enzyme that requires potassium to achieve maximum activity, has 50 times greater affinity for thallous ions than potassium ions.[42] Succinate dehydrogenase, an essential enzyme in the Krebs cycle, is inhibited by small doses of thallium in rats.[31] Sodium-potassium adenosine triphosphatase (ATPase), which is responsible for active transport of monovalent ions across cell membranes, can use thallous ions at extremely low concentrations because of an affinity that is 10-fold greater than that of potassium ions,[8,26] but is inhibited by thallium at higher concentrations.[39] Thallium also impairs depolarization of muscle fibers.[62] Mitochondrial energy is decreased as a result of the inhibition of pyruvate kinase and succinate dehydrogenase, resulting in a decrease of adenosine triphosphate (ATP) generation via oxidative phosphorylation. Enzymatic destruction results in swelling and vacuolization of the mitochondria after exposure to thallium.[87] At low levels, thallium can activate other potassium-dependent enzymes such as phosphatase, homoserine dehydrogenase, vitamin B_{12} -dependent diol dehydrogenase, L-threonine dehydrogenase, and adenosine monophosphate (AMP) deaminase.[62] The net result of these processes is a failure of energy production.

Thallous ions have been used to isolate riboflavin from milk in the form of a reversible precipitate. Thallous ions may also form insoluble complexes and cause intracellular sequestration of riboflavin in vivo.[10] Riboflavin is the vitamin precursor of the flavin coenzyme FAD (flavin adenine dinucleotide). Because of a decrease in riboflavin, metabolic reactions dependent on flavoproteins will decrease, causing disruption of the electron transport chain and a subsequent further decrease or impairment in the generation of cellular energy.[10] This decrease in cellular energy may lead to a decrease in mitotic activity and cessation of hair follicle formation resulting in the clinical sign of alopecia. Subsequent hair loss is the result of combined arrested formation and local destruction of hair shaft cells in the hair bulb.[10,76]

Unfortunately, riboflavin supplementation was not beneficial in one animal model of thallium poisoning.[4] Data also demonstrate that the dermatologic, neurologic, and cardiovascular effects of thallium toxicity mirror the side effects of thiamine deficiency (beriberi), highlighting the inhibitory effect of thallium on glycolytic enzymes.[10, 62] It is unclear whether thiamine administration has any beneficial effect in patients with thallium poisoning.

Thallium has a high affinity for the sulfhydryl groups present in many other enzymes and other proteins. Keratin, a structural protein, consists of many cysteine residues that cross-link and form disulfide bonds. These disulfide bonds add strength to keratin. Thallium interferes with the formation of disulfide bonds, which may lead to the development of alopecia and defects in nail growth resulting in Mees lines.[28, 62, 68, 81, 82] Additionally, the complexation of sulfhydryl groups with thallium results in a decrease in glutathione production secondary to a decrease in cysteine. This results in the accumulation of lipid peroxides in the brain, which is most prominent in the cerebellum, and appears as dark, pigmented, lipofuscinlike areas.[30] The complexity and presumable multifactorial nature of thallium poisoning are again highlighted by the inability of *N* -acetylcysteineâ€“induced augmentation of glutathione stores to protect against toxicity in an animal model.[4]

Thallium also adversely affects protein synthesis in animals by damaging ribosomes, particularly the 60S subunit.[37] Although ribosomes are primarily dependent on potassium and magnesium, thallium will be used if present. In an experimental model, low concentrations of thallium are protective against hypokalemia-induced ribosomal inactivation. As thallium concentrations increase, the protective effects diminish, resulting in progressive destabilization and destruction of the ribosomes. Ribosomal destruction can also be produced with exposure to potassium concentrations of 4.5â€“20 times higher than the thallium

concentrations necessary to achieve the same effect.[37]

Pathologic studies of the central nervous system in patients with thallium poisoning reveal localized areas of edema found in the cerebral hemispheres and brainstem. Chromatolytic changes are prominent in neurons of the motor cortex, third-nerve nuclei, substantia nigra, and pyramidal cells of the globus pallidus. In chronic exposures, there are signs of edema of the pial and arachnoidal membranes, and changes in the ganglion cells of the ventral and dorsal horns of the spinal cord, consisting of chromatolysis, swelling, and fatty degeneration.[5 , 76]

The peripheral nervous system, which is usually clinically affected before the central nervous system, develops a diffuse axonopathy in a classic dying back or Wallerian degeneration pattern.[5 , 6 , 15 , 21 , 58] Fragmentation and degeneration of associated myelin sheaths are accompanied by activation of Schwann cells.[5 , 10 , 11] Because thallium affects the longer peripheral fibersâ€”first sensory, then motor, and finally the shorter fibersâ€”toxic effects occur initially in the lower extremities.[49 , 67 , 101]

Clinical Manifestations

Many of the effects of thallium poisoning are somewhat nonspecific and occur over a variable time course.[47] When combined, however, a clear toxidrome can be defined (Table 96-1). Alopecia and painful ascending peripheral neuropathy are the most characteristic findings.[6 , 24 , 60 , 67] Because of the delayed development of alopecia, the diagnosis of thallotoxicosis is often delayed. In fact, with acute exposures, a dose-dependent latent period of hours to days may precede initial symptoms.[47 , 62] When death occurs, it is usually the result of coma with loss of airway-protective reflexes, respiratory paralysis, and cardiac arrest.

Unlike most other metal salt poisonings, gastrointestinal symptoms are usually modest or even absent in thallium toxicity.[13] The most

common symptom is abdominal pain, which may be accompanied by vomiting and either diarrhea or constipation.[19, 44, 47, 59, 81, 98, 99] Constipation may be a result of decreased intestinal motility and peristalsis caused by direct involvement of the vagus nerve.[13, 62] Rarely, severe symptoms, such as hematemesis, bloody diarrhea, or ulceration of the mucosal lining, occur.

Pleuritic chest pain was described in a small series of poisoned patients.[56] Another patient was reported to have developed â€œchest tightnessâ€• shortly after drinking thallium-poisoned tea.[60] There is no known etiology for this finding, although it may relate to involvement of the vagus nerve.

Tachycardia and hypertension frequently occur in patients with thallotoxicosis and usually develop during the first or second week following an acute ingestion. A poor prognosis may be associated with a persistent and pronounced tachycardia. No exact mechanism has been determined for these cardiovascular effects of thallium toxicity. Some authors theorize that they result from autonomic neuropathic dysfunction directly related to involvement of the vagus nerve,[67] but others have noted early electrocardiographic changes, such as prolongation of the QTc interval, T-wave flattening or inversion, and nonspecific ST-segment abnormalities, which might suggest direct myocardial damage.[6, 11, 59, 62, 78] Another theory suggests that thallium's stimulation of ATPase in the chromaffin cells can lead to increased output of catecholamines, resulting in sinus tachycardia.[3, 60]

Neurologic symptoms usually appear 2â€“5 days postexposure. Patients may develop severely painful, rapidly progressive, ascending peripheral neuropathies.[5, 6, 21, 56] Pain and paresthesias are present in lower extremities (especially the soles of the feet), and although numbness is present in fingers and toes, there is also decreased sensation to pinprick, touch, temperature, vibration, and proprioception.[6, 83] The weight of the bedsheets on the lower extremities may be sufficient to cause excruciating

pain.[56 , 58] Motor weakness is always distal in distribution, with the lower limbs more affected than the upper limbs.[11 , 62]

Symptoms of confusion, delirium, psychosis, hallucinations, seizures, headache, insomnia, anxiety, tremor, ataxia, and choreoathetosis are common. Onset is variable, and most likely dependent on dose. Ataxia can develop within 48 hours after ingestion. Insomnia occurs in almost every patient and may progress to total reversal of sleep rhythm. Coma may occur, especially with larger exposures.[11 , 47 , 62 , 81] All cranial nerves can probably be affected by thallium, although abnormalities of cranial nerves I, V, and VIII have

not been reported. Cranial nerve III involvement, as evidenced by ptosis, is common, and may be present asymmetrically.[11] Nystagmus, another common finding, demonstrates involvement of cranial nerves IV and VI.[11] Cognitive abnormalities may persist for months after exposure.[53]

Organ System	Onset of Effects			Residual Effects
	Immediate (<6 h)	Intermediate (Rarely in the first few days; within 2 wk)	Late (>2 wk)	

TABLE 96-1. Clinical Manifestations of Acute Thallium Poisoning

Thallium is toxic to both the retinal fibers and the neural retina.[84] In cases of a large, single ingestion of thallium, approximately 25% of patients may develop severe lesions of the optic nerve.[62, 81] Optic neuropathy can lead to optic atrophy and a permanent decrease in visual acuity. In early stages, the optic disk shows signs of neuritis, which is red and poorly defined, and later develops pallor from resultant optic nerve atrophy. In patients exposed to multiple small doses, nearly 100% suffer optic nerve injury.[59] Visual complaints may be delayed in comparison to other neurologic findings,[84] and can include decreased acuity and central scotomata. Other described ophthalmic effects are noninflammatory keratitis, cataracts, and the color vision defect of tritanomaly (blue color defect).[90, 91]

Renal function may remain normal in mild cases of thallium poisoning, even though the kidney bioaccumulates thallium more than any other organ. Changes in renal function in patients with severe thallotoxicosis include oliguria, diminished creatinine clearance, elevated blood urea nitrogen, and albuminuria.[3, 56, 59, 62] These findings correlate with morphologic studies in thallium-poisoned rats, demonstrating abnormalities in the renal medulla, mainly in the thick ascending limb of the loop of Henle, that occur by the 2nd day after exposure and resolve by the 10th

day.[3]

Alopecia is the most common and classic manifestation of thallium toxicity.[60 , 94] Typically occurring as the presenting symptom in patients with chronic exposures following an acute exposure, epilation begins in approximately 10 days and total hair loss usually occurs within a month.[24 , 60 , 65] Facial and axillary hair, especially the inner one-third of the eyebrows, may be spared, but in some cases, full beards, as well as all scalp hair, are lost.[76] Microscopic studies show thallium deposition as dark brown or black pigmentation located in the roots of hair samples. (See ILTHALLIUM in the Image Library at http://www.goldfrankstoxicology.com) These deposits can be found within 3â€“5 days of initial exposure.[9 , 59] In patients with chronic exposures, several bands may be noted on the hair shaft, demonstrating multiple exposures. Initial hair regrowth is very fine and unpigmented, but usually returns to normal following mild exposure.[59] In patients with severe exposures, alopecia may be permanent. Dermatologic effects that have been observed include acne, palmar erythema, and dry scaly skin that results from damage to the

sebaceous glands.[94] Mees lines appear within 2â€“4 weeks after exposure.[60 , 68 , 81] (See ILMEESLINES in the Image Library.)

Other less common findings include hepatotoxicity,[38] hypochloremic metabolic acidosis,[81] and anemia and thrombocytopenia.[48 , 81]

Teratogenicity

In animal models, thallium is teratogenic.[27 , 29] One study evaluated 297 children born in a region in which thallium levels were higher than normal because of industrial contamination.[20] Urine thallium levels in the exposed children were as high as 76.5 Âµg/L. Although these children had a slightly higher than expected

incidence of congenital abnormalities, no causal relationship could be established with regard to thallium exposure.[20]

There are few human reports of acute thallium poisoning during pregnancy. A comprehensive literature review demonstrated 25 cases, which included acute and chronic exposures that occurred during all trimesters.[34] Thallium slowly crosses the placenta and is able to cause characteristic fetal toxicity,[22,66] which manifests initially as decreased fetal movement, possibly as a consequence of fetal paralysis. The classic clinical signs and symptoms of thallium poisoning have been described in the neonate following delivery and the fetus following abortion.[22,59,66,74] However, outcome of the pregnancy may be normal despite significant maternal toxicity.[22,40] The only consistent finding is a trend toward prematurity and low birth weight, especially in those children exposed during the first trimester.[34] One author recommends continuing the pregnancy as long as the mother is clinically improving.[22] It is reasonable to conclude that a fetus exposed to thallium during organogenesis has the potential for permanent injury. Those exposed later in the pregnancy may recover without deficit if their exposures are limited and the mother recovers. If the exposure occurs closer to term, the child may be born with overt toxicity such as alopecia, dermatitis, nail growth disturbances, and permanent central nervous system lesions.[59]

These few case reports and animal studies provide confusing and sometimes contradictory results. It seems that fetal outcome is determined both by the stage of pregnancy and the extent of maternal toxicity. However, because there are insufficient data to predict the outcome of pregnancy complicated by maternal thallium poisoning, no specific course of action can be recommended other than extensive fetal monitoring and aggressive treatment for the mother. If a viable child is delivered, it is important to note that thallium is eliminated in breast milk, such that nursing provides ongoing exposure.[34]

Assessment

Most patients with acute thallium toxicity seek healthcare soon after exposure because of alterations in their gastrointestinal, cardiovascular, and neurologic function. Establishing the correct diagnosis at this early stage is essential to assure a satisfactory outcome. Unfortunately, many patients with either smaller acute exposures or chronic thallium poisoning first present days to weeks after their initial exposure, and diagnosis is often further delayed. In these instances, obtaining valuable aspects of the exposure history may be difficult. Gastrointestinal symptoms may not have occurred, or their consequence or etiology may have gone unrecognized because of their nonspecific, mild, and transient nature. Many patients with small acute or chronic exposures usually seek care because of alopecia or neuropathy.

The differential diagnosis of the neuropathy includes disorders such as poisoning by arsenic, colchicine, and vinca alkaloids; botulism; thiamine deficiency; and Guillain-BarrÃ© syndrome. Both the sensory neuropathy and the preservation of reflexes help differentiate thallium-induced neuropathy from Guillain-BarrÃ© syndrome and most other causes of acute neuropathy.[11] When gastrointestinal symptoms are present along with neuropathy and other end-organ effects, poisoning with metal salts such as arsenic and mercury should be considered (Chaps. 85 and 92). The differential diagnosis of abrupt and complete alopecia is more restricted and includes arsenic, selenium, colchicine, and vinca alkaloid poisoning (Chap. 29). When present, Mees lines indicate past exposure to metals, mitotic inhibitors, or antimetabolites, and as such are nonspecific for thallium (Chaps. 29 , 85 , and 92).

Diagnostic Testing

Radiographs of tampered food products[56] and the abdomen[28] can document the presence of a heavy metal such as thallium, which is

radiopaque. Although abdominal radiography may be useful shortly after a suspected exposure, the sensitivity and specificity of this test is unknown. Similarly, the yield from other routine studies, such as the complete blood count, electrolytes, urinalysis, and ECG, is limited in that these other studies are often normal, or, at most, merely demonstrate nonspecific abnormalities.

Microscopic inspection of the hair reveals a diagnostic pattern of black pigmentation of the hair roots of the scalp in approximately 95% of poisoned patients.[9, 60, 81, 94] However, for the inexperienced observer, this test is likely to be inconclusive.

The definitive clinical diagnosis of thallium poisoning can only be established by demonstrating elevated thallium concentrations in various body fluids or organs. Thallium can be recovered in the hair, nails, feces, saliva, CSF, blood, and urine, and standard assays and normal values for most of these sources can be found.[62] Urine spot tests notoriously give false-negative results and require the use of dangerous chemicals that are not routinely available (20% nitric acid), and therefore should be avoided.[81] The standard toxicologic method is to obtain a 24-hour urine sample for thallium to be assayed by atomic absorption spectroscopy.[14, 100] Normal urine values are below 5 Âµg/L. Some authors suggest a potassium mobilization test to enhance urinary elimination (similar to the ethylenediaminetetraacetic acid [EDTA] mobilization test) to assist in the diagnosis of thallium exposure.[9, 38, 81] We advise against this practice because of its lack of proven usefulness and its potential to exacerbate neurologic toxicity (see Potassium below).

Management

The treatment goals for a patient with thallium poisoning are initial stabilization, prevention of absorption, and enhanced elimination. Following the initial assessment and stabilization of the patient's airway, breathing, and circulatory status, gastrointestinal

decontamination should be instituted in all patients with suspected thallium ingestions because of the morbidity and mortality associated with a significant exposure.

Decontamination

Patients who present shortly after ingestion should be considered candidates for orogastric lavage (Chap. 8). If the patient presents more than a few hours after ingestion, or has had considerable spontaneous emesis, gastric emptying is unnecessary. Thallium

salts are substantially adsorbed to activated charcoal in vitro.[33, 44] Additionally, because thallium undergoes enterohepatic recirculation, activated charcoal may be useful both to prevent absorption following a recent ingestion and to enhance elimination of thallium in patients who present in the postabsorptive phase.[93] In fact, a rat model of thallium poisoning demonstrated that multiple-dose activated charcoal (given as 0.5 g/kg twice daily for 5 days) increased the fecal elimination of thallium by 82% and produced a substantial improvement in survival.[50] Other data demonstrate that activated charcoal alone is superior to either forced diuresis or potassium chloride therapy.[45] In patients with severe thallium toxicity, constipation is common, such that the addition of mannitol[52, 88, 98] or another cathartic to the first dose of activated charcoal seems logical. Although no studies address the usefulness of whole-bowel irrigation with polyethylene glycol electrolyte lavage solution, this technique may prove useful, especially when radiopaque material is demonstrated in the gastrointestinal tract by an abdominal radiograph.

Potassium

The similarities between the cellular handling of potassium ions and thallium ions led to the investigation of a role for potassium in the treatment of thallium poisoning. In humans, potassium

administration is associated with an increase in urinary thallium elimination.[13,25,69] The magnitude of this increase is reported to be on the order of 2â€“3-fold.[69] This is supported by animal models that demonstrate some benefit in terms of either enhanced thallium elimination or survival.[26,45,50] It is believed that potassium administration both blocks tubular reabsorption of thallium and mobilizes thallium from tissue stores, thereby raising thallium levels available for glomerular filtration.[63,81] However, it is this second mechanism that is of concern. Many authors report either the development of acute neurologic toxicity or the significant exacerbation of neurologic symptoms during potassium administration.[6,25,56,69,78,95] Others cite data demonstrating that potassium's augmentation of thallium elimination in humans is quite limited.[43] Additionally, animal models demonstrate that potassium loading enhances lethality[55] and permits thallium redistribution into the CNS.[31] For these reasons, the routine use of potassium should be considered potentially dangerous. Some authors recommend forced diuresis, especially in conjunction with potassium chloride.[17,93] However, no convincing experimental or clinical evidence can support the use of forced diuresis with or without potassium at this time.

Again, the similarities between thallium and potassium might suggest a role for administration of sodium polystyrene sulfonate (SPS) as a sodiumâ€“thallium exchange resin. Although in vitro binding between thallium and SPS is excellent, it is unlikely to be clinically useful because of preferential binding between potassium and SPS.[33] Consequently, neither the use of potassium nor of SPS is recommended.

Chelation

Thallium toxicity does not respond to traditional chelation therapy. Studies demonstrate that the use of EDTA and diethylenetriamine pentaacetic acid are without benefit.[62,81] Dimercaprol (British

anti-Lewisite, BAL) and D-penicillamine also fail to enhance thallium excretion in experimental models.[62,81] In one model in which D-penicillamine was able to enhance thallium elimination, it did so at the cost of substantial thallium redistribution into vital organs.[77] Similarly, sulfur-containing compounds such as cysteine or *N* -acetylcysteine (NAC) have not been demonstrated to be beneficial.[50,54] Another chelator, diphenylthiocarbazone (dithizone), forms a minimally toxic complex with thallium, resulting in a 33% increase in fecal elimination of thallium in rats.[85] Unfortunately, dithizone is goitrogenic and diabetogenic in animal studies.[50,61,93] Dithiocarb (sodium diethyldithiocarbamate), an intermediate metabolite of tetraethylthiuram disulfide (disulfiram, or Antabuse) (Chap. 77), also increases the urinary excretion of thallium.[85,89] Prior to thallium elimination, however, the formation of a lipophilic thalliumâ€“diethyldithiocarbamate complex can result in the redistribution of thallium into the central nervous system.[41,89] After decomposition of the chelate complex, thallium may remain in the central nervous system, potentially exacerbating neurologic symptoms.[41,89] Because of the significant adverse effects of dithizone and the redistribution of thallium following dithiocarb use, neither agent is recommended in the treatment of patients with thallium toxicity. Currently there is renewed interest in the water-soluble analogs of BAL (DMPS [dimercaptopropane sulfonate] and succimer). In an animal model, DMPS failed to decrease tissues levels of thallium.[61] Similarly, in another animal model, although succimer improved survival over control, the benefit was less than that achieved for Prussian blue (see below) and was at the cost of an increase in brain thallium concentrations.[80] In conclusion, the above data fail to support a role for any traditional metal chelators in thallium-poisoned patients.

Prussian Blue

Prussian blue is an FDA-approved antidote for thallium toxicity (see Antidotes in Depth: Prussian Blue).[92] When given orally, Prussian blue acts as an ion exchanger for univalent cations, with its affinity increasing as the ionic radius of the cation increases. As such, Prussian blue interferes with the enterohepatic circulation by exchanging potassium ions, from its lattice, for thallium ions in the gastrointestinal tract. This results in the formation of a concentration gradient causing an increased movement of thallium into the gut.

Humans with thallium poisoning are routinely given Prussian blue, which appears to result in clinical benefits, enhanced fecal elimination, and falling thallium concentrations.[14 , 16 , 56 , 72 , 88 , 95 , 96 , 98 , 99] One series of 11 thallium-poisoned patients demonstrated both the safety of Prussian blue and its ability to substantially increase fecal thallium elimination.[88] Unfortunately, because there are no controlled trials in humans that compare Prussian blue to other drugs, and many of the patients reported above received multiple therapies, the actual efficacy of Prussian blue is unknown.

The dose of Prussian blue is 250 mg/kg/d orally via a nasogastric tube in 2â€“4 divided doses.[88] For patients who are constipated, the Prussian blue may have greater benefit if dissolved in 50 mL of 15% mannitol.[93] Although any cathartic may be appropriate, most authors have used mannitol, possibly because of concerns regarding repeated magnesium use in patients with neurologic findings and sorbitol in patients with poor gastrointestinal mobility. (Other dosing regimens are discussed in Antidotes in Depth: Prussian Blue .)

Extracorporeal Drug Removal

Extracorporeal drug removal may have a limited beneficial role in patients with thallium toxicity, especially if begun shortly after the initial exposure while serum concentrations remain high prior to

effective tissue distribution. Because a frequently quoted review attests to the benefits of hemodialysis,[59] many patients still receive this therapy.[58] The actual data, however, show that hemodialysis, at

various stages of poisoning, is no better than forced diuresis.[16, 71] Reported thallium removal rates by hemodialysis are trivial: 143 mg of thallium were removed by 120 hours,[72] 222.8 mg were removed by 121 hours,[16] and 128 mg were removed by 54 hours of hemodialysis.[16] These values can be placed in perspective knowing that the minimum lethal adult dose of thallium is estimated to be on the order of 1 g,[62] and that many reported cases involve ingestions 10 times greater than the minimum lethal dose. Data from a more recent hemodialysis experience suggest that by using high blood-flow rates (300 mL/min), clearances as high as 90â€“150 mL/min could be obtained.[52] Although clearances seem encouraging, this should be interpreted with an appreciation of the large volume of distribution of thallium. With lower blood-flow rates, charcoal hemoperfusion may be 2â€“3 times more efficient than hemodialysis, providing clearance rates as high as 139 mL/min.[16] Furthermore, combined hemoperfusion and hemodialysis were used in several cases,[1, 16, 18] and were reported to remove as much as 93 mg of thallium within 3 hours of therapy.[1] While extracorporeal therapy alone is probably insufficient for patients with significant poisoning, and unnecessary in those with small exposures, it may have some benefit when used in combination with other therapies, especially in patients with renal insufficiency and those with early massive, and presumed lethal, exposures. As is the case with other xenobiotics, the use of peritoneal dialysis is probably ineffective in removing thallium.[43] Table 96-2 summarizes the suggested therapy for thallium-poisoned patients.

Early (patients who present in the first hours postexposure)

- Stabilize airway, breathing, and circulation if necessary
- Consider orogastric lavage if the patient has not vomited
- Consider whole-bowel irrigation with polyethylene glycol electrolyte lavage solution for patients with large ingestions or the presence of radiopaque material on abdominal radiograph
- Begin multiple-dose activated charcoal therapy; add a cathartic to the first dose if the patient does not have diarrhea
- Give Prussian blue 250 mg/kg/d in 2 or 4 divided doses, dissolved in water, or 50 mL of 15% mannitol if the patient does not have diarrhea
- Consider simultaneous charcoal hemoperfusion and hemodialysis, especially if the patient has renal insufficiency

Late (patients who present more than 24 hours postexposure or with chronic toxicity)

- Stabilize airway, breathing, and circulation if necessary
- Begin multiple-dose activated charcoal therapy; add a cathartic to the first dose if the patient does not have diarrhea
- Give Prussian blue 250 mg/kg/d in 2 or 4 divided doses, dissolved in water, or 50 mL of 15% mannitol if the patient does not have diarrhea

TABLE 96-2. Treatment for Thallium Poisoning

Summary

The elimination of thallium salts from common use as depilatories and rodenticides substantially reduced the incidence of both intentional and unintentional thallium toxicity in the United States. Despite this fact, cases of significant poisoning still occur in countries where thallium-containing rodenticides remain in use, as well as in this country, from attempted homicide and by personal injury from contamination of foods and illicit drugs. Early

recognition of the characteristic signs and symptoms of thallium poisoning and prompt initiation of safe and appropriate therapy will substantially improve the patient's prognosis. When recognition and subsequent treatment are delayed, morbidity and mortality can be consequential.

Antidotes in Depth

Prussian Blue

Robert S. Hoffman

Prussian blue, the first artificially synthesized pigment, was discovered unintentionally by Diesbach, in 1704, while he was attempting to make cochineal red lake. Although it immediately became popular in art and later in printing, it took approximately 250 years to recognize that Prussian blue was able to attract monovalent alkali metals into its crystal lattice. Subsequently, in 1963, Nigrovic was the first investigator to demonstrate that Prussian blue enhanced cesium elimination from the gut of rats.[33] In 2003, the FDA approved Prussian blue (Radiogardase) for the treatment of thallium and radioactive cesium poisoning.

The literature associated with Prussian blue is complicated by many confusing chemical and physical terms. The product synthesized by Diesbach, $Fe_4[Fe(CN_6)]_3$, commonly known as insoluble Prussian blue, is assigned the Chemical Abstracts Service (CAS) number 14038-43-8, and is the FDA-approved product Radiogardase (Fig. A26-1). Synonyms for Prussian blue include Berlin blue, Hamburg blue, mineral blue, Paris blue, and Pigment

blue 27, to name a few.[50] These names are often used interchangeably to refer to both insoluble Prussian blue and a soluble (colloidal) Prussian blue that has either the molecular formula $KFe[Fe(CN)_6]_3$ or $K_3Fe[Fe(CN)_6]_3$. Thus â€œPrussian blueâ€• also carries two additional CAS numbers: 25869-98-1 and 12240-15-2.[34] Compounds containing the same basic core structure, such as $NH_4Fe[Fe(CN)_6]_3$ (ammonium ferric ferrocyanide or Chinese blue) and sodium ferric ferrocyanide, may have similar efficacy in binding monovalent cations, and are also sometimes incorrectly called Prussian blue. For the purpose of clarity, general statements that follow use the term Prussian blue. In many instances the terms â€œinsolubleâ€• and â€œsolubleâ€• are specified to highlight differences between the compounds. Unfortunately, because many studies do not specify which Prussian blue is used, some inherent ambiguity persists.

Typically, the crystal lattice of Prussian blue takes up cationic potassium ions from the surrounding environment. However, because its affinity increases as the ionic radius of the monovalent cation increases, Prussian blue preferentially binds cesium (ionic radius: 0.169 nm) and thallium (ionic radius: 0.147 nm) over potassium (ionic radius: 0.133 nm).[6,15] Additionally, binding for rubidium (ionic radius: 0.148 nm) has been demonstrated.[43] Thus, when given orally, Prussian blue binds unabsorbed thallium or cesium in the gastrointestinal tract, preventing absorption as well as reversing the concentration gradient to enhance elimination through gut dialysis. In addition, in the gastrointestinal tract Prussian blue can interfere with enterohepatic circulation, causing a further reduction in tissue stores.

Pharmacology

Insoluble Prussian blue is essentially not absorbed from the gastrointestinal tract and is eliminated in the feces at a rate determined by gastrointestinal transit time. In a radiolabeled

study of healthy pigs, 99% of a single ingested dose was recovered unchanged in the stool.[29] In contrast, soluble Prussian blue is probably minimally absorbed based on the clinical finding of a blue discoloration that develops in the sweat and tears of patients undergoing prolonged therapy.[11] This discoloration appears to be benign and resolves when therapy is stopped. No significant food or drug interactions are known to exist. Animal studies show no adverse effects of therapeutic doses[38] and oral lethal doses are not known. The only significant adverse effects reported in humans from therapeutic doses are constipation and hypokalemia,[49] and the constipation may be related more to the xenobiotic than to the Prussian blue. Although there is some concern regarding cyanide liberated from Prussian blue, this release appears to be quantitatively minimal. In simulated gastric fluid, cyanide release from soluble Prussian blue was <3 mg/24 h; the insoluble form released even less.[55] When three human volunteers were given 500 mg of radiolabeled soluble Prussian blue, only 2 mg of cyanide were absorbed.[31]

In Vitro Adsorption of Thallium

In vitro and, presumably, in vivo binding of thallium to Prussian blue are influenced by its chemical formulation. An early investigation demonstrated that the soluble form more effectively adsorbs thallium than the insoluble form.[8] In a more rigorous study, the in vitro adsorptions of both forms were similar when thallium concentrations remained low.[14] However, as thallium concentrations increased, the colloidal (soluble) form demonstrated far greater adsorptive capacity. Although not proven, this difference may occur because the soluble form contains more potassium and can therefore exchange proportionally more cation. Furthermore, the actual size of the crystal lattice alters its efficacy. Laboratory synthesized Prussian blue (with a crystal size of 17.68 nm) was compared with a commercial preparation (with a crystal size of 31.19 nm). The

laboratory synthesized product adsorbed more thallium in vitro, because its smaller size increased its surface area.[15]

Thallium Poisoning

A thorough analysis of the efficacy of Prussian blue in thallium poisoning is severely hampered by many factors. First, and most importantly, there are no controlled human trials. Second, although multiple patients have received Prussian blue in the setting of thallium poisoning, many were simultaneously treated with a variety of therapies, including forced potassium diuresis, single- or multiple-dose activated charcoal, and either hemodialysis or hemoperfusion. Thus, it is impossible to determine the specific effects of Prussian blue on mortality or other clinical outcomes, and even toxicokinetic data must be interpreted with caution. Third, many of the in vitro and animal investigations fail to specify the exact type of Prussian blue used. Those investigations that do specify the type of Prussian blue used typically used the soluble form, which is presently unavailable as a pharmaceutical preparation. Discussions of the available data in the following sections are limited by these considerations.

In Vitro Comparison of Prussian Blue with Activated Charcoal

In one in vitro study, thallium was well adsorbed to Norit brand activated charcoal.[14] Although numerical data are not supplied in the body of the paper, the 10â€“20% adsorption to activated charcoal demonstrated in a figure was far less than the results achieved with several different forms of Prussian blue tested simultaneously.[14] Two other binding studies showed different results from the Norit study. An early investigation determined that the maximal adsorptive capacity (MAC) of activated charcoal

was 124 mg of thallium/g, whereas the MAC for Prussian blue was only 72 mg of thallium/g.[16] More recently, a MAC of only 59.7 mg of thallium/g was calculated for CharcoAid activated charcoal, compared to a higher MAC for insoluble Prussian blue of 72.7 mg of thallium/g.[12] Although the MACs for Prussian blue in these two studies are nearly identical, the variable results for activated charcoal may be a function of the study pH or the different types of activated charcoal used.

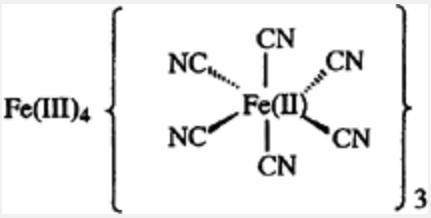

Figure A26-1. The chemical structure of insoluble Prussian Blue. The Roman numerals II and III denote the valence state of iron. Although in the most current nomenclature this would be expressed as Fe^{2+} and Fe^{3+}, the figure is drawn this way to be consistent with most available references, which use the older nomenclature.

Animal Data: Kinetics, Tissue Concentrations, and Survival

Sublethal doses of thallium were used to evaluate the effects of various antidotes in rats over an 8-day period.[16] Although the control group only eliminated 53% of the administered dose of

thallium, 93% of the dose was eliminated in the activated charcoal and 82% was eliminated in the insoluble Prussian blue groups. Although other investigators only demonstrated a modest increase in thallium elimination in rats treated with oral activated charcoal, a consistent benefit of Prussian blue is noted.[17]

Multiple studies clearly demonstrate that Prussian blue not only decreases the half-life of thallium in animals but also lowers thallium content in critical organs such as the brain and the heart.[10,26,27,42,44] Half-lives are typically reduced by approximately 50% when Prussian blue is given with or without a cathartic. The rationale for the cathartic is that constipation is invariably present in humans and animals with severe thallium poisoning.

Only a few studies evaluate the effects of Prussian blue on survival. In these studies, a statistically significant survival advantage has been shown in thallium-poisoned rats[15,44] and mice[21] treated with Prussian blue. The experimental benefit is on the order of a 31% increase in the LD_{50} (median lethal dose for 50% of test subjects) in poisoned animals.[45]

Radioactive Thallium

There is no published experience describing human poisoning with radioactive thallium. As would be expected, because the ionic radius of isotopes is generally very similar, Prussian blue has demonstrable efficacy in an animal model of radiothallium poisoning. In one small study, insoluble Prussian blue decreased the biologic half-life of radioactive thallium in rats by approximately 40%.[2]

Human Data

Three patients, in 1971, were the first to receive Prussian blue as a treatment for thallium poisoning.[14] Although daily fecal

determinations were not possible in 2 of the 3 patients because of severe constipation, an approximately 7-fold increase in fecal elimination over baseline was attributed to Prussian blue therapy in the third patient. Subsequently, many humans with thallium poisoning have received Prussian blue, with or without a cathartic, as part of their therapy.[1,3,5,6,9,14,37,40,48,52,53,57] Unfortunately, other components of therapy that may have confounded the effects of Prussian blue in these cases include single- or multiple-dose activated charcoal, D-penicillamine, dimercaprol, ethylenediaminetetraacetic acid (EDTA), succimer, 2,3-dimercaptopropane-1-sulphate (DMPS), forced potassium diuresis, and either hemodialysis or hemoperfusion. Again, there have been no controlled trials of any of these modalities alone or in combination, and most of the data are based on single case reports or small case series.

One of the largest series was composed of eleven thallium-poisoned patients who were treated with soluble Prussian blue.[48] This report not only demonstrated the tolerability of Prussian blue, but also was the first to systematically evaluate fecal elimination. In all individuals studied, fecal elimination remained high, even when urinary elimination fell, suggesting selective redistribution of thallium into the gut.[48] Although the authors commented on clinical improvement in these patients, the lack of controlled data make these subjective observations difficult to interpret. Similarly, a substantial reduction in half-life was demonstrated when Prussian blue was compared to no therapy at all in patients with thallium poisoning.[6]

Dosage and Administration

The dosage of Prussian blue has never been investigated systematically in either humans or animals. In most of the case reports and series mentioned above, a total dose of 150â€“250 mg/kg/d was administered orally or via a nasogastric tube in

2â€“4 divided doses.[48] Because constipation or obstipation is often present or expected, Prussian blue is generally dissolved in 50 mL of 15% mannitol.[49] Although any cathartic may be appropriate, mannitol is used most frequently, possibly because of concerns over the risks associated with repeated does of magnesium or sorbitol (see Antidotes in Depth: Whole-Bowel Irrigation and Other Intestinal Evacuants). The manufacturer of Radiogardase recommends that adults and adolescents with thallium poisoning receive a total dose of 9 g divided daily (3 g every 8 hours) and that children receive a total dose of 3 g divided daily (1 g every 8 hours). Although the manufacturer does not suggest the use or benefit of a cathartic, the use of a high-fiber diet is advocated when constipation is present. Because Prussian blue is well tolerated, the editors continue to favor the 150â€“250 mg/kg/d dosing because it provides more antidote. In addition, because many severely poisoned patients cannot eat, the use of a cathartic should be considered when constipation is consequential.

The end point of therapy is similarly poorly defined. By convention, Prussian blue is usually continued until urinary thallium concentrations fall below 0.5 mg/d. This end point may not be a meaningful measurement of thallium burden, as fecal elimination may continue, even when urinary elimination has diminished.[48] However, because most laboratories are not equipped to measure fecal thallium concentrations, the use of some urinary end point seems reasonable as the reported residual amounts of fecal elimination are small.

Cesium Poisoning

The radioactive isotope of cesium (^{137}Cs), a common byproduct of nuclear fission reactions, is a strong Î² and Î³ emitter with a physical half-life of more than 30 years and a biologic half-life of about 110 days. Another isotope (^{134}Cs) is only produced by

neutron activation of the stable isotope (^{133}Cs) and has a physical half-life of about 2 years and a biologic half-life comparable to ^{137}Cs. Like thallium, cesium is absorbed in the small bowel, distributes like potassium, and undergoes enteric recirculation.[25] Approximately 80% of a given dose is eliminated in the urine, with 20% cleared in the feces.

The isotope ^{137}Cs is used clinically as a radiation source in nuclear medicine. Although uncommon, radiologic disasters such as Chernobyl and GoiÃ¢nia (see Human clinical Trials below) have resulted in lethal incorporation exposures. Additionally, concerns over the use of ^{137}Cs in â€œdirty bombsâ€• have increased the awareness of, and the potential need to treat, patients with radiocesium poisoning. Toxicity from nonradioactive cesium is also reported. Many cases of QTc prolongation and torsade de pointes are reported in patients who take cesium chloride either as a dietary supplement or for its alleged antineoplastic effects.[4,19,36,41,46] To date, there have been no reports of Prussian blue therapy for nonradioactive cesium poisoning, but the following discussion is most likely applicable.

