fissures, poorly formed philtrum, wide mouth with thin vermilion, and microretrognathia.

Radiographic changes included delayed bone age, narrow thorax, short iliac bones, unusually-shaped humeral and femoral metaphyses, short broad metacarpals and phalanges, and short fourth metacarpals.

X-linked or autosomal recessive inheritance is possible.

Various short stature disorders including *Silver-Russell syndrome, 3-M syndrome*, and *mulibrey nanism* must be excluded.

Reference (Unusual facies, osteochondrodysplasia, and short stature, Brussels type)

1. Mievis C et al: A new familial short stature syndrome: Brussels type. Clin Dysmorphol 5:9–16, 1996.

Unusual facies, multiple pterygia, hypogonadism, and somatic and mental retardation (Haspeslagh syndrome)

Haspeslagh et al (2) described severe mental retardation, postnatal growth retardation, multiple pterygia with distal muscle wasting, hypogonadism, and unusual facies. Other examples or possible examples are those of Schrander-Stumpel et al (4) and van Bever and Hennekam (5).

De Vriendt et al (1) noted that the syndrome results from an unbalanced reciprocal 6q/9p translocation.

The facies is characterized by trigonocephaly, frontal bossing, hypertelorism, dysmorphic pinnae, and microretrognathia. Two patients had cleft palate (1–3).

Pterygia of the neck and other pterygia, arachnodactyly, camptodactyly, long toes, and scoliosis are other musculoskeletal problems.

Floating-Harbor syndrome (unusual facies, short stature, delayed bone age, and hypoplastic penis)

The name *Floating-Harbor syndrome* is derived from one patient seen at Boston Floating Hospital, and another being reported from Harbor General Hospital.

Pelletier and Feingold (14) and Leisti et al (8,9) independently described males with strikingly similar phenotype. Approximately 20 cases have been reported (1–9,11–15,17). We cannot accept as an example the patient noted by Zabransky (17). Affected sibs have been reported (4).

There is no sex or racial predilection. D Donnai (personal communication, 1989) informed us that paternal age is advanced, suggesting autosomal dominant inheritance. In one family, a mother was stated to be affected as well as her child (7), but we remain skeptical. There has been only one instance of parental consanguinity (15).

Birthweight in 50% and birth length in 70% are below the third centile, and stature in childhood is lower than −4 SD in 95% (5,7). Adult height is 130–140 cm (15). Head circumference is normal.

The face is triangular in about 50%. The eyes, which are prominent in infancy, become deep-set. The nose is outstanding or bulbous with a broad prominent bridge and wide columella. The eyelashes are long and the pinnae posteriorly angulated. Thin upper and lower lips, significantly short philtrum, wide mouth, and short neck with low posterior hairline are evident (Fig. 25–67).

Although motor development is retarded in only 25%, expressive speech delay is marked in 100% (3). Nasal speech and high-pitched voice have been reported (1,13). Mild mental retardation has been noted in about 50% (5).

Skeletal changes include delayed bone age (100%), brachydactyly (50%), clinodactyly V (75%), finger clubbing (45%), and joint laxity (50%). Pseudoarthrosis of the right clavicle has been noted in a few cases (5,7,8,13).

Celiac disease has been found in several patients (1,2,6,15).

Miscellaneous findings have included hirsutism (5,6,13), hypoplastic penis (8,9), high-pitched voice, and supernumerary upper incisor (1).

The facies is somewhat reminiscent of *Shprintzen syndrome* (10,16). One must also exclude *Silver-Russell syndrome, 3-M syndrome*, and *Dubowitz syndrome*.

Unusual facies, renal and Müllerian hypoplasia, and severe somatic and mental retardation

Davee et al (1), in 1992, documented a brother and sister with renal hypoplasia in both, Müllerian hypoplasia in the sister, and severe somatic and mental retardation and seizures. Both had similar craniofacial anomalies (open metopic suture, large anterior fontanel, high forehead, frontal bossing, hypertelorism, strabismus, short nose, low-set posteriorly angulated pinnae, and mild micrognathia). Large flat dimples were found at each elbow and wrist.

Inheritance is probably autosomal recessive.

Reference (Unusual facies, renal and Müllerian hypoplasia, and severe somatic and mental retardation)

Unusual facies, vitiligo, canities, and progressive spastic paraplegia

Lison et al (1) reported three affected sibs, the product of healthy consanguineous Arab parents. There were distinct facies, premature graying, vitiligo, and progressive spastic paraplegia. Mukamel et al (2) described an additional four Arab children.

The cutaneous findings included diffuse lentigines, graying of scalp and body hair, vitiligo, and hyperpigmentation of exposed areas (Fig. 25–68).

Microcephaly and mental retardation were evident in the family described by Mukamel et al (2). The face tended to be small and thin, producing moderately sharp features including pointed nose, small chin, and high cheek bones.

All exhibited decreased tendon reflexes, positive Babinski reflex, foot drop, and spastic gait. Thoracic scoliosis, lumbar lordosis, and loss of muscle mass of the lower limbs were evident (Fig. 25–69).

Inheritance is autosomal recessive.

A B

Fig. 25–68. *Unusual facies, vitiligo, canities, and progressive spastic paraplegia*. (A,B) Premature graying of scalp hair, eyebrows, eyelashes. Note midfacial vitiligo, sharpened features. (From M Lison et al, Am J Med Genet 9:351, 1981.)

Unusual facies-serpentine fibula-polycystic kidney syndrome (ter Haar syndrome)

Exner (2), in 1988, was the first to employ the name serpentine fibula–polycystic kidney syndrome. Earlier examples were classified as autosomal recessive Melnick–Needles patients (1,7). Since then, other examples have been documented (3,5,6,8). Löhr and Wiedemann (4) reported a male with many similar features. R Hennekam has seen another patient of Turkish descent in The Netherlands.

Inheritance is clearly autosomal recessive (6,7). Consanguinity has been found in four of five examples.

Intelligence is normal.

The syndrome is characterized by short stature, coarse hair, hirsutism of forehead and neck, arched heavy eyebrows, congenital glaucoma, hypertelorism, prominent eyes, large cornea, full cheeks, and marked micrognathia. The neck is short and the voice is hoarse (Fig. 25–70). Sensorineural hearing loss has been noted (2,7).

Skeletal changes include wormian bones in lambdoidal sutures, irregular serpentine fibulae, ulnar bowing, curved radius, joint limitation, scoliosis, flared iliac crest, metaphyseal flaring, acroosteolysis, bilateral pes valgus, and metatarsus adductus. Prominent anterior tibiae have been described (2). Other muscular-skeletal findings have been flaring of clavicles, lateral subluxation of talus, pes planus, prominent coccyx with skin fold (3,6), large anterior fontanel, scalloping of anterior surface of anterior vertebrae, and inguinal hernia.

All but one (8) has died at an early age from cardiovascular problems: double outlet right ventricle, VSD, tricuspid insufficiency.

Polycystic kidneys have been documented (2,7).

One must exclude *Melnick–Needles syndrome, megalocornea–mental retardation syndrome type 2*, and *Hajdu–Cheney syndrome*.

Fig. 25–69. *Unusual facies, vitiligo, canities, and progressive spastic paraplegia*. (A,B) Vitiligo, lentigines, mild scoliosis, muscle wasting, and tip-toe gait. (From M Lison et al, Am J Med Genet 9:351, 1981.)

Unusual facies, microcephaly, polycystic kidneys, brachymelia, Potter sequence, and congenital heart anomalies (Gillessen-Kaesbach syndrome)

In 1993, Gillessen-Kaesbach et al (1) reported a new lethal syndrome consisting of polycystic kidney, microbrachycephaly, brachymelia, and congenital heart disease. They described six patients, sibs from three unrelated families.

Inheritance is clearly recessive. Two of the sibships were Turkish with consanguineous parents.

The infants, after full term, have birthweights and lengths 4 SD below the mean Head circumference is even more reduced (−5 SD). All the infants died within the first few hours of life.

Craniofacial changes included microbrachycephaly, prominent forehead, hypertelorism, upslanting palpebral fissures, short beaked nose with wide bridge, cleft palate, flat philtrum, large deeply set posteriorly rotated pinnae, and loose neck skin (Fig. 25–71).

The abdomen was protuberant.

Autopsy showed hypoplastic genitalia, micro- and polycystic spongy kidneys (Potter I type) with smooth surface and ectasia of the collecting tubules, bile duct and pancreatic duct proliferation, and lung hypoplasia.

Loose neck skin, protuberant abdomen, brachymelia, extreme talipes, extreme ulnar deviation of hands, rocker-bottom feet. Note Potter facies. (From G Gillessen-Kaesbach et al, Am J Med Genet 45:511, 1993.)

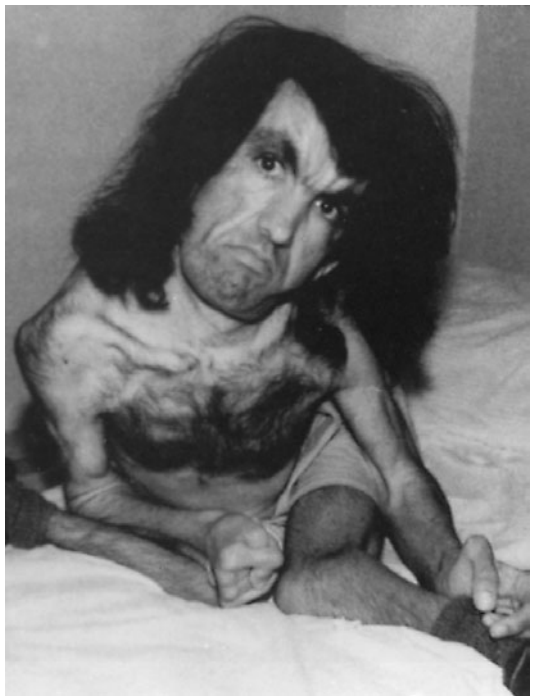

Fig. 25–72. *Unusual facies, musculoskeletal abnormalities and sensory defects*. Ridged triangular skin extends from glabella to anterior fontanel. Elevation of medial eyebrows, widow's peak, and short neck. Marked hirsutism, winged scapulae, kyphoscoliosis, dislocated hips, and joint contractures. (From LT Middleton et al, Am J Med Genet 44:757, 1992.)

Various heart anomalies were found in four of six patients including VSD, dextraposition of aorta, complex heart malformations, and transposition of great vessels.

The extremities exhibited ulnar deviation of the hands, microbrachydactyly, and rocker bottom feet.

Miscellaneous findings included one case each of omphalocele, myelomeningocoele, diaphragmatic hernia, bicornuate uterus, and situs inversus.

All males exhibited cryptorchidism.

Pathologic studies on the brain of one infant showed temporal lobe and cerebellar hypoplasia, irregular gyrations of the cortex, and internal hydrocephalus.

One should exclude other syndromes or association of Potter sequence, especially *Holzgreve–Wagner–Rehder syndrome* and *Thomas syndrome*.

Unusual facies, musculoskeletal abnormalities, and sensory defects

Middleton et al (1) described a syndrome of unusual facies, musculoskeletal abnormalities, and sensory defects in three generations of a Greek Cypriot family (Fig. 25–72).

The facies is striking. There is a thickened, ridged triangular skin fold extending from the glabella to the anterior fontanel, elevation of medial eyebrows, widow's peak, low hair line, hypertelorism, exotropia, ptosis, and short neck. Hirsutism is marked. Cataracts were noted in a few members of the family.

Musculoskeletal anomalies included winged scapulae, kyphoscoliosis, dislocated hips, talipes, wasting of muscles in both arms and legs, and joint contractures.

Inheritance is autosomal dominant with very variable expressivity.

1. Middleton LT et al: New hereditary malformation syndrome of unusual facial appearance, skeletal deformities, and musculoskeletal and sensory defects. Am J Med Genet 44:757–761, 1992.

Unusual facies, polysyndactyly of fingers and toes, and congenital heart disease

Bonneau et al (1), in 1983, reported three affected sibs. The polysyndactyly involved digits 3–4 leading to a mitten-shaped hand. In the feet, the hallux was duplicated. Complex cyanotic congenital heart disease with AV septal defects led to death. The nose was bulbous. A similar condition in sibs was found in Oman (2).

Fig. 25–73. *Unusual facies, oligodontia, and precocious choroid calcifications*. Identical twin daughters with inner telecanthus, downslanting palpebral fissures, flat nasal bridge, small nose with anteverted nares. (From R Pallotta and P Fusilli, J Med Genet 35:435, 1998.)

Unusual facies, oligodontia, and precocious choroid calcifications

Pallotta and Fusilli (1), in 1998, reported a mother and her identical twin daughters.

The facies was characterized by inner telecanthus, downslanting palpebral fissures, mild ocular proptosis, wide flat nasal bridge, small nose with anteverted nares, hypoplastic nasal septum, and full lips (Fig. 25–73).

Other concordant findings included pectus carinatum, clinodactyly of fifth fingers, hypoplastic distal second toes, hypoplastic sphenoid, and bilateral choroid plexus calcification.

All permanent teeth were missing save those of the maxillary central incisors and first maxillary and mandibular molars (Fig. 25–74). The deciduous precursors were not shed.

Reference (Unusual facies, oligodontia, and precocious choroid calcifications)

1. Pallotta R, Fusilli P: Unknown syndrome: Peculiar face, severe hypodontia of permanent teeth, and precocious choroid calcifications. J Med Genet 35:435–437, 1998.

Unusual facies, myelodysplasia, and immunodeficiency

Stoll et al (1) described three siblings born to first cousin parents. These sibs had neutropenia, immunodeficiency, steatorrhea, short stature, microcephaly, mild mental retardation, and characteristic facial appearance. The facial phenotype consisted of prominent forehead, narrow palpebral fissures, depressed nasal bridge, large nose, thick lips, and prominent chin. Two children also had cardiac defects and two had vesicoureteral reflux. One developed leukemia at age 14 years.

Unusual facies, Müllerian hypoplasia, and limb anomalies (Al-Awadi–Raas-Rothschild syndrome)

Al-Awadi et al (1), studying an inbred Jordanian Arab kindred, reported male and female sibs with unusual facies, limb anomalies, thoracic dysplasia, and normal intelligence. Similar examples have been found in Bedouins (3), Brazilians (5), Italians (2), and Iranian Jews (4).

The face is long with a broad nasal bridge that is almost as wide as the alae. The pinnae are dysplastic. The chin is pointed. The chest is barrel

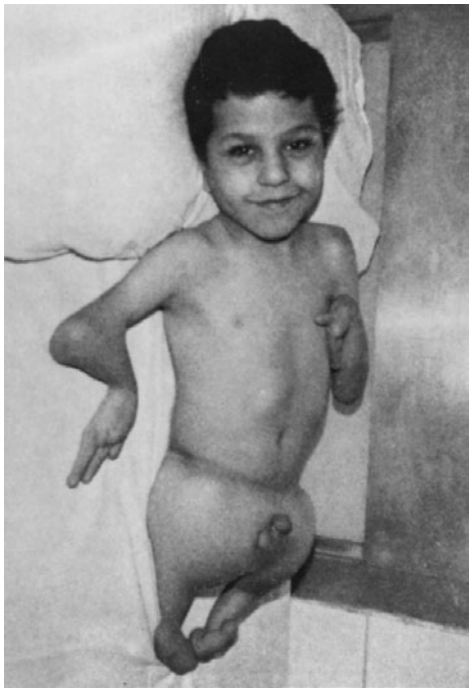

Fig. 25–76. *Unusual facies, Müllerian hypoplasia, and limb anomalies (Al-Awadi–Raas-Rothschild syndrome)*. Note absence of joints at elbows, short radii, absent ulnae. Malformed pelvis with one lower limb bone and reduced number of rays in feet. (From SA Al-Awadi et al, J Med Genet 22:36, 1985.)

shaped with prominent sternum. There are no joints at the elbows, but a contraction is evident. The radii are short, the ulnae absent. The hands have three or four digits, the fifth and/or fourth rays being missing. Some carpal bones are fused. The nails are vestigial. The pelvis is malformed with one lower limb bone and one tarsal bone. The feet have only two rays (Fig. 25–76).

The genitalia are displaced, the testes undescended. The anal pit is deep. The uterus is absent in females (1).

Inheritance is autosomal recessive (1-5).

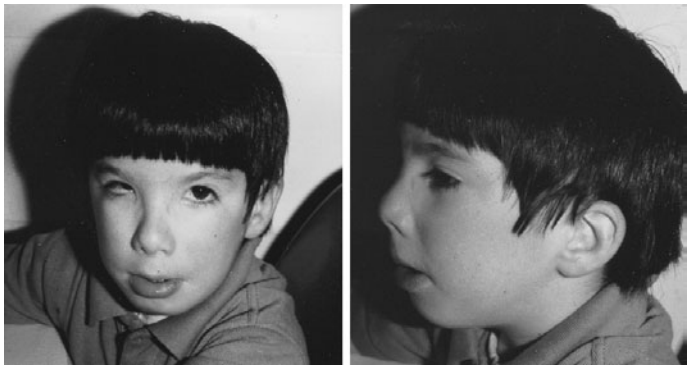
Unusual facies, hepatic fibrosis, renal cysts, and mental retardation

Hunter et al (1), in 1974, and Thompson and Baraitser (3), in 1986, described affected sibs with a syndrome of unusual facies, hepatic fibrosis,



A B

Fig. 25–77. *Unusual facies, hepatic fibrosis, renal cysts, and mental retardation*. (A,B) Note ptosis, marked strabismus, anteverted nares, everted lower lip. (Courtesy of P Labrune, Paris, France.)

renal anomalies, and mental retardation. Labrune et al (2) added another example.

The renal anomalies included cortical cysts, medullary cystic dilatation, and enlarged kidneys.

The facies was characterized by strabismus, nystagmus, ptosis, anteverted nares, and drooping mouth (Fig. 25–77). Ocular coloboma was found in two sibs (1).

Unusual facies, sparse hair, and mental retardation

Nicolaides and Baraitser (2) and Krajewska-Walasek et al (1) described patients with mild mental retardation, postnatal growth retardation, advanced bone age, sparse scalp hair, somewhat coarse facies, deeply-set eyes, narrow palpebral fissures, upturned nose with thick nares, prominent lower lip, brachydactyly, swelling of interphalangeal joints, and drumstick fingers.

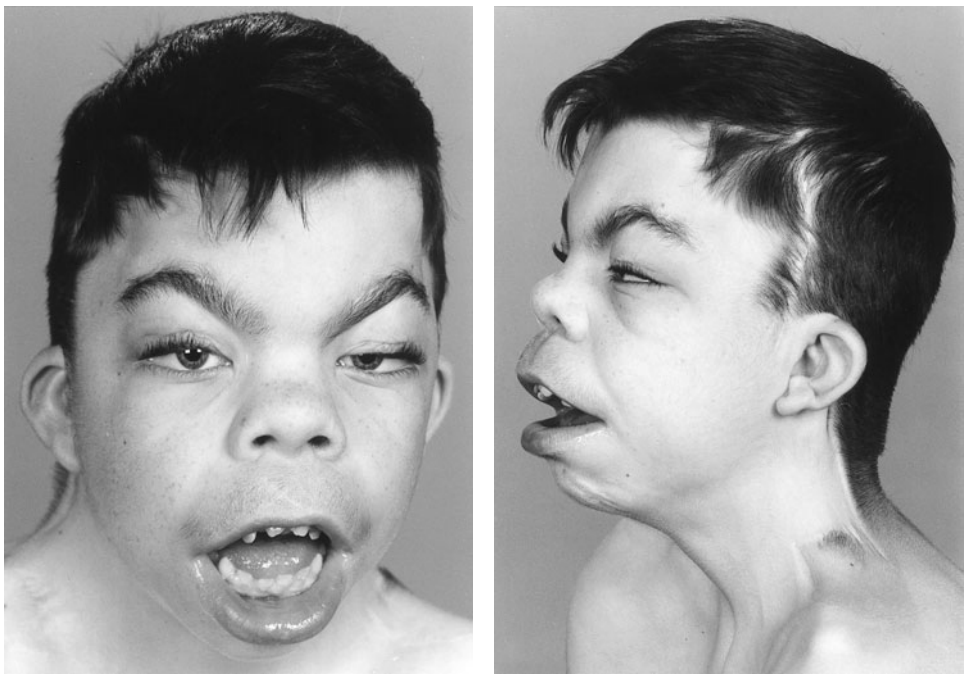
Unusual facies, broad webbed neck, inverted nipples, epilepsy, and pachygyria of frontal lobes (cerebro-fronto-facial syndrome)

Fryns and Aftimos (2), in 2000, described two unrelated boys with postnatal weight loss, short stature, unusual facies, broad webbed neck, broad thorax, hypoplastic and inverted nipples, seizures, and pachygyria of frontal lobes. Similarly affected patients were noted by der Kaloustian et al (1) and Guion-Almeida and Richieri-Costa (3). The latter child, a girl, also exhibited callosal agenesis, cleft lip/palate, grooved chin, and bifid thumbs. Winter (4) avers there is heterogeneity.

Microcephaly, trigonocephaly, facial edema, ptosis of upper eyelids, temporal flattening, posteriorly rotated pinnae with hypoplastic anthelix, broad nasal root, arched shaggy eyebrows, hypertelorism, long flat philtrum, and large mouth with thin upper lip and everted lower lip, at times with a central groove, were seen (Fig. 25–78). The upper dental incisors were prominent. The posterior hair line was low. The shoulders were downslanting. The hands were broad and short with permanent edema of the dorsum and tapering fingers. Extension deficit of the knees and elbows was evident. Hypertonia of the lower limbs resulted in toe walking. Scoliosis has been noted.



A B

Fig. 25–78. *Unusual facies, broad webbed neck, inverted nipples, epilepsy, and pachygyria of frontal lobes*. (A) Highly arched bushy eyebrows, broad nasal root, short upturned nostrils, low-set and posteriorly-rotated auricles, somewhat widened palpebral fissures. (B) Broad, flat philtrum, large mouth, thin upper lip, everted lower lip, pterygium colli. The child had poorly controlled seizures and inverted nipples. (Courtesy of V Der Kaloustian et al, Montreal, Quebec, Canada.)

The skin of the arms was especially loose and hyperextensible. Axillary pterygia were present in one case (1). The testes were undescended, and the scrotum was shallow.

Seizures of grand mal, petit mal, and myoclonic type began at about 3 to 5 years. Psychomotor retardation, at first mild, became more marked with age and following onset of seizures. Diffuse pachygyria, especially marked in the frontal area, was found on MRI. Mild spastic paraparesis appeared at about 6 years.

Vesicouteral reflux with hydronephrosis was observed (1,2) as well as inguinal herniae (1).

Such conditions as *frontonasal malformation* and *acrofrontofacionasal dysostosis* must be excluded.

Chapter 26
Syndromes with Gingival/Periodontal Components

Gingival fibromatosis and its syndromes

Gingival fibromatosis may exist as an isolated abnormality due to genetic or environmental causes or as part of a syndrome (19,25,40). As an isolated finding, it is often sporadic but may exhibit autosomal dominant inheritance (34,37) or rarely autosomal recessive inheritance (21,25,35,37). There appear to be two genes on chromosome 2, one in the 2p21→p22 region and the other at 2p13–p16, that can be mutated (20,23,23a,36).

Generalized gingival enlargement may occur as a result of inflammation, pregnancy, leukemia, *I-cell disease* and as a response to various medications [phenytoin (Dilantin), diltiazem, cyclosporin A, verapamil, and nifedipine] (6,8,30). In these disorders, the gingiva is usually not as enlarged or as fibrotic as in gingival fibromatosis where it may be so severe that the affected individual may appear to have no teeth. History and physical examination will serve to distinguish these disorders from gingival fibromatosis. Gingival fibromatosis with hypertrichosis is the most common of the syndromes.

Hirsutism may result from many causes (29). There are various forms of regional hypertrichosis with dominant and recessive patterns: hairy elbows (11–13), elbows and knees (11), and anterior neck with or without neuropathy and hallux valgus (7). Acquired lanuginous hypertrichosis may be associated with endocrine or metabolic disturbances or rarely may be a sign of internal malignancy (24).

Extreme hypertrichosis (hypertrichosis universalis congenita) may represent a heterogeneity. Some examples may have association with anodontia or oligodontia, manifesting X-linked dominant inheritance (4,18,27,31,33). Baumeister et al (3) proposed a subgroup, known as *Ambras syndrome*, characterized by abnormal hair distribution (forehead, eyelids, nose, cheeks, preauricular region and external auditory canals as well as the rest of the body, except for the palms and soles). The hair may grow to several decimeters if not cut. Baumeister (2) noted that the facial hair of the patient reported by Balducci et al (1) was not uniformly distributed. It was principally located on the face and in the frontal, temporal, and preauricular regions, the nose and ears being largely spared. Hence, he categorized the case of Balducci et al (1) as hypertrichosis universalis congenita. Since they both map to 8q22 (1,3), we doubt that the clinical variation is based on different disorders. Early examples have been elegantly illustrated by Baumeister et al (2) and Nowakowski and Scholz (31). The hair has been so profuse that some individuals have been exhibited in carnivals (9,15,17,38) (Fig. 26–1). With rare exceptions, Juliana Pastrana and a few others (5,16,26,28), these persons have not had gingival enlargement. Pastrana had congenital generalized hypertrichosis terminalis and four normal but unerupted teeth, according to Bondeson and Miles (5).

The pathogenesis of gingival fibromatosis is unknown, but the fibroblasts appear to have abnormal cellular properties (36) and there is altered postranslational modification of collagen (32). Occasionally calcifications or marked fibroblastic activity in the gingiva are found (14,16,31).

Gingival fibromatosis has been reported with prune belly, but we suspect that the association is aleatory (22). Wiedemann et al (39) reported an unusual syndrome of *hirsutism, mental retardation, skeletal abnormalities, and uric acid dysmetabolism*.

Fig. 26–1. *Hypertrichosis universalis congenita* or *Ambras syndrome*. Total face covered by lanugolike hair. (From IJ Lee et al, Pediatr Dermatol 10:263, 1993.)

Gingival fibromatosis, hypertrichosis, epilepsy, and mental retardation

This is the most commonly reported syndrome in which gingival fibromatosis is but one of the manifestations of a single gene mutation. The hypertrichosis is usually generalized, involving the eyebrows, face, ears, extremities, and sacral areas (12,13) (Fig. 26–2). Epilepsy and mental retardation are variable features. The binary combination of gingival enlargement and hypertrichosis (5,8,9,12–14,17,21–23) is probably much less common than is isolated gingival fibromatosis. The syndrome appears to have autosomal dominant inheritance (5,21,23). Two proximate genes have been mapped to 2p21 (6,7,15,24).

Associated mental retardation and/or epilepsy have been noted in some cases (1–3,6a,16,18,19,23). It is likely that this combination has genetic heterogeneity, some examples possibly having autosomal recessive inheritance (1,6a,9). Other possible aleatory skeletal alterations, such as narrow second cervical vertebra, long odontoid process, and abnormal first ribs, were described by Anderson et al (2). The gingival enlargement usually occurs at less than 5 years of age (18).

Affected female children of first cousin parents were described with gingival fibromatosis, hirsutism, mental retardation, and brachymetacarpalia (6a).

An unusual case reported by Vontobel (19) cannot be classified. Features included acromegaloid features, marked hypertrichosis, hyperconvex nails, and gingival fibromatosis. Nevin et al (11) reported male and female sibs with gingival fibromatosis, epilepsy, mental retardation, and bilateral camptodactyly of the third, fourth, and fifth fingers. Hypertrichosis was specifically denied. Inheritance was presumed autosomal recessive. Another unusual case described by Cohen et al (4) concerns a child with hirsutism, gingival fibromatosis, prominent frontal bone, soft alar and auricular cartilages, unilateral axillary pterygium, hepatomegaly, broad ribs, and metacarpal alterations. Intelligence was normal as were fingers and toes, and there was no seizure activity.

The reader is referred to the discussion of Ambras syndrome in the section above and in Chapter 13.

Gingival fibromatosis with juvenile hyaline fibromatosis (Murray-Puretić-Drescher syndrome)

This condition, first reported by Murray (22), in 1873, is characterized by multiple hyaline fibromas, white papules on the skin, flexion contractures, osteolytic bone lesions, and gingival fibromatosis (6,22,25,34). Affected sibs born to normal parents (50%) and parental consanguinity in at least 30% (6,8,13,16,18,22,23,29,30,36,37) indicate that inheritance is autosomal recessive. At least 40 patients have been described (11,28).

Skin. Multiple painless, freely movable, subcutaneous hyaline, fibrous tumors of the scalp, face, chin, ears, back, digits, thighs, and legs appear between 2 months and 4 years of age (31). They slowly enlarge, sometimes to the size of a small orange, and may ulcerate (6,15). Perianal lesions have also been noted (3,10,13,18–20). With puberty, masses may regress, and the number of new tumors decrease (Fig. 26–3A–C). There appears to be a marked tendency to suppurative infections of the skin and mucous membranes (25). The skin undergoes poikilodermatous and sclerodermatous changes. In addition, white papules are found on the neck, pinnae, nose, nasal septum, upper lip, and behind the ears (9,13, 16,30). The same material has been found in the tongue, esophagus, stomach, intestine, spleen, thymus, and lymph nodes (31).

On light microscopic examination, the tumors contain a homogeneous, amorphous, eosinophilic, PAS-positive ground substance that is sometimes chondroid in appearance (6,16,30,35). Spindle-shaped fibroblasts are present in this matrix in a streaklike pattern. The proportion of cells to ground substance varies from one tumor to another. Between the cells, argyrophilic fibers are sometimes found (Fig. 26–3H). Collagen fibers are thicker than normal. Ultrastructural studies have indicated excessive proliferation of fibroblasts, their organelles, and secretory products (16,20,30,35). Abnormalities in the Golgi apparatus have also been found (27,35). Ishikawa and co-workers (15,16) and Iwata et al (17) found an increased amount of chondroitin-6-sulfate in these tumors. Electrophoretically, it has been shown that an increased amount of acid mucopolysaccharides such as hyaluronic acid and dermatan sulfate is present in the urine (27,31).

Musculoskeletal. Painful progressive flexion contractures of the knees, elbows, hips, ankles, and shoulders appear within the first year of life in 75% (13,15,19,20,25,27). The temporomandibular joint may

also be affected (13). Contractures were absent in a few patients (26,32). Digital tumors, osteolysis of the terminal phalanges (2,13,27,30,31), and small cystic lesions of long bones, phalanges, and scapulae (9,28) have been noted in over 65% of the patients, as well as generalized osteoporosis and thoracolumbar scoliosis (25) (Fig. 26–3D,G). These lesions progress throughout life (4,9,26). Height and weight are reduced, and skeletal and sexual maturation are delayed (18).

Psychomotor development. Mental development is normal (9,13, 15,19,20,22,27).

Oral findings. Generalized gingival enlargement begins during the first year or so of life (8) and can extend onto the occlusal surfaces of the teeth (22) (Fig. 26–3E,F). Gingival biopsy has demonstrated findings similar to those of the skin (9). Patients with juvenile hyaline fibromas who do not have gingival enlargement (26,32) have been reported. The patient observed by Woyke et al (36) had skin lesions and gingival hyperplasia, but no flexion contractures.

Differential diagnosis includes *infantile systemic hyalinosis* (21), *neurofibromatosis*, and *Winchester syndrome* (7).

Infantile systemic hyalinosis, a disorder of collagen, is an autosomal recessive disorder which presents in infancy with hard diffusely thickened skin, persistent diarrhea, recurrent severe infections, and failure to thrive. Patients also have painful limitation of joints, hypoproteinemia, and papular lesions of the face, mouth, and abdomen. Life expectancy is less than 20 months. There is striking histologic similarity to juvenile hyaline fibromatosis (21). Type VI collagen accumulates in the tissues. It is possible that the infantile and juvenile forms of hyaline fibromatosis are allelic (5,12). *Winchester syndrome* lacks hyaline matrix.

Gingival fibromatosis and corneal dystrophy (Rutherfurd syndrome)

Relatively mild gingival enlargement, failure of tooth eruption, and corneal opacities were described in three generations as an autosomal dominant syndrome by Rutherfurd (2). This family was followed up and reported on again in 1966 by Houston and Shotts (1), who described the corneal opacities as curtainlike, involving the superior part of the cornea (Fig. 26–4). Although mental retardation and aggressive behavior have been noted, it is not certain whether these abnormalities are manifestations of the syndrome or are segregating independently.

Gingival fibromatosis; ear, nose, bone, and nail defects; and hepatosplenomegaly (Laband syndrome, Zimmermann-Laband syndrome)

Zimmermann (20), in 1928, and Laband et al (12), in 1964, described gingival fibromatosis manifested at birth or within the first few months of life, abnormalities of the nose and ears, and striking hypoplastic changes in the terminal phalanges of the fingers and toes. Although most are isolated examples, the syndrome has autosomal dominant inheritance (1,12). However, male and female sibs, the offspring of consanguineous parents, have been reported (2). Henefer and Kay (7) reported a patient with gingival fibromatosis and nasal and ear abnormalities, but the hands and feet were not described. Lacombe et al (13) noted the overlap with *gingival fibromatosis, hypertrichosis, epilepsy, and mental retardation*. About 35 patients have been described (1–15,17–20). We are not convinced that the patient reported by Pfeiffer et al (16) has the syndrome.

Facies. Mild hirsutism in the form of synophrys, hairy arms, back, and legs, thick eyebrows, and increased sacral hair has been noted (9,10,15,17,20) (Fig. 26–5A). Severe hirsutism was noted by Lacombe et al (13).

Skeletal alterations. The thumb nails are hypoplastic or absent. The nails and terminal phalanges on the fingers are usually rudimentary or missing. In most cases, all toes lack terminal phalanges; the first and second toes often have only one phalanx each (9,12,20). Toenails are usually absent (Fig. 26–5B). Pes cavus was noted in about half the kindred described by Laband et al (12). Joint hypermobility, especially involving the metacarpophalangeal, shoulder, and knee joints (1,12), is common. Spina bifida occulta of the fifth lumbar vertebra was described in a few cases (9,20). The third thoracic vertebra has been reported to be divided sagittally into two segments, with the fourth thoracic vertebra flattened (9).

Hepatosplenomegaly. Hepatomegaly (1,15) and splenomegaly (12) have been noted. Laband et al (12) suggested that splenomegaly might become more marked with age. On the other hand, enlargement of the liver and spleen has been specifically denied (15,20).

Other findings. Mental retardation has been reported in several cases (5,6,12,15,17–20). Seizures have also been documented (17) as has retinitis pigmentosa (11).

Oral manifestations. Gingival fibromatosis is a constant feature (Fig. 26–5C).

Gingival fibromatosis and sensorineural hearing loss (Jones syndrome)

Jones et al (4), in 1977, Hartsfield et al (3), in 1985, and Wynne et al (6), in 1995, reported autosomal dominant inheritance of generalized gingival fibromatosis and sensorineural hearing loss. Jorgenson and Crocker (5) described a family with gingival fibromatosis, hearing deficiency, and allergy.

Dental eruption was described as delayed in one family (1), with the first primary tooth erupting at 13 months in the proband. Eruption of permanent teeth was delayed as well. The proband in another family (3) had only eight permanent teeth at 12 years. The gingivae were described as hypertrophied, with stippled and nodular areas (Fig. 26–6).

In two of five patients, Wynne et al (6) noted supernumerary teeth.

Hearing loss became evident in the second decade. Audiometric testing revealed a sloping, moderate (30–70 dB) sensorineural hearing loss, which was greater for the higher frequencies. This loss was usually bilateral but varied between ears.

A gene for sensorineural hearing loss (1) and one for gingival fibromatosis (2) have been mapped to chromosome 2p21–p22. Could this represent a contiguous gene syndrome?

Gingival fibromatosis, hearing loss, and supernumerary teeth

Wynne et al (1), in 1995, described three generations of a family in which affected members had gingival overgrowth (onset at the time of deciduous tooth eruption). Hearing loss, supernumerary teeth, and hypertelorism were present in some affected family members. There are some similarities to *Jones syndrome* (gingival enlargement with hearing loss), but Wynne et al believe this is distinct.

Reference (Gingival fibromatosis, hearing loss, and supernumerary teeth)

1. Wynne SE et al: Hereditary gingival fibromatosis associated with hearing loss and supernumerary teeth—a new syndrome. J Periodontol 66:75–79, 1995.

Gingival fibromatosis, hypertrichosis, cherubism, mental and somatic retardation, and epilepsy (Ramon syndrome)

Ramon et al (4), in 1967, and de Pina-Neto et al (1), in 1986, reported sibs in two different families with gingival fibromatosis, hypertrichosis, cherubism, mental retardation, and seizures. In the first kindred, two sibs were involved; in the latter, four sibs and their second cousin. Sibs were described by Pridmore et al (3).

Progressively cherubic facies associated with bony changes characteristic of cherubism (bilateral multilocular radiolucent lesions of the mandible and maxilla) became evident after the fourth year.

The gingival enlargement has been a constant feature. It becomes manifest at 2 years of age, is slowly progressive, and ultimately prevents normal jaw closure (Fig. 26–7). Tooth eruption is considerably delayed and incomplete. In most cases, the incisors and canines erupt. The palate tends to be narrow. Gingival biopsy showed a peculiar perivascular pattern of collagen fibers that compress the blood vessels (3).

Pigmentary retinopathy was noted on follow-up (2).

Mild to moderate mental retardation became evident during the first few years of life. By the fourth year, all patients experienced major seizures. Stunted growth was evident in nearly all the affected. Hearing loss was found in two sibs (3).

Fig. 26–7. *Gingival fibromatosis, hypertrichosis, cherubism, mental and somatic retardation, and epilepsy (Ramon syndrome)*. Combination of cherubism and gingival fibromatosis. (From JM de Pina Neto et al, Am J Med Genet 25:433, 1986.)

Hypertrichosis was present in about 50%. de Pina-Neto et al (1) suggested that juvenile rheumatoid arthritis might also be a component of the disorder. It is entirely possible that this actually represents polyarticular pigmented villonodular synovitis (vide infra). Telangiectasia and angiokeratoma of the soles were documented (3). Giant hypertrophy of the labia minora has also been noted (2).

Affected sibs with normal but consanguineous parents certainly suggest autosomal recessive inheritance (1,4).

It should be pointed out that cherubism has also been found in association with *neurofibromatosis, Noonan syndrome*, and *Noonan-like syndrome with polyarticular pigmented villonodular synovitis*. Perhaps we are really dealing with a contiguous gene deletion syndrome.

Gingival fibromatosis and unusual facies

Goldblatt and Singer (1) reported male and female sibs with gingival fibromatosis and unusual facies characterized by macrocephaly, bushy eyebrows, hypertelorism, downslanting palpebral fissures, hypoplastic nasal alae, and cupid bow mouth. An isolated example was reported to one of us (RJG) in March 1998 by A. Lin.

Gingival fibromatosis and growth hormone deficiency

Oikarinen et al (1) described five of eight children with gingival fibromatosis in association with growth hormone deficiency due to lack of growth hormone release factor.

Inheritance appears to be autosomal recessive.

Reference (Gingival fibromatosis and growth hormone deficiency)

Hyperkeratosis palmoplantaris and periodontoclasia in childhood (Papillon-Lefèvre syndrome and Haim-Munk syndrome)

Papillon and Lefèvre (35), in 1924, described a syndrome consisting of hyperkeratosis of palms and soles and destruction of the supporting tissues of both primary and secondary dentitions. Over 250 cases have subsequently been described. Comprehensive surveys are those of Haneke (22), Hart and Shapira (23), and Hattab et al (28).

The syndrome has autosomal recessive inheritance. Parental consanguinity has been found in about 40% (8,14,21,32). The frequency of the disorder is approximately 1/4,000,000 (17). The disorder has high frequency in Saudi Arabia. The gene has been mapped to chromosome 11q14 (13,24,30) and represents mutations in the lysosomal protease, cathepsin C gene (22a,25,46). Cathepsin C is an enzyme which processes and activates several serine proteases critical to immune and inflammatory responses of myeloid and lymphoid cells. A founder effect has been noted (49).

For a discussion of Haim–Munk syndrome, see *Differential diagnosis*.

Skin. Sometime between the second and fourth years of life, or on rare occasions even earlier, the palms and soles become diffusely red and scaly. The hyperkeratotic involvement of the palms is usually quite well demarcated, extending to the edges and over thenar eminences and to the volar wrists. The soles are usually more severely involved, the process frequently spilling over the edges, where it may be marked, extending to the Achilles tendon (Fig. 26–8). Occasionally, the knees, elbows, external malleoli, tibial tuberosities, and dorsal finger and toe joints may exhibit a psoriasiform scaly redness (3,32). Thickening of plantar skin with resultant cracking may make walking difficult. The degree of hyperkeratosis is not severe, but normal skin markings become accentuated and involved skin may assume a parchmentlike quality. The degree of involvement seems to fluctuate, possibly becoming worse during winter. The skin apparently improves somewhat with age but some degree of palmoplantar hyperkeratosis remains throughout life. Nails are rarely, if ever, involved. Relapsing pyoderma is seen in 20% (14).

Other findings. Calcium deposits in the attachment of the tentorium and choroid plexus (17,37,40) have been reported, but possibly this finding is aleatory.

Increased susceptibility to infection with *A. actinomycetemcomitans* has been suggested, but its specificity is dubious (2,7,21,22,29) because

Fig. 26–8. *Hyperkeratosis palmoplantaris and periodontoclasia in childhood (Papillon-Lefèvre syndrome)*. (A–C) Sharply demarcated hyperkeratosis of hands and feet. (C from RK Hall, Aust Dent J 9:185, 1963.)

the same finding may occur in juvenile periodontitis (18) (see below). There is a 12% risk for liver abscess (34).

Oral manifestations. The development and eruption of the deciduous teeth proceed normally, but almost simultaneously with the appearance of palmar and plantar hyperkeratosis, the gingiva swell, bleed, and become boggy. Marked halitosis develops. Destruction of the periodontium follows almost immediately the eruption of the last primary molar tooth. The teeth are involved in roughly the same order in which they erupt. Deep periodontal pocket formation precedes the exfoliation of teeth. By the age of 4 years, nearly all primary teeth are lost. After exfoliation, the inflammation subsides and the gingiva resumes its normal appearance. The mouth then appears normal until the secondary (permanent) dentition erupts, when the process is repeated in essentially the same manner. Most teeth are lost by 14 years. In some cases, the third molars do not exfoliate. The alveolar process is often completely destroyed. Even during active periodontal breakdown, the rest of the oral tissues appears perfectly normal (Fig. 26–9).

Differential diagnosis. All disorders of diffuse palmoplantar hyperkeratosis must be excluded. However, none but Papillon–Lefèvre syndrome is associated with premature periodontal destruction with the exception of Haim–Munk syndrome (see below).

Haim and Munk (20) and others (1,19,39,40,43,47) reported an unusual syndrome in several members of three related, inbred Jewish families from Cochin, India. They exhibit congenital palmoplantar keratosis, progressive periodontal destruction, pes planus, recurrent pyogenic skin infections, arachnodactyly with tapered pointed phalangeal ends and a clawlike volar curve (Fig. 26–10). In contrast to Papillon–Lefèvre syndrome, the skin manifestations were more severe and extensive and had later onset. The periodontium also was less severely affected. It was shown in 2000 to be due to an allelic mutation (26) as was juvenile periodontitis (27).

Premature loss of deciduous and/or permanent teeth is seen in trauma, acrodynia, histiocytosis X, *hypophosphatasia*, leukemia, various neutropenias, acatalasia, Chediak–Higashi syndrome, and juvenile periodontitis (15,16,31) (see above). The defect in Chediak-Higashi syndrome appears to be due to mutations in cathepsin G (46).

Hypophosphatasia, a condition transmitted as an autosomal recessive trait because of a deficiency in alkaline phosphatase, may be associated with a ricketslike condition. In addition to genua valga, bowing of the femora and tibiae, enlarged wrists, and other signs, the teeth are prematurely shed, are often hypoplastic, and are deficient in cementum. There is no gingival inflammation. Increased amounts of phosphoethanolamine are present in the urine.

Acatalasia is transmitted as an autosomal recessive trait and rarely has been observed outside Japan or Korea. It is characterized by progressive gangrenous lesions involving the gingiva and alveolar bone, resulting in exfoliation of teeth (38).

Hyperkeratosis palmaris has been seen in binary association with a host of other disorders (15,17). It may also occur in the syndrome of *hyperkeratosis palmoplantaris and attached gingival hyperkeratosis*.

Autosomal dominantly inherited palmoplantar hyperkeratosis has been associated with short stature, unusual facies, hearing loss, seizures, clinodactyly, dysplastic nails, and oligodontia (42).

Brown et al (4) and Bullon et al (5) reported a late-onset (fourth decade) variant of Papillon-Lefèvre syndrome.

Laboratory aids. Various immunologic defects have been reported. These have included impaired in vitro reactivity to T and B cell mitogens

Fig. 26–10. *Hyperkeratosis palmoplantaris and periodontoclasia in childhood (Haim-Munk syndrome).* (A,B) Severe hyperkeratosis of hands with arachnodactyly. Note tapered pointed terminal phalanges exhibiting clawlike volar curve. (From S Haim and J Munk, Br J Dermatol 77:42, 1965.)

(30,48), a neutrophil chemotactic defect, altered phagocytosis, and reduced intracellular killing of *S. aureus* and *C. albicans* (7,10,11,13). Lymphocyte subset and monocyte function abnormalities have also been described (10,11,13,22,38). However, others have not found defective function (6,41,45).

Palmoplantar hyperkeratosis, atrichia, mental retardation, and premature loss of teeth

Steijlen et al (1) described four affected sibs (three female, one male) among seven children of unrelated parents.

The atrichia was congenital and generalized. Palmoplantar hyperkeratosis became apparent by 11/2–2 years. It extended to the dorsal surface of the hands. The achilles tendon area was similarly affected. All had keratosis pilaris. Teeth were lost early but were removed because of a dysplastic defect of unknown nature.

Retardation was moderate to severe.

Inheritance is probably autosomal recessive.

An extensive differential diagnosis was presented by the authors but none fit. Also see *atrichia, somatic and mental retardation, and skeletal anomalies.*

Reference (Palmoplantar hyperkeratosis, atrichia, mental retardation, and premature loss of teeth)

Hyperkeratosis palmoplantaris and attached gingival hyperkeratosis

Fred et al (1), in 1964, reported a kindred with hyperkeratosis palmoplantaris and attached gingival hyperkeratosis. In 1974, while visiting

Fig. 26–11. *Hyperkeratosis palmoplantaris and attached gingival hyperkeratosis*. Focal hyperkeratoses of palms.

Athens, Greece, RJ Gorlin had the opportunity to see another family with the same disorder (5). Other families have been reported (3,4,6,11). Another possible kindred has been noted by Roth et al (8).

Autosomal dominant inheritance is indicated by transmission of the disorder through several generations (1,3–5,11). There was male-to-male transmission in all kindreds. Although no specific gene mapping of this form has been carried out, there is resemblance to the tylosis-esophageal cancer gene at 17q24 (9).

Skin and skin appendages. Hyperkeratosis of the palms seems trauma related (Fig. 26–11). Hyperhidrosis is noted in the hyperkeratotic areas. The hyperkeratotic areas appear around puberty in most patients and progress in severity with age. The finger- and toenails exhibit subungual and circumungual keratin deposits. First involved are the toes at 4–5 years of age followed by fingernail changes at 8–9 years. Follicular keratosis of the sebaceous areas of the face is common. Focal to widespread hyperkeratosis of the sole is more marked over the weight-bearing areas: heels, toe pads, and metatarsal heads (Fig. 26–12). These may be painful, inhibiting ambulation (11).

Oral manifestations. Sharply marginated hyperkeratosis involves the labial and lingual attached gingiva (Fig. 26–13). The hard palate, beneath denture-bearing areas, and the lateral areas or dorsum of the tongue may be also affected. The hyperkeratotic areas appear in early childhood and increase in severity with age.

Differential diagnosis. There are many disorders that may be associated with hyperkeratosis palmoplantaris (2). Generalized oral hyperkeratosis, especially that of the buccal mucosa, has been noted in patients with *autosomal dominant tylosis and carcinoma* as well as with congenital strictures and squamous cell carcinoma of the esophagus (7,8,10).

Laboratory aids. Paranuclear bodies are seen in the spinous and granular cell layers of the keratinocytes of the gingival epithelium. Ultrastructural changes show these to be condensed tonofilaments (11).

Oral and conjunctival amyloidosis and mental retardation (Hornová-Dluhosová syndrome)

Hornová and Dluhosová (6) reported a boy and his mentally retarded sister. Within the first year of life, the eyelids were noted to be swollen, with nodular deposits of amyloid in the conjunctiva. Congenital cataracts, atrophy of ocular bulb, and amaurosis were also present. Amyloid deposits found in the enlarged boggy gingiva imparted the appearance of icing (Fig. 26–14).

Autosomal recessive ligneous conjunctivitis, caused by mutation in the plasminogen gene at 6q26, may also exhibit gingival and other mucosal involvement (1,2,5,7), and the relationship to a condition characterized by an amyloidaceous ulcerated gingival and conjunctival disorder is not known (2–4).

(B) Note microphthalmia, hypopigmented skin, enlarged gingiva. (A from MA Patton et al, J Med Genet 24:118, 1987. B from HE Cross et al, J Pediatr 70:398, 1967.)

Gingival fibromatosis, hypopigmentation, microphthalmia, mental retardation, and athetosis (Cross syndrome)

Cross et al (2), in 1967, described Amish sibs with microphthalmia, cloudy cornea, and hypopigmented skin (Fig. 26–15). Since then several examples have been reported in other groups (1–4,6,8–12).

There is severe postnatal growth retardation (4).

Ocular anomalies include microphthalmia, enophthalmia, microcornea, corneal opacities, cataracts, nystagmus, and blindness (1).

By the third month of life, there are signs of spastic tetraplegia with athetoid movement. All patients have been severely mentally retarded and exhibit axial hypotonia.