In Vitro Adsorption of Cesium

Standard binding studies compared the ability of activated charcoal, sodium polystyrene sulfonate (SPS), and both soluble and insoluble Prussian blue to bind ^{137}Cs over a range of gastrointestinal pHs.[54] Unlike thallium, the adsorption of cesium to activated charcoal was negligible. Comparable to thallium, SPS offered no benefit, likely because of preferential effects on potassium. Although both forms of Prussian blue adsorbed cesium, the insoluble form was consistently superior. A pH of 7.5 was selected to represent the pH of the small bowel lumen, the location where most adsorption would occur. At this pH, a MAC of 238 mg of ^{137}Cs/g of insoluble Prussian blue was determined. In an interesting extension, when the same authors bound insoluble

Prussian blue to a hemoperfusion column, they demonstrated a clearance of approximately 100 mL/min of ^{137}Cs from plasma, and projected that a 4-hour treatment would adsorb about 0.3 terra becquerel (TBq) of radiocesium.[56]

Animal Data: Kinetics, Tissue Concentrations, and Survival

Small animal investigations with either ^{134}Cs or ^{137}Cs consistently demonstrate that Prussian blue therapy reverses the urine-to-stool-elimination ratio from 8:1 to 0.3:1, and reduces the biologic half-life and the total body area under the curve by as much as 60%.[28,32,33,43,47] For example, rats given oral ^{134}Cs retained 84.7% of the ingested dose at 7 days. Treatment with insoluble and soluble Prussian blue, as well as Chinese blue, produced significant reductions in retained cesium (only 6.36%, 2.63%, and 2.43% of the dose was retained at 7 days, respectively).[7]

In addition to human toxicity, concern over radiocesium incorporation into cattle milk and meat has resulted in a number of large animal investigations. Daily Prussian blue therapy reduced radiocesium concentrations in sheep by as much as 42%.[13,39] Likewise, radiocesium transfer to milk was reduced by 85% in cows.[51] When dogs were contaminated with ^{137}Cs, Prussian blue reduced total-body burden by as much as 51%.[23] Similar efficacy in reducing the amount of cesium was demonstrated in meat from pigs fed ^{134}Cs-contaminated whey, with insoluble Prussian blue reducing activity from 359 Bq/kg to 11 Bq/kg.[7]

Human Volunteer Studies

Two human volunteers ingested meals contaminated with ^{134}Cs to compare the efficacy of both the soluble and insoluble forms of Prussian blue with controls.[7] At 14 days after loading and without therapy, the volunteers retained 94.7% of the ingested dose as

compared to a retention of only 5.1% following therapy with insoluble Prussian blue and 4.9% following soluble Prussian blue. In another study, two volunteers demonstrated that Prussian blue decreased the biologic half-life of ingested radiocesium by approximately 33%.[20] Finally, in two volunteers, the effects of pretreatment were compared to simultaneous posttreatment Prussian blue. When a single dose of Prussian blue was administered 10 minutes before ^{134}Cs, absorption decreased from 100% (without therapy) to 3â€“10%. However, simultaneous administration of 0.5 or 1 g of Prussian blue with ^{134}Cs resulted in 38â€“63% absorption. Finally, when Prussian blue was given daily at a dose of 0.5 g every 8 hours in the postabsorptive phase, the biologic half-life of ^{134}Cs was reduced from 106 to 44 days.[30]

Human Clinical Trials

There are no controlled trials of Prussian blue in radiocesium poisoning. Experience is derived exclusively from treating disaster victims. In 1987, a number of people in GoiÃ¢nia, Brazil, were contaminated with radiocesium from a discarded radiotherapy unit.[35] Although the reported total number of individuals treated is uncertain because of multiple reports that probably include overlapping patients, one group describes 37 patients who were given insoluble Prussian blue in doses ranging from 3g/d in children up to 10g/d in adults. Untreated, elimination kinetics were first order and half-lives varied extensively from 39 to 106 days in adults (mean: 65.5 days in women and 83 days in men). Half-lives were shorter in children. Therapy with insoluble Prussian blue reduced half-lives by a mean of 32%[18] and reduced the retained cesium dose 51â€“84%.[22]

The nuclear disaster at Chernobyl, Ukraine, resulted in many cases of acute radiation exposure as well as incorporation into the population of radioactive iodine, cesium, and strontium. In one trial, insoluble Prussian blue was given to three victims of

radiocesium incorporation many weeks after their exposure. The reported reduction in biologic half-life ranged from 12â€“52%.[24] The authors of this paper include data from the Chinese literature describing another six patients that demonstrate a similar reduction in cesium's biologic half-life following Prussian blue therapy.

Dosage and Administration

The manufacturer of Radiogardase recommends that for radiocesium poisoning, adults receive a total daily dose of 9 g divided into 3 g, 3 times per day. Children should receive a total daily dose of 3 g divided into 1 g, 3 times per day. Although these are the same doses used for thallium poisoning, therapy for cesium poisoning should be continued for least 30 days. Even though there are no recommendations of other criteria to determine the end point of therapy, quantitative and radiologic evaluations of cesium elimination should be performed.

Pregnancy Category

Insoluble Prussian blue is listed as pregnancy category C. Because of the severe consequences of poisoning from radiocesium and thallium and the lack of systemic absorption of insoluble Prussian blue, a risk-to-benefit analysis favors the use of the antidote in all poisoned pregnant patients.

Availability

Insoluble Prussian blue (Radiogardase) is available as a 0.5-g blue powder in gelatin capsules for oral administration manufactured from Haupt Pharma Berlin GmbH for distribution by HEYL Chemisch-pharmazeutische Fabrik GmbH & Co. KG, Berlin.

Chapter 97
Zinc

Michele Burns Ewald

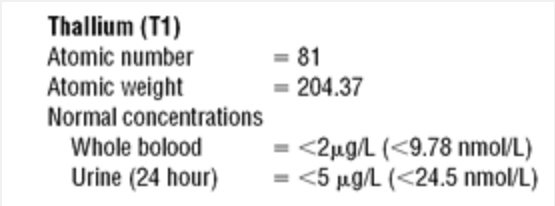

Figure. No Caption Available.

A 39-year-old woman presented to the emergency department with retrosternal chest pain and weakness. She had no history of cardiac or pulmonary disease, but had auditory hallucinations for

several years. She denied any trauma, nausea or vomiting, travel, or recent illnesses. Her vital signs were: blood pressure, 95/60 mm Hg; pulse, 120 beats/min; respiratory rate, 16 breaths/min; and temperature, 98.6Â°F (37Â°C) Oxygen saturation on room air was 100% by pulse oximetry. Her physical examination was notable for pale conjunctiva and mild erythema of the posterior pharynx without exudates, petechiae, or tonsillar enlargement. Auscultation of the chest revealed clear breath sounds with good air exchange. Her heart had a rapid, regular rhythm and no murmurs were appreciated. Her abdomen was slightly distended, but it was soft, and no masses, involuntary guarding, or rebound was noted. Her stool was negative for occult blood. The neurologic examination was within normal limits. Her skin was noted to be pale but without any rashes. She had full range of motion of all joints.

Intravenous fluid therapy was initiated with 0.9% sodium chloride and the patient was attached to a cardiac monitor. With the exception of sinus tachycardia, the electrocardiogram was normal and did not show any evidence of ischemia. A chest radiograph revealed a normal cardiac silhouette and no abnormal pulmonary lesions. However, the stomach was visualized on the chest film and appeared to contain circular foreign bodies. An abdominal radiograph showed the foreign bodies traversing the entire gastrointestinal tract. Upon further questioning, the patient admitted that for more than a year â€œherâ€• voices had instructed her to ingest coins. The patient described a preference for pennies because of their small size.

Laboratory evaluation was significant for a hematocrit of 16% and a blood smear showed ringed sideroblasts. No other abnormal cells were visualized on the peripheral smear. Hemoglobin electrophoresis excluded thalassemia, and a venous lead concentration was 1.2 Âµg/dL (normal: <10 Âµg/dL). A whole-blood zinc concentration was 298 Âµg/dL and her serum copper concentration was 50 Âµg/dL (normal: 70â€“140 Âµg/dL). A blood

transfusion was given, as well as whole-bowel irrigation to facilitate passage of the coins. The patient received chelation therapy with intravenous $CaNa_2EDTA$ (edetate calcium disodium). Two weeks later, the hematocrit, zinc, and copper concentrations had normalized, and the patient was transferred to an inpatient psychiatric hospital.

History and Epidemiology

The Babylonians used zinc alloys more than 5000 years ago[1] and references to zinc oxide can be found in the Ebers papyrus, written in 1500 B.C.[17] This papyrus is the oldest preserved medical document and it contains magical formulas and folk remedies to cure various diseases. Topical zinc is listed as a calamine lotion to heal lesions around the eye. Zinc oxide and zinc sulfate were used in Western Europe during the late 1700s and early 1800s for gleet (urethral discharge), vaginal exudates, and convulsions. In the late 1800s, brass workers who inhaled zinc oxide fumes were noted to develop â€œzinc fever,â€• â€œbrass founders' ague,â€• and â€œsmelter shakes,â€• all of which are now identified as metal fume fever (Chap. 119).[55]

Throughout history, humans have contaminated the environment with zinc. For example, release of zinc and other metals from mines produces elevated levels of zinc in the local water supply and vegetation, and may lead to elevated tissue zinc concentrations and clinical effects in the nearby population.[41,48]

Medicinal Exposures

Zinc salts have several medicinal uses, including enhancing the solubility of pharmaceutical agents such as insulin (eg, rapid

insulin zinc, extended insulin zinc, and protamine zinc insulin). The salts are used in baby powder (zinc oxide), sun blocks, and topical

burn preparations (zinc oxide). Furthermore, zinc oxide powders are used on some latex and latex-free gloves. Given zinc's antiinflammatory effects, zinc sulfate was studied in the late 1970s for acne vulgaris with mixed results. However, a double-blinded controlled group found no difference between zinc and placebo.[60]

Zinc gluconate-containing lozenges are sold as dietary supplements with conflicting evidence that they can shorten the duration of the common cold.[37,51] One placebo-controlled study found that zinc nasal gel shortened the duration of the common cold when applied within 24 hours of the onset of symptoms.[32]

The FDA approved zinc acetate in 1997 for maintenance therapy of Wilson disease.[11,46] Its use in this disorder is related to the ability of zinc to induce the formation of metallothionein, which assists in the elimination of copper from the blood and body tissues (Chap. 90).[6]

Occupational Exposures

Occupational exposures during coin production may involve contact with zinc. The United States penny has been made with a zinc coating since the introduction of the Lincoln penny in 1943. Its composition was altered in 1982 from 95% copper and 5% zinc to the current 97.5% zinc and 2.5% copper. The reason for this change was 2-fold: it reduced both production costs and the weight of the coin.[78]

Zinc is widely used in industry because it enhances the durability of iron and steel alloys; it also is commonly used in construction. Inhalational zinc oxide exposure commonly occurs in those who weld galvanized steel (galvanization involves coating metal with zinc to protect the metal from rust). Zinc is routinely encountered by electroplaters, smelters, jewelers, in yellow paint production, artists working on stained glass or sculpting metal, as well as aircraft manufacturing workers. The United States mines only a

small percentage of the world's zinc, with the state of Alaska being the main producer.[2]

Chemistry

Zinc is a divalent cation that, like iron and cadmium, is a transition metal. Zinc is among the most common elements comprising the earth's crust and is present in air, soil, and water. It has two common oxidation states, Zn^0 (elemental or metallic) and Zn^{2+}. The pure element exists as a blue to white shiny metal, but it also combines with other elements to form many familiar compounds: zinc chloride ($ZnCl_2$), zinc oxide (ZnO), zinc sulfate ($ZnSO_4$), and zinc sulfide (ZnS). Once the metal is exposed to moisture, it becomes coated with zinc oxide or carbonate ($ZnCO_3$).[2]

Like other transition metals, zinc is able to participate in reactions that result in the generation of reactive oxygen species. As with other transition metals, such as iron (Chap. 40) and copper (Chap. 90), the liberation of superoxide radicals or hydroxyl radicals results in toxicity to the tissues in which it is generated.

Physiology

Zinc is an essential nutrient and found in more than 200 metalloenzymes, including acid phosphatase, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, superoxide dismutase, and DNA and RNA polymerases.[2] Zinc contributes to gene expression and chelates with either cysteine or histidine in a tetrahedral configuration, forming looped structures known as â€œzinc fingers,â€• which bind to specific DNA regions.[10,81] Other functions of zinc include a role in membrane stabilization, vitamin A metabolism, and the development and maintenance of the nervous system. Zinc and copper concentrations generally have an inverse relationship in the plasma (Chap. 90).

Zinc is important in maintaining olfactory and gustatory function.

Serum, urine, and salivary zinc concentrations are lower in patients with dysfunctional senses of smell or taste. This is supposedly related to an abnormality in a salivary growth factor known as gustin/carbonic anhydrase VI.[30] Because this enzyme is zinc dependent, oral zinc produces some subjective improvement in taste and smell in patients with a known decrease in salivary growth factor and increased parotid saliva gustinâ€“carbonic anhydrase VI complex.[31] Oral zinc sulfate also improved subjective findings in a group of 25 patients with posttraumatic olfactory disorders.[4]

Zinc is important for fetal growth. Accordingly, when 29 pregnant mothers were given zinc citrate, sulfate, or aspartate because they were at risk for small-for-gestational age babies, no intrauterine growth retardation was observed.[72] Similarly, no reproductive effects were observed in a rodent model exposed to inhalational zinc oxide.[52]

The role of zinc within the immune system is undefined. Zinc may be effective in the treatment of infectious diarrhea generically and specifically in the management of Shigella by improving the shigellacidal antibody response and increasing circulating B lymphocyte and plasma cells.[66,67] Zinc deficiency, or hypozincemia, is a well-described clinical entity. It can either be inherited in an autosomal recessive pattern known as acrodermatitis enteropathica that was first described in 1973, or it can be an acquired deficiency.[61] A defect in zinc absorption in the GI tract is thought to be responsible for the disorder, and those patients at risk for acquiring the disorder include patients who receive total parenteral nutrition without adequate zinc supplementation, patients who have undergone intestinal bypass procedures, those with Crohn disease, and premature infants with low zinc storage. Physical findings that suggest the diagnosis, regardless of etiology, include the triad of dermatitis (acral and perioral), diarrhea, and alopecia. Zinc gluconate, acetate, or sulfate in initial doses of 5â€“10 mg/kg/d followed by maintenance

doses of 1â€“2 mg/kg/d is highly effective; in fact, skin lesions typically heal within 2â€“4 weeks and hair growth also restarts during this time frame.

Pharmacokinetics and Toxicokinetics

The average daily intake of zinc in the United States is 5.2â€“16.2 mg; foods that contain zinc include leafy vegetables (2 ppm), meats, fish, and poultry (29 ppm).[2] The recommended daily allowance is 11 mg/d for men and 8 mg/d for women. Pregnant and nursing women require 12 mg/d. Zinc is present in drinking water, and beverages stored in metal containers or that flow through pipes coated with zinc. Zinc levels in air are typically low; average zinc levels in the United States are <1 Âµg/m^3. Air near industrial areas can be higher, and may be greater in certain occupational settings (see Occupational Exposures above).

The main site of oral zinc absorption is the jejunum, although absorption is reported to occur throughout the intestine by binding to a metallothionein as a zincâ€“protein complex in the luminal cells.[80]

Metallothioneins are specific metal-binding proteins with diverse functions considered essential to metal homeostasis. The metallothioneins are of low molecular weight (6000 daltons) and are rich in thiol ligands; it is these ligands that allow high-affinity binding to metals such as zinc, copper, cadmium, mercury, and silver. The primary route of excretion of the complex is fecal. Albumin binds about two-thirds of zinc in the plasma and the remainder is bound to Î±$_2$-globulins. Zinc concentrations in the body show a great variability by organ, with the prostate having the highest amount of the zinc-containing enzyme acid phosphatase.[8]

Clinical Manifestations

Acute

The hallmark of acute zinc toxicity is gastrointestinal (GI) distress, including nausea, vomiting, abdominal pain and gastrointestinal bleeding.[8] In initial studies that evaluated the oral use of zinc sulfate as an acne therapy, epigastric distress was noted,[22,27] One patient developed GI bleeding within a week of therapy initiation with zinc sulfate at a therapeutic dose of 220 mg twice a day.[58] Zinc chloride in concentrations greater than 20% are particularly corrosive when ingested. Partial- and full-thickness burns to the oral mucosa, pharynx, esophagus, and stomach, as well as to the laryngotracheal tree, can occur following unintentional ingestions of zinc chloride by children.[20,43,56] Delayed gastric stricture may occur after acute[56] or chronic zinc chloride consumption.[19] Pancreatitis was noted in a piglet model[26] and in a 24-year-old male who inadvertently ingested liquid zinc chloride.[20] Finally, hyperamylasemia, vomiting, diarrhea, and jaundice occurred following an intentional intravenous injection of zinc sulfate.[12]

Acute inhalation of zinc chloride from smoke bombs produces lacrimation, rhinitis, dyspnea, stridor, and retrosternal chest pain. Upper respiratory tract inflammation, acute lung injury (ALI), and acute respiratory distress syndrome (ARDS) may occur, generally with no suggestions of systemic absorption such as pathologic changes in the liver or kidneys.[34,36,53] Morbidity and mortality increases when the exposure to a zinc chloride smoke bomb is in an enclosed space.[69] Of 70 individuals exposed to a zinc chloride smoke bomb in a tunnel during World War II, 10 died within 4 days.[23] Ambient zinc concentrations in the tunnel were measured at 33,000 mg zinc/m^3 (33,000 times greater than the currently accepted occupational threshold limit value [TLV]- time-weighted average [TWA] of 1 mg zinc/m^3). Inhalation of zinc oxide, a far less water soluble zinc salt, is associated with metal fume fever and not pneumonitis despite similar ambient zinc concentrations.[8]

Animal research suggests that intranasal zinc sulfate use can cause at least transient anosmia as a consequence of disruption of functional connections between the main olfactory bulb and the olfactory epithelium.[54] Topical zinc sulfate is used experimentally in both the rat and mouse model to eliminate olfactory input so that further nerve fiber density and behavioral discrimination testing can be performed.[79] A case report describes a 55-year-old patient who developed an immediate burning sensation after intranasal zinc gluconate application with subsequent anosmia that had persisted for 23 months at the time of publication.[40] Five other patients, ages 31â€“55 years, are described where application of zinc gluconate to the olfactory epithelium resulted in either long-lasting or permanent olfactory dysfunction.[40]

US pennies lodged in the distal esophagus release reactive zinc ions following exposure to gastric acids[16] and can damage the local esophageal tissue. The phenomenon of acid dissolution is demonstrated in animal[3] and in vitro models.[59]

Rare reports of renal complications exist. Microhematuria was observed in a 24-year-old male who ingested liquid zinc chloride but whose renal function did not deteriorate.[20] Intentional intravenous zinc sulfate administration can result in acute tubular necrosis and renal failure as manifestations of systemic zinc poisoning.[12]

Certain zinc salts, as found in baby powders and calamine lotion, are nonirritating.[5] Although older studies suggested the possibility of pruritic, pustular rashes in workers who are exposed to zinc oxide, other causative factors, including personal hygiene, were not considered.[77] One case report describes urticaria and angioedema in a 34-year-old welder following contact with zinc fumes at a smelting plant.[24] The patient was asymptomatic once he was removed from the environment and was able to return to work once full protective gear was used during the welding process.

Chronic

Chronic zinc toxicity can produce a reversible sideroblastic anemia, as well as a reversible myelodysplastic syndrome; 2 patients with zinc exposures, one from nutritional supplements and the other from ingested coins, each had a reversible myelodysplastic syndrome.[13] Both anemia and granulocytopenia occur with the bone marrow showing vacuolated precursors and ringed sideroblasts; the mechanism appears to be a zinc-induced copper deficiency.[25] A 54-year-old schizophrenic patient with a 15-year history of pica (typically metal objects) presented with pancytopenia, including a hemoglobin of 3 g/dL and a white blood cell count of 1300/mm^3.[44] A serum zinc concentration of 280 Âµg/mL and low serum copper concentration of <0.05 Âµg/mL reflected his ingestion of zinc-containing coins over many years. The patient refused surgery to remove the coins from his GI tract. Meat tenderizer and pancreatin were given in an unsuccessful to attempt to loosen the objects. During his medical therapy, he continued to ingest coins. Despite treatment efforts, he died of sepsis and multiorgan failure; an autopsy revealed a coin mass weighing 1870 g in his stomach and another bezoar at the site of a sigmoid volvulus. A 17-year-old boy used megadoses of oral vitamins and mineral supplements containing zinc to treat acne over a 6â€“7 month period.[68] He developed copper deficiency and anemia, leukopenia, and neutropenia. Hemolysis requiring blood transfusions is described in a dog model.[75]

It is suggested that zinc and other transition metals may be important in the pathogenesis of demyelinating diseases.[45,64] Clusters of cases of multiple sclerosis (MS) were described in northern New York in a factory where zinc was the primary substance to which workers were exposed. One hypothesis is that the allele frequency for transferrin (an iron- and zinc-binding protein) may differ in these MS subjects.[70,74] Another cluster was found in Canada where excess metals, including zinc, were found

in the soil and water.[28,38,39] A conclusive link to MS, however, has not been established. Finally, a mutation of one of the copper-zinc superoxide dismutase forms may play a role in a familial forms of amyotrophic lateral sclerosis.[50]

Since the prostate contains the highest concentration of zinc in the human body, the role of zinc in the development of prostate cancer has been investigated. Specifically, American men participating in the Health Professionals Follow-Up Study were followed for 14 years, from 1986â€“2000. Of the 46,974 in the cohort, 2901 new cases of prostatic cancer were diagnosed, with 434 of them considered to be in an advanced stage.[47] Men who used zinc

supplementation at a dose >100 mg/d had a relative risk of advanced prostate cancer of 2.29, and those using zinc for longer than 10 years had a relative risk of 2.37. To date, neither the International Agency for Research on Cancer (IARC) or the Environmental Protection Agency (EPA) have classified zinc as a carcinogen.

A zinc overload syndrome has been described.[29] A 46-year-old male presented with evidence of bone marrow suppression followed by sensory ataxia and a progressive myelopathy. The neuroimaging evaluation was normal. His only remarkable laboratory studies included an elevated serum zinc concentration of 184 Âµg/dL (28.2 Âµmol/L) and a low copper concentration of <10 Âµg/dL (<12.6â€“18.9 Âµmol/L). There was no known exposure to or supplementation of zinc by history. Although his copper deficit improved with copper therapy, hyperzincemia persisted for more than three years that he was followed. This report and three others suggest the possibility of an inherited zinc overload syndrome;[64,65,73] researchers believe the pattern of inheritance is either autosomal recessive or autosomal dominant, with reduced penetrance or new mutations. Whether the pathophysiology is analogous to the iron overload of

hematochromatosis or to the copper overload with subsequent decreased zinc excretion of Wilson disease, remains to be determined.

Metal Fume Fever

Metal fume fever (MFF) typically occurs within 12 hours after an exposure to zinc fumes. Patients develop fever, chills, cough, chest pain, dyspnea, dry throat, and a metallic taste in the mouth. Although exposure to zinc oxide fume is most commonly associated exposure with this syndrome, other zinc compounds and other metal oxides may be implicated. The chest radiograph is often normal, but may show an infiltrate. Hypoxia and tachycardia are rare, but may be noted. Overall, however, the syndrome is relatively benign, with tolerance developing within days. An immune mechanism is suggested, and chronic exposure is needed for sensitization (Chap. 119).

Diagnostic Testing

Because zinc is ubiquitous in the environment and laboratory, great care must be taken to avoid contamination of any samples for investigation.[2] Because elevated zinc concentrations cause copper deficiency, a serum copper concentration should always be obtained simultaneously. Whole-blood zinc concentrations exceed serum concentrations by a ratio of approximately 6â€“7:1 because the metal accumulates in erythrocytes.[57]

Urine zinc concentrations are not well defined. In a cohort of nonoccupationally exposed Italians, the mean urine concentrations were 0.45 mg/L, with a range up to 0.85 mg/L.[57] In the United States, normal urine values are generally accepted as <0.5 mg/d. The National Institute for Occupational Safety and Health states the detection limits in urine are as low as 0.1 Âµg per sample, with extraction of the urine with polydithiocarbamate resin

required prior to digestion and analysis.[2]

Errors can be caused by incorrect sample collection, equipment malfunction or miscalibration, inadequate reagent purity, and atmospheric deposition. Zinc oxide powder in some gloves can contaminate specimens, as can the rubber stopper in the blood collection tubes. Specific tubes are recommended with negligibly low concentrations of trace elements.[18] During sample analysis, laminar flow is recommended to prevent airborne particles from interfering.

Management

Treatment for acute oral zinc toxicity is primarily supportive. Efforts should be focused on hydration, as well as on antiemetic therapy. H_2 receptor antagonists or proton pump inhibitors may relieve abdominal discomfort when given for several days following the zinc salt ingestion.[8]

Gastrointestinal decontamination after zinc salt ingestions may include whole-bowel irrigation (WBI). A radiograph in a 16-year-old boy who ingested 50 zinc sulfate tablets noted no change in their position 4 hours after gastric evacuation. Within 1 hour of institution of WBI therapy, zinc tablets were present in the rectal effluent.[15]

The data regarding the efficacy of chelation therapy for zinc is limited in humans. Edetate calcium disodium ($CaNa_2EDTA$) was used successfully in several cases, including in a child who was exposed to zinc chloride that was a component of soldering flux[63] and in a 24-year-old man exposed to liquid zinc chloride.[20] The combination of $CaNa_2EDTA$ and BAL (British anti-Lewisite) was used successfully in a 16-month-old toddler 74 hours after ingestion.[56] Both DTPA (diethylenetriaminepentaacetic acid) and EDTA (ethylenediaminetetraacetic acid) were effective in enhancing the urinary excretion of zinc in a rodent model of zinc

acetate poisoning.[21] DTPA had its greatest antidotal efficacy when given within 30 minutes of the intraperitoneal injection of zinc acetate.[49] The urinary excretion of zinc increased 1.6â€“44-fold following a 3 mg/kg intravenous dose of DMPS (sodium 2,3-dimercaptopropane-1-sulfonate) in one human study where metal toxicity in patients with dental amalgams was the focus.[76] Two potential zinc-selective chelators, DPESA (4-{[2-(bis-pyridin-2-ylmethylamino)ethylamino]-methyl}phenylmethanesulfonic acid) sodium salt, as well as TPESA (4-{[2-bis-pyridin-2-ylmethylamino)ethyl]pyridine-2-ymethylamino}-methyl)phenyl]methanesulfonic acid) sodium salt,[42] rapidly chelate zinc in vitro, but further detailed in vivo studies are needed before its clinical use can be considered. Finally, an iron-chelating agent, deferiprone, was incidentally noted to cause decreased serum zinc concentrations in a transfusion overload study.[33] A subsequent prospective trial showed enhanced urinary excretion of zinc in children with thalassemia major who had been transfused with blood multiple times.[9]

Intravenous *N*-acetylcysteine (NAC) increased the urinary zinc excretion in a patient who had inhaled zinc chloride smoke.[62] Two individuals with inhalational zinc chloride-induced ARDS[34] had simultaneous transient decreases in plasma zinc concentrations and increases in urinary zinc excretion with intravenous and nebulized NAC. However, they succumbed at days 25 and 32 after inhalation. Although an increase in urinary zinc excretion was noted in one rat model,[7] 10 healthy volunteers who were treated with oral NAC for 2 weeks had no significant change in either their serum or urine zinc concentrations.[35]

Supportive care is used for patients with inhalational zinc exposures, including oxygen therapy and bronchodilators as clinically indicated, but these patients may necessitate ventilatory support in severe cases. Exposure to zinc oxide vapors by rescuers is minimal, although respiratory protective equipment should be worn.[71] In a case series of five soldiers exposed to zinc chloride

during military training, the two individuals not wearing gas masks developed ARDS;[34] the others remained clinically well.

Metal fume fever is typically self-limited. Nonsteroidal antiinflammatory drugs should be sufficient to relieve the transient discomfort. Personal protection equipment and/or adequate engineering strategies may allow the individual to continue to work in this setting.

Dermal decontamination is paramount to prevent direct epidermal effects or systemic absorption of zinc salts.[14] However, water should not be used to perform dermal decontamination of patients exposed to metallic zinc because of concerns that zinc metal will ignite when wet. Treatment in these situations includes mechanical removal of any metallic particles with forceps and the application of mineral oil to the affected skin to protect the metal from ambient moisture.

Summary

Zinc is a ubiquitous element found throughout the environment. Exposures to humans occur as part of the diet, medicinal uses, nutritional supplements, and in certain occupational settings. Clinical manifestations include acute, life-threatening gastrointestinal and pulmonary effects, which are generally treated with supportive care. Systemically poisoned patients should receive chelation therapy. Care must be taken to avoid specimen contamination during laboratory analysis.

Chapter 98

Antiseptics, Disinfectants, and Sterilants

Paul M. Wax

A 60-year-old woman with a history of ethanol abuse was brought to the emergency department (ED) from home, 3 hours after drinking a few ounces of a liquid from an old liquor bottle that was stored in her garage. In the ED, the patient was unresponsive to voice but responded to deep pain. Her vital signs were: blood pressure, 80/40 mm Hg; pulse, 130 beats/min and regular; respiratory rate, 14 breaths/min; and temperature, 98.6Â°F (37Â°C). An unusual, somewhat sweetish odor was noted on her breath. The patient was comatose with normal muscle tone and symmetrical reflexes. Her physical examination was otherwise unremarkable. Her initial electrocardiogram (ECG) showed sinus tachycardia with normal conduction and no evidence of ischemia.

In the ED, the patient continued to vomit. She underwent endotracheal intubation for airway protection and was treated with aggressive fluid resuscitation. Her blood pressure gradually improved, but she exhibited episodic atrial fibrillation and was

admitted to the intensive care unit (ICU). Her electrolytes, renal function tests, and glucose were normal. The arterial blood gas on room air showed: pH, 7.28; PCO_2 , 50 mm Hg; and PO_2 , 70 mm Hg. A urine toxicology screen was negative for drugs of abuse. Serum ethanol concentration was 30 mg/dL. The old liquor bottle that the patient had drunk from was noted to have a disinfectantlike odor that resembled formaldehyde and was sent to the medical examiners office for a formaldehyde analysis.

In the ICU, the patient remained comatose for the first 48 hours. Esophagogastroscopy revealed gastric inflammation, but no burns. There were no further dysrhythmias. The patient was extubated and fully awake within 96 hours of the ingestion and admitted that she had run out of liquor in her house and had gone out to the garage, looking for other sources of ethanol. She believed that she had been drinking from an old rum bottle. The medical examiner's report of the analysis of the liquid from the old bottle revealed the presence of phenol. No formaldehyde, ethanol, or other chemicals were detected.

Antiseptics, disinfectants, and sterilants are a diverse group of antimicrobials used to prevent infection (Table 98-1). Although these terms are sometimes used interchangeably and some of these xenobiotics are used for both antisepsis and disinfection, the distinguishing characteristics between the groups are important to emphasize. An antiseptic is a chemical that is applied to living tissue to kill or inhibit microorganisms. Iodophors, chlorhexidine, and the alcohols (ethanol and isopropanol) are commonly used antiseptics. A disinfectant is a chemical or physical agent that is applied to inanimate objects to kill microorganisms. Bleach (sodium hypochlorite), phenolic compounds, and formaldehyde are examples of currently used disinfectants. Neither antiseptics nor disinfectants have complete sporicidal activity. A sterilant is a chemical or physical process that is applied to inanimate objects to kill all microorganisms as well as spores. Ethylene oxide and glutaraldehyde are examples of sterilants. Unsurprisingly, many of

the xenobiotics used to kill microorganisms also demonstrate considerable human toxicity.[15 , 55]

The use of these xenobiotics evolved during the 20th century as their toxicity and the principles of microbiology became better understood. Two of the more toxic antisepticsâ€”iodine and phenolâ€”were gradually replaced by the less toxic iodophors and substituted phenols. The use of mercuric chloride was superseded by the organic mercurials (eg, merbromin, thimerosal), which also proved toxic. In recent years, newer compounds, such as quaternary ammonium compounds, ethylene oxide, and glutaraldehyde, are used extensively.

Antiseptics

Chlorhexidine

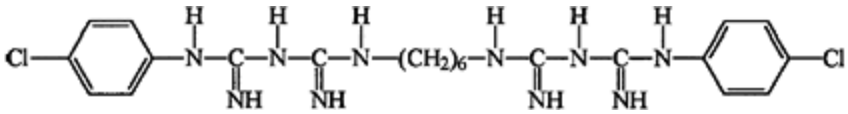

Figure. No Caption Available.

This cationic biguanide compound has been in use as an antiseptic since the early 1950s. It is found in a variety of skin cleansers, usually as a 4% emulsion (eg, Hibiclens), and may also be found in mouthwash. Chlorhexidine is reported to have low toxicity.

Chemical	Commercial Product	Use	Toxic Effects	Therapeutics and Evaluation

TABLE 98-1. Antiseptics, Disinfectants, Sterilants, and Related Compounds

Clinical

Few cases of deliberate oral ingestion of chlorhexidine are reported. Symptoms are usually mild and gastrointestinal irritation is the most likely effect after oral ingestion.[21] Chlorhexidine has poor enteral absorption. In one case, ingestion of 150 mL of a 20% chlorhexidine gluconate solution resulted in oral cavity edema and significant irritant injury of the esophagus.[107] In the same case, liver enzymes rose to 30 times normal on the fifth day after ingestion. Liver biopsy showed lobular necrosis and fatty degeneration. Subsequently, the liver enzymes normalized. In another case, the ingestion of 30 mL of a 4% solution by an 89-year-old woman did not result in any GI injury.[40] An 80-year-old woman with dementia ingested 200 mL of a 5% chlorhexidine solution and subsequently aspirated.[65] She rapidly developed hypotension, acute respiratory distress, and coma, and died 12 hours after ingestion.

Intravenous administration of chlorhexidine is associated with hemolysis, although this may be caused by the hypotonicity of the injected solution,[23] and acute respiratory distress syndrome.[75] Inhalation of vaporized chlorhexidine is reported to cause methemoglobinemia as a consequence of the conversion of chlorhexidine to *p* -chloraniline.[173] In one patient, the rectal administration of 4% chlorhexidine resulted in acute colitis with ulcerations.[54]

Topical absorption of chlorhexidine is negligible. Contact dermatitis is reported in up to 8% of patients who received repetitive topical applications of chlorhexidine.[55] More ominously, anaphylactic reactions, including shock, are associated with dermal application.[5 , 121] Some of these cases of chlorhexidine-related anaphylaxis occurred during surgery, appearing 15â€“45 minutes after application of the antiseptic prep.[11] Eye exposure may result in corneal damage.[168]

Management

Treatment guidelines for chlorhexidine exposure are similar to those for other potential caustics. Patients with significant symptoms may require endoscopy, but the need for such extensive evaluation is quite uncommon.

Hydrogen Peroxide

Hydrogen peroxide, an oxidizer with weak antiseptic properties, has been used for many years as an antiseptic and a disinfectant. This oxidizer is generally available in two strengths: dilute hydrogen peroxide, with a concentration of 3â€“9% by weight (usually 3%), sold for home use, and concentrated hydrogen peroxide, with a concentration greater than 10%, used primarily for industrial purposes. Commercial-strength hydrogen peroxide is most commonly found as a 27.5â€“70% solution. Home uses for dilute hydrogen peroxide include ear cerumen removal, mouth gargle, vaginal douche, enema, and hair bleaching. Dilute hydrogen peroxide is also sometimes used as a veterinary emetic. Commercial uses of the more concentrated solutions include bleaching and cleansing textiles and wool, and producing foam rubber and rocket fuel. A 35% hydrogen peroxide solution is also available to the general public in health food stores and is sold as â€œhyperoxygenation therapyâ€• and as a health food additive to aerate health food drinks.[71] This potentially dangerous therapy is touted as a treatment for a variety of conditions, including AIDS and cancer.[72]

Hydrogen peroxide has two main mechanisms of toxicity: local tissue injury and gas formation. Toxicity from hydrogen peroxide may occur after ingestion or wound irrigation. The extent of local tissue injury and amount of gas formation is determined by the strength of the hydrogen peroxide. Dilute hydrogen peroxide is an irritant and concentrated hydrogen peroxide is a caustic. Gas

formation results when hydrogen peroxide interacts with tissue catalase, liberating molecular oxygen and water. At standard temperature and pressure, 1 mL of 3% hydrogen peroxide liberates 10 mL of oxygen, whereas 1 mL of the more concentrated 35% hydrogen peroxide liberates more than 100 mL of oxygen. Gas formation can result in life-threatening embolization. Gas embolization may be a result of dissection of gas under pressure into the tissues or of liberation of gas in the tissue or blood following absorption. The use of hydrogen peroxide in closed spaces, such as operative wounds, or its use under pressure during wound irrigation, increases the likelihood of embolization.

Clinical

Determining the concentration of hydrogen peroxide is important as the more toxic manifestations from ingestion are usually associated with the more concentrated formulations. The combination of local tissue injury and gas formation from the ingestion of concentrated hydrogen peroxide may cause GI disturbances, such as abdominal bloating, abdominal pain, vomiting, and hematemesis.[72, 102] Endoscopy may show esophageal edema and erythema and significant gastric mucosal erosions.[146] Airway compromise manifested by stridor, drooling, apnea, and radiographic evidence of subepiglottic narrowing may occur.[37]

Symptoms consistent with sudden oxygen embolization include rapid deterioration in mental status, cyanosis, respiratory failure, seizures, and ischemic ECG changes.[44] A 2-year-old boy died after ingesting 120â€“180 mL of 35% hydrogen peroxide.[25] Antemortem chest radiography showed gas in the right ventricle, mediastinum, and portal venous system. Portal vein gas is also a prominent feature in other cases.[71, 102] Arterialization of oxygen gas embolization may result in cerebral infarction.[150] Encephalopathy with cortical visual impairment[19] and bilateral hemispheric

infarctions detected by MRI imaging may occur after ingestion of concentrated hydrogen peroxide.[74]

Clinical sequelae from the ingestion of dilute hydrogen peroxide are usually much more benign.[37, 62] Nausea and vomiting are the most common symptoms.[37] A whitish discoloration may be noted in the oral cavity. Gastrointestinal injury is usually limited to superficial mucosal irritation, but multiple gastric and duodenal ulcers, accompanied by hematemesis, are reported.[62] Portal venous gas embolization may occur as a result of the ingestion of 3% hydrogen peroxide.[26, 136] Death from intravenous injection of 35% hydrogen peroxide is also reported.[92]

The use of 3% hydrogen peroxide for wound irrigation may result in significant complications. Extensive subcutaneous emphysema occurred after a dog bite to a human's face was irrigated under pressure with 60 mL of 3% hydrogen peroxide.[153] Systemic oxygen embolism, causing hypotension, cardiac ischemia, and coma, resulted from the intraoperative irrigation of an infected

herniorrhaphy wound.[10] Gas embolism, resulting in intestinal gangrene, was reported to occur following colonic lavage with 1% hydrogen peroxide during surgical treatment of meconium ileus.[149] Multiple cases of acute colitis are reported as a complication of administering 3% hydrogen peroxide enemas.[109] The use of 3% hydrogen peroxide as a mouth rinse is associated with the development of oral ulcerations.[138] Ophthalmic exposures may result in conjunctival injection, burning pain, and blurry vision.[37, 108]

A careful examination should be performed to detect any evidence of gas formation. A chest radiograph might reveal gas in the cardiac chambers, mediastinum, or pleural space. An abdominal radiograph might show gas in the GI tract or portal system and define the extent of bowel distension. MRI and CT scan might be useful for detecting brain lesions secondary to gas embolism.[4, 74]

Endoscopic evaluation might be necessary in patients who ingest concentrated hydrogen peroxide to determine the extent of mucosal injury.