The hypopigmented skin and silver-gray metallic-appearing hair, evident at birth, are deficient in tyrosinase-positive melanosomes (1,12).

Gingival fibromatosis, less severe than in *gingival fibromatosis, hypertrichosis, epilepsy, and mental retardation*, is a rare feature. We suspect that it is secondary to an antiseizure medication and not primary. Witkop et al (12) were the first to note the association. Courtens et al (1) and Passarge and Fuchs-Mecke (7) found enamel and dentin hypoplasia.

Autosomal recessive inheritance has been established (2,4,9).

The syndrome of oculocutaneous hypopigmentation with osteoporosis and a Morquio-like body phenotype , described by Hernández et al (5), appears not to be Cross syndrome, although osteoporosis has occasionally been reported in Cross syndrome (2,9). The syndrome has been described in association with Bartter syndrome, but we suspect that this is aleatory (11).

Chapter 27
Syndromes with Unusual Dental Findings

Oculo-facio-cardio-dental syndrome

Marashi and Gorlin (5,6), in 1990 and 1992, described three examples of binary combination of congenital cataracts and canine radiculomegaly. They cited an earlier example of Hayward (3) in which canine radiculomegaly, delayed dentition, persistent primary teeth, oligodontia, and congenital cataracts were found in an 18-year-old female. Wilkie et al (11) reported a mother and daughter with congenital cataract, microphthalmia, and septal heart defect, suggesting that this combination represented a new syndrome. Gorlin et al (2) employed the name *oculo-facio-cardio-dental syndrome*. About a dozen examples have been described to date (1–11).

The occurrence of this syndrome in two generations (4,11, van der Smagt and Hilhorst-Hofstee, personal communication, 1998) and in 12 females but in no males suggests that the syndrome is X-linked dominant, lethal in the male.

Facies. The patient has long and narrow facies. The eyebrows are laterally curved and thick. The nose is sharp with a clearly defined bifid tip. High nasal bridge was noted in at least seven patients. The philtrum tends to be long. Cleft palate or submucous cleft palate has been noted in 50% (1,5,7,10) (Fig. 27–1).

Fig. 27–1. *Oculo-facio-cardio-dental syndrome*. Patient has long sharp nose with indented tip. Congenital cataracts were removed with secondary glaucoma. VSD has been reported. Hammer toes had been corrected.

Eyes. Eye changes, noted in 80% and evident at birth, consist of congenital cataract with or without luxated lenses (1,3,5,7,10,11) and microphthalmia or microcornea (1,5,10,11) with resultant or secondary glaucoma (1,5,10,11). There may be persistent hyperplasia of the primary vitreous. Ptosis and/or blepharophimosis has also been noted (1,3,10,17). Exotropia is very common.

Teeth. Surely the most unmistakable and constant finding is canine radiculomegaly (Fig. 27–2). This is not manifest orally, but its unique nature is seen on a panoramic radiograph of the jaws and may be discovered accidentally. The root ends of the canine teeth do not close until adulthood, the roots continuing to grow until the orbit and lower border of the mandible are reached by the maxillary and mandibular canines, respectively (Fig. 27–3). Other teeth may exhibit root elongation. Other dental anomalies include oligodontia, significantly delayed eruption, persistence of primary teeth, and malocclusion. Fused teeth and supernumerary teeth were noted by Schulze et al (10). One of us (RJG) has noted an elongated canine in a male who otherwise has no stigmata of the syndrome. A single elongated canine has been reported in a short female. The case was not otherwise elaborated (12).

Heart. Cardiac anomalies of various types (ASD, VSD, mitral valve prolapse) have been documented in at least 7 of the 12 patients (1,3,9–11).

Extremities. Cutaneous soft tissue syndactyly of toes 2–3 was found in six patients and hammertoes 2–4 have been described (3,7,9–11). Radioulnar synostosis has been noted (9). The small joints of the hand may be hyperextensible, and the feet may be flat.

Miscellaneous. Findings included septate vagina (11), sensorineural hearing loss (1), nasolacrimal duct obstruction (1,11), small corpus callosum (9), and Dandy-Walker malformation (van der Smagt and Hilhorst-Hofstee, personal communication, 1998) or small vermis (9). Depressive disorder has been reported in a few cases (4,7). Mild scoliosis has been noted.

Diagnosis. Because of the congenital cataracts and congenital heart anomalies, many patients have been misdiagnosed as having *rubella embryopathy*.

Cataracts and dental abnormalities (Nance-Horan syndrome)

The syndrome of screwdriver-shaped incisors and congenital posterior cataracts was first described in detail by Nance et al (9) and Horan and Billson (5) in 1974. However, Walsh and Wegman (16) may have described the disorder as early as 1937, although they did not evaluate the dentition. The disorder has X-linked inheritance. Several other families have been published (2,4,6,10,14,15). The gene has been mapped to Xp22.13–p22.31 (1,7,8,11,12,17). The gene appears to be proximate to the amelogenin gene (3).

Eye. Congenital cataracts or microcornea are constant features in affected males, resulting in impaired vision and nystagmus. Posterior Y-sutural cataracts are constant in female carriers. Their corneal diameters are reduced (Fig. 27–4). However, females usually have normal vision. Rarely, cataracts in females are progressive and, with age, may become complete (14). Glaucoma develops in approximately one-half the males.

Intelligence. Mild or moderate mental retardation has been reported in 30% in several kindreds (2,5,7,13–15). In general, it is not associated with motor delay but may be associated with autism (13). It is not expressed in female carriers.

Other findings. Shortened fifth metacarpals are seen in at least 90% of affected males and females. The face is long. The pinnae tend to be simplified and outstanding in over 90% of males and 40% of females. The nose is prominent with a prominent bridge. The vermilion of the upper lip is thin and flat.

Oral manifestations. Affected males have characteristic dental anomalies that include tapered, screwdriver-shaped notched incisors, resulting in diastemas between the teeth (9) (Fig. 27–5A,B). Molars and premolar cusps may also be tapered, the cervical width being greater than the occlusal width (LS Levin, unpublished). The molars may have a mulberrylike form (5). Deciduous and permanent teeth are affected. Maxillary supernumerary incisors (mesiodens) are also noted in at least 65%.

LS Levin has evaluated an affected male in the kindred reported by Goldberg and Hardy (4) who had a supernumerary tooth in the anterior mandible. Carrier females have similarly, although less severely affected, dentitions (Fig. 27–5C). Bixler et al (2) found bilateral absence of the mandibular canines.

There is some overlap with *Lenz microphthalmia syndrome*. There are many syndromes with gene localization overlapping that of Nance–Horan syndrome (13).

Tricho-dento-osseous syndrome and tricho-onycho-dental syndrome

Robinson et al (28), in 1966, and Lichtenstein, Jorgenson, Melnick, and co-workers (14,20,22) described a syndrome of amelogenesis imperfecta, taurodontism, curly hair, and, at times, sclerotic bones. Inheritance is autosomal dominant. Other reports have described binary combination of amelogenesis imperfecta of the hypomaturation-hypoplasia type and taurodontism (3,4,7,9,23,25,37,39). Tricho-dento-osseous syndrome stands on its own as a distinct entity on clinical (5,38) and molecular grounds (25). Tricho-dento-osseous syndrome has autosomal dominant inheritance (7,32), the gene having been mapped to 17q21 (11) due to a deletion mutation on a transcription factor, *DLX3*. Mutations in the *DLX3* gene have been identified (25). Gage (9) suggested X-linked inheritance in a family he described, indicating heterogeneity.

There may be two types of tricho-dento-osseous (TDO) syndrome. In the classic form (TDO-I), the scalp hair is kinky or curly in 85% (43), and the lashes are long (32) (Fig. 27–6). The nails may exhibit splitting of the superficial layers in 40% (21,28). The hair tends to straighten in approximately 50% by the second or third decade (22,43). The teeth have pitted thin hypoplastic yellowish-brown enamel and are prone to abscess formation in over 75% (2,7,11,14,21,24,43) (Fig. 27–7). Pulp chambers are enlarged. The roots tend to be short and open. The deciduous and permanent molars are all severely taurodont (43) (Fig. 27–8). The teeth may be delayed in eruption and, not uncommonly, several permanent teeth are impacted. Electron microscopic study has shown a thin enamel layer with randomly distributed depressions and pits. The mineral content of the enamel is close to that of the underlying dentition (22).

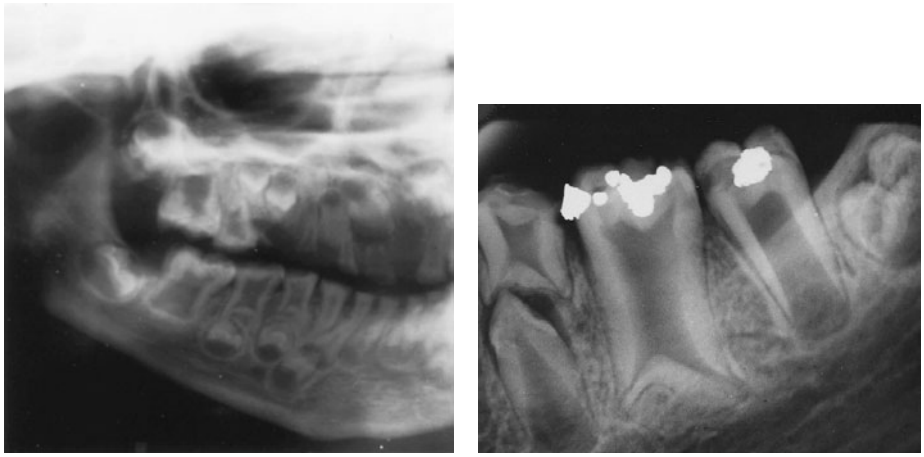
Fig. 27–6. *Tricho-dento-osseous syndrome*. Uncombable hair.

Only Lichtenstein et al (21) suggested sagittal synostosis, but this has never been confirmed. The long bones, calvaria, skull base, frontal bone, and mastoids have increased density with decreased pneumatization of sinuses in 65% of families (Fig. 27–9). Skeletal maturation is delayed and some patients exhibit short ramus, long mandibular body length, longer cranial base, and wider mandibular angle (18,21).

TDO-II, described by Shapiro et al (33) and Quattromani et al (26), is also manifest by curly hair and the same dental changes seen in TDO-I although there is no tendency toward discoloration of the enamel. The long bones do not appear to have increased density. The clavicles are undertubulated. The calvaria manifests not only increased density but increased thickness and obliterated diploë. Frontal sinuses and mastoids tend to be obliterated. The base of the skull shows both increased density and thickness. In contrast to TDO-I, patients with TDO-II have macrocephaly. Whether these two forms represent true heterogeneity is not known. Rivas et al (27) found evidence for linkage between TDO-I locus and ABO, Kell, and Gc loci in the family reported by Lichtenstein et al (21). One would anticipate linkage studies in TDO-II families.

Tricho-onycho-dental syndrome, described by Leisti and Sjöblom (19) and others (17,34,36), is characterized by curly hair that is relatively sparse and easily detachable. There is decreased facial, axillary, and pubic hair. The enamel is hard and thin and has indistinct enamel rods. The dentin is dysplastic and fills the pulp, being similar to that seen in dentin dysplasia, type I. There is some tendency toward precocious eruption of teeth, taurodontism, and short open roots, but no tendency for the permanent teeth to be impacted. The teeth are lost early. The long bones and calvaria have increased density, and the calvaria is increased in thickness. There is narrowing of ear canals among affected males and a tendency toward mandibular prognathism.

Taurodontism may occur as an isolated finding in 0.5%–4% of the population (16) and in many syndromal associations (13): *taurodontism, oligodontia, and sparse hair*; microcephalic dwarfism, microdontia, and diminished anterior root formation (10,29); *trisomy 21 syndrome* (12); *X-chromosome aneuploidy* (1,6,13,35); osteoporosis (8); *Ackerman syndrome, taurodontism, microdontia, and dens invaginatus*, and apparent *monosomy 21* (44). There are many forms of amelogenesis imperfecta



A B

Fig. 27–8. *Tricho-dento-osseous syndrome*. (A) Radiograph of deciduous dentition and developing permanent dentition. Deciduous molars and first permanent molars are taurodont, and the enamel is thin. (B) Extreme taurodontism. (A from RJ Jorgenson and RW Warson, Oral Surg 36:693, 1973. B courtesy of EJ Burkes, Chapel Hill, North Carolina.)

(40,41). Seow (30) distinguished amelogenesis imperfecta from TDO syndrome by the finding of taurodontism in the lower first permanent molar. The trichodental syndrome (16) consists of autosomal dominant inheritance of short hair and oligodontia. A superb discussion of taurodontism is that of Witkop et al (42). Approximately 33% of patients with hypodontia have at least one permanent molar with taurodontism (31).

Short stature with pitted enamel hypoplasia has been noted (16a).

Odontoonychodermal dysplasia

Fadhil et al, in 1983, described three inbred Lebanese kindred and seven individuals with hyperhidrosis, palmoplantar hyperkeratosis, dry sparse hair, dystrophic nails, teeth with reduced crown form, and oligodontia. Arnold et al (1) reported a similarly affected Dutch case.

Inheritance is autosomal recessive.

Witkop tooth-nail syndrome (hypodontia and nail dysgenesis) and Fried syndrome

Hypodontia and nail dysgenesis ("tooth and nail" syndrome) was first delineated by Witkop (23), although an earlier case was described by Weech in 1929 (22). It is characterized chiefly by missing teeth and nail dysplasia. Evidence suggests that the syndrome has autosomal dominant inheritance (2,6,8,14). We cannot be certain regarding classification of the disorder documented by Langsteger and Hartwagner (15). Several authors (1–5,8,12,19) reported isolated patients with hypodontia and nail anomalies but without family history. Heterogeneity cannot be excluded (11,14). Nonsense mutations in *MSX1* at 4p16.1 cause the disorder (14a).

Oral findings. Many permanent teeth are congenitally missing or have coniform crowns (4,8,14) (Fig. 27–10A). In some patients, deciduous teeth are also coniform or absent (11,14). The teeth most often missing are mandibular incisors, second molars, and maxillary canines. Taurodontia is apparently not a common finding in this syndrome, although one patient depicted by Hudson and Witkop (14) had taurodont first permanent molars. Deciduous teeth had normal pulp chambers and root canals.

Fig. 27–10. *Witkop tooth-nail syndrome*. (A) Oligodontia and conical tooth crown form. (B,C) Hypoplasia of fingernails and toenails. (A from JS Giansanti et al, Oral Surg 37:576, 1974.)

A

B

C

Nails. Fingernails and/or toenails are hypoplastic, spoon shaped, and slow growing (8,14) (Fig. 27–10B,C).

Other findings. Although some patients have fine, thin, slow-growing hair (8,14), this abnormality has not been documented in all patients with the disorder. Microscopic examination of the hair has not revealed any obvious abnormality (9,17). Sweating was reported as normal (8,14).

Differential diagnosis. Differential diagnosis includes X-linked and autosomal recessive *hypohidrotic ectodermal dysplasia*. However, patients with this disorder have a typical facies, thin, sparse, slow-growing hair, decreased sweating, and lack of many teeth. Nails are usually not dysplastic. Patients with hypodontia and taurodontia have been reported (21); however, nails and hair were not described. Hypodontia and hypoplastic nails may occur with hearing loss (16).

LS Levin has seen two sibs with hypodontia, taurodontia, and sparse, slow-growing, blond hair. Fingernails and toenails were spoon shaped, thin, and slow growing. The sibs lacked primary maxillary incisors and molars, and the anterior primary teeth were pegged. The deciduous molars were taurodont and nearly all permanent teeth were missing. The parents were normal. Inheritance may be autosomal recessive. Four sibs with a similar constellation of abnormalities were reported by Stenvik et al (20), but the parents were not examined. Fried (7) reported first cousins, each born to consanguineous couples who had congenitally absent and conically shaped deciduous teeth, fine, slow-growing scalp hair, scanty eyebrows, thin fingernails, small thin concave toenails, and normal sweating. The status of the permanent teeth was unknown (Fig. 27–11). This has been called *Fried syndrome*.

We cannot accept the cases of Murdoch-Kinch et al (18) or Hodges and Harley (13) as examples of Witkop tooth and nail syndrome.

Autosomal dominant choanal atresia with maxillary hypoplasia, prognathism, and hypodontia

Ramos-Arroyo et al (1) reported two sibs and a cousin with bilateral choanal atresia, tall forehead, maxillary hypoplasia, relative mandibular prognathism, and hypodontia.

Inheritance appears to be autosomal dominant with variable expressivity.

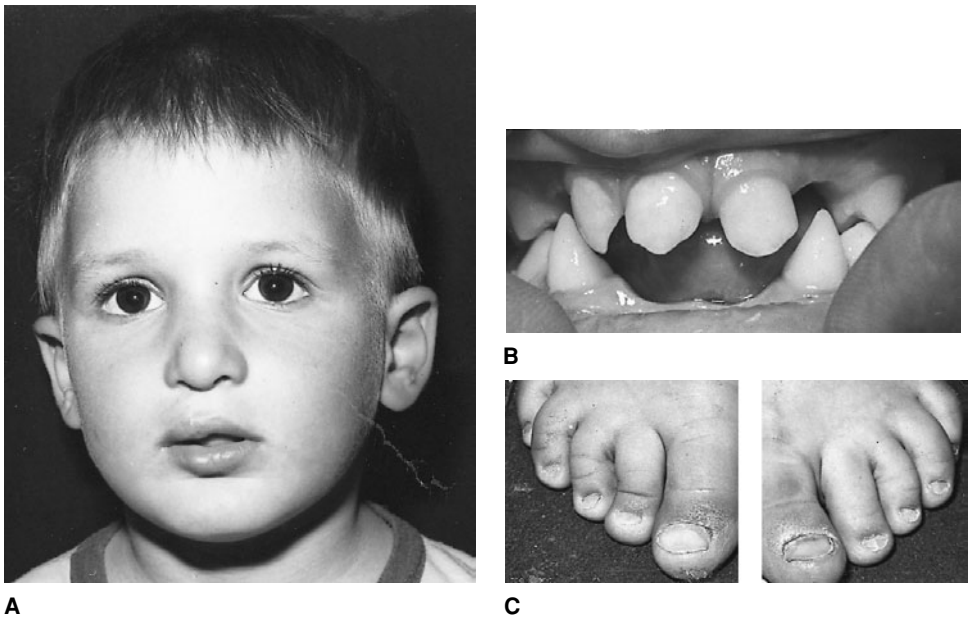

Fig. 27–11. *Fried syndrome*. (A) One of two sibs with fine slow-growing scalp hair and scanty eyebrows. (B) Conical crown forms and oligodontia. (C) Thin concave toenails. (From K Fried, J Med Genet 14:137, 1977.)

Anodontia and strabismus

Beierle and Jorgenson (1), in 1978, described a male child with complete failure of formation of deciduous or permanent teeth. Superior oblique muscles of the eye were overactive, and strabismus and rotary nystagmus were evident bilaterally on lateral gaze. Brows, lashes, and lacrimation were normal. Scalp hair was normal in distribution and amount.

Seaver (L Seaver, personal communication, 1998), on follow-up, discovered the same phenotype in the patient's son.

Autosomal dominant inheritance is apparent.

Acrodental dysostosis (Weyers syndrome, Curry-Hall syndrome)

Weyers (7–9) reported several unrelated children with postaxial hexadactyly, bony cleft of the mandibular symphysis, and anomalies of the incisors and oral vestibule. Curry and Hall (1) reported several members of a large family with postaxial polydactyly, conical teeth, nail dysplasia, and short limbs. Additional affected kindreds have been described by Shapiro et al (5) and Roubicek and Spranger (3). There is autosomal dominant inheritance (1–7,9). It maps to chromosome 4p16 where it is allelic with *Ellis-van Creveld syndrome* (2,4).

Somatic growth is somewhat retarded. Shortening of limbs is very mild. Postaxial hexadactyly of the hands and feet is variable in expression. There may be fusion of the fifth and sixth metacarpals. Rarely, hexadactly is limited to a postminimus digit. In some cases there has been complete or partial fusion of the proximal phalanges of the fifth and sixth toes (Fig. 27–12).

Fingernails and toenails may be dysplastic and discolored with thick vertical striations and splitting. The thumb and hallucal nails and the fifth toenails are most severely affected.

The facies, apart from the short somewhat retroussé nose with anteverted nostrils, is not unusual. The alae are rounded, giving the end of the nose a somewhat bulbous appearance. Although failure of fusion of the mandibular symphysis was a constant finding in patients of Weyers, all were under 1 year of age. We suspect there was only delay in fusion. Incisors in both dentitions have been described as small with conical crown form but, in some cases, as absent (Fig. 27–13). Occasionally, there are mucosal bands that obliterate the oral vestibule anteriorly, similar to those seen in *Ellis-van Creveld syndrome*. Spranger and Tariverdian (6) reported a father with Weyers syndrome and a daughter with *Ellis-van Creveld syndrome*.

Hyperhidrosis, premature graying of the hair, and premolar hypodontia (PHC syndrome, Böök syndrome)

Böök (1), in 1950, reported the PHC syndrome: *P*remolar aplasia, *H*yperhidrosis, and *C*anities prematura in a large kindred. The syndrome has autosomal dominant inheritance with complete penetrance. Salinas et al (2) reported a single patient with absence of premolar teeth and hyperhidrosis.

Canities prematura (early, diffuse whitening of the hair) was the most common sign. It appeared usually between the sixth and twenty-third years of life and progressed slowly. About one-third of the patients presented whitening of the hair in other parts of the body. About 65% had marked functional hyperhidrosis. Although often palmoplantar, it involved the axillas and forehead less severely. One or more premolars were absent, with corresponding retention of the deciduous precursors.

Amelogenesis imperfecta and terminal onycholysis (ameloonychohypohidrotic dysplasia)

Witkop and colleagues (1–3) described a kindred exhibiting hypoplastic hypocalcified enamel, multiple unerupted permanent teeth that underwent resorption, terminal onycholysis, seborrheic dermatitis of scalp, xerosis with keratosis pilaris of buttocks, and functional hypohidrosis (Fig. 27–14). Inheritance is autosomal dominant.

Amelogenesis imperfecta, epilepsy, and mental deterioration (Kohlschütter syndrome)

Kohlschütter et al (3), in 1974, reported five male sibs with a sudden generalized seizure disorder that had its onset between 1 and 4 years of age. Infants had normal development until the appearance of epilepsy; progressive mental and motor deterioration followed, the degree being correlated with the frequency and severity of the seizures. MRI showed cerebral atrophy. Death occurred between 4 and 9 years. All had markedly hypocalcified amelogenesis imperfecta (Fig. 27–15). Associated findings included hypohidrosis, mildly elevated sodium and chloride, but markedly increased potassium in the sweat, and myopia. Other kindreds were reported by Christodolou et al (1), Petermöller et al (4), Zlotogora et al (6), Guazzi et al (2), and Wygold et al (5). Approximately 20 cases have been reported.

Inheritance is autosomal recessive. However, we suspect that it is heterogeneous.

Amelogenesis imperfecta and platyspondyly

In 1996, Verloes et al (2) described male and female sibs, the offspring of consanguineous Moroccan parents. In addition to mild growth retardation, both manifested generalized platyspondyly with short pedicles, narrow intervertebral and interpediculate distances, rectangular-shaped vertebral bodies with posterior scalloping with herniation of nuclei, and broad femoral necks (brachyolmia). The boy had pectus carinatum and

Fig. 27–15. *Kohlschütter syndrome*. Note extensive loss of enamel even on unerupted teeth. (Courtesy of R Kuba and M Ahmad, Minneapolis, Minnesota.)

limited extension at the elbows. In addition, both sibs had hypoplastic amelogenesis imperfecta and oligodontia.

Houlston et al (1) noted a Pakistani boy, the offspring of consanguineous parents, with amelogenesis imperfecta, taurodontism, platyspondyly, and short stature.

Four other forms of brachyolmia are discussed by Verloes et al (2). One must exclude *tricho-dento-osseous (TDO) syndrome*.

Inheritance of this syndrome is probably autosomal recessive.

2. Verloes A et al: A new form of skeletal dysplasia with amelogenesis imperfecta and platyspondyly. Clin Genet 49:2–5, 1996.

Amelogenesis imperfecta and nephrocalcinosis

MacGibbon (4), Lubinsky et al (3), and Hall et al (1) reported sibs with amelogenesis imperfecta, nephrocalcinosis, aneuresis, and polyuria. The aneuresis and polyuria began at approximately 2 years of age. The nephrocalcinosis became apparent radiographically at 5 years. Urinary tract infections and pyelonephritis developed in late childhood and early adulthood with malignant hypertension and uremia eventuating during the third decade.

Both primary and secondary dentitions completely lacked enamel. The primary teeth erupted on time, but several permanent teeth remained unerupted with resorption of crowns within the alveolus. Large follicles were noted around the crowns of developing teeth, and multiple pulp calcifications, frequently dagger shaped, were present in the pulp chambers.

Lubinsky et al (3) found abnormalities of calcium-binding proteins with increased levels of osteocalcin, reduced urinary carboxyglutamic acid, and reduced urinary excretion of calcium and phosphate.

Nephrocalcinosis is rare in children but has been associated with renal tubular acidosis, hyperparathyroidism, medullary sponge kidney, Bartter syndrome, hyperoxaluria, and various conditions in which blood calcium is increased or there is increased excretion of calcium in the urine from whatever etiology. It has even been associated with *McCune–Albright syndrome* and *Janssen metaphyseal chondrodysplasia*.

Amelogenesis imperfecta has been seen in a number of conditions, inter alia *Morquio syndrome, tricho-dento-osseous syndrome, amelogenesis imperfecta with taurodontism* (see *TDO syndrome* for discussion)*, oculo-dento-osseous dysplasia,* and the various *epidermolyses bullosa*.

Inheritance is autosomal recessive.

Amelogenesis imperfecta and cone-rod dystrophy

Jalili and Smith (1), in 1988, described 29 affected with progressive cone-rod dystrophy and amelogenesis imperfecta in an extended Arab family from the Gaza Strip. Inheritance was clearly autosomal recessive.

Photophobia and pendular nystagmus starting in the first 2 years of life and total achromatopsia characterized the ophthalmologic findings. Visual acuities ranged from 6/36 to no light perception.

All those affected with the eye problems had rough brown teeth. The enamel was rapidly lost due to hypocalcified amelogenesis imperfecta.

Unusual facies and lobodontia

The canines and premolars have pointed cusps, causing Robbins and Keene (3) to label the condition lobodontia. The molars are multituberculate with single conical roots (Fig. 27–16).

There is general reduction in crown size and there may be hypodontia. The incisors tend to be invaginated or shovel shaped. The cingulum of incisors and premolars is accentuated (1–5).

Inheritance is autosomal dominant (3).

Unusual facies, digital anomalies, and supernumerary teeth

Ravine et al (personal communication, 1995) corresponded regarding a syndrome of supernumerary teeth and tracheal subglottic hypoplasia predisposing to recurrent croup in childhood.

The hands appeared unusual with prominent distal and proximal interphalangeal joints, clinodactyly of the fifth fingers, brachydactyly of fingers and toes, club feet, and external rotation of hips.

The facies is unusual due to prominent forehead and prominent widow's peak. Progressive conductive hearing loss and supernumerary teeth were noted.

Four generations were involved with male-to-male transmission. Autosomal dominant inheritance is evident.

Unusual facies and autosomal dominant hypohidrotic ectodermal dysplasia (Bocian-Rimoin syndrome)

Bocian and Rimoin (1), in 1979, reported an autosomal dominant form of ectodermal dysplasia characterized by hypohidrosis; sparse body hair, scalp hair, eyebrows, and eyelashes; thin, slow-growing nails; hypoplastic nasal bridge; hypoplastic nasal alae; anteverted nostrils; long philtrum; and thin inverted upper lip. Tooth eruption was somewhat delayed. Oligodontia resulted in a number of deciduous teeth being maintained. The enamel was hypoplastic.

Somewhat similar findings are seen in the autosomal dominantly inherited disorder(s) described by Harrod et al (2), Saihan and Warin (4), and Jorgenson et al (3). However, unusual facies was not noted.

We wonder if this is not *Hay-Wells syndrome*.

Unusual facies and autosomal recessive hypohidrotic ectodermal dysplasia (Kopyść syndrome)

Kopyść et al (1) described two sibs, male and female, with hypodontia, teeth with conical crown form, sparse, thin, brittle scalp hair, pili annulati, follicular hyperkeratosis of trunk and limb, and hyperopia. Sweating was normal (Fig. 27–17).

Inheritance is probably autosomal recessive.

Reference [Unusual facies and autosomal recessive hypohidrotic ectodermal dysplasia (Kopyść syndrome)]

Lacrimo-auriculo-dento-digital (LADD) syndrome (cup-shaped ears, anomalies of the teeth and lacrimal ducts, and mixed hearing loss) (Levy-Hollister syndrome)

The lacrimo-auriculo-dento-digital (LADD) syndrome was first delineated in 1973 by Hollister et al (7). Features included nasolacrimal duct obstruction with chronic dacryocystitis, absent lacrimal puncta, cup-shaped ears, peg-shaped teeth with enamel hypoplasia, various preaxial digital anomalies, clinodactyly, and hearing loss. A single patient described by Levy (11) probably had the same syndrome, leading to an alternate eponym, Levy-Hollister syndrome. A possible earlier example is that of Faber (4). Over 35 cases have been described in the literature (1–16).

Inheritance is clearly autosomal dominant.

Almost all affected persons had nasolacrimal duct anomalies, including duct aplasia or hypoplasia, nasolacrimal duct obstruction, absent

Fig. 27–17. *Unusual facies and autosomal recessive hypohidrotic ectodermal dysplasia (Kopyść syndrome).* (A) Sparse, thin and brittle scalp hair. Note broad dorsum of nose. (B) Note conical crown form of upper incisors. (B from Z Kopyść et al, Hum Genet 70:376, 1985.)

Fig. 27–18. *Lacrimo-auriculo-dento-digital syndrome*. (A,B) Prominent cup-shaped ears extend at right angles from the side of the head. The eyes have a watery, glistening appearance, and on the right there is an overflow of tears from the outer canthus. (C,D) Long, tapering thumbs with large nail, bifid thumb tip with extra ectopic nail and tapering of second and third digits bilaterally. (E) Right hand has long, tapering thumb with ectopic nail and syndactyly. Left hand has rudimentary thumb fused to index finger, prominent interdigital cleft between second and third fingers, and ulnar deviation of third digit. (F) Maxillary lateral incisors have conical crown form. Premolar cusp patterns are abnormal and show excessive wear. (G) Radiograph of hands seen in E. Tip of right thumb has extra tuftlike ossification center. Left hand shows hypoplasia of greater multangular and phalanges of thumb. Metacarpal is represented by two widely separated ossification centers. (From D Hollister et al, J Pediatr 84:438, 1972.)

lacrimal puncta usually associated with chronic epiphora, dacryocystitis, and recurrent kerato-conjunctivitis. Nasolacrimal duct fistulas (9) and completely absent tearing (15,16) were also described. Absence of the parotid glands and Stensen's ducts has been noted (4,13) as well as salivary gland anomalies (10,15,16).

Digital anomalies are variable and include duplicated terminal phalanx of the thumb, digitalized thumb, triphalangeal thumb, thenar muscle hypoplasia, preaxial polydactyly, exaggerated interdigital cleft between the second and third fingers, syndactyly of the second and third digits, and fifth finger clinodactyly (Fig. 27–18). Metacarpophalangeal profiles show shortness of distal phalanges. Other limb anomalies include shortening of the radius and ulna, radioulnar synostosis, and, occasionally, absent radius (5,9). The multiplicity of radial anomalies led Temtamy and McKusick (14) to suggest that LARD (lacrimo-auriculo-radio-dental) syndrome might be a better acronym. Lower limb anomalies are unusual, but Roodhooft et al (12) described one patient with a supernumerary "metatarsoid" bone and possible phalangeal duplication of the fifth toe. Bamforth and Kaurah (1a) noted broad halluces and anomalies of the first two toenails, and Francannet et al (5) reported 1–2 syndactyly of toes.

Dental anomalies have included hypodontia and peg-shaped incisors, as well as enamel dysplasia of both deciduous and permanent teeth. Tooth discoloration, enamel thinning, excessive wear, and premature decay have often led to full mouth edentulation by adolescence or early adulthood. Hollister et al (7) suggested that the dysplasia might be due to a mild amelogenesis imperfecta-like defect, probably of the hypocalcification type, but this has not been confirmed by pathologic studies.

Hollister et al (7) reported one family member with unilateral renal agenesis. Shiang and Holmes (13) noted a patient with unilateral small scarred kidney and first degree hypospadias. Roodhooft et al (12) described one patient with blunted and dilated renal calyces. Bamforth and Kaurah (1a) reported two deaths due to renal agenesis.

Characteristically, simple cup-shaped ears with a short helix and underdeveloped anthelix have been present in 17 of 20 reported cases. The cup-shaped ears may be unilateral, bilateral, or asymmetrical (7,15) (Fig. 27–18).

Mixed conductive and sensorineural hearing loss, either unilateral or bilateral, has frequently been reported. It has ranged in severity from mild to severe (3,7).

Epiglottic hypoplasia has been noted (1).

While each individual feature of the LADD syndrome may occur as an isolated autosomal dominant trait, their combination is unique. The autosomal dominant *branchio-oto-renal (BOR) syndrome* is similar, with

hearing loss, malformed pinnae, lacrimal duct stenosis, and renal anomalies. It is distinguished from LADD syndrome by auricular pits, branchial fistulas or cysts, and the absence of dental and digital anomalies. *Townes-Brocks syndrome*, in which there is ear deformity, sensorineural hearing loss, preaxial polydactyly, and imperforate anus, can be distinguished from LADD syndrome by the presence of anomalies of the anus and feet, and the absence of abnormalities of the lacrimal ducts and teeth. Absence of the parotid glands has been associated with lacrimal apparatus malformations in the *ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome*. Occasionally individuals with LADD syndrome have split-hand malformation (6,10). However, the EEC syndrome can usually be distinguished by the presence of ectodermal defects, renal anomalies, and oral clefting. In point, Hennekam (6) and Lacombe et al (10) raised the question whether LADD syndrome and EEC syndrome represent a single causal entity.

Multiple anterior dens invaginatus and sensorineural hearing loss

A female child seen by Kantaputra and Gorlin (1) had double dens invaginatus of maxillary central incisors combined with premolarization of maxillary lateral incisors and first deciduous molars. She was missing two lower right permanent incisors. There was dens invaginatus of the lower left central and lateral incisors (Fig. 27–19).

Facial appearance was normal except for some fullness at the bridge of the nose and somewhat dilated nostrils). She had bilateral, moderately severe sensorineural hearing loss. Although estimate of IQ was approximately 75, this may well have been in error due to a combination of hearing loss and shyness.

Reference (Multiple anterior dens invaginatus and sensorineural hearing loss)

Supernumerary teeth and steroid dehydrogenase deficiency

Lyngstadaas et al (1) described a highly inbred Saudi-Arabian family in which three sibs and a cousin exhibited progressive liver degeneration. Two of the sibs developed giant cell hepatitis early in infancy and died before the fourth year of life. A deficiency of 3β-hydro-Δ5-C27 steroid dehydrogenase was demonstrated, an enzyme that synthesizes bile acids from cholesterol. The propositus exhibited 11 supernumerary teeth.

Inheritance is autosomal recessive.

Reference (Supernumerary teeth and steroid dehydrogenase deficiency)

1. Lyngstadaas SP et al: Severe dental aberrations in familial steroid dehydrogenase deficiency: A new association. Clin Genet 49:249–254, 1996.

Natal teeth and Turnpenny ectodermal dysplasia

Turnpenny et al (1,2), in 1994–5, suggested a new form of ectodermal dysplasia involving skin, hair, and teeth. Inheritance was autosomal dominant.

Scalp hair was thin and body hair was sparse. Sweating appeared to be normal. Two of four had natal teeth.

Acanthosis nigricans was manifested in late childhood.

One must exclude *Clouston syndrome*. Natal teeth occur with a plethora of syndromes such as *Wiedemann-Rautenstrauch syndrome, pachyonychia congenita, Ellis-van Creveld syndrome, Hallermann-Streiff syndrome*, and others.

Natal teeth and steatocystoma multiplex

There have been two reports of the binary combination of natal teeth and steatocystoma multiplex. This was first noted by McDonald and Reed (2) in 1976. A five-generation kindred with large numbers of affected has been reported by King and Lee (1) in 1987.

This obviously overlaps with *pachyonychia congenita*, but in no case were the nails involved. The reader is also referred to *natal teeth, oligodontia, and syringomas* (see below).

Natal teeth, oligodontia, and syringomas

Morrison and Young (2) reported a father and daughter with variable expression of multiple syringomas, natal teeth, and oligodontia.

A single maxillary incisor was found in the daughter at birth. The secondary dentition consisted of only four molars. Multiple natal teeth

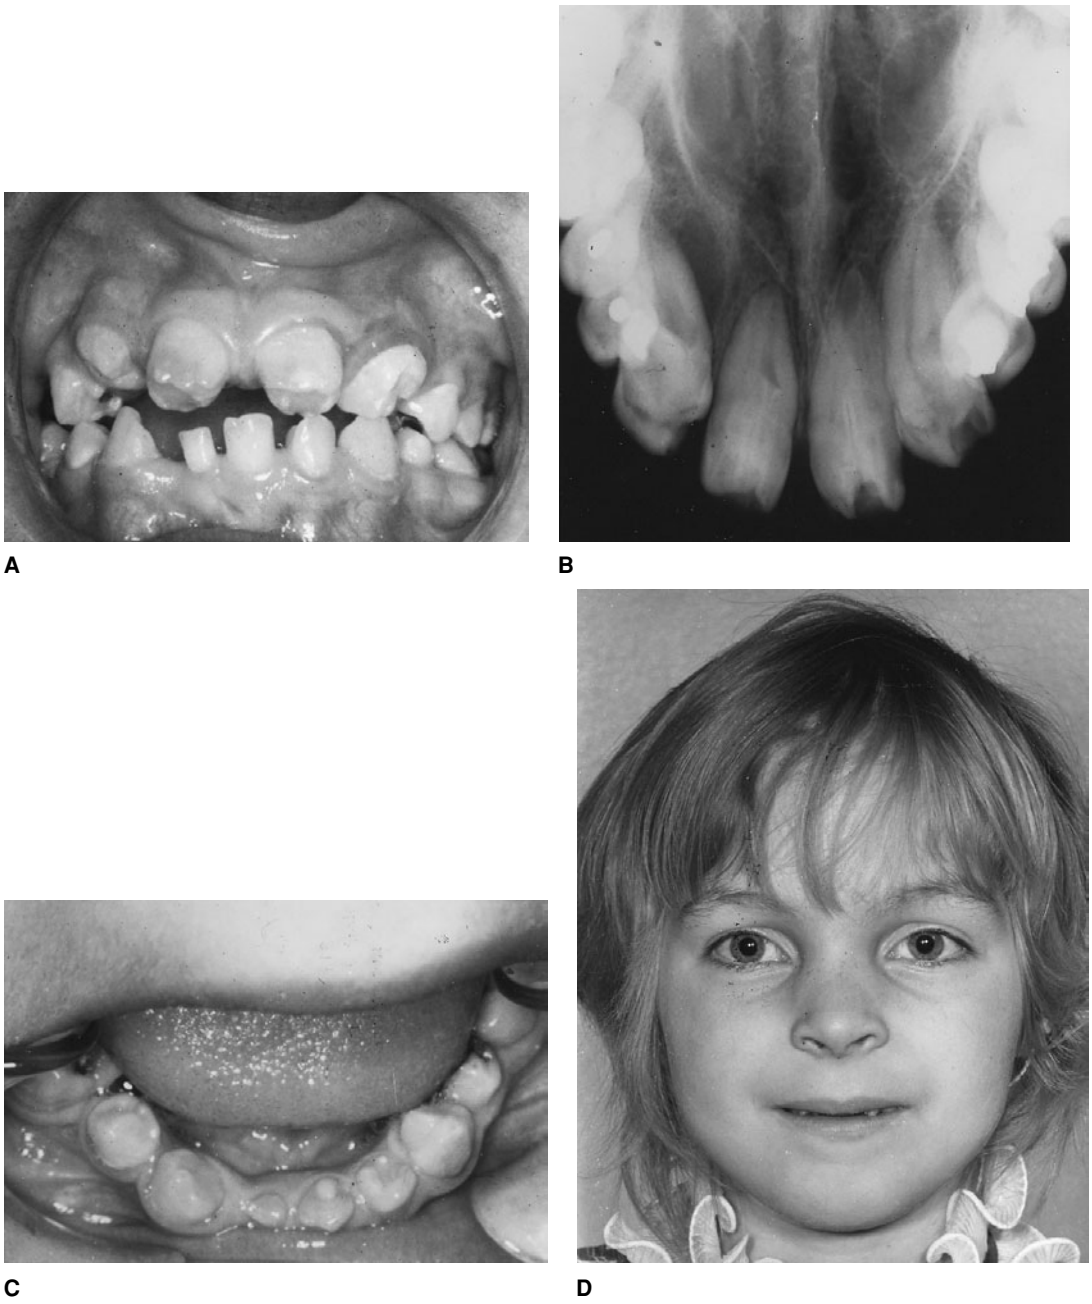

Fig. 27–19. *Multiple anterior dens invaginatus and sensorineural hearing loss*. (A) Molarized maxillary central incisors having three cusps labially, two cusps lingually, and one cusp mesially. Premolarized maxillary lateral incisor with one cusp labially and lingually. (B) Radiograph reveals both maxillary central and lateral incisors with two root canals. Double dens invaginatus is observed in the maxillary central incisors. (C) Multituberculism of the mandibular left incisors, canines, and first premolars. (D) Seven-year-old female with broad nasal bridge, dilated nostrils, and sensorineural hearing loss. (From PN Kantaputra and RJ Gorlin, Clin Dysmorphol 1:128, 1992.)

were also found in the father. As in the case of his daughter, his primary dentition was very incomplete and his secondary teeth consisted of only two large molars.

At puberty, numerous syringomas appeared over the forehead and malar areas of the daughter.

Syringomas may occasionally occur in two or more generations (1) with greater expression in females.

Natal teeth, patent ductus arteriosus, and intestinal pseudo-obstruction

Harris et al (1) reported brothers with dilatation and hypomobility of the small bowel and short or microcolon without anatomic obstruction. Incomplete rotation of the midgut was also noted. Both had congenital mandibular central incisors and patent ductus arteriosus, and both died within the first few months of life (Fig. 27–20). X-linked or autosomal recessive inheritance is possible.

Natal teeth, bifid tongue, and profound sensorineural hearing loss

An apparently unique association of natal teeth, bifid tongue, and profound sensorineural hearing loss was reported in a Saudi Arabian male child by Darwish et al (1).

The natal teeth were lower central incisors. The tongue tip was bifid. The lingual frenum was in normal position without undue traction on the tongue. Hearing loss was profound without additional description.

While the association of the three anomalies may be one of chance, odds against this would appear to be great.

Reference (Natal teeth, bifid tongue, and profound sensorineural hearing loss)

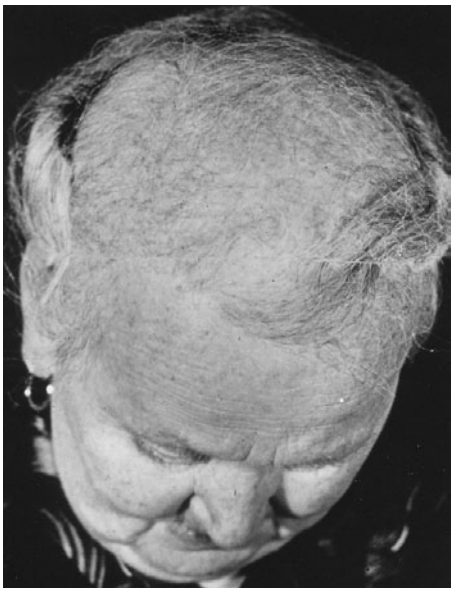
Oligodontia, hypotrichosis, palmoplantar hyperkeratosis, and apocrine hidrocystomas of eyelid margins (Schöpf-Schulz-Passarge syndrome)

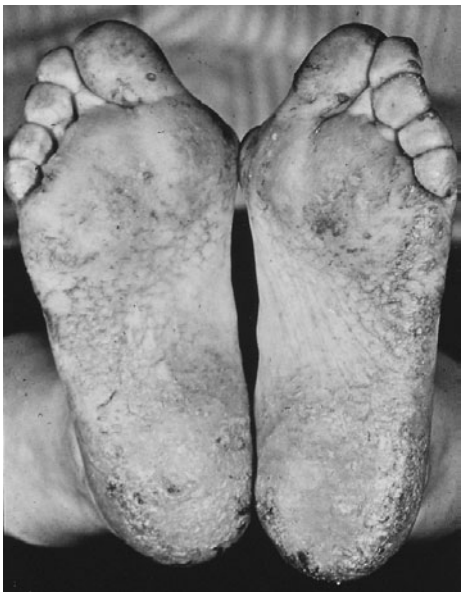
Schöpf et al (11) described two sisters with oligodontia, palmoplantar hyperkeratosis, and hyperhidrosis that began at puberty with hair loss occurring at 25 years, rosacea at 50 years, and 1–3 mm beaded cysts of both upper and lower eyelid margins at 60 years (Figs. 27–21 and 27–22). The deciduous teeth were lost late and only a few if any rudimentary permanent teeth developed. This was also documented by Monk et al (7). The nails were brittle, narrow, and exhibited longitudinal furrowing. About 15 patients have been described (1–5,7–9,11–14).

Fig. 27–21. *Oligodontia, hypotrichosis, palmoplantar hyperkeratosis, and apocrine hidrocystomas of eyelid margins*. (A–C) Proposita had oligodontia, sparse scalp hair, eyelid margin cysts, hyperkeratosis of soles. (Courtesy of E Schöpf, Heidelberg, Germany.)

A



B



C

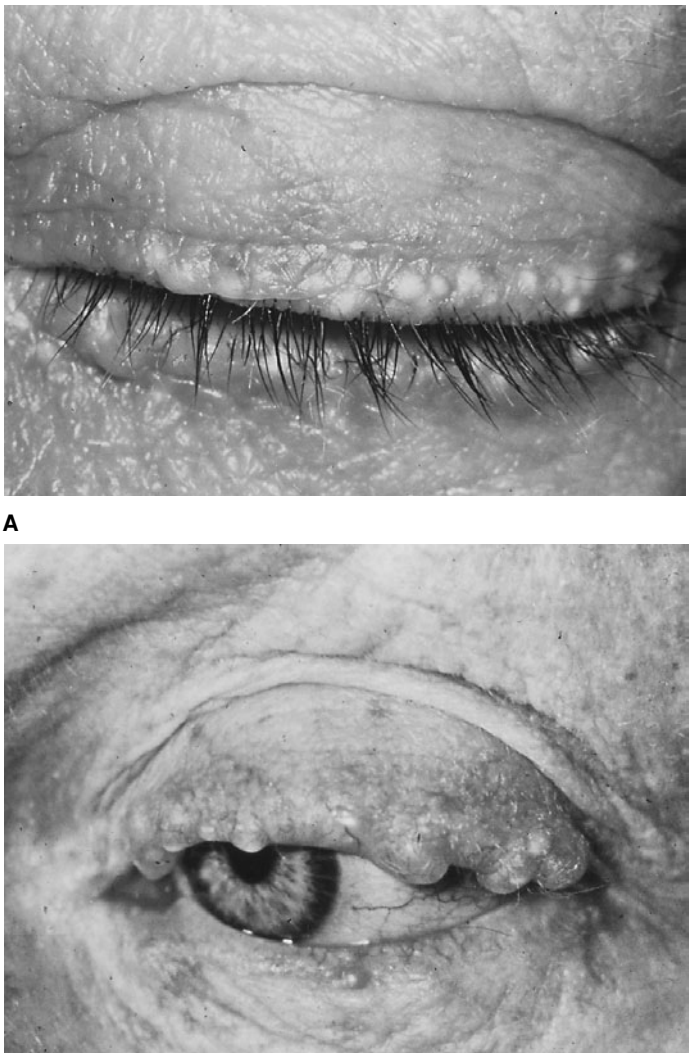


Fig. 27–22. *Oligodontia, hypotrichosis, palmoplantar hyperkeratosis, and apocrine hidrocystomas of eyelid margins*. (A,B) Beaded eyelid margins. (A from RL Font et al, Arch Ophthalmol 104:1811, 1986. B courtesy of E Schöpf, Heidelberg, Germany.)

The eyelid cysts are lined by two layers of cells: an outer myoepithelial layer and an inner layer of cuboidal cells with acidophilic cytoplasm. There were papillary infoldings. The cysts were interpreted as apocrine hidrocystomas arising from the glands of Moll. Photophobia, basal cell carcinoma, squamous cell carcinoma, eccrine poroma, and hypernephroma have been found in some patients (7–9).

Affected sibs (3,7,8,11) and consanguinity (7,11) indicate autosomal recessive inheritance. Küster and Hammerstein (5) showed autosomal dominant inheritance. Craigen et al (2) reported four males, three from one sibship, the other a half brother through the father. Uniparental isodisomy is possible, but it is probably a heterogeneity. Although classified as a keratoderma, there is as yet no evidence that the gene maps to 17q24 (13).

Multiple bilateral apocrine hidrocystomas of the eyelids may be an isolated finding (6,10).

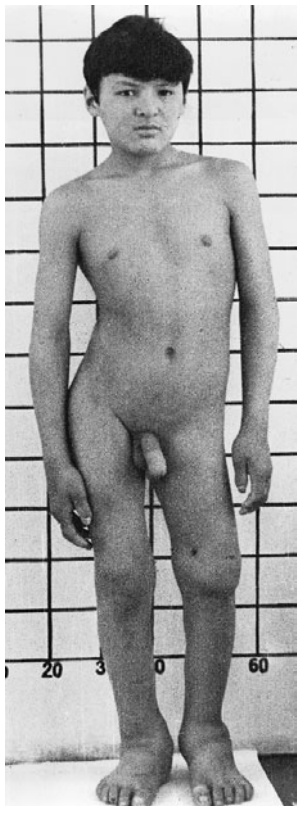
Oligodontia, keratitis, skin ulceration, and arthroosteolysis

Kozlova et al (1) described five sibs with a syndrome of recurrent skin ulceration, arthralgias, fever, fistulous osteolysis around joints, nail dystrophy, and keratitis that eventuated in blindness. The fingers became clawed. Involvement of the growth plates of the tibia and femur led to asymmetric shortness with secondary scoliosis (Fig. 27–23).