Management

The treatment of patients with hydrogen peroxide ingestions depends, to a large degree, on whether the patient has ingested a diluted or concentrated solution. Those with ingestions of concentrated solutions require expeditious evaluation. Dilution with milk or water, although unstudied, is unlikely to be helpful. Nasogastric aspiration of hydrogen peroxide might be helpful if the patient presents immediately after ingestion. Induced emesis is contraindicated and activated charcoal offers no antidotal benefit. Patients with abdominal distension from gas formation should be treated with nasogastric suctioning. Those with clinical or radiographic evidence of gas in the heart should be placed in the Trendelenburg position to prevent gas from blocking the right ventricular outflow tract. Careful aspiration of intracardiac air through a central venous line may be attempted in patients in extremis.[25] Case reports suggest that hyperbaric therapy may be useful in cases of life-threatening gas embolization after hydrogen peroxide ingestion.[71, 102, 114, 174] Asymptomatic patients who unintentionally ingest small amounts of 3% hydrogen peroxide can be safely observed at home.

Iodine and Iodophors

Iodine usually refers to molecular iodine, also known as I_2, free iodine, and elemental iodine. This chemical is the active ingredient of iodine-based antiseptics. The use of ethanol as the solvent, such as tincture of iodine, allows substantially more concentrated forms of I_2 to be available. I_2 and tincture of iodine ingestions are much less common than in the past as a result of the change in antiseptic use from iodine to iodophor antiseptics.[38]

Iodophors have molecular iodine compounded to a high-molecular-weight carrier or to a solubilizing agent. Povidone-iodine (Betadine), a commonly used iodophor, consists of iodine linked to polyvinylpyrrolidone (povidone). Iodophors, which limit the release of molecular iodine and are generally less toxic, are the standard iodine-based antiseptic preparations. Iodophor preparations are formulated as solutions, ointments, foams, surgical scrubs, wound-packing gauze, and vaginal preparations. The most common preparation is a 10% povidone-iodine solution that contains 1% â€œavailableâ€• iodine (referring to all oxidizing iodine species), but only 0.001% free iodine (referring only to molecular iodine).[15, 55]

Iodine is one of the oldest topical antiseptics.[147] It is also used to disinfect medical equipment and drinking water. Iodine is an effective antiseptic against bacteria, viruses, protozoa, and fungi, and is used both prophylactically and therapeutically.[35] Iodine is cytotoxic and an oxidant. It is thought to work by binding amino and heterocyclic nitrogen groups, oxidizing sulfhydryl groups, and saturating double bonds. Iodine also iodinates tyrosine groups.[55]

There may be significant systemic absorption of iodine from topical iodine or iodophor preparations.[128] Markedly elevated iodine concentrations do occur in patients who receive topical iodophor treatments to areas of dermal breakdown, such as burn injuries.[90] Significant absorption occurs when iodophors are applied to the vagina, perianal fistulas, umbilical cords, and the skin of low-birth-weight neonates.[175] A fatality following intraoperative irrigation of a hip wound with povidone-iodine is reported.[32] In this case, the postmortem serum iodine concentration was 7000 Âµg/dL (normal: 5â€“8 Âµg/dL).

Clinical

Problems associated with the use of iodine include unpleasant odor, skin irritation, allergic reactions, clothes staining, and poor

stability. Ingestion of iodine may cause abdominal pain, vomiting, diarrhea, GI bleeding, delirium, hypovolemia, anuria, and circulatory collapse. Severe caustic injury of the GI tract may occur.

Reports of adverse consequences from iodophor ingestions are rare. In one case report, a 9-week-old infant died within 3 hours of receiving povidone-iodine by mouth.[87] In this unusual case, the child was administered 15 mL of povidone-iodine mixed with 135 mL of polyethylene glycol by nasogastric tube over a 3-hour period for the treatment of infantile colic. Postmortem examination showed an ulcerated and necrotic intestinal tract. A blood iodine concentration of 14,600 Âµg/dL was recorded. Significant toxicity from intentional ingestions of iodophors in adults is not documented.

Acidâ€“base disturbances are among the most significant abnormalities associated with iodine and iodophors. Metabolic acidosis occurred in several burn patients after receiving multiple applications of povidone-iodine ointment.[90 , 129] These patients had elevated serum iodine concentrations and normal lactate levels. The exact etiology of the acidosis remains unclear. Postulated mechanisms for the acidosis include the povidone-iodine itself (pH 2.43), bicarbonate consumption from the conversions of I_2 to NaI, and decreased renal elimination of H^+ as a consequence of iodine toxicity.[129] Metabolic acidosis associated with a high lactate level after iodine ingestion likely reflects tissue destruction.[35]

Electrolyte abnormalities also may occur following the absorption of iodine. A patient with decubitus ulcers who received prolonged wound care with povidone-iodineâ€“soaked gauze developed hypernatremia, hyperchloremia, metabolic acidosis, and renal failure.[35] The hyperchloremia was thought to be caused by a spurious elevation of measured chloride ions as a consequence of iodine's interference with the chloride assay. This interference

occurs on the Technicon STAT/ION autoanalyzer, but does not occur when the silver halide precipitation assay is used.[35] Spurious hyperchloremia from iodine (or iodide) may result in the calculation of a low or negative anion gap (Chap. 17).[20 , 42]

Other problems associated with topical absorption of iodine-containing preparations are hypothyroidism (particularly in neonates),[20 , 154] hyperthyroidism,[137 , 140] elevated liver enzymes, neutropenia, and hypoxemia.[35] Because of the lack of consistency between iodine concentrations and symptomatology, and because many of these patients had significant secondary medical problems that may have accounted for their symptoms, the exact relationship

between iodine absorption and the development of a specific clinical syndrome remains speculative. However, a clinical controlled trial that compared preterm infants exposed to either topical iodinated antiseptics or to chlorhexidine-containing antiseptics showed that the infants exposed to topical iodine-containing antiseptics were more likely to have higher thyrotropin levels and elevated urine iodine concentrations than was the chlorhexidine group.[96]

Contact dermatitis can result from repetitive applications of iodophors.[104] A dermal burn may result from the trapping of an iodophor solution under the body of a patient in a pooled dependent position or under a tourniquet.[99 , 117] Anaphylaxis after vaginal application of povidone-iodine solution is also reported.[1]

Management

The patient who ingests an iodine preparation requires expeditious evaluation, stabilization, and decontamination. Careful nasogastric aspiration and lavage may be performed to limit the caustic effect of the iodine if signs of perforation are absent. Irrigation with a starch solution will convert iodine to the much less toxic iodide

and, in the process, turn the gastric effluent dark blue-purple. This change in color may serve as a useful guide in determining when lavage can be terminated. If starch is not available, milk may be a useful alternative. Instillation of 100 mL of a solution of 1â€“3% sodium thiosulfate can also be used to convert any remaining iodine to iodide. Activated charcoal binds iodine and may be useful.[34] Early endoscopy may help assess the extent of the gastrointestinal injury.

Most patients with iodophor ingestion require only supportive management. The use of starch or sodium thiosulfate may be considered in symptomatic patients. Hemodialysis and continuous venovenous hemodiafiltration was used successfully to enhance elimination of iodine in patient with renal insufficiency who had become iodine toxic after undergoing continuous mediastinal irrigation with povidone-iodine.[83] The role of hemodialysis or continuous venovenous hemodiafiltration is unknown in patients with normal renal function and therefore not recommended.

Potassium Permanganate

Potassium permanganate ($KMnO_4$) is a violet water-soluble compound that is usually sold as crystals or tablets or as a 0.01% dilute solution.[80] Historically, it was used as an abortifacient, urethral irrigant, lavage fluid for alkaloid poisoning, and snakebite remedy. Currently, potassium permanganate is most often used in baths and wet bandages as a dermal antiseptic, particularly for patients with eczema.

Potassium permanganate is a strong oxidizing agent and poisoning may result in local and systemic toxicity.[156] Upon contact with mucous membranes, potassium permanganate reacts with water to form manganese dioxide, potassium hydroxide, and molecular oxygen. Local tissue injury is the result of contact with the nascent oxygen, as well as the caustic effect of potassium hydroxide. A brown-black staining of the tissues occurs from the manganese

dioxide. Systemic toxicity may occur from free radicals generated by absorbed permanganate ions.[182]

Clinical

Following ingestion, initial symptoms include nausea and vomiting. Laryngeal edema and ulceration of the mouth, esophagus, and, to a lesser extent, the stomach, may result from the caustic effects. Airway obstruction and fatal gastrointestinal perforation and hemorrhage may occur.[36 , 110 , 123] Esophageal strictures and pyloric stenosis are potential late complications.[85]

Although potassium permanganate is not well absorbed from the GI tract, systemic absorption may occur, resulting in life-threatening toxicity. Systemic effects include hepatotoxicity, renal damage, methemoglobinemia, hemolysis, hemorrhagic pancreatitis, airway obstruction, acute respiratory distress syndrome, disseminated intravascular coagulation, and cardiovascular collapse.[94 , 103 , 110 , 123] Elevation in blood or serum manganese concentration may also occur, confirming systemic absorption (normal levels: blood manganese 3.9â€“15.0 Âµg/L; serum manganese 0.9â€“2.9 Âµg/L).

Chronic ingestion of potassium permanganate may result in classic manganese poisoning (manganism) characterized by behavioral changes, hallucinations, and delayed onset of parkinsonianlike symptoms. A 66-year-old man who mistakenly ingested 10 g of potassium permanganate over a 4-week period (because of medication mislabeling) developed impaired concentration and autonomic and visual symptoms. He also developed abdominal pain, gastric ulceration, and alopecia. Serum manganese was elevated. Nine months later, the patient's neurologic examination displayed extrapyramidal signs consistent with parkinsonism (Chap. 19).[69]

Management

Because the consequential effects of potassium permanganate ingestion are a result of its liberation of strong alkalis, the initial treatment of such a patient should include assessment for evidence of airway compromise. Dilution with milk or water may be useful. Patients with symptoms consistent with caustic injury should undergo early endoscopy. Corticosteroid agents along with antibiotics may be warranted if laryngeal edema is present. Analysis of liver enzymes, BUN, creatinine, lipase, serum manganese, and methemoglobin concentrations should be performed when systemic toxicity is suspected. Methemoglobinemia, if clinically significant, should be treated with methylene blue. Dermal irrigation with dilute oxalic acid may be successful in removing cutaneous staining.[156] The administration of *N* -acetylcysteine (see Antidotes in Depth: *N* -Acetylcysteine) to increase reduced glutathione production, thereby limiting free radical-mediated oxidative injury in cases of systemic potassium permanganate poisoning, has been suggested, but clinical trials have not been performed.[182]

Other Antiseptics

Alcohols

Isopropanol and ethanol are commonly used as skin antiseptics. Sold as rubbing alcohol, the standard concentration for these solutions is usually 70%. Their antiseptic action is thought to be a result of their ability to coagulate proteins. Isopropanol is slightly more germicidal than ethanol.[55] These agents have limited efficacy against viruses or spores. Isopropanol tends to be more irritating than ethanol and may cause more pronounced central nervous system depression.[176] The greater toxicity of isopropanol has caused some emergency departments to switch rubbing alcohol formulations from isopropanol to ethanol (Chaps. 75 and 103).

Chlorine and Chlorophors

Chlorine, one of the first antiseptics, is still used in the treatment of the community water supply and in swimming pools. Chlorine

is a potent pulmonary irritant that can cause severe bronchospasm and acute lung injury. Chapter 119 further discusses chlorine.

Sodium hypochlorite, found in bleach (eg, Clorox) and Dakin solution, remains a commonly used disinfectant. First used in the late 1700s to bleach clothes, its usefulness arises from its oxidizing capability, measured as â€œavailable chlorine,â€• and its ability to release hypochlorous acid slowly. It is used to clean blood spills and to sterilize certain medical instruments. A 0.5% hypochlorite solution is sometimes recommended for dermal and soft-tissue wound decontamination after exposure to biologic and chemical warfare agents (Chaps. 126 and 127).[73] Toxicity from hypochlorite is mainly a result of its irritant effects. The ingestion of large amounts of household liquid bleach (5% sodium hypochlorite) on rare occasions can result in esophageal burns with subsequent stricture formation.[43] In a cat model of bleach ingestion, a high incidence of mucosal injury and stricture formation was noted.[178] However, the vast majority of household bleach ingestions in humans do not cause significant GI injuries.[130] Accordingly, endoscopic evaluation is usually not warranted when assessing most patients with household liquid bleach ingestions. The ingestion of a more concentrated â€œindustrial strengthâ€• bleach preparation (eg, 35% sodium hypochlorite) increases the likelihood of local tissue injury and should be managed accordingly (Chap. 100).

Mercurials

Both inorganic mercurials, such as mercuric bichloride, and organic mercurials, such as merbromin (mercurochrome) and thimerosal

(merthiolate), which contains 49% mercury, were used in the past as topical antiseptic agents. The usefulness of mercurials is significantly limited because of their relatively weak bacteriostatic properties and the many problems associated with mercury toxicity (Chap. 92). Repeated application of topical mercurials may result in significant absorption and systemic toxicity.[115 , 141] The use of high-dose hepatitis B immunoglobulin (HBIg) may cause mercury toxicity because of the use of thimerosal as a preservative in the HBIg preparation.[101] In one case, a 44-year-old male patient received 250 mL of HBIg (containing about 30 mg of thimerosal) over 9 days following liver transplantation.[150] He developed speech difficulties, tremor, and chorea. His whole blood mercury concentration was 104 Âµg/L (normal >10 Âµg/L). Increased mercury concentrations in both preterm and term infants, following immunizations with thimerosal-containing hepatitis B vaccine, have also generated much concern and led to the call to reduce or eliminate the mercury content of vaccines (Chaps. 53 and 92).[52 , 158]

Disinfectants

Formaldehyde

Formaldehyde is a water-soluble, highly reactive gas at room temperature. Formalin consists of an aqueous solution of formaldehyde, usually containing approximately 37% formaldehyde and 12â€“15% methanol. Formaldehyde is irritating to the upper airways, and its odor is readily detectable at low concentrations. Lethality in adults begins to occur following ingestion of 30â€“60 mL of formalin.[39]

Formerly used as a disinfectant and fumigant, its role as a disinfectant is now largely confined to the disinfection of hemodialysis machines. Nonetheless, formaldehyde has many other applications. Healthcare workers are probably most familiar

with the use of formaldehyde as a tissue fixative and embalming agent.

Exposure to formaldehyde, a potent caustic, may result in both local and systemic symptoms, causing coagulation necrosis, protein precipitation, and tissue fixation. Ingestions of formalin may result in significant gastric injury, including hemorrhage, diffuse necrosis, perforation, and stricture.[3,9] The most extensive damage appears in the stomach, with only occasional involvement of the small intestine and colon. Chemical fixation of the stomach may occur. Esophageal involvement is not very prominent, and, if present, is usually limited to its distal segment.

The most striking and rapid systemic manifestation of formaldehyde poisoning is metabolic acidosis, resulting both from tissue injury and from the conversion of formaldehyde to formic acid. The patient may present with profound acidemia, accompanied by a large anion gap metabolic acidosis. Although the methanol component of the formalin solution is readily absorbed and has resulted in methanol levels of 40 mg/dL,[18,39] the rapid metabolism of formaldehyde to formic acid appears to be responsible for much of the acidosis (Chap. 103). Blindness as a consequence of the accumulation of formate, a retinal toxin, is not reported.

Clinical

Patients presenting after formaldehyde ingestions complain of the rapid onset of severe abdominal pain, which may be accompanied by vomiting and diarrhea. Altered mental status and coma usually follow rapidly. Physical examination may demonstrate epigastric tenderness, hematemesis, cyanosis, hypotension, and tachypnea. Hypotension may be profound with decreased myocardial contractility, as well as hypovolemic shock, contributing to the cardiovascular instability.[64,167] Early endoscopic findings include ulceration, necrosis, perforation, and hemorrhage of the stomach,

with infrequent esophageal involvement. Chemical pneumonitis occurs after significant inhalational exposure.[132] Intravascular hemolysis is described in hemodialysis patients whose dialysis equipment contained residual formaldehyde after undergoing routine cleaning.[124, 135]

Occupational and environmental exposure to formaldehyde receives considerable attention. In particular, there is concern over the potential off-gassing of formaldehyde from the widely used urea formaldehyde building insulation and particle boards.[122] Headache, nausea, skin rash, sore throat, nasal congestion, and eye irritation are associated with the use of these polymers.[31] Formaldehyde, at concentrations as low as 1 ppm, may cause significant irritation to mucous membranes of the upper respiratory tract and conjunctivae.[68, 100] Formaldehyde is also a potential sensitizer for immune-mediated reversible bronchospasm.[61] The exact immunologic mechanism is not yet elucidated, although it is likely that formaldehyde acts as a hapten. In addition, formaldehyde is thought to be a dermal sensitizer.[155]

Both animal and human data suggest that formaldehyde exposure is associated with an increased incidence of nasopharyngeal carcinoma.[2, 57, 127, 142] Although its role in the pathogenesis of cancer in humans is the subject of much debate,[28, 105] in 2004 the International Agency for Research on Cancer (IARC) reclassified formaldehyde from a Group 2 *probable* to a Group 1 *known* carcinogen.

Management

The immediate management of a patient who has ingested formaldehyde includes dilution with water. Although such an approach may be useful in reducing the caustic effect,

strong evidence for a beneficial result is lacking. Careful gastric

aspiration with a small-bore nasogastric tube may limit systemic absorption. The role of activated charcoal is not studied and it probably should not be used if endoscopy is considered likely. Significant acidemia should be treated with sodium bicarbonate and folinic acid (Chap. 103). Immediate hemodialysis may remove the accumulating formic acid as well as the parent molecules, formaldehyde and methanol.[39] Independent treatment for methanol toxicity may be indicated. Early endoscopy is recommended for all patients with significant GI symptoms to assess the degree of burn injury. Surgical intervention may be required for those with severe burns. Emergent gastrectomy, as well as late surgical intervention to relieve formaldehyde-induced gastric outlet obstruction, is infrequently required.[58 , 86]

Phenol

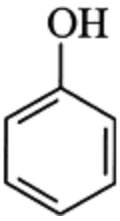

Figure. No Caption Available.

Phenol, also known as carbolic acid, is one of the oldest antiseptic agents. It is rarely used as an antiseptic today, secondary to its toxicity, and has been replaced by the many phenolic derivatives. Currently, phenol is used as a disinfectant, chemical intermediary, and nail cauterizer. The last application uses a highly concentrated 89% solution. Phenol is also a component (0.1â€“4.5%) of various lotions, ointments, gels, gargles, lozenges, and throat sprays.[55] Campho-Phenique and Chloraseptic contain 4.7% and 1.4% phenol, respectively. Although many cases of phenol poisoning were reported in the past, acute oral overdoses of phenol-containing solutions are relatively uncommon today.[49]

Phenol acts as a caustic causing cell wall disruption, protein denaturation, and coagulation necrosis. It also acts a central nervous system stimulant. Intentional ingestion of concentrated phenol, ingestion of phenol-containing water, occupational exposure to aerosolized phenol, dermal contact, and parenteral administration may all result in symptomatic phenol poisoning. Phenol demonstrates excellent skin penetrance.[13] Severe dermal burns from phenol have resulted in systemic toxicity, even death within minutes to hours.[13, 93] Parenteral administration of phenol has also resulted in death.[97] The lethal dose may be as little as 1 g.[70]

Clinical

Clinical manifestations can be divided into local and systemic symptoms. Systemic symptoms from gastrointestinal (GI) or dermal absorption of phenol are usually more dangerous than the local effects and can result in significant morbidity and mortality. Manifestations of systemic toxicity include central nervous system (CNS) and cardiac symptoms. CNS effects include central stimulation, seizures, lethargy, and coma.[51] In a study of patients who had ingested Creolin (26% phenol), CNS symptoms predominated.[157] Of the 52 patients who were evaluated at the hospital, 9 developed lethargy and 2 developed coma. Seizures were not reported. Cardiac symptoms from phenol include tachycardia, bradycardia, and hypotension.[51] Excessive dermal absorption of phenol during chemical peeling procedures is associated with dysrhythmias.[177]

Other systemic symptoms that may develop include pulmonary disturbances, hypothermia, metabolic acidosis, methemoglobinemia, and rabbit syndrome.[70, 81] Rabbit syndrome is most commonly observed as a distinctive extrapyramidal effect from antipsychotic drugs and is characterized by fine rapid repetitive movements of the perioral musculature resembling a

rabbit's chewing movements. Increased acetylcholine release and a relative dopaminergic hypofunction may explain the development of rabbit syndrome after phenol exposure.[81]

Local toxicity to the GI tract from the ingestion of phenol may result in nausea, vomiting, bloody diarrhea, and severe abdominal pain. Serious GI burns are uncommon, and strictures are rare. White patches in the oral cavity may be detected. In the Creolin study cited above, only 1 of 17 patients who underwent endoscopy had a significant esophageal burn.[157] Ingestions of phenol-contaminated water are associated with the development of nausea, vomiting, diarrhea, burning sensation in the mouth, mouth sores, and dark urine.[6, 79] Dermal exposures to phenol usually result in a light-brown staining of the skin.

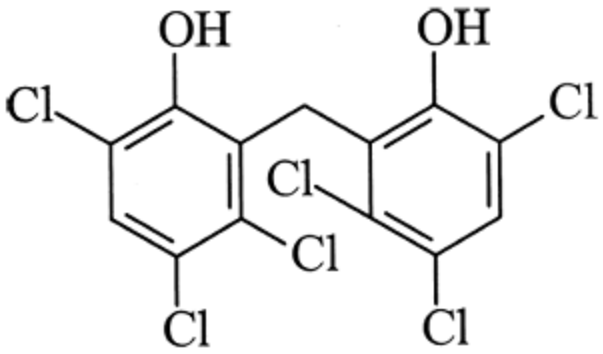
Markedly elevated blood and urine levels of phenol may be detected after ingestion, or dermal absorption, of phenol and phenol-containing compounds (eg, Campho-Phenique).[13, 70, 88]

Management

A variety of treatments have been suggested for dermal and gastric decontamination of phenol. A study employing a rat model showed that cutaneous decontamination with a low-molecular-weight polyethylene glycol solution decreased mortality, systemic effects, and dermal burns.[17] Although this study suggested that polyethylene glycol (PEG) was superior to water as a decontamination agent, a subsequent study using a swine model could not demonstrate a difference between these two therapies.[134] In another swine model, PEG 400 and 70% isopropanol were both superior to water washes and equally effective in decreasing dermal burn.[112] Given the lack of definitive efficacy data, either low-molecular-weight PEG, for example, PEG 300 or 400 (not to be confused with high-molecular-weight PEG that is used for whole-bowel irrigation), or water is currently recommended for dermal irrigation and careful gastric

decontamination. Isopropanol could also be considered as another treatment for dermal decontamination. Endoscopic evaluation, as needed to determine the extent of GI injury, and good supportive care are also recommended.

Substituted Phenols and Other Related Compounds



Hexachlorophene

Hexachlorophene (pHisoHex), a trichlorinated *bis* -phenol, is one of the best known substituted phenols. Hexachlorophene, considered generally less tissue-toxic than phenol, was formerly used extensively as a disinfectant in hospitals. During the 1970s, an association was observed between repetitive whole-body washing of premature infants with 3% hexachlorophene and the development of vacuolar encephalopathy and cerebral edema.[106] There were also multiple reports of significant neurologic toxicity and death in children who became toxic after ingesting hexachlorophene.[63] In addition, fatalities

also occurred after patients absorbed substantial amounts of hexachlorophene during the treatment of burn injuries.[24] The use of hexachlorophene has declined significantly.

Clinical

pHisoDerm, contains sodium octylphenoxyethoxyethyl ether sulfonate and lanolin, and is a safe antiseptic. Irritative effects (nausea, vomiting, diarrhea) would be the main adverse effects with oral ingestions.

In a study of poisoning admissions to Hong Kong hospitals, the ingestion of Dettol liquid, a household disinfectant that contains 4.8% chloroxylenol, 9% pine oil, and 12% isopropanol, accounted for 10% of admissions.[22] Aspiration (perhaps, in part, because of the pine oil) occurred in 8% of these patients, resulting in upper airway obstruction, pneumonia, and acute respiratory distress syndrome. More common symptoms included nausea, vomiting, sore mouth, sore throat, drowsiness, abdominal pain, and fever. Dermal contact with Dettol may result in full-thickness chemical burns.[33]

Cresol, a mixture of three isomers of methylphenol, has better germicidal activity than phenol and is a commonly used disinfectant. Exposure to concentrated cresol may result in significant local tissue injury, hemolysis, renal injury, hepatic injury, and CNS and respiratory depression.[33,56,82,181] Phenol concentrations, as well as cresol concentrations, serve as markers of exposure.[181]

Management

Treatment is mainly supportive.

Quaternary Ammonium Compounds

Quaternary ammonium compounds are a type of cationic surfactant (surface-active agent); they are used as disinfectants, detergents, and sanitizers. Chemically, the quaternary ammonium compounds are synthetic derivatives of ammonium chloride, and structurally similar to other quaternary ammonium derivatives,

such as cholinesterase inhibitors and neuromuscular blockers. Other cationic surfactants include the pyridinium compounds and the quinolinium compounds. Benzalkonium chloride (Zephiran) was one of the most commonly employed quaternary ammonium compounds in the past. Many newer quaternary ammonium compounds have supplanted its use. However, nebulized solutions used for the treatment of asthma, including albuterol and ipratropium bromide, may contain small amounts of benzalkonium chloride. Newer quaternary ammonium compounds are currently used as hospital disinfectants, including Coverage 256, which contains 6% alkyl dimethyl ammonium chloride and 5% octyldecyldimethyl ammonium chloride, and Render, which contains 5% alkyl dimethyl benzyl ammonium chloride.

Clinical

Quaternary ammonium compounds are less toxic than phenol or formaldehyde. Most of the infrequent complications that are described result from ingestions of benzalkonium chloride. Complications of these ingestions include burns to the mouth and esophagus, CNS depression, elevated liver enzymes, metabolic acidosis, and hypotension.[66, 172, 179] Paralysis is also occasionally described as a complication of these ingestions and is presumably a result of cholinesterase inhibition at the neuromuscular junction.[49] Chronic inhalational exposure is associated with occupational asthma.[14] Topical use of the quaternary ammonium compounds can cause contact dermatitis.[151] Few data are available on the toxicity of the newer quaternary ammonium compounds.

Ingestions of other cationic surface-active agents, such as the pyridinium agent cetrimonium bromide (Cetrimide), are associated with caustic burns to the mouth, lips, and tongue.[113] Peritoneal irrigation with cetrimonium bromide can produce metabolic abnormalities, hypotension, and methemoglobinemia.[7, 111]

Intravenous administration of cetrimide produced cardiac arrest, hemolysis, and muscle paralysis.[45]

Management

Treatment recommendations following the ingestion of the quaternary ammonium compounds and other cationic surface-active agents are similar to those for other potentially caustic ingestions. Emergency department evaluation should be considered for all patients who ingest more than a taste of a dilute (less than 1%) solution. Therapy is mainly supportive. Endoscopy may be warranted if symptoms suggest the possibility of a burn injury.

Sterilants

Ethylene Oxide

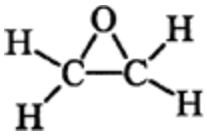


Figure. No Caption Available.

Ethylene oxide is a gas that is commonly used to sterilize heat-sensitive material in healthcare facilities. Unlike antiseptics and disinfectants, which generally do not exhibit full sporicidal activity, sterilants, such as ethylene oxide, inactivate all organisms. Ethylene oxide is also used in the synthesis of many chemicals, including ethylene glycol, surfactants, rocket propellants, and petroleum demulsifiers, and has been used as a pesticide fumigant. Ethylene oxide has a cyclic ester structure that acts as an alkylating agent, reacting with most cellular components, including DNA and RNA.

Medical attention regarding ethylene oxide toxicity has centered on its mutagenic and possible carcinogenic effects.[89] Approximately 270,000 workers (including 96,000 hospital workers) in the United States are at risk for occupational exposure to ethylene oxide.[161] Retrospective studies suggest a possible excess incidence of leukemia and gastric cancer in ethylene oxide-exposed workers.[67, 161] These studies are inconclusive, and the carcinogenicity of ethylene oxide remains subject to debate. It is also suggested that an increased incidence of spontaneous abortions may be associated with occupational exposure to ethylene oxide.[60]

Clinical

The acute toxicity of ethylene oxide is mainly the result of its irritant effects. Conjunctival, upper respiratory tract, GI, and dermal irritation may occur. Dermal burns from acute exposure to ethylene oxide are reported. Acute exposure to a broken ethylene oxide ampule by a 43-year-old recovery room nurse resulted in nausea, light-headedness, malaise, syncope, and recurrent seizures.[145] There were no long-term complications. In another case of acute exposure, coma was followed by an irreversible parkinsonism.[8]

Chronic exposure to high levels of ethylene oxide may cause mild cognitive impairment and motor and sensory neuropathies.[50, 16, 120] The risk of cancer with occupational exposure is low.[27, 160]

Management

Treatment for patients with ethylene oxide exposure is supportive.

Glutaraldehyde

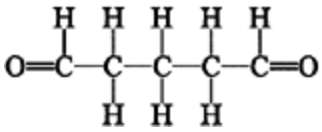

Figure. No Caption Available.

Glutaraldehyde is a liquid solution used in the cold sterilization of nonautoclavable endoscopic, surgical, and dental equipment. It is also employed as a tissue fixative, embalming fluid, preservative, and tanning agent, in radiographic solutions, and in the treatment of warts.[47] Glutaraldehyde is a dialdehyde with two active carbonyl groups that is less volatile than formaldehyde. It kills all microorganisms, including viruses and spores. The germicidal ability of glutaraldehyde results from the alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, within microbes interfering with RNA, DNA, and protein synthesis.[144] It is prepared as a 2% alkaline solution in 70% isopropanol (Cidex). Healthcare workers may be exposed to glutaraldehyde vapors when equipment is processed in poorly ventilated areas, or in open immersion baths or after spills. Under these circumstances, the evaporation of glutaraldehyde may result in the increase in ambient air levels that may easily exceed recommended limits. Approximately 35,000 workers are occupationally exposed to glutaraldehyde.[131] Patients may be exposed when diagnostic instruments are inadequately rinsed following cold sterilization with glutaraldehyde.

Clinical

Clinical signs and symptoms are thought to be comparable to those of formaldehyde exposure although human toxicity data is limited. Animal studies show that glutaraldehyde's inhalational and dermal toxicity is comparable to formaldehyde at equivalent doses.[166]

Glutaraldehyde is a mucosal irritant. Coryza, epistaxis, headache, asthma, chest tightness, palpitations, tachycardia, and nausea are all associated with glutaraldehyde vapor exposure.[12 , 29 , 118 , 126]

Contact dermatitis and ocular inflammation may also occur.[30, 148] Proctitis has been reported following the use of endoscopes contaminated with residual glutaraldehyde solution.[53] The IARC has not ranked the carcinogenic potential of glutaraldehyde.

Management

Treatment recommendations are similar to those for patients with formaldehyde exposure. Prompt removal from the exposure is essential. Copious irrigation with water provides adequate dermal decontamination. Severe inhalational exposures may require hospital admission for observation, supportive care, and treatment of bronchospasm.

Other Products

Boric Acid

Boric acid is an odorless, transparent crystal, although it is most commonly available as a finely ground white powder. It is also commonly found as a 2.5â€“5% aqueous solution. Boric acid (H_3BO_3), prepared from borax (sodium borate; $Na_2B_4O_7 Â·10 H_2O$), was first used as an antiseptic agent by Lister in the late 19th century. Although used extensively over the years for antisepsis and irrigation, boric acid is only weakly bacteriostatic. As a result of its germicidal limitations and its inherent toxicity, boric acid is nearly obsolete in modern antiseptic therapy. Nonetheless, it continues to be used as an antimicrobial to treat such conditions as vulvovaginal candidiasis.[133] Boric acid is also employed in the treatment of cockroach infestation and as a soap, contact lens solution, toothpaste, and food preservative.

Boric acid is readily absorbed through the GI tract, wounds, abraded skin, and serous cavities. Absorption does not occur through intact skin. Boric acid is predominantly eliminated

unchanged by the kidney. Small amounts are also excreted into sweat, saliva, and feces.[46] Boric acid is concentrated in the brain and liver.

The exact mechanism of action of boric acid's toxicity remains unclear. Although it is an inorganic acid, it does not behave as a caustic. Local effects are limited to tissue irritation.

Over the years, boric acid has developed a reputation as an exceptionally potent toxin. This reputation was derived in great part from a series of reports involving neonatal exposures to boric acid resulting in high morbidity and mortality. Life-threatening toxicity resulted from the repetitive topical application of boric acid for the treatment of diaper rash or the use of infant formulas unintentionally contaminated with boric acid.[46 , 180] Fatality rates greater than 50% were reported in some series.[180] Although infants appear to be the most sensitive to the toxic effects of boric acid, many cases of significant adult toxicity are also reported. These cases date predominantly from the time when boric acid was widely used as an irrigant. Routes of exposure to boric acid, resulting in fatalities, include wound irrigation, pleural irrigation, rectal washing, bladder irrigation, and vaginal packing.[171]

Clinical

Classic boric acid poisoning usually involves multiple exposures over a period of days. Gastrointestinal, dermal, CNS, and renal manifestations predominate. The initial symptomsâ€”nausea, vomiting, diarrhea, and occasionally crampy abdominal painâ€”may be confused with an acute gastroenteritis. At times, the emesis and diarrhea are greenish blue.[180] Following the onset of GI symptoms, the majority of patients develop a characteristic intense generalized erythroderma.[180] This rash, described as producing a â€œboiled lobsterâ€• appearance, may appear indistinguishable from toxic epidermal necrolysis or staphylococcal scalded skin syndrome in the neonate.[143] The rash may be

especially noticeable on the palms, soles, and buttocks.[46] Typically, extensive desquamation takes place within 1â€“2 days. On occasion, prominent mucous membrane involvement of the oral cavity and conjunctivae is also apparent.[180] At about the time of the development of the erythroderma, patients, particularly young infants, may develop prominent signs of CNS irritability, resembling meningeal irritation. Seizures, delirium, and coma can occur.[46] Renal injury is common, both a result of the renal elimination of this compound and prerenal azotemia from GI losses.[46] Other complications of boric acid poisoning include hepatic injury, hyperthermia, and cardiovascular collapse. The abandonment of boric acid as an irrigant and particularly its removal from the nursery setting have led to a marked decrease in the incidence of significant boric acid poisoning.

Two retrospective studies on boric acid ingestions suggest that a single acute ingestion of boric acid is generally quite benign.[95, 98] In these studies, 79â€“88% of patients remained asymptomatic. Symptoms, when present, primarily consist of GI irritative symptoms, such as nausea and vomiting. None of the 1184 patients in these two studies manifested the generalized erythroderma so commonly described in previous reports. Central nervous system manifestations of acute overdose were infrequent and limited to occasional lethargy and headache. Renal toxicity did not occur following single acute ingestions.

Several reports suggest, however, that significant toxicity from massive acute ingestion of boric acid can occur. Fatality resulted from a single ingestion of 2 cups (280 g) of boric acid crystals by a 45-year-old man.[139] Symptoms on presentation (2 days after ingestion) included nausea, vomiting, green diarrhea, lethargy, hypotension, renal failure, and a prominent â€œboiled lobsterâ€• rash on his trunk and extremities. In another case, the ingestion of 30 g of boric acid by a 77-year-old man resulted in similar symptoms and death 63 hours postingestion, despite

hemodialysis.[76] The diagnosis of boric acid poisoning can be confirmed with the measurement of blood or serum boric acid levels (normal = 1.4 nmol/mL), but this test is not routinely available.

Long-term chronic exposure to boric acid results in alopecia in adults and seizures in children.[125] A 32-year-old woman who chronically ingested mouthwash containing boric acid over a 7-month period developed progressive hair loss.[165, 166] The chronic application of a borax and honey mixture to pacifiers resulted in the development of recurrent seizures in 9 infants, which resolved after the mixture was withheld.[48, 125]

Management

Treatment of boric acid toxicity is mainly supportive. Activated charcoal is not recommended because of its relatively poor adsorptive capacity for boric acid.[34] In cases of massive oral overdose or renal failure, hemodialysis, or perhaps exchange transfusion in infants, may be helpful in shortening the half-life of boric acid.[98, 169, 180] In patients with normal renal function, forced diuresis enhances renal elimination.[170]

Chlorates

Sodium chlorate is a strong oxidizing agent. At one time, the chlorate salts, sodium chlorate and potassium chlorate, were used as medicinal agents to treat inflammatory and ulcerative lesions of the oral cavity and could be found in various mouthwash, toothpaste, and gargle preparations.[159] Although their use as local antiseptics is obsolete, chlorates are used as herbicides and in the manufacture of matches, explosives, and dyestuffs.[77] More recent cases of chlorate poisoning resulted from the ingestion of the sodium chlorate-containing weed killers, or dispensing errors that confused sodium chlorate with sodium sulfate or sodium chloride.[77] Sodium chlorate in the form of white crystals has also

been mistaken for table sugar.[59] A case of significant toxicity from the inhalation of atomized chlorates is also reported.[77]

Sodium chlorate is rapidly absorbed from the GI tract and eliminated predominantly unchanged from the kidneys.[78] Its systemic effects are chiefly hematologic and renal. Chlorate's major mechanism of toxicity is its ability to oxidize hemoglobin and increase red blood cell membrane rigidity.[152] Consequently, significant methemoglobinemia and hemolytic anemia may result. Chlorates may also be directly toxic to the proximal renal tubule.[91] The hemolytic anemia and the resultant hemoglobinuria may secondarily cause disseminated intravascular coagulation and potentiate renal toxicity. The worsening renal function is especially problematic because of its adverse effect on chlorate elimination. The methemoglobinemia may be severe and cause significant hypoxic stress. Methemoglobinemia may occur prior to or after the development of hemolytic anemia.[119 , 162] Chlorates may also act locally as a GI irritant, and cause mild CNS depression after absorption.[49]

Clinical

Clinical signs and symptoms of chlorate poisoning usually begin 1â€“4 hours after ingestion.[84] The earliest symptoms are GI, including nausea, vomiting, diarrhea, and crampy abdominal pain. Subsequently, the patient may exhibit cyanosis from the methemoglobinemia and black-brown urine from the hemoglobinuria. Obtundation and anuria may ensue. Laboratory studies may show methemoglobinemia, anemia, Heinz bodies, ghost cells, fragmented spherocytes, metabolic acidosis, decreased platelet count, and abnormal coagulation.[41] Hyperkalemia may be particularly problematic if the patient ingests potassium chlorate preparations.[116] In a recent case of chlorate poisoning from the ingestion of 120 potassium chlorate-containing matchsticks, an MRI revealed symmetric abnormal signal intensity within the deep

gray matter and medial temporal lobes.[116] This finding can be explained by the basal ganglia's increased vulnerability to oxygen deprivation. Followup MRI 2 months later was normal.