Fig. 27–23. *Oligodontia, keratitis, skin ulceration, and arthroosteolysis*. Note severe scoliosis, shortening of left leg, enlargement and deformity of knees and ankles, and cicatrized fistulous scars about knees. (From SI Kozlova et al, Am J Med Genet 15:205, 1983.)



Several teeth were missing; others had reduced crown form.
Inheritance is autosomal recessive.

Reference (Oligodontia, keratitis, skin ulceration, and arthroosteolysis)

1. Kozlova SI et al: Self-limited autosomal recessive syndrome of skin ulceration, arthroosteolysis with pseudoacromegaly, keratitis and oligodontia in a Kirghizian family. Am J Med Genet 15:205–210, 1983.

Oligodontia and congenital sensorineural hearing loss

Two pairs of sibs with sensorineural hearing loss and oligodontia have been reported by Lee et al (2), in 1978, and Glass and Gorlin (1), in 1979.

In one family (2), both children were missing permanent maxillary lateral incisors; one was missing the permanent canines as well. In the second family (1), at least 10 permanent teeth were missing, with several diastemas present (Fig. 27–24).

Both children in the first family (2) experienced episodes of dizziness beginning at age 2. Projectile vomiting accompanied the dizzy spells beginning at age 6 1/2 in one child. This finding was not present in the other family (1).

In all four children, profound bilateral sensorineural hearing loss was diagnosed by 11 months of age. Tympanograms and vestibular responses were normal in all the children.

Oligodontia and polycystic ovarian syndrome

Hattah and Angmar-Månsson (1) described two sisters with marked oligodontia with pubertal hirsutism, menstrual disturbances, and enlarged polycystic ovaries.

Parental consanguinity was reported. Possibly the syndrome has autosomal recessive inheritance. No other cases of this combination have been described (2).

References (Oligodontia and polycystic ovarian syndrome)

Oligodontia, microcephaly, short stature, and characteristic facies

Bankier et al (1) reported autosomal dominant inheritance of a syndrome of microcephaly, low normal intelligence, short stature, and dental anomalies.

The face was characterized by a broad forehead, long narrow nose, and flat recessed midface. Scalp hair tended to be fine and wispy. There was marked deficiency of teeth, and those that were present often had conical crown form and/or diminished crown size.

Other examples are those of Stoll et al (3) and Melamed et al (2).

Hypodontia and Dupuytren contracture

Three three-generation Finnish families were investigated for hypodontia with Dupuytren contracture.

Among 32 members, 5 had contractures and 4 had hypodontia (1).

Reference (Hypodontia and Dupuytren contracture)

1. Ranta H et al: Familial hypodontia associated with Dupuytren's disease. Scand J Dent Res 98:457–460, 1990.

Medullary sponge kidney and anodontia of permanent dentition

Khowry et al (2), in 1988, described two male and two female sibs with absence of permanent teeth and familial medullary sponge kidney.

Absence of the permanent dentition in individuals who have deciduous precursors has been shown to be an autosomal recessive trait by Gorlin et al (1). Medullary sponge kidney is not considered to be a genetic disorder but has been seen in association with congenital *hemihyperplasia*; yet among these four sibs, each affected had both diseases. Therefore, it is very unlikely that two different disorders are running in the same family.

Microdontia, hypodontia, short bulbous roots and root canals with strabismus, short stature, and borderline mentality

A 15-year-old female was reported by Bazopoulou-Kyrkanidou et al (1) with absence of permanent teeth. The deciduous dentition was marked by microdontia, hypodontia, and short bulbous roots. Short stature and borderline mentality were also noted (1). Absence of permanent teeth was described by Gorlin et al (3) as an autosomal recessive trait. Witkop and Jaspers (6) noted short roots and short stature as a dominant trait. Sauk and Delaney (5) and Gardner and Girgis (2) reported short roots, taurodontism, and microcephaly, and Ireland et al (4) noted short roots, taurodontism, and multiple dens invaginatus.

References (Microdontia, hypodontia, short bulbous roots and root canals with strabismus, short stature, and borderline mentality)

Otodental syndrome

In 1972, Levin and Jorgenson (7) described a syndrome of dental anomalies and sensorineural hearing loss. To date, several unrelated families have been described (1–3,5–10,12–14); one case report is doubtful (11). Inheritance is clearly autosomal dominant with variable expressivity.

The incisors of both dentitions are spared. The crowns of the canines and posterior teeth are enlarged, bulbous, and malformed with multiple prominent lobules. The deciduous dentition is more severely involved. The relation between cusps and major grooves is eliminated, hence the use of the term, *globodontia*. An enamel defect is frequently noted on the facial surface of the canine teeth. Premolar teeth are frequently missing or small in size. There is often delayed eruption of the deciduous malformed teeth or even of the permanent posterior teeth (1,2,13). One can observe duplicated pulp chambers with denticle formation and a longitudinal dental septum and early pulpal obliteration. The molar teeth have a tendency toward conical or taurodont root form. Complex and/or compound odontomas have also been described in the posterior maxilla and mandible (1,9,13) (Figs. 27–25 to 27–27).

Sensorineural hearing loss to about 65 dB is found at all frequencies but is more pronounced at about 1000 Hz. It usually plateaus by the fourth decade (3). The age of onset of the hearing loss ranges from early childhood to middle age (3,6,8), which may complicate making the diagnosis of the disorder.

Postaxial polydactyly-dental-vertebral syndrome

Rogers et al (1) and Temtamy and McKusick (2) reported a syndrome of bilateral broad halluces, postaxial polydactyly of hands and feet, short middle phalanges of hands, short pointed distal phalanges,

Fig. 27–26. *Otodental syndrome*. Globodontia of 6-year-molar. (From J Beck-Mannagetta et al, Dtsch Zahnarztl Z 39:232, 1984.)

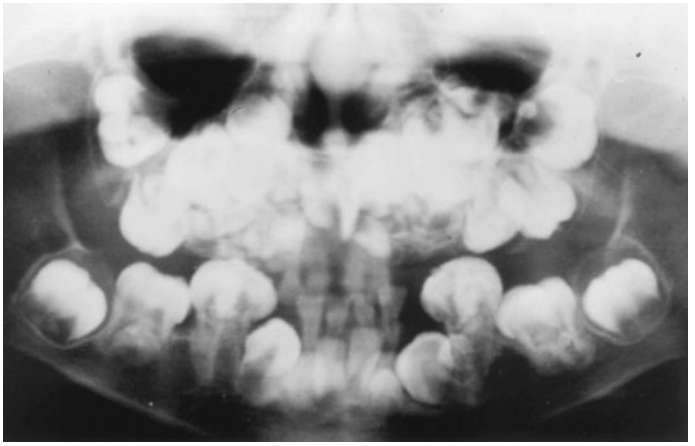

Fig. 27–27. *Otodental syndrome*. Panoramic radiograph showing 5-year-old with normal anterior teeth, globodontia of canines and molars. (From J Beck-Mannagetta et al, Dtsch Zahnarztl Z 39:232, 1984.)

abnormal vertebral bodies (variable fusion, hemivertebrae, butterfly form, small size), congenital torticollis, narrow spinal canal, kyphoscoliosis, and pectus (Figs. 27–28 and 27–29A,B). The pinnae were malformed, the neck was webbed with low posterior hairline, and the mandible was prognathic. Dental anomalies included dens invaginatus, fusion, macrodontia, hypodontia, enamel dysplasia, and short roots (Fig. 27–29C).

Inconstant features included high forehead, hydrocele, phimosis, agenesis of lower ribs, and congenital heart defects.

Inheritance appears to be autosomal recessive (1).

Short stature and delayed dental eruption

Arvystas (1) described autosomal dominant inheritance of short stature, prolonged retention of deciduous dentition, and delayed eruption of secondary teeth. There was frontal bossing, midface hypoplasia, Wormian bones in the lambdoidal sutures, widely open anterior fontanel in infancy, and delayed skeletal maturation.

Reference (Short stature and delayed dental eruption)

1. Arvystas MG: Familial generalized delayed eruption of the dentition with short stature. Oral Surg 41:235–243, 1976.

Short stature and short, thin, dilacerated dental roots

Witkop and Jaspers (3) reported a family with short stature and teeth with short, thin, dilacerated roots in four generations. Inheritance was compatible with either autosomal or X-linked dominant inheritance.

The tooth crowns were somewhat bulbous with cervical constriction and drastically abbreviated short, thin, dilacerated (bent) roots. The enamel was normal (Fig. 27–30).

Height did not exceed 155 cm. Wormian bones were observed in lambdoidal and coronal sutures.

Perhaps the condition reported by Shaw (2) is a different one. No taurodontism was noted, nor was dilaceration. Bazopoulou-Kyrkanidou et al (1) reported a female with short bulbous roots and short stature, but that is still a different condition.

Solitary maxillary central incisor, short stature, and choanal atresia (monosuperocentroincisivodontic dwarfism)

Rappaport et al (22,23), in 1976–1977, described the association between single maxillary central incisor and isolated growth hormone deficiency (Fig. 27–31). Vanelli et al (28) and Bierman-Franke et al (6) discussed

Fig. 27–29. *Postaxial polydactyly-dental-vertebral syndrome.* (A) Hypoplasia and fusion of cervical vertebrae. (B) Talus, calcaneus, and first and second cuneiforms are fused. Distal end of right fourth metatarsal is bifurcated. (C) Radiograph of extracted teeth showing grossly widened incisors with dens invaginatus, obliterated pulp chambers and canals, short roots. (From JG Rogers et al, J Pediatr 90:230, 1977.)

the association. Superb analyses are those of Hall et al (12) and Lo et al (17). RJ Gorlin has seen this combination with congenital cataracts.

About 70% of patients are short (17). Growth hormone levels are reduced in approximately 50% (11,17). Choanal atresia and/or nasal pyriform aperture stenosis is a constant feature of the syndrome (1,12,17,29) as is prominent midpalatal ridge (12). About 35% exhibit hypotelorism.

It is not rare to have a single maxillary central incisor, normal growth, and normal growth hormone levels (18,21,24,30). Combinations with VACTERL association (12,30) and CHARGE association (12,13) have been noted. Single central incisor has been reported in approximately 20% of those with *del(18p)* or *r*(18) (3,10,17,24). It may also occur with short stature and ocular coloboma (16), with del(7q36.1) (19), *XXX syndrome* (20), and with autosomal dominant *holoprosencephaly* (6,8,14,25) due to mutation of the *Sonic Hedgehog* gene. More mothers than fathers have this mutation (27). Süss et al (26) described a single maxillary central incisor in one sib and holoprosencephaly in another sib. Single maxillary central incisor occurs much more frequently in alobar *holoprosencephaly* with severe facial dysmorphism than it does as a "microform" in autosomal dominant holoprosencephaly (9). These patients lack a superior

Fig. 27–30. *Short stature and short thin dilacerated dental roots*. Bulbous crowns and short dilacerated roots. (From CJ Witkop Jr and MT Jaspers, Oral Surg 54:553, 1982.)

Fig. 27–31. *Solitary maxillary central incisor and short stature*. Note single central incisor.

labial frenum. Winter et al (32) described solitary maxillary central incisor with precocious puberty and hypothalamic hamartoma. Microphthalmia has been reported with single central incisor and hypopituitarism (2). *Hypophyseal short stature and cleft lip* is discussed in Chapter 23. Single maxillary central incisor has been found in association with iris coloboma and hypomelanosis of Ito (5) (a nonspecific chromosomal mosaicism) and with unusual forms of ectodermal dysplasia (7,31). Fleming et al (11) reported that they had seen single central incisor in *Klippel–Feil anomaly*.

Taurodontism, microdontia, and dens invaginatus

Casamassimo et al (1) described a family in which there was simultaneous occurrence of generalized microdontia, taurodontism of the first permanent molars, and teeth with multiple dens invaginatus (Figs. 27–32 and 27–33). The pedigree contained five affected males in five generations. There is good reason to suspect X-linked recessive inheritance.

Ireland et al (2) described taurodontism, multiple dens invaginatus, and short tooth roots in male and female sibs. Additional children of the father had similar anomalies. They suggested autosomal dominant inheritance.

Taurodontism, oligodontia, and sparse hair

Stoy (6) appears to be the first author to describe a syndrome of taurodontism, oligodontia, and sparse hair growth (Fig. 27–34). Several authors subsequently reported cases (1–5). Affected sibs were noted by Stenvik et al (5). All other examples were isolated cases. Care must be taken to exclude females heterozygous for *hypohidrotic ectodermal dysplasia*. Some examples may represent *Witkop tooth-nail syndrome*.

Taurodontism, pyramidal and fused molar roots, juvenile glaucoma, and unusual morphology of upper lip (Ackerman syndrome)

Ackerman et al (1) described a family in which several members in two generations exhibited pyramidal, taurodont, or fused molar roots with a single root canal, a finding noted on both sides of the kindred. Three of six sibs had only pyramidal molar roots.

Juvenile glaucoma was present in two of three sibs, and all had sparse body hair. The upper lip was full without cupid's bow, and there were thickening and widening of the philtrum. One of the sibs also had eruption of both lower eyelids, 3–4 soft tissue syndactyly of one hand, indurated hyperpigmented skin over the interphalangeal joints of the fingers, and clinodactyly of the fifth fingers (Fig. 27–35).

1. Ackerman JL et al: Taurodont, pyramidal, and fused molar roots associated with other anomalies in a kindred. Am J Phys Anthropol 38:681–694, 1973.

Taurodontism and disproportionate short stature

Houlston et al (2), in 1944, reported a male with disproportionate short stature and taurodontism. Intelligence was normal. Seizures were noted at 12 years of age. His parents were consanguineous.

Thoracolumbar platyspondyly, lumbar lordosis, and dorsal concavity of lumbar vertebrae were found. The ilia were square with widening and flattening of the acetabular roof. Radiographs of the teeth showed amelogenesis imperfecta and marked taurodontism.

While there is overlap with the autosomal dominant *tricho-dento-osseous syndrome* and *Kohlschütter syndrome* (amelogenesis imperfecta, epilepsy, and mental retardation), this syndrome most clearly resembles that described by Congleton and Burkes (1).

2. Houlston RS et al: Taurodontism and disproportionate short stature. Clin Dysmorphol 3:251–254, 1994.

Trichodental dysplasia

Eteson and Clark (1) reported a three-generation family with generalized shell teeth, sparse, short, slow-growing, brittle scalp hair, and curly eyelashes and eyebrows (Fig. 27–36).

An unrelated trichodental syndrome was described by Kersey (3). He reported the binary combination of sparse hair and oligodontia as an autosomal dominant disorder. Giannotti et al (2) found an isolated female with microcephaly and mental retardation. It is likely that these examples are heterogeneous.

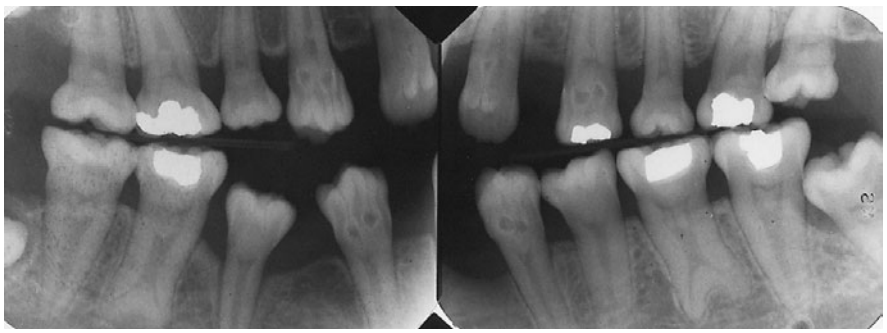

Fig. 27–33. *Taurodontism, microdontia, and dens invaginatus*. Periapical views showing taurodontism and multiple invaginations. (From PS Casamassimo et al, Oral Surg 45:107, 1978.)

ADULT syndrome

Propping and Zerres (2) reported autosomal dominant inheritance of what they call ADULT syndrome , an acronym for *A*cro-*D*ermato-*U*ngual-*L*acrimal-*T*ooth syndrome. There was considerable overlap with EEC syndrome (ectrodactyly, lacrimal duct obstruction, sparse hair, nail dysplasia, hypodontia, and loss of permanent teeth), but there were excessive freckling and hypoplastic breasts. There is good evidence that the syndrome results from mutation of the p63 gene with R298Q in the DNA-binding domain (2).

Boudghene-Stambouli and Merad-Boudia (1) noted recessive inheritance of a syndrome characterized by hypotrichosis, hyperkeratosis, nail dysplasia, small pointed teeth, and syndactyly of fingers and toes to various degrees.

Multiple odontoma-esophageal stenosis syndrome

Herrmann (3) reported a young male with huge tumors of the maxilla and mandible containing 1200 and 900 teeth, respectively, in various stages of development, including geminated and invaginated teeth. In 1973, Schmidseder and Hausamen (5) studied the same patient,noting that his two sons (one dying from pneumonia soon after birth) also manifested multiple odontomas of both jaws in infancy. The surviving infant was found to have a liver disorder and pulmonary stenosis. Subsequently, a daughter was born who again manifested odontomas. The boy experienced recurrences of odontomas that exhibited a higher degree of differentiation. He also suffered esophageal stenosis, as did his father (7).

Bader (1) reported multiple odontomas of both jaws in a female infant with calcified aortic stenosis, congenital cylindric bronchiectasis, leiomyomatosis of the esophagus with stenosis, hyperplasia of the myenteric plexus, and chronic interstitial cirrhosis of the liver. GL Barnes (personal communication, 1974) observed sibs with odontomas in four quadrants, malrotation and stenosis of the bowel, and iris colobomas.

Multiple odontomas were documented in male sibs by Schmitz and Witzel (6), but associated anomalies were not mentioned. Beisser (2) and Malik and Khalid (4) also reported multiple bilateral odontomas in both jaws.

In view of the occurrence of what appears to be a syndrome of multiple odontomas, chronic interstitial cirrhosis of the liver, and esophageal stenosis in two generations, it must be assumed that the disorder is inherited as an autosomal dominant trait. In the case of Schmitz and Witzel (6), the parents of the male sibs were normal.

Compound odontomas, maxillary hypoplasia, rectal stenosis, and sensorineural hearing loss

Seinsch (2), in 1982, described a boy with several anomalies including multiple compound odontomas, marked hypoplasia of the maxilla, submucous cleft palate, persistent buccopharyngeal membrane, high rectal stenosis, and sensorineural hearing loss. Although Gorlin et al (1) described several multiple odontomas-intestinal stenosis syndromes, none was associated with hearing loss.

Enamel hypoplasia, leukonychia, and sensorineural hearing loss (Heimler syndrome)

A syndrome characterized by sensorineural hearing loss, amelogenesis imperfecta, and leukonychia was described in a pair of sibs by Heimler et al (1) in 1991 and by Tischkowitz et al (2) in 1999.

Primary teeth were normal, but the permanent teeth exhibited enamel hypoplasia. The teeth were discolored and, in addition, the molars and premolars were hypoplastic in both children (Fig. 27–37A).

The nails had transverse lines proximally (Beau's lines) and punctate leukonychia (Fig. 27–37B,C).

Profound bilateral sensorineural hearing loss was diagnosed at 18 months in one child and 2 1/2 years in the other. Hearing was normal for the first 2 years in the second child, so the loss was not congenital.

Urinalysis, serum calcium, phosphorus, and creatinine were all normal.

The presence of this condition in sibs of each sex and unaffected parents is strongly suggestive of autosomal recessive inheritance.

The differential diagnosis includes *Robinson syndrome*, which is inherited as an autosomal dominant trait and includes syndactyly and/or polydactyly in addition to nail and tooth anomalies.

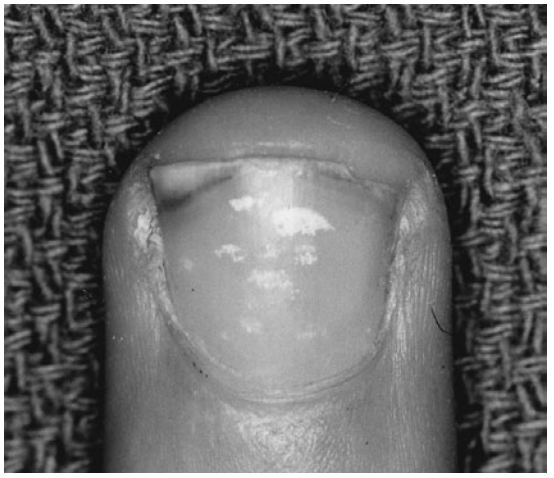
Multiple non-eruption of teeth, genua valga, and dysmorphic pinnae

Stoelinga et al (3) described autosomal recessive inheritance (parental consanguinity, four affected sibs) of multiple non-eruption of teeth with

A



B

C

Fig. 27–37. *Enamel hypoplasia, leukonychia, and sensorineural hearing loss*. (A) Severe enamel dysplasia. (B) Leukonychia. (C) Beau's lines on toe nail. (From A Heimler et al, Am J Med Genet 39:192, 1991.)

resultant overclosure of bite. In addition to genua valga, the pinnae were low and posteriorly rotated.

Other cases of tooth retention which may be autosomal dominant are those of Pönitz (1) and Shokeir (2). Facially, the patients shown somewhat resembled those having *cleidocranial dysplasia*. We suspect that these represent cases of *pseudohypoparathyroidism*.

Ankylosed teeth, maxillary hypoplasia, and fifth finger clinodactyly

Pelias and Kinnebrew (1) reported a syndrome of ankylosed teeth, bilateral clinodactyly of the fifth fingers, and mild relative mandibular prognathism due to maxillary hypoplasia in four generations. Ankylosis of the teeth, usually an isolated finding, has also been reported in association with enamel defects (2) and with multiple missing teeth (3) (Fig. 27–38).

Neuroendocrine carcinoma of salivary glands, sensorineural hearing loss, and enamel hypoplasia

Michaels et al (1) described four sibs from the Isle of Man with low-grade neuroendocrine carcinoma of salivary glands, severe sensorineural hearing loss, and enamel hypoplasia.

The submandibular glands were involved in three cases, and the minor salivary glands of the nasal cavity and maxillary sinuses in one. The tumors manifested when the patients were in their thirties. The tumors consisted of well-differentiated neoplastic ducts surrounded by neoplastic myoepithelial cells, together with sheets of epithelial cells expressing neuroendocrine markers by immunohistochemistry (Fig. 27–39). Metastasis to the cervical neck nodes occurred in all four individuals.

In the two male patients, there was severe sensorineural hearing loss which developed in adult life, unilateral in one brother and bilateral in the other. In the brother with the bilateral sensorineural hearing loss, a vestibular schwannoma was noted on one side.

Amelogenesis imperfecta was seen in three of the four siblings and in four of their offspring. The teeth were described as having a brown-yellow surface with vertical bands suggestive of the X-linked hypoplastic type.

Chapter 28
Well-Known Miscellaneous Syndromes

Alagille syndrome (arteriohepatic dysplasia)

In 1973, Watson and Miller (47) reported the association between intrahepatic cholestasis and pulmonary arterial stenosis. Alagille and coworkers (2), in 1975, added characteristic facies, mental, somatic, and sexual retardation, and vertebral and cardiac malformations. An earlier reference to the same condition is that of Vermassen and Boddaert (46). Low birthweight and growth retardation occur in about 50% , being more common in those with vertebral anomalies. Mueller et al (26) noted that about 25% die prior to the age of 5 years due to cardiovascular or hepatic complications. The chances of survival to 20 years without liver transplantation is about 50% (13). At least 150 cases have been reported (18).

Autosomal dominant inheritance with 95% penetrance and highly variable expressivity has been amply demonstrated (11,15a,18,21, 26,38,39,42,47). There is a high occurrence of new mutations (11). In at least 70%, various mutations in human *JAGGED 1 (JAG1)* gene have been found (45a,48). The gene encodes for a ligand for *NOTCH 1*, a transmembrane receptor (5,23,28). NOTCH intercellular signaling pathway mediates cell fate decisions during embryogenesis (23). Patients with isolated tetralogy of Fallot may have *JAG1* mutations (44). About 15% of the cases are sporadic (10). A deletion has been found at 20p12 in less than 7% (4,14,34,49). FISH is used. The frequency has been estimated at 1/70,000 live births (9).

Facies. Earlier than 1 year of age, the facies is not especially distinctive. Later prominent forehead, deep-set eyes, and long straight nose with flattened tip are seen in 95%. The frontonasal angle is straight, and there are flat midface, mild hypertelorism, and prominent chin. The pinnae are often outstanding (2,3,37,38). The postpubertal male has sparse facial hair (Fig. 28–1). Sokol et al (45) pointed out that the facies is not specific for Alagille syndrome but is a general feature of congenital intrahepatic cholestatic liver disease. In a recent study, about 80% were identifiable by the facies (19). Oligodontia and oral xanthomas have been noted in a patient (12a).

Eyes. Bilateral posterior embryotoxon (white line showing 2 mm over the limbus), pigmentary retinopathy, and strabismus are seen in about 85% (Fig. 28–2). Less frequent are ectopic pupil, band keratopathy, iris stromal hypoplasia (45%), choroidal folds, diffuse fundus hypopigmentation (57%), anomalous elevated optic disc and optic disc drusen (75%), and infantile myopia (7,12,15,27,31,32,35–37,39). Similar findings were found in one parent in 36% (12).

Cardiovascular. Peripheral pulmonary artery stenosis is found in 85%–95% (3). This may be an isolated finding (55%), but it may be found in combination with ASD, VSD, coarctation of the aorta, and tetralogy of Fallot (7%–10%) (26,38). In about 15%, there are isolated examples of congenital heart anomalies without peripheral pulmonary artery stenosis. The stenosis may occur at a single site or at multiple sites. Intracranial vascular anomalies may be found (6a,48a). Mutations in the *JAG1* gene can cause familial tetralogy of Fallot (10a).

Liver. Chronic cholestasis due to intrahepatic bile duct paucity with associated pruritus becomes evident during the first few months of life and persists (22). However, perhaps 25% do not manifest jaundice until later in infancy. Acholic stools and xanthomas may appear. There is hepatosplenomegaly, but no hepatic failure or portal hypertension. Cirrhosis eventuates in 10%–15% (17). Hepatic failure may eventuate (41). Hepatocarcinoma has been reported (1,6,16,17,20,30,33,41), perhaps being related to the loss of the gene on chromosome 20.

Skin. Palmar erythema and small telangiectases are frequent on the face and trunk. The skin of the proximal phalanges may be somewhat redundant (Fig. 28–3A), and supernumerary flexion creases of the digits are seen in about 30% (ID Krantz, personal communication, 2000).

Musculoskeletal. Vertebral anomalies of shape and/or segmentation (butterfly vertebrae, hemivertebrae, vertebral arch defects, reduced interpediculate distances, and plate irregularities) are present in about 85% (3,8,25,29) (Fig. 28–3B). A pointed anterior process on C-1 has been noted (38,40). Shortened distal phalanges and ulnae are common (8,22,37,38,40). Eleven pairs of ribs and fused ribs have also been observed. Osteopenia and retarded bone age are common (38,47). Radioulnar synostosis and narrow lumbar spine have also been reported (8). Short ulnae and short distal phalanges have been described (38). Those with short stature exhibit resistance to growth hormone (9).

A B C

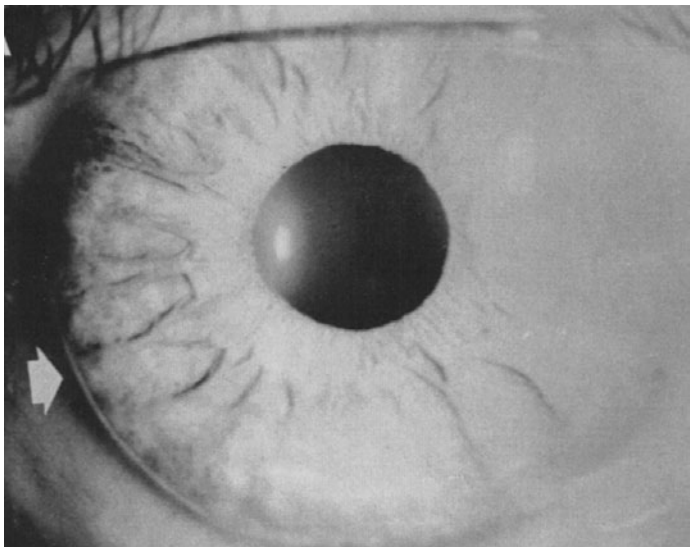

Fig. 28–2. *Alagille syndrome*. Posterior embryotoxin. Arrow points to white line that extends about 2 mm over the limbus. (From RF Mueller, J Med Genet 24:621, 1987.)

Genitourinary. Facial and body hair is sparse, but normal sexual function in males is common. Small kidneys, agenesis of a kidney, bifid kidney and its pelvis, mesangiolipidosis, and medullary cystic disease have been noted in 75% (3,38,47). Cystic dysplastic kidneys have also been reported (24).

Central nervous system. Minimal cerebral dysfunction has been described in about 60%. Poor school performance and misdemeanors are common. Reflexes may be absent or diminished. Moderate mental retardation has been reported in about 15% (2,3,47). The voice is often high pitched.

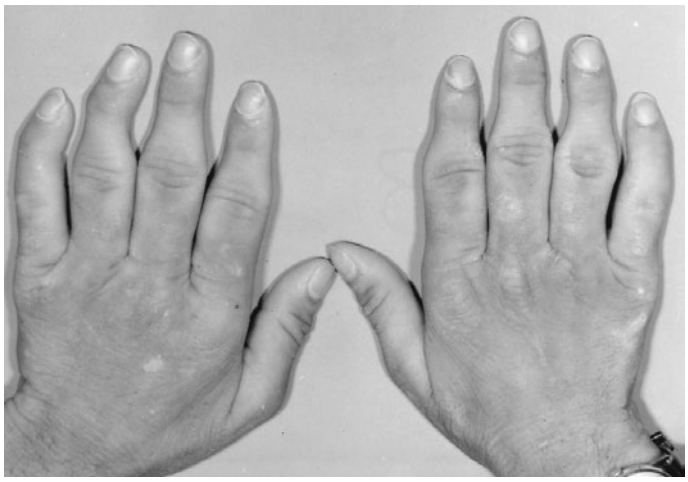
Pathology. Liver biopsy shows cholestasis and continued loss to the point of absence of interlobular bile ducts without fibrosis or cirrhosis in 95% (25,26). The common bile duct is hypoplastic but patent. Thyroid carcinoma has also been described (16).

Differential diagnosis. Prolonged neonatal cholestasis must be differentiated from extrahepatic biliary atresia, giant cell hepatitis, and various infections (rubella embryopathy). Arteriohepatic dysplasia must be differentiated from other forms of familial intrahepatic cholestasis such as Byler syndrome (a syndrome of abnormal bile acid synthesis), *Zellweger syndrome*, cholestasis-lymphedema syndrome, and α1-antitrypsin deficiency (46). Prominent Schwalbe lines (posterior embryotoxon) are seen in 8%–15% of normal individuals, in *Rieger syndrome* and other anterior chamber cleavage syndromes, and in *Bannayan–Riley–Ruvalcaba syndrome*. Pigmentary retinopathy is seen in a host of disorders. Riely et al (37,38) have exhaustively discussed differential diagnosis.

Peripheral pulmonary stenosis can be seen in myriad other conditions: rubella embryopathy, *Down syndrome, Williams syndrome, thalidomide embryopathy*, and various forms of nanism.

Laboratory aids. Atrophy of the interlobular bile ducts leads to defective secretion of bile. During the first 3 months of life there is moderate elevation of serum bilirubin and bile acids. The urine is dark and the stool is clay-colored. There is mild malabsorption of fat in children but not in adults. After 6 months of age, serum triglycerides and cholesterol become markedly elevated but this elevation also gradually disappears.

Hepatobiliary scintigraphy or operative cholangiography may be used to exclude obstructive causes of jaundice (e.g., biliary atresia). Ultrasound in older patients shows diffuse increases in echogenicity and loss of fine detail consistent with parenchymal liver disease (43). Kidney biopsy has shown mesangiolipidosis in about 70% (3).



A

B

Fig. 28–3. *Alagille syndrome*. (A) Note enlarged proximal fingers. (B) Butterfly vertebra.

Pulmonary artery stenosis can be demonstrated by cardiac catheterization or inferred from Doppler echocardiography.

CHARGE association and Hall-Hittner syndrome

Although the association was described earlier by a number of authors (2,19,20,34), Pagon et al (27), in 1981, employed the mnemonic CHARGE (*C*oloboma, *H*eart defects, *A*tresia choanae, *R*etarded growth and development and/or CNS anomalies, *G*enital hypoplasia, and *E*ar anomalies and/or deafness). Several excellent reviews are available (11,20,24,26,27,30,35). At least 250 cases have been reported. Prevalence has been estimated to be 1 per 10,000 (5). The role of the neural crest has been discussed (33–35). Although most instances are sporadic, affected parent and child, affected sibs, and monozygous and dizygous twins have been reported (4,6,11,18,23,26,27). North et al (25) suggested that one or more responsible genes map to the 14q22 area. Other authors have noted a deletion in the 22q11 area (13,14). Martin et al (23) noted t(2;7)(p14;q21.11).

Hall-Hittner syndrome is a recognizable subgroup. Diagnostic characteristics include coloboma, choanal atresia, asymmetric facial palsy, neurogenic swallowing deficit, classic CHARGE ears, and absence/hypoplasia of semicircular canals (1,5,16).

Polyhydramnios has been noted in about 50% of the cases and in nearly all of those with bilateral choanal atresia. Approximately 35% die during the first 3 months of life. Males with bilateral choanal atresia, central nervous system anomalies, esophageal anomalies, and congenital heart disease have a higher mortality rate (35).

If ascertainment is done by using choanal atresia as a constant feature (100%), variable mental retardation, motor delay, and postnatal growth retardation (95%) are the most constant abnormalities. If this bias is not

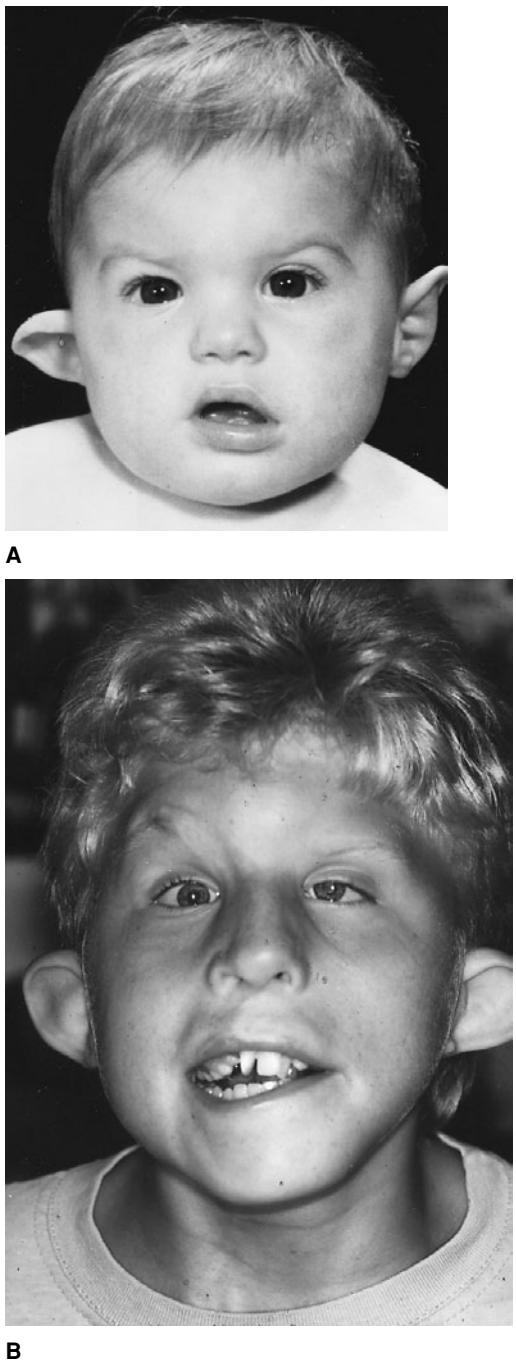
A B

Fig. 28–4. *CHARGE association*. (A,B) Mentally retarded child with choanal atresia, repaired cleft lip-palate, dysmorphic right ear with conduction hearing loss, right-sided facial palsy, coloboma of choroid and optic nerve, micropenis, cryptorchidism, pulmonary stenosis, and ASD. (Courtesy of HH Kramer, Düsseldorf, West Germany.)

introduced, about 55%–65% have choanal atresia (35). Birthweight and length are usually normal but postnatal growth is poor in 50%. Feeding problems are common in early infancy (17). Seen in about 90% are low-set, short, wide, asymmetric, outstanding, cup-shaped, simplified or lop ears, square face with malar flattening, pinched nostrils, long philtrum, prominent columella, cardiac defects (PDA, VSD, ASD, endocardial cushion defect, coarctation of aorta, vascular ring, hypoplastic left heart, tetralogy of Fallot) (10,21), unilateral or bilateral ocular coloboma of iris, retina, and/or disc, hypogenitalism in males (microphallus, poorly developed scrotum, cryptorchidism), and mental retardation (10,12,20,36,38). About 50% have central nervous system anomalies ranging from arhinencephaly to holoprosencephaly to other forebrain or hindbrain defects (22). Facial asymmetry, congenital microcephaly, high nasal bridge, malar hypoplasia, small mouth, cleft palate, swallowing difficulties, and congenital unilateral facial palsy have been noted in 40%–50% (Figs. 28–4 and 28–5 (8). Van Meter and Weaver (37) described two children with features linking CHARGE association and oculo-auriculo-vertebral spectrum. About 10%–15% exhibit postnatal microcephaly, micrognathia, and short neck. Mixed, progressive hearing loss, characterized by a wedge-shaped audiogram, is noted in 60% (35,36). Histologic examination of temporal bones has revealed the Mondini defect of the pars inferioris with complete absence of the pars superioris (28,32).

Less common anomalies (10%–30%) include tracheoesophageal fistula, esophageal atresia, minor renal malformations, and athelia (7,11, 15,26).

Choanal atresia is bilateral in 65% and it occurs more often on the left side (5,29). The ocular colobomas ranging from iris coloboma to clinical anophthalmia are seen in 80%–85% (31,35). Not uncommonly the coloboma is limited to the choroid and/or optic nerve. Nystagmus is noted in 25% (31). Occasionally, microphthalmos is noted. However, it



A B

Fig. 28–5. *CHARGE association*. (A,B) Rather typical face. Notice unusual pinnae. Mild degree of facial palsy. (A from CA Oley et al, J Med Genet 25:147, 1988.)

should be pointed out that if colobomatous microphthalmia is used as the constant feature, the overlap of the two associations is remarkable (18,19). Some patients exhibit the *DiGeorge sequence* (9). Hypopituitarism has been reported (3).

CHARGE association exhibits some overlap with *trisomy 13, del(4p), dup(4p), cat-eye syndrome, trisomy 22, del(9q), del(11q), del(13q)*, and VATER association (11,34). Choanal atresia is seen in combination with numerous syndromes (20). Undoubtedly many of the cases cited under our heading *cleft lip–palate, eye colobomas, vertebral anomalies, and mental retardation* are examples of CHARGE association. The X-linked *Abruzzo–Erickson syndrome* must be excluded. It combines cleft palate, short stature, hypospadias, and eye colobomas.

FG syndrome (unusual facies, mental retardation, congenital hypotonia, and imperforate anus)

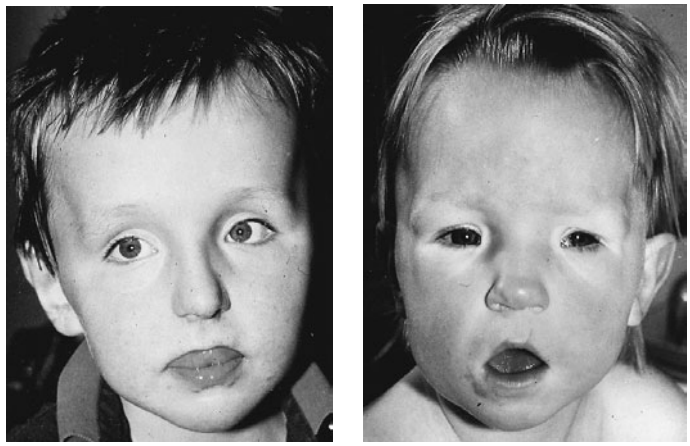
Opitz and Kaveggia (13), in 1974, reported a syndrome consisting of mental retardation, unusual facies, imperforate anus, and other anomalies. Opitz et al (14,15) subsequently expanded the syndrome to include characteristic personality, megalencephaly, joint contractures, and broad thumbs and/or halluces. About 55 patients have been reported 1,5,10,11,15,15a,17–19,21,25).

Inheritance is clearly X-linked with about 30% of heterozygotes manifesting stigmata (21,22). The *FGS1* gene has been mapped to Xq12–q21.31 (3,8,25). A second gene appears to be involved (4a,5a). There appears to be skewed inactivation of the X chromosome (8). A paracentric inversion has been noted (4).

Stature is variable. Initial size is short but there is catch-up growth. In others, birth size is normal but there is postnatal growth failure in 65%, possibly because of severe illness. About 30% of the patients die during the first few weeks of life from congenital heart disease or amniotic fluid aspiration. There also appears to be a second peak at about 2 years when death results from pneumonia.

Facies. The facies is quite variable and gradually disappears with age (19). The head, usually normal size at birth, becomes relatively macrocephalic and plagiocephalic in about 70%. Craniosynostosis has been documented in one instance (13). The anterior fontanel tends to remain open for a prolonged period. The forehead is high and broad. The frontal hair is upswept (cowlick) in 90% and its quality is soft, silky, and sparse in about 60%. There may be several hair whorls. The palpebral fissures frequently slant downward, less often upward, and the eyes appear deep set. The medial eyebrows flare. Hypertelorism, divergent strabismus (50%), epicanthic folds, and large corneae are common. The mouth is often kept open (facial hypotonia). The philtrum is long and the upper lip is thin. The lower lip is prominent and often there is drooling. Mild micrognathia and a high narrowly arched or cleft palate (1) are reported in 5% (Figs. 28–6 and 28–7). The teeth are usually crowded. Minor anomalies of the auricles are seen in about

Fig. 28–6. *FG syndrome*. (A) Broad forehead, downslanting palpebral fissures, strabismus, prominent lower lip, micrognathia. (B) Tall forehead, wide nasal bridge, downward slanting short palpebral fissures, long philtrum, open mouth. (From EM Thompson et al, Clin Genet 27:582, 1985.)



A B

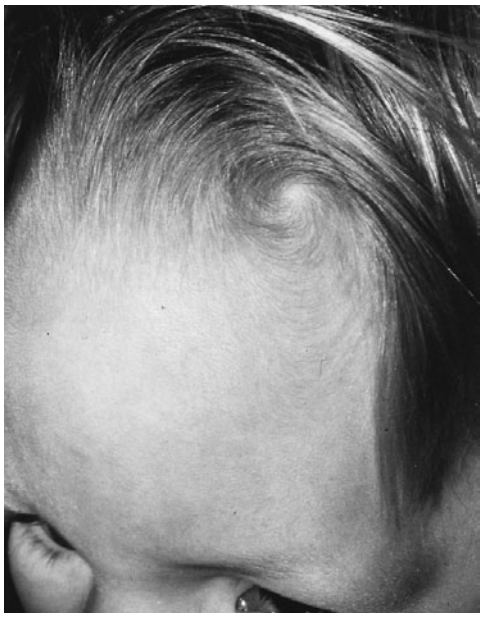


Fig. 28–7. *FG syndrome*. Frontal hair whorl. (From EM Thompson et al, Clin Genet 27:582, 1985.)

Fig. 28–8. *FG syndrome*. Toe padding. (From EM Thompson et al, Clin Genet 27:582, 1985.)

60%: small, simplified, occasionally protruding pinnae with mild posterior angulation and overfolded helix. Sensorineural hearing loss has been documented in 30% (11). Possibly parietal foramina are part of the syndrome (16).

Central nervous system. Mental retardation is constant and ranges from severe to mild but generally is moderate. Electroencephalographic disturbances are common but seizures are rare. The affect is one of hyperactivity (50%), affability, short attention span, and, occasionally, temper tantrums or aggression. Voice and speech are characteristic (9,25).

Partial absence, complete absence, or thinning of the corpus callosum has been reported (10,13,21–23). Thompson et al (23) reported necropsy findings consisting of simple convolutional patterning and large cavum septi pellucidi. Opitz et al (14) described midline fusion of mammillary bodies, heterotopia of neuroglial tissue in the seventh and eighth nerves, ependymal cell replacement by neuroglial tissue, and diffuse defect of neuronal cell migration.

In 90% there is severe congenital hypotonia, with secondary effects such as delayed motor development, feeding difficulties, and chronic bronchopulmonary problems. Other anomalies secondary to the central nervous system disorder include squint, ptosis, open mouth, malocclusion, variable degrees of congenital joint contractures (40%), winged scapulae, clinodactyly, pes planus, and genua recurvata.

Intestines. The most frequent intestinal and anogenital anomalies include severe constipation (70%), anal defect [imperforate, stenotic, anteriorly displaced, perianal skin tags (60%)], sacral dimple, malrotation of the bowel, small bowel atresia, absence of the mesentery, pyloric stenosis (10%), cryptorchidism (35%), hypospadias (25%), and inguinal and/or umbilical hernia (55%).

Other findings. There is a high fingertip whorl count (18) and there are fetal toe pads (Fig. 28–8). Broad thumbs and halluces are seen in 80% (10,15). Congenital heart defects are uncommon. Split hand has also been found (8).

Differential diagnosis. The dominantly inherited *Townes–Brocks syndrome* (imperforate anus, abnormalities of hands and feet, and sensorineural hearing loss) should be excluded. There is some overlap with the neurofaciodigitorenal syndrome (severe mental retardation, megalencephaly, high forehead, cowlick, groove of nasal tip, acrorenal field defect) (6). *Simpson–Golabi–Behmel syndrome* also needs to be excluded. Thompson et al (24) reported an X-linked mental retardation syndrome in which there was overlap with FG syndrome but without macrocephaly and with a different facies. Fryns et al (7) described two unrelated males with a syndrome overlapping FG syndrome but the small nose, relative microcephaly, and pre- and postnatal overgrowth make it distinctive. Another family that doesn't quite fit the FG syndrome is that of Stoll et al (2,20). Fetal toe pads are also seen in *Kabuki syndrome, Weaver syndrome*, and *del(18q) syndrome* (19).

Kartagener syndrome (immotile cilia syndrome, primary ciliary dyskinesia)

The relationship between situs inversus viscerum and bronchiectasis was pointed out by Siewert (49) in 1904. Kartagener (29,30), in a series of papers from 1933 through 1935, added chronic rhinosinusitis, that is, nasal polyposis, chronic hyperplastic rhinitis, and ethmoidomaxillary sinusitis. Numerous investigators have also noted the absence or hypoplasia of the frontal sinuses. More than 500 cases have been recorded.

The syndrome exhibits autosomal recessive inheritance (1,33,54). Consanguinity has been found in about 25%. However, there is marked genetic heterogeneity (7,7a,22,36). Identical twins with discordant laterality have been noted (38).

Primary ciliary dyskinesia has at least one gene mapped to 19q13.3-qter (31). A gene for situs inversus viscerum is located at 14q32 (35). That this may be the site for one form of ciliary dyskinesia is bolstered by the finding of two brothers with a form of type I Usher syndrome which also maps to 14q32 (7). A familial situs ambiguus has been mapped to Xq26 (18). Inversion of the long arm of chromosome 11 has also been cited (24a) as well as 5p (38a).

Narayan et al (36) described a mother and five sons with three different fathers. Heterotaxia syndrome may have autosomal recessive, autosomal dominant, or even X-linked inheritance (4).

There is no racial predilection (54). The frequency of immotile cilia (primary ciliary dyskinesia) syndrome is about 1/16,000 population (45,54).

Abnormal cilia are considered the underlying cause of the anomalies observed in Kartagener syndrome (17,44). Most studies have found partial or total absence of dynein side arms (11,59) that would inhibit mucociliary transport. Transposed ciliary microtubules, missing radial spokes, and supernumerary microtubules have also been found (8,10,21,42,51–53,58). It has been suggested that ciliary defects may develop with age (24,41) since children may have normal nasal ultrastructure. An animal model has been found (15).

Respiratory tract. Sinusitis is a frequent finding (Fig. 28–9). Similarly, nasal polyps, found in about 20%, have been reported with situs inversus in the absence of bronchiectasis. Agenesis or diminution of the frontal sinuses is common (34,39) but also is rather frequently seen in bronchiectasis and sinusitis without situs inversus, indicating a relationship between the sinuses and the rest of the respiratory tract, but not necessarily with visceral inversion.

Fig. 28–9. *Kartagener syndrome*. Bilateral maxillary sinusitis, more pronounced on right side.

In early infancy, nasal discharge, frequent colds, and chronic bronchitis are observed, as well as recurrent bouts of pneumonia. Nasal catarrh and anosmia soon intervene and are followed in most cases by chronic cough productive of foul-smelling phlegm. Nasal mucosal cilia are defective (56). Bronchiectasis is found is about 30% of older children and adults. In some persons, however, bronchiectasis seems to precede involvement of the upper part of the respiratory tract. Occasionally, there are accompanying asthma, hemoptysis, and pulmonary osteoarthropathy. Life expectancy is normal.

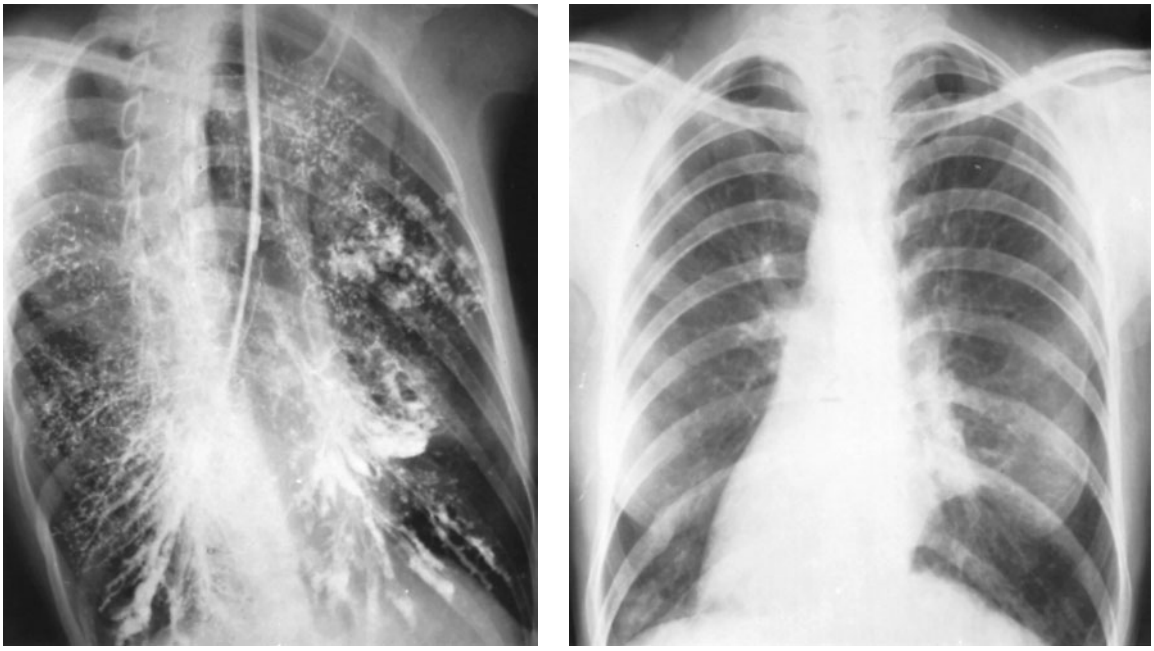
Among cases of situs inversus viscerum (see below), bronchiectasis is present in from 15% to 25% (34). This is far higher than the incidence among the general population (0.25%–0.50%) (30).

The bronchietasis is generally tubular or varicose, rather than cystic. There is still disagreement as to whether the bronchiectasis is of the acquired or congenital type (Fig. 28–10A).

Situs inversus viscerum. As an isolated phenomenon, situs inversus viscerum occurs once in about 8000 to 10,000 births (14,39). There is no unanimity of opinion concerning the relationship between visceral inversion and bronchiectasis, but possibly some factor predisposes the neonate with situs inversus to defective postnatal lung growth and atelectasis. About 50% of patients with immotile cilia syndrome manifest situs inversus (22,54). Ciliary orientation is more random than those in a control group (16,43). Rott (45) suggests that ciliary beats in the early embryo determine the type of laterality. Without the ciliary action, laterality develops randomly (16).

Dextrocardia, without further evidence of visceral inversion, has been frequently detected (56) (Fig. 28–10B), and corrected transposition has been reported once (50). Furthermore, investigators (20,47) have reported patients with Kartagener syndrome and features of the polysplenia field defect, suggesting a pathogenesis common to the two entities.

Fertility. Most males with Kartagener syndrome are infertile (2), due to an ultrastructural defect of sperm tails similar to that of respiratory cilia (16). There have been case reports of males with normal fertility (28) and normal spermatozoa (46). Female patients were originally considered to be normally fertile (3,6). However, Afzelius and Eliasson (2) found evidence that female fertility is also impaired, the Fallopian cilia being deficient in dynein arms (6,40).



A B

Fig. 28–10. *Kartagener syndrome*. (A) Bronchography showing bronchiectasis of left middle and both lower lobes. (B) Dextrocardia. Atelectasis of left middle lobe and right basal infiltration. (From A Glay, J Can Assoc Radiol 12:22, 1961.)

Other findings. Cases have been described with anomalous subclavian artery, malformation of retinal vessels, cardiac and renal anomalies, turricephaly, absence of the xiphoid process, thyrotoxicosis, spinal arteriovenous malformation (23), Paterson-Brown-Kelly syndrome (postcricoid web dysphagia, anemia, glossitis, cheilosis, and koilonychia) (55), mesangiocapillary glomerulonephritis (14), polysplenia (20,47) and extrahepatic biliary atresia (20).

Various associated eye anomalies have been reviewed by Segal et al (48). Chronic otitis media and hearing loss have been reported in several patients (26); Fischer et al (19) demonstrated that middle ear cilia were abnormal.

Valerius et al (57) noted depressed motility of polymorphonuclear leukocytes.

Differential diagnosis. Thick tenacious sinus and bronchial secretions, nasal polyposis, chronic sinusitis, and bronchiectasis also occur in cystic fibrosis. The histologic appearance of the respiratory epithelium, the bronchial plugging, and the absence of other stigmata (situs inversus viscerum) clearly distinguish cystic fibrosis from Kartagener syndrome. Ultrastructural defects may be seen in many individuals with repeated upper and lower respiratory infections (10). An especially good discussion of etiologies of familial bronchiectases is that of Davis et al (12).

Laboratory aids. Diagnosis can be achieved by studying mucociliary clearance (5) or ultrastructural examination of ciliary structures from samples obtained by nasal and bronchial brushing (32) (Fig. 28–11). Transmission EM with tannic acid staining is especially effective in demonstrating dynein abnormalities (27). Deficiencies in dynein arms on the outer microtubular doublets of cilia are most often (40%) evident. However, a host of other ultrastructural abnormalities have been reported [complete or incomplete absence of inner arms (6%), inner and outer arms (30%), radial spoke defect (10%), microtubular transposition, lack of central core structures, etc.] (1,9,13,52,54) (Fig. 28–12). Occasionally, no ciliary abnormalities are found (22). Abnormally long cilia have also been reported (37). Holtzmann et al (25) discussed a diagnostic approach.

Klippel-Feil anomaly

Klippel–Feil anomaly is characterized by faulty segmentation of two or more cervical vertebrae and, in its most severe form, consists of massive cervical vertebral "fusion," short neck, limitation of head movement, and low posterior hairline. The condition is morphologically and etiologically heterogeneous. Over 450 papers have been written on the subject (18), approximately 500 patients have been recorded to date (18,30), and extensive reviews are available (28,30).

Vertebral "fusion" is actually an inaccurate term, the condition resulting from failure of normal segmentation, which can be traced back to the third embryonic week when segmentation of mesodermal somites takes place (37). Although iniencephaly has been considered to be a severe form of Klippel-Feil anomaly (11,25,53), it has also been classified with anencephaly with retroflexion (52). Furthermore, little is gained by identifying iniencephaly with Klippel-Feil anomaly as the latter is neither a morphologic nor an etiologic entity.

Klippel–Feil anomaly was described as early as the sixteenth century, and involvement of the second and third cervical vertebrae has even been found in an Egyptian mummy of about 500 B.C.(26). In 1912, Klippel and Feil (34) described the postmortem findings of a 46-year-old French tailor who had a short immobile neck with massive fusion of cervical and upper thoracic vertebrae. Feil (22), in 1919, added 13 cases, 12 of which had been published previously. He defined three morphologic subtypes. Type I consisted of massive fusion of the cervical and upper thoracic vertebrae. In type II, fusion occurred at only one or two interspaces, but various anomalies such as hemivertebrae, occipitoatlantal fusion, and other defects could be present. Type III had both cervical and lower thoracic or lumbar fusion.

For type I, birth prevalence estimates have varied from a minimum of 0.025–0.03/1000 (36) to a maximum of 0.16/1000 (30). Sex predilection for females has been recorded by several authors (25,46), and Helmi and Pruzansky (30) have estimated the male:female ratio to be 1:1.3. Type II occurs more commonly, with a prevalence of 7.3/1000 (9,30), the most frequent sites of cervical fusion being at C_{2-3} and C_{5-6}.

Etiologic heterogeneity is evident and Gunderson et al (28) used Feil's (22) classification. For type I, almost all cases have been sporadic, although there have been a few familial examples (24,28). Autosomal recessive inheritance has been postulated (28), although among sporadic cases there has been female predilection, as indicated. Type II is transmitted as an autosomal dominant disorder and, in some instances, atlantooccipital fusion or other abnormalities may be observed (28). It has been suggested that type II is genetically heterogeneous with an autosomal recessive form also (33). For type III, an autosomal recessive mode of inheritance has been suggested (28). Da Silva (18) reported 12 cases of a newly recognized autosomal recessive disorder in an inbred kindred; patients had variable fusions of cervical, upper thoracic, and/or lumbar vertebrae, some presenting type I, others type III patterns. Raas-Rothschild et al (49) have opined that Klippel-Feil anomaly and sacral agenesis constitute a type IV. This and other examples have been represented by isolated cases (5,26,31). A dominant form associated with malformed larynx has been reported (13). In this form (vide infra), a gene has been mapped.

Clarke et al (14,15) reported a large family in which a chromosome inversion was found, suggesting that the gene is located at 8q22.2, the site of *SGM1.HOX* genes are involved in vertebral segmentation (40).

A large number of teratologic experiments in animals have resulted in vertebral malformations, suggesting that Klippel-Feil anomaly might occur on a teratogenic basis in humans. In this connection, Gunderson et al (28) reported a case of type I fusion in which the mother had attempted abortion with oral and parenteral agents on three occasions during the first trimester. The possibility of Klippel-Feil anomaly occurring on the basis of subclavian artery supply disruption has also been raised (8).

Bouwes Bavinck and Weaver (6) further suggested that a subclavian artery supply disruption to the developing embryo around the sixth week is responsible not only for Klippel-Feil anomaly, but Poland and Moebius anomalies, isolated terminal transverse limb defects, and Sprengel deformity.

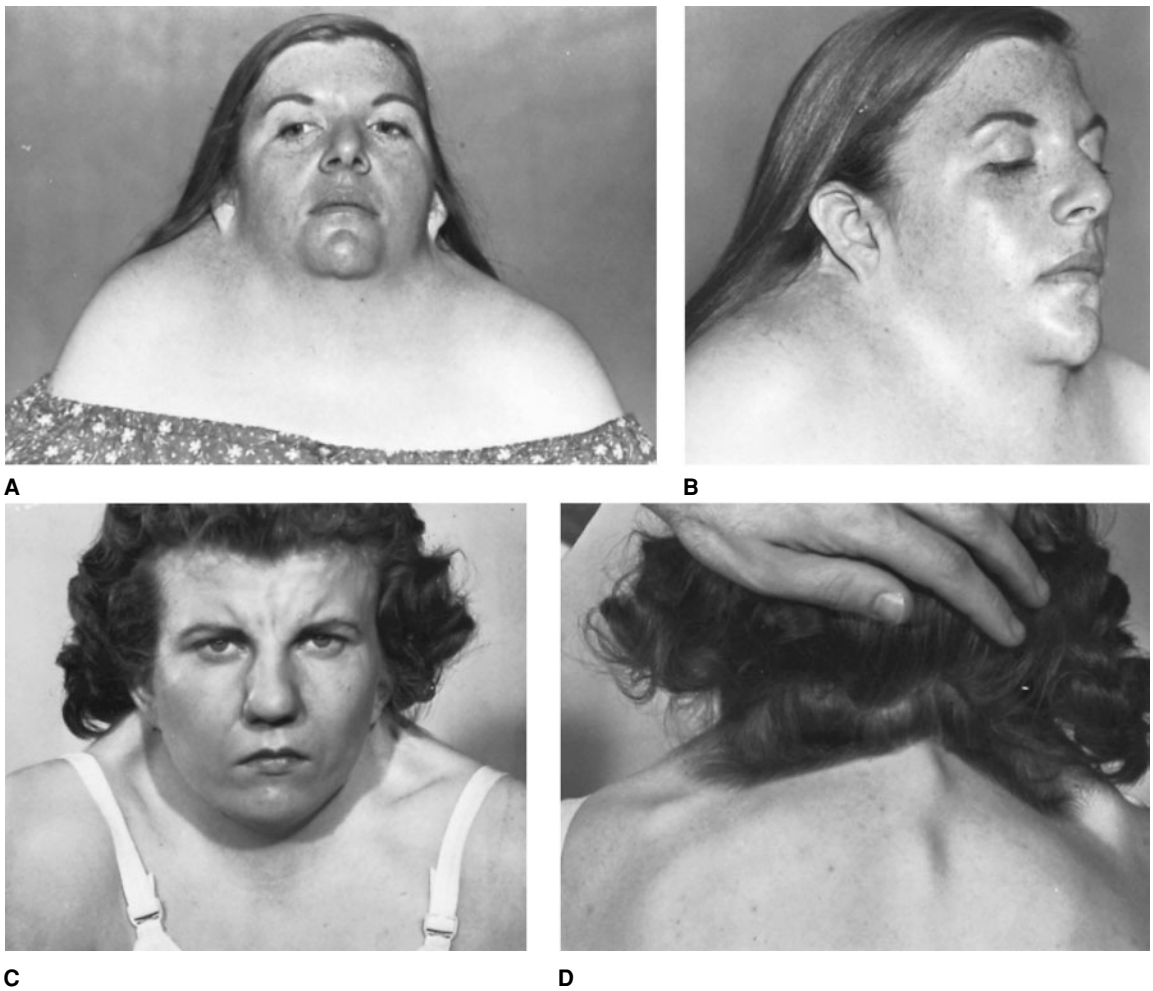

Fig. 28–13. *Klippel-Feil anomaly*. (A–D) Because of fusion of cervical vertebrae, the head appears to rest directly on the thorax, without an intervening neck. The pterygiumlike structures are actually the trapezius muscles. Note pulled-down slanted auricles in B and low-set posterior hairline in D.

Wildervanck syndrome consists of Klippel-Feil anomaly, abducens paralysis with retracted bulb, and sensorineural or conduction deafness (21). The appearance is striking, the head seeming to sit directly on the trunk with frequent facial asymmetry and/or torticollis. On medial gaze, the adducted globe becomes retracted as the eye slit narrows, a phenomenon known as Duane syndrome. Involvement may be unilateral or bilateral. Mental retardation has been noted on occasion. An overwhelming preponderance of females has been reported.

The MURCS association consists of *Mü*llerian duct aplasia, *R*enal aplasia, and *C*ervicothoracic *S*omite dysplasia. Vertebral defects occur especially from C_5 to T_1. Anomalies include Klippel-Feil anomaly, absent vagina, absence or hypoplasia of the uterus, renal agenesis, and a variety of low-frequency defects (1,7,10,29,41,43,47,57,63). This is the same as Rokitansky-Küster-Hauser syndrome. The corresponding disorder in males is characterized by azospermia (38,42,62,66). Hearing loss is found in 25% (17,57).

Chemke et al (12) described a patient with Klippel-Feil anomaly, torticollis, preauricular appendages, cleft palate, Sprengel deformity, absent ulna, and flexion contractures of the affected upper extremity.

Fragoso et al (23) reported a female with Klippel-Feil anomaly, ocular hypertelorism, broad nose, Sprengel deformity, and postaxial polydactyly. The patient may represent an example of craniofrontonasal dysplasia. However, no craniosynostosis was evident.

JW Hanson and MM Cohen Jr (personal observation, 1975) noted two male sibs with Klippel-Feil anomaly, mild ocular hypertelorism, downslanting palpebral fissures, prominent nasal bridge, micrognathia, submucous cleft palate, dislocated radial heads, positional foot deformities, and scoliosis.

Various authorities differ in their interpretation of what constitutes Klippel-Feil anomaly. The following description is confined to massive cervical vertebral fusion (type I) only.

Head and neck. The head seems to sit directly on the thorax, without an interposing neck. The flaring trapezius muscles extend from the mastoid areas to the shoulders, producing a pterygiumlike effect. Occasionally, there is facial asymmetry, with one eye situated lower than the other (44). Posteriorly, the hairline extends to the shoulders (Fig. 28–13).

Associated abnormalities (Table 28–1) have been especially well reviewed by Helmi and Pruzansky (30). The most common eye finding has been convergent strabismus (4). Less frequently found are horizontal nystagmus and chorioretinal atrophy. From 25% to 50% have exhibited hearing loss that may be sensorineural, mixed, or conductive (30,32,38a,39,50,56); many likely represent Wildervanck syndrome. Mondini type dysplasia has been found in some cases (64). Cleft palate is present in about 17% (1,16,30,46,55,59).

There have been several examples of partial duplication of the jaws in a Klippel-Feil-like syndrome (3,19,35) (Fig. 28–14).

Musculoskeletal system. Characteristically, several, occasionally all, cervical vertebrae are fused into a solid mass. In some instances, upper thoracic vertebrae may be involved. Scoliosis, cervical ribs, and/or the Sprengel deformity have been noted in about 30% (26,34,54). Other

Table 28–1. Klippel-Feil anomaly associated abnormalities

Abnormalities	Percentage ($n = 160$)
Neurological abnormalities	49
Mirror movements	(16)
Paralysis and palsy	(9)
Astereognosis	(4)
Syringomyelia	(1)
Paresthesia	(4)
Mental retardation	(9)
Meningocele	(4)
Occipital encephalocele	(4)
Hydrocephaly	(2)
Other neurological problems	(16)
Hearing deficits	24
Speech defects	17
Ocular abnormalities	21
Cleft palate	17
Congenital heart defects	9

(Based on C Helmi and S Pruzansky, Cleft palate J 17:65, 1980. Percentages are rounded off to nearest whole number. Percentages sum to greater than 100% because several abnormalities frequently occur in same patient.)

common findings include spina bifida occulta, fusion of the atlas with the occipital bone, cleft vertebrae, and hemivertebrae.

Central nervous system. A large number of associated neurologic disturbances have been recorded: spasticity or hyperreflexia, bimanual synkinesis or mirror movements (2,4,27), syringomyelia or syringobulbia (44,54), hemiplegia, paraplegia, triplegia, quadriplegia, and others. The neurological findings have been thoroughly reviewed by Mosberg (44). A case with neuroschisis of the cervical spinal cord has been noted (45).

Other findings. Congenital heart defects, usually ventricular septal defect, are occasionally reported (46,60). Situs inversus has been noted (12a) as well as Kallman syndrome (65).

Differential diagnosis. The flaring trapezius muscles give the patient an appearance that may simulate that in *Turner syndrome* or *Noonan syndrome*. The position of the head on the thorax may resemble that seen in tuberculosis of the cervical spine or in *Morquio syndrome*. Spondylothoracic dysplasia is genetically heterogeneous, consisting of dominant and recessive forms. The entire vertebral column is involved in fusions, hemivertebrae, scoliosis, etc. (10,48,61). In the *nevoid basal cell carcinoma syndrome*, cervical or upper thoracic vertebral fusion is observed in about 40%. In the *fetal alcohol syndrome*, cervical fusion occurs in approximately 40%, especially involving C_{2-3}. In *Crouzon syndrome*, approximately 30% have cervical fusion most commonly involving C_{2-3}. With *Apert syndrome* and with *Binder phenotype*, fusion of C_{5-6} (58%) or involvement of three or more vertebrae has been reported. Cervical vertebral anomalies and other defects of the spine may occur with *oculo-auriculo-vertebral spectrum* and in between 5% and 15% of those with cleft lip and palate (51). Mirror movements as an isolated finding may be inherited as an autosomal dominant trait (50). In addition, one must exclude the associations described in the introduction to this chapter such as *Wildervanck syndrome*, MURCS association, etc. For further discussion, see *Wildervanck syndrome*.

Fig. 28–14. *Klippel-Feil-like syndrome*. (A,B) With the mouth closed, indentations extend from the angle of the mouth toward the ears. When the mouth is agape, the child looks normal. One of us (RJG) is aware of three examples: those of H-R Wiedemann, GH Vance, and C Morris. The patients have mild cervical fusion, mild hearing loss, and partial duplication of the maxilla. (Courtesy of GH Vance, Indianapolis, Indiana.)

Opitz trigonocephaly syndrome (C syndrome)

In 1969, Opitz and co-workers (16) reported on a newly recognized syndrome in two sibs, naming it the "C syndrome of multiple congenital anomalies." The condition has subsequently been known as "Opitz trigonocephaly" syndrome (8,14). It comprises trigonocephaly, unusual facial appearance, wide alveolar ridges, multiple buccal frenula, limb defects, visceral anomalies, redundant skin, mental deficiency, and hypotonia.

To date, at least 40 published and 30 unpublished cases have been seen (2,4–8,10–13,15–21,23,24). It is unlikely that case 13 reported by Pfeiffer (17) also represents the disorder in two affected sibs; they more likely had Smith–Lemli–Opitz syndrome. Normal chromosomes, normal parents with multi-affected offspring, equal sex ratio of affected individuals, and consanguineous matings (2,12,16,21) suggest autosomal recessive inheritance. However, it is possible that we are dealing with heterogeneity.

Approximately half of the patients die within the first year of life. The patient reported by Golabi et al (11) was alive at 3 years.

Clinical features. The clinical findings are summarized in Table 28–2. Trigonocephaly, upslanting palpebral fissures, conspicuous epicanthic folds, strabismus, hypoplastic nasal root, anomalous and posteriorly angulated pinnae, glabellar capillary hemangioma, loose skin with cutis marmorata, and joint contractures and dislocations are observed in over 70% (Figs. 28–15 to 28–17).

Some abnormalities may change with age. Head size, for example, is normal at birth, but there is a tendency to develop microcephaly postnatally. In addition to the metopic suture, other sutures may be involved. Flatz et al (8) observed craniosynostosis involving the coronal, sagittal, and lambdoid sutures.

Wide alveolar ridges and deep midline palatal furrow are also common characteristics. Cleft palate was reported in one case (17). The ears are soft. Extracranial findings, seen in about 50%, include genital abnormalities, various congenital heart anomalies (2,8,10), and hemangiomas. Omphalocele has been noted (13).

Neurologic findings include hypotonia (30%), poor sucking reflex, and severe mental retardation (95%). Seizures (2), agenesis of corpus callosum (6,10,21,25), Dandy–Walker malformation (25), occipital meningocele (25), and medulloblastoma (15) have been observed in some cases. Normal (or nearly normal) intelligence has been noted by a few authors (13,24).

Low frequency findings include hypoplasia of middle and distal phalanges, renal cortical cysts, omphalocele (13), anal stenosis, microcornea (13), clitoral enlargement (2), and pectus (2,8,16).

Differential diagnosis and laboratory aids. Patients with Opitz trigonocephaly syndrome should be studied carefully for possible cytogenetic abnormalities. In two instances, patients originally diagnosed as having C syndrome were found to have abnormalities involving chromosome 3. One patient reported by Preus et al [18(case 2)] was later

Table 28–2. Opitz trigonocephaly syndrome (C syndrome)

Findings	Frequency
Performance	
Hypotonia	12/19
Mental deficiency	18/19
Seizures	5/19
Cranial	
Trigonocephaly	23/23
Postnatally developing microcephaly	13/21
Premature closure of other sutures	7/19
Cowlick	11/22
Facial	
Upslanting palpebral fissures	22/23
Epicanthic folds	20/22
Strabismus	16/22
Broad depressed nasal bridge	15/22
Long philtrum/small nose	21/23
Wide mouth	12/23
Wide alveolar ridges	10/18
Deep midline palatal furrow	16/21
Attached frenula	6/19
Micrognathia	15/22
Anomalous, posteriorly angulated ears	18/21
Neck	
Short neck	15/20
Limbs	
Polydactyly, postaxial	3/21
Bridged palmar creases	10/22
Ulnar deviation of fingers	4/21
Short limbs	5/22
Hip dysplasia	6/21
Dislocated knee	4/21
Equinovarus or valgus deformity	8/21
Contractures	7/21
Skin	
Redundant skin	14/20
Hemangiomas	9/17
Deep sacral dimple	5/17
Cardiovascular	
Congenital heart anomaly	11/22
Genital	
Cryptorchidism	7/9

Approximaly one-half of all patients die within the first year of life. Survivors develop microcephaly and mental deficiency. [From MM Cohen Jr (ed), Craniosynostosis, Diagnosis, Evaluation and Management, Raven Press, New York, 1986.]

found to have dup(3)(q23–qter);del(p25–pter) (19), and another studied by Sargent et al (21) had 46,XY,del(3)(pter–q27:). Preus et al (19) and McGaughran et al (13a) suggested that other C syndrome patients from the literature had a phenotype compatible with *dup(3q) syndrome*. The C syndrome patient reported by Golabi et al (11) had 47,XXY karyotype.

Differential diagnosis includes isolated trigonocephaly, other chromosomal syndromes with trigonocephaly such as *del(9p), del(11q)*, and *dup(13q)* (21). Monogenic syndromes with trigonocephaly include *Frydman trigonocephaly syndrome* (9) and *Say-Meyer trigonocephaly syndrome* (22).

Bohring et al (3), Addor et al (1), Oberklaid and Danks (14), Nakane et al (13b), and Brunner et al (3a) reported isolated examples of a syndrome that has considerable overlap with Opitz (C) trigonocephaly syndrome. However, they differed on the basis of intrauterine growth retardation, cleft lip/palate, exophthalmos, retinal involvement, flexion deformities of the upper limbs, dislocation of radial heads, situs abnormalities, nephroblastomatosis, and forehead hirsutism, seen in Bohring syndrome. This may be due to a 3q subtelomeric duplication (A Bohring, personal communication, 2000).

Fig. 28–15. *Opitz trigonocephaly syndrome*. Trigonocephaly, long upper lip, contractures at wrist. (From F Oberklaid and DM Danks, Am J Dis Child 129:1348, 1975.)

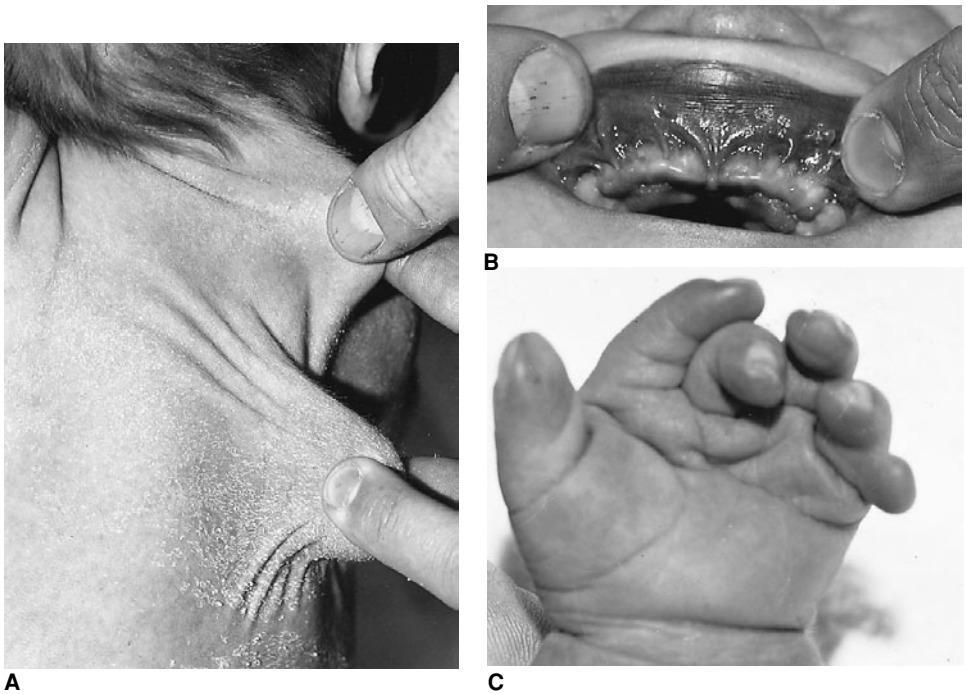
Smith-Lemli-Opitz syndrome

The syndrome, first defined by Smith et al (58), in 1974, is characterized by microcephaly, growth and mental retardation, soft-tissue syndactyly of toes 2–3, and genital abnormalities. Donnai et al (19) and Curry et al (13) drew attention to those at the severe end, that is, those affected with marked failure of masculinization of the external genitals in XY males or even "sex reversal." These infants also exhibited multiple visceral abnormalities and frequent neonatal lethality. For a while, it was thought there were two allelic forms, designated types I and II, but biochemical findings indicated that division was spurious (see below) (44,50). At least 350 patients have been described. Comprehensive review and bibliographies are those of Opitz et al (45–47). Excellent discussions are those of Kelley and Hennekam (29) and Ryan et al (54). The syndrome at various ages is described by Krajewska-Walasek et al (33).

Decreased fetal movement and oligohydramnios are often encountered, as is reduced or absent production of midtrimester estriol in affected fetuses. Breech presentation occurs in 50% and birth asphyxia is extremely common. Birthweight is less than 2500 g in approximately 35%.



A B C

Fig. 28–17. *Opitz trigonocephaly syndrome*. (A) Redundant skin. (B) Multiple frenula. (C) Postaxial polydactyly. [From JM Opitz et al, Birth Defects 5(2):161, 1969.]

Prematurity is noted in 25%. Neonatal feeding difficulties and irritability are seen in 90%. Prolonged high-pitched screaming has been described in 20%. Severely affected infants may die neonatally due to failure to thrive and hepatic dysfunction. Short stature is noted in those that reach childhood (33). Survival to adulthood is rare (49).

The syndrome has autosomal recessive inheritance (13,36,43). More males (70%) have been diagnosed, but we suspect that this is due to the frequent hypospadias. The gene has been mapped to 7q32.1 (2,3,56,63) and 11q12–q13 (64). The former reflects a defect in the Sonic Hedgehog pathway (see below). There is quite variable expression (13,39). Phenotypic expression has varied from 2–3 syndactyly of the toes to holoprosencephaly (12). Estimates of the occurrence of the syndrome in white North Americans have been between 1 per 20,000 and 1 per 40,000 births making it the third most common autosomal recessive disease after cystic fibrosis and phenylketonuria (60). An estimate of 1 per 60,000 has been made in the United Kingdom (54).

Tint et al (60,61), in 1994, found that patients with the syndrome have abnormally low levels of plasma and tissue cholesterol and extremely high levels of 7-dehydrocholesterol reflecting a defect in 3β-hydroxysterol-Δ^7–reductase (31,57,65). However, about 10% have normal cholesterol levels and would have been missed had not levels of 7-dehydrocholesterol been observed (12). A rapid ultraviolet spectrometric method for 7-dehydrocholesterol estimation has been described (23). Animal models have been created (17,35,67). Abnormal cell populations have been found at the rim of the developing forebrain and in the alar plate of the lower midbrain and hindbrain (17). Cholesterol is needed, inter alia, for morphogenetic signaling during embryogenesis (51). There is a presumed loss or defect of *Sonic Hedgehog* protein function in the syndrome (30). Tint et al (62) demonstrated that those with the more clinically severe syndrome had far lower levels of serum cholesterol, that is, the block was more complete. However, Cormier-Daire et al (11) and Cunniff et al (12) did not verify this correlation. Mutational analysis of 84 patients revealed that those with mutations in the transmembrane and c-terminal regions had the mildest phenotype (65,66). Rapid PCR-based assays have been used for the more common mutations (33a).

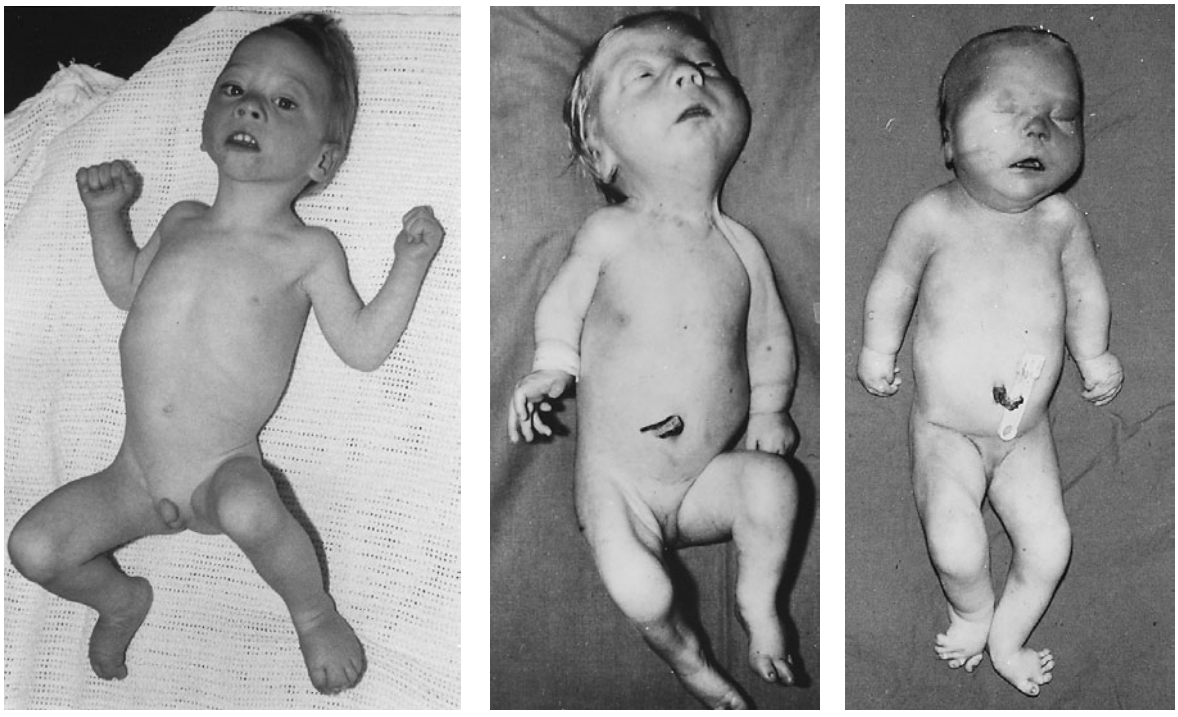
Facies. The face tends to be round with microcephaly (95%), ptosis (occasionally unilateral) (85%), strabismus (40%), epicanthal folds (40%), wide nasal bridge (50%), anteverted nares (75%), low-set and/or retroverted (35%) or outstanding pinnae (60%), micrognathia (80%), and short neck with redundant skin folds (5,43,58) (Figs. 28–18 and 28–19). A nevus flammeus over the glabella may be noted. The facies normalizes with age (15), but the lips become thick and pouting (33). Diagnosis becomes difficult during adolescence (33).

Eyes. Ptosis (60%), convergent strabismus (40%), epicanthus (40%), and hypertelorism (25%) have been documented. Cataracts are noted in 10% in those at the milder end of the spectrum (7) and in 45% of those with more severe expression (13,19,21,36).

Central nervous system. The most extreme form is holoprosencephaly (12,30). Microcephaly is found in over 90%, with 40% having abnormal skull shape. Patients have a wide range of developmental defects of the brain (ventricular dilatation, seizures, partial agenesis of cerebellar vermis and/or corpus callosum, hypoplasia of frontal lobes), associated with severe retardation (10,43). During the neonatal period, hypotonia is noted in about 50%, while, later in life, hypertonia is documented in 30%. Aggressive behavior and self-injuries are often noted in those that survive (54). There is markedly reduced myelination of both brain and peripheral nervous system. Reflexes are brisk (41). Motor skills seem to improve with age (33). Abnormal sleep patterns have been noted in 70% (54). An excellent summary of the behavior phenotype is that of Tierney et al (59a).

Limbs. Postaxial polydactyly of hands or feet ranges from 25% in milder examples (7) to 75% in severely affected (13,36). A short first metacarpal with secondary short thumb has been seen in nearly all (54). A peculiar short first metatarsal and valgus foot positioning are frequent. About 50% of the infants have dislocated hips. Transverse palmar creases are frequent (36). Soft-tissue syndactyly of the second and

Fig. 28–18. *Smith-Lemli-Opitz syndrome*. (A) Note microcephaly, small upturned nose, epicanthal folds, abnormal genitalia, soft tissue syndactyly of second or third toes. (B,C) Unusual facies, superficial angiomas, limb shortening, inguinal skin creases, postaxial polydactyly. Note apparent female genitalia in 46,XY patients. (A,C courtesy of D Donnai, Manchester, England. B from CJR Curry et al, Am J Med Genet 28:45, 1987.)



A B C

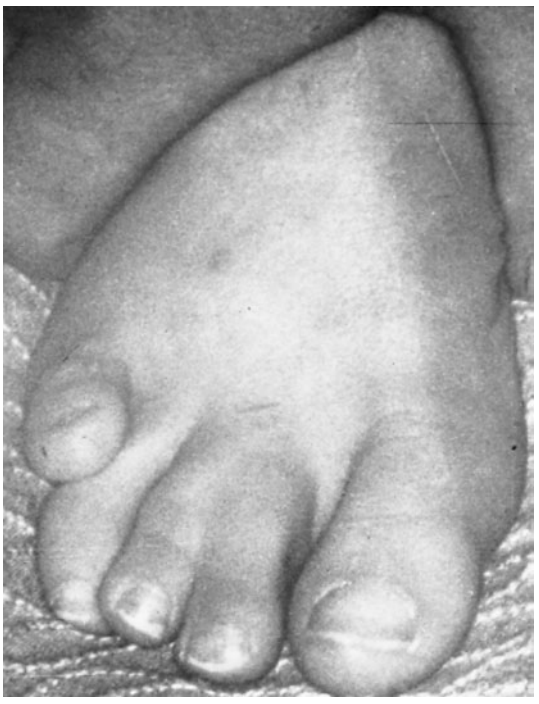
A B

Fig. 28–19. *Smith-Lemli-Opitz syndrome*. (A,B) Facial angiomas, short nose, micrognathia, short neck. (Courtesy of D Donnai, Manchester, England.)

third toes has been noted in about 80% (43) (Fig. 28–20). The thumbs are often short (54). The proximal limbs are short without evidence of primary bone dysplasia (Fig. 28–21). Positional foot abnormalities are common: metatarsus adductus, pes equinovarus, and metatarsus varus. Other findings have included clinodactyly of fingers, hallucal hammertoe, proximally placed thumbs, and long tapered fingers. Rare patients have ectrodactyly and/or preaxial polydactyly (18). Dermatoglyphics may be abnormal and diagnostic with high absolute and relative total ridge count, interdigital and hypothenar patterns with increased *atd* angle, distal triradii, and occasional zygodactyly.

Genitalia. In males, genital changes, found in 70%, range from mild abnormality to genital ambiguity or "sex reversal" or male pseudohermaphroditism (perineoscrotal hypospadias with perineal urethral opening); most common are bilateral cryptorchidism (50%) and hypospadias (50%) (7). Microphallus and/or chordee have been documented in 20% (Fig. 28–22). No male with more severe expression has had normal genitalia; the majority have been assigned female gender and, among the rest, sex assignment has been unclear. Features noted in XY males have included hypoplastic labia majora, absent labia, scrotalization of the labia, prominent clitoris, third degree hypospadias, micropenis, and bifid scrotum (see Fig. 28–18B,C). Autopsies in severely ambiguous XY infants have revealed intraabdominal or inguinal testes, and, in most, Müllerian duct remnants. A few XY infants have had hypoplastic vagina and uterus (13,36). Occasionally, males have normal female genitalia (22,48). Females have hypoplastic labia.

Fig. 28–20. *Smith-Lemli-Opitz syndrome*. Soft-tissue syndactyly of second and third toes. Note short fifth toes with tibial clinodactyly. (From CG Judge et al, Med J Aust 2:145, 1971.)



Kidney. Upper urinary tract changes, found in 55%, have been reported in 45% of those at the mild end: ureteropelvic obstruction, hypoplasia, renal duplication, hydrocephalus, cystic and dysplastic alterations. Renal cysts and hypoplastic kidney are frequent in severe examples (7,19,22,28,32,38).

Fig. 28–21. *Smith-Lemli-Opitz syndrome*. Valgus deformity of feet, short halluces, polysyndactyly. (Courtesy of D Donnai, Manchester, England.)

Fig. 28–22. *Smith-Lemli-Opitz syndrome*. Hypospadias and hypoplastic scrotum. (From CG Judge et al, Med J Aust 2:145, 1971.)

Heart. Various congenital heart anomalies (PDA, VSD, tetralogy of Fallot, aberrant right subclavian artery, ASD) have been reported in 20% to 100%, depending on severity of expression (10,22,43,48,52,55). The most comprehensive study is that of Lin et al (37). They found that 45% had cardiovascular malformations, the most frequent being secundum type ASD, PDA, AV canal, and anomalous pulmonary venous return. We have seen coarctation of the aorta in an 11-year-old male.

Oral manifestations. Cleft palate has been found in about 50% (7,13,22,36,48) and broad maxillary alveolar ridges in over 60%. However, the maxilla is relatively small and the anterior spine may be absent. The tongue tends to be small. There may be redundant sublingual tissue (Fig. 28–23). Lingual cysts have been found in a few cases (36).

Miscellaneous. At autopsy, unusual findings have included pancreatic islet cell "giant cell" hyperplasia, unilobate lungs, pyloric stenosis, and Hirschsprung disease (8,22,36,48,69). Photosensitivity has been noted in about 65% (4,54).

Differential diagnosis. Differential diagnosis of Smith-Lemli-Opitz syndrome can be quite extensive. A chromosome anomaly should clearly be ruled out. In severe examples of SLO syndrome, major diagnostic confusion can exist with *Meckel syndrome*. Some patients initially diagnosed and published as examples of Meckel syndrome likely represent such cases. Sibs published by Casamassima et al (9) have features of both Smith-Lemli-Opitz syndrome and Meckel syndrome. They had cerebellar findings similar to those of Joubert syndrome but this disorder seems to stand as a distinct condition (24,59). There are some similarities with *Pallister-Hall syndrome*. However, the presence of a hypothalamic hamartoblastoma appears to be unique in the latter syndrome. *Hydrolethalus syndrome* may present occasional diagnostic difficulty in the hydrocephalic patients. In *Meckel syndrome*, there is a characteristic cystic kidney dysplasia. SLO syndrome may possibly be the same as *genito-palato-cardiac* or *Gardner-Silengo-Wachtel syndrome*. In SLO the testes are present; in *genito-palato-cardiac syndrome*, there is gonadal dysgenesis. We are uncertain how to classify the disorder reported by Rutledge et al (53), but that also may be SLO. Joint contractures, cerebellar hypoplasia, and tongue cysts seem to distinguish it from SLO syndrome. An apparently unique condition resembling *Raine syndrome* and, to some degree, that of SLO is due to desmosterolosis (20).

Laboratory aids. Prenatal diagnosis in SLO has been accomplished sonographically (27) and by finding accumulation of 7-dehydrocholesterol in amniotic fluid (1,14,40) and in chorionic villus specimens (26,34). Increased nuchal translucency was found on ultrasound (25).

Fig. 28–23. *Smith-Lemli-Opitz syndrome*. Palatal cleft, small tongue, redundant sublingual tissue. (From CJR Curry et al, Am J Med Genet 28:45, 1987.)

Cholesterol values in Smith-Lemli-Opitz syndrome are often less than 1.00 mmol/l (normal 4.83 ± 0.8), while 7-dehydrocholesterol, normally less than 0.002 mmol/l, may reach 0.800 in those with Smith-Lemli-Opitz syndrome (16). Cholesterol determination/fractionation can aid in diagnosing atypical cases (56), and old specimens (42). Newborn screening cords can be used for definitive diagnosis. Filter paper blood specimens using secondary ion mass spectrometry has been advocated (68).

Chapter 29
Other Miscellaneous Syndromes

Acro-renal-mandibular syndrome

Halal et al (3) reported two French-Canadian female sibs whose parents were consanguineous. Both exhibited severe split hand and foot malformations, renal (polycystic kidneys, renal agenesis, and absent ureters) and genital (septate uterus, unicornuate uterus, and single tube) abnormalities, and very severe micrognathia (Fig. 29–1). Although split hand and foot occurs in the classic acro-renal syndrome, no patient has had micrognathia as severe as that observed in Halal's patients. Moreover, all known instances of acro-renal syndrome have been isolated males with no history of parental consanguinity. They have had unilateral renal agenesis, crossed renal ectopy, hypospadias, and/or cryptorchidism. The female reported by Fitch and Lachance (2) did not have micrognathia. The three sibs described by Evans et al (1) were more severely affected. Hennekam et al (4) also noted sibs with a similar phenotype.

Inheritance is autosomal recessive.

Aberrant oral frenula, cataracts, and growth retardation

Wellesley et al (1), in 1991, described a mother and her son and daughter with posterior polar cataracts, numerous aberrant frenula, growth retardation, and unusual facies.

Growth retardation was below the third centile. Facial changes included epicanthic folds, short upslanting palpebral fissures, small nose with upturned tip, and posteriorly angulated ears with a creased lobule. The scalp hair was coarse, blond, and curly. The son exhibited unilateral ptosis, the daughter, a cavernous hemangioma at the corner of her mouth.

Inheritance is presumably autosomal dominant.

Agenesis of salivary and lacrimal glands

Major salivary glands and lacrimal glands have been reported to be symmetrically aplastic or severely hypoplastic. Early examples are those of Bradbury (3) in 1879, Ramsay (18) in 1924, and Blackmar (2) and Raison (17) in 1925. At least 30 case reports are available. Duct orifices are often missing, but ducts may be present (1,16). The lacrimal points may be missing or hypoplastic (1,2,5,9,13,14,23). Early cases of isolated absence

Fig. 29–1. *Acro-renal-mandibular syndrome*. (A) Note severe mandibular hypoplasia and mild Potter facies. (B) Bilateral split foot anomaly. Cleft involves lower third of leg. Note hypoplastic toes. Sib was similarly affected. (From F Halal et al, Am J Med Genet 5:277, 1980.)

Fig. 29–2. *Agenesis of salivary and lacrimal glands*. Severe lack of saliva results in extensive dental caries.

of glands have been reviewed (20,23,25). The resultant lack of secretions causes severe dryness of the oral and conjunctival mucosae. The lips are often cracked. The teeth decay and fracture at the neck (Fig. 29–2). Mastication is extremely difficult (7).

There are several reports of the disorder affecting two or more generations (4,5,6a,18,20,26). Others have been isolated examples (8,11,15,19,21–23). There are also numerous reports of dominantly inherited isolated deficiency of lacrimal glands or atresia of the lacrimal puncta (12). The literature has been reviewed by Caccamise and Townes (4) and McDonald et al (10). Computerized tomography, MRI, and (99m) Tc-pertechnetate scintigraphy have been used in diagnosis (14,22,26,27).

Aplasia of salivary glands may be an isolated finding or may be seen in *lacrimo-auriculo-dento-digital (LADD) syndrome*, in *oculo-auriculo-vertebral spectrum* (24), or in the rare example of *hypohidrotic ectodermal dysplasia* (6). It has been noted in association with cleft lip and palate (9a).

Achalasia, alacrima, and adrenal deficiency (triple A syndrome, Allgrove syndrome)

To be separated from *familial dysautonomia* is the syndrome of achalasia, alacrima, and adrenal deficiency because the first two symptoms are seen in that disorder. The syndrome was first reported by Allgrove et al (1) in 1978. At least 50 examples have been described (10).

Growth and psychomotor development are mildly to moderately retarded (2,5,9).

Inheritance is clearly autosomal recessive (5,6,9,15). The gene, *ALADIN*, maps to 12q13 (19).

Achalasia. Achalasia of the cardia, that is, functional obstruction due to increased lower esophageal sphincter pressure, absent esophageal peristalsis, and failure of the lower sphincter to relax in swallowing, is rare in children (18). In this syndrome, it most often presents at 3–4 years but may not be evident until the second decade (3,6,10,16).

Lacrimal glands. There is defective tear formation from birth. It is the most consistent early finding (1,6).

Adrenal insufficiency. Allgrove et al (1) and others (7,8) reported acquired glucocorticoid deficiency, which may lead in some cases to hypoglycemic shock or even death. In some families, however, adrenal function is normal (7,9,12–14). Hyperpigmentation of the skin is common.

Neurologic findings. In addition to autonomic dysfunction and moderate psychomotor retardation, some exhibit dysdiadochokinesis (9), epilepsy (5,9), cerebellar ataxia (2,12), stiff gait (9), speech disorder (7), optic atrophy (2), microcephaly (2,7), peripheral neuropathy (5,16), clumsiness (5), anisocoria (5), brisk deep tendon reflexes (5), and velopharyngeal insufficiency (4,13).

Autonomic dysfunction is variable, presenting in adolescence with postural hypotension and heart rate variability during deep breathing. Alacrima, achalasia, and, possibly, adrenal hypofunction are the result of parasympathetic failure.

Laboratory findings. Histamine skin testing is negative. Cardiac autonomic tests are abnormal. EMG shows slowed motor conduction velocities and reduced amplitude of sensory action potentials. Some patients have normal adrenal function (9), most have reduced glucocorticoids and, less often, mineralocorticoids (1,2,4–7,12–14,16,17). Microscopic examination of the adrenal glands shows absence of the zona fascicula with normal zona glomerulosa of the adrenal glands.

Diagnosis. In *familial dysautonomia*, there are deficient fungiform and circumvallate papillae, and hypomotility, atony, and dilatation of the esophagus. Achalasia usually occurs as an isolated finding and may be found in families. Achalasia and gastric hyposecretion (10,11) may occur with Sjögren syndrome.

Noonan-like/multiple giant cell lesion syndrome (including cherubism and polyarticular pigmented villonodular synovitis)

Falace (12) described the combination of polyarticular pigmented villonodular synovitis, "jaw cysts," cardiac defects, mild developmental delay, and distinctive facies. In their review of the literature, Cohen and Gorlin (7) found several additional cases (4,8,16,18,21,25,26,28). The combination of Noonan syndrome and cherubism (or multiple giant cell lesions) has been reported by Addante and Breen (1), Chuong et al (6), Bianchi (5), Hoyer and Neukam (14), Dunlap et al (11), Salinas et al (20), Levine et al (17), Bertola et al (3a), and others (see *Noonan syndrome*).