Management

Treatment of a patient with a significant chlorate ingestion should include orogastric lavage and the use of activated charcoal.[59] It has been suggested that administration of sodium thiosulfate may inactivate the chlorate ion by reducing it to the chloride ion,[59] but an in vitro study did not confirm this hypothesis.[164] Although methylene blue is used in the treatment of symptomatic methemoglobinemia, its efficacy in the treatment of chlorate-induced methemoglobinemia may be limited, as compared to its efficacy in the treatment of other oxidant-induced methemoglobinemias.[119 , 163] This may be a consequence of the inactivation by chlorates of glucose-6-phosphate dehydrogenase, an enzyme that is required for methylene blue to effectively reduce methemoglobin.[152] Exchange transfusion, peritoneal dialysis, and hemodialysis have all been advocated in the treatment of patients with severe chlorate poisoning.[119 , 162] Because the chlorate ion is easily dialyzable, hemodialysis is capable of removing this xenobiotic as well as treating any concomitant renal failure that may have developed.[77 , 84 , 91]

Summary

A chemically diverse group of antiseptic, disinfectant, and sterilant agents exist. Many of the more toxic xenobioticsâ€”such as iodine, phenol, and chloratesâ€”are no longer commonly used as cleansing agents but may still be available in some settings. Formaldehyde exposures, although also uncommon, can also cause significant problems. Frequently employed antiseptics, such as chlorhexidine, pHisoDerm, and many of the currently used quaternary ammonium compounds, have a relatively limited toxicity. Ingestions of the

iodophors do not usually cause significant toxicity, but absorption through other routes may produce significant adverse effects. Ingestions of hydrogen peroxide, particularly the more concentrated formulations, may result in life-threatening injuries.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 99
Camphor and Moth Repellents

Edwin K. Kuffner

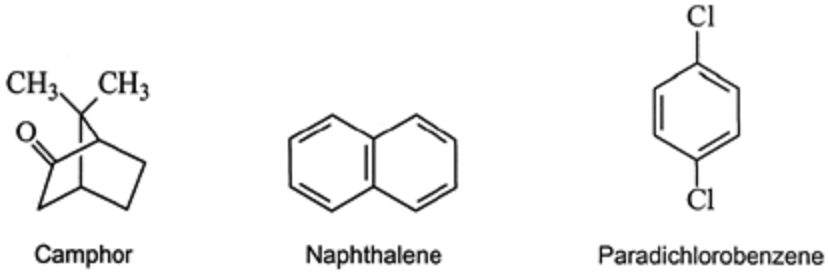

Figure. No Caption Available.

A healthy 3-year-old boy was brought, to the emergency department (ED) with approximately 24 hours of fever as high as 101Â°F (38.3Â°C), nonbloody vomiting, dark urine, yellow eyes, and lethargy. No rhinorrhea, cough, difficulty breathing, diarrhea, or bleeding was reported. He was not taking any medications, and other family members were well. His family history was negative for blood dyscrasias. No history of a toxic exposure was provided.

There was no history of toxic exposure. Physical examination revealed

a pale, jaundiced, and lethargic child. His vital signs were: blood pressure, 72/42 mm Hg; pulse, 138 beats/min; respiratory rate, 44 breaths/min; rectal temperature, 101.5Â°F (38.6Â°C); and an O_2 saturation of 100% on supplemental oxygen. A rapid-bedside blood glucose analysis was 92 mg/dL. There was no evidence of trauma. Ocular examination revealed 4-mm, equally reactive pupils, icteric sclerae, and pale conjunctivae. Mucous membranes were dry. Cardiopulmonary and abdominal examination were normal except for tachycardia and tachypnea. The stool tested negative for occult blood. Strength, sensation, and reflexes were normal.

Initial laboratory evaluation included a complete blood count: white blood cell count of 16,800 cells/mm^3 with 59% neutrophils, 34% lymphocytes, 3% monocytes and 3% eosinophils, a hemoglobin of 10.2 g/dL, a hematocrit of 33% and a platelet count of 314,000 cells/mm^3 . The reticulocyte count was 6.8%. The peripheral smear revealed spherocytosis, anisocytosis, microspherocytosis, Heinz bodies, and red blood cell fragmentation. Methemoglobin level was 2.3%. Both direct and indirect Coombs tests were negative. The serum electrolytes were normal. The total bilirubin was 19 mg/dL with a direct bilirubin of 1.2 mg/dL. Hepatic aminotransferases and alkaline phosphatase were normal. Serum acetaminophen was undetectable. The urine was brown with 0â€“3 red blood cells and, 0â€“3 white blood cells/high power field, and positive for urobilinogen and hemoglobin. A chest radiograph was clear. Cerebrospinal fluid analysis was normal.

The child was treated with intravenous fluids and ceftriaxone and admitted to the intensive care unit. Over the first 2 days of hospitalization, the white blood cell count dropped to 8,800 cells/mm^3 , the hemoglobin to 5.2 g/dL, and the hematocrit to 17%. After 2 units of packed red blood cells were transfused, the hemoglobin increased to 10.5 g/dL and the hematocrit increased to 34%. Blood, urine, and cerebrospinal fluid cultures ultimately showed no growth. The boy's bilirubin gradually decreased over the first week. Both his red blood cell count and his bilirubin normalized after 3 weeks.

A child care provider eventually admitted that the boy was found playing with mothballs 2â€“3 days prior to the onset of illness. The number of mothballs, if any, that the child may have ingested could not be determined. After the additional history was obtained, a urine specimen obtained on the day of the boy's presentation was analyzed and naphthol, a metabolite of naphthalene, was detected, supporting the diagnosis of naphthalene-induced hemolysis. Glucose-6-phosphate dehydrogenase activity, tested 3 months after the exposure, was normal.

Many different products have historically been used as moth repellents. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene as the most common active component of moth repellent and moth flakes because of its decreased toxicity. However, because paradichlorobenzene is widely available and because life-threatening camphor and naphthalene

toxicity still occur, all of these xenobiotics need to be considered in evaluating possible exposure moth repellent.

Camphor

History and Epidemiology

Camphor (2-bormanone, 2-camphonone), a cyclic ketone of the terpene group, is an essential oil distilled from the bark of the camphor tree, *Cinnamomum camphora.* Today, most camphor is synthesized from the hydrocarbon pinene, a derivative of turpentine oil. Camphor has been used as an aphrodisiac, contraceptive, abortifacient, suppressor of lactation, analeptic, cardiac stimulant, antiseptic, cold remedy, muscle liniment, and drug of abuse.[23 , 28 , 33 , 38 , 50]

Camphorated oil and camphorated spirits contain varying concentrations of camphor. Historically, most camphorated oil was

20% weight (of solute) per weight (of solvent) (w/w) camphor with cottonseed oil, and most camphorated spirits contained 10% w/w camphor with isopropyl alcohol. Toxicity and death following ingestion of camphorated oil, which was confused with castor oil and cod liver oil, prompted the FDA to ban the nonprescription sale of camphorated oil in the United States in 1983.[3,17,33,53,69] Today, based on the 1983 FDA ruling, nonprescription camphor-containing products may not have greater than an 11% concentration of camphor. Camphorated oil is still used as an herbal remedy and muscle liniment, and products containing greater than 11% camphor can still be purchased outside of the United States.[66]

Common camphor-containing products include cold sore ointments (usually <1% camphor), muscle liniments, rubefacients (usually 4â€“7% camphor), and camphor spirits (usually 10% camphor). Paregoric, camphorated tincture of opium, contains a combination of anhydrous morphine (0.4 mg/mL), alcohol (46%), and benzoic acid (4 mg/mL) but only a small amount of camphor.[36] Camphor for industrial use can be purchased legally in the United States and contains up to 100% camphor. Occupational exposures to camphor occur during the manufacture of plastic, celluloid, lacquer, varnish, explosives, embalming fluids, and numerous pharmaceuticals and cosmetics.[29]

Although products containing lower concentrations of camphor are implicitly safer, life-threatening toxicity and death still result, usually from misuse or intentional overdose. Most reported cases of acute camphor poisoning are unintentional ingestions of camphor-containing liquids mistaken for other medications.[3,33,52,67] According to data obtained by the American Association of Poison Control Centers (AAPCC), between 1998 and 2003 there were fewer than 50 reports of â€œmajorâ€• toxicity secondary to camphor. Over the past 20 years, according to the AAPCC, only 5 reported deaths were attributable to camphor, all in adults, at least 2 of which occurred in the setting of an intentional suicidal overdose. Chapter 130 contains complete references and discussion of the AAPCC data.

Pharmacology

Camphor is a colorless glassy solid. Camphor's pharmacologic activity is not well studied and its mechanism of action remains unclear. It is unlikely that camphor has therapeutic benefit as an expectorant or an antiinfective agent. Camphor may provide some local analgesic and antipruritic effects, but much safer drugs are available for these indications. No therapeutic benefit of camphor has been proven in any well-controlled clinical trials.

Pharmacokinetics and Toxicokinetics

There are limited data on the pharmacokinetics and toxicokinetics of camphor. Toxicity is reported following ingestion, dermal application, inhalation, intranasal instillation, intraperitoneal administration, and transplacental transfer.[11, 54, 57, 63, 64, 71] Camphor from liquid preparations is rapidly absorbed from the gastrointestinal tract and camphor can be detected in the blood within 15â€“20 minutes postingestion.[54] Camphor is highly lipid soluble and is predominantly metabolized in the liver where it undergoes hydroxylation followed by conjugation with glucuronic acid. Inactive metabolites, including campherol, borneol, hydroxy-camphor, and camphoglycuronic acid, are excreted by the kidneys.[55]

As with many xenobiotics, the toxic dose of camphor reported in the medical literature is highly variable.[25, 33, 62] As little as 1 teaspoon (1 g) of 20% camphorated oil caused death in an infant.[62] Workplace standards include the Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL), which is 2 mg/m^3, the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV), which is 12 mg/m^3 (2 ppm), and the ACGIH short-term exposure limit (STEL), which is 19 mg/m^3 (3 ppm).

Pathophysiology

The mechanism of toxicity of camphor is unknown. Camphor is an

irritant. Pathologic changes following ingestion include cerebral edema, neuronal degeneration, fatty changes, centrilobular congestion of the liver, and hemorrhagic lesions in the skin, gastrointestinal tract, and kidneys.[34 , 62 , 71]

Clinical Manifestations

Exposure to camphor can often be detected by its characteristic aromatic odor (Chap. 21). Ingestion of camphor typically produces oropharyngeal irritation, nausea, vomiting, and abdominal pain. Generalized tonicâ€“clonic seizures may be the first sign of camphor toxicity, usually occurring within 1â€“2 hours postingestion.[5 , 7] Most seizures are brief and self-limited, although some patients may have a more protracted course.[5 , 40 , 63] Central nervous system (CNS) depression is common, but rarely compromises respiratory function.[11 , 39] Other neurologic effects include headache, lightheadedness, transient visual changes, confusion, myoclonus, and hyperreflexia.[37 , 54 , 57] Psychiatric effects include agitation, anxiety, and hallucinations.[25 , 37 , 39] Dermal effects include flushing and petechial hemorrhages.[11 , 28 , 64] Camphor does not cause life-threatening cardiovascular effects.[28] Death is reported secondary to respiratory failure or seizures.[11]

Case reports suggest that acute ingestion of camphor can cause transient elevations of the hepatic aminotransferases.[3 , 34 , 62 , 54 , 57] Chronic administration of camphor to a child caused altered mental status and elevated hepatic aminotransferases suggestive of Reye syndrome.[34] When hepatotoxicity occurs, however, camphor does not typically produce morphologic changes of the liver characteristic of Reye syndrome. Albuminuria can also occur.[62]

Camphor crosses the placenta. Both fetal demise and delivery of healthy neonates are reported in mothers who develop camphor toxicity within 24 hours of term delivery.[8 , 54 , 71] Specific dose-related toxicity could not be determined from these case reports.

Inhalational and dermal exposure from camphor usually produces only mucous membrane and dermal irritation, respectively.[24]

Diagnostic Testing

When managing most patients with camphor toxicity, no specific toxicologic diagnostic testing is indicated. Although camphor and its metabolites can be identified in blood and urine, concentrations are not useful in most cases of acute toxicity because they are not readily available and have not been proven to correlate with clinical toxicity.[28 , 38 , 55]

Management

The patients who should be evaluated in a healthcare facility after an acute ingestion include those who have signs or symptoms consistent with camphor toxicity, those who have ingested more than 1 g of camphor (1 teaspoon of 20% camphorated oil or approximately 2 teaspoons of 11% camphorated oil), suicidal patients, and any patient with a high occupational exposure.

Gastric decontamination is not well studied in patients who have ingested camphor. If lavage is deemed necessary following recent ingestion of a camphor-containing solution, nasogastric suctioning and lavage are preferable to orogastric lavage. Because camphor-containing solutions are so rapidly absorbed, the benefit of gastrointestinal decontamination is expected to rapidly diminish as the time following ingestion increases. Emetic agents should not be administered because camphor-induced seizures can occur rapidly prior to the onset of emesis, raising the risk of pulmonary aspiration. Although not of proven efficacy, administration of activated charcoal, 1 g/kg, is also reasonable because it is considered safe. There is no antidote for camphor. Most patients survive with supportive care. Although the management of camphor-induced seizures is not well

studied, patients should be treated with benzodiazepines. Repeat doses of benzodiazepines may be needed to control seizures. If benzodiazepines fail to control seizures, other sedative-hypnotic agents, including phenobarbital, pentobarbital, and propofol, should be administered. Case reports suggest that most patients who develop life-threatening camphor toxicity develop symptoms within a few hours postexposure. Based on this, an observation period of at least 2â€“4 hours following a potentially toxic ingestion of camphor is reasonable.

In case reports, hemodialysis with a lipid dialysate and either hemoperfusion using an Amberlite resin or charcoal hemoperfusion successfully removed camphor.[3,21,39,40,44] Neither isolated lipid hemodialysis nor lipid dialysis in combination with hemoperfusion is routinely recommended or widely available.

Naphthalene

History and Epidemiology

Historically, naphthalene toxicity has resulted from its use as an antihelminthic and an antiseptic.[61] Toilet-bowl and diaper-pail deodorizers containing naphthalene have also caused toxicity.[10,75] Naphthalene is the single most abundant component of coal tar and is a component of petroleum. Occupational exposures to naphthalene may occur during the manufacture of dyes, synthetic resins, celluloid, solvents, and fuels.

Most unintentional exposures to naphthalene-containing moth repellents occur in children and do not cause life-threatening toxicity. According to Toxic Exposure Surveillance System (TESS) data from the AAPCC, between 1998 and 2003 there were approximately 9000 exposures to naphthalene, no deaths, and 15 cases of â€œmajor toxicityâ€• (see Chap. 130 for complete references).

Pharmacology, Pharmacokinetics, and Toxicokinetics

Naphthalene ($C_{10}H_8$), an aromatic bicyclic hydrocarbon, is a white, flaky crystalline solid with a noxious odor. Synonyms include white tar and tar camphor. Naphthalene toxicity is reported following ingestion, dermal application, and inhalation.[12,14,16,56,70] Although the absorption of naphthalene is not well studied, highly lipid-soluble compounds may increase both oral and dermal absorption.

Naphthalene is slowly metabolized in the liver to Î±- and Î²-naphthol and to Î±- and Î²-naphtholoquinone.[53] These hepatic metabolites, primarily Î±-naphthol, but not the parent compound,[53,74] cause the oxidant stress responsible for naphthalene-induced hemolysis and methemoglobinemia. As with most xenobiotics, the toxic amount of naphthalene reported in the medical literature is highly variable. As little as one naphthalene mothball has resulted in toxicity, including hemolysis in an infant.[20,75] Workplace standards include the OSHA PEL and ACGIH TLV, which are 50 mg/m^3 (10 ppm), and the ACGIH STEL, which is 75 mg/m^3 (15 ppm).

Pathophysiology

To understand naphthalene-induced hemolysis and methemoglobinemia, it is important to understand how oxidant stress affects erythrocytes and the normal mechanisms erythrocytes use to prevent and reverse the effects of oxidant stress.

Oxidant stressors can cause methemoglobinemia and/or hemolysis. When oxidant stress causes an iron atom from any of the 4 globin chains of hemoglobin to be oxidized from the ferrous state (Fe^{2+}) to the ferric state (Fe^{3+}) state, methemoglobin is formed (Chap. 122). When oxidant stress causes hemoglobin denaturation, the heme groups and the globin chains dissociate and precipitate in the erythrocyte, forming Heinz bodies. An erythrocyte with denatured hemoglobin is more susceptible to hemolysis and to removal by the

reticuloendothelial system (Chap. 24).

Hemolysis and methemoglobinemia can occur independently of each other or simultaneously in patients with either normal or deficient glucose-6-phosphate dehydrogenase activity.[20 , 32 , 70 , 75]

Theoretically, patients with glucose-6-phosphate dehydrogenase deficiency are at increased risk for both hemolysis and methemoglobinemia following oxidant stress. In practice, however, patients with glucose-6-phosphate deficiency are at much greater risk of xenobiotic-induced hemolysis than of xenobiotic-induced methemoglobinemia.

Patients with known glucose-6-phosphate dehydrogenase (G6PD) deficiency are at increased risk for hemolysis because they have decreased glutathione stores.[74 ,87] Glucose-6-phosphate deficiency affects all races but is most prevalent in Africans, African Americans, and patients of Mediterranean and Asian descent. The gene that codes for G6PD is X-linked; consequently, males are affected more often than females.

Infants are also at increased risk of methemoglobinemia because fetal hemoglobin is more susceptible to the formation of methemoglobin and also because nicotinamide adenine dinucleotide (NADH) methemoglobin reductase activity is decreased, impairing the reduction of methemoglobin to hemoglobin.[35]

Clinical Manifestations

Both acute and chronic exposures to naphthalene result in similar toxicity.[10 , 74] Ingestion and inhalational exposures to naphthalene

commonly cause headache, nausea, vomiting, diarrhea, abdominal pain, fever, and altered mental status.[10 , 43 , 48] Dermal exposure results in dermatitis.[23]

Hemolysis or methemoglobinemia usually becomes clinically evident, as early as 24â€“48 hours postexposure, but more typically on the

third day postexposure because of the time necessary for the metabolism of naphthalene.[14] Anemia secondary to hemolysis often does not reach its nadir until 3â€“5 days postexposure.

Signs and symptoms of hemolysis and methemoglobinemia are nonspecific and include tachycardia, tachypnea, shortness of breath, generalized weakness, decreased exercise tolerance, and altered mental status. Methemoglobinemia may produce cyanosis, whereas hemolysis may produce pallor and jaundice (Chap. 122). Renal failure as a complication of naphthalene-induced hemolysis and hemoglobinuria is reported. Naphthalene or its metabolites cross the placenta.[4] Naphthalene pica during pregnancy causes both maternal and fetal toxicity. Children born to mothers who were experiencing naphthalene toxicity at the time of delivery have developed hemolytic anemia believed to be related to the maternal naphthalene exposure.[74]

Diagnostic Testing

No specific diagnostic testing is indicated, although both naphthalene and its metabolites can be identified in blood and urine. Identification of 1-naphthol and 2-naphthol in the urine can confirm exposure to naphthalene;[49] qualitative or quantitative testing for naphthalene or its metabolites is rarely clinically indicated when managing a case of an acute overdose.

The presentation of naphthalene-induced hemolysis is similar to that of hemolysis from other causes. Reticulocytosis occurs as a response to restore a normal hemoglobin concentration. Hyperbilirubinemia from hemolysis is characterized by an elevation of the indirect bilirubin (unconjugated bilirubin) and a relatively normal direct fraction. Serum haptoglobin is usually low because the haptoglobinâ€“ hemoglobin complex is cleared by the kidneys. Both the direct and indirect Coombs tests are negative in naphthalene-induced hemolytic anemia. Lactate dehydrogenase is elevated because it is released from hemolyzed red blood cells. Gross or microscopic hemoglobinuria is

confirmed by a urine dipstick that reacts strongly positive for hemoglobin with a paucity of red blood cells on microscopic examination of the urine sediment. This should be differentiated from myoglobinemia by measuring the serum creatine phosphokinase, which will be elevated in patients with rhabdomyolysis and myoglobinuria.

Examination of a peripheral blood smear can reveal evidence of hemolysis before a patient develops clinical or laboratory evidence of anemia. The peripheral smear may reveal red blood cell (RBC) fragmentation, anisocytosis, microspherocytosis, reticulocytosis, nucleated RBCs, and Heinz body formation (Chap. 24). Peripheral smear abnormalities and anemia may occur within the first 24 hours following ingestion.[10 , 58 , 74 , 75] Testing for G6PD activity is not routinely recommended during an acute episode of hemolysis. Reticulocytes have higher G6PD activity than do older RBCs. If G6PD activity is measured during an episode of hemolysis when many of the older RBCs have already been destroyed, the G6PD activity may be falsely normal. It is best to delay testing for G6PD activity for a few months following an episode of hemolysis. Family members of patients with life-threatening G6PD deficiency should also be tested.

Naphthalene-induced methemoglobinemia is similar in presentation to methemoglobinemia from other xenobiotics. The percentage of methemoglobin can rapidly be determined using a cooximeter (Chap. 122).

Management

Most patients with an unintentional exposure to all or part of one naphthalene-containing mothball or do not require medical evaluation. Patients who should be evaluated in a healthcare facility following an acute ingestion include those who recently ingested more than one naphthalene-containing mothball equivalent, those with signs or symptoms of toxicity, especially hemolysis and/or methemoglobinemia, those with known or suspected G6PD deficiency,

all intentional ingestions, and those patients with large inhalational exposures, especially after exposure occurs in an occupational setting.

Gastrointestinal decontamination is not well studied in patients who have ingested naphthalene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Emesis may be useful following ingestion of multiple naphthalene-containing mothballs in children, provided it can be administered within 30â€“60 minutes postingestion. Administration of activated charcoal, 1 g/kg, although not of proven efficacy, is also reasonable because it is considered safe. Repeat doses of activated charcoal 0.5 g/kg and/or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution would only be indicated for patients with large ingestions of naphthalene who are expected to have significant ongoing absorption of naphthalene within the gastrointestinal tract.

Diagnostic testing within the first 24â€“48 hours postexposure may detect the onset of methemoglobinemia and/or hemolysis before a patient becomes symptomatic. Most low-risk patients who are asymptomatic within the first 24â€“48 hours postexposure and who have no laboratory evidence of hemolysis or methemoglobinemia can be managed as outpatients if reevaluation within 24 hours can be arranged. Patients who are discharged should be instructed to return if they become symptomatic. High-risk patients, patients with laboratory evidence of hemolysis and/or methemoglobinemia and patients who cannot reliably be managed as outpatients should be admitted.

Patients with life-threatening hemolysis and anemia should be transfused with packed red blood cells. However, most patients with functioning bone marrow are able to compensate for the hemolysis by increasing reticulocytosis and will not require a transfusion. Patients with symptomatic methemoglobinemia should receive methylene blue, 1â€“2 mg/kg (0.1â€“0.2 mL/kg of a 1% solution) intravenously. Repeat doses may be necessary (see Antidotes in Depth: Methylene Blue).

Paradichlorobenzene

History and Epidemiology

Paradichlorobenzene is widely used as a deodorizer, disinfectant, repellent, fumigant, insecticide, fungicide, and industrial solvent. Today, paradichlorobenzene is the most common component of moth repellents. Exposure to paradichlorobenzene in the United States is extremely common. A 1995 study suggested that 2,5-dichlorophenol, a metabolite of paradichlorobenzene, was detectable in the urine in 98% of the US population.[31]

Most unintentional exposures to paradichlorobenzene-containing moth repellents occur in children and do not cause toxicity. According to the TESS data by the AAPCC, there have been no deaths and

no reports of major toxicity from paradichlorobenzene between 1998 and 2003.

Pharmacology, Pharmacokinetics, Toxicokinetics, and Pathophysiology

Paradichlorobenzene ($C_6 H_4 Cl_2$) is a colorless solid with a noxious odor. It is available as pure white crystals, as a solid in combination with other chemicals, or as a liquid dissolved in volatile solvents or oil. The mechanism for the effects, pharmacology, and toxicokinetics of paradichlorobenzene have not been studied. Although rare, paradichlorobenzene toxicity has been reported following ingestion and inhalation.[31, 45] Workplace standards include the OSHA PEL and ACGIH TLV, which are 450 mg/m^3 (75 ppm), and the ACGIH STEL, which is 675 mg/m^3 (110 ppm).

Clinical Manifestations

Inhalation of paradichlorobenzene may cause nausea and vomiting, headache, and mucous membrane irritation.[13,31]

Only a single case report links acute ingestion of a moth repellent, purportedly containing paradichlorobenzene with hemolysis. The demothing agent itself was not confirmed to be paradichlorobenzene.[26]

Case reports associate chronic exposure to paradichlorobenzene with weight loss, ataxia, pulmonary granulomatosis, dyspnea, hepatotoxicity, anemia, and fixed drug eruptions.[9,13,18,45,46,65,72]

Diagnostic Testing

Both paradichlorobenzene and its metabolite, 2,5-dichlorophenol, can be identified in blood and urine following exposure. Identification of 2,5-dichlorophenol can confirm exposure to paradichlorobenzene. Quantifying the amount of paradichlorobenzene in the urine of workers may be useful for monitoring occupational exposures.[19] Qualitative or quantitative testing for paradichlorobenzene or its metabolites is not generally indicated when managing a patient with an acute overdose.

Management

Referral to a Healthcare Facility

Most unintentional exposures to paradichlorobenzene do not cause life-threatening toxicity. Thus most asymptomatic patients with unintentional exposures can be managed as outpatients. Patients who should be evaluated in a healthcare facility include those with clinical signs or symptoms, suicidal patients, and patients who have sustained a large exposure.

Gastrointestinal Decontamination

Gastrointestinal decontamination has not been studied in patients who ingest paradichlorobenzene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Administration of activated charcoal, 1 g/kg, although not studied, is

reasonable for patients with large, intentional ingestions.

Moth Repellent Recognition

Healthcare providers occasionally must determine whether a mothball is made of naphthalene, paradichlorobenzene, or camphor. When the container is unavailable, as is often the case, mothballs are difficult to distinguish based on appearance, odor, texture, or size. Most mothballs are white, crystalline, and have a noxious

odor.[73] Camphor moth repellents are more oily than both naphthalene and paradichlorobenzene mothballs. If controls are available, moth repellents can often be differentiated based on their odor and texture.[1] Although most new paradichlorobenzene moth repellents are slightly larger than most new naphthalene moth repellents, all moth repellents shrink over time when exposed to air, making size an unreliable differentiating characteristic. Identifying a moth repellent as paradichlorobenzene can often result in outpatient management, saving both money and undue worry. The tests described in Table 99-1 and shown in Figure 99-1 might allow rapid identification of the component of an unknown moth repellent. When performing these tests it is most helpful to have camphor, naphthalene, and paradichlorobenzene controls available for comparison.

Summary

Historically, the most common components of moth repellents are camphor, naphthalene, and paradichlorobenzene. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene. If an unknown moth repellent can be identified as paradichlorobenzene, limited toxicity is expected following an acute exposure. It is important for clinicians to understand how to use simple tests to identify the component of an unknown mothball. Because life-threatening camphor and naphthalene toxicity are still reported, it is important for clinicians to understand how to manage

patients exposed to both of these xenobiotics.

Chapter 100
Caustics

Jessica A. Fulton

Rama B. Rao

A 20-year-old man ingested a cup of liquid drain opener (100% sodium hydroxide) in an attempted suicide. He presented to the emergency department (ED) 4 hours later complaining of oropharyngeal, chest, and abdominal pain. His vital signs were: blood pressure, 130/80 mm Hg; pulse 100 beats/min; respiratory rate, 22 breaths/min; and temperature, 99Â°F (37.2Â°C). His lips, tongue, and oral cavity were erythematous and swollen with evidence of significant epithelial sloughing (Fig. 100-1). He was drooling, but had no stridor and his lungs were clear. His heart was regular in rhythm without murmurs or gallops. Bowel sounds were present and his abdomen was soft with mild epigastric tenderness. His stool was negative for occult blood. The patient's extremities were warm and well perfused, and his neurologic examination was unremarkable.

Two large-bore intravenous lines were inserted and 0.9% sodium chloride was infused at 250 mL/h. Blood was sent for serum

electrolytes, complete blood count, platelet count, coagulation profile, type and cross-match, and arterial blood gas analysis. Chest and abdominal radiographs were unremarkable. A fiberoptic inspection of the oro- and nasopharynx revealed laryngeal and cricopharyngeal burns, prompting nasotracheal intubation with an intubating bronchoscope. The arterial blood gas analysis revealed: pH, 7.30; PCO_2, 30 mm Hg; and PO_2, 88 mm Hg. Subsequent upper gastrointestinal endoscopy performed revealed a grade IIa noncircumferential burn of the midesophagus, a grade IIb circumferential burn of the distal esophagus, and ulcerations penetrating the mucosal surface of the gastric antrum (Fig. 100-2). Over the next few hours his vital signs remained unchanged, as did the rest of his physical examination.

The patient was started on IV steroids (methylprednisolone 40 mg every 8 hours) and IV antibiotics (piperacillin/tazobactam 3.375 g every 6 hours and vancomycin 1 g every 12 hours) and was transferred from the ED to the intensive care unit. Following intensive medical care for 1 week, and surgical release of oral cavity contractures, he was extubated and able to tolerate clear liquids by mouth within 2 weeks. He was discharged with both medical and psychiatric followup care after several weeks in the hospital.

History and Epidemiology

Caustics cause both clinical and histologic damage on contact with tissue surfaces. Table 100-1 lists common caustics and the commercial products that contain them. They are available, many for home use, in both solid and liquid forms, with variations in viscosity, concentration of solution, and pH.

As early as 1927, regulatory legislation in the United States governing the packaging of lye- and acid-containing products mandated that warning labels be placed on products containing these xenobiotics. In response to the recognition that caustic

exposures were more frequent in children, in 1970 the Federal Hazardous Substances Act and Poison Prevention Packaging Act was passed stating that all caustic agents with a concentration >10% must be placed in child-resistant containers. By 1973, the household concentration for child-resistant packaging was lowered to 2%. In addition, the subsequent development of poison prevention education has led to a dramatic decrease in the incidence of unintentional caustic injuries in children in the United States. The positive impact of both regulatory legislation and education is evident when observing the decrease of exposures in the United States compared to the number of exposures in developing nations that lack these policies.

Usually, children are unintentionally exposed to household products. Adults may be exposed to household or industrial products that result in either occupational exposure or are used in suicide attempts.

Although less frequent, intentional exposures by adults are invariably more significant. One study noted that although children comprised 39% of admissions for caustic ingestions, adults comprised 81% of patients requiring treatment.[45] The severity of a caustic injury may not be immediately evident in patients who present shortly after exposure. Predicting which patients will require immediate interventions to prevent morbidity and mortality requires multiple clinical and laboratory parameters. This chapter reviews the pathophysiology and approach to patients with potentially serious exposures.

Pathophysiology

A caustic is a xenobiotic that causes both functional and histologic damage on contact with tissue surfaces. Although there are many ways to categorize caustics, they are most typically classified as acids or alkalis. An acid is a proton donator[78] and causes significant injury, generally at a pH below 3. An alkali is a proton

acceptor[78] and causes significant injury, generally at a pH above 11. The extent of injury is determined by duration of contact; ability of the substance to penetrate tissues; volume, pH, and concentration; the presence or absence of food in the stomach; and a property known as titratable acid or alkaline reserve (TAR). TAR quantifies the amount of neutralizing xenobiotic needed to bring the pH of a

caustic to that of physiologic tissues. Neutralization of caustics takes place at the expense of the tissues, resulting in the release of thermal energy, producing burns. Generally, as the TAR of caustics increases, so does their ability to produce tissue damage.[6,11,30,43,48,93] Some xenobiotics, such as zinc chloride and phenol, have a high TAR and are capable of producing severe burns even though they possess a near-physiologic pH. Chapter 12 contains a more detailed discussion of the chemistry of acids and bases.

Figure 100-1. Photograph demonstrating burns to the lips and tongue of a 20-year-old man following ingestion of 100% sodium hydroxide.

Alkalis

Following exposure to an alkaline xenobiotic, dissociated hydroxide (OH^-) ions penetrate tissue surfaces producing what is histologically described as liquefactive necrosis. This process includes protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, transmural thrombosis, and cell death.[6,43] Animal studies following alkali exposure to the eye[47] demonstrate rapid formation of corneal epithelial defects with eventual deep penetration that may lead to perforation. Similarly, animal studies of the esophagus demonstrate that erythema and edema of the mucosa occur within seconds followed by an inflammatory reaction extending to the submucosa and muscular layers. The alkali, such as sodium hydroxide (â€œliquid lyeâ€•), then continues to penetrate until the OH^- concentration is sufficiently neutralized by the tissues.[6,61,65,114]

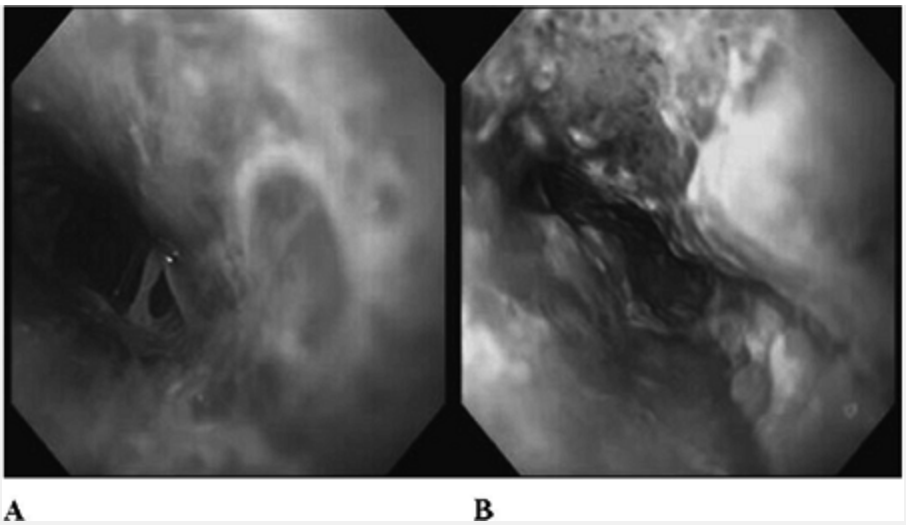

Figure 100-2. Endoscopy images of a 20-year-old man following ingestion of 100% sodium hydroxide. A. Grade IIa noncircumferential burn of the midesophagus B. Grade IIb circumferential burn of the distal esophagus.

TABLE 100-1. Sources of Common Caustics

Chemical	Applications
Acetic acid	Permanent wave neutralizers, photographic stop bath
Ammonia (ammonium hydroxide)	Toilet bowl cleaners, metal cleaners and polishes, hair dyes and tints, antirust products, jewelry cleaners, floor strippers, glass cleaners, wax removers

Benzalkonium chloride	Detergents
Boric acid	Roach powders, water softeners, germicide
Formaldehyde, formic acid	Deodorizing tablets, plastic menders, fumigant, embalming agent
Hydrochloric acid (muriatic acid)	Metal and toilet bowl cleaners
Hydrofluoric acid	Antirust products, glass etching, microchip etching
Iodine	Antiseptics
Mercuric chloride ($HgCl_2$)	Preservative
Methylethyl ketone peroxide	Industrial synthetic agent
Oxalic acid	Disinfectants, household bleach, metal polish, antirust products, furniture refinisher
Phenol (creosol, creosote)	Antiseptics, preservatives

Phosphoric acid	Toilet bowl cleaners
Phosphorus	Matches, fireworks, rodenticides, methamphetamine synthesis
Potassium permanganate	Illicit abortifacient, antiseptic solution
Selenious acid	Gun bluing agent
Sodium hydroxide	Detergents, Clinitest tablets, paint removers, drain cleaners and openers, oven cleaners
Sodium borates, carbonates, phosphates, and silicates	Detergents, electric dishwasher preparations, water softeners
Sodium hypochlorite	Bleaches, cleansers
Sulfuric acid	Automobile batteries, drain cleaners
Zinc chloride	Soldering flux

Although federal regulations have lowered the maximal available household concentration of many caustics, there are two products of industrial strength that seem to be readily available and therefore warrant special mention: ammonium hydroxide and

sodium hypochlorite. Ammonia (ammonium hydroxide) products are weak basesâ€”partially dissociated in waterâ€”that can cause significant esophageal burns, depending on the concentration and volume ingested.[45,105,112,114] Household ammonium hydroxide ranges in concentration from 3â€“10%. Strictures have formed in patients who ingested 28% solutions.[87] Sodium hypochlorite (bleach) is the major component in most industrial and household bleach preparations. Large case series and reports have found that grades II and III injuries occur only in patients with large-volume ingestions of concentrated products[24] and that most other patients do well with supportive care.[17,45,111] A series of 393 patients with household bleach ingestions demonstrated no stricture formation,[64] and

a canine model found that although vomiting was a common effect of bleach, no esophageal lesions were noted, and perforation only occurred following prolonged contact.