Facial features include mild hypertelorism, oculomotor defect (26,28), and low-set ears (26,28) (Fig. 29–3). In one family, multiple lentigines were found (28). Although jaw lesions were stated to be fibrous dysplasia (28) and giant cell granuloma (18,23a), we believe that they really represented cherubism. In addition, cavernous hemangioma of the lip (16) and orbit (J Hoza, personal communication, 1989) has been documented.

As in *Noonan syndrome* and *LEOPARD syndrome*, pulmonic stenosis (4,16,18,26), mitral valve prolapse (28), mild growth retardation, peripheral lymphedema, and developmental delay have been evident (4,18,25,26). It should be noted that Noonan syndrome maps to chromosome 12q (15). A few patients exhibited pectus (26,28).

In contrast to monoarticular villonodular synovitis, which occurs in adults in their third to fifth decades, in this syndrome the villonodular synovitis is polyarticular, and patients are less than 10 years old. Most often the knees and ankles are involved, less often the wrists or elbows.

Inheritance may be autosomal dominant (28), but the vast majority are isolated examples.

Cherubism usually is a lone finding with autosomal dominant inheritance (13,29). It maps to 4p16.3 (19,22). Extraoral bone involvement has been described by many authors cited by Cohen and Gorlin (7). Bianchi et al (5) and Weldon and Cozzi (27) have noted pulmonary stenosis in patients with cherubism or multiple giant cell lesions of the jaws. Pulmonary stenosis may also be found with *Noonan syndrome* and with *neurofibromatosis* in binary combination and with *gingival fibromatosis, hypertrichosis, mental and somatic retardation, and epilepsy (Ramon syndrome)*. Cherubism has been described with short stature and optic atrophy (2). De Pina-Neto et al (9,10) suggested that some members of the family they investigated had juvenile rheumatoid arthritis. Could this have been polyarticular pigmented villonodular synovitis? RJ Gorlin believes that these associations are examples of contiguous gene syndromes. Multiple central giant cell granulomas have been noted in hyperparathyroidism (24) and in *neurofibromatosis* (3). A possibly aleatory combination of craniosynostosis, cherubism, and drum-stick terminal phalanges was reported Stiller et al (22a).

Noonan-like phenotype, myopathy and malignant hyperthermia (King syndrome)

King et al (6), in 1972, reviewed children who exhibited predisposition to malignant hyperthermia and noted a distinct phenotype. There have been approximately 16 cases reported to date. Nearly all were males. Inheritance is debatable. All have been isolated examples (1–7,9–14). In a few cases, first-degree relatives have been stated to have subtle features (2). Chitayat et al (1) suspect that King syndrome represents a heterogeneous phenotype. At least one gene for malignant hyperthermia maps to 19q13 (9a). We believe that the patient of Kousseff and Nichols (8) has still a different condition, because of the presence of multiple severe contractures, skin dimpling, axillary webbing, and hypoplastic nipples.

Normal intelligence has usually been found. Short stature has been associated with spinal anomalies in 90%. Delayed motor development is a common finding.

Craniofacial changes include ptosis or blepharophimosis (75%), downslanting palpebral fissures (75%), malar hypoplasia (70%), cleft palate (5,11), micrognathia (100%), and webbed neck (2). Musculoskeletal abnormalities include pectus carinatum or excavatum (90%), scoliosis (100%), lumbar lordosis (10%), and scapular winging (2,4–6,9,11). The muscles are often weak. The myopathy is exhibited by elevated creatinine kinase, abnormal electromyograms, abnormal muscle biopsy, and malignant hyperthermia.

Malignant hyperthermia may be associated with several myopathies, principally central core disease. It may be dominantly inherited and at least six susceptibility loci have been identified (2). To be excluded is *Noonan syndrome*. Also see *hyperthermic embryopathy*. A recessive disorder, Native American (Lumbee), myopathy consists of short stature, ptosis, cleft palate, scoliosis, congenital joint contractures, camptodactyly, and talipes equinovarus. Inheritance is autosomal recessive. Death has occurred during the first year of life in 35% from severe pulmonary hypoplasia and apnea.

Bifid mandibular condyle, polythelia, and postaxial hexadactyly

Zohar and Laurian (1) described an unusual group of findings in a female patient: bifid mandibular condylar head, polythelia, bilateral postminimum digits, and clinodactyly.

It is possible that these findings were of chance occurrence.

Reference (Bifid mandibular condyle, polythelia, and postaxial hexadactyly)

Facio-audio-symphalangism

Maroteaux et al (11), in 1972, and Herrmann (5), in 1974, reported kindreds with multiple synostoses and conductive hearing loss. The face is characteristic and symphalangism of the fingers and toes occurs together with other skeletal anomalies. Several papers on the subject have appeared (1,2,6,7,14,16,17,19). Less certain are other cases in which facial features (8,12,13) or hearing loss (10,15) were not mentioned. The case of Tsuruta et al (19) is unusual. The question of whether multiple synostoses without facial and audiological abnormalities should be treated differently is discussed by Sugiura and Inagaki (18). Besides facio-audio-symphalangism, the term *WL syndrome* has been used (5,6).

Autosomal dominant inheritance is evident. The gene maps to 17p22 (9). It is related to the *Noggin (NOG)* gene (3).

Features of the syndrome are summarized in Table 29–1. The nose is long and thin and has minimal alar flare, that is, it is hemicylindrical (Fig. 29–4). Progressive conductive hearing loss is characteristic (5–7,11). Ankylosis of the stapedial footplate and malformation of the stapes and the incus have been recorded (5,11,16). Even though the patient is of normal height, proportions appear abnormal. The gait is waddling; the patient often walks on the outer border of the feet without resting on the heels.

The upper arms are short. There is cubitus valgus with dislocation of the head of the radius and limitation of pronation, supination, and extension at the elbow.

The fingers are short. There is absence of creases over all proximal interphalangeal joints of fingers and over the fifth, or less often the fourth, distal interphalangeal finger joints (Fig. 29–5). One or more fingernails and/or toenails may be hypoplastic. One or more terminal portions of

B

Fig. 29–5. *Facio-audio-symphalangism syndrome*. (A) Clinodactyly, mild syndactyly, brachydactyly, and absence of digital creases suggesting symphalangism. (B) Note finger contractures, palmar thumb. (A from SA Hurvitz et al, Clin Genet 28:61, 1985. B courtesy of K North, Boston, Massachusetts.)

fingers (rarely the third) and/or toes may be missing. The fifth finger may exhibit clinodactyly. The hallux is often short; there may be an increase in the space between the hallux and second toe.

The hands and feet are most severely affected. Starting in childhood, there is progressive coalition of the lesser multangular-capitate-hamate and triquetral bones, short and broad first metacarpal, progressive

proximal symphalangism of the second, third, fourth, and fifth digits, and progressive distal symphalangism of the fifth and often the fourth digits. One or more distal phalanges may be hypoplastic and one or more metacarpals and proximal phalanges may be overtubulated (Fig. 29–6).

The forefoot is short and shows coalition of the talus and navicular bone, fusion between second and third cuneiforms, and coalition between both the first two cuneiforms and the tarsometatarsal joints. There are progressive hallux valgus and proximal symphalangism of the second, third, and fourth digits, and hypoplastic or absent middle and distal phalanges of the fourth and/or fifth digits. The first metatarsal is often short and, like the other metatarsals, may be overtubulated.

The metaphyses of long bones are broad and irregular. The diaphyses may be somewhat bowed. Radiohumeral synostosis, malformed distal humerus and proximal radius, and subluxation of the radial head are common findings.

Spinal anomalies include hypoplastic spinal processes of cervical vertebrae, fused arches, spinal canal stenosis, and osteolytic defects in the anterior superior portions of the lower thoracic and upper lumbar vertebrae (2a). The patient of Pfeiffer et al (16) had block fusion of C_2–C_3, C_5–C_7, and T_4–T_{10}.

Single palmar creases are a common finding. The absence of some digital triradii and the presence of two palmar axial triradii have been observed (11). Strabismus has been noted (5).

Symphalangism and conductive hearing loss can be excluded since facial appearance is not altered. Furthermore, the skeletal findings are limited to the hands and feet and aplasia/hypoplasia of the terminal phalanges and nails does not occur (4).

A B C D

Fig. 29–7. *Facio-auriculo-radial dysplasia*. (A) Midface hypoplasia, downslanting palpebral fissures, long philtrum. Bilateral mesomelic shortening of arms and rudimentary thumbs. (B) Pinna is microtic. (C) Arm of mother of patient shown in A. Note absent radius, shortening and bowing of ulna, absent thumb, rudimentary second metacarpal. (D) Proximal shortening of fibulae with exostosis at one metaphysis. (From AE Harding et al, J Med Genet 19:110, 1982.)

Facio-auriculo-radial dysplasia

Harding et al (1), in 1982, described the association of unusual facies, asymmetrical radial dysplasia, abnormal pinnae, and conductive hearing loss in a mother and daughter. They pointed out that a similar family had been reported by Stoll et al (2) in 1974. There was midfacial hypoplasia. The pinnae were dysplastic. The philtrum was long and prominent. Aplasia of thumbs and index fingers, hypoplastic thumbs, aplastic or hypoplastic radii, radioulnar synostosis, somewhat hypoplastic fibulae, and minor changes in the vertebrae were found (Fig. 29–7).

Inheritance is autosomal dominant with variable expression. There is overlap with the VATER association and with *oculo-auriculo-vertebral spectrum*.

Facio-cardio-renal syndrome (Eastman-Bixler syndrome)

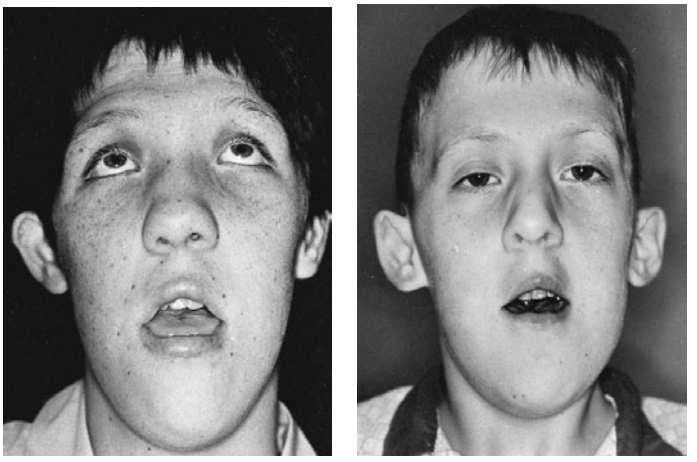
Eastman and Bixler (1) reported three sibs with characteristic facies, severe mental retardation, congenital heart anomalies, and horseshoe kidneys. There were plagiocephaly, broad nasal root, malar hypoplasia, stiff outstanding pinnae, hypoplastic philtrum, nasal alae, and thin vermilion. The antegonial notch of the mandible was prominent. One child had cleft palate (Fig. 29–8).

Various heart anomalies, including endocardial fibroelastosis, were found in all three children. All were subject to cyanotic and respiratory problems at birth and, later, to bronchopneumonia. The musculature was poorly developed. The heel cords were tight, the gait waddling, and there was limitation of motion in ankles and knees. The halluces were broad, and the thumbs were clinodactylous. The nails were hypoplastic.

Inheritance is probably autosomal recessive.

The facies is similar to that of *cleft lip, microbrachycephaly, long thin face, ptosis, hypotelorism, lumbosacral/pelvic anomalies, and*

Fig. 29–8. *Facio-cardio-renal syndrome*. (A,B) Facies of two of three affected sibs. In addition to severe mental retardation, all had plagiocephaly, long face with malar hypoplasia, broad nasal root, poorly developed philtrum, and prominent relatively inflexible pinnae. (From JR Eastman and D Bixler, Clin Genet 11:424, 1977.)



A B

mental retardation. Nevin et al (2) described a boy under the title "facio-cardio-renal (Eastman-Bixler) syndrome." While, indeed, the child had several of the same features (moderate mental retardation, broad nasal root, prominent ears, cleft palate, and horseshoe kidneys), he had tricuspid valve prolapse, isolated growth hormone deficiency, and a quite different facies.

Cleft lip-palate, urogenital anomalies, somatic and mental retardation (Malpuech syndrome) has some overlapping findings but clearly is a different entity.

Facio-cardio-musculo-skeletal syndrome

Quadrelli et al (1), in 2000, described three male patients from a single family with brachyturricephaly, a somewhat pugilistic facial appearance, muffled voice, cardiomyopathy, marked muscular hypertrophy, broad hands, wide feet with progressive pes cavus, dislocation of toes, variable congenital hip dislocation, and scoliosis. Three other males in the family, now deceased from heart disease, appeared to have had the same disorder.

X-linked recessive inheritance is clearly evident.

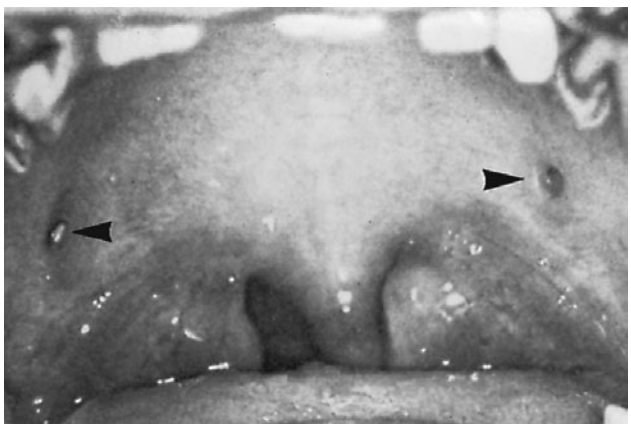
Fistulas of lateral soft palate and associated anomalies

A number of cases of bilateral symmetrical defects of the soft palate have been reported (1–19). The reader is referred to the paper of Campbell (3) for review of early cases. Several examples have been found in association with other anomalies such as absence or hypoplasia of one or both palatine tonsils (3,5,7,9,16), preauricular fistulas (9), hearing loss (4), and strabismus (3). We are truly mystified by the apparent disappearance of this anomaly in the recent literature.

Though usually bilateral, the defects may be unilateral (3,7,9,16). The disorder may be familial, having been seen in two brothers (9) (Fig. 29–9).

Fig. 29–9. *Fistulas of lateral soft palate and associated anomalies*. Arrows point to bilateral fistulas, often associated with agenesis of one, or both, of the palatine tonsils. (From O Neuss, Z Laryngol Rhinol 35:411, 1956.)



The defect appears to be related to irregularity in development of the second pharyngeal pouch (12). Several early cases were attributed to infection, either primary or secondary to surgical complications.

Keutel syndrome (calcification of cartilages, brachytelephalangy, multiple peripheral pulmonary stenoses, and mixed hearing loss)

Keutel et al (9,10), in 1971–72, reported a syndrome of multiple peripheral pulmonary stenoses, brachytelephalangy, diffuse calcification and/or ossification of cartilages, and mixed hearing loss in two sibs. Approximately 12 patients have been documented to date (2,5,9,10,11,15,16,19).

Affected sibs (10,11) and parental consanguinity (2,3,10,11) clearly indicate autosomal recessive inheritance. The gene has been mapped to 12p12.3–13.1. Mutations in the gene encoding human matrix Gla protein cause the syndrome (13).

Stature has been at or below the 25th centile in all, and below the 3rd centile in a few (5,11,15). Increased miscarriage has been noted (6).

The face is somewhat flattened with a small depressed nose, small alae nasi, and mild midface hypoplasia, becoming more pronounced with age. The pinnae are somewhat large and prominent, and are pale, stiff, and hard in consistency (Fig. 29–10). The cartilaginous ossification begins within the first three years of life and is progressive (2,9,11). Hearing loss is noted prior to admission to school. Sensorineural, mixed, or conductive hearing loss of 30–75 dB, being greater at higher frequencies, has been found in nearly all affected (2,5,9,11,12,16,19). The conductive component is probably related to recurrent middle-ear infections.

Some patients have normal intelligence (2,9,11), whereas others have been mildly retarded (5,6,16).

Variable shortening of the terminal phalanges of the hands (brachytelephalangy) has been a constant finding. The halluces also tend to be short.

A B

Fig. 29–10. *Keutel syndrome*. (A,B) Sibs with syndrome. Facies is essentially normal except for calcified pinnae. (Courtesy of G Jörgensen, Göttingen, Germany.)

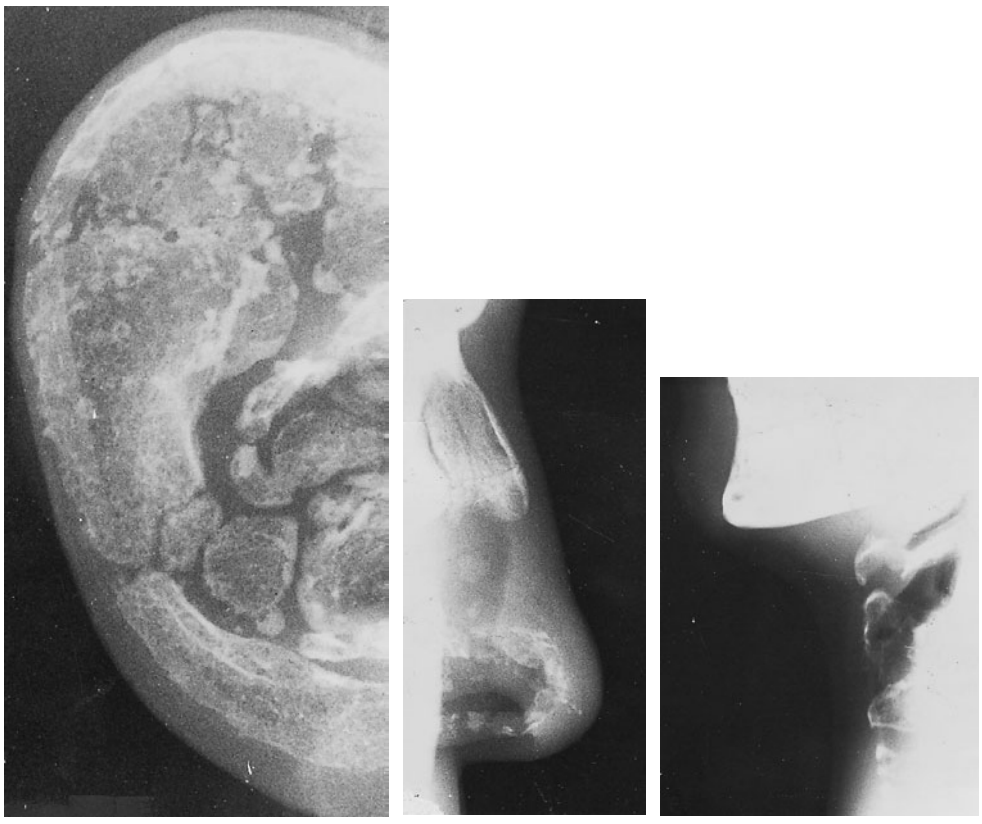
Radiographic studies show calcification of the pinnae (Fig. 29–11A), cartilaginous portions of ribs, and laryngotracheal, bronchial, and nasal cartilages (Fig. 29–11B,C). The mastoid processes are abnormally dense. Variable shortening of the terminal phalanges of the fingers and halluces and premature fusion of the epiphyses of these phalanges are evident (Fig. 29–12).

Peripheral pulmonary stenosis and pulmonary artery hypoplasia have been found in at least 50% (5,9,11,12,17,18). Angiography has revealed systolic pressure elevation in the right ventricle and in the main pulmonary artery and lowered diastolic pressure in the pulmonary vein together with a systolic pressure gradient—a picture compatible with multiple peripheral pulmonary stenoses.

Recurrent bronchitis, chronic sinusitis, and otitis media have occurred in nearly all the patients (12).

Fig. 29–12. *Keutel syndrome*. Radiograph showing abbreviation of terminal phalanges of several fingers. (Courtesy of R Walbaum, Roubaix, France.)

Multiple pulmonary stenoses and associated hearing loss have been reported (1). Gyllenswärd et al (7) noted "malformation of the external ears" in two patients with multiple peripheral pulmonary stenoses, but further definition was not made. Multiple peripheral pulmonary stenoses can been seen in combination with supravalvular aortic stenosis and in *Williams syndrome* (6).



A B C

Fig. 29–11. *Keutel syndrome*. (A–C) Calcification of cartilages of ear, nose, and trachea. (From G Jörgensen, Arch Klin Exp Ohren Nasen Kehlkopfheilkd 202:1, 1972.)

Calcification and/or ossification of the auricular cartilage can follow frostbite, physical trauma, perichondritis, and in *diastrophic dysplasia* (4,12). Auricular ossification has also been reported as a dominant trait (11), and Primrose (14) described a mentally deficient male with ossification of the ear cartilages who had hearing loss. Ectopic calcification, in general, has been discussed under *chondrodysplasia punctata*.

Macrocephaly, short stature, and mental retardation (Atkin syndrome)

Atkin et al (1), in 1985, reported a new mental retardation syndrome of macrocephaly, short stature, and coarse facial features. Additional families have been documented (2–5).

The facies is characterized by macrocephaly, prominent forehead, heavy supraorbital ridges, hypertelorism, broad nasal tip, anteverted nostrils, and thick lips.

Intelligence varies from moderate to severe retardation.

Skeletal changes are mostly minor: hyperextensible joints, tapering fingers, genua valga and recurvata, scoliosis, and hyperkyphosis.

Inheritance is either autosomal dominant or X-linked dominant. There is some similarity to *Coffin-Lowry syndrome*.

Martsolf syndrome (cataract-mental retardation-hypogonadism)

In 1978, Martsolf et al (3) reported two brothers with unusual facies, severe mental retardation, short stature, cataracts, and hypogonadism.

Sanchez et al (6) described male sibs with similar problems. Hennekam et al (2) and Harbord et al (1) described an affected brother and sister. Another possible example is that of Strisciuglio et al (7). Inheritance is autosomal recessive.

In addition to the severe mental retardation, frequently there are feeding problems in infancy. Height, weight, and head circumference are usually below the third percentile. The facies is characterized by an aged appearance, brachycephaly, cataracts, epicanthal folds, low nasal bridge, broad nasal tip, maxillary retrusion, short philtrum, pouting lips, and micrognathia (Fig. 29–13).

Various other anomalies have included prominent nipples, lumbar hyperlordosis, thin limbs, broad fingertips, short palms, lax finger joints, various foot anomalies including abnormal toenails, hypogonadism, and cryptorchidism.

There are several similarities to *Cohen syndrome* and Mirhosseini-Holmes-Walton (4,5) syndrome, a disorder of short stature, mental retardation, microcephaly, maxillary hypoplasia, cataracts, mottled retinal pigmentation, short philtrum, narrow hands and feet with long digits, delayed puberty, and hyperextensible joints. There is also resemblance to *COFS*.

Midface hypoplasia, corneal clouding, subvalvular aortic stenosis, and mental and somatic retardation

Fryns and Van den Berghe (1), in 1979, described male and female sibs with microcornea with diffuse clouding (Peters anomaly), glaucoma, and internal strabismus. The face was round and hypoplastic. The nose was relatively small with anteversion of the nostrils and a broad nasal bridge (Fig. 29–14).

Membranous subvalvular aortic stenosis was detected during infancy. Hands and feet were short and stubby. Mental and growth retardation were more marked in the sisters.

Haney and Falls (2) reported Peters anomaly in association with hypertelorism, upslanting palpebral fissures, brachydactyly, and mental and somatic retardation in two sibs, but we believe that this condition represents a different disorder.

Mietens-Weber syndrome

Four of six children of consanguineous normal parents were reported by Mietens and Weber (2) in 1966 with a syndrome of marked growth

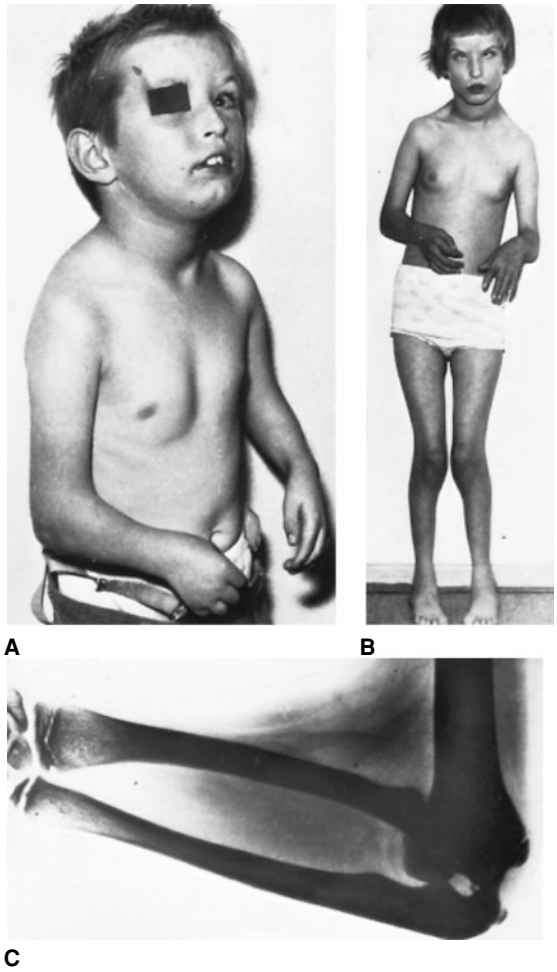

Fig. 29–15. *Mietens-Weber syndrome*. (A,B) Two of four affected sibs with convergent strabismus, narrow pointed nose, short forearms, contraction at elbows, atrophic calves. (C) Short radius and ulna; radial head dislocated, its epiphysis absent. (From C Mietens and H Weber, J Pediatr 69:624, 1966.)

retardation (−3 SD) and mild mental retardation (IQ 70–80). A child of unrelated parents was documented by Waring and Rodrigues (4). There was bilateral microsclerocornea and absent left fibula. Intelligence was normal. Resemblance to the kindred reported by Mietens and Weber is otherwise marked. Other cases have been described (1,3).

Clinical appearance was striking, the facies being marked by convergent strabismus and a small, narrow, pointed nose. Disclike central opacities of the cornea, located mainly in the superficial layers, were noted bilaterally. Short forearms and flexion of the elbows with proliferation and contraction of the connective tissues on the volar aspect were also marked. Calf muscles were atrophic, and pes valgus planus was evident (Fig. 29–15).

Radiographically, the ulna and radius were abbreviated. The head of the radius was dislocated and its epiphysis was absent bilaterally.

The disorder has autosomal recessive inheritance.

Short stature, auditory canal atresia, mandibular hypoplasia, and skeletal abnormalities (SAMS syndrome)

Lemire et al (1) reported a female Mennonite child with *S*hort stature, *A*tresia of the external auditory canals, *M*andibular hypoplasia, and *S*keletal anomalies. The mnemonic SAMS was suggested.

The facies was characterized by deep-set eyes, hypotelorism, downslanting palpebral fissures, malar hypoplasia, and small mouth (Fig. 29–16).

Skeletal defects consist of bilateral humeral hypoplasia, delayed ossification of pubic rami, and humero-scapular synostosis (Fig. 29–17).

She was the product of a consanguineous union. Autosomal recessive inheritance is likely.

Ptosis-aortic coarctation syndrome

Cornel et al (2), in 1987, reported autosomal dominant inheritance of eyelid ptosis with coarctation of the aorta. Noted in a four-generation pedigree, the syndrome is characterized by congenital bilateral ptosis, sensorineural hearing deficit, coarctation of the aorta, and asthma. Larned et al (3) noted the nonspecific association of congenital ptosis and congenital heart defects. The combination of ptosis and congenital heart defects may also be observed with *Turner syndrome* and *Noonan syndrome*. Bazopoulou-Kyrkanidou et al (1) reported an affected mother.

Craniodigital syndrome

In 1971, Scott et al (2) reported a newly recognized craniodigital syndrome in three affected brothers who were said to resemble patients with *Saethre–Chotzen syndrome* but who differed significantly by having growth deficiency, moderate to severe mental retardation, and brachycephaly with absence of craniosynostosis. Other features included thick scalp hair, temporal and sideburn hair extension, prominent eyebrows, long dark eyelashes, startled facial expression, small pointed nose, micrognathia, soft-tissue syndactyly between the second, third, and fourth fingers, and soft-tissue syndactyly between the second and third toes (Fig. 29–18). A similarly affected male child was described by Lorenz et al (1). The mother had 2–3 syndactyly of the toes. A new family (personal communication, CR Scott, 1997) confirms the inheritance pattern. Unaffected sisters each had an affected son.

The mode of inheritance is X-linked.

Singleton-Merten syndrome

A syndrome consisting of calcification of the aortic arch and aortic valve, hypoplastic tooth buds, and osteoporosis and widening of the metacarpals, carpals, and phalanges was described in two unrelated female children by Singleton and Merten (4). Additional patients were reported by McLoughlin et al (3), Gay and Kuhn (2), and Feigenbaum et al (1).

The deciduous teeth become carious at any early age and are lost prematurely, producing decreased vertical height. The permanent teeth are dysplastic, some never develop, and others erupt late (Fig. 29–19A,B).

Cardiac enlargement with calcification of the thoracic aorta was seen in all children in mid or later childhood (Fig. 29–19C). Death results from calcific aortic stenosis leading to heart failure usually in the teen years.

Severe to moderate muscular weakness becomes manifest in the first or second year of life following a febrile illness. There are secondary hip and foot deformities. Stature is small. Osteoporosis of the cranial vault and all long bones is significant, being most marked in the hand bones (Fig. 29–19D). A psoriasiform skin eruption was reported by Gay and Kuhn (2).

Unusual facies, congenital corneal anesthesia with retinal abnormalities, sensorineural hearing loss, patent ductus arteriosus, and mental retardation

Ramos-Arroyo et al (1) and Saksena et al (2) described male and female sibs with failure to thrive and deficient stature and weight. In addition to mental retardation and persistent ductus arteriosus, the facial and ocular findings included broad flat face, upslanting palpebral fissures, ocular hypertelorism, frontal bossing, depressed nasal root and bridge, and midface hypoplasia. Keratitis, absence of peripapillary choriocapillaris, absence of retinal pigment epithelium, and poor visual acuity were noted. Both exhibited sensorineural hearing loss and patent ductus arteriosus (Fig. 29–20). The mother had mild to moderate sensorineural hearing loss, retinal changes, and similar facial features. Inheritance appears to be autosomal dominant.

Unusual facies, mental retardation, cataracts, muscle wasting, and skeletal abnormalities

Primrose (4), in 1982, described a slowly progressive degenerative disorder characterized by mental deficiency, wasting of limb musculature, bone abnormalities, and ossification of the pinnae. A virtually identical example was described by Collacott et al (1).

Relative macrocephaly, large calcified pinnae, sensorineural hearing loss, cataracts, and torus palatinus were found (Fig. 29–21A,B). Body build in the two males was markedly feminine. There was distal muscle wasting with contractures of fingers, hips, and knees (Fig. 29–21C).

Radiographically, generalized osteoporosis was noted. The skull was large with basilar impression and midface hypoplasia. The chest was narrow with downward-sloping ribs. The lumbar spine showed kyphosis with endplate irregularities, posterior scalloping of vertebral bodies, and collapse-wedging of lumbar vertebrae. There were well-defined radiolucencies in the proximal femoral and humeral shafts and in both patellae. The iliac wings were narrow. The terminal phalanges were short and there were erosions at the bases of the proximal phalanges of the index and middle fingers.

The disorder appears to be different from *Keutel syndrome* (2,3) in which patients have normal or low normal intelligence, brachytelephalangy, diffuse cartilage calcification, and peripheral pulmonary stenosis. Calcified pinnae may result from trauma.

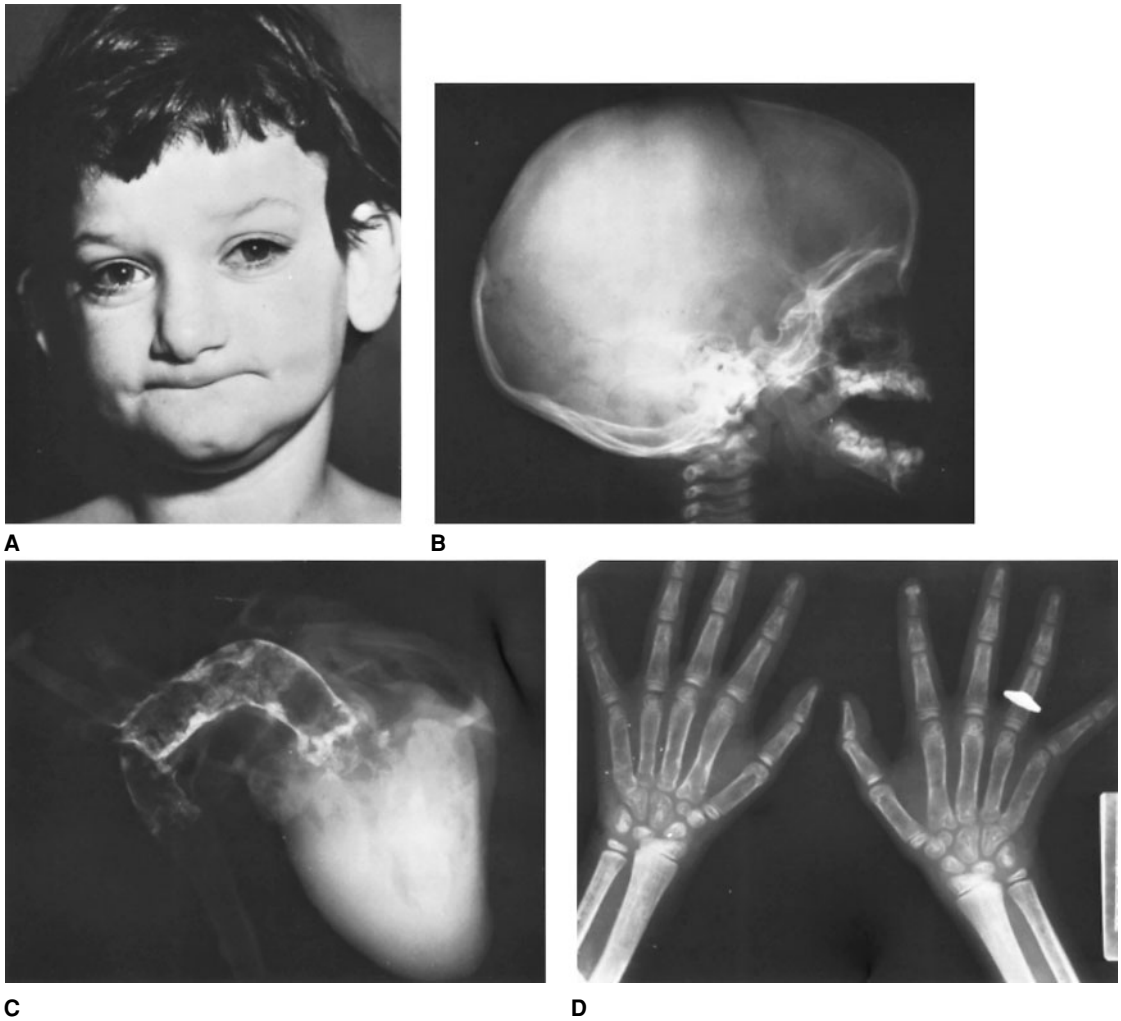

Fig. 29–19. *Singleton-Merten syndrome*. (A) Loss of vertical height in lower face due to unerupted teeth makes child look older than 10 years of age. (B) Radiograph shows mild maxillary hypoplasia, mild diffuse osteoporosis, and multiple unerupted teeth. (C) Extensive calcification of aortic arch and aortic valve. (D) Marked osteoporosis of hand bones, subungual calcification of second finger. (From EB Singleton and DF Merten, Pediatr Radiol 1:2, 1973.)

Unusual facies, short limbs, and congenital heart disease

Barrow and Fitzsimmons (1) described an apparently unique lethal disorder in a male infant. The child had severe rhizomelic shortening of the limbs, more marked in the upper extremities, and mild talipes equinus.

There were posterior sloping of the forehead, prominent nasal bridge, epicanthal folds, narrow palpebral fissures with mild upslant, capillary hemangiomas involving the glabellar area and both lips, thin vermilion, micrognathia, and short neck (Fig. 29–22).

Postmortem examination revealed a single ventricle leading into the truncus arteriosus that divided into right and left pulmonary arteries and continued as the aorta. The testes were intraabdominal.

Cerebro-oculo-nasal syndrome

Richieri-Costa and Guion-Almeida (3) in 1993, reported two unrelated girls with bilateral anophthalmia, abnormal nares and central nervous system anomalies (Fig. 29–23A–C). A third example, also a female, was provided by Ercal and Say (1). Case 1 of Temple et al (4) has similar nose and microphthalmic left eye but otherwise appears different. Two additional examples were added by Guion-Almeida et al (2). Another patient was reported by C Booth to MM Cohen, Jr (personal communication, 1998).

All patients were mentally retarded. Hydrocephalus was constant. Encephalocele and craniosynostosis were reported in one patient each (3).

The facies is striking. All had frontal prominence and bilateral anophthalmos. Eyebrows and eyelashes were sparse and irregularly placed.

Fig. 29–20. *Unusual facies, congenital corneal anesthesia with retinal abnormalities, sensorineural hearing loss, patent ductus arteriosus, and mental retardation*. Affected sibs with frontal bossing, hypertelorism, depressed nasal bridge, midfacial hypoplasia. Female has tarsorrhaphies. (Courtesy of ME Hodes, Indianapolis, Indiana.)

Two had a midline nasal appendage (1,3) (Fig. 29–23D). The nose was short with an elevated bridge and anteverted nostrils. The mouth is down-turned. Cleft palate was found in one case as was single maxillary central incisor (3) (Fig. 29–23E). The pinnae were low set and outstanding.

Dermal pigmentation over the neck was noted in one case (1).

CHANDS syndrome

Baughman (1), in 1971, and Toriello et al (6), in 1979, reported a rather large inbred kindred of Dutch extraction with *C*urly *H*air, *A*nkyloblepharon filiforme, *N*ail *D*ysplasia from which the acronym CHANDS was created. Additional examples were contributed by Ohishi et al (3) and Toriello (5).

Inheritance is clearly autosomal recessive.

Commisural lip pits were noted by Ohishi et al (3).

There is overlap with *Hay-Wells syndrome* (2). The relationship to the syndrome reported in sibs by Seres-Santamaria et al (4) consisting of cleft palate, ankyloblepharon, alveolar synechiae, nail dystrophy, coarse hair and pits of the lower lip is not known. See *EEC syndrome*.

Cerebro-facio-thoracic syndrome

Pascual-Castroviejo et al (3), in 1975, were the first to describe a syndrome of abnormal facies, costovertebral abnormalities, and mental retardation with hypoplasia of the corpus callosum in three unrelated children. They entitled the syndrome *cerebro-facio-thoracic dysplasia*. To date, six examples have been documented.

Inheritance is autosomal recessive (3,4).

Birthweight above the 90th centile was noted in three cases (1,3).

Craniofacial anomalies included macrocephaly, brachycephaly, low hairline, narrow forehead, hypertelorism, epicanthic folds, synophrys,

A B C

Fig. 29–22. *Unusual facies, short limbs, and congenital heart disease*. (A) Rhizomelic shortening of upper limbs more severe than of lower limbs, micrognathia, short neck, talipes equinus. (B,C) Shortened and thickened long bones. Femora and humeri especially shortened. (From M Barrow and JS Fitzsimmons, Am J Med Genet 18:431, 1984.)

short broad nose, hypoplastic maxilla, low-set posteriorly rotated pinnae, and short neck. Three of six had cleft lip–palate (1,4) (Fig. 29–24).

All exhibited mental retardation but were affable. CT studies revealed hypoplastic corpus callosum in two of five patients. A large septum pellucidum was noted in three. The petroclinoid ligament was calcified.

The thorax and shoulders were narrowed, and the scapulae elevated. Costovertebral anomalies (bifid and fused ribs, fused or wedged vertebrae, hemivertebrae) resembling those in *cerebro-costo-mandibular syndrome* were a constant feature.

One must exclude autosomal recessive spondylocostal dysostosis; Moerman et al (2) described a syndrome of macrocrania, spondylocostal anomalies, and agenesis of the corpus callosum, but there were other findings: congenital heart and renal anomalies and severe growth retardation.

Coarse facies, mental retardation, and heavy breathing (Pitt-Hopkins syndrome)

Pitt and Hopkins (1), in 1978, described a syndrome, the common findings of which were mental retardation, coarse face, and abnormal breathing pattern. Other examples have been reported by Singh (2) and van Balkom et al (3).

All share poor motor development and voluntary overbreathing. Facially, all exhibit a wide nasal bridge, prominent nose, flared nares, macrostomia, thick fleshy lips, and dysmorphic pinnae. Skeletal changes were minimal but all exhibited clubbing of fingers and most had club foot. Short great toes were noted in two (1,3) (Fig. 29–25).

All cases have been isolated.

Differential diagnosis should exclude Joubert syndrome and Rett syndrome.

Facio-skeleto-genital syndrome

Mollica et al (2) reported an infant, the daughter of consanguineous parents. The child had tetramelic limb deficiency, bilateral cleft lip–palate, athelia, low umbilicus, bladder exstrophy, no external genitalia, and anteriorly displaced anus.

The authors suggested resemblance to limb/pelvis-hypoplasia/aplasia syndrome of Al-Awadi et al (1) and Raas-Rothschild et al (3).

Faciodigitogenital syndrome, Kuwaiti type

Teebi et al (2), in 1988, reported what they called a new autosomal recessive faciodigitogenital syndrome. They contrasted it with Aarskog syndrome, which it resembles but has X-linked inheritance. The highly inbred family, of Bedouin Kuwaiti origin, consisted of three male and two female affected sibs.

In addition to short stature, common features included skull bossing, triangular facies, coarse dry hypopigmented scalp hair, widow's peak, hypertelorism, short stubby nose with anteverted nostrils, flat nasofrontal angle, dysmorphic pinnae, long deep philtrum, wide mouth, pouty lower lip, small broad hands, clinodactyly of fifth fingers, bulbous toes, and shawl scrotum in males. There was no ptosis of eyelids, nor were there downslanting palpebral fissures.

Teebi and Al-Awadi (1) increased the number of observed examples to 16.

Aarskog syndrome must be excluded.

Faciothoracoskeletal syndrome

In 1994, Richieri-Costa et al (1) noted two Brazilian brothers, born to consanguineous parents, presenting with long thin face, hypertelorism, short upslanting palpebral fissures, malar hypoplasia, small pinnae with hypoplastic lobules, long neck, pectus excavatum, winged scapulae, brachycamptodactyly, sacral dimple, and seizures (Figs. 29–26 and 29–27).

Inheritance is probably autosomal recessive.

To be excluded are various camptodactyly syndromes.

Craniofacial dysostosis, limb malformations, and omphalocele

Gardner et al (1) reported a combination of a craniofacial dysostosis, unusual facies, limb malformations, and omphalocele.

The face was remarkably striking with severe hypertelorism and frontal bossing. The mouth was very small and in-drawn. The nasal bridge was depressed. A nevus flammeus extended from the glabellar area to the forehead. A tag was present in the philtral area. Colobomata were evident in the lower eyelids and nasal alae. The eyes bulged, the corneas were cloudy, and the sclera encroached on the cornea. A bald patch was noted at the vertex of the scalp. The palate was cleft (Fig. 29–28).

The limbs were asymmetrically shortened, and the hands were in ulnar deviation. Fingers 3–4 on one hand were fused and overlapped by other digits. Talipes and variable syndactyly of toes were present. The thorax was small and the sternum short.

Other anomalies were omphalocele, anteriorly displaced anus, and bicornuate uterus.

Radiographic changes included indented occiput, poorly ossified skull, variably sized vertebral bodies, irregular ribs, and variably deformed long bones.

Reference (Craniofacial dysostosis, limb malformations, and omphalocele)

Fig. 29–28. *Craniofacial dysostosis, limb malformations, and omphalocele*. Note marked hypertelorism, frontal bossing, small mouth, depressed nasal bridge, nevus flammeus of glabellar area, colobomata of lower eyelids, and exophthalmos. Limbs are asymmetrically shortened, and hands show ulnar deviation. Talipes is marked. (From RJ Gardner et al, Am J Med Genet 36:133, 1990.)

Giannotti syndrome

A progeroid syndrome with unusual facies and hand anomalies was described in a father and son by Giannotti et al (1) in 1997.

The phenotype appeared quite distinctive with sparse subcutaneous fat, prominent veins, blepharophimosis, extremely prominent nose, short philtrum, thin lips, and prominent ears. The son exhibited microcephaly, congenital heart anomaly, and bilateral conductive hearing loss.

In the son, the fingers were long with partial cutaneous syndactyly of fingers 2–3 and clinocamptodactyly of 5. Hallux valgus was also noted. In the father, radial deviation of the third fingers with ulnar deviation of the fourth fingers and camptodactyly of the fifth fingers were observed.

Brachycephaly, hearing loss, cataracts, and mental retardation (Fine-Lubinsky syndrome)

In 1993, Suthers et al (8) reported a single patient with brachycephaly without craniosynostosis, hearing loss, cataract, dysmorphic face, and developmental delay. Aymé and Philip (1,2) reported a similar patient and suggested that the cases reported by Fine and Lubinsky (3) and Preus et al (7) had the same entity. Gripp et al (4,5) described two other cases as having a possible "new" syndrome. All cases were singletons, no consanguinity was reported, and chromosome studies were normal.

Clinical features include borderline growth, both prenatal and postnatal, small or large head circumference, and a remarkable "Down syndrome-like" face (Fig. 29–29): flat, brachycephalic, flat nasal bridge that becomes prominent later on, shallow orbits, hypertelorism, upward-slanting palpebral fissures in infancy but downward-slanting at older ages, small nose, thin nares, long philtrum, thin upper vermilion border, small mouth, and small, low-set, and posteriorly rotated ears. Two patients had cleft palate (3,7). The auditory canals may be very narrow. All had bilateral congenital hearing loss, and most, a congenital dense zonular cataract.

The thorax may show pectus carinatum superiorly and excavatum inferiorly. One patient had diaphragmatic hernia and idiopathic pericardial effusions (4), another, pyloric stenosis and unilateral hydronephrosis (8). Inverted and widely set nipples (1,7), underdeveloped breast in adolescence (1), and shawl scrotum (8) have been reported. Other features are radioulnar synostosis, camptodactyly of fifth fingers, and dystrophic nails. Central nervous system anomalies include enlarged cerebral ventricles with normal pressure, EEG anomalies, and agenesis of callosal body (3). All were hypotonic and had mild to severe mental retardation. Radiologic changes include fusion and sclerosis along the metopic sutures, no true craniosynostosis, very large frontal sinuses (1), slender long bones, carpal synostosis, and brachydactyly. Two patients (4) developed idiopathic chondrolysis of the hip.

The differential diagnosis includes *Martsolf syndrome* (6), *Tuomaala-Haapanen syndrome* (9), *maxillonasal dysplasia*, and Insley-Astley syndrome.

Hypertelorism, tetralogy of Fallot, and hypospadias

Farag and Teebi (1) reported an autosomal recessive syndrome in an inbred Arab family. The syndrome, present in four members of the extended kindred (three male sibs and female cousin), consisted of early cyanosis, feeding problems, hypertelorism, epicanthic folds, narrow palpebral fissures, flat nasal bridge, dysmorphic pinnae, hypospadias, tetralogy of Fallot and other cardiac defects, and mild mental retardation.

One must exclude *Opitz BBB/G syndromes*.

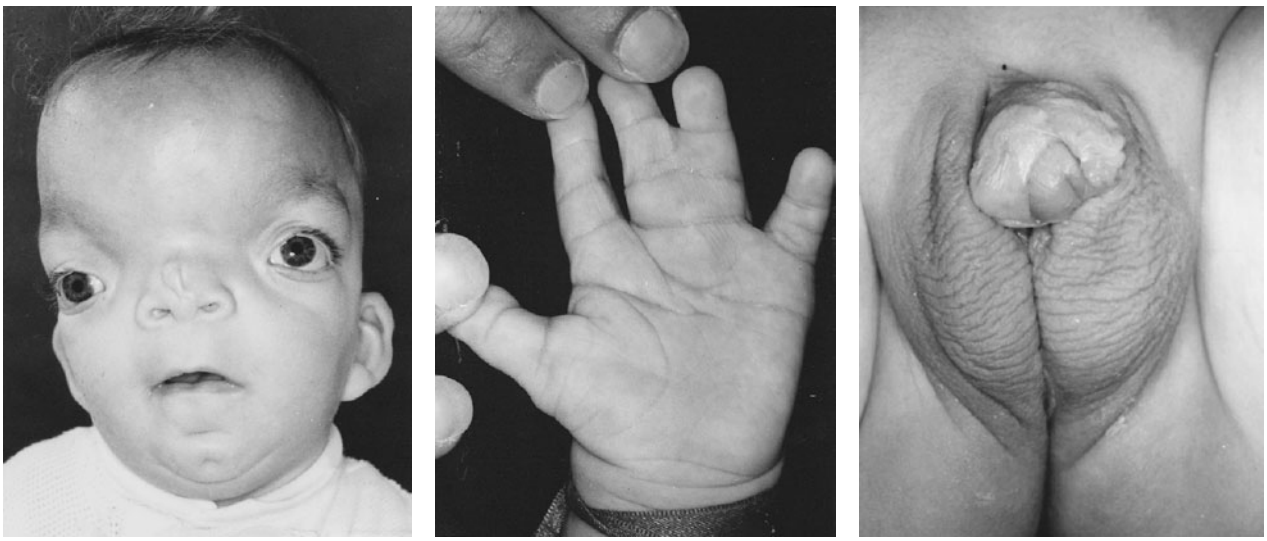
Reference (Hypertelorism, tetralogy of Fallot, and hypospadias)

1. Farag TI, Teebi AS: Autosomal recessive inheritance of hypertelorism, hypospadias and tetralogy of Fallot? Am J Med Genet 35:516–518, 1990.