Historically, ingestion of button batteries has been considered a unique caustic exposure. Composed of metal salts and a variety of alkaline xenobiotics, such as sodium and potassium hydroxide, leakage of battery contents was a legitimate concern. In recent years, however, new techniques used in the production of button batteries that effectively prevent leakage of battery contents within the gastrointestinal tract have shifted the concern following their ingestion from caustic to foreign-body exposure. For a more in depth review of the management of button battery ingestion, the reader is referred to the literature and the previous editions of this text.

Household detergents, such as laundry powders and dishwasher detergents, contain silicates, carbonates, and phosphates, and have the potential to induce caustic burns and strictures even when ingested unintentionally.[18,112] Airway compromise also can occur,[18,27,71] but the majority of exposures result in only minor toxicity.

Cationic detergents include quinolinium compounds, pyridinium compounds, and quaternary ammonium agents. These are frequently found in products for industrial use, as well as household fabric softeners. A concentration >7.5% can cause severe burns.[69] These xenobiotics bind well to activated charcoal;[69] however, because no large series has been evaluated with this therapy, all patients with symptoms or signs of caustic injury, intentional ingestions, or exposures to concentrations >7.5% should be evaluated endoscopically and activated charcoal should be avoided.[69]

Acids

In contrast to alkaline exposures following exposure to an acid, hydrogen (H^+) ions desiccate epithelial cells, producing an eschar and resulting in what is histologically referred to as coagulation necrosis. This process leads to edema, erythema, mucosal sloughing, ulceration, and necrosis of tissues. Dissociated anions of the acid (Cl^-, SO_4^{2-}, PO_4^{3-}) also act as reducing agents further injuring tissue.

Ophthalmic exposure to acids results in coagulative necrosis that tends to prevent further penetration into deeper layers of the eye.

In most series, following an acid ingestion, both the gastric and esophageal mucosa are equally affected.[25,54,128] On occasion, the esophagus may be spared damage while severe injury is noted in the stomach.[21,40,45,112] (See ILCAUSTICS1 in the Image Library at http://www.goldfrankstoxicology.com). This tends to be a rarer finding than concomitant injury to both stomach and esophagus, and is probably related to the rapid transit time of liquid acids through the upper gastrointestinal tract. Skip lesions from acid ingestions may be a function of viscosity and contact time.[45] Additionally, acid-induced pylorospasm may lead to gastric outlet obstruction, antral pooling, and

perforation.[16,21,24,25,40,54,62,63,74,85,110,111,124,127] A cat model of the effects of sulfuric acid on the esophagus revealed a coagulative necrosis of the mucosa with whitish discoloration of the tissues and underlying smooth muscle spasm.[6] Other animal models demonstrate esophageal motility dysfunction and shortening.[108,109]

Chapters 92 and 101 contain a more detailed discussion of mercury and hydrofluoric acid, respectively, each a uniquely caustic compound, and the management specific to their exposure.

Classification and Progression of Caustic Injury

Esophageal burns, secondary to both alkali and acid exposures, are classified based on endoscopic visualization that employs a grading system similar to that used with burns of the skin. Grade I burns are generally described as hyperemia or edema of the mucosa without evidence of ulcer formation.[20,60,127] Grade II burns include submucosal lesions, ulcerations, and exudates. Some authors further divide grade II lesions into grade IIa, noncircumferential lesions, and grade IIb, near-circumferential injuries.[17] Grade III burns are defined as deep ulcers and necrosis into the periesophageal tissues.[33,37,44,60]

Human case reports, postmortem studies, histologic inspection of surgical specimens and experimental animal models reveal a consistent pattern of injury and repair following caustic injury.[1,31,38,72,80,102] As wound healing of gastrointestinal tract tissue occurs, neovascularization and fibroblast proliferation take place, laying down new collagen and replacing the damaged tissue with granulation tissue. A similar pattern of repair occurs following caustic injuries of the eye.

Burns of the esophagus may persist for up to 8 weeks as remodeling takes place, and may be followed by esophageal

shortening.[122] If the initial injury penetrates deeply enough, there is progressive narrowing of the esophageal lumen. The dense scar formation presents clinically as a stricture.[22,43] Strictures can evolve over a period of weeks to months, leading to dysphagia and significant nutritional deficits.[98,103,122] Grade I burns carry no risk of stricture formation.[20,60,127] Grade II circumferential burns lead to stricture formation in approximately 75% of cases. Grade III burns invariably progress to stricture formation and are also at a high risk of perforation.[4,45,80]

Clinical Presentation

The gastrointestinal tract, respiratory tract, eyes, and skin of a patient can be sites of caustic injury. Caustics may produce severe pain on contact with any of these tissues. By far, the majority of long-term morbidity and mortality from caustic exposure results from oral ingestion.

In general, patients who have ingested alkaline or acid agents have similar initial presentations. Depending on the type, amount, and formulation (solid vs. liquid) of the substance, ingestion may lead to the development of severe pain of the lips, mouth, throat, chest, or abdomen. Oropharyngeal edema and burns may lead to drooling and rapid airway compromise. Symptoms of esophageal involvement include dysphagia and odynophagia, whereas epigastric pain and hematemesis may be symptoms of gastric involvement.

Respiratory tract damage may occur through direct inhalation or aspiration of vomitus leading to the clinical manifestations of hoarseness, stridor, and respiratory distress. Injury may result in epiglottitis, laryngeal edema and ulceration, pneumonitis, and impaired gas exchange. Patients may also be tachypneic or hyperpneic as a compensatory response to the metabolic acidosis generated by elevated lactate from necrotic tissue or hemodynamic compromise.

Predictors of Injury

Many attempts have been made to define a method for clinical identification of patients with grade II or III esophageal injuries as

these injuries typically progress to severe complications. Various studies, all involving alkaline xenobiotics, examine the predictive value of stridor, oropharyngeal burns, drooling, vomiting, and abdominal pain. A retrospective study of 378 children admitted for a caustic injury found that signs or symptoms could not be used to predict significant esophageal injury.[33] However, one prospective study of 79 children evaluated for vomiting, drooling, and stridor found that a combination of two or more of these signs was a predictor of significant esophageal injury as visualized on endoscopy.[20] Studies of the presence or absence of oropharyngeal burns identified on examination as a predictor of distal esophagogastric injury have repeatedly found this finding to be poorly predictive.[2,12,20,33,37,95,118] In one study there was a 37.5% incidence of esophageal lesions in the absence of oropharyngeal lesions, and 22.2% of these were second- and third-degree burns.[95] A prospective study of alkali ingestions by both adults and children found that stridor was 100% specific for significant esophageal injury, but was based on only three patients with this sign.[37]

Based on the findings above, endoscopy, a standard diagnostic tool used in the management of caustic ingestions, should be performed in all patients with intentional ingestions. Endoscopy should also be performed in any patient with an unintentional ingestion in the presence of stridor, and in any patient with one or more of the following findings: pain, vomiting, and drooling.[20] Children with unintentional caustic ingestions who remain completely asymptomatic and tolerate liquids after a few hours of observation probably require no further medical care.

The abdominal examination is likewise an unreliable indicator of the severity of injury. The presence of abdominal pain suggests tissue injury, but the absence of pain or findings on abdominal examination do not preclude life-threatening gastrointestinal damage.[28,54,98,105,126] Esophageal perforations result in mediastinitis and are commonly associated with fever, dyspnea, chest pain and subcutaneous emphysema of the neck and chest. Abdominal peritoneal signs indicate viscus perforation.

In addition to the direct effects that occur with tissue contact, acids are systemically absorbed, resulting in damage to the spleen, liver, biliary tract, pancreas, and kidneys, as well as producing a metabolic acidosis, hemolysis, and, ultimately, death.[50,122]

Significant complications can occur at various stages of wound recovery. Most importantly, these include airway compromise, hemodynamic instability secondary to hemorrhage from vascular erosion or septic shock, and perforations of the gastrointestinal tract with the development of mediastinitis or peritonitis, and other overwhelming infections from bacteria residing in the oropharynx. A patient who survives acute injury with an acid or an alkali may also subsequently develop stricture formation, gastric atony, decreased acid secretion, pseudodiverticula, and gastric outlet obstruction.[13,36,62,110,127]

Other complications reported include motility abnormalities of the pharynx and esophagus,[23] formation of aorto- and tracheoesophageal fistulas, delayed massive hemorrhage from erosion into a great vessel, and pulmonary thrombosis.[10,45,60,86,105,107]

Those patients surviving a few weeks after a grade II or III injury may subsequently present with dysphagia and vomiting from stricture formation. One study suggested that involvement of the entire length of the esophagus, as well as hematemesis and increased serum lactic dehydrogenase, are useful indicators for the

development of strictures.[88] Strictures may also present with esophageal motility disorders caused by impaired smooth muscle reactivity.[117] The early assessment and long-term prognosis may be better defined by manometric studies of the esophagus which provide precise information on the severity of the initial injury and aid in long-term prognosis.[35]

Although the risk of carcinoma after caustic ingestions is inadequately studied, three patients developed squamous cell cancer of the stomach following acid ingestion[26] and 15 patients developed squamous cell cancer of the esophagus following lye ingestion many years after their initial injuries.[57] Long-term survivors of moderate and severe injury of the esophagus have a risk of esophageal carcinoma that is 1000 times higher than that of the general population and appears to present with a latency of up to 40 years.[5]

Diagnostic Testing

Laboratory

All patients with presumed caustic exposure should have an evaluation of pH, blood type and cross-match, hemoglobin, coagulation parameters, electrolytes, and urinalysis. Elevated prothrombin time (PT) and partial thromboplastin times,[126] as well as an arterial pH lower than 7.22,[14] are associated with severe caustic injury.

Absorption of nonionized acid from the stomach mucosa may result in acidemia. Following ingestion of hydrochloric acid, hydrogen and chloride ions (both of which are accounted for in the measurement of the anion gap) dissociate in the serum resulting in a hyperchloremic normal anion gap metabolic acidosis. Other acids, such as sulfuric acid, result in an elevated anion gap metabolic acidosis because the anionâ€”sulfate (SO_4^{2-})â€”is indirectly

measured in the calculation of the anion gap. Although alkalis are not absorbed systemically, necrosis of tissue may result in a metabolic acidosis with an elevated lactate.

A gastric pH >7.30 correlated retrospectively with severe alkaline injury. The prospective usefulness of this information is limited, as obtaining gastric secretions without direct visualization is dangerous. One prospective study in children also found an increase in uric acid and decreases in phosphate and alkaline phosphatase concentrations to be useful in predicting the presence of esophageal injuries.[90]

Radiology

Chest and abdominal radiographs are used in the initial stages of management to detect gross signs of esophageal or gastric perforation. Signs of alimentary tract perforation that may be seen on plain radiographs include pneumomediastinum, pneumoperitoneum, and pleural effusion. However, these studies have a limited sensitivity, and an absence of findings does not preclude perforation.[126] Free intraperitoneal air is best seen on an upright chest radiograph. Occasionally, free air may only be visible on the lateral view.[125] In patients too ill to obtain an upright chest radiograph, an abdominal radiograph obtained with the patient in a left-side down position may reveal free intraperitoneal air adjacent to the liver. CT is considerably more sensitive than radiography for detecting viscus perforation and should be obtained in patients with potentially serious caustic ingestions as soon as is feasible.[29,120]

A contrast esophagram is useful for defining the extent of esophageal injury (Fig. 100-3). Late after the ingestion, it can detect stricture formation. In patients for whom there is a high suspicion

for esophageal perforation and in whom adequate visualization of

the upper gastrointestinal tract by endoscopy is not possible (grade IIb circumferential burns or grade III burns), an enteric contrast study (esophagram and upper GI series) can be obtained 24 hours after the ingestion.[97,129] Extravasation of contrast outside of the gastrointestinal tract is diagnostic of perforation.[127] Water-soluble contrast should be used when perforation is suspected as it is less irritating to mediastinal and peritoneal tissues if extravasated.[31] However, barium contrast agents are more radiopaque than water-soluble agents and offer greater radiographic detail. Consequently, some authors recommend barium swallow if the water-soluble contrast study is nondiagnostic but demonstrates no leak.[41,68,113] In addition, if there is risk of aspiration, barium is preferred because water-soluble contrast material can cause a severe chemical pneumonitis. Significant necrosis with impending perforation may be suspected on enteric contrast studies when there is esophageal dilation, displacement of the pleural reflection, and widening of the pleuroesophageal line.[72] Enteric contrast studies may fail to detect perforation, and therefore must be interpreted within the context of the patient's clinical status.[10,19,42,54,72]

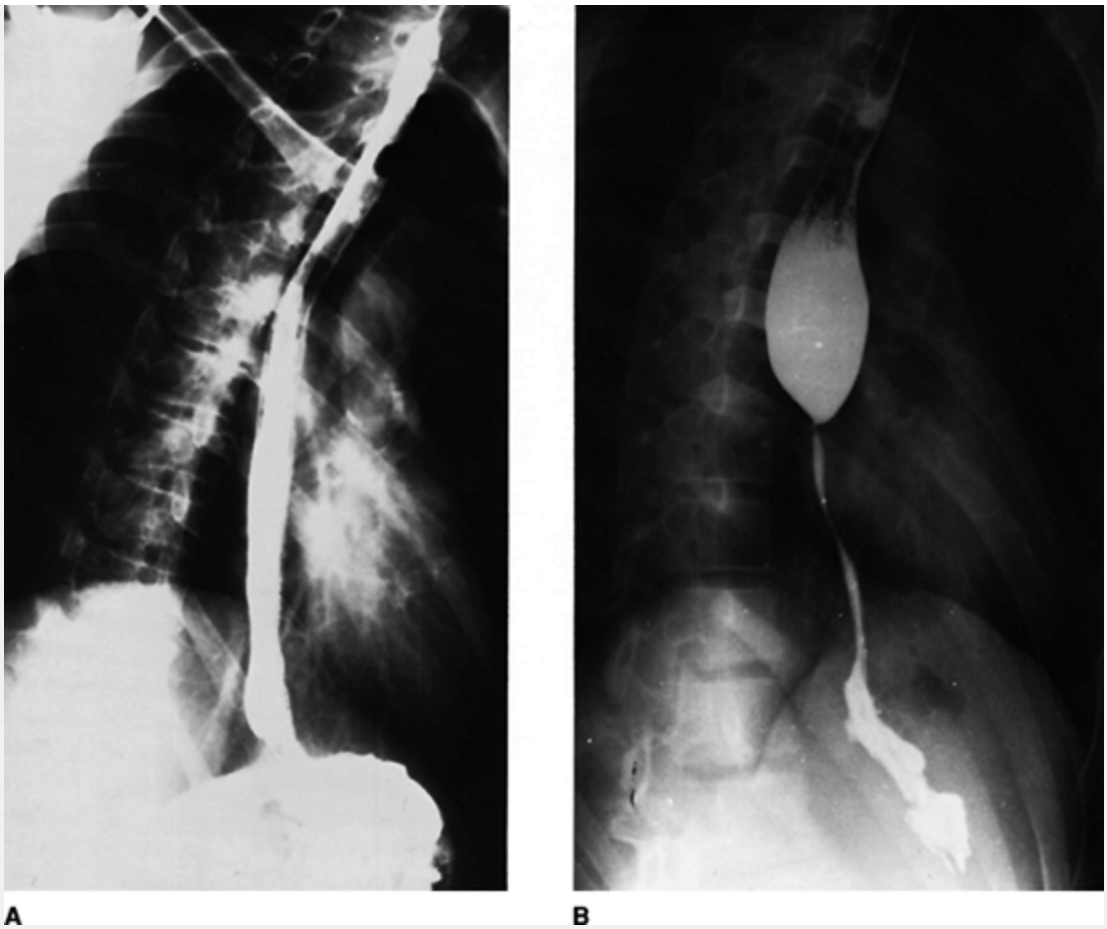

Figure 100-3. A. Barium swallow several days after ingestion of liquid lye shows the esophagus to be atonic. There is poor coating of the esophagus, suggesting edema and intramural penetration. Note that the initial evaluation immediately following a caustic ingestion to assess the extent of injury is esophagoscopy, rather than a contrast esophagram. B. Four months later, a repeat barium esophagram shows a severe stricture below the middle third of the esophagus. The barium barely passes the stricture, and the remainder of the esophagus is pencil thin. *(Courtesy of Emil J. Balthazar, MD, Professor of Radiology, New York University.)*

Although promising, a role for CT in caustic ingestions has not been formally investigated. CT has great sensitivity at detecting extraluminal air in the mediastinum and peritoneal cavity as a sign of perforation. In addition, CT can visualize the esophagus and stomach distal to severe caustic burns that cannot be safely seen using endoscopy or an esophagram. CT may therefore replace enteric contrast radiography for detection of perforation in the acute stage (within 24 hours) of a caustic ingestion. Other imaging modalities have been proposed. One study suggested a role for a technetium 99m-labeled sucralfate swallow for assessing esophageal injury after ingestion of caustic substances.[81] In another study, esophageal ultrasonography was helpful in determining the depth of injury.[84]

Another use of radiographic imaging is to noninvasively follow the patient after initial evaluation and stabilization. For example, contrast radiography is routinely used in the weeks or months following a caustic ingestion to detect esophageal narrowing representing stricture formation.[72,115] Chest CT may also be useful to determine the response of strictures to dilation procedures.[63]

Endoscopy

Endoscopy should be performed within 12 hours and generally not later than 24 hours postingestion. Numerous case series demonstrate that the procedure is safe during this period. Early endoscopy serves multiple purposes in that it allows patients with minimal

or no evidence of gastrointestinal injury to be discharged. It also offers a rapid means of obtaining diagnostic and prognostic information while shortening the period of time that patients forego nutritional support, permitting more precise treatment regimens.[17,22,24,28,43,45,67,79,105,106,119,123,127] The use of

endoscopic assessment from the 2nd or 3rd day postingestion is discouraged and should be avoided between 5 days and 2 weeks postingestion as it is at this time that wound strength is least and the risk of perforation is greatest.

The choice of rigid versus flexible endoscopy is dependent on the comfort and experience of the endoscopist. The flexible endoscope has a smaller diameter but may require gentle insufflation of air to achieve and enhance visualization. A prospective evaluation of the role of fiberoptic endoscopy in the management of caustic ingestions recommended the following guidelines: (a) direct visualization of the esophagus prior to advancing the instrument, (b) minimal insufflation of air, (c) passage into the stomach unless there is a severe (particularly circumferential) esophageal burn, and (d) avoidance of retroversion or retroflexion of the instrument within the esophagus. Provided that the patient is hemodynamically stable and endoscopy is indicated, every attempt should be made to visualize the esophagus, stomach and duodenum after a caustic ingestion.

The absence of burns in the esophagus does not imply that severe necrosis and ulcerations do not exist in the stomach[79,112,118,127] and duodenum. In the case of termination of endoscopy because of grade IIb or grade III esophageal burns, barium studies,[97] CT, or consideration of surgical exploration should be undertaken to visualize remaining structures.

Endoscopy permits limited evaluation of gastrointestinal injury. For example, the endoscopist is only able to appreciate the mucosal surface of tissues, and not the serosal side. This is especially evident in stomach ulcerations, which may appear black and necrotic from a true burn through the layers of the stomach, or from the effect of stomach acid on the blood exposed from a shallow lesion. Recent studies suggest that the use of endosonography during endoscopy may improve assessment of injury depth.[7,59] Often, though, only direct visualization of serosal

and mucosal tissues with laparoscopy or laparotomy allows for definitive evaluation.

Most cases of perforation clearly linked to endoscopy have occurred when the endoscope was advanced through an esophagus with severe circumferential lesionsâ€”a violation of current endoscopic standards.[119] In addition, perforations are also more likely to occur when rigid instruments are used in children or in uncooperative patients. The use of the flexible endoscope has decreased the risk of endoscopic evaluation.[97] Some authors advocate the presence of a surgeon during endoscopy to assist in the assessment for potential surgical intervention.[105]

Management

Acute Management

As in the case of any patient presenting with a toxicologic emergency, initial stabilization should always begin with basic decontamination of the patient and observation of universal precautions by the examiner. Airway inspection and protection should be followed by basic resuscitation principles. Examination of the oropharynx for signs of injury, drooling, and vomitus, as well as careful auscultation of the neck and chest for stridor, may reveal signs of airway edema that should prompt airway protection. Careful and constant attention to signs and symptoms of respiratory distress and airway edema, such as stridor and change in voice, are mandatory and should prompt intubation as airway edema may rapidly progress over minutes to hours.

If airway involvement is significant enough to warrant intubation, it is best to mobilize a team of the most skilled physicians early in case of unforeseen complications. A delay in prophylactic airway protection may make subsequent attempts at intubation or bag-valve-mask ventilation difficult or impossible. Direct visual

inspection of the vocal cords with a fiberoptic laryngoscope may also reveal signs of impending airway compromise. Patients necessitating intubation are best served by direct visualization of the airway either via direct laryngoscopy or fiberoptic endoscopy as perforation of edematous tissues of the pharynx and larynx is a grave complication that may occur during blind nasotracheal intubation attempts. Paralytic agents for induction of intubation should be avoided as airway edema and bleeding may distort the ability to successfully ventilate via bag-valve-mask.

Nonsurgical airway placement is recommended whenever possible as both cricothyrotomy and tracheostomy will interfere with the surgical field if esophageal repair is required.[126] Some patients with significant ingestions, however, may require emergent surgical airway intervention. The decision to perform the technique of a surgical airway is dependent on the status of the patient, the ability to orotracheally or nasotracheally intubate via a fiberoptic endoscope, and the comfort of the physician performing the procedure.

Following control of the airway, large-bore intravenous access should be secured and volume resuscitation initiated. Although unstudied, most clinicians agree that patients with signs of caustic-induced airway edema benefit from dexamethasone 10 mg IV in adults and 0.6 mg/kg up to a total dose of 10 mg in children. Both acid and alkali ingestions cause â€œthird spacingâ€• of intravascular fluid to the interstitial space, which can result in hypotension. Empiric rehydration with clinical assessment of central venous pressures and neck vein distension should be used to guide individual fluid requirements.

Serial physical examinations and constant monitoring of heart rate, respiratory rate, blood pressure, and urine output may provide information on the severity of the exposure and the progression in clinical status.

Decontamination, Dilution, and Neutralization

Decontamination should begin with careful, copious irrigation of the patient's skin and eyes when indicated to remove any residual caustic agent and to prevent contamination of other patients and staff.

Gastrointestinal decontamination is usually limited in the patient with a caustic ingestion. Induced emesis is contraindicated, as it may cause reintroduction of the caustic to the upper gastrointestinal tract and airway. Activated charcoal is also contraindicated, as it will interfere with tissue evaluation by endoscopy and preclude a subsequent management plan. Additionally, most caustics are not adsorbed to activated charcoal.

Gastric emptying via cautious placement of a narrow nasogastric tube with gentle suction may be attempted to remove the remaining acid in the stomach in patients with large intentional ingestions of acid who present within 30 minutes.[93] Although this technique has never been studied and carries the risk of perforation, the outcome for these patients is often grave and options for treatment are limited. Therefore, preventing absorption of some portion

of the ingested acid may have potential benefit in reducing systemic toxicity. Although the procedure has the potential to induce injury, a risk-to-benefit analysis favors gastric emptying following a presumed lethal ingestion.

In contrast, gastric emptying should be avoided with alkaline and unknown caustic ingestions as blind passage of a nasogastric tube carries the risk of perforation of damaged tissues, a risk that outweighs the benefit.

Exceptions to the general rules of gastrointestinal decontamination

of caustic agents exist in the management of zinc chloride ($ZnCl_2$) and mercuric chloride ($HgCl_2$). Both are caustics with severe systemic toxicity.[15,75,76,94] Ingestion of these xenobiotics causes life-threatening illness from cationic metal exposure. The local caustic effects, though of great concern, are less consequential than the manifestations of systemic absorption. For this reason, aggressive decontamination with gentle nasogastric tube aspiration and administration of activated charcoal serve as primary gestures in the initial management of patients with these ingestions. Additionally, there are some in vitro data to suggest adequate charcoal adsorption of Hg^{2+}.[3] The local effects of these xenobiotics can be managed supportively and directly assessed after systemic absorption has been prevented or treated.

The use of dilutional therapy has been examined using in vitro, ex vivo, and in vivo models in an attempt to assess its efficacy in caustic ingestions. An early in vitro model demonstrated a dramatic increase in temperature when either water or milk was added to crystal Drano.[104] Another in vitro model found less consequential increases in temperature despite large volumes of diluent. Results of both studies suggested that dilutional therapy was of limited benefit.[73] Dilutional therapy was also attended by an increase in temperature in an ex vivo study of harvested rat esophagi that examined the histopathologic effects of saline dilution after an alkali injury. Additionally, the usefulness of dilution appeared to be inversely related to the length of time from exposure, with minimal efficacy noted in as little as 30 minutes.[50,51] In contrast, an in vivo canine model of alkaline injury demonstrated that water dilution did not cause an increase in either temperature or intraluminal pressures.[53]

The extrapolation of these variable results to humans with caustic ingestions is limited, and suggests that histologic damage can only be attenuated by milk or water when administered within the first seconds to minutes following ingestion.[6,50,51,52,53,65,114] For solid, as opposed to liquid, substances (eg, crystal lye), there may be

some value for delayed dilutional therapy, as tissue contact time is increased with solid agents and their concentration is usually 100% over a small surface area. Milk may be the best agent to attenuate the heat generated by a caustic.[112]

Caution should be used in advising patients or family members about the use of dilutional agents. A child who refuses to swallow or take oral liquids should never be forced to do so. In general, dilutional therapy should be limited to patients within the first few minutes after ingestion who have no airway compromise, who are not complaining of significant pharyngeal, chest, or abdominal pain, who are not vomiting and who are alert. Dilutional therapy should be avoided in patients with nausea, drooling, stridor, or abdominal distension as it may stimulate vomiting and result in reintroduction of the caustic into the upper gastrointestinal tract.[104]

Attempts at neutralization of caustics should likewise be avoided. This technique has the potential to worsen tissue damage by forming gas and generating an exothermic reaction. In vitro and ex vivo models demonstrate that neutralization of caustics generates heat, requires a large volume to attain physiologic pH, and may have limited usefulness in preventing histologic damage after the first several minutes of caustic exposure.[49,74,104] In one in vivo canine model, orange juice was used to neutralize sodium hydroxide-induced gastric injury and demonstrated no change in temperature or intraluminal pressure.[53] Despite this study, neutralization is not recommended at this time as there are no other data demonstrating that clinical outcome is improved.

Surgical Management

The decision to perform surgery in patients with caustic ingestions is obvious in the presence of either endoscopic or diagnostic imaging evidence of perforation,[126] severe abdominal rigidity, or persistent hypotension. Hypotension is a grave finding and often

indicates perforation or significant blood loss.

Many patients will not have an obvious indication for surgical intervention despite impending perforation, necrosis, sepsis, or delayed hemorrhage. Although more challenging to diagnose, all of these sequelae are potentially avoidable if surgery is performed early[89] as morbidity and mortality increase in patients whose surgery is delayed.[28,54,56,101,105] For this reason, some surgeons advocate surgery for all patients with grades II and III esophageal burns identified on endoscopy.[28,79] This aggressive approach allows for direct inspection of serosal surfaces and an opportunity for early surgical repair.

Multiple studies have attempted to codify the signs and symptoms necessary or sufficient to rapidly identify patients who would benefit from surgery, but who lack clear clinical indications. Several retrospective and prospective series of caustic ingestions found that patients with large ingestions (>150 mL), shock, acidemia, or coagulation disorders had severe findings on surgical exploration. These studies also reinforce that the abdominal examination was frequently unreliable in predicting the need for surgery.[105,126,128] It should be noted, again, that patients with severe acid injuries may lack abdominal pain, abdominal tenderness, and have positive findings on diagnostic imaging.[25,54,128] One author used a stepwise approach of bronchoscopy, endoscopy, and abdominal ultrasonography to provide additional information regarding extent of injury prior to surgery. Respiratory distress, ascites, pleural fluid, and a serum pH below 7.2 were used as indications for surgery.[126] A history of a large-volume caustic ingestion (between 40 and 200 mL) should also prompt consideration of early surgical intervention as delay is associated with increased mortality.[25,54,126]

Surgical intervention may include laparotomy for tissue visualization, resection, and repair of perforations. Laparoscopy may also be used, although it may not allow inspection of the

posterior aspect of the stomach.

Subacute Management

Grade I Esophageal Injuries

The extent of tissue injury dictates the subsequent management and disposition of patients with caustic ingestions. Patients with isolated grade I injuries of the esophagus do not develop strictures and are not at increased risk of carcinoma. Their diet can be resumed as tolerated. No further therapy is required. These patients can be discharged from the hospital as long as they are able to eat and drink and their psychiatric status is stable.

Grade IIa Esophageal Injuries

If endoscopy reveals grade IIa lesions of the esophagus and sparing of the stomach, a soft diet

can be resumed as tolerated, or a nasogastric tube can be passed under direct visualization. If oral intake is contraindicated because of the risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition should be instituted as rapidly as possible. Providing interim enteral support is imperative as metabolic demands are increased in any patient with a significant burn.

Grades IIb and III Esophageal Injuries

Patients with grades IIb and III lesions must be followed for the complications of perforation, infection, and stricture development. There is some evidence that grade III burns, in particular, will progress to stricture formation regardless of therapy.[4,45,80,119] Additionally, patients with grade III burns are also at high risk for other complications, including fistula formation, infection, and

perforation with associated mediastinitis and peritonitis. The use of corticosteroids in the management of these burns may mask infection and make the friable, necrotic esophageal tissue more prone to perforation.[92] For these reasons, steroid therapy is not recommended for grade III esophageal burns. When required in these patients for other indications such as caustic-induced airway inflammation, steroids should be administered in conjunction with antibiotics.

Strictures form as a result of the natural process by which the body repairs injured tissue through the production of collagen with resultant scar formation. Strictures are a debilitating complication of both acid and alkaline ingestions that can evolve over a period of weeks or months. A variety of management strategies have been used in an attempt to prevent strictures and esophageal obstruction. Currently, controversy exists regarding the use of steroid therapy in the management of grade IIb circumferential esophageal burns. Steroid therapy is theorized to arrest the process of inflammatory repair and potentially prevent stricture formation. A meta-analysis of studies completed from 1956â€“1991, with a total of 361 patients, evaluated the efficacy of corticosteroid therapy and found that in patients with grade II and grade III esophageal burns, strictures formed in 19% of the corticosteroid-treated group and in 41% of the untreated group.[55] The usefulness of the results of this study, however, are limited as no distinction was made between grade II and grade III burns. Another meta-analysis of studies from 1991â€“2003, with a total of 211 patients, was unable to find a benefit in treating patients with steroids with grade II and grade III esophageal burns.[92] However, no distinction was made between grade IIa and grade IIb lesions. In addition, a multitude of case series also failed to clearly differentiate between grades IIa, IIb, and III lesions, making clinical application of their results difficult.[4,19,80,83,105,119]

Two prospective studies attempted to evaluate the efficacy of steroid therapy for caustic injuries to the esophagus. The first

spanned an 18-year period during which a total of 60 children with caustic esophageal injury were randomized to corticosteroid therapy plus antibiotics or no corticosteroid therapy. In this study, circumferential burns (grades IIb and III) were distinguished from those that were not circumferential (grades I and IIa). The incidence of stricture was comparable for the treated and untreated groups.[3] This study is limited in that no distinction was made between grades IIb and III circumferential burns, and it lacked the power to find a 30% difference. The second prospective study spanned a 3-year period during which a total of 104 patients with grades IIa, IIb, or III lesions were treated with corticosteroids plus antibiotics or no corticosteroid therapy. In this study, although no distinction was made between grades IIa, IIb, or III burns, there was no evidence that corticosteroid treatment could prevent the development of strictures. Additionally, it was observed that patients treated with corticosteroids had a higher incidence of esophageal and antipyloric stenosis.[58]

Adequate human data demonstrating the efficacy of corticosteroids with or without antibiotics in the treatment of grade IIb circumferential lesions have yet to be generated. Although both prospective studies discussed above failed to demonstrate a benefit of corticosteroid treatment, it is imperative that the clinician understands that neither study clearly differentiates between grades IIb and III lesions. Because of the inherent risks involved in this therapy, and the paucity of data supporting their use, steroid therapy in the management of grade IIb esophageal burns can no longer be routinely recommended at this time.

No major outcome studies have investigated the use of antibiotics alone as prophylactic treatment for stricture prevention, but most clinicians would agree that it is probably best to reserve antibiotics for an identified source of infection.

In both animal models[100] and in human case series,[46,82,99] intraluminal stents and nasogastric tubes[82,123] made of silicone

rubber tubing can successfully maintain the patency of the esophageal lumen. For nutritional support, the stents are usually attached to a feeding tube secured in the nasopharynx through which the patient can receive feedings without interfering with esophageal repair. These tubes are left in place for 3 weeks.[99,100] and are often used with concomitant corticosteroid and antibiotic therapy. In animal models, the use of a stent for 3 weeks is superior in maintaining esophageal patency when compared to corticosteroids and antibiotics alone.[100]

Potential disadvantages of esophageal stents include mechanical trauma at the site and increased reflux, both of which may inhibit healing.[109] A feline model of esophageal exposure to sodium hydroxide used stents but reported deaths from aspiration and mediastinitis.[100] One series of 251 humans exposed to caustics who were managed with silicone rubber stents found that the procedure was successful in preventing stricture formation.[9]

Additionally, multiple xenobiotics have been studied in various animal models in an attempt to identify agents that either inhibit synthesis or stimulate breakdown of collagen and thereby prevent stricture formation. Î²-Amino propionitrile (BAPN), penicillamine, *N*-acetylcysteine (NAC), halofuginone, vitamin E, and colchicine are some of these agents.[116] BAPN was examined in a canine model in conjunction with dilation, and there was some suggestion that it was useful.[70] Both penicillamine and NAC were of some benefit in preventing strictures in rats and rabbits.[34,66,116] Halofuginone, a specific inhibitor of collagen type I synthesis, and vitamin E, a known antioxidant, significantly reduced esophageal stricture[91] and collagen synthesis in rats,[39] respectively. In addition, epidermal growth factor and interferon-Î³ also decreased collagen synthesis and stenosis following sodium hydroxide burns in rats.[8] Colchicine, which decreases collagen synthesis, was found to delay wound healing and was associated with stricture formation in rabbits with sodium hydroxide-induced esophageal burns. As none of these xenobiotics have been adequately studied

in humans, they cannot currently be recommended in the routine management of caustic ingestions.

Currently, in patients with endoscopically identified grade IIb lesions, esophageal stents may be considered for the prevention of esophageal strictures but steroids should not be routinely used.

Chronic Treatment of Strictures

Commonly, the management of esophageal strictures includes early endoscopic dilation for which a variety of types of dilators

are available. Contrast CT can be used to determine maximal esophageal wall thickness, which can then be used to predict response,[63] as well as the number of sessions required to achieve adequate dilation. Multiple dilations are often necessary. In one study, patients with a maximal esophageal wall thickness of 9 mm or greater required more than 7 sessions to achieve adequate dilation. This was significantly higher than in patients with a lesser maximal wall thickness.[63] Measurement of maximal wall thickness may be also be useful in determining long-term followup, type of nutritional support, and the potential need for surgical repair as an alternative to dilations. It may also provide an indication for those who should undergo dilations under fluoroscopy to limit the risk of perforation.

The risk of perforation from esophageal dilation is decreased if the initial procedure is delayed until at least 4 weeks postingestion, when healing, remodeling, and potential stricture formation in the esophagus have taken place. Several series report perforation secondary to esophageal dilation.[45,60,63,96,119] Following perforation, patients may complain of dyspnea or chest pain with associated subcutaneous emphysema or pneumomediastinum. Diagnostic imaging may identify the perforation and provide information for emergent surgical repair if the diagnosis is unclear.

Patients with stricture formation require long-term endoscopic followup for the presence of neoplastic changes of the esophagus that may occur with a delay of several decades.[5]

Management of Ophthalmic Exposures

Ophthalmic exposures frequently occur from splash injuries, and, more recently, from the alkaline byproducts of sodium azide released in automobile air bag deployment and rupture.[121] The mainstay of therapy for these patients is immediate irrigation of the eye for a minimum of 15 minutes with 0.9% sodium chloride, lactated Ringer solution, or tap water, if it is the only agent immediately available. Several liters of irrigation fluid are recommended. The normal pH of ophthalmic secretions is close to 7.40. This can be tested colorimetrically by using a urine dipstick, which can test a range of pH from 5 to 9 using a color chart.[77] Litmus paper can be used in the same fashion. Another option is Nitrazine paper, which changes color from yellow to dark blue at a pH above 6.5,[32] and which may be useful in acid exposures. These different test strips can be applied to the ophthalmic secretions to test the baseline pH, and followed with intermittent evaluations after 15 minutes to determine the adequacy of irrigation. If these xenobiotics are not readily available, irrigation should not be delayed, as the depth of penetration of the caustic agent will determine outcome. Anterior chamber irrigation may be required; if required, it is performed emergently by an ophthalmologist. A thorough eye examination should be completed and followup should be arranged. Chapter 20 contains a more detailed description of the evaluation and management of toxicologic emergencies of the eye.

Summary

Assessing the severity of injuries in patients with caustic exposures can be clinically challenging. For all patients with

caustic exposures, the primary consideration is basic decontamination of the patient, as well as adherence to universal precautions by healthcare professionals, in an effort to prevent further exposures. For patients with ingestions, this must be immediately followed by airway assessment and stabilization and consideration of multiple bedside, laboratory, and diagnostic imaging factors to decide how best to inspect the tissues of the gastrointestinal tract. Ideally, early in the course of management, gastroenterologists and surgeons are involved in the care of the patient, so that any surgical intervention deemed necessary can be performed promptly. Exposures to the skin and eyes require rapid decontamination with simple irrigants such as 0.9% sodium chloride solution.

Household and industrial exposures to caustic agents constitute a potentially life-threatening global health concern. Public health efforts, such as the successful implementation of child-proofing caustic substance containers and limiting the concentration of caustic agents in household items in the United States should be encouraged in developing nations as well.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 101
Hydrofluoric Acid and Fluorides

Mark Su

A 32-year-old migrant worker was asked to clean graffiti off a building. After cleaning a single facade of a building with hydrofluoric acid solution on a sponge, he noticed intense pain to his right (dominant) hand. He presented to the emergency department 6 hours later. He complained of severe hand pain but had a normal physical examination. A calcium gluconate slurry was made and placed in a sterile surgical glove that the patient wore on his right hand. The patient's pain temporarily resolved but recurred after 20 minutes. An additional calcium gluconate slurry was made and the same therapy was applied with the same result. The patient was admitted to the hospital for pain control with opioids. Over the next 12 hours, the skin of the affected hand appeared raised, dusky, and pale on the palmar surface. The hand surgery service transferred the patient to the regional burn center. At the burn center, debridement of the abnormal-appearing tissue was performed. The patient was discharged after several days in the hospital and was lost to followup.

History and Epidemiology

Hydrofluoric acid (HF) has been known for centuries for its ability to dissolve silica. The Nuremberg artist Schwanhard is given credit for the first attempt (in 1670) to use HF vapors to etch glass.[40] Since then, HF has developed multiple uses in addition to glass etching, such as brick cleaning, etching microchips in the semiconductor industry, electroplating, leather tanning, rust removal, and the cleaning of porcelain.[22,40] During the past 3 years, the American Association of Poison Control Centers (AAPCC) has reported more than 2000 exposures to HF and several deaths. Hand exposures are by far the most common presentation. Exposures to HF are often unintentional and they can be an occupationally related hazard. The actual number of work-related poisonings from HF appears difficult to quantitate because of limitations in ICD (*International Classification of Diseases*) medical coding and lack of notification of regional poison centers by worksites.[7]

Hydrofluoric acid is also the most common cause of fluoride poisoning, although other forms of fluoride, including sodium fluoride (NaF) and ammonium bifluoride (NH_4HF_2), may also produce significant toxicity. Historically, sodium fluoride has been used as an insecticide, rodenticide, antihelminthic agent in swine, and a delousing powder on poultry and cattle. Ammonium bifluoride is mainly used in industrial inorganic chemistry, especially in the processing of alloys and in glass etching. Other sodium salts are widely used in, for example, the steel industry, drinking water, toothpaste additives, electroplating, lumber treatment, and the glass and enamel industries.

The widespread use of HF and fluoride-containing compounds has resulted in significant toxicity. In 1988, an oil refinery in Texas released a cloud of hydrogen fluoride gas that resulted in 36 people requiring hospital treatment.[40] The petroleum industry has been plagued by similar HF incidents since then. NaF was

responsible for the poisoning of 263 people and 47 fatalities when it was mistaken for powdered milk and unintentionally combined with scrambled eggs.[50] These and other forms of fluoride salts can be converted to HF in vivo after ingestion. Consequently, many inorganic fluoride compounds can result in significant fluoride toxicity, especially when large exposures occur.

Chemistry

Hydrofluoric acid has unique properties that can cause life-threatening complications following seemingly trivial exposure. Anhydrous HF is highly concentrated (>70%) and used almost exclusively for industrial purposes. The aqueous form of HF, which generally ranges in concentrations from 3â€“40%, is commonly used in both industrial and household products.

Hydrofluoric acid is synthesized as the product of gaseous sulfuric acid and calcium fluoride, which is subsequently cooled to a liquid.[51] The pK_a of aqueous HF is 3.5; consequently, it is classified as a weak acid. As such, it is approximately 1000 times less dissociated than equimolar hydrochloric acid.

NaF is commonly synthesized by the reaction of sodium hydroxide (NaOH) with HF, with subsequent purification by recrystallization. Compared to other fluoride salts that are relatively water insoluble, such as potassium fluoroborate and potassium hexafluorophosphate, NaF is highly soluble and readily dissociates.[2]

To synthesize NH_4HF_2 ammonium fluoride (NH_4F) is first formed by the reaction of ammonium hydroxide (NH_4OH) and HF. Ammonium fluoride is then converted to bifluoride by dehydrating an aqueous solution.

Pathophysiology

Exposures to HF occur via dermal, ocular, inhalation, and oral

routes with one reported case of toxicity from an HF enema.[15] A permeability coefficient of 1.4 Ã— 10^{24} cm/sec allows HF to penetrate

deeply into tissues prior to dissociating into hydrogen ions and highly electronegative fluoride ions.[28] These fluoride ions avidly bind to extracellular and intracellular stores of calcium and magnesium, ultimately leading to cellular dysfunction and cell death.[8,49,58] The alteration in local calcium homeostasis probably causes neuroexcitation and accounts for the development of neuropathic pain.

There are several theories regarding the fate of calcium and fluoride ions in tissues. Formation of insoluble calcium fluoride (CaF_2) is proposed as the etiology for both the precipitous fall in serum calcium concentration and the severe pain associated with tissue toxicity. In vitro evidence suggests that fluorapatite is formed in the presence of phosphate and hydroxyapatite. This may be a more likely pathway for deposition of the fluoride ion.[8]

In the anhydrous form, the high concentration of hydrogen ions in HF also produce a corrosive burn similar to that caused by strong acids.

A final mechanism for fluoride toxicity includes in vitro evidence for the interference of many enzyme systems by binding with magnesium and manganese. The minimal lethal dose in humans is approximated to be 1 mg/kg of fluoride.[40]

Clinical Manifestations

Local Effects

Skin

The extent of tissue injury in dermal exposures is determined by

the volume, concentration, and contact time with the tissues. Dermal exposures to HF typically involve low concentrations of the agent. Following dermal exposure, it is usually recognized that the higher the concentration of HF, the more rapid the onset of excruciating pain at the site of contact.[26,51,83] Concentrations of greater than 50% cause immediate pain with visible tissue damage.[78] Household rust-removal products have concentrations ranging between 6 and 12%. Consequently, exposure to these products often result in a delay of several hours before patients develop pain.[26,79,87,88] The initial site of injury may also appear relatively benign, despite significant subjective complaints of pain. Over time, the tissue may become hyperemic, with subsequent blanching and coagulative necrosis as calcium precipitates.[67] (See ILHFHAND in the Image Library at http://www.goldfrankstoxicology.com) Ulcerations may form at a rate dependent on the concentration and duration of contact.[22,41,52] If more than 20% of the body surface area is burned with high-concentration HF, life-threatening systemic toxicity should be expected.[16,64,66,78,83] Small body surface area exposures to low concentrations typically do not result in life-threatening systemic toxicity, although fatalities have resulted with dermal exposures to concentrated (anhydrous) HF covering only 2.5% body surface.[83]

Pulmonary

Patients with inhalational exposures can present with a variety of signs and symptoms depending on the HF concentration and exposure time. Thirteen oil refinery workers exposed to a low-concentration HF mist experienced minor upper respiratory tract irritation.[47] Alternatively, in a mass inhalational exposure to HF, throat burning and shortness of breath were among the more common chief complaints.[91] Some of these patients had altered pulmonary function tests and hypoxemia, and 16% developed hypocalcemia. Stridor, wheezing, rhonchi, and erythema and

ulcers of the upper respiratory tract were described. Eye pain was also noted, reinforcing that ophthalmic injury can accompany inhalational or dermal exposures.[47,56,73,91]

Gastrointestinal

Intentional ingestion of concentrated HF (or other fluoride-containing compounds such as NaF) causes significant gastritis yet often spares the remainder of the gastrointestinal tract. Patients promptly develop vomiting and abdominal pain. Although systemic absorption is rapid and almost invariably fatal, there is at least one report of a patient with an ingestion of a low concentration of HF who suffered multiple episodes of ventricular fibrillation and was successfully resuscitated.[81] Following HF ingestion patients may present with an altered mental status, airway compromise, and dysrhythmias.[10,50,53,81]

Ophthalmic

Hydrofluoric acid appears to result in more extensive injury to the eye than most other acids.[59] Ophthalmic exposures from liquid splashes or hydrogen fluoride gas denude the corneal and conjunctival epithelium, and lead to stromal corneal edema, conjunctival ischemia, sloughing, and chemosis.[40] Fluoride ions can penetrate deeply to affect the anterior chamber structures.[40] The effects are usually noted within one day.[40] Other possible findings include corneal revascularization, recurrent epithelial erosions, and, sometimes, keratoconjunctivitis sicca (dry eye) developing as a long-term complication.[4,59,74]

Systemic Effects

Significant systemic toxicity can occur via any route because of the ability of HF to penetrate tissues. Potential for systemic toxicity is an important consideration in the management of these

patients as they should be rapidly decontaminated and treated.[9,13,27,77,78,84,85] As these examples describe, fatal exposures to HF share the similar features of hypocalcemia, hypomagnesemia, and, in many cases, hyperkalemia as preterminal events.[2,10,19,27,46,51,53,60,61,83] In some circumstances, the hypocalcemia severely disrupts the coagulation cascade, resulting in coagulopathy on postmortem examination.[53,62,63]

Fatalities from HF may occur as a result of either sudden-onset myocardial conduction failure or ventricular fibrillation. Although the evidence regarding the mechanism of myocardial irritability is inconclusive, electrolyte disturbances that lead to ventricular dysrhythmias and fibrillation are thought to be the primary cause of death in patients with severe systemic fluoride poisoning.[16,64,78,83,94] Some postmortem cases reveal significant structural myocardial injury.[62] However, these findings are inconsistently encountered in humans and in animal cardiac arrest models that fail to demonstrate any histologic abnormalities of the myocardium.[21,57]

Most theories regarding myocardial irritability relate to the hypocalcemia causing an efflux of potassium ions into the extracellular space.[21,49,62] The subsequent hyperkalemia may alter the automaticity and resting potential of the heart, leading to fatal dysrhythmias.[61] Dogs treated with quinidine, a potassium efflux blocker, are protected from lethal doses of intravenous sodium fluoride.[21] Likewise, the antidysrhythmic agent amiodarone, which also possesses potassium efflux blockade properties, has demonstrable efficacy both in vitro and in vivo.[18,82] However, efficacy in humans has not been studied or documented. Furthermore, the mechanism of toxicity may be much more complicated.[96] A child with systemic fluoride toxicity, who was appropriately repleted with calcium, and who had normal electrolytes still experienced nonfatal ventricular fibrillation.[9,96] Perhaps this is because serum potassium, calcium,

and magnesium concentrations only partly represent tissue concentrations.[8,9,21,60,61] Furthermore, HF may directly impair myocardial function. Rabbits exposed to topical HF over 2% of their total body surface area developed focal necrosis of myocardial fibers, as well as significant elevations in cardiac enzymes that persisted for almost 5 days after injury.[95]

Assessing Severity of Clinical Exposures

Historical and clinical features of an exposure will determine which HF exposures are life-threatening. All oral ingestions and inhalational exposures should be considered potentially fatal, as well as burns of the face and neck, regardless of HF concentration. Inhalational exposure should be assumed for all patients with skin burns of greater than 5% body surface area, exposure to HF concentrations greater than 50%, and head and neck burns.[39] Patients presenting with altered mental status are critically ill and necessitate rapid therapy.

Hydrofluoric acid concentrations of greater than 20% have potential for significant toxicity in a patient even if only a small surface area has been exposed. As a general rule, patients who experience severe pain within minutes of contact are most likely exposed to a very high concentration of HF and their condition can rapidly deteriorate. An otherwise well-appearing patient may have a precipitous demise without any clinical manifestations of hypocalcemia.

Diagnostic Testing

Diagnostic testing for systemic fluoride poisoning is currently based on monitoring of serum electrolytes. Ionized calcium should be serially monitored along with magnesium and potassium.[27]

Additional information may be obtained from a venous or arterial blood gas analysis. As systemic toxicity progresses, there is potential for development of metabolic acidosis.[8] Serum fluoride concentrations may be assessed but the results will not be returned in a clinically relevant timeframe. Although a serum fluoride concentration of 0.3 mg/dL has been reported as a fatal, one patient survived with a serum fluoride concentration of 1.4 mg/dL.[83,96]

Electrocardiographic findings of both hypocalcemia (prolonged QTc interval duration) and hyperkalemia (peaked T waves), in both human case reports and in dog studies, may be reliable indicators of toxicity.[2,13,27,35,63,83] In fact, ECG findings of peaked T waves from hyperkalemia have preceded the onset of ventricular dysrhythmias, thus potentially serving as a marker of severe fluoride toxicity.[9,60] The ECG is therefore an important screening tool for systemic fluoride toxicity and may also be used to monitor therapeutic efficacy.

Management

General

For all types of exposures, the mainstay of management is to prevent or limit systemic absorption, assess for systemic toxicity, and rapidly correct any electrolyte imbalances. Intravenous access should be obtained. An ECG should be examined for signs of hypocalcemia, hypomagnesemia, and hyperkalemia. The patient should be placed on continuous cardiac monitoring, and have a rapid assessment of serum electrolyte concentrations. A Foley catheter should be placed as needed to follow urine output.

Rapid airway assessment and protection should occur early in patients with inhalation or ingestion, respiratory distress, ingestion with vomiting, or burns significant enough to cause a

change in mental status or voice.

For patients with less-significant dermal exposures, recent studies have focused on alternatives to irrigation with water or saline as topical decontamination techniques. One group advocates the use of the compound Hexafluorine for dermal and ocular decontamination of HF splashes.[54,80] Despite anecdotal supportive data, in a controlled and blinded experimental study Hexafluorine treatment was less effective than irrigation with water followed by the application of topical calcium.[34] In a followup animal study, water irrigation was as effective as Hexafluorine in preventing systemic toxicity from HF.[36] At this time, until further objective data are available, it is premature to recommend the routine use of Hexafluorine for initial decontamination of HF exposures. Topical iodine ointment was studied for HF-induced burns in guinea pigs.[92] Iodine has demonstrated protective effects against burns from various alkylating agents, including mustard gas, and is hypothesized to inhibit apoptosis.[92] Because experience with iodine treatment of human HF burns is lacking at this time, it cannot be recommended. To prevent absorption from dermal exposures, irrigation with copious amounts of water should be done. The most important therapy for skin exposures is rapid removal of clothing and irrigation of the affected area with copious amounts of water or saline, whichever is more readily available.[1,44,48,52]

One report describes a woman who was dying from severe HF toxicity who was treated by amputation of the affected limb, and survived. Although not routinely recommended, this may be an alternative measure for patients who are inadequately responding to all other therapeutic modalities.[12,43]

Dermal Toxicity

Several therapeutic options have been studied and described in animal models for treatment of topical HF burns. Unfortunately,

many study designs use histologic or subjective wound inspection as outcome parameters,[14,69] some with unblinded inspection.[11,24,43,44] These animal models do not address the parameters of pain reduction, cosmesis, and functionality that are clinically important.

Topical calcium gel should be applied to the affected area. This is prepared by mixing 3.5 g of calcium gluconate powder in 150 mL of sterile water-soluble lubricant, or 25 mL of 10% calcium gluconate in 75 mL of sterile water-soluble lubricant.[1,14,39] If calcium gluconate is unavailable, calcium chloride or calcium carbonate can be used in a similar formulation.[17] Topical therapy for both severe and nonâ€“life-threatening exposures scavenges fluoride ions. An animal study examining the efficacy and mechanism of topical calcium gel therapy found that the fluoride ion concentration of the calcium gel was significantly higher than nonâ€“calcium-containing gel controls. Although a limited study, these animals also had a decrease in urinary fluoride ion concentration as compared to controls, suggesting less overall absorption of the HF into the tissues.[44] Quaternary ammonium compounds, such as topical benzalkonium chloride, have also been advocated in the treatment of HF burns and can be used when available;[52] however, calcium-containing gels appear to be more efficacious. Delivery of calcium transcutaneously may be enhanced by various means. In a rodent study of HF burns, iontophoretic (facilitated transport using an electromotive force) delivery of calcium

appeared to increase calcium concentrations in vitro and improve pathologic changes in vivo.[93] Significant limitations to this study are time to administration of therapy and feasibility in patients with complex burns.[75] Human data are lacking. Dimethyl sulfoxide (DMSO) mixed with topical calcium salts may also facilitate the transport of calcium ions through the skin to penetrate deeply into the tissues. It also is able to act as a scavenger of free radicals,

thus limiting inflammation and ongoing injury.[30] Although one group of authors recently advocated the combined use of DMSO and calcium,[30] concerns remain over reported adverse effects of DMSO.[40] There is currently inadequate data to support the use of DMSO in the treatment of HF burns.

Four therapies have had variable success in human exposures: the application of calcium via topical, intradermal, intravenous, and intraarterial routes. After irrigation, a gel solution of calcium carbonate or gluconate can be mixed directly into a sterile surgical glove and then placed on the patient's hand for 30 minutes. Two case series report limited success with this therapy.[1,17] Some patients describe prompt and dramatic relief of pain. Alternatively or simultaneously, analgesics can be administered orally or intravenously as needed, but preferably not to the point of sedation, because local pain response will guide therapy. Digital blocks with subcutaneous lidocaine or bupivacaine can be used for patients presenting 12â€“24 hours after the injury from a low concentration of HF and no systemic signs of toxicity.[23]

If topical gel therapy fails within the first few minutes of application, consideration should be given to intradermal therapy with calcium gluconate, because the benefit in pain control often occurs immediately. This treatment may have limited usefulness, however, in small spaces, such as fingertips. Histologic studies in animal models demonstrate that 10% calcium chloride solution can be damaging to the tissues and should be avoided.[23,29] The preferable method is to approach the wound from a distal point of injury and inject intradermally no more than 0.5 mL/cm^2 of 5% calcium gluconate. Although one author recommends a palmar fasciotomy whenever this method of treatment is used,[1] this practice is not currently recommended unless a compartment syndrome is present. The potential for iatrogenic injury exceeds potential benefit. The limits of intradermal injection include the potential to increase soft-tissue damage without adequate relief, infection, and inadequate space to safely inject without causing a

compartment syndrome. Effective pain relief is especially problematic for nail involvement, leading some authors to suggest removal of the nail. This approach has some advantages in accessing the affected area; however, it is a painful procedure that is often cosmetically undesirable and the outcome is not always significantly improved. If considering local injection of calcium salts, distensible areas of the body such as the arm or thigh are acceptable, but injection into the digits should be avoided.

If the wound is large or on a section of the fingerpad or an area that is not amenable to intradermal injections, consideration should be given to the use of intraarterial calcium gluconate. This procedure delivers calcium directly to the affected tissue from a proximal artery. Placement should be ipsilateral and proximal to the affected area, usually in the radial or brachial artery. The method of obtaining access is somewhat debated. Because of the potential to damage the endothelial lining of the artery, and because extravasation can have potentially devastating consequences, angiographic confirmation or direct visualization of the vessel was formerly recommended. This practice is still prudent if cannulation of the artery is expected to be difficult because of prior surgery or if an anatomic deformity is suspected. If the arterial line is carefully placed in a single attempt, and a good confirmatory arterial tracing is obtained, the infusion can be started. The recommended protocol consists of 10 mL of 10% calcium gluconate added to either 40 mL of D_5W (dextrose 5% in water) or 0.9% sodium chloride solution infused continuously over 4 hours.[1,42,70,79,87,88] This results in a 2% calcium gluconate solution. An animal model examined the effect of undiluted 10% calcium gluconate intraaortically. Although the model did not involve exposure to HF, there was significant tissue injury in the vessel wall as compared to a 2% calcium gluconate solution.[23] Calcium chloride has also been used successfully, although the potential for vessel injury and extravasation are significant and there is no defined benefit over calcium gluconate.[86,97] The

complications associated with the use of intraarterial calcium infusion in several case series were relatively benign, and include radial artery spasm, hematoma, inflammation at the puncture site, and a fall in serum magnesium.[79,87] After the infusion is initiated, patients typically experience significant pain relief. Patients requiring an arterial line for treatment should be admitted to the hospital, as the majority will require more than one treatment, and some patients may require as many as five separate infusions of calcium gluconate. Although wounds may require dÃ©bridement,[1] some suggest that following intraarterial calcium infusion, tissue can be salvaged that initially would not have been considered viable.[88] There have been no reported cases of clinically significant hypercalcemia following infusion as the total dose infused is quite low, although serum calcium concentrations were not always routinely recorded.

Administration of magnesium salts is an alternative or adjunctive therapy to the administration of calcium for dermal HF burns. Magnesium hydroxide and magnesium gluconate gel used in rabbit models show some histologic evidence of efficacy in dermal HF burns.[14] Two other animal models of intravenous magnesium for the management of dermal HF burns also suggest efficacy in terms of wound healing.[20,90] In theory, magnesium appears to be an excellent antidote for fluoride poisoning because magnesium fluoride is more soluble than calcium fluoride and magnesium is readily excreted by the kidneys.[90] However, these magnesium models are limited and both topical and intravenous magnesium therapy are insufficiently evaluated in humans.

Another reported therapy for localized HF poisoning is an intravenous Bier block technique that uses 25 mL of 2.5% calcium gluconate. In one case, the effects lasted 5 hours and there were no adverse events.[33] In two other cases of patients exposed to HF, a 6% calcium gluconate solution administered using this procedure resulted in rapid and complete analgesia and minimal tissue necrosis.[76] Although the intravenous Bier block technique is not

reported as being used in a substantial number of patients, it may be particularly useful when intraarterial infusion is problematic.[76] Further data are required before this therapy is routinely recommended.

All patients with digital exposures should be observed over 4â€“6 hours, as the pain is likely to recur and reapplication of the gel or an alternative therapy may be necessary. Even if successful pain control is achieved, the patient will require specialized followup and wound care.

Inhalational Toxicity

Patients with symptomatic inhalational injuries can be treated with nebulized calcium gluconate. A report of patients exposed to a low concentration of HF and treated with 4 mL of a 2.5% nebulized

calcium gluconate solution demonstrated a subjective decrease in irritation with no adverse effects.[47] Another report demonstrated a good outcome following nebulization of a 5% calcium gluconate solution in a patient with an inhalational exposure.[45] Because nebulized calcium gluconate appears to be a relatively benign therapy, it should be given to all patients with symptomatic inhalational exposures to any concentration of HF because of the possibility of systemic toxicity.[25]

Ingestions

In patients with intentional ingestions of HF, gastrointestinal decontamination poses a dilemma. Induction of emesis is also potentially harmful. Although placement of a nasogastric tube to perform gastric lavage in these patients is clearly associated with risks to the patient, insertion of a nasogastric tube may be beneficial if safely done and in a timely manner. Consequently, gastric emptying via a nasogastric tube should be considered

because these exposures are almost universally fatal.[2,10,53,63] Healthcare providers should exercise extreme caution during this procedure because dermal or inhalational exposures can occur in the absence of appropriate protection. Because aqueous HF is a weak acid, the risk of perforation by passage of a small nasogastric tube may be lower than the risk of death from systemic absorption.[2,53] In the acidic environment of the stomach, more of the weak acid solution remains unionized, thus penetrating the gastric mucosa and causing rapid systemic poisoning. Moreover, activated charcoal is unlikely to adsorb the relatively small fluoride ions.

If an oral exposure occurs, a solution of calcium or magnesium salt should be delivered to the stomach as soon as possible to prevent HF penetration and to provide an alternative source of cations for the damaging electronegative fluoride ions.

When comparing the efficacy of calcium to magnesium salts, calcium may be better than magnesium in reducing the bioavailability of fluoride as described in a murine model.[32] Magnesium citrate (in a standard cathartic dose; see Antidotes in Depthâ€"Calcium), magnesium sulfate, or any of the calcium solutions can be administered orally to prevent absorption. Although intuitive, evidence for the benefit of oral calcium or magnesium salts is limited. In a mouse model of oral HF toxicity, administration of calcium- or magnesium-containing solutions did not change average survival time.[31] The study results, however, were limited because the calcium and magnesium salts were premixed together with the HF during administration, thus being an atypical model of HF ingestion. In a more recent study, the survival rate of mice poisoned with NaF was significantly greater when treated with high doses of oral $CaCl_2$ or $MgSO_4$.[38]

Ophthalmic Toxicity

Patients with ophthalmic exposures should have each eye irrigated

with 1 L of 0.9% sodium chloride solution, lactated Ringer solution, or water.[59] Although there are limited data, repetitive or prolonged irrigation appears to worsen outcome.[59] A complete ophthalmic examination should be performed after the patient is deemed stable, and an ophthalmology consultation should be obtained. One case report demonstrated a good outcome following ocular HF exposure with the use of 1% calcium gluconate eyedrops.[4] Although two recent reviews also recommend the use of 1% calcium gluconate for this purpose,[25,30] calcium salts tend to be irritating to the eye and this therapy has not been adequately studied; consequently, routine use is not indicated at this time. There is no role for gel therapy or intraocular injection in these patients, again, because most calcium and magnesium salts are potentially toxic to ocular tissues and may actually worsen outcome.[3,59]

Systemic

If there is a clinical suspicion of severe toxicity, the immediate intravenous administration of calcium and magnesium salts is recommended. In general, calcium gluconate is preferred over calcium chloride because of the risks associated with extravasation (see Antidotes in Depth: Calcium). Patients can require several grams of calcium to treat severe HF toxicity.[27,81] Intravenous magnesium can be administered to adults as 20 mL of a 20% solution (4 g) over 20 minutes. An approach that uses intravenous calcium or magnesium, and local calcium or magnesium gels to limit absorption may protect against life-threatening hypocalcemia and hyperkalemia. An animal model of hydrogen fluoride toxicity found that maintaining a normal acidâ€“base balance was protective against HF toxicity.[72] Furthermore, in a study of patients receiving enflurane anesthesia, urine alkalinization improved the excretion of fluoride.[71] Thus, it may be beneficial to correct any significant acidemia with hydration and IV sodium bicarbonate.

Treatment with large quantities of calcium and magnesium has not generally resulted in significant hypercalcemia or hypermagnesemia.[25] Several explanations are proposed. First, total-body calcium and magnesium stores are severely decreased so that large doses are required for adequate repletion. Also, most patients who are exposed to HF, are young and healthy, with intact renal function.[25] Administration of calcium also results in antidiuretic hormone antagonism on renal tubular reabsorption resulting in polyuria which facilitates the urinary excretion of calcium and magnesium.[25]

Standard treatment for systemic fluoride toxicity includes administration of calcium salts and sodium bicarbonate, which may also antagonize hyperkalemia.

Because most of the fluoride ions are eliminated renally,[5,37,44,77] hemodialysis may be considered in patients with severe HF poisoning if renal function is compromised. There are several reported cases of successful clearance of fluoride ions via hemodialysis with one case also using continuous venovenous hemodialysis.[5,6] Because the reported clearance rate did not differ significantly from normally functioning kidneys, it is unclear whether hemodialysis alters outcome in patients with normal renal function.

Although the use of quinidine is protective in dogs,[62] it has not been studied or used in humans, and at this time cannot be routinely recommended.

Summary

Hydrofluoric acid and fluoride salts are extremely potent cellular toxins. Hydrofluoric acid exposure typically results in isolated local tissue damage but may also result in severe systemic toxicity and death especially in large exposures. Fluoride salts cause systemic toxicity only when ingested. Development of fluoride toxicity is

dependent on many variables including form, concentration, route(s) of exposure, and immediacy and completeness of decontamination, as well as premorbid health conditions. Treatment consists of immediate decontamination, protection of staff, rapid administration of agents to detoxify fluoride ions, enhancement of

elimination of fluoride ions, and, rarely, extracorporeal removal. It is imperative for physicians to be aware of the potentially deceptive nature of the fluoride toxin, as well as the possible therapeutic modalities used to treat these patients.

Antidotes in Depth

Calcium

Mary Ann Howland

Calcium is essential in maintaining the normal function of the heart, vascular smooth muscle, skeletal system, and nervous system. It is vital in enzymatic reactions, in neurohormonal transmission, and in the maintenance of cellular integrity.[28,45] The endocrine system maintains calcium homeostasis. Approximately half of the total serum calcium is ionized and active, and the remainder is bound to albumin. Hypercalcemia raises the threshold for nerve and muscle excitation, resulting in muscle weakness, lethargy, and coma.[28] Hypocalcemia can result in tetany and seizures (Chap. 17).[28]

Calcium Channel Blockers

Calcium enters cells in numerous ways; of these, only the voltage-dependent L-type channels in cardiac and smooth muscles are inhibited by calcium channel blockers (CCBs) available in the United States.[4,62] Because CCBs do not alter either receptor-operated channels or the release of calcium from intracellular

stores,[66] in overdose with CCBs, the serum calcium concentration remains normal. Calcium channel blocker overdoses (Chap. 58) may result in hypotension, myocardial depression, bradycardia, sinus arrest, atrioventricular (AV) block, shock, pulmonary edema, altered mental status, nausea, vomiting, constipation, metabolic acidosis with hyperglycemia, and seizures.[51]

Intravenous administration of calcium to dogs poisoned with verapamil or diltiazem improves cardiac output secondary to an increase in inotropy.[4,26] Heart rate and cardiac conduction are affected minimally, if at all, until much larger doses of calcium are given.[22,26,58] Case reports and reviews of the literature suggest similar findings in humans.[1,2,12,21,30,41,54,55,64]

Calcium should be administered to symptomatic patients with CCB overdoses. Unfortunately, the sickest patients respond inadequately, and other measures are often required. The dose of calcium needed to treat patients with CCB overdose is unknown. In animal experiments, there appears to be a dose-related improvement.[12,26] The customary approach is to administer an initial intravenous dose of 3 g of calcium gluconate (30 mL of 10% calcium gluconate) or 1 g of calcium chloride (10 mL of 10% calcium chloride) in adults.[51] Based on recent case reports, this dose may need to be repeated every several minutes, as needed. The hypothesis is that sufficient calcium needs to be present to compete with the CCB for binding to the L-type calcium channel. One author used a total of 10 g of calcium gluconate as 1 g boluses over 12 minutes after diltiazem-induced asystole and another 2.5 g of calcium gluconate minutes later for a second asystolic event, for a total of 12.5 g of calcium gluconate over 28 minutes in an adult. The corrected serum calcium concentration was 3.36 mmol/L (normal: 2.2â€“2.6 mmol/L) about 1 hour after administration of the calcium gluconate.[32] Several authors have successfully treated patients with a total of 18â€“30 g of calcium gluconate either by intermittent bolus dose or infusion without adverse effects.[12,40]

However, if calcium is administered to a patient with cardioactive steroid toxicity, it could prove quite harmful.[25,70] In the event of concurrent overdose with both a cardioactive steroid and a calcium channel blocker, the early use of digoxin-specific antibody fragments should enable the subsequent safe use of calcium.

Therapy in children is based on even more limited data. The current pediatric guidelines of the American Heart Association[24] suggest an initial dose of 20 mg/kg of 10% calcium chloride (0.2 mL/kg) up to the adult dose infused over 5â€“10 minutes, followed by infusions of 20â€“50 mg/kg/h if a beneficial effect is observed. They suggest calcium chloride based on one study that compared the chloride to the gluconate salt in critically ill children.[11] However, in patients in cardiac arrest, this dose can be given by slow intravenous push over 10â€“20 seconds.[24] This dose should be repeated as necessary. Extrapolating from adult data, repeating the dose every several minutes is warranted, depending on the life-threatening nature of the ingestion. Calcium chloride can be irritating to tissues if extravasated, leading to necrosis and the need for skin grafting.[37] Consequently, calcium gluconate may be preferable. A starting dose in children should be about 60 mg/kg of 10% calcium gluconate (0.6 mL/kg) titrating to the adult dose if needed. To avoid hypercalcemia, serum calcium concentration should be monitored when more than 2 doses are administered.

Ethylene Glycol

Ethylene glycol poisoning (Chap. 103) results in the generation of oxalic acid, which complexes with calcium and subsequently precipitates in the kidneys, brain, and elsewhere, resulting in hypocalcemia.[1,31,50,62,65] After exposure to ethylene glycol, serum calcium should always be monitored. Signs of hypocalcemia include prolongation of the QTc interval on the electrocardiogram (ECG), the presence of Chvostek and Trousseau signs, and tetany. Intravenous calcium should be administered in the customary

doses (as above) to patients with these findings, accompanied by frequent monitoring of serum calcium.

Hydrofluoric Acid and Fluoride and Bifluoride Salts

Soluble salts of fluoride and bifluoride (eg, sodium, potassium, and ammonium) have all of the toxicity associated with hydrofluoric acid and should be managed accordingly. Any body contact with hydrofluoric acid (Chap. 101) can result in severe burns and death, depending on concentration and duration of exposure. The pathophysiologic derangements noted result from (a) release of free hydrogen ions; (b) complexation of fluoride with calcium and magnesium to form insoluble salts, which cause cellular necrosis; (c) liberation of potassium ions; and (d) cellular dehydration.[7,8,13,20,42,44,46,67] Following hydrofluoric acid exposure, the gluconate salt of calcium is used topically and subcutaneously to manage minor to moderate cutaneous burns, intravenously to treat systemic hypocalcemia, and intraarterially to manage significant

burns.[1,7,8,13,14 and 15,18,20,23,42,44,47,52,57,59,61,67,68 and 69,73] Experimental studies demonstrate that when concentrated hydrofluoric acid burns are immediately flushed with water and then covered with 2.5% calcium gluconate gel or topical dimethyl sulfoxide (DMSO)/10% calcium gluconate plus subcutaneous 10% calcium gluconate, there is a significant reduction in burn size.[8,67] A randomized clinical trial comparing the DMSO/calcium gluconate combination to calcium gluconate alone is currently underway in Australia.[27] Although a DMSO preparation is not commercially available, a 2.5% calcium gluconate topical gel is marketed. In the event that the commercial preparation is inaccessible, a topical calcium gel can be prepared from calcium carbonate tablets or calcium gluconate powder or solution, and a water-soluble jelly

such as K-Y Jelly (mix 3.5 g calcium gluconate powder or 25 mL of calcium gluconate 10% solution or 10 g of calcium carbonate tablets with 5 ounces of K-Y Jelly). An experimental study in rats demonstrated that iontophoretic delivery of calcium chloride appeared to enhance the delivery of calcium and to reduce the burn area significantly if applied within 30 minutes and may be a promising modality in the future.[58,72]

The chloride salt is also acceptable for topical therapy. Calcium chloride should never be injected if subcutaneously extravasated, it can result in severe tissue necrosis.

Deaths from hypocalcemia secondary to skin, gastrointestinal, and inhalational hydrofluoric acid toxicity are documented in the literature.[14,23] In severe hydrofluoric acid exposures, aggressive administration of intravenous calcium using a Bier block technique (10 mL of 10% calcium gluconate plus heparin 5000 units in a total volume of 40 mL) or intraarterial calcium (10 mL of 10% calcium gluconate in 50 mL of 0.9% sodium chloride solution over 4 hours) may be required, along with frequent serum calcium determinations to titrate the dose.[27] One patient who was massively exposed to hydrofluoric acid required a total of 267 mEq of calcium over 24 hours.[23] An ingestion of 30 mL of 70% hydrofluoric acid theoretically generates 660 mEq of fluoride.

To facilitate the availability of the maximum amount of calcium, simultaneous administration of IV, oral, and nebulized 2.5% calcium gluconate should also be given, if there are no contraindications. To prepare nebulized calcium gluconate, mix 1.5 mL of 10% calcium gluconate solution with 4.5 mL of sterile water or saline to make a 2.5% solution. For moderate to severe burns (generally from hydrofluoric acid concentrations >10%) of the fingers and hands, an intraarterial calcium infusion may be more effective than local (or IV) therapy, although it is more invasive[52,61,68,69] and more hazardous.[61] One group successfully used 10 mL of 10% calcium gluconate solution mixed in 40â€“50

mL of 5% dextrose infused intraarterially over 4 hours followed by subsequent 40-mL infusions after 4 hours when pain persisted.[68] Serum calcium and serum magnesium concentrations should be carefully monitored in all severely poisoned patients.[61,68]

Phosphates

Inappropriate use of oral and rectal phosphates (eg, laxatives) can result in hypocalcemia, hyperphosphatemia, and hyperkalemia, as well as significant morbidity and mortality.[3] Intravenous calcium may be needed for life-threatening hypocalcemia. The administration of calcium in the presence of hyperphosphatemia risks precipitation of calcium phosphate throughout the body. Hemodialysis and other therapies should be considered.

Hypermagnesemia

Hypermagnesemia causes both direct and indirect depression of skeletal muscle, resulting in neuromuscular blockade, loss of reflexes, and profound muscular paralysis (Chap. 17).[28] Excess magnesium also causes widening of the PR interval and QRS complex on the ECG, and depression of the sinoatrial (SA) node, leading to a bradycardic cardiac arrest. Intravenous calcium serves as a physiologic antagonist to these effects of magnesium (see Table A27-1).

Hyperkalemia

Hyperkalemia causes significant myocardial depression. Electrocardiographic changes are well defined: the height of the T wave increases and lengthening of the PR interval and QRS complex occur; ultimately, a sine wave pattern leading to cardiac arrest may occur (Chap. 5).[28] Calcium makes the membrane threshold potential less negative so that a larger stimulus is required to depolarize the cell. This stabilization antagonizes the

hyperexcitability caused by modest hyperkalemia. However, when severe hyperkalemia exists, voltage-gated sodium channels are inactivated and cannot be depolarized, regardless of the strength of the impulse. Calcium may transform the voltage sensor of the sodium channel from inactive to closed, thus allowing the sodium channel to be opened with depolarization.[29] If hyperkalemia is secondary to the toxic effects of cardioactive steroids on the Na^+-K^+-adenosine triphosphatase (ATPase) pump, intravenous calcium can potentially exacerbate an already excessive intracellular calcium concentration, making IV calcium potentially harmful.

Î²-Adrenergic Antagonists

In vitro studies suggest that the negative inotropic action of propranolol (Chap. 59) and analogs is related to interference with both the forward and reverse transport of calcium in the sarcoplasmic reticulum and to inhibition of microsomal and mitochondrial calcium uptake.[19,38,44] In a canine model of propranolol poisoning, the administration of a bolus of calcium chloride followed by a continuous infusion improved mean arterial pressure, maximal left ventricular pressure change over time, and peripheral vascular resistance, but had no effect on bradycardia or QRS prolongation.[39] Several case reports attest to the beneficial effects of calcium in Î²-adrenergic antagonist overdose.[10,33,53,60] Because distinguishing an overdose of a calcium channel blocker from a Î²-adrenergic antagonist is difficult and often the two are taken simultaneously, as long as no contraindications exist, a trial of intravenous calcium seems reasonable.

Black Widow Spider Envenomation

Envenomation by the black widow spider (*Latrodectus spp*) (Chap. 115) leads to local and systemic symptoms. Most commonly, severe abdominal or back pain begins within several hours of envenomation.[16] The venom exerts its effects by opening sodium

channels leading to calcium influx; the release of synaptic transmitters, including norepinephrine and acetylcholine, are believed to be involved.[56] Intravenous calcium, along with analgesics,

benzodiazepines, and muscle relaxants, is used to successfully relieve the pain and muscle spasms.[16,34] Rarely, antivenom may be indicated. Animal studies suggest that the venom induces changes in the permeability of calcium that may be overcome by increasing the extracellular concentration of calcium.[35,49] One prospective study noted improvement in 6 of 13 patients treated with calcium gluconate.[34] However, a large retrospective study of 163 patients casts doubt on the effectiveness of calcium.[16] Very few patients in the study had received adequate pain relief from calcium, and all but one patient also required opioids.[16] Most research suggests that there is no longer a role for calcium in the management of black widow spider envenomation (see Chap. 115).