Hypertelorism, hypospadias, polydactyly syndrome (Naguib and Richieri-Costa syndrome)

Naguib (1), in 1988, reported three sibs with marked hypertelorism, downslanting palpebral fissures, ptosis of eyelids, broad nasal bridge and tip with midline groove, dysmorphic pinnae, variable soft tissue syndactyly of fingers 2– 4, hypospadias, shawl scrotum, and normal psychomotor development. There was parental consanguinity.

Richieri-Costa et al (2), in 1989, reported an unusual form of acrofronto-facial-nasal dysostosis in which sibs exhibited microbrachycephaly, wide forehead, marked hypertelorism, broad nose with midline groove, soft tissue syndactyly of fingers 3–4, broad thumb and hallux, hypospadias and shawl scrotum (Fig. 29–30). There was parental consanguinity.



A B C

Fig. 29–30. *Hypertelorism, hypospadias, polydactyly syndrome (Naguib and Richieri-Costa syndrome)*. (A–C) Note wide forehead, marked hypertelorism, broad nose with midline groove, syndactyly of fingers 3–4, and hypospadias with shawl scrotum.

Teebi (3) suggested that they had the same disorder. There is some resemblance to *Aarskog syndrome*.

Inheritance is autosomal recessive.

Hyperparathyroidism and multiple ossifying fibromas of the jaws

The association of hyperparathyroidism and multiple ossifying fibromas of the jaws was first pointed out by Jackson (5) in 1958. Originally thought to be related to MEN1, no pancreatic islet cell or pituitary lesions were found. Several other families have been described (1,2,4,6–15).

Solitary (rarely multiple) parathyroid adenomas with associated hypercalcemia is the rule. The adenomas generally present in the fourth decade giving rise to hypercalcemia and renal stones. However, they have been reported in children as young as 10 years (11). Occasionally, they may recur (5,8,9). Some are cystic (9). Parathyroid carcinomas have been reported in 6 of 16 families (1,7,10,12,13,15). Ultrasonography and scintigraphy can be utilized in diagnosis (4).

Multiple ossifying fibromas are located in the premolar and molar areas of the mandible and, less often, the maxilla. They present usually during adolescence and have been detected in approximately 50% of the affected. Unrelated to the "brown tumors" of hyperparathyroidism, the multiple ossifying and/or cementifying fibromas appear and enlarge even though the hypercalcemia is corrected by surgical removal of parathyroid adenomas.

Microscopically, the jaw lesions are multiple and fibroosseous with irregular trabeculae. Multinucleated giant cells are absent, in contrast to the "brown tumors," which are usually single and loaded with giant cells. The fibroosseous lesions do not heal after the parathyroid adenoma has been removed.

Other aspects are severe recurring pancreatitis (6). Wilms tumor may be associated, presenting as late as 50 years (4,7,11–13). Renal hamartomas and cystic kidney disease have been described (12).

Inheritance is autosomal dominant (6). The *HRPT2* gene maps to 1q21–q31 (3,11–13).

Differential diagnosis would include multiple endocrine neoplasia syndromes, types 1 and 2A.

Mutilating keratopachydermia, hypotrichosis, acrodermatitis enteropathica-like lesions, and sensorineural hearing loss (Olmsted syndrome)

Olmsted (15), in 1927, first described a syndrome of infantile onset of progressive hyperkeratosis of palmar and plantar surfaces and flexor areas of extremities. About 20 examples have subsequently been reported (1–22).

Beginning in early childhood, hyperkeratosis is noted around body orifices, periorally, in the groin, and on the inner thighs resembling acrodermatosis enteropathica (22). Oral and perioral hyperkeratosis may be marked (4,17,21) (Fig. 29–31A,B). The keratoses are diffuse, symmetric, and sharply marginated. They lead to flexion contractures of the fingers (Fig. 29–31C,D). There is associated hypohidrosis. Linear papules are observed at friction sites. Nail dystrophy may be mild to severe. The distal phalanges of the extremities undergo dissolution (Fig. 29–31E,F). Hypotrichosis or generalized alopecia may be present from birth (1,9,13,17,19). The joints may be excessively lax (Fig. 29–31G).

Hearing loss has been noted at higher frequencies.

It has been suggested that there is an alteration in keratin expression (failure of switching from keratins 5 and 14 to keratins 1 and 10 (11).

Involvement of a mother and son (1,10) and identical twins (3) suggests autosomal dominant inheritance.

Most examples have been misdiagnosed as acrodermatitis enteropathica or any of various keratopachydermias. Vohwinkel syndrome must be excluded.

(A,B from RJ Richardson and JM Kirk, Arch Dis Child 65:1113, 1990.)

life-threatening infections, and unusual facies. There were severe hypocalcemia, hyperphosphatemia, and normal response to vitamin D. An additional dozen cases were added by Hershkovitz et al (1).

The face was characterized by frontal prominence, deep-set eyes, depressed nasal bridge, beaked nose, long philtrum with thin upper lip, large floppy pinnae, bifid uvula, and micrognathia (Fig. 29–32). Low levels of insulinlike growth factor were noted by Hershkovitz et al (1).

Inheritance is autosomal recessive. Parental consanguinity has been noted in all three families.

One must exclude *DiGeorge sequence*, *del(10p) syndrome*, and *Kenny syndrome*.

Hypohidrotic ectodermal dysplasia-type Viljoen-Winship

Viljoen and Winship (1) reported a new tricho-onycho-hypohidrotic ectodermal dysplasia characterized by primary interdigital webbing and camptodactyly of fingers and toes, nasolacrimal duct atresia, sparse eyelashes, eyebrows, and scalp hair, brittle dysplastic nails, and hypohidrosis. Pili torti was demonstrated. Neither clefting nor dental anomalies were observed (Fig. 29–33).

In addition to the host of disorders excluded in their differential diagnosis, one must also exclude *Hay-Wells syndrome*.

Reference (Hypohidrotic ectodermal dysplasia-type Viljoen-Winship)

1. Viljoen DL, Winship WS: A new form of hypohidrotic ectodermal dysplasia. Am J Med Genet 31:25–32, 1988.

Hypotrichosis, syndactyly, and retinal degeneration

Albrectsen and Svendsen (1) noted male and female sibs with severe hypotrichosis, retinal degeneration, and strabismus. The female had syndactyly of fingers 3–4; the boy had syndactyly of fingers 4–5, ectrodactyly, and terminal aplasia of digits (Fig. 29–34).

The parents were consanguineous.

Reference (Hypotrichosis, syndactyly, and retinal degeneration)

Macrosomia, obesity, macrocephaly, and ocular abnormalities (MOMO) syndrome

Moretti-Ferreira et al (1) described the occurrence of overgrowth (*M*acrosomia, *O*besity, *M*acrocephaly, and *O*cular abnormalities). Eye anomalies included retinal coloboma and nystagmus. Zannolli et al (2) reported another example.

Patients exhibited overgrowth but low birthweight, obesity, eye problems, and moderate psychomotor delay in childhood. Head circumference was above the 97th centile.

To be excluded are the *Simpson-Golabi-Behmel syndrome* and *macrosomia, microphthalmos, cleft palate, and early infant death*.

2. Zannolli R et al: MOMO syndrome: A possible third case. Clin Dysmorphol 9:281–284, 2000.

Oto-facio-osseous-gonadal syndrome

Da Silva (1), in 1997, described two male sibs and possibly a female sib, the product of a consanguineous union, with short stature, brachycephaly with prominent forehead, flat midface, downslanting palpebral fissures, low nasal root, hypoplastic alae and round nasal tip, prominent low-set pinnae, sensorineural hearing loss, narrow thorax, genua valga, inguinal hernia, and cryptorchidism (Fig. 29–35).

Radiographs showed Wormian bones, fusion of carpal bones, and delayed bone age.

There was some resemblance to *otopalatodigital syndrome*.

Mutchinick syndrome

Mutchinick (2), in 1972, described two sisters with microcephaly, high forehead, prominent nose and nasal bridge, large mouth, thin upper lip, dental malocclusion, protruding low-set, poorly differentiated pinnae, and prognathism. There was mental retardation and speech impairment. Three similarly affected brothers were reported by Doerfler et al (1). An isolated example is that of Tonoki et al (3).

While there was consanguinity in the first family, none was evident in the second. Inheritance is probably autosomal recessive.

Odonto-tricho-ungual-digital-palmar syndrome

Mendoza and Valiente (1), in 1997, described autosomal dominant inheritance in a five-generation kindred involving 20 individuals. Findings included natal teeth, trichodystrophy, prominent interdigital folds, nail dystrophy, and transverse palmar creases. The patients also exhibited hypoplasia of the first metacarpal and metatarsal bones and distal phalanges of the toes (Fig. 29–36).

Reference (Odonto-tricho-ungual-digital-palmar syndrome)

Hypertelorism, upper eyelid colobomas, mixed hearing loss, and hypospadias

Balci et al (1), in 1998, reported two brothers with hypertelorism, upper eyelid colobomas, saddle nose deformity, wide bulbous nose with dimpled tip, midfacial hypoplasia, mandibular prognathism, prominent eyes, mixed hearing loss, and hypospadias. Cranial sutures were found to be open at 17 years in one brother (Fig. 29–37).

The parents were first cousins. Autosomal recessive inheritance is surmised.

Possibly related is a syndrome of hypertelorism, unilateral upper eyelid coloboma, aberrant anterior hairline pattern, and anal anomalies described by Marles et al (2) in six Manitoba Indian children from four related families. One of the children had unilateral anophthalmia. Two had nasolacrimal duct obstruction, three a grooved nasal tip, and three anal stenosis and/or anteriorly displaced anus.

To be excluded are *cryptophthalmos, frontonasal malformation, oculo-auriculo-vertebral spectrum, cat eye syndrome,* and *Lenz microphthalmia*.

References (Hypertelorism, upper eyelid colobomas, mixed hearing loss, and hypospadias)

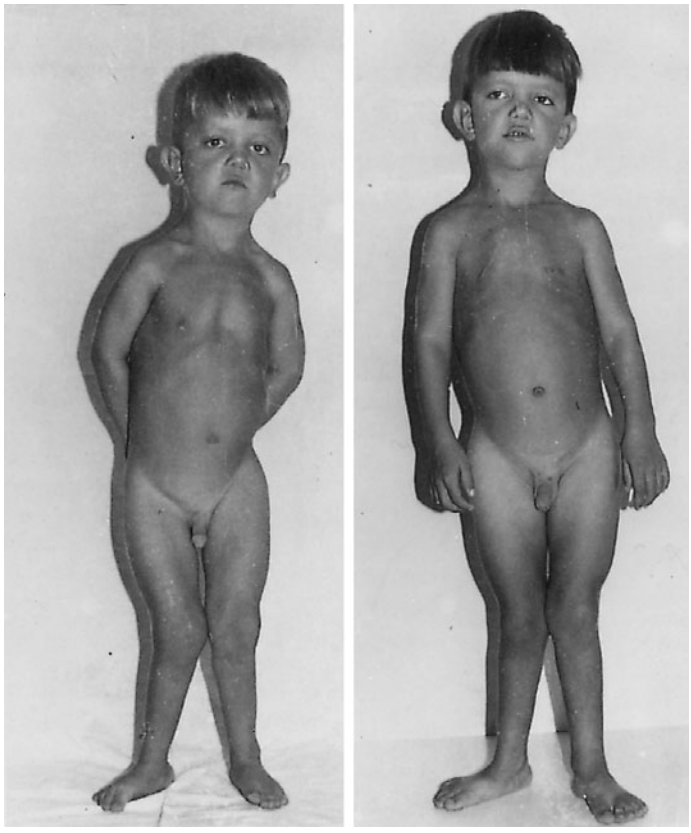
The boy has unusual ectrodactyly and terminal aplasia of digits. (From B Albrechtsen and IB Svendsen, Acta Derm Venereol 36:96, 1956.)

Pseudotrisomy 13 (holoprosencephaly-polydactyly syndrome)

Cohen and Gorlin (5), in 1991, proposed the term *pseudotrisomy 13* to designate infants that resembled trisomy 13 but had normal karyotypes.

Fig. 29–35. *Oto-facio-osseous-gonadal syndrome*. (A,B) Brachycephaly, flat midface, downslanting palpebral fissures, low nasal root, round nasal tip, outstanding pinnae, narrow thorax, genu valgum, and pes planus. (From EO da Silva et al, Clin Genet 52:51, 1997.)



A B

Approximately 30 examples have been reported (1–7,9–25). A good summary is that of Ramos-Arroyo et al (21).

Inheritance is uncertain. Sibs have been reported (2,7,23) as has parental consanguinity (3,9,24). However, we find the dearth of affected sibs to be disconcerting for autosomal recessive inheritance. There is a 2.5M:1F predilection (21). Perhaps there is heterogeneity. All infants die within days of birth.

Central nervous system. All, by definition, have holoprosencephaly (alobar-55%, semilobar-25%, lobar-20%). Approximately 70% exhibit hydrocephalus, 15% have cerebellar hypoplasia, and 10% encephalocele.

Craniofacial findings. The face is that of holoprosencephaly with various degrees of hypotelorism (cyclopia-5%, cebocephaly-35%, premaxillary agenesis-60%). Microphthalmia is present in 55%, and the pinnae are dysplastic and/or low set in 40% (Fig. 29–38).

Musculoskeletal system. Postaxial polydactyly is present in over 80%, but the hands may be normal (21). Various foot deformities are seen in 20%. The limbs may be short (20%).

Genitourinary system. Micropenis or ambiguous genitalia is present in 65%, and cryptorchidism is noted in 10%. The uterus may be hypoplastic or duplicated or bicornuate. Renal agenesis is evident in 20%.

Other findings. Miscellaneous findings include lung malsegmentation (25%), adrenal hypoplasia (25%), anal atresia (15%), and gut malformation (10%).

Diagnosis. One must obviously exclude *trisomy 13*. There is similarity to *hydrolethalus syndrome* and *Dincsoy syndrome* (midline malformations, limb abnormalities such as midshaft tibial notch, camptodactyly and overlapping fingers, and hypopituitarism (8).

Rambam-Hasharon syndrome

Frydman et al (1) described two Arab males, the offspring of inbred families, with short stature, seizures, psychomotor retardation, cortical atrophy, hypotonia, recurrent infections with defective neutrophil chemotaxis, and Bombay phenotype.

In addition to microcephaly, there were low hairline, flat face and nasal bridge, hypertelorism, epicanthic folds, anteverted nostrils, large protruding tongue, and prominent mandible.

Reference (Rambam-Hasharon syndrome)

1. Frydman M et al: Ramban-Hasharon syndrome of psychomotor retardation, short stature, defective neutrophil motility and Bombay phenotype. Am J Med Genet 44:297–302, 1992.

Weaver-like syndrome

Teebi et al (1) noted two sibs of Bedouin origin with accelerated prenatal growth, psychomotor retardation, hypotonia, hernias, excess loose skin, and joint laxity. One had excess postnatal growth.

Craniofacial changes included thin hypopigmented scalp hair, frontal bossing, prominent metopic sutures, shallow orbits, hypertelorism, downslanting palpebral fissures, long grooved philtrum, large mouth, dysplastic teeth with serrated gingiva, dysmorphic pinnae, and short broad neck. Other findings were fetal finger pads, transverse palmar creases, short fifth fingers, joint laxity, talipes, pes planus, and long first toe.

Reference (Weaver-like syndrome)

1. Teebi AS et al: A new autosomal recessive disorder resembling Weaver syndrome. Am J Med Genet 33:479–482, 1989.

X-linked mental retardation, Prieto type

Prieto et al (2), in 1987, reported a large kindred with mental retardation with subcortical cerebral atrophy, febrile seizure, unusual facies, patellar luxation, clinodactyly, sacral dimple, and pale atrophied optic papillae.

Coxa valga was found in some of the affected.

Inheritance is clearly X-linked. The syndrome has been mapped to Xp11.22 (1,3).

The nose was prominent. A double row of lower incisors was reported but this may represent crowding or delayed shedding. The facies resembles that of *Rubinstein-Taybi syndrome*.

3. Watty A et al: Gene localization in a family with X-linked syndrome mental retardation (Prieto syndrome). Am J Med Genet 38:234–239, 1991.

Keppen-Lubinsky syndrome

L Keppen and M Lubinsky (personal communication, July, 2000) described a five-year-old child with severe developmental delay. Growth parameters were all above the 75th centile at birth, but fell to the 5th centile by 9 months. The facial appearance suggested severe lipodystrophy (Fig. 29–39). The skin was tightly adherent. The nose was small with no apparent subdural tissue. There was wrinkling of the forehead and chin, excess skin at the shoulders, and some laxness in the abdominal area.

Chromosomal analyses were normal. MRI of the brain was normal. There was no known parental consanguinity. *Beare-Stevenson syndrome* was excluded.

Hemangio-oculo-cardio-digital syndrome

Hall et al (1) reported three female infants with craniofacial defects (large anterior fontanel, eye colobomas, high nasal bridge, well-defined philtrum, multiple frenulae, micrognathia), congenital heart anomalies (truncus arteriosus, VSD), and digital anomalies (mild camptodactyly, missing nails of toes, digital hypoplasia). All had small, thick, low-set ears.

Two had hyperbilirubinemia and feeding and respiratory difficulties. All has extensive hemangiomas of the back.

Autosomal recessive inheritance with increased lethality has been posited.

Fig. 29–39. *Keppen-Lubinsky syndrome*. Five-year-old with severe developmental delay. Facial appearance suggests severe lipodystrophy. Skin tightly adherent, nose small with no apparent subdural tissue. Note wrinkling of forehead and chin. (Courtesy of L Keppen and M Lubinsky.)

Hypoplastic/absent mandibular frenum, infantile hypertrophic pyloric stenosis, and Ehlers-Danlos syndromes

DeFelice et al (1,2) in a fascinating series of articles demonstrated that among 25 patients with hypertrophic pyloric stenosis, hypoplastic or absent mandibular frenum was noted in 92%, compared with 1.6% of 319 control infants. Further, they noted absence of both lingual and inferior labial frenum in Ehlers-Danlos syndromes I and III.

These observations need confirmation.

Chapter 30
Syndromes of the Eye

Rieger syndrome (hypodontia and primary mesodermal dysgenesis of the iris)

Hypodontia in combination with malformation of part of the anterior chamber of the eye was described as early as 1883 by Vossius (43). However, the condition was not recognized as a heritable syndrome until the report of Rieger (34), in 1935. The syndrome has been expanded to include absent maxillary incisor teeth, malformations of the anterior chamber of the eye (Rieger anomaly), and umbilical anomalies (11,22,38). Its frequency has been estimated as 1/200,000 population (2).

The syndrome has autosomal dominant inheritance (2,6,8,12,22) with almost complete penetrance and very variable expressivity (2). There is genetic heterogeneity (27). Two genes for Rieger syndrome have been mapped, a bicoid-related homeobox transcription factor gene, *RIEG1*, at 4q25–q26 (15,17,20,28,29,31,37,42) and another, *RIEG2*, at 13q14 (3,32,40). The former is near the epithelial growth factor gene (39). The two forms are called type 1 and type 2, respectively. Type 1 appears to be caused by haplotype insufficiency (36). There has been some difference in expression in monozygotic twins (18). Some evidence exists that mutations of *RIEG1* also cause Peters anomaly. Legius et al (27) demonstrated that the genetic defect in Rieger eye anomaly was different from that in Rieger syndrome. However, it is possible that this family had the 13q14 deletion. Dental and umbilical anomalies were not present. The type 2 gene in the mouse regulates lung asymmetry, cardiac positioning, and pituitary and tooth morphogenesis (28a,28b).

Facies. Some patients have broad flat nasal root, prominent supraorbital ridges, and relative prognathism due to underdevelopment of the maxilla and/or to loss of vertical height because of hypodontia (7,11,23,38) (Fig. 30–1).

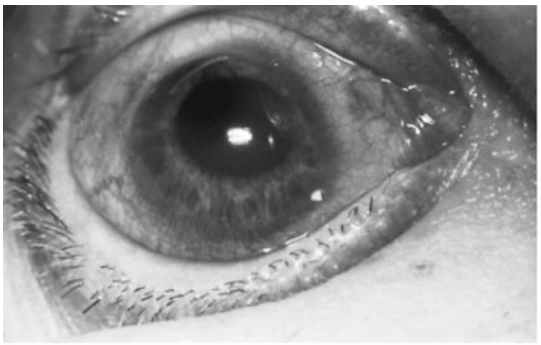
Eyes. Iridogoniodysgenesis, that is, abnormal development of the anterior chamber of the eye (Axenfeld–Rieger or Reiger anomaly), is characteristic. Anterior displacement and thickening of the Schwalbe line (posterior embryotoxon) with attached strands of iris and stromal hypoplasia are hallmarks (8,11).

Pupils may be normal but are frequently displaced and nonspherical (dyscoria) or even slitlike. Polycoria is common and may be progressive, occasionally leading to secondary aniridia. Iris strands to the Schwalbe line are present in 90%. Absence of the anterior iris layer in the presence of a prominent Schwalbe line is diagnostic (Fig. 30–2). Anterior segment dysgenesis results from faulty migration of the third wave of neural crest cells to this region (9,45). Corneal leukomas may occur peripherally. Waring et al (44) noted onset of increased intraocular pressure in 50% by age 20. An additional 10%–15% per decade develop increased intraocular pressure thereafter. Shields et al (38) also found glaucoma in about half the patients. The glaucoma is difficult to control and may lead to significant damage to the optic nerve head and to blindness (8,11,38). Microcornea, megalocornea, corneal opacity, aniridia, and strabismus may occur (38).

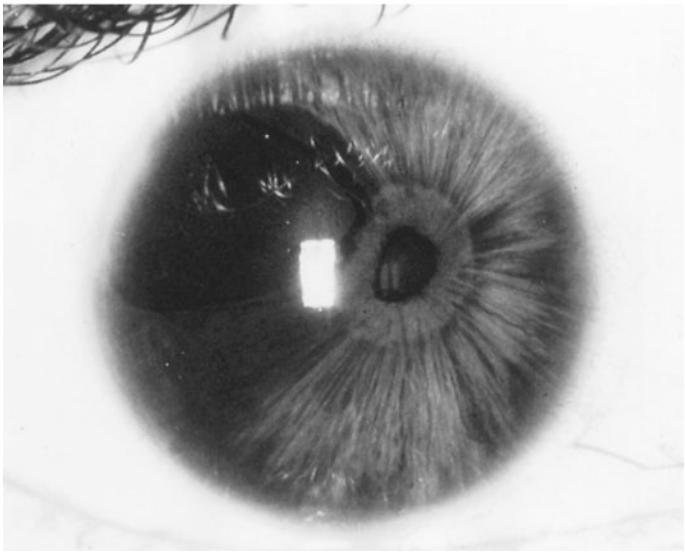
Umbilical abnormalities. The only other frequent anomaly is failure of the periumbilical skin to involute (8,12,16,38,41) (Fig. 30–3). Reddihough et al (33) found exomphalos in two patients. *RIEG2* gene mutations do not appear to affect the umbilicus.

Fig. 30–1. *Rieger syndrome*. (A,B) Note midfacial hypoplasia with relative mandibular prognathism. [From E Frandsen, Acta Ophthalmol (Kbh) 41:757, 1963.]

A B



A



B

Fig. 30–2. *Rieger syndrome*. (A) Vertical slit pupil and polycoria are evident. (B) Congenital hypoplasia of anterior iris layer. The patient had prominence of the Schwalbe line and the dental and umbilical changes of Rieger syndrome. (A from W Lemmingson, Klin Monatsbl Augenheilkd 138:96, 1961. B courtesy of IH Maumenee, Baltimore, Maryland.)

Other abnormalities. Hypospadias (8,22,23), inguinal hernia (2,8,12), anal stenosis (4,10,13), and Meckel's diverticulum (26,33) have been found. Empty sella syndrome has been documented (24,38). A wide spectrum of other abnormalities has been tabulated by Alkemade (2), Fitch and Kaback (13), and Brooks et al (5), but they are inconsistent and some are certainly aleatory. Psychomotor retardation has been described

Fig. 30–3. *Rieger syndrome*. Umbilical defect with characteristic projection of periumbilical skin. (From DS Reddihough et al, Aust Paediatr J 18:130, 1982.)

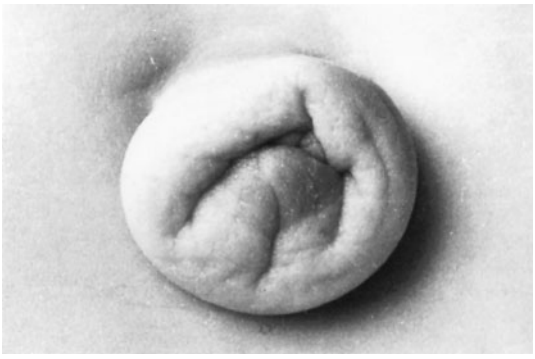


Fig. 30–4. *Rieger syndrome*. Absence of maxillary incisors and peg-shaped crowns of lower incisors and canines. (From M Feingold et al, Pediatrics 44:564, 1969.)

(2,13,23). Koshino et al (25) reported prominent posterior clinoid process, pseudoepiphyses of fifth metacarpals and metatarsals, and irregular ossification of femoral heads and distal femoral and distal tibial epiphyses.

Oral manifestations. The premaxillary area is relatively underdeveloped (2,6,28), and a reduced number of teeth is frequent, more often in the upper jaw (6,7,12,14,22). The maxillary deciduous and permanent incisors and second premolars are most commonly missing (22,23). Conical crown form of anterior teeth has been recorded by several authors (12,22,28,43) (Fig. 30–4). Cleft palate has been described by Fitch and Kaback (13). Hyperplastic frenula are occasionally noted (11,12).

Differential diagnosis. Congenital absence of teeth and teeth with conical crowns are seen in *hypohidrotic ectodermal dysplasia, Ellis-van Creveld syndrome, incontinentia pigmenti, hypodontia, and nail dysgenesis*, and *acrodental dysostosis*. Autosomal dominant glaucoma iridogoniodysgenesis, an overlapping condition, maps to 6p25 (21).

Goniodysgenesis has been found in binary combination with anal atresia, arachnodactyly, hearing loss, glaucoma, and myopathy (22). *SHORT syndrome* consists of goniodysgenesis, severe growth retardation, inguinal hernia, joint hypermobility, deep-set eyes, and delayed teething. The disorder has autosomal recessive inheritance. A similar disorder was reported by Sadeghi-Nejad and Senior (35) and Aarskog et al (1), but inheritance was autosomal dominant.

Mesodermal dysgenesis of the iris (Rieger anomaly) has been reported in association with orbital hypertelorism, psychomotor retardation, moderate sensorineural hearing loss, dilatation of the cerebral ventricles, generalized hypotonia, and pelvic anomalies (*DeHauwere syndrome*). No dental abnormalities were found. Inheritance was autosomal dominant. The patient described by Brooks et al (5) did not correspond to any of the above mentioned associations with Rieger anomaly. She had a wide nasal bridge, choanal atresia, kyphoscoliosis, and short stature. Moog et al (30) reported female sibs with Rieger anomaly, sensorineural hearing loss, hydrocephalus, and leptomeningeal calcifications as a new autosomal recessive syndrome.

Dysgenesis of the anterior chamber angle is also found with Peters anomaly, and congenital hypoplasia of iris stroma (faulty migration of neural crest cells), *rubella embryopathy*, Norrie syndrome, *Marfan syndrome*, and in some chromosomal aberrations.

DeHauwere (iris dysplasia, hypertelorism, and mental retardation) syndrome

In 1973, DeHauwere et al (3) described a syndrome of mesodermal dysgenesis of the iris, hypertelorism, telecanthus, sensorineural hearing loss, mild psychomotor retardation, and hypotonia in a mother and her three children. Possible cases were reported by Von Noorden and Baller (9). Chitty et al (1) described a three-generation family with absence of eye muscles, anterior chamber defects, strabismus, proptosis, and minor skeletal changes. However, no developmental delay was present. Three unpublished familial cases are known to RC DeHauwere (personal communication 1995), and another familial case and a single case are known to RCM Hennekam.

Craniofacial findings. Head circumfence was below the third centile in one of the original patients, but in all other patients there was macrocephaly. Ossification of the calvaria can be delayed. The face tends to be flat, especially the midface. There is hypertelorism, mild proptosis, and a relatively large chin (Fig. 30–5A–C).

Eyes. Hypoplasia of the iris stroma, abnormally prominent line of Schwalbe, adhesions between the iris and the posterior surface of the cornea, and pear-shaped pupils (Rieger anomaly) have been constant features. Strabismus is marked. The medial and lateral rectus muscles were found to be absent in two patients (1), the other eye muscles being hypertrophied and abnormally inserted (Fig. 30–5D).

Hearing. Mild sensorineural hearing loss was noted by DeHauwere et al (3). It was non-progressive in an adult female at 60 years (RCM Hennekam, unpublished).

Musculoskeletal system. Hypotonia and hyperlaxity of joints with dislocation of the hips was reported by DeHauwere et al (3). One unpublished patient had hallux valgus. Height is generally below the 3rd centile. Chitty et al (1) reported tall lumbar vertebrae, mild metaphyseal flare with unusually flat epiphyses at the hips, and delayed ossification at radiological investigations.

Central nervous system. Ventricular dilatation has been found in all patients. In one adult female intracerebral vascular spasms occurred, causing mild hemiplegia. Corpus callosum may have been absent in one patient (3).

Differential diagnosis. One must exclude *Peters plus syndrome*, and *Rieger syndrome*, in which hypodontia and umbilical anomalies

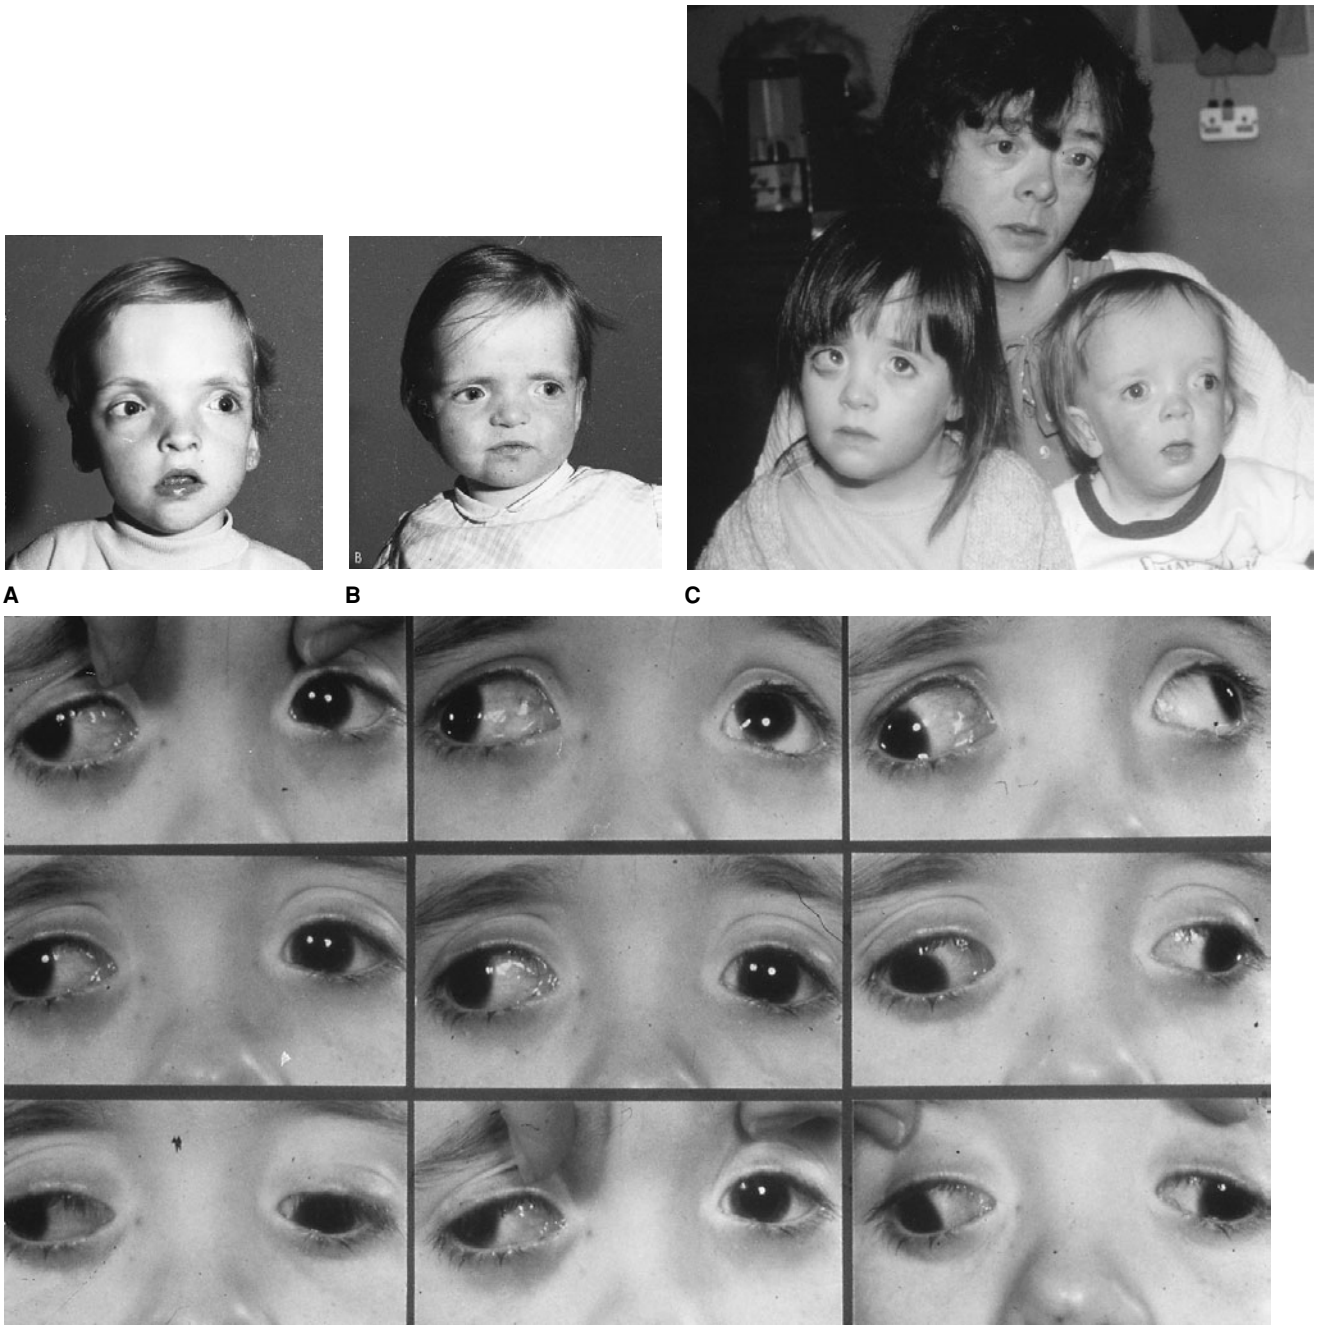

Fig. 30–5. *DeHauwere (iris dysplasia, hypertelorism, and mental retardation) syndrome*. (A,B) Note irregular pupils and orbital hypertelorism in two children. A similarly affected sib had died. Mother was also involved. *Absent eye muscles, unusual facies, hydrocephaly, and skeletal anomalies*. (C) Mother and two affected children with macrocephaly, proptosis, maxillary hypoplasia. (D) Limited eye movement in 5-year-old girl. (A,B from RC De Hauwere et al, J Pediatr 82:679, 1973. C,D from LS Chitty et al, Am J Med Genet 40:417, 1991.)

are common (4). Congenital absence of eye muscles has been reported together with anterior chamber anomalies in an isolated case without other symptoms (6). Sommer et al (7) reported two sibs from unrelated parents with partial aniridia, glaucoma, agenesis of the medial rectal muscle, hypertelorism, psychomotor retardation, dilated cerebral ventricles, and short stature, and, in another case, they also had hip dysplasia and sensorineural hearing loss. This may still represent DeHauwere syndrome, although no microsymptoms were present in the parents (A Sommer, personal communication 1992). Absent eye muscles have occasionally been noted in *Crouzon syndrome* and *Apert syndrome* (2,5).

Absent eye muscles, unusual facies, hydrocephaly, and skeletal anomalies

Chitty et al (1) described a grandmother, mother and her daughter and son with absent eye muscles, anterior chamber defects (prominent Schwalbe ring, hypoplasia of anterior iris stroma, and iris processes), strabismus, downslanting palpebral fissures, proptosis, hydrocephalus, hypertelorism, maxillary hypoplasia, and skeletal changes including tall lumbar vertebrae, flat capital femoral epiphyses, and delayed appearance of carpal bones.

DeHauwere syndrome had some overlap. Absent eye muscles are very unusual. This condition has been described in association with *Crouzon syndrome* and with *Apert syndrome* (2,3).

Ophthalmo-mandibulo-melic (Pillay) dysplasia

A father and his son and daughter were described by Pillay (1) in 1964, with dense corneal opacities, macrocorneae, possibly glaucoma, temporomandibular fusion with agenesis of the coronoid processes and obtuse mandibular angle, mesomelic shortening of the upper limbs, aplastic lateral humeral condyle and caput radii, radiohumeral and proximal radioulnar dislocations, agenesis of the lower third of the ulna, bowed radii, ulnar deviated club hands, diminished mobility of the third, fourth, and (especially) fifth fingers, coxa valga, and mild genua valga. There were no internal anomalies, and development was normal (Fig. 30–6).

Pattern of inheritance is likely autosomal dominant.

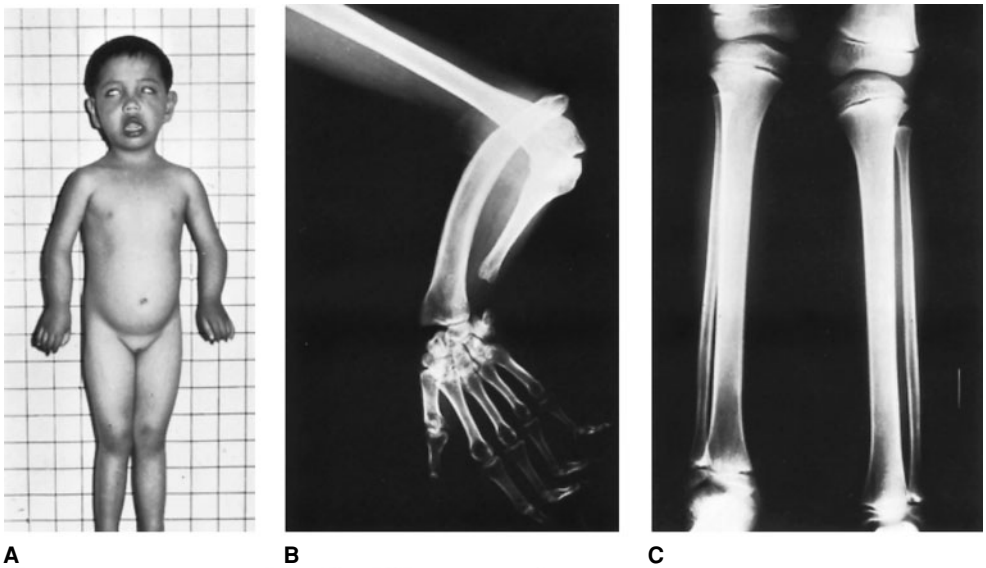

Fig. 30–6. *Ophthalmo-mandibulo-melic dysplasia*. (A) Seven-year-old girl with bilateral complete corneal opacities, shortened forearms. Father and brother similarly affected. (B) Aplastic lateral humeral condyle, abnormal trochlea, and olecranon. Coronoid processes absent, as are radial heads. Both radial shaft heads end in points that are located posterolateral to lower end of humerus. Radius bowed and short, ulna short with distal third absent. Articulation of radius only with lunate. Distal interphalangeal fusion. (C) Lateral malleolus higher than medial malleolus. Fibula shorter than tibia. (D) Temporomandibular joint ankylosis, lack of mandibular angle, and absence of coronoid process. (From VK Pillay, J Bone Joint Surg Am 46: 858, 1964.)

Anophthalmia-syndactyly (ophthalmo-acromelic) syndrome

A syndrome described in two families by Waardenburg (12), in 1935, consisted of anophthalmia and syndactyly. Two sisters had unilateral anophthalmia, four toes, and proximal synostosis of metatarsals 4–5. Bilateral anophthalmia, short fingers, four toes, and cutaneous syndactyly were seen in sibs in the other family. Richieri-Costa et al (7) reported five children from two families. Four had bilateral and one had unilateral anophthalmia. All had similar limb anomalies. Traboulsi et al (11) noted male and female sibs and a cousin with the syndrome. Turkish brothers were described by Sayli et al (8). They exhibited bilateral anophthalmia, soft tissue syndactyly of toes 2–5, and partial synostosis of metatarsals 4–5. A Turkish girl was reported by Cogulu et al (2) and a Turkish boy by Tekin et al (10).

Al-Gazali et al (1) reported a male infant of Syrian consanguineous parents with microphthalmia and distal limb abnormalities. Quarrel (6) reported a male child of nonconsanguineous parents. The infant had anophthalmia and postaxial polydactyly of the feet. Suyugül et al (9) reported two inbred Turkish families. There were two affected in the first family and one in the second family. All had bilateral anophthalmia and mental retardation. There were also fused metacarpals 4–5 and a reduced number of metatarsals and corresponding toes (Fig. 30–7). Pallotta and Dallapiccola (5) also found mental retardation. Le Merrer et al (3) noted three sibs and suggested the term *ophthalmo-acromelic syndrome*. Mégarbané et al (4) reported a Lebanese boy with split hand and polydactyly.

Inheritance is clearly autosomal recessive.

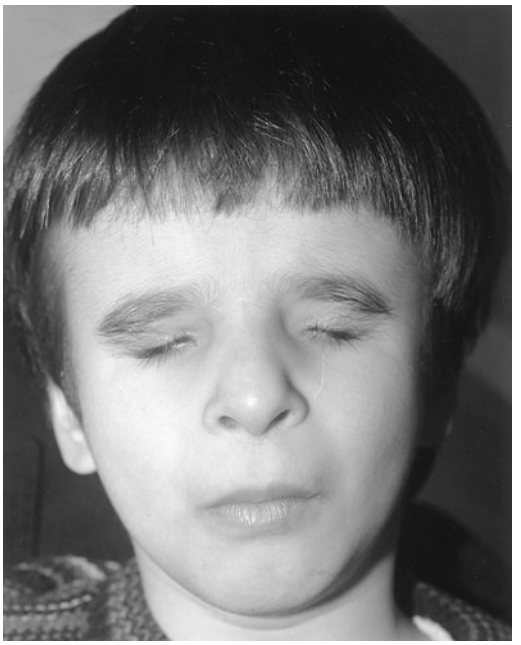
Bardet-Biedl syndrome

A syndrome characterized by mental retardation, hypogenitalism, retinopathy and ataxia was first described in four sibs by Laurence and Moon (53) in 1866. All four later developed spastic paraplegia. Independently, Bardet (3), in 1920, and Biedl (8), in 1922, described another disorder with similar features, but without ataxia and spasticity, and with obesity and polydactyly. Shortly afterward, both entities were subsumed under one heading: Laurence-Moon-Bardet-Biedl or



A

B

Fig. 30–7. *Anophthalmia-syndactyly (ophthalmo-acromelic) syndrome*. (A) Female with bilateral anophthalmia, bushy eyebrows, downslanting palpebral fissures, long philtrum. (B) Oligodactyly, wide gap between halluces and rest of toes, syndactyly of toes 2–3. (From Z Suyugül et al, Am J Med Genet 62:391, 1996.)

Laurence-Moon-Biedl syndrome (10,19,22,29,32,39,43,45,51,57–59, 61,63,64,66,67,69,71–74,79–81). However, especially through the work of Ammann (1) it became clear that Laurence-Moon syndrome and Bardet-Biedl syndrome are different disorders, and we and others concur (77,81). Bauman and Hogan (4) were the first to add renal anomalies as a cardinal sign of the entity.

There are about 850 cases of Bardet-Biedl syndrome described in the literature. Epidemiologic estimates vary: Klein and Amman estimated the prevalence in Switzerland to be 1 in 160,000 (49), in Norway prevalence was 1 in 128,000 (57), in Denmark 1 in 59,000 (41), in the United Kingdom 1 in 125,000 (5), and in Kuwait 1 in 65,000 (33). Unusual high frequencies were reported by Green et al (39) in Newfoundland of 1 in 17,500, and by Farag and Teebi (34) among the Bedouins of 1 in 13,500. In some countries, clustering of the geographic distribution was found (34), but in others, this was not present (39,49,81).

Inheritance is clearly autosomal recessive. Both sexes are equally affected; some reports have mentioned an excess of affected males (1,6,7),

leading some authors to suggest that the entity follows a polygenic inheritance (7), but others found an excess of females (39,81). Concordant monozygotic twins have been reported (59). Parental consanguinity of various series has ranged from 20% (6,9) to 35% (39), to 50% (1), to 100% (34). Heterozygous relatives have been described to have polydactyly (77), retinitis pigmentosa (29,47,61), hypospadias (70), developmental delay (29), diabetes (24,29,49), obesity (24,25,49), renal disease (25,76), and hypertension (25), but probably only renal diseases and hypertension, and possibly obesity, are truly more common in relatives compared to the population frequency. Beales et al (5) did not find a difference in weight in the parents of their study group.

The entity was linked first to chromosome 16q21 (52) in a large inbred Bedouin family, followed by linkage to chromosome 11q13 studying 28 families from Northern European descent and three Hispanic families (54), to chromosome 3p12–13 in an isolated Bedouin tribe and a large family from Newfoundland (78,85), and again in a highly inbred Bedouin family to chromosome 15q22–23 (18). Hence, nonallelic heterogeneity exists, and locus distribution is likely to be subject to regional variation. Bruford et al (13) studied 29 families from predominantly European ethnic origin and confirmed linkage to 11q13 in 36%–56%, to 15q22–23 in 32%–35%, to 16q21 in 24%–27%, and to an unknown other locus in 8%; no linkage to 3p12–13 was found. They found no major clinical differences between the families linked to the different loci. Carmi et al (17) suggested that affected members of families linked to chromosome 3p12–13 were clinically different in having polydactyly of all four limbs, but this was not confirmed by Young et al (85). Beales et al (5), studying 14 families of Northern European descent and 4 from the Middle East, confirmed linkage to 11q13 in 44%, to 15q22 in 6%, to 16q21 in 17%, and no linkage to 3p12–13; in 28% no linkage to any known locus was found. Linkage to the McKusick-Kaufman gene at 20p12 was found in 10% (78a,b). The gene is a chaperonin. Patients born in families linked to 11q13 were found to be somewhat taller compared to their parents and had atopic asthma more often (5).

Absence of linkage to the known loci indicate that at least one other locus for Bardet-Biedl syndrome exists. Chromosome anomalies that have been described are sex chromosome mosaicisms (10,12,40,65) and an apparently balanced translocation between chromosome 2p and 17p (26). Linkage to the 2p and 17p loci was excluded (13). A patient reported to have Oliver-McFarlane syndrome (27) with a partial trisomy of chromosome 13q may have had Bardet-Biedl syndrome. A high resolution cytogenetic study in 28 patients failed to show anomalies (32). There is evidence that one form of Bardet-Biedl syndrome is allelic to McKusick-Kaufman syndrome (47a,78b).

Ammann (1), and Klein and Ammann (41), Bell (6), Green et al (39), and Stiggelbout (81) surveyed the disorder.

Central nervous system. In early reports development was often reported to be severely impaired, but this has probably been due to the diminished vision and accordant deprivation (1,6). Green et al (39) reported an IQ below 70 in 41%, 9% being severely retarded, and Beales et al (5) found 36% to have a developmental delay. Speech defects, that is, poor articulation, slurring, and dropping of consonants, were common in one investigation (5). Dyslexia was reported (49). Although no formal behavioral studies have been reported, inappropriate mannerisms and shallow affect has been noted (39,49). Several authors reported normal findings in neuroradiologic studies, but rarely hypothalamic hamartoma and other hypophyseal or suprasellar tumors were found (28). Brain autopsy findings were limited and have included small gyri, especially of the frontal lobes, gliosis, fibrosis of blood vessels, and moderate internal hydrocephaly (58). Convulsions occur, especially in early childhood, but only rarely (49,81). Nyska et al (66) described a patient who developed spastic quadriparesis at 36 years because of cervical myelopathy due to cervical canal stenosis. Rizzo et al (74) described a case with ataxia and cerebellar vermis hypoplasia, but this patient probably had Laurence-Moon syndrome.

Growth. Although obesity may already be present at birth, it usually develops in infancy. It is not accompanied by an increased appetite similar to that in Prader-Willi syndrome, although hyperphagia during childhood was noted by parents in 64% (5). The localization is of the 'Frohlich' type, that is, along the trunk and proximal parts of the limbs. The obesity becomes more prominent through the usually somewhat diminished height (Fig. 30–8). Green et al (39) reported 88% of patients to be obese and 64% to have a stature below the 50th centile. Beales et al (5) found a mean height of offspring to be 3 cm below that of the parents. On the contrary, when dissected for linkage to the different loci of Bardet-Biedl syndrome, males and females showing linkage to chromosome 11q13 locus were taller (mean, 6 cm and 11 cm) than their fathers and mothers, respectively (5). Body mass was higher in all offspring compared to their parents (5). A patient weighing more than 200 kg has been reported (49). After renal failure, myocardial infarction has been the major cause of death in Bardet-Biedl syndrome (72). Type II diabetes mellitus occurs (31,39,47), but the frequency has varied widely from 0% (5) to 45% (39). Fatal diabetic coma was reported (31). Hypopituitarism with growth hormone deficiency has been described (70) as well as sibs with hypopituitarism without growth hormone deficiency (83).

Fig. 30–8. *Bardet-Biedl syndrome*. Obesity and hypogenitalism.

Eye findings. The retinal disorder is primarily a degeneration of the photoreceptors (76) and affects both rods and cones, causing both central and more peripheral functions to be affected (36). The macula is involved early (39,67). Retinal dystrophy is found in 85%–100% of reported series (1,6,39,48,81) (Fig. 30–9). The entity constitutes 5% of all cases with retinitis pigmentosa (41). Onset of the visual impairment is in the first and, especially, the second decade (36,71), and leads to legal blindness in 85% of cases by the age of 30 years (49), or, in another study, a visual acuity less than adequate to count fingers in 73% of cases older than 30 years (39). This is more rapid than in isolated retinitis pigmentosa. Light perception is retained. Eye symptoms rarely debut after 18 years of age (41). In individual cases the progression of visual impairments is variable and unpredictable (36,55). The fundoscopic appearance can be that of typical retinitis pigmentosa but more often is atypical with sparse

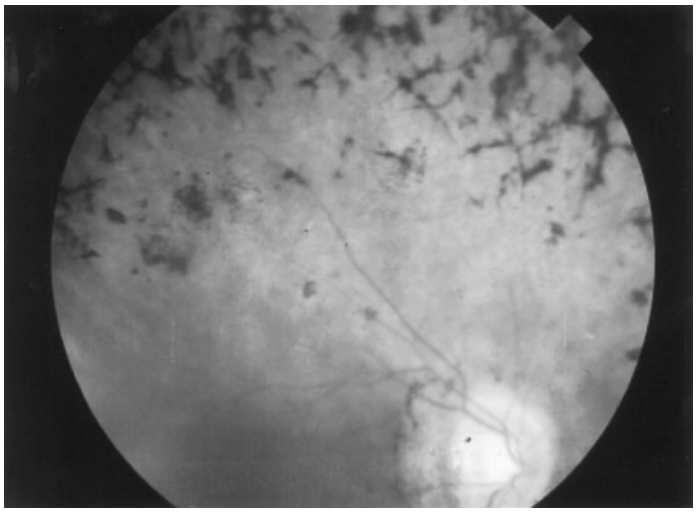


Fig. 30–9. *Bardet-Biedl syndrome*. Fundus showing retinal pigmentation.

pigmentation, central and peripheral atrophy, and especially attenuated vessels and pale optic disks (39).

Electroretinographic abnormalities precede retinal anomalies and can already be present in infancy or early childhood (29,58). Other eye symptoms have been cataract (8,14,29,39,47,51,69,71,77), myopia (39,47,48,71,79), nystagmus (39,47,71), glaucoma (39), and microphthalmia (4).

Renal system. The renal symptoms in the entity are well reviewed by Harnett et al (43). In an unbiased series they found structural or functional renal abnormalities in all 20 studied adults. The characteristic radiologic changes are symmetrical and irregular parenchymal reduction, fetal type lobulation, noncommunicating cysts and diverticula, and blunting and clubbing of the calyces (23,56), all suggesting a defect in renal maturation. Other reported structural renal anomalies have included hypoplasia, hydronephrosis, and focal scarring (2,23,43,56,58). Ultrastructural findings were mesangial proliferation and sclerosis, increase in mesangial matrix, and glomerular basement membrane abnormalities (19).

Sonography of the kidneys prenatally or in the neonatal period may show findings identical to those of autosomal recessive polycystic kidneys (37,38,73). Confusion with the latter entity can become even stronger because of the occurrence of congenital hepatic fibrosis in Bardet–Biedl syndrome (64,68,75). Biliary cirrhosis (24), cholecystitis (80), and portal hypertension (75) have been reported.

Functional renal problems are hypertension, partial defects in urine concentration, incomplete or complete renal tubular acidosis, and end stage renal disease (43,45). Nephrolithiasis has been mentioned repeatedly (51,80). Functional problems may become apparent in infancy, but usually in the first two decades (45), and do not show a strong correlation with the structural defects (23,43). First symptoms can be polyuria, polydipsia, proteinuria (2), and pyelonephritis (14). Remission of proteinuria may be established with steroids, but residual proteinuria and recurrence have been described (20). Severe, progressive renal disease occurs in 15% of cases (43). Renal transplantations have mostly been successful, without recurrence of the renal problems, but follow-up was usually only very short (56,75). Increased obesity as a complication of the transplantation has been noted (22,82). End stage renal disease is the major cause of death in Bardet-Biedl syndrome (72). The average age of death of 43 years mentioned by Riise (72) is too low because of biased ascertainment. Autopsies of nine patients who died because of uremia showed chronic glomerulonephritis, cystic tubulo- interstitial disease, and advanced sclerosis (20).

Urogenital system. Hypogenitalism is almost universal in male patients. It is primary, and not secondary to hypopituitarism (39) (see Fig. 30–8). Cryptorchidism was found in 25% (5). Testicular biopsies showed fibrosis (68) and degenerative lesions of the seminiferous tubules (83). Hypospadias was reported (81). Pubertal development is normal, with normal hair distribution and other secondary sexual characteristics. No fully affected male is known to have fathered a child, but one male with a "forme fruste" had three sons (81).

Stoler et al (82) have summarized the genital anomalies in females. Vaginal atresia (23,39,49,80,82), ovarian cysts (77), uterus duplex with vaginal septum (49,58), hypoplastic uterus and ovaries (14,58), hydrometrocolpos (60,82), hematocolpos (23,49), female hypospadias (opening of urethra into upper vaginal wall) (23), and persistent urogenital sinus (63,82) are found. One patient was virilized because of ovarian dysfunction due to stromal hyperplasia with focal hyperthecosis (42). Most females have normal menarche and menses, and normal secondary sexual characteristics (14,39), although primary amenorrhea and absence of breast occur (13). Hypogonadotrophic hypogonadism may occur but is not a common symptom in females (39). At least seven females have given birth to healthy children (5,6,9,39,81).

Skeletal system. Polysyndactyly is extremely common, occurring in 93% (39) to 98% (5) (Fig. 30–10). Polydactyly, almost exclusively on the ulnar side, can be postaxial and paraaxial, unilateral or on all four limbs, and usually asymmetrical. Some reports did not find a difference between hands and feet (5); others found the feet to be more commonly affected (39,49). Hexadactyly up to octodactyly occurs. Syndactyly is usually subtle, between the second and third toes, and between the polydactylous fingers or toes. If no polydactyly is present, hands and feet are usually broad. Brachydactyly is proven with metacarpophalangeal pattern profiles in 93% (39). Intrafamilial variability is extremely large.

Other symptoms include hip dislocations (29,61,81), genua valga (49,79,81), tibia vara (62), club feet (49,68,81), camptodactyly (35), and kyphoscoliosis (12,49,81). The skeleton may be osteoporotic (12).

Oral manifestations. Kobrin et al (50) noted oligodontia and microdontia in two sibs. One of the authors (RCMH) has seen these brothers and their nephew who may have an X-linked disorder. A Norwegian study showed hypodontia, short roots, tendency to taurodontia, obliterated pulp chambers, and sclerotic areas in the jaws (57). This was confirmed in another Scandinavian study (11), which also found that the saliva showed a higher buffering capacity than normal.

Other findings. Conductive hearing deficits due to chronic middle ear effusions were reported in 35% (5). Cardiac anomalies have included dilated cardiomyopathy (30), bicuspid aortic valves (20,30,55), aortic (20) and tricuspid (30) regurgitation, pulmonic valve stenosis (30,55,58), atrial septal defect (30,35,81), ventricular septal defects (58), transposition of the great vessels (58,81), and hypertrophy of the intraventricular septum (30) or left ventricle (30,58). Other reported anomalies have been sparse hair (13), skin depigmentations (14), supernumerary nipples (68), basal cell carcinoma of the skin of the nose (69), choanal stenosis (4), anal atresia (8,79,81), and Hirschsprung disease (46,70).

Differential diagnosis. There is marked overlap with McKusick-Kaufman syndrome (hydrometrocolpos, poataxial polydactyly, and congenital heart anomalies) (60,78a). This should not be surprising as the disorders are allelic. Many components of the syndrome can occur as isolated findings or as features of other syndromes, making a firm diagnosis in the isolated, young patient, that is, without symptoms yet of retinal dystrophy, difficult. Entities to be considered are *Meckel syndrome* (38), *Pallister-Hall syndrome* (28), mitochondrial disorders (76), and *Smith-Lemli-Opitz syndrome*. Several authors have discussed the difference with other multiple congenital anomalies syndromes that show retinitis pigmentosa such as Alstrom syndrome, Biemond syndrome, *Cohen syndrome*, Laurence-Moon syndrome, and several case reports (9,15,77). Pigmented retina without retinitis pigmentosa occurs in *Cohen syndrome*. About 30 cases of Laurence-Moon syndrome have been described (33,74,77). Besides the absence of polydactyly and the presence of ataxia and spastic paraplegia in this entity, the retinal dystrophy also differs from Bardet-Biedl syndrome, resembling more

A B

Fig. 30–10. *Bardet-Biedl syndrome*. (A,B) Polydactyly ranges from postminimum digit to postaxial extra digits with variable digital distortion.

choroideremia (77). Nephronophthisis, congenital hepatic fibrosis, and retinal degeneration can occur as separate entities (16). The sibs reported by McLoughlin et al (58) had *Carpenter syndrome*. Case 58 of Klein and Ammann (49) obviously had *Rubinstein-Taybi syndrome*, and Farag et al (35) and Hauser et al (44) may have described Alström syndrome. The case reported by Whitaker et al (84) as having Kearns-Sayre syndrome is likely to have had the entity, and a case with Oliver-McFarlane syndrome may also have had Bardet-Biedl syndrome (27).

Laboratory findings. In familial cases linkage studies are helpful. Prenatal diagnosis using the hand anomalies and renal cysts as clues have been accomplished (32,33,72).

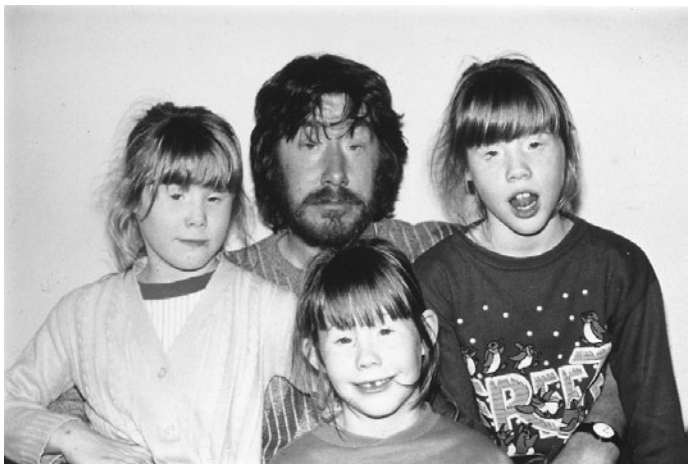
Blepharophimosis-ptosis-epicanthus inversus (BPES)

Initial description of blepharophimosis, ptosis, and inverse epicanthus was probably that of Vignes (23) in 1889. An earlier example has been suggested by Harrar et al (9). At least 180 families have been described (15).

Inheritance is autosomal dominant (16,20,21). Several patients with chromosome deletions or rearrangements led to the gene being mapped to 3q22–6q23 (1,2,8,9). Crisponi et al (2a) found the forkhead transcription factor *FOXL2* to be mutated. Both type 1 and type 2 (vide infra) map to this region (2). There is evidence that this may represent a contiguous gene deletion (6–8,19). There is current debate regarding the *SOX14* gene (8a,24). However, there appears to be genetic heterogeneity with other families mapping to 7p13–p21 (14,24). The facies is different in the 7p13 type. A maternal age effect for new mutations has been demonstrated (4). Occasionally, nonpenetrance can cause a counseling problem (21).

The facies is distinct (3). It appears flattened and expressionless due to taut facial skin. In addition to the narrow palpebral fissures [18–22 mm versus 25–33 mm (normal range)], there are telecanthus and ptosis of the upper eyelids. The supraorbital ridges are flattened. The head is often held tilted backward and the brow is furrowed to compensate. Eyebrows are highly arched and elevated (Fig. 30–11). The margin of the upper eyelid may have a mild S-shaped curve. Due to drooping of the lateral canthus, there may be some ectropion of the lower lids. Trichiasis has been reported. Lateral displacement of the lacrimal puncta is common. The superior rectus, less often the lateral rectus, is hypoplastic and fibrotic. Epicanthal folds run upward and inward from the lower lid rather than downward. The lid folds are usually absent with smooth overlying skin. The normal depression at the inner canthus is missing. The caruncle and plica semilunaris are hypoplastic and secluded beneath the epicanthic fold. The nasal bridge is rather low (11,13,15,16). The nostrils may be obliquely shaped.

Affected females have amenorrhea, irregular menses, infertility and/or elevated gonadotropin levels due to primary ovarian failure (5,17,19,22).



A

B

Fig. 30–11. *Blepharophimosis-ptosis-epicanthus inversus (BPES)*. (A) Note ptosis, narrow palpebral fissures, highly arched eyebrows in several members of a family. (B) Observe telecanthus, smooth skin of eyelids, inverse epicanthus, flat nasal bridge. (A courtesy of MA Patton, London, England. B from C Oley and M Baraitser, J Med Genet 25:47, 1988.)

Endometrial carcinoma has been noted (13a). Breast development is normal, but axillary and pubic hair is scant. Zlotogora et al (26) suggested that there were two forms: one with infertile females (type 1), the other without (type 2).

Occasionally, microcephaly and/or hypoplasia of the cerebellar vermis have been described. Such examples have been attributed to contiguous gene deletion (8,10–12). Mental retardation has been common in those with obvious deletions (8).

Hypoplasia of superior rectus muscle and occasionally the lateral rectus muscle occurs.

Differential diagnosis would include autosomal dominant congenital ptosis (18) and a host of syndromes with blepharophimosis and/or ptosis. One must exclude *Schwartz-Jampel syndrome, Marden-Walker syndrome, Dubowitz syndrome, Ohdo syndrome*, and *Michels syndrome*.

Blepharophimosis-ptosis, mental retardation, and hearing loss (Ohdo syndrome)

Ohdo et al (11), in 1986, reported a syndrome of blepharophimosis, blepharoptosis, hypoplastic teeth, mental retardation, and hearing loss in two sibs and their first cousin. About 15 examples have been subsequently documented (1,3,7,8,11–13).

Inheritance is unknown. Nearly all examples have been sporadic except for the affected sibs reported by Ohdo et al (11). Mhanni et al (10) reported a mother and son but raised the possibility of mitochondrial inheritance.

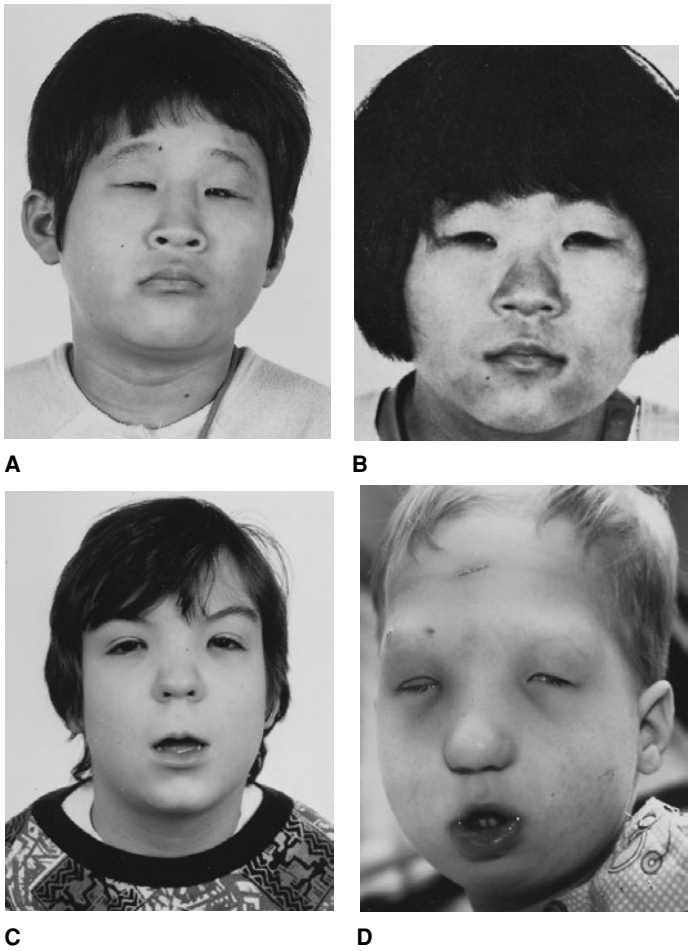

Fig. 30–12. *Blepharophimosis-ptosis, mental retardation, and hearing loss (Ohdo syndrome)*. (A,B) Two sibs with blepharophimosis, blepharoptosis, wide and depressed nasal bridge, and microstomia. (C,D) Similarly affected children. (A,B from S Ohdo et al, J Med Genet 23:242, 1986. C courtesy of A Chudley, Calgary, Alberta, Canada. D courtesy of L Biesecker, Bethesda, Maryland.)

The facies is characterized by blepharophimosis, blepharoptosis, epicanthus, amblyopia, wide and depressed nasal bridge, short upturned nose, long flat philtrum, thin vermilion, microstomia, hypoplastic teeth, and small mandible (Fig. 30–12). Auricular stenosis (1,11) and small pinnae (4,6,11,13) were documented. Hearing loss was noted in 50% but was not a well-documented feature (1,3,7,9,11,12).

Mental retardation is a constant feature, with IQs ranging from 37 to 56. Hypotonia is present in 70% (1,3,7,12,13).

Cryptorchidism has been a constant feature in males (1,7,12,13).

Variable features have included congenital heart anomalies (3,11–13), cleft palate (6), hyperextensible joints and clinodactyly of fifth fingers (1,7,13), café-au-lait spots (1,7), bladder diverticula (6), and proteinuria (11,13).

Differential diagnosis would include *dup(10q), trisomy 18, dup(20p), Dubowitz syndrome, Michels syndrome, COFS syndrome, craniocarpotarsal dysplasia, Schwartz-Jampel syndrome, Marden-Walker syndrome*, Tsukahara syndrome, and *alcohol embryopathy* (3). Buntinx and Majewski (2) reported a patient with blepharophimosis, iris coloboma, postaxial polydactyly, agenesis of corpus callosum, hydroureter, developmental delay, and hearing loss. Biesecker (1) has elegantly discussed differential diagnosis. Also to be considered in diagnosis is *blepharophimosis-ptosis epicanthus inversus syndrome* (BPES) for which the gene has been mapped to 3q22 (5). The ROCA-Wiedemann syndrome (growth and developmental retardation, ocular ptosis, cardiac anomalies, and anal atresia) must be excluded.

Microcephaly, blepharophimosis, esophageal/duodenal atresia, and digital anomalies [oculodigitoesophageal duodenal (Feingold) syndrome, MODED]

Feingold (5,6) briefly described two families with microcephaly, normal intelligence, blepharophimosis, and hand and foot anomalies (clinodactyly of V, syndactyly of toes 2–3), and duodenal atresia. Fourteen additional families involving 50 persons have expanded the syndrome more fully (1,4,7–13). Other less certain examples have been cited (4,9).

Inheritance is clearly autosomal dominant (9). The gene maps to 2p23–p24 (3).

About 80% had microcephaly with short palpebral fissures. Intelligence in most patients has been normal, but learning disabilities have been noted in 30% (8).

All had absent or hypoplastic middle phalanges of I and II bilaterally (brachydactyly A4). Syndactyly of toes 2–3 and/or 4–5 was noted in 60%–85%. The middle phalanges of the last four toes is often absent.

Intestinal atresia or obstruction (esophageal atresia, TE fistula, duodenal atresia or duodenal obstruction) was documented in about 25%. Imperforate anus was noted by Büttiker et al (2).

Miscellaneous findings have included congenital heart anomalies (1) and vertebral abnormalities (13).

Blepharophimosis, ptosis, syndactyly, and mental retardation

Cohen et al (1) described a single male mentally retarded case with blepharophimosis, ptosis, deficient lashes of the lower eyelids, maxillary hypoplasia, a grooved nasal tip, and small protruding ears. There was complete cutaneous syndactyly of the third and fourth finger, kyphoscoliosis, mild hypospadias, and diminished movements in fingers, elbows, and toes. It was reported that the mother took phenobarbital during pregnancy.

Reference (Blepharophimosis, ptosis, syndactyly, and mental retardation)

1. Cohen MM Jr et al: Case report 26. Syndrome Ident 3:1–2, 1975.

Blepharophimosis, atrial and ventricular septal defects, and anal and radial anomalies

Houston et al (1) reported male and female sibs with atrioventricular septal defect, blepharophimosis, and anal and radial anomalies. In addition to blepharophimosis, there were upslanting palpebral fissures, and convergent squint. Other anomalies included growth retardation, anteriorly placed anus, aplastic radius, clinodactyly V, and atrioventricular septal defect.

VACTERL association and *Ohdo syndrome* were considered.

Reference (Blepharophimosis, atrial and ventricular septal defects, and anal and radial anomalies)

1. Houston RS et al: Association of atrial-ventricular septal defect, blepharophimosis and radial defects in sibs: A new syndrome? Genet Couns 5:93–96, 1994.

Blepharophimosis, hypotelorism, pseudopapilledema, and anomalies of the hands (acro-oto-ocular syndrome)

Paes-Alves et al (2), in 1991, reported three individuals in a Brazilian inbred family. Bertola et al (1) described another isolated case.

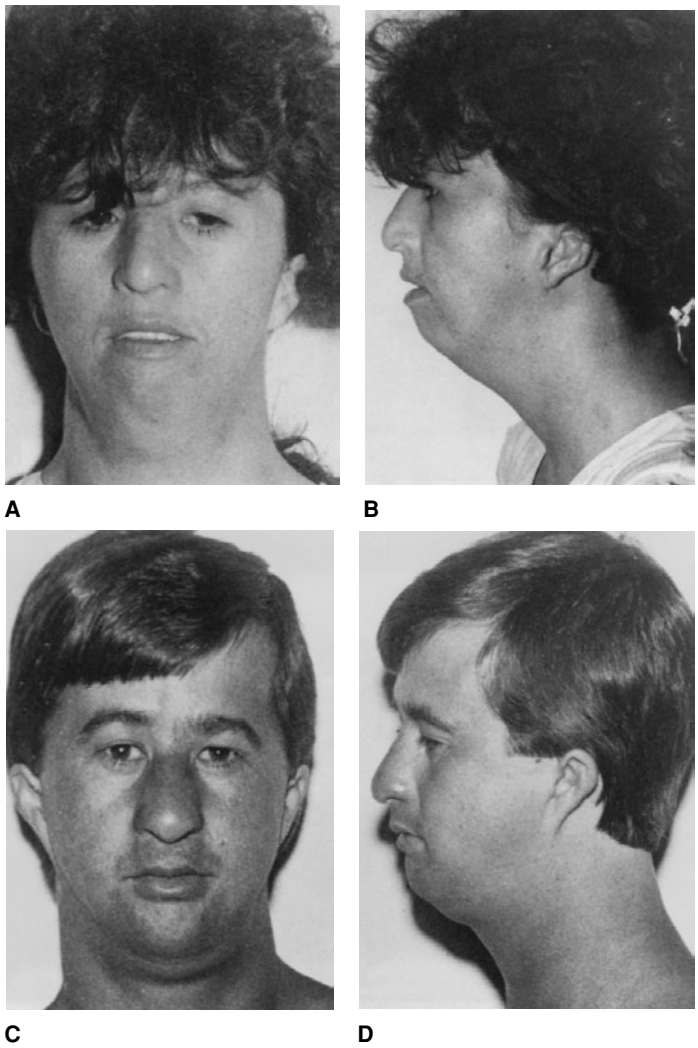

Fig. 30–13. *Blepharophimosis, hypotelorism, pseudopapilledema, and anomalies of the hands (acro-oto-ocular syndrome).* (A–D) Brother and sister with ocular hypotelorism, blepharophimosis, deep base of nose, and downslanting palpebral fissures. Note malformed, low-set pinnae. (From AF Paes-Alves et al, Am J Med Genet 41:141, 1991.)

The affected were small at birth and subsequently had small stature. In addition to blepharophimosis, the patients exhibited hypotelorism and epicanthic folds (Fig. 30–13).

Pseudopapilledema and mixed hearing loss were documented.

The nasal base was broad. The pinnae were small and low-set with narrow canals. Teeth were late in eruption. Intelligence was normal.

The thenar, hypothenar, and interdigital areas of the hands were flattened, and a wide space was evident between the hallux and the second toe. The calcaneus protruded.

Inheritance is probably autosomal recessive.

A B C

Fig. 30–14. *Blepharophimosis, large cylindrical nose, and severe intrauterine growth retardation*. (A–C) Female infant with blepharophimosis, hypotelorism, large nose with broad nasal bridge and midline groove, flexed posturing of hands. (From CEM de Die-Smulders et al, J Med Genet 30: 525, 1993.)

Blepharophimosis, large cylindrical nose, and severe intrauterine growth retardation

De Die-Smulders et al (1) described a female child of nonconsanguineous parents with blepharophimosis, hypertelorism, micrognathia, large nose with broad nasal bridge and midline groove, flexed posturing of the hands, severe growth retardation, and early death (Fig. 30–14).

Reference (Blepharophimosis, large cylindrical nose, and severe intrauterine growth retardation)

1. De Die-Smulders CEM et al: Severe intrauterine growth retardation, blepharophimosis, and cylindrical nose with midline groove: A new syndrome? J Med Genet 30:525, 1993.

Blepharophimosis, ptosis, syndactyly, and short stature

Frydman et al (1) reported several sets of Yemenite Jewish sibs from a highly inbred family with blepharophimosis, ptosis, and weakness of extraocular and frontal muscles. V-esotropia and upper gaze paralysis were demonstrated. Synophrys of thick eyebrows and mandibular prognathism contributed to the unusual facies. Short stature and syndactyly of toes 2–3 were also noted.

The autosomal recessive inheritance pattern makes this a very distinct entity among the many blepharophimosis-ptosis syndromes. One must exclude the autosomal recessive *Mutchinick syndrome* (2).

References (Blepharophimosis, ptosis, syndactyly, and short stature)

Blepharophimosis, telecanthus, microstomia, and unusual facies (Simosa syndrome)

Simosa et al (1) described a mother and son with elongated and somewhat flattened face, short palpebral fissures, long nose with hypoplastic alae, chin dimples, and unusually formed pinnae. Suri et al (2) reported a male infant with a similar facies and camptodactyly of the fingers (Fig. 30–15).

References [Blepharophimosis, telecanthus, microstomia, and unusual facies (Simosa syndrome)]

Blepharophimosis, ptosis, polythelia, and brachydactyly

Wittebol-Post and Hennekam (1) reported a father and two sons who all three had blepharophimosis, ptosis, and brachydactyly type A3. Father

Fig. 30–15. *Blepharophimosis, telecanthus, microstomia, and unusual facies (Simosa syndrome)*. Note blepharophimosis, small mouth, and unusual ear malformations. (From M Suri et al, Am J Med Genet 51:222, 1994.)

A B

and one son had polythelia, the other son had a congenital hyperpigmentation above one of his nipples. The sons had protruding ears, but otherwise no other anomalies were present. Development was normal. Inheritance is probably autosomal dominant.

Reference (Blepharophimosis, ptosis, polythelia, and brachydactyly)

1. Wittebol-Post D, Hennekam RCM: Blepharophimosis, ptosis, polythelia and brachydactyly (BPPB): A new autosomal dominant syndrome? Clin Dysmorphol 2:346–350, 1993.

Cataracts, microcephaly, rhizomelia, and micropenis

Verloes et al (3) described a single case with severe microcephaly, borderline intelligence, cataracts detected in early childhood, rhizomelic shortness, especially of the lower limbs, giving rise to a muscular build, advanced bone age, and micropenis. Facial features included hypotelorism, long nose with anteversion of the nares in infancy, flat malae, highly arched palate, crowded teeth, and micrognathia (Fig. 30–16). The extension of elbows was limited, the second and third toes showed a Y-shaped cutaneous syndactyly. The case resembled *Smith-Lemli-Opitz syndrome* to a great extent, but cholesterol metabolism was reported to be normal. Parents were consanguineous.

The case reports by Harrod et al (1) and Pavone et al (2) need to be excluded.

Fig. 30–16. *Cataracts, microcephaly, rhizomelia, and micropenis*. Seven-year-old male with juvenile cataract, muscular build, rhizomelic shortness of limbs, advanced bone age, and micropenis. (From A Verloes et al, Am J Med Genet 68:455, 1997.)

Cataracts, enamel hypoplasia, and aqueductal stenosis

Seow et al (1) reported a single female case who was found to have anterior and posterior subcapsular cataracts with radial spoke opacities in the cortex in childhood, generalized enamel defects of the hypomaturation-hypocalcification type in primary and permanent teeth, anterior overbite, and aqueductal stenosis at brain imaging. There were no other anomalies, and intelligence was normal.

Reference (Cataracts, enamel hypoplasia, and aqueductal stenosis)

1. Seow WK et al: Enamel hypoplasia, bilateral cataracts, and aqueductal stenosis: A new syndrome? Am J Med Genet 58:371–373, 1995.

Cataracts, multiple oral frenula, and growth retardation

Wellesley et al (1) described a mother and two children with posterior polar cataracts in early childhood, multiple oral frenula, growth retardation, microcephaly, and borderline intelligence. One child had unilateral ptosis. Facial features were epicanthal folds, small nose with upturned tip, somewhat prominent premaxilla, and posteriorly angulated ears. Inguinal and umbilical hernias occurred. Inheritance appears to be autosomal dominant.

Reference (Cataracts, multiple oral frenula, and growth retardation)

1. Wellesley D et al: Cataracts, abberant oral frenula, and growth retardation: A new autosomal dominant syndrome. Am J Med Genet 40:341–342, 1991.

Cataracts, hearing loss, hypertrichosis, short stature, and mental retardation

Schaap et al (3), in 1995, reported three brothers with congenital lamellar cataracts, sensorineural hearing loss that became apparent in early childhood, moderate to severe growth retardation, and mild mental retardation, especially involving speech. All had generalized hypertrichosis and a somewhat triangular-shaped face and full eyebrows (Fig. 30–17). Two sibs had blue sclerae and mild gingival hyperplasia. Pubertal development was delayed in all three. Radiologically, there were a partial fusion of the second and third cervical vertebrae and a moderately delayed bone age in two. As the parents were consanguineous, autosomal recessive inheritance was suggested, although X-linked recessive inheritance was also possible. The authors provide a useful differential diagnosis, which included mainly *Martsolf syndrome* (2) and the entity described by Begeer et al (1).

CHIME (neurectodermal dysplasia) syndrome

In 1983, Zunich and Kaye (4) described a child with migratory ichthyosiform erythroderma, retinal colobomas, ectodermal anomalies, and neurologic involvement. Five other patients have been described (1–3,5,7). Autosomal recessive inheritance has been suggested because of recurrence in one family (7), although none of the parents were consanguineous. CHIME is an acronym for *C*olobomas of the eyes, *H*eart defects, *I*chthyosiform dermatosis, *M*ental retardation, and *E*ar defects (2).

Features have included high birthweight and normal growth. All patients have been moderately to severely mentally retarded and may show episodes of violent behavior, sometimes correlating with exacerbation of the skin rash (2). Seizures are common and often therapy resistant. Neuroradiology may show cerebral atrophy (1,3–5).

Craniofacial findings. Brachycephaly, retinal colobomas,and sometimes cloudy corneas (5) or ptosis (3,4), epicanthal folds, hypertelorism, conductive hearing loss, overfolded helices, broad nasal tip and root, short philtrum (3–5), wide mouth with full lips, widely spaced teeth, bifid or additioal incisors (4,5) and cleft uvula or soft palate (3–5) have been described.

Cardiovascular system. Cardiac anomalies that were reported were Fallot's tetralogy (5), transposition of the great arteries (6), peripheral pulmonic stenosis (7), and a ventricular septal defect (2,3).

Skin. The skin showed a migratory ichthyosiform rash in all patients, present at birth or shortly afterward, and sometimes difficult to manage. Palms and soles can be thickened without scaling. Ultrastructural characteristics were nonspecific, and included disturbed keratinization with incomplete cornified cells in the lower horny layer, perinuclear edema of granular cells surrounded by a shell of keratin filaments and small keratinhyalin granules, inflammatory cells in the epidermis, and disorganization of myelin sheaths (2,6). Hair was sparse and fine. In one patient trichorrhexis nodosa was described (3). Sweating was normal. Nails may be dystrophic (3).

Skeletal system. Symptoms have been a broad second toe, brachydactyly (1,2,4,5), hypoplasia of the terminal phalanges (3), clubfoot (3,5), deviated fingers (5) or toes (3), and hypermobile joints (1). Radiological changes in one patient were short clavicles, brachydactyly of fingers and toes, pseudoepiphyses of the second and third metacarpal bones, and hypoplasia of terminal phalanges of toes (3). Bone age was normal. Their gait was often described as wide based.

Neoplasms. Three patients had a skin lipoma (3,4,6), and the patient described by Schnur et al (2) developed fatal leukemia at 5 years of age.

Other findings. Clavicles may be short (3) and nipples small and low set (1,2,4–6); one patient had a supernumerary nipple (1). Patients have been described with a duplicated renal collecting system, partially ectopic renal pelvis (3), and a ureteropelvic junction obstruction (2).

Differential diagnosis. Rud syndrome, *infantile Refsum syndrome*, Sjögren-Larsson syndrome, Netherton syndrome, *KID syndrome, IBIDS syndrome*, and *trichothiodystrophy* should be considered (2).

Coloboma of eyelid, abnormal anterior hairline, and anal anomalies

Marles et al (1) reported six Manitoba Indian cases from four related families with asymmetrical facial anomalies consisting of upper lid colobomata, in one accompanied with anophthalmia, and in others with palpebral synechiae and nasolacrimal duct obstruction, and hypertelorism. Three had mild groove of the nasal tip. The anterior hairline extended

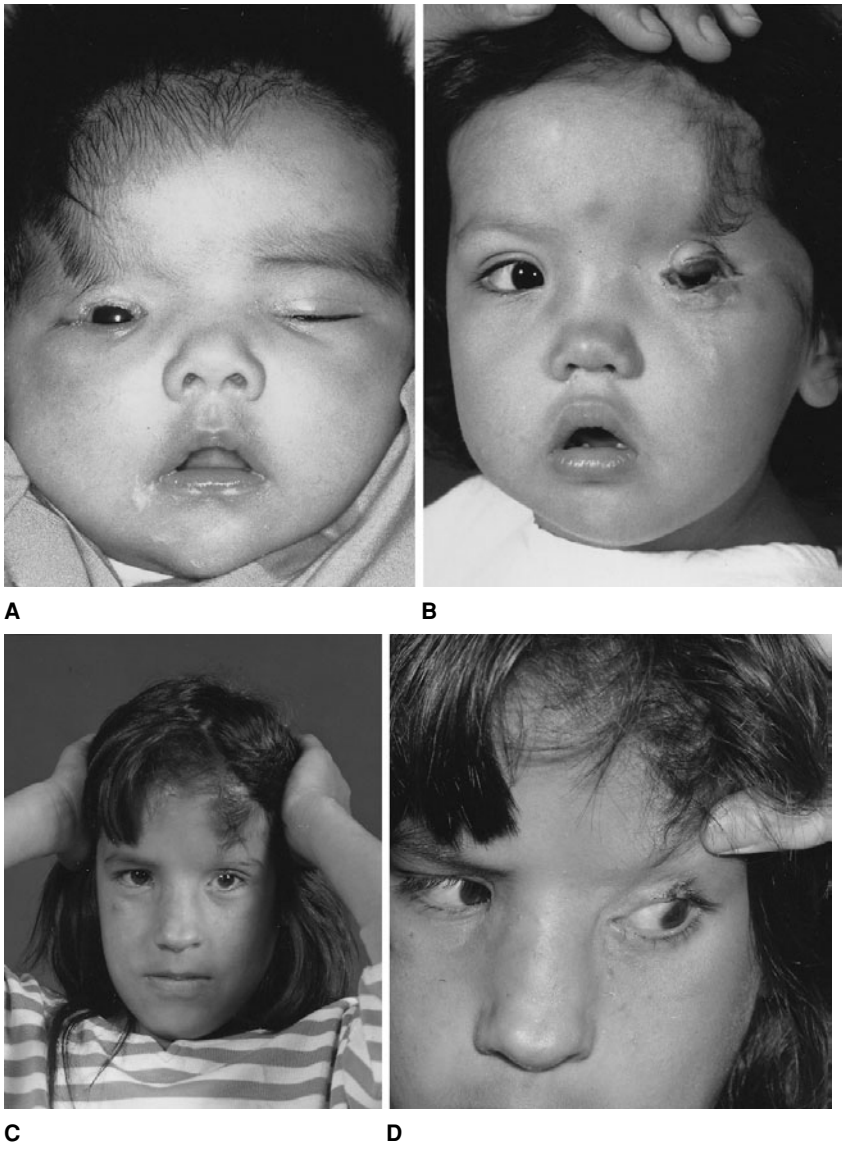

Fig. 30–18. *Coloboma of eyelid, abnormal anterior hairline, and anal anomalies*. (A–D) Compare children of various ages. Note coloboma of upper eyelids, aberrant wedge of scalp hair, absent eyelashes, slight groove of nasal tip. (A,B from SL Marles et al, Am J Med Genet 42:793, 1992. C,D from AE Chudley, Winnipeg, Manitoba, Canada.)

onto the forehead down to the affected eye (Fig. 30–18). Macrocephaly was present in two. Anal anomalies consisted of stenosis or anterior displacement. No syndactyly was found. Growth and development was normal. Inheritance is probably autosomal recessive.

The symptoms resemble *cryptophthalmos syndrome* and *cat eye syndrome*.

Coloboma of lens and nasal alae

In 1983, Magli et al (1) reported a monozygotic twin with either unilateral or bilateral coloboma of the lens and unilateral coloboma of the nasal alar cartilage. There was also a disorganized vitreous and a chorioretinal myopic dystrophy, but these were also present in otherwise unaffected family members. Bone age was retarded. Both had an open first sacral neural arch, but otherwise no anomalies were present and development was normal.

In differential diagnosis, coloboma of the nasal alae with pseudohypertelorism (2) and arhinia with hypertelorism and Peters anomaly (3) should be considered.

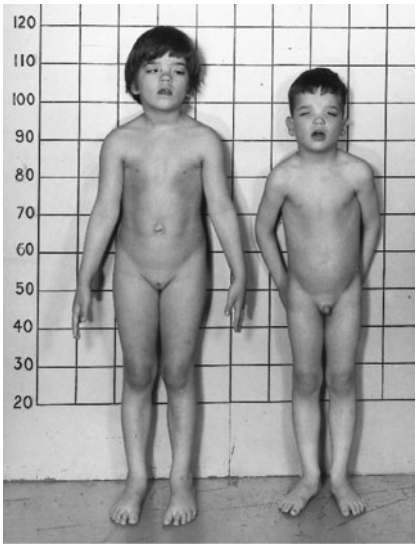
Diaphragmatic hernia-exomphalos-hypertelorism (Donnai-Barrow, FOAR, Holmes-Schepens) syndrome

Donnai and Barrow (2), in 1993, described three unrelated sets of sibs with hypertelorism, severe myopia, diaphragmatic hernia, omphalocele and/or malrotation of the bowel, and sensorineural hearing loss. Gripp et al (4) confirmed the syndrome and added two examples. Schowalter et al (10) noted that it is the same as facio-oculo-acoustico-renal (FOAR,

A



B

Fig. 30–19. *Diaphragmatic hernia-exomphalos-hypertelorism (Donnai-Barrow, FOAR, Holmes-Schepens) syndrome*. (A) Open metopic suture, frontal bossing, hypertelorism, omphalocele. (B) Sibs with severe congenital hearing loss, hypertelorism, ptosis, flat nasal bridge. [A from K Gripp et al, Am J Med Genet 68:441, 1997. B from FL Özer, Birth Defects 10(4):168, 1974.]

Holmes–Schepens) syndrome (6–10), which was confirmed by Devriendt et al (1).

The disorder appears to be autosomal recessive. The parents were normal. There were affected sibs and parental consanguinity (2,4,7,10). Mutations in the *PAX2* gene have been suggested as a possible cause (10).

Birthweight was at the 97th centile for two of the children (2). Macrocephaly has been noted repeatedly (1,2,4,5,10).

Craniofacial findings. The face exhibited wide anterior fontanel, marked hypertelorism, downslanting palpebral fissures, prominent eyes, and short nose with broad, indented lip (Figs. 30–19 and 30–20). The myopia is exceptionally severe. Bilateral inferior iris coloboma has been present (1,4,10). The ears were low and posteriorly rotated. Sensorineural hearing loss was marked (1,2,4,5,7,9,10).

Other findings. Developmental delay varied from mild to severe. On ultrasound scan, agenesis of the corpus callosum was found (2,4). Diaphragmatic hernia, exomphalos, and/or intestinal malrotation were present in almost all cases. VSD was also found (4). Proteinuria has been reported (1,4,7,10), usually without structural anomalies.

Differential diagnosis. The facies is similar to that of *DeHauwere syndrome*, but that disorder has autosomal dominant inheritance and is not associated with diaphragmatic hernia or exomphalos. Diaphragmatic hernia and omphalocele has been reported to occur together with bilateral radioulnar synostosis, hepatic cyst, unilateral absent thumb and contralateral triphalangeal thumb (3).

Gum/jaw fusion (syngnathia), colobomata, and developmental delay

Dobrow (1) reported a 6-month-old female with bony fusion of the maxillary and mandibular bones except for the incisor region, bilateral iris coloboma giving rise to microphthalmia on one side, and global developmental delay. There was in addition microcephaly, thin blond scalp hair, a small fontanel, unilateral choanal atresia, cleft palate, hypoplasia of the tongue, and pursed lips. Growth was delayed. Radiographs showed the bony fusion of mandible and maxilla, and hemivertebrae at the first, second, and third thoracic level. A brain CT scan gave normal results.

Iris coloboma, macrocephaly, agenesis of the corpus callosum, brachydactyly, and mental retardation

Temtamy et al (1) reported three sibs with colobomata of the iris, retina, and choroid, upward dislocated lenses and myopia, macrocephaly, dolichocephaly, hypertelorism, beaked nose, long philtrum, thin upper vermilion border, micrognathia, and prominent, simple ears. The published figures also show sparsely implanted curly hair, and full lower lip. The teeth were crowded and hypoplastic. In one case the closure of the fontanels was delayed. Cardiovascular examination showed moderate dilatation of the aorta and aortic regurgitation in two. One of them died at 22 years of sudden heart failure. Bulbous thumbs and brachydactyly of the second to fifth finger were present in all three. One case had talipes equinovarus, and developed contractures and hip dislocations at 10 years of age. Radiologically there were striking digital markings of the skull and complete agenesis of the callosal body. Development was mildly delayed. Parents had no anomalies and were first cousins, suggesting autosomal recessive inheritance.

The authors provide a useful differential diagnosis of entities accompanied by iris coloboma. The facial features resemble those of *trichorhinophalangeal syndrome* to some extent. The lens dislocations, aortic dilatation, and joint problems may point to a connective tissue disorder.

Reference (Iris coloboma, macrocephaly, agenesis of the corpus callosum, brachydactyly, and mental retardation)

1. Temtamy SA et al: New autosomal recessive multiple congenital anomalies/mental retardation syndrome with craniofacial dysmorphism, absent corpus callosum,iris colobomas and connective tissue dysplasia. Clin Dysmorphol 5:231–240, 1996.

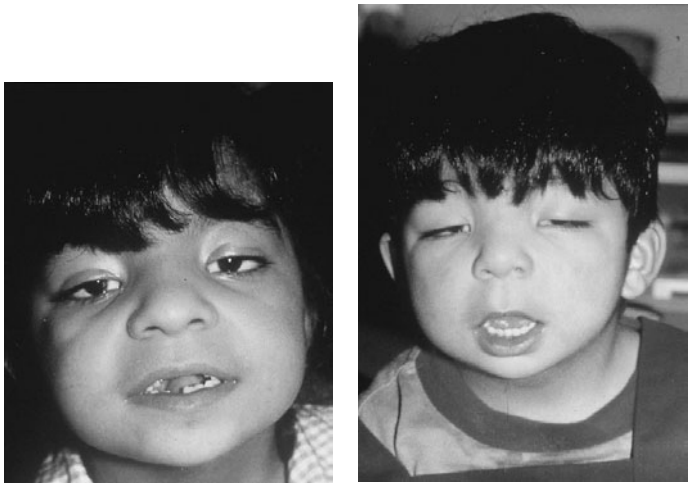
Iris coloboma, ptosis, hypertelorism, and mental retardation (Baraitser-Winter syndrome)

Baraitser and Winter (2) reported the occurrence of coloboma of the iris, ptosis, hypertelorism, broad flat nasal bridge, and growth retardation in patients with mental retardation. Seventeen other patients were described (1,3–11), although some authors were of the opinion that their cases had a similar but still different entity (4), or Noonan syndrome (3). Inheritance may be autosomal recessive (2,4), but as two cases had an apparently balanced pericentric inversion of chromosome 2 (breakpoints p12 and q14)(1,6,7), a submicroscopic deletion or duplication can not be discarded. Ramer et al (9) drew attention to the localization of the *PAX8* gene at chromosome 2q12–14.

Postnatal growth is retarded in all patients. Ramer et al (9) and Megarbane et al (4) provide useful reviews.

Craniofacial findings. Usually there is microcephaly, but normal head circumference is also described. There is trigonocephaly or metopic ridging, epicanthal folds, hypertelorism, ptosis with virtual absence of folding of the eyelids, downslanting of the palpebral fissures, broad and flat nasal bridge, short nose with a broad and sometimes upturned tip, long and hypoplastic philtrum, and thin upper vermilion border. The mouth is large, and the palate may be highly arched (Fig. 30–21). Most but not all (1,4) patients have colobomas of the iris, sometimes unilateral (2). Also chorioretinal colobomas may be present. The colobomas can cause microphthalmia and microcornea. The ears may be short and low set with overfolded helices. Several patients had sensorineural hearing loss (8,9,11). In one patient the synostosis of the metopic ridge was of sufficient severity to warrant surgery (8).

Cardiac manifestations. Ventricular septal defects (8), pulmonary stenosis (3,8), tricuspid insufficiency (11), and bicuspid aortic valve (9) are described.



A B

Fig. 30–21. *Iris coloboma, ptosis, hypertelorism, and mental retardation (Baraitser-Winter syndrome)*. (A) Seven-year-old girl with bilateral ptosis, hypertelorism, epicanthic folds, broad and flat nasal bridge. (B) Sib with similar features. (A,B from M Baraitser and RM Winter, J Med Genet 25:41, 1988.)

Central nervous system. Most patients are moderately to severely mentally retarded. Reported structural brain anomalies are lissencephaly (type I) (9), focal pachygyria (2,8), lobar holoprosencephaly (9), generalized bilateral cerebral atrophy (4), thin corpus callosum (4), and occipital and temporal ischemic lesions (8).

Other findings. Most had a short and webbed neck, with low posterior hairline. The chest has been descibed as broad (9) with pectus excavatum (3,11), short sternum (9), and hypoplastic nipples (4,9). One case had multiple hemivertebrae and apparently unilateral absent lung (9), another had an omphalocele and accessory spleen (5), and yet another, a horseshoe kidney (11). Clinodactyly of the fifth finger (8), and cryptorchidism and hypoplasia of the external genitalia were mentioned.

Differential diagnosis. A host of other syndromes combining coloboma-ptosis-hypertelorism have been reviewed by Verloes (11), but all manifest additional findings. There is superficial resemblance to *Noonan syndrome*, but we concur that the facial features in *Baraitser-Winter syndrome* are different (2).

Kaufman (oculo-cerebro-facial) syndrome

In 1971, Kaufman et al (5) documented four of seven sibs with mental retardation, microcephaly, long narrow face, and ocular and skeletal anomalies. Five other cases were reported (1–4), although the diagnosis in case B described by Figuera et al (2) seems doubtful to us. Autosomal inheritance seems likely (1).

Height is at or just below the third centile, although the original patients had normal height (5). Developmental delay is severe. In three cases, pubertal development was reported to be normal (1,5). Briscioli et al (1) provide a useful review.

Craniofacial findings. Almost all patients had microcephaly, brachycephaly, and a long and narrow face (Fig. 30–22). There are upward slanted palpebral fissures, sparse eyebrows that are laterally broadening, mild blepharophimosis, and epicanthi or telecanthi. Eye symptoms include myopia, microcornea, and pale optic discs. Several patients had nystagmus and strabismus. One case had a subluxated lens (1). The columella is especially low in part due to a hypoplasia of the alae, the tip of the nose is rounded. The philtrum is poorly defined, the vermilion border thin, but the total upper lip is protruding. The mouth is usually large, the teeth small, the palate high and narrow, and the chin small. One patient had increased dental caries (1,5); another had a single upper central incisor (2). The ears are small, and posteriorly rotated. Most cases had preauricular tags. In one case thin blond hair was noted (5).

Musculoskeletal findings. Almost all cases had a diminished muscle tone. A moderately increased kyphosis or lordosis may be present. Hands and feet are reported to be thin and long. There may be pes

Fig. 30–22. *Kaufman (oculo-cerebro-facial) syndrome*. Note microcornea and unusual nasal configuration. [From RL Kaufman et al, Birth Defects 7(1):135, 1971.]

varus (3). Radiographs have showed turricephaly and hypoplastic medial and distal phalanges (1).

Other findings. Respiratory problems in the neonatal period are very common. One case had pyloric stenosis (4), another had hypsarrhythmia (1), and yet another prolonged neonatal jaundice (5). Mitral valve prolapse (3) and enlarged clitoris (2,4) have been described.

Differential diagnosis. Heart-hand syndrome type IV, *oculodentoosseous dysplasia*, and *Hallermann-Streiff syndrome* should be considered (1).