TABLE A27-1. Calcium Salts for Intravenous Use

	Calcium Gluconate (Ca^{2+} Gluconate)	Calcium Chloride ($CaCl_2$)
10% Solution	10 mL = 1 g of Ca^{2+} gluconate	10 mL = 1 g of $CaCl_2$
	1 mL = 0.45 mEq elemental Ca^{2+}	1 mL = 1.36 mEq elemental Ca^{2+}
Adult dose	3 g (30 mL of 10% Ca gluconate)	1 g (10 mL of 10% $CaCl_2$)

	Repeat every several minutes as necessary	Repeat every several minutes as necessary
Pediatric dose (not to exceed the adult dose)	60 mg/kg (0.6 mL/kg) of Ca^{2+} gluconate 10% infused by slow intravenous bolus over 10â€“20 seconds in cardiac arrest or over 5â€“10 minutes in a well-perfused patient	20 mg/kg (0.2 mL/kg) infused by slow intravenous push over 10â€“20 seconds in cardiac arrest or over 5â€“10 minutes in a hemodynamically stable patient
	Repeat every several minutes as necessary	Repeat every several minutes as necessary

Safety Issues and Calcium Preparations

Severe hypercalcemia is defined by a serum calcium concentration greater than 3.5 mmol/L (14.0 mg/dL) in a patient with a normal albumin concentration. The adverse effects of hypercalcemia (independent of the rate of administration) include nausea, vomiting, constipation, hypertension if intravascular volume is maintained, polyuria, polydipsia, cognitive difficulties, hyporeflexia, coma, and enhanced sensitivity to cardioactive steroids.[5] Significant hypercalcemia may lead to myocardial

depression. The symptoms exhibited depend on the patient's age, rate of increase in the serum calcium, and duration of the hypercalcemia.[5]

A variety of calcium salts are available for parenteral administration. The two most commonly used are calcium chloride and calcium gluconate (Table A27-1). Neither salt should be mixed with sodium bicarbonate because calcium carbonate, a precipitate, is formed. Calcium chloride is an acidifying salt and is extremely irritating to tissue. It should never be given intramuscularly, subcutaneously, or perivascularly.[28,45] Calcium gluconate is less irritating, but care should also be taken to avoid extravasation. The best reason for choosing calcium gluconate in almost all clinical situations is that the tissue risk is far less. Equivalent doses of calcium chloride and calcium gluconate produce similar serum ionized calcium measurements, with peaks occurring within 30 seconds and accompanied as measured by hemodynamic values.[43] These measurements support the idea that simple dissociation of calcium from gluconate is responsible for releasing calcium, rather than hepatic metabolism. Earlier evidence suggesting that infusions of intravenous calcium chloride produce slightly larger increases in ionic calcium than do infusions of calcium gluconate has been challenged.[43,71] Intravenous calcium must be administered slowly, at a rate not exceeding 0.7â€“1.8 mEq/min or one 10-mL vial of calcium chloride over 10 minutes in adults. More rapid administration may lead to vasodilation, hypotension, bradycardia, dysrhythmias, syncope, and cardiac arrest.[6,17,36,45,63]

In cases of extreme life-threatening hypocalcemia or for a patient in extremis, a slow IV push may be required.

Summary

Intravenous calcium is an effective antidote for the hypocalcemia induced by ethylene glycol and hydrofluoric acid. It serves as a

physiologic antagonist to the cardiac and/or neurologic effects of hypermagnesemia and hyperkalemia and counteracts the effects of calcium channel blocker overdoses. It may have some benefit in the treatment of Î²-adrenergic receptor antagonist overdoses. The efficacy of calcium in the management of patients with black widow spider envenomation is of limited value. Great care must be taken to avoid extravasation. Calcium chloride, in particular, can cause tissue necrosis. Equivalent doses of calcium gluconate and calcium chloride deliver equal amounts of ionic or active calcium. Electrocardiographic monitoring and frequent serum calcium determinations are required to prevent iatrogenic toxicity. Although most clinical experience involves intravenous use, advances in intraarterial, topical, and inhalational calcium therapy offer unique potential advantages in certain circumstances.

Chapter 102 Hydrocarbons

David D. Gummin

Daniel O. Hryhorczuk

An 18-month-old girl was found by her mother immediately after ingesting â€œa mouthfulâ€• of clear oil from a decorative oil lamp. The child coughed and gagged, and within a few minutes began vomiting fluid that smelled similar to the oil that remained in the lamp. Within 90 minutes of the ingestion, the child had 3 episodes of vomiting, and her respirations were increasingly sonorous. The mother called the poison center, and the child was referred to the nearest emergency department (ED).

In the ED, the child was tachypneic and agitated. Vital signs were: blood pressure, 110/50 mmHg; pulse, 110â€“160 beats/min; respiration, 60 breaths/min; and she was afebrile. Pulse oximetry was 82% on room air. The mucous membranes were moist, and no oropharyngeal lesions were noted. Nasal flaring was present. Tachypnea and chest retractions were noted, although the breath sounds were clear and equal. The heart was rapid and regular. Bowel sounds were decreased, but the abdomen was soft. She was awake,

agitated, and moved all extremities equally. The skin was dry, with capillary refill of less than 2 seconds. Supplemental oxygen by nasal cannula raised the oxygen saturation to 94%. Chest radiograph showed right middle and lower lobe infiltrates.

The child was given intravenous methylprednisolone and ceftriaxone in the ED and was transferred to a pediatric intensive care unit (PICU). A nasogastric tube was placed and attached to suction, and additional thin, oily liquid was removed from the patient's stomach. Despite poison center recommendations to hold antibiotics and corticosteroids, these were continued in the PICU. Overnight she was able to maintain her oxygen saturation at greater than 90% with supplemental oxygen. The child never required assisted ventilation. After 24 hours in the PICU, her respirations improved, such that she was transferred to a general pediatric ward, still on supplemental oxygen. Her status continued to improve and she was discharged home on the third day.

Follow up was obtained at 2 months, at which time crackles were auscultated over her lower lung fields. Chest radiography revealed pneumatoceles in both lower lobes.

Spawned during the industrial revolution, organic chemistry evolved out of advances in coal tar technology. The discovery of aniline dye led to bulk distillation of coal tar to recover crude naphtha and aromatic hydrocarbons such as benzene. Additional coal tar distillation products included light oil, creosote oil, anthracene oil, road tar, and pitch. Eventually, petroleum replaced coal tar as the primary source of fossil fuel, naphtha, aromatic solvents, and other organic compounds. Besides fuels, the heterogeneous petroleum distillate compounds are used as solvents, lubricating oils, chemical feedstocks, and as chemical intermediates. There are numerous consumer and household applications of petroleum distillates as paint thinners, furniture polish, lamp oils, and lubricants (Table 102-1).

Although *hydrocarbons* represent chemically diverse substances, they are related primarily by the ways in which they are used. Most hydrocarbons in everyday use, such as gasoline, kerosene, and fuel

oils, are variable mixtures obtained as distillation fractions. This complicates the assessment of their toxicity. As a result, in discussing hydrocarbon toxicology, generalities are often used to discuss the behavior of these complex mixtures. This chapter highlights the toxicology of individual hydrocarbons when they are commercially available in purified form, or when individual compounds present unique toxicologic issues.

Chemistry

A *hydrocarbon* is an organic compound made up primarily of carbon and hydrogen atoms, typically ranging in length from 1â€“60 carbon atoms. This definition includes products derived from plants (pine oil, vegetable oil), animal fats (cod liver oil), natural gas, petroleum, and coal tar. There are two basic types of hydrocarbon molecules, *aliphatic* (straight or branched chains) and *cyclic* (closed ring), each with its own subclasses. The aliphatic compounds include the *paraffins* (*alkanes* , with a generic formula $C_n H_{2n+2}$); the *olefins* (*alkenes* have 1 double bond and *alkadienes* have 2 double bonds); *acetylenes* (generic formula $C_n H_{2nâ€“2}$ with a triple bond); and the *acyclic terpenes* (polymers of isoprene, $C_5 H_8$). Some aliphatic compounds have branches in which the subchain also contains carbon atomsâ€”both the chain and branches are essentially straight.

Solvents are a heterogenous class of chemicals used to dissolve and to provide a vehicle for delivery of other chemicals. The most common industrial solvent is water. The common solvents most familiar to toxicologists are the *organic solvents* (containing 1 or more carbon atom), and most of these are hydrocarbons. Most are liquids under the conditions in which they are used. Specifically named solvents (Stoddard solvent, white naphtha, ligroin) represent mixtures of hydrocarbons emanating from a common distillation fraction.

Saturated hydrocarbons contain carbon atoms only in their most reduced state, with each carbon bound to either hydrogen or to another carbon. No double or triple bonds are present. Conversely,

unsaturated compounds are those with hydrogens removed, and double or triple bonds are present.

The cyclic hydrocarbons include the *alicyclics* (3 or more carbon atoms in a ring structure, with properties similar to those of aliphatics), *aromatics* , and *cyclic terpenes.* The alicyclics are further divided into the *cycloparaffins* (*naphthenes*) such as cyclohexane, and the *cycloolefins* (2 or more double bonds) such as cyclopentadiene.

[a] Direct values for kinematic viscosity in Saybolt seconds universal (SSU) were not available for the following compounds: naphtha, xylene, methylene chloride, carbon tetrachloride, trichloroethylene, perchloroethylene, and toluene. SSU was calculated by converting from available measurements in centipoise viscosity and/or centistokes viscosity using the following conversions: the value in centistokes is estimated by dividing centipoise by density at 68Â°F (20Â°C); SSU is approximated from centistokes using $y = 3.2533x + 26.08$ ($R^2 = 0.9998$). Centipoise viscosity for naphtha was estimated from the value for butylbenzene. Centipoise viscosity for xylene is the average of *o*- , *m*- , and *p*- xlylene.

Compound	Carbon Atoms/Formula	Common Uses	Boiling Point Â°F (Â°C)	Viscosity (SSU)[a]

TABLE 102-2. Physical Properties of Common Hydrocarbons

The aromatic hydrocarbons are divided into the *benzene* group (1 ring), *naphthalene* group (2 rings), and the *anthracene* group (3 rings). *Polycyclic aromatic hydrocarbons* (polynuclear aromatic hydrocarbons) have multifused benzenelike rings. Aromatic organic compounds may also be *heterocyclic* (eg, where oxygen or nitrogen substitutes for carbon in the ring). Structurally, these molecules are flat, with reactive electron clouds above and below the ring.

The *cyclic terpenes* are the principal components of a variety of plant-derived essential oils, often providing color, odor, and flavor. *Limonene* in lemon oil, *menthol* in mint oil, *pinene* in turpentine, and *camphor* are all terpenes (Chap. 42).[140]

The physical properties of hydrocarbons vary by the number of carbon atoms and molecular structure (Table 102-2). Unsubstituted, aliphatic hydrocarbons containing up to 4 carbons are gaseous at room temperature, 5â€“19 carbon molecules are liquid, and longer-chain molecules tend to be tars or solids. Branching of chains tends to destabilize intermolecular forces, such that less energy is required to separate the molecules. The result is that, for a given molecular size, highly branched molecules have lower boiling points, and tend to be more volatile.[137]

As discussed previously, most commercial hydrocarbon products are variable mixtures of individual hydrocarbon compounds. An illustrative example of a *mixture* is gasoline. Gasoline is a mixture of alkanes, alkenes, naphthenes and aromatic hydrocarbons, predominantly 5â€“10 carbon molecules in size.[209] Natural gasoline is separated from

crude oil in a common distillation fraction. However, most commercially available gasolines are actually blends of up to 8 component fractions from refinery processors. More than 1500 individual compounds may be present in commercial grades, but most analytical methods are only able to isolate 150â€“180 compounds from gasolines. Notably, *n* -hexane is present at up to 6%, and benzene is present between 1 and 6%, depending on the grade and the place of origin of the product. In addition, a number of additives may go into the final formulation: alkyl leads, ethylene dichloride, and ethylene dibromide in leaded gasoline, and oxygenates like methyl *t* -butyl ether (MTBE), as well as methanol and ethanol.

Organic halides contain 1 or more halogen atoms (fluorine, chlorine, bromine, iodine) usually substituted for a hydrogen atom in the parent structure. Examples include chloroform, trichloroethylene (TCE), and the freons.

Oxygenated hydrocarbons demonstrate toxicity specific to the oxidation state of the carbon, as well as to the atoms adjacent to it (the â€œRâ€• groups). The *alcohols* are widely used as solvents in

industry and in household products. Their toxicity is discussed in Chaps. 75 and 103 . *Ethers* contain an oxygen bound on either side by a carbon atom. Acute toxicity from ethers tends to mirror that of the corresponding alcohols. *Aldehydes* and *ketones* contain a single carbon-oxygen double bond (C=O)â€”the former at a terminal carbon, the latter somewhere in the middle. Organic *acids* , *esters* , *amides* , and *acyl halides* represent more oxidized states of carbon; human toxicity is agent specific.

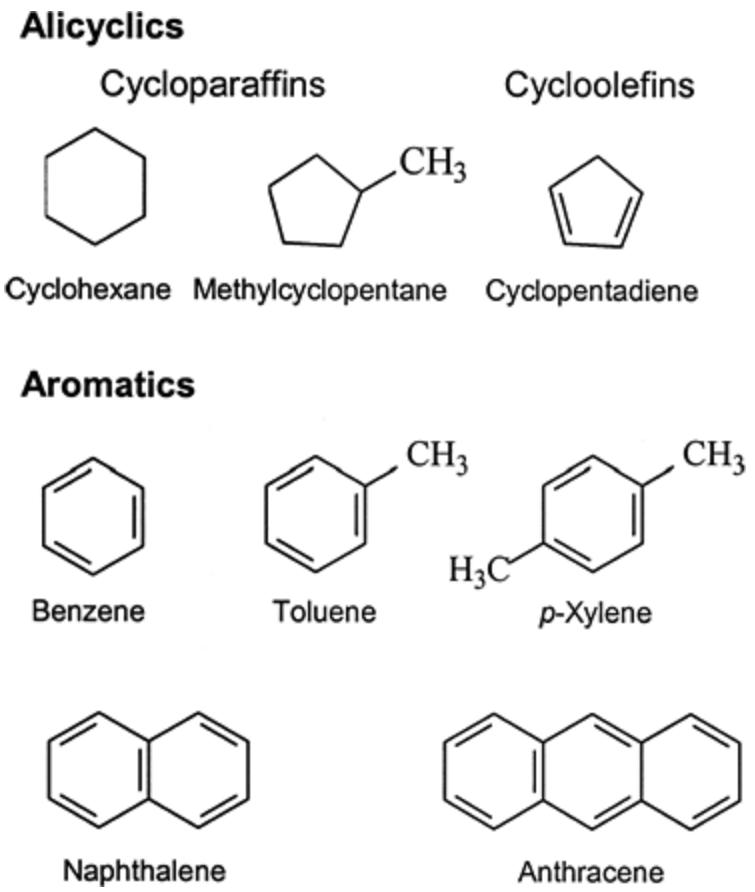

Figure 102-1. Basic hydrocarbon structures.

Phenols consist of benzene rings with an attached hydroxyl (alcohol) group. The parent compound, phenol, has only one hydroxyl group attached to benzene. The toxicity of phenol can be dramatically altered by addition of other functional groups to the benzene ring (Chap. 98). Cresols, catechols, and salicylate are examples of substituted phenols.

A variety of amines, amides, nitroso and nitro compounds, as well as phosphates, sulfites, and sulfates are used commercially and in industry. The addition of these functional groups to hydrocarbons dramatically alters the toxicity of the compound.

Figure 102-1 presents the chemical structures of some of the more commonly encountered hydrocarbons.

History and Epidemiology

The process of obtaining hydrocarbons from coal involves distillation of bituminous (soft) coal to remove *coal gas* , which can then be separated into a variety of natural gases. A large amount of distillate residue from the heating process remains as *coal tar* , which can be separated into kerosene and a variety of other hydrocarbon mixtures. The principal commercial source of hydrocarbons today involves distillation of crude oil. Petroleum is heated to fixed temperatures in a large-scale distillation procedure, allowing separation of hydrocarbons into distillation fractions by vapor (boiling) point. Because of the relationship between boiling point and molecular weight, this process roughly divides substances into like-sized mixtures. The most-volatile fractions come off early as gas, and are used primarily for heating. The least-volatile fractions (larger than about 10 carbons) are used chiefly for fuel and/or lubricants, paraffins, petroleum jelly, and asphalt. The remaining volatile hydrocarbon fractions (C_5 to C_{10}) form the fractions most commonly used as solvents.

Longer alkanes are often submitted to an industrial process known as *cracking* , in which they are superheated in a chamber, where catalytic pyrolysis converts them into shorter-chain alkanes and alkenes. Refineries then typically employ processes such as *catalytic isomerization* , to increase the amount of branching in the hydrocarbon chain (which increases the â€œoctaneâ€• of the fuel), and *catalytic reforming* , which converts alkanes and cycloalkanes into aromatic compounds.[137]

Essential oils (or volatile oils) are typically fragrant hydrocarbon plant extracts. Examples include menthol, eucalyptus oil, clove oil, sassafras oil, and pennyroyal oil, among others. These oils have been used from antiquity for a variety of medicinal reasons, and are enjoying resurgence with recent popularity of herbal supplements (Chap. 43). Mineral oil, castor oil, and glycerine are commonly used as laxatives. Hydrocarbon-based ointments, petroleum jelly, and camphor are used topically on skin and mucous membranes. Phenol and substituted

phenols are common medical disinfectants (Chap. 98). Diethyl ether and halogenated hydrocarbon compounds, like chloroform, were among the first general anesthetics, used more than 150 years ago.[125, 168] Cyclopropane and TCE have been widely used as general anesthetics.[125]

Occupations at risk for solvent exposure include petrochemical workers, plastics and rubber workers, printers, laboratory workers, painters, and hazardous waste workers. But exposures are ubiquitous in many occupations, and even in everyday life. In fact, the Occupational Safety and Health Administration estimates that nearly 238,000 American workers are exposed annually to significant concentrations of benzene alone.[95] The epidemiology of hydrocarbon exposure and hydrocarbon-related illness is particularly difficult to analyze. Because a common property of organic solvents is their high volatility, inhalational exposure occurs frequently and their high lipid solubility allows for dermal absorption.[83] Most exposures do not involve ingestionâ€”they may range from pumping your own gasoline to painting the spare bedroom, to applying or removing fingernail polish. Tables 102-1 and 102-2 list frequently encountered hydrocarbon-containing compounds.

In the years 1999â€“2003, a yearly average of 59,370 human exposures to hydrocarbon were reported to poison centers that contribute to the Toxic Exposures Surveillance System (TESS) database of the American Association of Poison Control Centers (AAPCC). These exposures accounted for 2.6% of the total human exposures reported, and resulted, on average, in 13 deaths per year. The incidence of both exposures and deaths has not changed appreciably in this database since the first AAPCC report in 1983. Over the 5-year period 1999â€“2003, 36â€“39% of exposures were unintentional exposures in children younger than 6 years of age. Although exposures in children appear to be declining compared to prior years of TESS data, this may be an artifact of the way that cases are coded in the database. Within the TESS database, many thousands of hydrocarbon exposures are not listed as such, but are ascribed to

â€œchemicals, pesticides, personal care products, cleaning substances, paints, automotive products,â€• and the like (see Chap. 130 for references). Certainly, these numbers dramatically underestimate North American exposures. More concerning is a

trend toward increased intentional abuse of volatile solvents by young people in our country (Chap. 79).

Three populations appear to be at risk for hydrocarbon-related illness: children with unintentional exposuresâ€”often ingestions; workers with occupational exposuresâ€”often dermal and inhalational; and adolescents/young adults who intentionally abuse solvents through inhalation.

Pharmacology

The acute toxicity of inhaled hydrocarbon vapor manifests principally through depression of consciousness. The acute central nervous system (CNS) toxicity of solvent vapors from occupational overexposure or recreational abuse, parallels the pharmacology of an inhaled general anesthetic.[176] The concentration of a volatile anesthetic that will produce loss of nociception in 50% of patients is defined as the minimum alveolar concentration (MAC) required to induce anesthesia. Inhaled solvent vapor will similarly produce unconsciousness in 50% of subjects when the partial pressure in the lung reaches its median effective dose (ED_{50}). Essentially all patients will be anesthetized when the partial pressure is raised 30% above the MAC (MAC Ã— 1.3). The doseâ€“response curves suggest that essentially no individual will be rendered unconscious by an inhaled dose 30% below the MAC. However, acute impairment of cognitive and motor function may occur at much lower exposures.[24]

Industrial exposure to lipid-soluble solvents, such as aromatic, aliphatic, or chlorinated hydrocarbons, are more likely to cause both acute and chronic CNS effects than will industrial exposure to water-soluble hydrocarbons like alcohols, ketones, and esters.[120] The

property of an inhaled anesthetic that correlates most closely with its ability to extinguish nociception is its lipid solubility.[84] The Meyer-Overton hypothesis, proposed more than 100 years ago, implies that an anesthetic agent dissolves into some crucial lipid compartment of the CNS causing inhibition of neuronal transmission.[125] Nonspecific inhibition of neuronal transmission through membrane or membrane protein conformational changes may occur.[166, 174]

At least some hydrocarbons may have specific cellular sites of action within the CNS.[16] Volatile anesthetics, for example, can affect ligand-gated ion channels. They interact with acetylcholine receptors to increase neurotransmitter binding[66] and to potentiate nicotinic blockade.[30] Anesthetics stimulate Î³-aminobutyric acid type A ($GABA_A$) activity,[118, 134] as do toluene and trichloroethane (TCA);[22] and anesthetics may inhibit GABA catabolism.[46] Some agents stimulate glutamate release.[92] Toluene, on the other hand, inhibits neurotransmission at glutamate *N*-methyl-D-aspartate receptors. Toluene and TCE enhance glycine receptor function. Prolonged exposure to toluene can perturb dopaminergic transmission.[22] General anesthetic effects are modulated by adenosine[171] and by $Î±_2$ agonism.[169] This line of mechanistic research suggests that the Meyer-Overton hypothesis may be too simplistic to explain the differences in pharmacologic profiles observed with this wide class of individual chemicals.

Toxicokinetics

Human toxicokinetic data are lacking for most hydrocarbons, and much of our understanding of the kinetics of this large family of chemicals comes from animal studies. Hydrocarbons are variably absorbed through ingestion, inhalation, or dermal routes of exposure, depending on their structure and chemical properties. Partition coefficients, in particular, are useful predictors of the rate and extent of the absorption and distribution of hydrocarbons into tissues as the higher the value the greater the potential for redistribution. A partition

coefficient for a given chemical is the ratio of concentrations achieved between two different media at equilibrium. The blood-to-air and tissue-to-air or tissue-to-blood coefficients directly relate to the pulmonary uptake and distribution of hydrocarbons. The tissue-to-blood partition coefficient is commonly determined by dividing the tissue-to-air coefficient by the blood-to-air coefficient.[70 , 150] Table 102-3 lists the partition coefficients for commonly encountered hydrocarbons. Where human data is limited, rat data is presented in the table as human and rat data often correlate.[150]

Inhalation is a major route of exposure for most volatile hydrocarbons. The absorbed dose is determined by the air concentration, duration of exposure, minute ventilation, and the blood-to-air partition coefficient. Most hydrocarbons cross the alveolus through passive diffusion. The driving force for passive diffusion across the alveolus is the difference in vapor concentration between the alveolus and the blood. Hydrocarbons that are highly soluble in blood and tissues are readily absorbed through inhalation, and blood concentrations rise rapidly following inhalation exposure. Although aromatic hydrocarbons are generally well absorbed through inhalation, for aliphatic hydrocarbons, absorption through inhalation varies by molecular weight: Aliphatic hydrocarbons with between 5 and 16 carbons are readily absorbed, whereas those with more than 16 carbons are not as readily absorbed.[3]

Absorption of aliphatic hydrocarbons through ingestion is inversely related to molecular weight, ranging from complete absorption at lower molecular weights, to approximately 60% for 14C hydrocarbons, 5% for 28C hydrocarbons, and essentially no absorption for aliphatic hydrocarbons with >32 carbons.[3] Oral absorption of aromatic hydrocarbons with between 5 and 9 carbons ranges from 80â€“97%. Oral absorption data for aromatic hydrocarbons with more than 9 carbons are limited.

While the skin is a common area of contact with solvents, for most hydrocarbons the dose received from dermal exposure is a small

fraction of the dose received through other routes, such as inhalation. The skin is composed of both hydrophilic (proteinaceous portion of cells) and lipophilic (cell membranes) regions. While many hydrocarbons can remove lipids from the stratum corneum, permeability is not simply a result of lipid removal; permeability is also increased with hydration of the skin. When compounds have near equality in the water-to-lipid partition coefficient, their rate of skin absorption is increased. Solvents that contain both hydrophobic and hydrophilic moieties (eg, glycol ethers, dimethylformamide, dimethylsulfoxide) are particularly well absorbed.[120] Other factors, in addition to the partition coefficient and permeability constant, that determine penetration across the skin include the thickness of the skin layer, the difference in concentration of the solvent on both sides of the epithelium, the diffusion constant, and skin integrity (ie, normal vs. cut or abraded).

The dose received via skin absorption will also depend on the surface area of the skin exposed and the duration of contact. Although highly volatile compounds may have a short duration of skin contact because of evaporation, skin absorption can also occur from contact with hydrocarbon vapor. In studies with human volunteers exposed to varying concentrations of hydrocarbon vapors, the dermal dose accounted for only 0.1â€“2% of the inhalation

dose. With massive exposure (eg, whole-body immersion), dermal absorption may contribute significantly to toxicity.[83] Significant dermal absorption with resultant toxicity has been described with carbon tetrachloride,[99] tetrachloroethylene,[83] and phenol.[117]

TABLE 102-3. Kinetic Parameters of Select Hydrocarbons

Once absorbed into the central compartment, hydrocarbons are distributed to target and storage organs based on their tissue-to-blood partition coefficients, and on the rate of perfusion of the tissue with blood. During the onset of systemic exposure, hydrocarbons accumulate in tissues, such as fat, that have coefficients between tissue and blood that are >1 (eg, for toluene, the fat-to-blood partition coefficient is 60). Table 102-3 lists the distribution half-lives of selected hydrocarbons.

Hydrocarbons can be eliminated from the body unchanged, for example, through expired air, or can be metabolized to more polar compounds, which are then excreted through urine or bile. Table 102-3 lists the blood elimination half-lives (for first-order elimination processes) and metabolites of selected hydrocarbons. Some hydrocarbons are metabolized to toxic compounds (eg, methylene chloride, carbon tetrachloride, *n* -hexane, methyl-*n* -butyl ketone). The specific toxicities of these metabolites are discussed under Special Cases below.

Pathophysiology

Pulmonary

For years, the medical literature held stage for debate over the

pathogenesis of lung injury after hydrocarbon exposure. Early investigators debated whether pulmonary toxicity was caused by gastrointestinal absorption of hydrocarbons with subsequent pulmonary toxicity, or by direct aspiration into pulmonary parenchyma.[28, 54, 58, 71, 94, 115, 155, 158, 206] The rat and baboon models made it clear that hydrocarbons are absorbed in the gastrointestinal tract and can be recovered from lung and many other tissues.[14, 122] Based on the amounts absorbed in these animal studies, however, the volume of ingested hydrocarbon needed to cause pulmonary toxicity would be enormous. A number of other animal models (dogs, monkeys, and baboons) employing gastric instillation of hydrocarbon demonstrated lack of pulmonary toxicity when aspiration did not occur.[56, 94, 215, 220] It is currently held that aspiration is the main route of injury from ingested hydrocarbons.

The mechanism of pulmonary injury, however, is not completely understood. Intratracheal instillation of 0.2 mL/kg of kerosene causes physiologic abnormalities in lung mechanics (decreased compliance and total lung capacity) and pathologic changes such as interstitial inflammation, polymorphonuclear exudates, intraalveolar edema and hemorrhage, hyperemia, bronchial and bronchiolar necrosis, and vascular thrombosis.[71, 72, 81, 89, 163, 164] These changes most likely reflect both direct toxicity to pulmonary tissue and disruption of the lipid surfactant layer.[75, 173, 213]

Several factors are associated with pulmonary toxicity after hydrocarbon ingestion. These include specific physical properties of the hydrocarbon ingested (Table 102-2), the volume ingested, and the occurrence of vomiting. The properties of *viscosity*, *surface tension*, and *volatility* of a particular hydrocarbon are the main determinants of its aspiration potential (Table 102-2).[73, 94]

Viscosity is the measurement of a fluid's resistance to flow. *Kinematic viscosity* is the absolute viscosity divided by the fluid's

density, usually expressed in stokes or in centistokes (mm^2/sec). One

method of quantifying viscosity is by the rate of flow through a calibrated orifice. This is measured in Saybolt Seconds Universal (SSU). At a given temperature, viscosity values can be converted from International System of Units (SI) units of kinematic viscosity (eg, the stoke or the centistoke) to SSU by dividing by the density of the compound. Substances with low viscosities (SSU <60; eg, turpentine, gasoline, naphtha) are associated with a higher tendency for aspiration in animal models. The US Consumer Products Safety Commission has issued a rule requiring child-resistant packaging for products that contain 10% or more hydrocarbon by weight and that have a viscosity <100 SSU.[198]

Surface tension is a cohesive force generated by attractionâ€"Van der Waals forcesâ€"between molecules.[148] This influences adherence of a liquid compound along a surface (â€œits inability to creepâ€•), and is measured using a modified Wilhelmy balance.[94] The lower the surface tension, the higher the aspiration risk.[73 , 94]

Volatility is the tendency for a liquid to become a gas. Hydrocarbons with high volatility tend to vaporize, displace oxygen, and lead to transient hypoxia.

It is not clear which of the physical properties of the hydrocarbon is most important in predicting toxicity. Several studies have examined the risk of pulmonary toxicity relative to the amount of hydrocarbon ingested, with or without vomiting. Some have found an association between the volume ingested and risk for pulmonary toxicity, whereas others have not.[21 , 26 , 49] Similar discrepancies hold for presence of vomiting.[21 , 26 , 38 , 144 , 145] Moreover, the validity of these studies has been questioned because of retrospective methodology and poor response rates regarding the volume ingested. Only one prospective study addressed these issues: the Co-Operative Kerosene Poisoning Study (COKP). Forty-six hospitals participated in this series of 760 cases. Of these, 54% of patients had clear estimates of the amount of kerosene ingested: 29% were reported to have ingested >30 mL; 35% ingested were reported to have 10â€“30 mL; and 35% were reported

to have ingested <10 mL. No association was found between amount of kerosene ingested and the age of the patient. In patients who ingested more than 30 mL, there was a 52% chance of developing pulmonary complications.[151] Those patients who ingested this amount were found to have a higher chance of developing central nervous system complications than did those who ingested less than 30 mL. Regarding spontaneous vomiting, the cooperative study was able to provide data on only 273 of the 760 patients. There was a 54% incidence of pulmonary toxicity when vomiting occurred, and 39% when there was no history of vomiting.[151] Although these features may be useful for predicting the possibility of hydrocarbon-induced pulmonary toxicity, none of these parameters is 100% predictive. Serious poisoning may be less likely with hydrocarbons that have higher viscosity and higher surface tension, such as mineral oil. However, severe hydrocarbon pneumonitis also is associated with â€œlow-riskâ€• hydrocarbons.[162] Furthermore, it is suggested that patients are severely injured with low-volume (<5 mL) ingestions, as well as in ingestions without a history of coughing, gagging, or vomiting.[9]

Intravenous (IV) and subcutaneous injection of hydrocarbons are reported.[160, 170, 200] Severe hydrocarbon pneumonitis may occur following intravenous exposure. Animal experiments show that intravascular hydrocarbons injure the first capillary bed encountered.[28] Intravenous injection causes pulmonary toxicity, and portal vein injection leads to direct hepatic injury.[28, 54, 94, 158, 216, 220] The clinical course after IV hydrocarbon injection mirrors that of aspiration injury.

Cardiac

Exposure to hydrocarbons by any route may cause cardiotoxicity. Halogenated hydrocarbons and benzene are most frequently implicated, although toluene and gasoline may also induce dysrhythmias.[19] A canine model demonstrated ventricular premature

beats and/or ventricular fibrillation after inhalation of trichloroethane followed by intravenous injection of epinephrine.[157] Dysrhythmia-induced sudden death, termed the â€œsudden sniffing death syndrome,â€• is well-described after inhalation of chlorinated hydrocarbons, but also for aromatic compounds.[110] Classically, sudden death in the setting of hydrocarbon exposure follows an episode of sudden exertion.[20, 67, 156] Tachydysrhythmias, cardiomegaly, and myocardial infarction are uncommonly reported after exposure by ingestion.[97, 179] A retrospective followup cohort of exposed methylene chloride workers did not find evidence of excess long-term cardiac disease.[146]

Central Nervous System

The specific mechanism of CNS depression from hydrocarbon toxicity is unclear. It is enticing to propose that specific channel inactivation or stimulation of inhibitory channels is responsible (see Pharmacology above). However, to date, no unifying theory or evidentiary support for specific receptor binding explains the acute CNS impairment that occurs with either volatile anesthetic or other hydrocarbon inhalation. In cases of hydrocarbon aspiration, hypoxia from pulmonary damage may contribute to the CNS depression.[122, 217]

The CNS toxicity of chronic toluene abuse is well-described, and illustrates the ability of some hydrocarbons to produce pathologic changes in the CNS. Prolonged, moderate-to-heavy exposure to hydrocarbons, as occurs in volatile solvent abuse (Chap. 79), can lead to irreversible CNS damage. The primary pathologic process is white matter degeneration (*leukoencephalopathy*). Autopsy studies of the brains of chronic toluene abusers show profound atrophy and mottling of the white matter, as though the lipid-based myelin were dissolved away. These pathologic features correlate with the clinical syndrome of a â€œwhite matter dementia.â€• [61, 69] Microscopic examination shows a consistent pattern of myelin and oligodendrocyte loss with relative preservation of axons.[109] Animal studies of toluene poisoning

have also revealed biochemical changes including diminished norepinephrine and dopamine concentrations and alterations in various neurotransmitter levels.[165]

Peripheral Nervous System

Peripheral neuropathy is well described following occupational exposure to *n* -hexane or methyl-*n* -butyl ketone (MnBK).[27] Methyl ethyl ketone (MEK) may exacerbate this neurotoxicity, probably by interfering with metabolic pathways of *n* -hexane and MnBK.[8 , 161] This axonopathy results from a metabolic intermediateâ€”2,5-hexanedioneâ€”common to both hexane and MnBK. The mechanism by which this intermediate causes peripheral neuropathy may relate to decreased phosphorylation of neurofilament proteins, with disruption of the axonal cytoskeleton (see Special Cases below). Other organic solvents, such as carbon disulfide, acrylamide, and ethylene oxide, may cause a similar peripheral axonopathy.[77]

Cranial and peripheral neuropathies are reported after acute and chronic exposure to trichloroethylene (TCE).[36 , 100 , 114 , 187] Pathologically, TCE appears to induce a myelinopathy.[62 , 77]

Hepatic

Chlorinated hydrocarbons (Table 102-2) are particularly hepatotoxic. In most cases, this occurs via phase I activation to a reactive intermediate (Chap. 13). In the case of carbon tetrachloride, this intermediate is the trichloromethyl radical. This toxic metabolite forms covalent bonds with hepatic macromolecules, and may initiate lipid peroxidation.[29] Hepatic injury, manifested as aminotransferase elevation and hepatomegaly, is usually reversible, except in massive overexposures (see Special Cases below). Hepatotoxicity in animals has been ranked for common hydrocarbons as follows: carbon tetrachloride >> benzene, trichloroethylene > pentane.[214]

Dermal

Most hydrocarbon solvents cause nonspecific irritation of the skin and mucous membranes. Repeated, prolonged contact can dry and crack the skin. The mechanism of dermal injury appears to be defatting of the lipid layer of the stratum corneum. Up to 9% of workers may develop eczematous lesions from dermal contact.[221] Limonene and turpentine contain sensitizers, that rarely can result in contact allergy (Chap. 29).

Immunologic

Hydrocarbons disturb the integrity of membrane lipid bilayers, causing swelling and increased permeability to protons and other ions. This alters the structural and functional integrity of the membrane. Changes in the lipid composition of the membrane occur, and membrane lipopolysaccharides and proteins are disturbed.[174] Resultant toxicity may directly destroy capillary endothelium.[28] Additionally, there appears to be derangement of basement membranes, and this is postulated to underlie both alveolar and glomerular toxicity of hydrocarbons.[181] Immune mechanisms may account for basement membrane dysfunction in chronic exposures. Hydrocarbon exposure is suggested as a possible cause of Goodpasture syndrome (immune dysfunction causing both pulmonary damage and glomerulonephritis),[25] although the association is not widely accepted. Measurable changes in immune function occur after hydrocarbon exposure,[17] but our knowledge of any clinical implications is incomplete.