Knobloch syndrome (myopia, retinal detachment, and encephalocele)

In 1971, Knobloch and Layer (4) reported a syndrome in four sibs characterized by high myopia, vitreoretinal degeneration which eventuated in detachment, and encephalocele. Most encephaloceles are occipital, but anterior examples have been noted (9). Several other authors have confirmed the syndrome (2,3,5,6,10).

The myopia is severe, greater than 20 diopters. Vitreous syneresis leads to retinal detachment. There is no lattice degeneration. Nystagmus, macular abnormality, early cataract formation, and young age of onset of retinal detachment (from 2–10 years of age) are seen (1).

CT scan or MRI often shows a cranial bone defect (5), most often occipital, or an extracranial nodular lesion covered by skin. Congenital occipital scalp defects with heterotopic neuronal tissue is the least expression of the encephalocele (Fig. 30–23).

Miscellaneous findings include duplicated collecting system and bifid ureter (2), mild hyperextensibility (6), scimitar syndrome (4), patent ductus arteriosus (10), single umbilical artery (10), and pyloric stenosis (10).

Inheritance is clearly autosomal recessive, there being multiple affected sibs (1–6,9,10) and parental consanguinity (5). The gene has been mapped to 21q22.3 (7). Type 18A1 collagen gene has been suggested as a possible candidate (8).

Two other autosomal recessive disorders with scalp defects and retinal dysplasia are *Walker-Warburg syndrome* and *Meckel syndrome*.

Megalocornea and mental retardation

Although at least two dozen examples of this combination have been described, there is pronounced heterogeneity which encompasses at least four syndromes. A thoughtful analysis is that of Verloes et al (17), although this has been criticized (2). Barisic et al (2) provide a useful tabulation of the total group of disorders.

Megalocornea is a congenital symmetrical nonprogressive enlargement of the cornea (13 mm or above) with normal intraocular pressure. It may be (a) an isolated finding, (b) in combination with iris hypoplasia or iridocorneal dysgenesis, probably due to abnormal migration of neural crest cells, or (c) in syndromal combination. X-linked inheritance is common in the isolated form, the gene having been mapped to Xq21–q22 (4).

At least four types of megalocornea-mental retardation syndrome can be delineated (17):

1. Neuhäuser syndrome—megalocornea, iris hypoplasia, mild telecanthus, epicanthal folds, broad nasal base, long philtrum, mental retardation,

A B

Fig. 30–24. *Megalocornea and mental retardation (Frank-ter Haar type).* (A,B) Megalocornea, frontal bossing, hypertelorism, downslanting palpebral fissures, bushy eyebrows, outstanding pinnae, short nose with anteverted nostrils, prominent lips and ears, finger contractures. (From T Billette de Villemeur et al, Eur J Pediatr 151:146, 1992.)

hypotonia, seizures, and autosomal recessive inheritance [1,2,5(Case 1), 11,13(Cases 1–3),15].

2. Frank–ter Haar syndrome—megalocornea, frontal bossing, flat occiput, hypertelorism, downslanting palpebral fissures, bushy eyebrows, short saddle nose with broad nasal tip, anteverted nostrils, large ears, prominent lips, carp-shaped mouth, gingival enlargement, micrognathia, normal intelligence, delayed closure of anterior fontanel, short extremities, camptodactyly, scoliosis, talipes, growth retardation, prominent coccyx with skin fold, and autosomal recessive inheritance (2,3,8,10,12,16) (Fig. 30–24). Some of the cases cited, however, have congenital glaucoma (12).

3. Verloes syndrome—megalocornea, mental retardation, short saddle nose, large ears, short stature, talipes, delayed closure of fontanels, hypertelorism, micrognathia, prominent coccyx with skin fold, frontal bossing, broad prominent nasal root, downslanting palpebral fissures, malar hypoplasia, long thorax, thin fingers [5(Case 2),9,17(Cases 1 and 4)].

4. Frydman form—megalocornea, mental retardation, downslanting palpebral fissures, macrocephaly, fleshy ears, obesity, long fingers, joint hypermobility, and unknown inheritance [5(Case 2),8].

Several other syndromes associated with megalocornea have to be taken into account in the differential diagnosis (14,17).

Michels syndrome (craniosynostosis and lid anomalies)

In 1978, Michels et al (5) reported four siblings with anomalies of the anterior chamber of the eye, the triad blepharophimosis, ptosis, and epicanthus inversus, clefting, craniosynostosis, and mild developmental delay. The same sibship was updated by de La Paz et al (3), and two other patients were described (2,4). Affected sibs born to unaffected parents (3,5), and consanguinity (4) suggest autosomal recessive inheritance.

Postnatal growth deficiency and in one case postnatal overgrowth occurs. A useful tabulation of the symptoms is available (4).

Craniofacial findings. Two cases were microcephalic, one had a large head (2). Craniosynostosis of the lambdoid (5) and coronal sutures (2,4) is common. The skull may be markedly asymmetrical, especially in infancy. The anterior fontanel can be large. Supraorbital ridges were found hypoplastic (2,4). Cleft lip and palate was present in three cases. As a consequence, teeth were sometimes crowded. Conductive hearing loss has been found (3,4).

Eye symptoms were increased arching of the eyebrows, hypertelorism, blepharophimosis, ptosis, epicanthus inversus, and anterior chamber anomalies: opacities of the corneal stroma, conjunctival telangiectasia, and iridocorneal adhesions (3). One patient developed glaucoma (3), another had astigmatism.

Other findings. A periumbilical depression and short fifth finger are common other findings. Rare symptoms are accessory nipple (5), small omphalocele (5), hydronephrosis (5), limited pronation-supination in the elbows (4,5), short and broad feet (4), sacral dimple (4,5), and seizures associated with fever (2).

Differential diagnosis. There are similarities with *Peters plus syndrome, Ohdo syndrome, Saethre-Chotzen syndrome*, and the family described by Paes-Alves et al (6). The condition reported by Al-Gazali et al (1) may be related.

Midline craniofacial anomalies and morning glory disc anomaly

The morning glory disc anomaly is a large scleral defect with an elevated funnel-shaped optic disc. The center of the funnel is usually filled with white glial tissue, while the disc is surrounded by a raised chorioretinal pigmentary border. Ocular, craniofacial, and renal anomalies are frequently associated. Nucci et al (11) described a girl with unilateral morning glory anomaly and a 4q12–qter duplication. Morioka et al (10) reviewed the literature.

Craniofacial anomalies. Marked hypertelorism, basal encephalocele and cleft lip/palate are the most common findings. The cleft is usually midline, separating the two nostrils (1–10,12,13), resulting in a frontonasal malformation appearance (Fig. 30–25).

The most common ocular complication is retinal detachment (35%). However, other findings include decreased visual acuity, strabismus, cataract, anterior segment dysgenesis, and persistent hyaloid remnants (Fig. 30–26A). The morning glory defect is usually unilateral (10), but bilateral defects have been documented (6,8,13).

Brain malformations include basal encephalocele, porencephaly, and agenesis of the corpus callosum (3) (Fig. 5– 26B). Pituitary dwarfism can complicate the picture (3,7).

Myopia, cataracts, saddle nose, and sensorineural hearing loss (Marshall syndrome)

Seven members in four generations of a family studied by Marshall (5), in 1958, had short stature, hypoplastic nasal bones, congenital and juvenile cataracts, myopia with vitreoretinal degeneration, and sensorineural hearing loss. Other kindreds have been reported (4,6,7,9–12,14,15). There has been considerable debate concerning the identity of this disorder with Stickler syndrome, a condition that has considerable overlap (3,8,11a,14,16). Aymé and Preus (2) suggested that they are separate conditions. Griffith et al (3) demonstrated a splicing defect at the COL11A1 locus at 1p21. This would raise the question of identity with type 2 Stickler syndrome. Shanske et al (11) have questioned the diagnosis of Griffith et al (3). COL11A1 gene is a good candidate for Marshall syndrome (13).

The disorder, occurring in several generations, is clearly dominant. However, since there have been no examples of male-to-male transmission, X-linkage cannot yet be excluded.

The facies, produced by the markedly small nose with sunken nasal bridge, anteverted nostrils, and hypoplastic or flattened midface, is striking (Fig. 30–27).

Failing vision usually occurs in the second decade of life, but in one patient of Ruppert et al (9) and in another of Marshall (5), it occurred within the first 6 months. Posterior polar cortical and subcapsular opacities that were spontaneously resorbed were noted in the second, third, and fourth decades by Ruppert et al (9). Although the mother reported by Zellweger et al (15) had cataracts since 15 years of age, her children had not yet developed cataracts at 7–11 years of age. Severe myopia (10 diopters or more) was also evident from birth, as was fluid vitreous. Retinal detachment occurred in one patient of Marshall (5) and in the father of the Ruppert et al (9) proband at 14 years of age.

In the kindred studied by Marshall (5), affected family members reported some hearing loss in childhood. This loss progressed and eventually hearing aids were required. Audiometric tests were reported as showing about 50 dB mixed or mostly sensorineural hearing loss in several members. Ruppert et al (9) found severe hearing loss as early as 9 months of age in one child; at 6 years it did not appear to be progressive. A moderate high-tone sensorineural loss was noted in the father, and there were normal vestibular findings.

Radiographic changes include hypoplastic nasal bones, hypoplastic maxilla, absent frontal sinuses, and thickening of the outer table of the skull. O'Donnell et al (7) noted intracranial calcifications, beaked or bullet-shaped vertebrae in children, markedly concave vertebral margins in adults, small irregular pelvis with delayed closure of pubic and ischial bones, coxa valga, mild bowing of radius and ulna, and somewhat irregular epiphyses of extremities.

Saddle-nose defect may be seen in congenital syphilis, *acrodysostosis, chondrodysplasia punctata, coumarin embryopathy*, and *OSMED*. Myopia may occur as an isolated finding, as an autosomal dominant or recessive trait, or as a component of numerous syndromes such as X-linked myopia and external ophthalmoplegia, *spondyloepiphyseal dysplasia congenita, Stickler syndrome*, and *Wagner syndrome*.

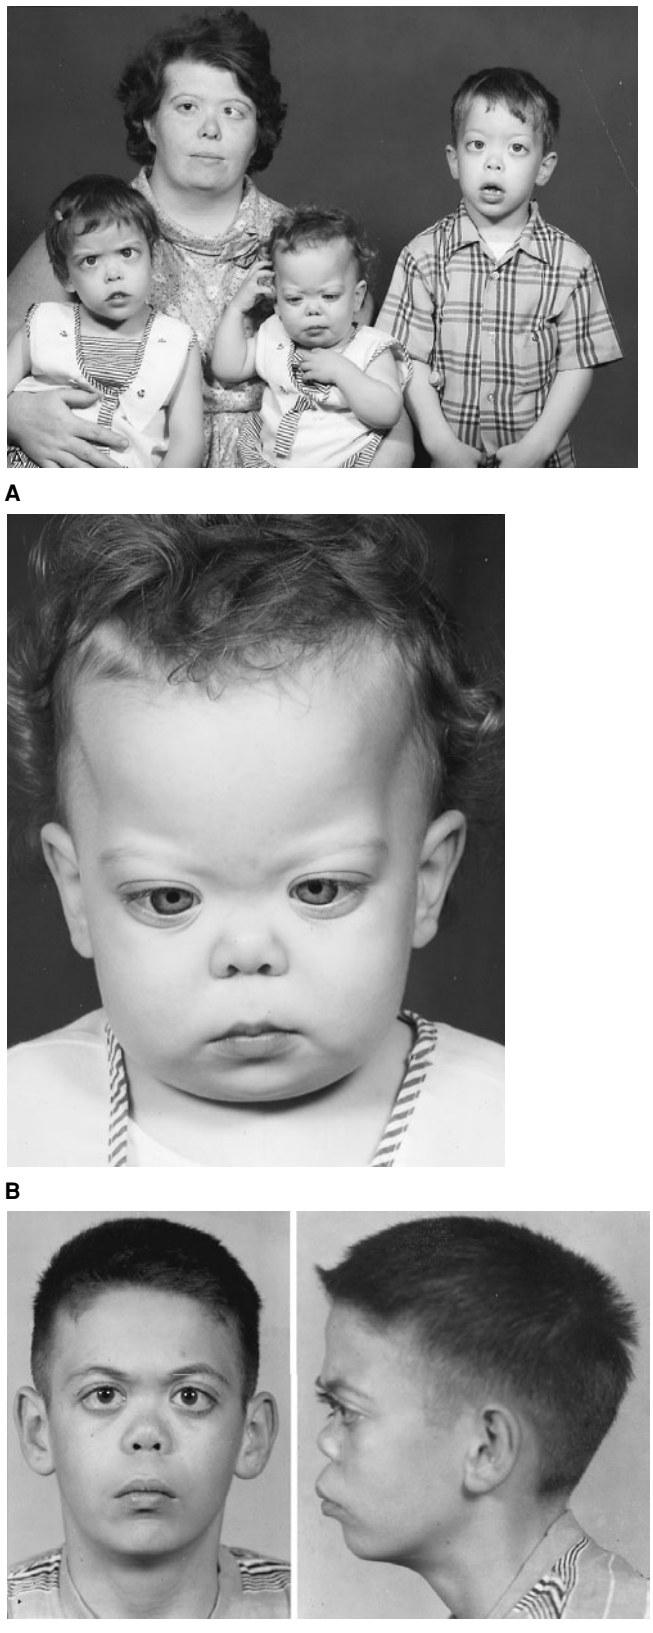

Fig. 30–27. *Myopia, cataracts, saddle nose, and sensorineural hearing loss (Marshall syndrome)*. (A) Similar facies in a mother and three of her affected children. (B) Facies of child seen in A. (C) Facies shows small nose, depressed nasal bridge, and anteverted nostrils. Note that both eyes may be seen from the side. (A,B from H Zellweger et al, J Pediatr 84:868, 1975. C from D Marshall, Am J Ophthalmol 45:143, 1958.)

Oculocerebrocutaneous syndrome (Delleman syndrome)

Delleman et al (7,8) first delineated the syndrome of orbital cysts, cerebral malformations, accessory skin tags, and focal cutaneous hypoplasia (aplasia cutis congenita). About 35 other cases have been published (1,3,4,6,9–17,19–27). All have been isolated examples. Happle (12) suggested the disorder is due to an autosomal dominant lethal somatic mutation that survives by mosaicism. The male:female ratio is 3:2. Disruption of the anterior neuroectodermal plate has been posited (19,20). We believe that this disorder has been underreported, since many examples of cystic eye represent incomplete forms. Some cases have been labeled as examples of rhabdomyomatous mesenchymal hamartomas (24).

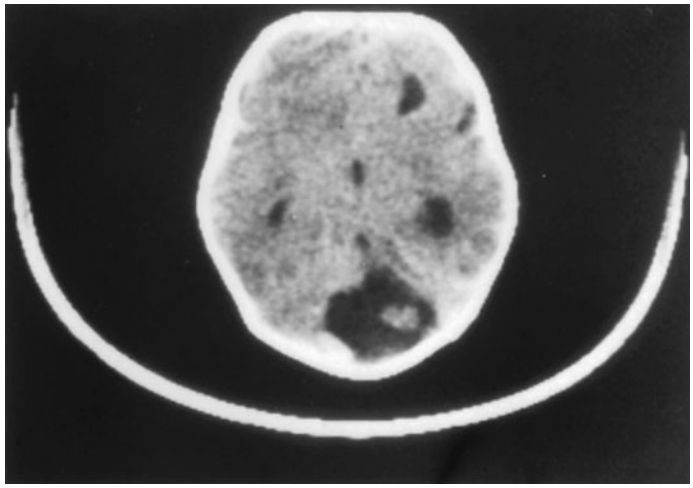
Facies. The face is asymmetric in 60%. Other findings include unilateral or bilateral orbital cysts (65% with microphthalmia), upper or lower eyelid coloboma (50%), and iris coloboma. In the contralateral eye, persistent hyaloid artery hamartomas or opacified cornea have been reported (Fig. 30–28). Cleft lip/palate has been noted in 15% (19,20).

Skeletal findings. Skeletal defects include underdeveloped orbits, zygomas, and the sphenoid part of the lateral orbital wall on the side of the involved eye (60%) as well as scoliosis and rib malformation (40%) (1,7,9,11). Some patients have exhibited body asymmetry, and several have manifested hip dislocations (1,7,11,19).

Skin. Cutaneous appendages (85%) have largely been periorbital but crescentric postauricular, malar, and even labial examples have been noted (1–4,7,8,10,16) (Fig. 30–29). Rarely, tags are present on the trunk. Focal skin lesions have been of three types: aplasia, hypoplasia, and/or punchlike defects (75%) (Fig. 30–29C). The postauricular crescent-shaped hypoplastic skin lesion is pathognomonic (20). A few patients have involvement of the trunk. Multiple trichofolliculomas have been reported (10,19).

Central nervous system. Most patients have exhibited severe psychomotor retardation (75%) and seizures (75%) , but some have been only mildly retarded. CAT scans have revealed agenesis of the corpus callosum (50%) and multiple fluid-filled spaces in the cortex (75%) (Fig. 30–30).

Fig. 30–30. *Oculocerebrocutaneous syndrome*. Fluid-filled spaces in cortex.



Occipital meningoencephalocele, hypoplasia of cerebellum (20%), Dandy–Walker malformation (10) polymicrogyria and heterotopias, and spastic tetraplegia have also been reported (1,6,7,19,27).

Differentiation for *encephalocraniocutaneous lipomatosis* must be made (13,18,19,20). We are uncertain regarding the diagnosis in the cases of Brodsky et al (5) and Angle and Hersch (2).

Peters plus (Krause-Kivlin) syndrome

The term Peters plus syndrome was first coined in 1984 by Van Schooneveld et al (43) in describing 11 patients with defects in the anterior chamber of the eye, typical face, clefting, short limb dwarfism, and developmental delay. Kivlin et al (26) later pointed out that Krause et al (28) had already described a single case in 1969, and others (20,41) mentioned the 1961 report of Haney and Falls (18) regarding two cases. Because of the mnemonic value of the term Peters plus, this is most commonly used in literature. In total almost 50 cases have been described (2,8,9,13,14,18–20,24,26,28,29,35,37,38,40–45). Other reports (17,23) might have also described the entity, but lack sufficient data for us to be sure about the diagnosis.

Table 30–1. Peters plus (Krause-Kivlin) syndrome

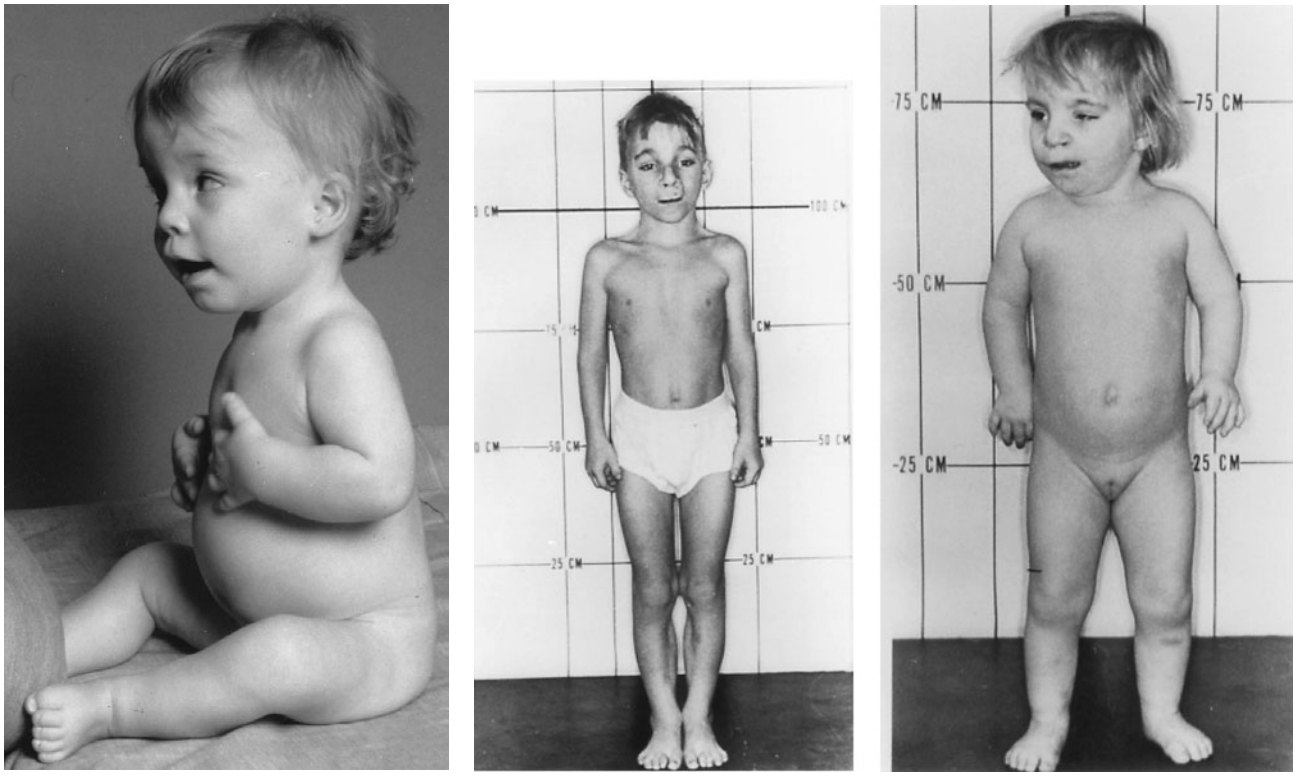
Major symptoms	Percent ($n = 49$)
Growth	
Birthweight at/below 3rd centile	87
Birth length at/below 3rd centile	63
Postnatal height below 3rd centile	92
Developmental delay	83
Eye	
Peters anomaly	73
Any anterior chamber defect	98
Any congenital eye malformation	100
Face	
Microcephaly	22
Macrocephaly	8
Prominent forehead	70
Hypertelorism	76
Narrow palpebral fissures	79
Upslanted palpebral fissures	32
Long philtrum	91
Cupid bow upper lip	98
Cleft lip/palate	45/33
Micrognathia	44
Small ears	42
Preauricular pits	37
Broad neck	73
Extremities	
Short limbs	95
Short, broad hands	100
Clinodactyly 5th finger	91
Congenital heart malformations	31
Congenital renal anomalies	19

Inheritance is clearly autosomal recessive, consanguinity being present in about one-third of the families. Hennekam et al (20) pointed out that the increased rate in miscarriages and fetal losses may well indicate that the entity causes intrauterine death in some cases. In one case a familial and probably coincidental balanced translocation between chromosome 2q21 and 15q26.1 was found (26). In another example, a mutation in the *RIEG1* gene was found (11a). The reader should also see the discussion in Differential diagnosis. Hanson et al (18a) found a point mutation in the *PAX6* gene, located at 11p13.

Extensive reviews are available (13,20,41). The major clinical symptoms are summarized in Table 30–1.

Growth and development. Most cases have prenatal growth retardation, and virtually all cases are disproportionally short postnatally. Arms and legs are equally shortened, and, although formal studies are lacking, published pictures usually show rhizomelic shortening. Adult height varies from 1.28 m to 1.51 m in females and 1.41 m and 1.55 m in males.

Mental delay is present in 83% of cases, and varies from mild (34%), to moderate (20%) and severe (26%). There is no correlation between physical findings and mental development. Specific behavioral studies have not been performed, but Young et al (45) and Hennekam et al (20) mentioned a strikingly friendly and amiable personality in several patients;



A B C

Fig. 30–31. *Peters plus (Krause-Kivlin) syndrome*. (A) Rhizomelic shortened limbs and relatively large head. (B,C) Mentally retarded brother and sister with cleft lip-palate, short stature, mild neck webbing, small hands and feet. (A from RCM Hennekam et al, Clin Dysmorphol 2:283, 1993. B,C courtesy of ID Young et al, J Med Genet 19:332, 1982.)

Thompson et al (41) reported outbursts of anger and difficult behavior in another case.

Craniofacial features. The most specific facial features are a round face in infancy, prominent forehead, hypertelorism, short palpebral fissures, long philtrum, and cupid bow shape of the upper lip with a thin vermilion border (Fig. 30–31). The latter is difficult to determine in the presence of a cleft lip, but after surgical repair the typical lip configuration becomes evident. A cleft lip is present in 45% of cases and can be accompanied by a cleft palate. Sometimes only the vermilion border is irregular, as an incomplete form of cleft lip (20). Other signs are small and mildly dysmorphic ears, preauricular pits, narrow auditory canals (26), unilateral or bilateral ptosis, mild malar hypoplasia, micrognathia, and a broad and sometimes webbed (45) neck. The lingual frenulum is frequently short. Absent (20) or abnormally pointed (41,42) lateral upper incisors, facial hirsutism (41), and prominent ears (41) have been described.

Eyes. The Peters anomaly is characterized by central corneal opacity (leukoma), thinning of the posterior cornea, and iridocorneal adhesions (33). It has formerly been called anterior chamber cleavage defect, but as early as 1969 Alkemade (1) explained that the anterior chamber does not arise by cleavage. Posterior embryotoxon (also indicated as thickening of Schwalbe's line) is the least severe expression of abnormal anterior chamber development, more severe expressions being keratoconus posterior (or keratoconus posticus circumscriptus), Axenfeld anomaly, Rieger anomaly, and iridogoniodysgenesis. In Peters plus syndrome, bilateral Peters anomaly is most often found, but it can also occur unilaterally or as another form of anterior chamber defect. Some patients do not have any anterior chamber anomaly and are recognized only because of the family history (20). In several cases, corneal opacities have gradually diminished in density in infancy (20,38,41,45). Cataract and glaucoma are common complications that can also occur at a later age. Unusual eye symptoms are severe myopia (20,41), iris coloboma (20,26), retina coloboma (2,20,45), optic atrophy (2), and microphthalmia (14,40).

Skeletal system. Short limbs and brachydactyly are invariably present. The hands and feet can be very broad, which may give considerable problems in wearing shoes. Clinodactyly of the fifth finger can be very marked. The elbows often show diminished mobility; the other joints can be hyperextensible. Pectus excavatum (18,20), broad (14) or narrow (20) thorax, hyperkyphosis (20), scoliosis (45), and pes cavus (20,45) occur, as do mild cutaneous syndactylies (8,14,20,41) and proximally placed thumbs (35). Ossification of the skull can be unusual: often the fontanel is large at birth, extending to the forehead, but within the first months rapid ossification closes the fontanels before 1 year of age (20). No genuine craniosynostosis has been reported. Cabral de Almeida et al (8) and Hennekam et al (20) mentioned prominent metopic ridges. Both microcephaly and macrocephaly can be present.

Specific radiographic findings are uncommon but can include early arthritic changes of the upper cervical (20) or lumbar (41) spine, thoracic hemivertebrae (20), multiple vertebral segmentation defects (45), square pelvis with flat iliac crests (41), and underdevelopment of the proximal radii (35). Hand and foot radiographs show general shortening of metacarpals, metatarsals, and (especially proximal and middle) phalanges. In one case, a regular bony defect of the proximal part of the first phalanx of the thumbs was found (29), and in another case there were cone-shaped epiphyses (45).

Other findings. Hearing loss (20), recurrent cystitis (13,20,26,28, 29,38,45), intractable diarrhea (20), fat malabsorption (35), seizures (2,13,20), stereotypic movements (20), and high-pitched voice or dysphonia (20,38) have been noted. Almost all cases have feeding problems in infancy. Other reported congenital anomalies have included heart defects such as atrial septal defect (13,20), ventricular septal defect (29,35,37), subvalvular aortic stenosis (14), pulmonary stenosis (8,20,29), and recurrent endocarditis (41). Genitourinary problems have included

hydronephrosis (2,13,20,38), renal or uretral duplication (2,20,35,41,45), renal hypoplasia with oligomeganephronia (29), hypospadias (13,20), incomplete foreskin (13), cryptorchidism (13,20,26,45), hypoplastic clitoris (37), hypoplastic labia majora (20,37), rudimentary vagina and uterus (38,41), ureteral orifice opening in the vagina. Anal stenosis (20), double gall bladder (41), hypoplastic adrenals at autopsy (13), soft skin (20), widely spaced nipples (8,14,35), diastasis recti (40), and umbilical and inguinal herniae (8,20,45) have been reported.

Central nervous system. Anomalies have commonly included enlarged ventricles, sometimes necessitating shunting, and mild spastic diplegia, and rarely agenesis of the corpus callosum (8), porencephaly (6), parietotemporal (13) or general (24) brain atrophy.

Differential diagnosis. The Peters anomaly is in general a sporadic, nongenetic condition (1). Genetically determined forms are usually autosomal recessive (7), but autosomal dominant forms are also known (22). The Peters anomaly has been described in several chromosome anomalies: terminal *deletion of chromosome 4p* (30), *mosaic trisomy 9* (30), deletion of 11q14 or q22 (5), *trisomy 13* (30), *terminal deletion of 18q* (15), and *ring 21* (10). Anterior chamber defects of the eye are also found in *Rieger syndrome*, *SHORT syndrome, Abruzzo-Erickson syndrome, alcohol embryopathy*, GMS syndrome, *Weill-Marchesani syndrome, Michels syndrome*, and *Walker-Warburg syndrome*. The entity has been confused with *de Lange syndrome* (20,35,44) and compared with *Robinow syndrome* (37,40,42). Jung et al (25) reported on a similar disorder, but the facial features were different, and the affected sibs had also cerebellar hypoplasia, tracheostenosis, and hypothyroidism. Moog et al (31) mentioned two sibs with anterior chamber defects, mild mental retardation, diminished growth, hydrocephaly, and intracranial calcifications. Inheritance was probably autosomal recessive. Peters anomaly with brachymesomelia, but with different facial features, no brachydactyly, bowed radii, long thumbs, and normal intelligence was published by Kivlin et al (27). Appelmans et al (3) described a case with microcephaly, growth delay, and mental retardation, but without other abnormalities, and a case with mental retardation, large anterior fontanel, and intestinal atresia. A family with three brothers with anterior chamber anomalies, mental retardation, microcephaly, growth delay, slender build, long face, multiple lentigines, and situs inversus was reported by Elmer et al (12). The father had anterior chamber anomalies and lentigines; the mother was mentally retarded. Two sibs were described with anterior chamber anomalies, corneal dermoids, and growth delay (16). Ruprecht and Majewski (36) reported on two sisters with Peters anomaly and arhinia, and Tabuchi et al (39) three sibs with Peters anomaly and cardiac malformations including Fallot's tetralogy. Alkemade (1) and Heon et al (21) described large series of patients with Peters anomaly, of whom several had solitary other symptoms, and Kivlin et al (26) and Holmstrom et al (22) reviewed the literature for symptoms additional to anterior chamber anomalies. Natarajan et al (32) published a case with facial features similar to Peters plus syndrome, but the boy had cataract and no short limbs or brachydactyly.

Phillips-Griffiths (macular coloboma, cleft palate, and abnormal finger mobility) syndrome

In 1969 Phillips and Griffiths (1) described a brother and sister with both bilateral macular coloboma, nystagmus, hypermetropia, cleft palate, diminished mobility in the fifth fingers, and bilateral hallux valgus. The girl was mentally retarded, had small canines and upper lateral incisors, delayed sexual maturation, bilateral genua valga and coxa valga, and recurrent patella dislocation. The boy had a sloping forehead, platybasia, hyperextensibility of the second and third finger, and irregularly implanted toes.

There is some resemblance with Sorsby syndrome, in which macular coloboma is found together with brachydactyly type B, and in some unilateral renal agenesis, uterine anomalies, and hearing loss (3), and the case described by Smith et al (2) with macular coloboma and short limbed dwarfism (Fig. 30–32).

Uncombable hair, retinal pigmentary disorder, oligodontia, and brachydactyly

Bork et al (1), in 1987, described hypotrichosis with uncombable properties, retinal pigmentary disorder, juvenile cataract, oligodontia, and brachydactyly with brachymetacarpalia. An additional patient was reported by Silengo et al (2) (Fig. 30–33).

Inheritance is autosomal dominant.

Uncombable hair may be seen in *tricho-dento-osseous syndrome, Rapp-Hodgkin (Hay-Wells) syndrome, EEC syndrome*, and in unusual facies, uncombable hair, mental retardation, postaxial polydactyly, phalangeal hypoplasia, and 2–3 toe syndactyly.

Wagner syndrome (hyaloideoretinal degeneration)

Wagner syndrome, an autosomal dominant hyaloideoretinal degeneration, was described in a Swiss family by Wagner (6) in 1938. Additional affected members were subsequently observed by several other authors (1,4). Other kindreds have been noted (3).

Empty vitreous with avascular strands is a constant feature. Chorioretinal atrophy and cataract are common features in those over 45 years. Peripheral retinal detachment and glaucoma were found in about 50% and 20%, respectively, in that group. Over 65% manifested elevation of rod and cone thresholds.

Inheritance is autosomal dominant with mapping to 5q13–q14 by Brown et al (2) in 1995. Fryer et al (3), in 1990, excluded a type 2 collagen defect, but a report by Korkko et al (5), in 1993, described a kindred with a type 2 collagen defect. Apparently there is genetic heterogeneity.

Weill-Marchesani (spherophakia-brachymorphism) syndrome

In 1932, Weill (23) described a patient with dislocated lenses, short stature, brachydactyly, and stiff joints, within a group of patients with Marfan syndrome. Marchesani (11), in 1939, recognized this to be a separate entity. About 125 cases have been described. Some families may in fact have autosomal dominant ectopia lentis in a generally short-statured family (12–14). The entity is especially frequent among the Amish (14).

Pattern of inheritance is unclear. In one of the original family of Marchesani (11) affected sibs born to unaffected, consanguineous parents pointed to autosomal recessive inheritance. Other similar families were reported (1,2,9,10,15,19,21,28). In several families it was noted that one or both parents had short stature with or without brachydactyly, suggesting mild heterozygote expression (2,8,15,17,18,24,28). On the other hand, families with clearly autosomal dominant inheritance have been published (5,7,8,16,22,25,27). Verloes et al (22) suggested that the latter entity be named glaucoma, ectopia, microspherophakia, stiff joints, short stature (GEMSS) syndrome. In the family originally described by Gorlin et al (7), possible linkage to chromosome 15q21.1, the localization of fibrillin-1 and microfibrillin-associated protein-1, was reported (25). Decreased fibrillin staining was found in the dermal-epidermal junctions and capillary dermis at immunohistochemical studies. Linkage to fibrillin-2 was excluded (25). Chromosome studies yielded normal results (14a). However, Mégarbané et al (14a) excluded 15q21.1 as the site for the autosomal recessive form.

Mental development is normal, although not in all cases (2,19,21).

Eye. There is congenital microspherophakia, that is, reduced horizontal and sagittal diameters of the lens giving it a spheric appearance. Severe myopia (5–20 diopters) is universally present. The anterior chamber is reduced. Glaucoma is a frequent complication in late childhood (4,6,8,24). In the absence of lens dislocation, the glaucoma is due to obstruction of the aqueous flow through the pupil (24). The lens dislocates usually forward or downward, either unilaterally or bilaterally, before the age of 10. Secondary features may be nystagmus, megalocornea, strands in the anterior chamber, fraying of the iris root, abnormal angle vessels, cataract, ablatio retina, and rupture of the globe (2,5,8,11,19,22,25,27,28). Microscopic studies of the lens are available (5).

Skeletal system. Proportionate short stature is the rule, varying in adults from 130 cm to 157 cm in females and 142 cm to 169 cm in males (6,7,11,22,23,25,27) (Fig. 30–34A,B). Hands are broad (2,4,6,19,28). Joint stiffness is especially prominent in the hands, but can be present in the shoulders (4,18,22,27), elbows (6,7,19,22,25,27), knees (4,27) (Fig. 30–34C), and ankles (4,27). Many patients have muscular build (2,11,19,28), as can be seen in hypochondroplasia. Scoliosis (6,22) and increased lumbar lordosis (4) occur. Adults with carpal tunnel syndrome have been reported (10,14,25). Radiological changes have included short and relatively wide phalanges, metacarpals and metatarsals, widening of other long bones (4), mild beaking of distal radii (27), wide ribs (4), thin cortex (4), and narrow spinal canal (4). A rare feature may be osteoporosis (6).

Other findings. The face may show brachycephaly, roundness, shallow orbits, narrow palpebral fissures, and maxillary hypoplasia. The palate may be highly arched and narrow. Ferrier et al (4) reported a patient with subvalvular fibromuscular aortic stenosis, another had mitral valve insufficiency (22), and two had pulmonic stenosis (19,28), but usually cardiac investigations have yielded normal results (2). The skin can be thick (2,22,25) and show stretch marks (22,27).

Differential diagnosis. The condition has to be differentiated from isolated autosomal dominant lens dislocation, *Marfan syndrome*, and Moore-Federman syndrome (22). The patients described by Feinberg (3) probably had *Gorlin-Chaudhry-Moss syndrome*.

Fronto-ocular syndrome

Schneider et al (1), in 2000, described an autosomal dominant disorder characterized by trigonocephaly due to coronal and metopic synostosis, ocular hypotelorism, proptosis and ptosis, epicanthic folds, hypoplastic supraorbital ridges, elevated nasal bridge, thin philtrum, and narrow bifrontal region (Fig. 30–35). Other possible components include glabellar capillary hemangiomas, congenital heart anomalies (pulmonary stenosis, atrial septal defect), and mild developmental disabilities.

Trigonocephaly may be an isolated finding or be part of other syndromes such as *holoprosencephaly, Frydman trigonocephaly syndrome, Opitz trigonocephaly syndrome* (*C syndrome*), and *Say-Meyer trigonocephaly syndrome*, but has been seen in *valproate embryopathy* and various chromosomal abnormalities [*del(9p)*, *del(11q)*, *del(13q)*, and *dup(13q)*].

Appendix

Documentation of dysmorphic features is an essential part of clinical evaluation. Although some features can only be visualized, others require quantification to decide whether the feature in question deviates from the norm and, if so, by how much. Objective measurements often belie subjective clinical impression. For example, the patient with Down syndrome is sometimes described as having a highly arched palate. However, metric studies show that palatal height is normal, but palatal length is dramatically shorter than normal. Some features such as epicanthic folds cannot be precisely measured, but can be graded as being mild, moderate, or severe. Other features such as Brushfield spots are of the presence-absence type. Because some dysmorphic features defy measurement and even convincing verbal description, photographic documentation is very important in syndromology; phenotypic features may change with time. In some conditions, such as the de Lange syndrome, the phenotypic features, especially of the face, are usually constant enough at any age to impart the correct diagnostic impression, and the striking resemblance of affected individuals transcends the racial background of the patient. Occasionally, mild expression may render clinical diagnosis difficult, especially at birth. In some instances, for example, the characteristic phenotype of the de Lange syndrome may evolve with time. In other conditions, such as del(5p) syndrome, the phenotypic features tend to become less distinct with time (3).

This appendix provides a number of measurements of use in evaluating the face and cranium. The more practical and efficient but less accurate measures are most commonly used. Soft-tissue measurements take precedence over radiographic ones and the use of simple rather than sophisticated techniques is the rule. In this appendix, anthropometric measurements of the face and cranium are provided, but in addition there are a large number of radiographic and cephalometric standards. In some instances, several standards for the same measurement are provided. For example, inner and outer canthal distances suffice for clinical measurement of hypertelorism. However, when craniofacial surgery is contemplated, radiographic standards for interorbital distance are mandatory. An excellent study of bony interorbital distance has been provided by Costaras et al (5,6) and is highly recommended; their standards are not found here because their use of PA cephalometric landmarks and the indices they derive are too complex to present in this appendix. Finally, the canthal index is useful for evaluating possible hypertelorism in relatives of a proband who are not available for study but whose photographs are available.

The best general groups of growth references for dysmorphic conditions are found in the atlases of Saul et al (14) and Hall et al (8a). The reader is referred to the following references for special coverage: facial anthropometry (7), craniofacial anthropometric measurements in the newborn (27–41 gestational weeks) (1,9–11), anthropometric measurements of various syndromes and genetic conditions (8,8a,14–16), cephalometric atlases (2,12,13), cephalometric studies of syndromes and genetic conditions (4), and limitations of published metric studies for clinical use (3). Contents of the Appendix are listed on page 1216.

Cranial measurements

Fig. A–1. Anterior fontanel size. Percentiles from term to age of 24 months for both sexes. Inset, measurement of oblique diameter. (From G Duc and RH Largo, Pediatrics, 78:904, 1986.)

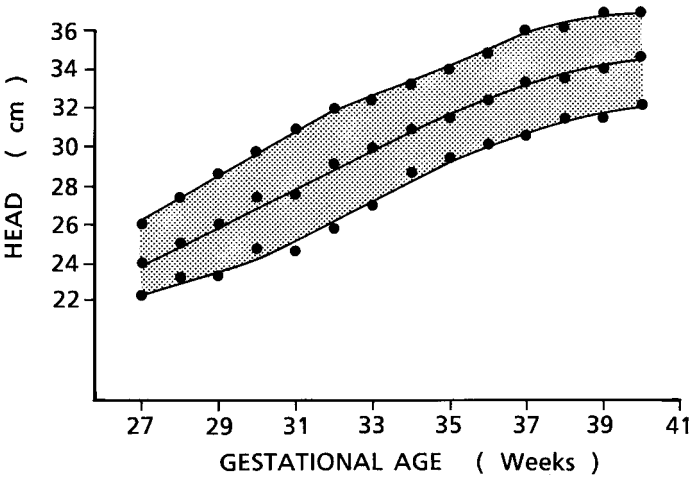

Fig. A–2. Head circumference from 27 to 41 gestational weeks. [From P Merlob et al, Birth Defects 20(7):1, 1984.]

Table A–1. Fontanel and suture closure

Closure	Time
Anterior fontanel	1 year ± 4 months
Posterior fontanel	Birth ± 2 months
Anterolateral fontanel	By third month
Posterolateral fontanel	During second year
Metopic suture	By third year (10 %, never)
Clinical closure of sutures	6–12 months
Anatomic closure of sutures	By thirtieth year

(From RJ Gorlin and JJ Pindborg, Syndromes of the Head and Neck, 1st ed, McGraw-Hill, New York, 1964.)

Table A–2. Detailed suture closure

Cranial suture	Closure begins (years)	Facial suture	Closure begins (years)
Interfrontal (metopic)[a]	2	Intermaxillary	
Interparietal (midsagittal)	22	(midpalatal)	30–35
Frontoparietal (coronal)	24	Frontomaxillary	68–71
Occipitoparietal (lambdoidal)	26	Frontonasal	68
Masto-occipital	26–30	Frontozygomatic	72
Sphenotemporal	28–32	Zygomaticotemporal	70–71
Temporoparietal (squamosal)	35–39	Zygomaticomaxillary	70–72
Sphenoparietal	29	Nasomaxillary	68
Sphenofrontal	22		

[a] Usually obliterated by third year; persists throughout life in 10%.

(From VC Kokich, The biology of sutures. In: Craniosynostosis: Diagnosis, Evaluation, and Management, MM Cohen Jr (ed), Raven Press, New York, 1986, p 94.)

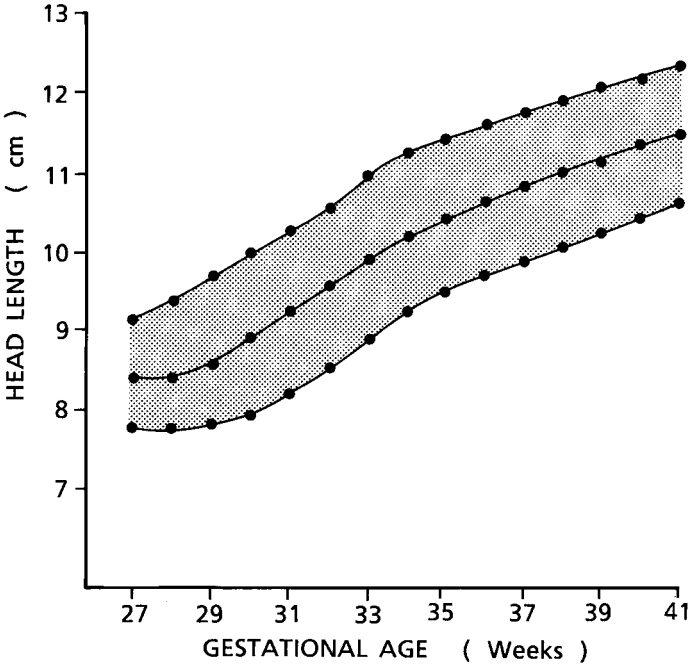

Fig. A–3. Head length from 27 to 41 gestational weeks. [From P Merlob et al, Birth Defects 20(7):1, 1984.]

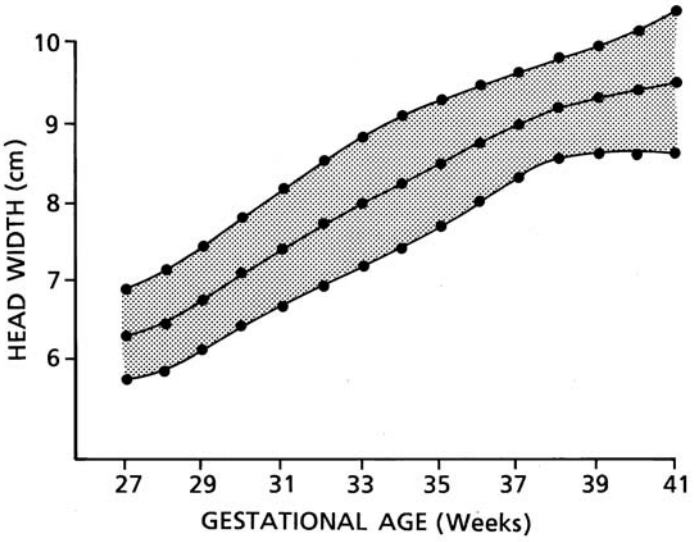

Fig. A–4. Head width from 37 to 41 gestational weeks. [From P Merlob et al, Birth Defects 20(7):1, 1984.]

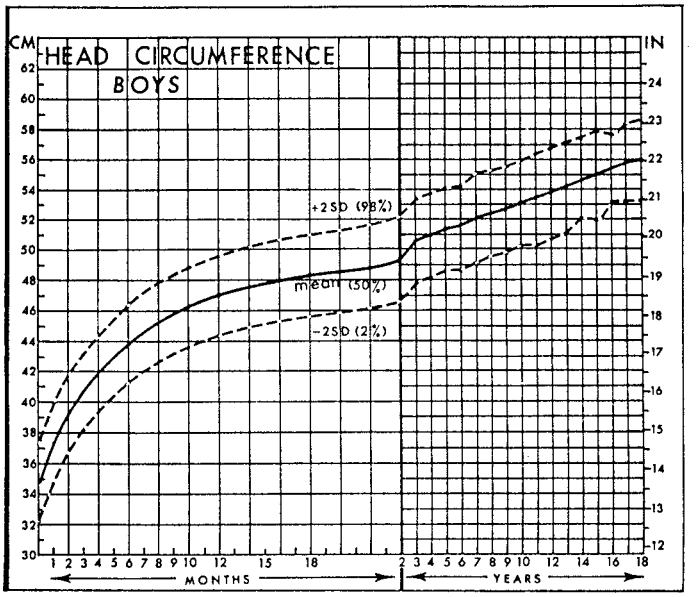

Fig. A–5. Head circumference to 18 years (males). (From G Nelhaus, Pediatrics 41:106, 1968.)

Teeth, primary (6,18)	17.0
Maxillary canines, secondary (6)	0.9
Natal teeth (2)	0.03–0.05
Pegged	
Primary teeth (26)	0.2
Secondary maxillary lateral incisors	
White (27)	1.0–2.0
Japanese (30)	6.2
Shovel-shaped incisors	
Amerindian, Inuit, Oriental (15)	60–75
Supernumerary teeth	
Primary dentition (9,16,19,22)	0.3–0.8
Secondary dentition	
White (4,5,16,28)	1.0–3.5
Japanese (21)	2.2–5.3
Maxillary incisors, secondary (2,3)	0.3–0.5
Fourth molars, secondary (28)	0.2

Table A–12. Nondental anomalies and their frequencies

Anomaly	Frequency in ostensibly normal population, approximate percentage
Cheek biting (39)	2
Cleft	
Lip–palate	
White (12,14)	0.06–0.15
Afro-American (3,4,10,24)	0.04
Japanese (20,33)	0.17
Amerindian (33,45)	0.3
Palate, isolated	
White (10,12)	0.04–0.05
Oriental (33)	0.06–0.07
Afro-American (3,4)	0.02–0.04
Uvula	
Amerindian (8,41)	10–20
Inuit (16)	3–6
Japanese (16)	1–2
White (30,44)	1–2
Afro-American (36,38)	0.25–0.50
Cysts, eruption (12)	0.2
Fordyce granules (sebaceous glands)	
Lips	
White (15,25,40)	50–80
Buccal mucosa	
White (15,25,40)	60–95
Afro-American (29)	55
Lip pits	
Paramedian (46)	1:200,000
Commissural	
Afro-American (5,38)	20
Caucasian (5)	12
Oriental (5)	6
Amerindian (8)	9
Inuit (19)	8
Tongue	
Ability to touch nose with (personal observation)	7–10
Ankyloglossia (7,28,48)	1:300 to 1 per 2000
Fissured	
5–18 years (9,35)	
Overall (1,15,48)	2–5
Folding of tip	
Within mouth	1–2
Outside mouth (47)	1 per 600
Geographic	
White (9,15)	1.0–2.5
Median rhomboid “glossitis”	
Caucasian (15,48)	0.2–0.3
Inuit (19)	0.6
Rolling or tubing	
White (13,42)	60–75
Afro-American (23)	80
Japanese (22)	25–30
Thyroid gland inclusion	
Microscopic evidence (6,37)	10
Clinical evidence (6)	1 per 10,000
Torus mandibularis	
White and Afro-American (17,21,43)	3–16
Inuit (17,18,19,26,27)	10–80
Oriental (38)	20–30
Torus palatinus	
White and Afro-American (21,31,38,43)	20(F-2, M-15)
American and Inuit (17,19,32)	25–75
Oriental (2,38)	40–90