Clinical Manifestations

Pulmonary

Most patients who develop pulmonary toxicity after hydrocarbon ingestion have an episode of coughing, gagging, and choking. This

occurs shortly after ingestion, usually within 30 minutes, and is presumptive evidence of aspiration.[123] Absence of tachypnea on initial evaluation has an 80% negative predictive value for aspiration pneumonitis.[207] More severely affected patients may rapidly develop progressive pulmonary toxicity over the subsequent hours to days. Pulmonary toxicity manifests as crackles, rhonchi, bronchospasm, tachypnea, hypoxia, hemoptysis, acute lung injury (hemorrhagic or nonhemorrhagic), or signs of respiratory distress.[194] Cyanosis develops in approximately 2â€“3% of patients.[129] This may be caused by simple asphyxiant effects from volatilized hydrocarbons, ventilationâ€“perfusion mismatch, or, rarely, by methemoglobinemia (aniline, nitrobenzene, nitrite-containing hydrocarbons). Clinical findings often worsen over several days but typically resolve within 5â€“7 days. Death is rare (<2%), and is typically a consequence of severe progressive respiratory insult marked by hypoxia, ventilationâ€“perfusion mismatch, and barotrauma.[20, 59, 91, 128, 177, 205, 224]

Radiographic evidence of pneumonitis develops in 40â€“88% of admitted patients.[18, 21, 26, 58, 115, 145, 155] Findings can develop as early as 15 minutes or as late as 24 hours after exposure (Fig. 102-2).[49, 68, 89, 102, 151, 201] Ninety percent of patients who develop radiographic abnormalities develop evidence by 4 hours postingestion.[49] The majority of patients who have respiratory signs and symptoms beyond the initial history of gagging, choking, and coughing develop radiographic pneumonitis.[9] Clinical signs of pneumonia (eg, crackles, rhonchi) are evident in 40â€“50% of patients.[58] A small percentage (<5%) are completely asymptomatic after a period of observation, but have radiographic findings.[9] Chest radiographs performed immediately on initial presentation are not useful in predicting infiltrates in either symptomatic or asymptomatic patients.[207]

Specific radiologic findings include perihilar densities, bronchovascular markings, bibasilar infiltrates, and pneumonic consolidation.[18, 74] Right-sided involvement occurs in 75% of cases and bilateral

involvement in approximately 50%. Upper lobe involvement is uncommon.[18 , 32 , 89] Pleural effusions develop in 3% of cases,[126] with one third appearing within 24 hours. Pneumothorax, pneumomediastinum, and pneumatoceles are uncommonly reported.[15 , 23 , 40 , 101 , 116] Initial radiographs after ingestion may reveal two liquid densities in the stomach, known as the â€œdouble-bubbleâ€• sign.[50] This represents an airâ€“fluid (hydrocarbon or water) and a hydrocarbonâ€“water interface, as the hydrocarbon is not miscible with gastric fluids (primarily water) and may have a specific gravity less than that of water.

Radiographic changes often progress over several days, typically reaching a maximum at 5â€“7 days with resolution over several weeks. Radiographic resolution does not correlate with clinical improvement, which usually lags behind by several days to weeks.[71] Long-term followup in patients with hydrocarbon pneumonitis is limited.[32 , 68 , 82 , 155 , 190] Frequent respiratory tract infections are described in individuals after hydrocarbon pneumonitis, but studies addressing this are poorly controlled.[68 , 156 , 194] As with other pneumonic infiltrates, delayed formation of pneumatoceles may occur.[23 , 101 , 116] Bronchiectasis and pulmonary fibrosis are reported, but appear to be uncommon.[78 , 127 , 155] In one study, 82% of patients examined 8â€“14 years after hydrocarbon-induced pneumonitis had asymptomatic minor pulmonary function abnormalities.[82] The abnormalities were consistent with small-airway obstruction and loss of elastic recoil. The authors hypothesized that this group may be predisposed to chronic obstructive pulmonary disease.

Cardiac

The most worrisome cardiotoxicity associated with hydrocarbon exposure is that of myocardial sensitization and dysrhythmias.[19 , 157] This phenomenon is well described for halogenated hydrocarbons and less so for aromatic compounds. Sudden death can occur after

exposure to high concentrations of volatile inhalants or inhaled anesthetics, apparently resulting from tachydysrhythmias. Atrial fibrillation, ventricular fibrillation, and sudden cardiac death are reported.[79, 143, 156] Myocardial depression occurs by an unclear mechanism.[10] The mechanism of dysrhythmia induction appears to be endogenous catecholamine mediated extrasystoles occurring in the setting of altered repolarization, manifested by QTc interval prolongation.[20, 67, 110, 156, 157]

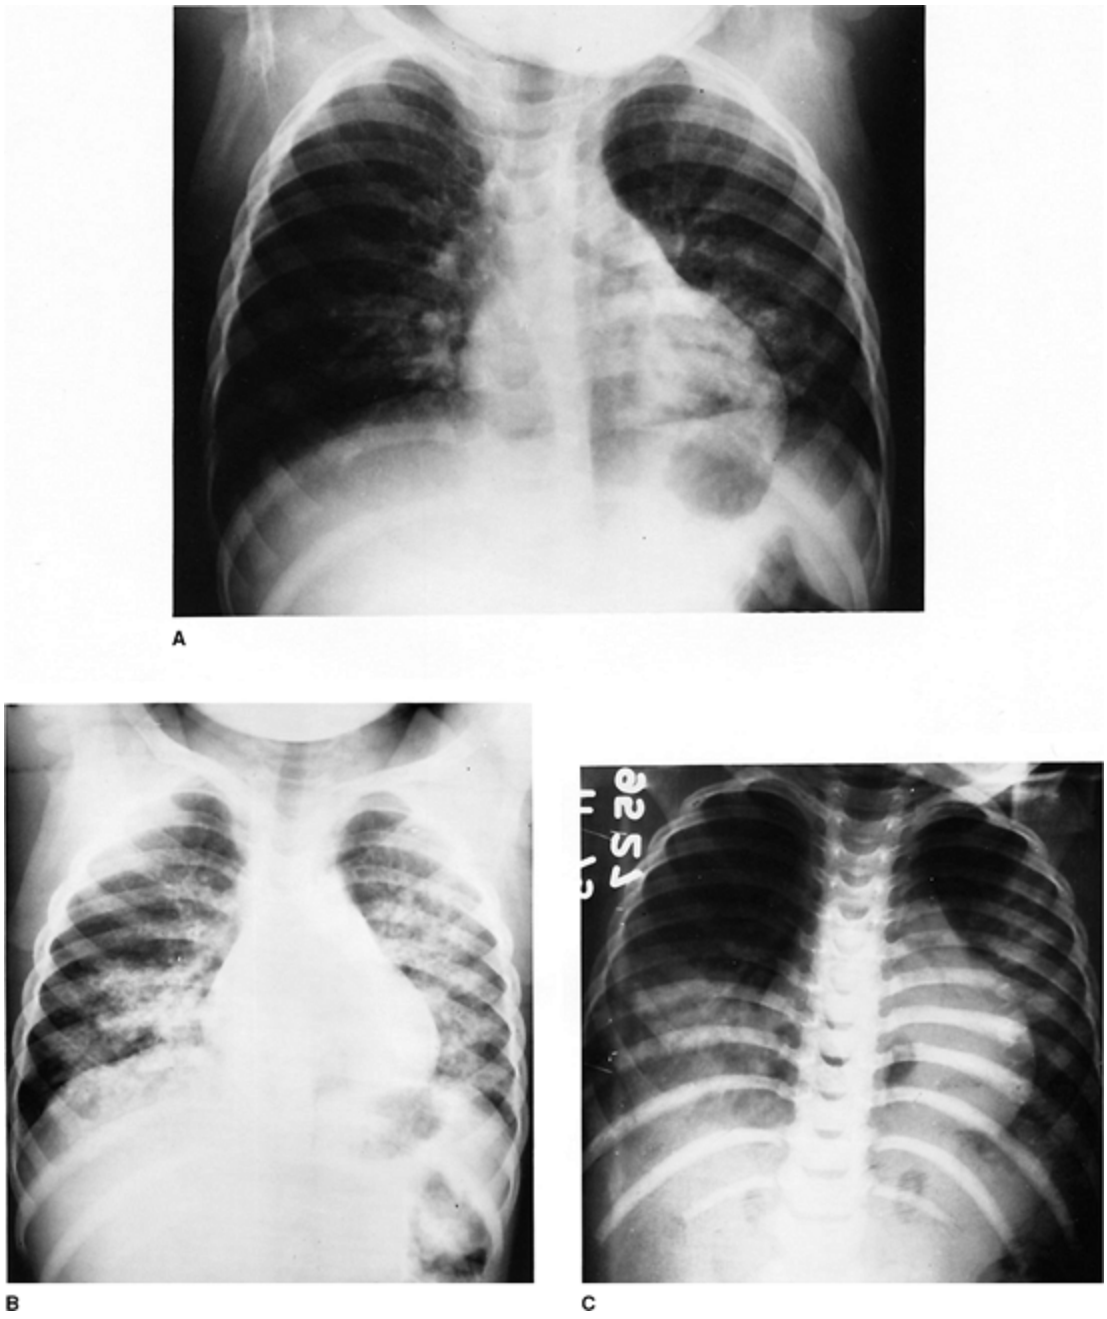

Figure 102-2. Three sequential radiographs of a young girl with severe hydrocarbon aspiration pneumonitis. A. Initial: Patchy densities appear in basilar areas of both lung fields with increased interstitial markings and peribronchial thickening. B. Day 2: More extensive diffuse alveolar infiltrates are apparent. C. Day 6: Dense consolidation and atelectasis are evident in the right lower lobe. *(Courtesy of Nancy Genieser, MD, Professor of Radiology, New York University.)*

Central Nervous System

Transient CNS excitation may occur initially after acute hydrocarbon inhalation or ingestion.[110] More commonly, CNS depression or general anesthesia occurs, and may be profound.[58] Coma and seizures are reported in 1â€“3% of cases.[115 , 145 , 155 , 223] Chronic occupational exposure or volatile substance use may lead to a chronic neurobehavioral syndrome; the painter's syndrome, most completely described after chronic toluene overexposure. The clinical features include ataxia, spasticity, dysarthria, and dementia, consistent with a leukoencephalopathic syndrome.[64] The severity and reversibility of this syndrome depends on the intensity and duration of toluene exposure.[165] Infrequent exposure may produce no clinical neurologic signs, whereas heavy (eg, daily) use can lead to significant neurologic impairment after as little as 1 year, but more commonly after 2â€“4 years of use. The specific cognitive and neuropsychological findings in toluene-induced dementia are termed a â€œwhite matter dementia.â€•[61 , 64 , 69]

Initial findings include behavioral changes, impaired sense of smell, impaired concentration, and mild unsteadiness of hand movements and gait. Further exposure leads to slurred speech, head tremor, poor vision, deafness, stiff-legged and staggering gait, and dementia. Physical findings can include nystagmus, ataxia, tremor, spasticity with hyperreflexia and abnormal Babinski reflexes, deafness, impaired vision, and a broad-based, staggering gait. An abnormal brainstem auditory-evoked response appears to be a sensitive indicator of toluene-induced CNS damage. Electroencephalograms can show mild, diffuse slowing. Computed tomography in severe cases shows mild-to-moderate cerebellar and cortical atrophy. MRI findings are consistent with white matter disease. Most cases show significant clinical

improvement after 6 months of abstinence, although with moderate to severe abuse, improvement may be incomplete.[165] Chronic toluene use is addictive and can produce withdrawal.

In the occupational setting, the extent of the exposure is rarely as substantial as during volatile substance misuse. Given the significantly lower exposures, the findings among workers overexposed to solvents (ie, exposure above permissible exposure limits) are often subclinical, and detected primarily through neurobehavioral testing. In rare cases, however, a worker may be acutely overexposed to solvent concentrations that can produce central nervous system depression. Repeated symptomatic overexposures over long periods of time have the potential to lead to a chronic encephalopathy as evident from the experience with solvent abusers.[61]

Peripheral Nervous System

Peripheral neuropathy may occur after exposure to *n* -hexane, MnBK, and possibly to toluene.[27 , 88 , 105 , 186] The axonopathy typically begins in the distal extremities and progresses proximally (a classic â€œdying-backâ€• neuropathy), and should be considered in the assessment and differential diagnosis of the patient with Guillain-BarrÃ© syndrome (GBS) although sensory finding are present with MnBK and absent with GBS.[175] The longest axons appear to be affected initially, so that the patient manifests a â€œlength-dependent polyneuropathy.â€• With discontinuation of exposure many of the effects reverse over weeks to months.[90 , 105 , 152 , 222] However, the phenomenon of â€œcoastingâ€• may occur, in which neuropathy progresses for a time (weeks to months) after discontinuation of the toxic insult.[175] A reversible peripheral neuropathy occurring in 40% of chronic toluene abusers is manifested by severe motor weakness, without sensory deficits or areflexia.[186] It is unclear whether the toluene in these early series may have been contaminated by *n* -hexane or MnBK.[8 , 176]

Trichloroethylene is associated with trigeminal neuralgia.[36 , 43 , 60 ,

[114] Trigeminal nerve damage was documented by evoked potentials follows 15 minutes of TCE inhalation.[114] Some evidence suggests that decomposition products or impurities in TCE may be responsible for cranial neuropathy.[43, 60]

Gastrointestinal

Hydrocarbons are irritants to the gastrointestinal mucous membranes. Nausea and vomiting are common after ingestion. As discussed earlier, vomiting may be associated with increased risk of pulmonary toxicity.[26, 144, 145, 162] Hematemesis can occur, and was reported in 5% of cases in one study.[144] Gastrointestinal ulcerations are found in animal studies.[14, 106]

Hepatic

Hepatic injury may occur after exposure to halogenated hydrocarbons, particularly carbon tetrachloride. Carbon tetrachloride can produce fatal centrilobular necrosis by inhalational, oral ingestion, or dermal exposure.[131] Vinyl chloride is a known liver carcinogen. Trichloroethylene, tetrachloroethylene, and 1,1,1-trichloroethane are considered less hepatotoxic than vinyl chloride.[131, 192] Hepatotoxicity rarely follows ingestion of petroleum distillates.[98] Jaundice, right upper quadrant pain, and encephalopathy may occur. Aminotransferase elevation typically resolves with cessation of exposure, except in extreme poisoning.

Renal

Halogenated hydrocarbons such as chloroform, carbon tetrachloride, ethylene dichloride, tetrachloroethane, and 1,1,1-trichloroethane are also nephrotoxic. Acute renal failure and distal renal tubular acidosis occur in some painters and volatile-substance abusers.[104] Toluene may cause a renal tubular acidosis-like syndrome (see Toulene below). Human studies of nephrotoxicity are confounded by other exposures,

and the findings in many animal studies conflict.[2]

Hematologic

Hemolysis has been sporadically reported to occur after hydrocarbon ingestion.[1, 7, 184] One retrospective study of 12 patients showed hemolysis in 3 individuals and disseminated intravascular coagulation in another.[7] Although 1 patient required transfusion, hemolysis is usually mild and does not require red blood cell transfusion (see discussion of benzene and its effects on the bone marrow under Benzene below).

Dermatologic

Contact dermatitis and blistering may progress to partial- and even full-thickness burns.[85] Severity is proportional to duration of exposure. Hydrocarbons are irritating to skin. Acute, prolonged exposure can cause dermatitis and even full-thickness dermal damage.[85] Chronic dermal exposure to kerosene or diesel fuel can cause oil folliculitis.[51, 199] A specific skin lesion called *chloracne* is associated with exposure to chlorinated aromatic hydrocarbons with highly specific stereochemistry (eg, dioxins, polychlorobiphenyls).

Soft-tissue injection of hydrocarbon is locally toxic, leading to necrosis. Secondary cellulitis, abscess formation, and fasciitis can occur. Infectious complications are treated by meticulous wound

care, with surgical dÃ©bridement as necessary. A particularly destructive injury involves high-pressure injection-gun injury. These injuries typically involve the extremities, with high-pressure injection of grease or paint into the fascial planes and tendon sheaths. Emergent surgical debridement is necessary in most of these cases.[63, 139]

Hydrocarbons with Specific and Unique

Toxicity

n -Hexane

Hexane is a 6-carbon simple aliphatic hydrocarbon. It is a constituent of some brake-cleaning fluids, rubber cement, glues, spray paints, coatings, and silicones. Outbreaks of *n* -hexaneâ€“related neurotoxicity have occurred in printing plants, sandal shops, furniture factories, and automotive repair shops.[44] Human exposure occurs primarily by inhalation. Both *n* -hexane and MnBK are well-known peripheral neurotoxins that cause a classic â€œdying-backâ€• peripheral polyneuropathy, beginning in a â€œstocking-gloveâ€• distribution (see Fig. 102-3).[27 , 45] Neurotoxicity does not appear to be directly caused by the parent compounds, but results from a common metabolic intermediateâ€”2,5-hexanedione. Toxicity appears related to the ability of this intermediate to form a ringed pyrrole structure, which causes decreased phosphorylation of neurofilament proteins, disrupting the axonal cytoskeleton.[77] Similar 5- and 7-carbon species do not induce similar neurotoxicity, except those that are direct precursor intermediates in the metabolic pathway producing 2,5-hexanedione.[77 , 188]

Methylene Chloride

Methylene chloride is commonly encountered in paint removers, as well as in cleaning and degreasing agents and in aerosol propellants. Like other halogenated hydrocarbons, it can rapidly induce general anesthesia by inhalation or ingestion. Unlike other hydrocarbon agents, methylene chloride and similar halomethanes (eg, methylene dibromide) are metabolized by liver P450 mixed-function oxidase to carbon monoxide. Significant, delayed, and prolonged carboxyhemoglobinemia can occur (Table 102-3 and Chap. 120).[4 , 153 , 154 , 180 , 183]

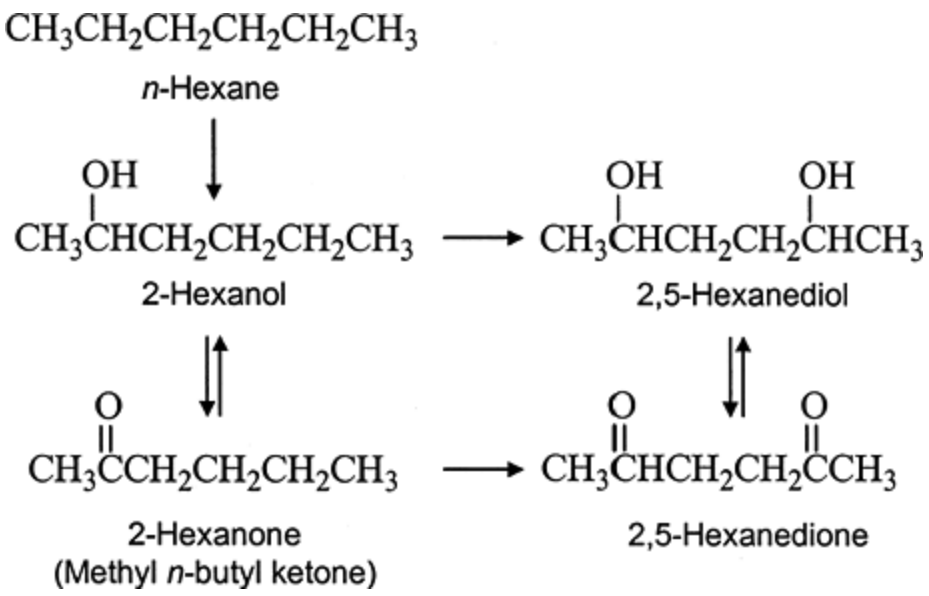

Figure 102-3. The metabolism of both organic solvents *n* -hexane and methyl *n* -butyl ketone produce the same neurotoxic metabolite, 2,5-hexanedione.

Carbon Tetrachloride

Carbon tetrachloride (CCl_4) although not actually a hydrocarbon, has been used as an industrial solvent and reagent. Its use in the United States has declined dramatically since recognition of its toxicity caused the Environmental Protection Agency to restrict its commercial use.[3] Absorption occurs by all routes, including dermal. It is an irritant to skin and mucous membranes, and is a potent gastric irritant when ingested. As with other halogenated hydrocarbons, aspiration can result in pneumonitis, and systemic absorption may result in ventricular dysrhythmias.[57]

More unique to CCl_4 exposures are hepatotoxicity and nephrotoxicity. Both occur more commonly with repetitive exposure (eg, occupational exposures).[47 , 99 , 191] Toxicity follows phase I dehalogenation of the parent compound, which produces free radicals, causes lipid peroxidation and the production of protein adducts.[29] Localization of specific phase I hepatic enzymes in the centrilobular area of the liver

results in regionalized (zone 3) centrilobular injury after CCl_4 exposure (Chap. 26). Hepatotoxicity is typically manifested as reversible aminotransferase elevation with or without hepatomegaly. Cirrhosis is reported in both animal models and in humans with prolonged overexposures. Nephrotoxicity is less-well studied, but may result from a similar mechanism.[33] The proximal convoluted tubule and the loop of Henle appear to be specifically targeted.[65] Carbon tetrachloride is a suspected human carcinogen.[3]

Benzene

Benzene is hematotoxic and associated with acute hemolysis, or the delayed development of aplastic anemia and acute myelogenous leukemia.[5 , 76 , 111 , 130 , 149] Other aromatic hydrocarbons that are reported to cause similar hematologic effects most likely are contaminated with benzene. An excess risk has not been demonstrated in groups with long-term exposure to toluene, xylene, or other aromatic hydrocarbons.[13 , 53 , 159 , 202 , 212] Other hematologic malignancies also may be linked to benzene, including chronic myelocytic leukemia, myelodysplastic syndromes, and lymphoma.[193] Chromosomal changes are believed to provide a marker for carcinogenicity.[197] Because of the carcinogenic risk, most benzene-based solvents have been unilaterally removed from the US market, and the Occupational Safety and Health Administration (OSHA) has limited the permissible worker exposure level to 1 ppm.[95]

Toluene

Toluene has essentially replaced benzene as the primary organic solvent in many commercial products. Many oil paints and stains contain primarily toluene as solvent. As such, it is readily available and readily abused as an inhalant. The CNS sequelae of chronic solvent inhalation are most frequently related to chronic toluene exposure.

Chronic toluene abuse can cause a syndrome that resembles transient distal renal tubular acidosis (RTA).[189 , 203] Although the mechanism is incompletely understood, the acidosis results in great part from the urinary excretion of hippuric acid (Table 102-3).[42 , 103] Renal potassium loss may be severe and can result in symptomatic hypokalemia.[103] Clinical findings are a hyperchloremic metabolic acidosis, hypokalemia, and aciduria. There is typically an associated transient renal azotemia, as well as proteinuria and an active urine sediment.[186 , 203] Some have reported a proximal RTA, or the Fanconi syndrome.[138 , 203] A metabolic acidosis resulting from the

metabolism of toluene to benzyl alcohol through alcohol dehydrogenase to benzoic acid may be an adequate explanation for the serum and urine acidâ€“base disturbances.

Pine Oil and Terpenes

Pine oil is an active ingredient in many household cleaning products. It is a mixture of unsaturated hydrocarbons comprised of terpenes, camphenes, and pinenes. The major components are terpenes, which are found in plants and flowers. Wood distillates are products derived from pine trees and include pine oil and turpentine. Patients who ingest pine oil often emit a strong pine odor. Wood distillates are readily absorbed from the gastrointestinal tract and ingestion may cause CNS and pulmonary toxicity without aspiration.

The clinical features of pine oil ingestion can include central nervous system depression, respiratory failure, and gastrointestinal dysfunction and are rarely fatal.[108 , 210] Aspiration pneumonitis remains the primary clinical concern. Acute toxicity is similar to that of petroleum distillate ingestion, and management is similar. Rare reported complications of wood distillate ingestion include turpentine-associated thrombocytopenic purpura, acute renal failure, and hemorrhagic cystitis.[112 , 204]

Tar and Asphalt Injury

Tar and asphalt injuries are common occupational hazards among construction workers. Asphalt workers are at risk for toxic gas exposure of hydrogen sulfide, carbon monoxide, propane, methane, and volatilized hydrocarbons.[93] In addition, cutaneous exposure to these hot hydrocarbon mixtures can cause severe burns. The material quickly hardens and is very difficult to remove. Immediate cooling with cold water is important to limit further thermal injury. Complete removal is essential to ensure proper burn management and to limit infectious complications. Attempts to mechanically remove hardened tar or asphalt often cause further damage. Dissolving the material with mineral oil, petroleum jelly, or antibacterial ointments (Neosporin, Polysporin) have met with variable success. Surface-acting agents combined with an ointment (De-Solv-it, Tween-80, Polysorbate 80) are more effective.[55 , 185 , 196]

Diagnostic Testing

Laboratory and ancillary testing for hydrocarbon toxicity should be guided by available information regarding the specific agent, the route of exposure, and the best attempt at quantifying the exposure. Inhalation or ingestion of hydrocarbons associated with pulmonary aspiration are most likely to result in pulmonary toxicity. The use of pulse oximetry and arterial blood gas testing in this group of patients is warranted when clinically indicated. Early radiography is indicated in patients who are severely symptomatic; however, radiographs performed immediately after hydrocarbon ingestion demonstrate a low predictive value for the occurrence of aspiration pneumonitis. In the asymptomatic patient, early radiography is not cost-effective. Patients observed for 6 hours after an ingestion, who demonstrate no abnormal pulmonary findings, have adequate oxygenation, are not tachypneic, and have a normal chest radiograph after the 6-hour observation period, have a good medical prognosis with very low risk of subsequent deterioration.[9 , 207]

The choice of specific diagnostic laboratory tests to assess organ system toxicity or function following exposure to a hydrocarbon depends on the type, dose, and route of exposure, and on the assessment of the patient's clinical condition. Useful clinical tests may include pulse oximetry, an electroencephalogram, or EEG.[147] Laboratory tests include serum or urine electrolytes, arterial blood gas, complete blood counts, and creatine phosphokinase. If a hydrocarbon has specific target organ toxicities (eg, benzene/bone marrow, carbon tetrachloride/liver, or *n* -hexane/peripheral nervous system), evaluation and monitoring of target organ system function is indicated.

Specific diagnostic testing for hydrocarbon poisoning can include (a) bioassays for the specific hydrocarbon or its metabolites in blood, breath, or urine, or (b) assessment of toxicity or function of the hydrocarbon's target organ. Bioassays for a hydrocarbon are seldom necessary for diagnosis or management of hydrocarbon poisoning in the emergency setting. Exceptions include testing to assist in differential diagnosis (eg, testing for carbon tetrachloride in a comatose patient with unexplained hepatic and renal toxicity or a carboxyhemoglobin determination in a paint stripper with chest pain), testing for worker compensation purposes (eg, testing for urinary trichloroethanol and trichloroacetic acid in a worker exposed to trichloroethylene with unexplained bouts of dizziness), or for forensic purposes (eg, sudden death in a huffer).

When deciding whether to obtain a bioassay for a hydrocarbon, the clinician should determine (a) what is the most informative biologic sample (blood, urine, breath) and how should it be collected, handled, and stored? (b) What are the kinetics of the hydrocarbon and the timing of exposure, and how should the results be interpreted in light of these kinetics? (c) What ranges of concentrations are associated with toxicity? Most hydrocarbon bioassays are performed by only a few, specialized clinical laboratories. The analytic toxicologist can often assist the clinician in determining the appropriate choice and timing of a bioassay. Table 102-3 provides useful information on the

elimination kinetics of selected hydrocarbons and on their common metabolites.

Chronic overexposures to hydrocarbons, as occur with volatile substance use, can result in persistent damage to the central nervous system. Damage can be detected and quantified using neuroimaging methods such as magnetic resonance imaging (MRI) or positron emission tomography (PET). Major MRI findings in patients with chronic toluene abuse include atrophy, white matter T2 hyperintensity, and T2 hypointensity involving the basal ganglia and thalamus.[39] Neurobehavioral testing can be used to detect subtle central nervous system effects following chronic occupational overexposures.

Management

Hydrocarbons are a diverse family of compounds with a wide spectrum of toxicities. Moreover, many exposures deal with mixtures of hydrocarbons rather than with individual agents. As such, identification of the specific type, route, and amount of hydrocarbon exposure is essential to effective management.

Decontamination is one of the cardinal principles of toxicology, with priority that is second only to stabilization of the cardiopulmonary status. Safe decontamination can avoid further absorption of toxicant(s), and avoids secondary casualties in those attempting to provide care. Protection of rescuers with appropriate personal protective equipment and rescue protocols is paramount, especially in situations where the victim has lost consciousness. The principle of removing the patient from the exposure (eg, vapor

or gaseous hydrocarbon) or the exposure from the patient (eg, hydrocarbon liquid on skin or clothing), while protecting the rescuer, implies that personal protective equipment be considered at each level of the healthcare delivery system.

Contraindications

- Occurrence of spontaneous vomiting
- Asymptomatic intially and at initial medical evaluation

Indications

- A hydrocarbon with inherent systemic toxicity (CHAMP)
  - C: camphor
  - H: halogenated hydrocarbons
  - A: aromatic hydrocarbons
  - M: hydrocarbons containing metals
  - P: hydrocarbons containing pesticides

TABLE 102-4. Gastric Emptying for Hydrocarbon Ingestion

Exposed clothing should be removed and safely discarded as further absorption or inhalation of hydrocarbons from grossly contaminated clothing can worsen systemic toxicity.[182] Decontamination of the skin should have a high priority in massive hydrocarbon exposures, particularly those exposures involving highly toxic hydrocarbons (Table 102-4). Water may be ineffective in decontaminating most hydrocarbons, but early decontamination with soap and water may be adequate. The caregiver should remain aware that certain hydrocarbons are highly flammable and pose a fire risk to hospital staff (Chap. 125).

Despite decades of vigorous debate, the role of gastric decontamination after hydrocarbon ingestion remains controversial.[19 , 54 , 132 , 133 , 218 , 220] Many clinical studies have addressed the efficacy of gastric lavage versus ipecac-induced emesis to prevent pulmonary toxicity.[9 , 21 , 38 , 49 , 141 , 142 , 144 , 145 , 151] Results of these studies are equivocal, but the studies were predominantly retrospective and nonrandomized. It is likely that patients manifesting greater toxicity underwent gastric emptying more frequently, and that this biased early studies against a demonstrable benefit from gastric

emptying. Moreover, patients with spontaneous vomiting were frequently included in the gastric emptying group.[49] This may have further biased these studies, as vomiting appears to increase risk of pneumonitis.[49 , 151]

Two studies prospectively randomized patients who underwent gastric lavage. Neither study had uniform indications for gastric lavage. One study, the COKP trial, was only able to randomize patients at 7 of 46 hospitals. In the subset of randomized gastric lavage patients, 44% had pulmonary complications versus 47% of those who were not lavaged. The other study reported pulmonary complications in 47% of the lavaged group, versus 61% of controls. Available studies do not offer a definitive answer to the debate over gastric emptying after hydrocarbon ingestion, although many authors have offered opinions.[11 , 12 , 71 , 119 , 132 , 133 , 211]

If there are no contraindications, gastric emptying is potentially useful when the hydrocarbon has inherent severe toxicity or the hydrocarbon is used to solubilize a potent xenobiotic or is coingested with a more potent xenobiotic (Table 102-4). Patients who have no symptoms at home or upon initial medical evaluation may not need gastric emptying.[9 , 121] For patients who do require gastric emptying gastric lavage is the superior method.[141 , 142 , 151] If gastric lavage is performed, a small nasogastric tube (18-French, not a large-bore tube) should be employed. If there is no gag reflex, an endotracheal tube should be placed prior to lavage (Chap. 8). In summary, gastric emptying is probably indicated after massive (eg, intentional, suicidal) ingestions, or after ingestion of severely toxic hydrocarbons, such as those denoted in the mnemonic CHAMP (Table 102-4).

Activated charcoal (AC) has limited ability to decrease gastrointestinal absorption of hydrocarbons and may distend the stomach and predispose patients to vomiting and aspiration.[112 , 135 , 208] As discussed earlier, gastrointestinal absorption plays a small role in hydrocarbon toxicity. The use of AC may be justified in patients with mixed overdoses, but its role in isolated hydrocarbon ingestions

appears limited. The use of cathartics and promotility agents for hydrocarbon ingestions is also of limited importance in current management.

The use of olive oil or mineral oil was previously suggested as management for hydrocarbon ingestions.[21, 68, 223] Although these hydrocarbon oils have very high viscosities and low aspiration potential, they show no benefit in animal models,[135] can cause hydrocarbon pneumonitis and lipoid pneumonia themselves, and are therefore not indicated.[52]

Antibiotics are frequently administered in the setting of hydrocarbon pneumonitis to treat possible bacterial superinfection.[49, 94, 101, 144, 151, 201] In experimental models superinfection occurs as rapidly as 7 hours after aspiration.[94] Using radiolabeled *Staphylococcus aureus*, hydrocarbon-injured lungs were shown to have a decreased ability to clear bacteria by 4 hours after insult.[35]

Despite this, animal models, including guinea pigs, dogs, and baboons, did not demonstrate any efficacy of prophylactic antibiotics.[31, 178, 216] One study showed that administered antibiotic altered bacterial lung flora to predominantly Gram-negative organisms, compared to Gram-positive lung cultures in the controls.[31] These studies led to decreased use of prophylactic antibiotics, so that clinical evidence of infection dictated therapy for most clinicians.[58] This approach, however, is not without limitations. Abnormal lung auscultation, fever, leukocytosis, and abnormal radiographic findings are the initial manifestations of both bacterial pneumonia and hydrocarbon pneumonitis. Abnormal temperatures are reported to occur in 50â€“90% of patients with hydrocarbon toxicity.[21, 38, 49, 71, 115, 144, 145] An elevated temperature is often initially noted, with the temperature reaching maximum at 8â€“12 hours, then declining over several days.[49, 145] Leukocytosis is frequently reported, present in up to 60% of patients who aspirate hydrocarbons.[115, 144, 145, 155]

Antibiotic administration may be justified in severely poisoned patients. Ideally, sputum cultures should direct antibiotic use. These,

however, are often delayed and are not useful in critically ill patients. Most authorities do not recommend prophylactic antibiotics. Most recommend close observation of temperature and blood leukocyte count, as delayed elevation (24 hours after presentation) of temperature and/or leukocytes may signal bacterial superinfection. No human studies are available to support either approach, and this issue remains controversial.

Corticosteroids, like antibiotics, have been prophylactically administered in the setting of hydrocarbon pulmonary toxicity.[41, 78, 127, 151] The rationale for their use is prevention and limitation of the inflammatory response in the lungs after hydrocarbon injury. Animal models do not show any benefit of corticosteroid administration.[6, 31, 178, 219] In one study, corticosteroids increased the risk for bacterial superinfection with or without concomitant antibiotics.[31, 172] Furthermore, two controlled human trials failed to show a benefit from corticosteroid administration.[86, 124] It is clear that corticosteroid use does not improve the acute course of hydrocarbon pulmonary toxicity, but some authors purport improved

outcome with delayed corticosteroid therapy (5â€“10 days after onset of acute respiratory distress syndrome).[101, 107] None of the experimental or human studies, however, address long-term effects such as pulmonary fibrosis, chronic obstructive pulmonary disease, or bronchiectasis. The incidence of long-term effects is poorly studied, but they appear to be relatively uncommon. Coupled with the possible increased risk of bacterial superinfection, corticosteroid administration in this setting is not recommended.

Patients with severe hydrocarbon toxicity pose unique problems for management. Respiratory distress requiring mechanical ventilation in this setting may be associated with a large ventilationâ€“perfusion mismatch. The use of positive end-expiratory pressure (PEEP) in this setting is often beneficial.[162, 224] However, very high levels of PEEP may be required with subsequent increased risk of barotrauma.[162, 224] High-frequency jet ventilation (HFJV), using very high respiratory

rates (220â€“260) with small tidal volumes, has helped to decrease the need for PEEP.[37 , 162 , 224] Patients who continue to have severe ventilationâ€“perfusion mismatch despite PEEP and HFJV have benefitted from extracorporeal membrane oxygenation (ECMO).[87 , 96 , 224] ECMO appears to be a useful option in severe pulmonary toxicity after other treatments have failed.

As discussed, the toxic mechanism for hydrocarbon-induced pulmonary damage may in part be a result of detrimental effects on surfactant.[75] Several commercial surfactant preparations are available and are useful for other disease conditions associated with inadequate surfactant function. One animal model did not show benefit, whereas another showed increased survival and improved pulmonary function after exogenous surfactant.[173 , 213] No studies are currently available to suggest the clinical effectiveness in humans. Further study is warranted prior to use in hydrocarbon aspiration pneumonitis.

Cyanosis is uncommon after hydrocarbon toxicity. Although this is most often caused by severe hypoxia, methemoglobinemia associated with hydrocarbon exposure is reported.[48 , 113] The potential for methemoglobinemia should be investigated in patients who remain cyanotic following normalization of arterial oxygenation.

Hypotension in severe hydrocarbon toxicity raises additional concerns. The etiology of hypotension in this setting is often compromise of cardiac output because of high levels of PEEP. Hydrocarbons do not have significant direct cardiovascular effects, and decreasing the PEEP may improve hemodynamics. The use of Î²-adrenergic catecholamines (eg, dopamine, epinephrine, isoproterenol, norepinephrine) should be avoided if possible, as certain hydrocarbons predispose to dysrhythmias.[20 , 67 , 156 , 157]

Management of dysrhythmias associated with hydrocarbon toxicity should be include consideration of electrolyte and acidâ€“base abnormalities (eg, hypokalemia and acidosis from toluene), hypoxemia, hypotension, and hypothermia. Ventricular fibrillation poses a specific concern, as common resuscitation algorithms

recommend epinephrine administration to treat this rhythm. If it is ascertained that the dysrhythmia emanates from myocardial sensitization by a hydrocarbon solvent, catecholamines should be avoided. In this setting, lidocaine has been used successfully, as has Î²-adrenergic antagonism.[136]

Hyperbaric oxygen (HBO) was studied in a rat model of severe kerosene-induced pneumonitis.[167] HBO at 4 ATA showed some benefit in 24-hour survival rates. No followup studies have been performed. Patients with carbon tetrachloride poisoning, however, may benefit from hyperbaric oxygen (see Antidotes in Depth: Hyperbaric Oxygen).[34 , 195]

In the past, hospital admission was routinely recommended for patients who had ingested hydrocarbons, because of concern over possible delayed symptom onset and progression of toxicity.[38 , 49 , 80] Several reports documented patients with relatively asymptomatic presentations who rapidly decompensated with respiratory compromise.[9 , 80 , 121] However, progressive symptoms after hydrocarbon ingestion are rare.[9 , 121] In a retrospective study of 950 patients, only 14 (1.5%) had progression of pulmonary toxicity.[9] Of these 14, 7 had persistence of symptoms for less than 24 hours. Eight hundred patients were asymptomatic on initial evaluation with normal chest radiographs, remained asymptomatic after 6â€“8 hours of observation, and had a normal repeat radiograph. No patient in this group of 800 had progressive symptoms, and all were discharged without clinical deterioration. Seventy-one of the 950 patients had initial respiratory symptoms but were asymptomatic at initial medical evaluation. Of the 71 patients, 36 had radiographic evidence of pneumonitis. Among these 36 patients, 2 (6%) developed progression of pulmonary symptoms during their 6-hour observation period. Of the 35 who had a normal radiograph, 2 (6%) developed pulmonary symptoms and radiographic pneumonitis during the 6-hour observation period. The 4 patients who were hospitalized for progression of symptoms became asymptomatic over the next 24 hours and had no complications.

A separate poison center-based study evaluated 120 asymptomatic patients for an 18-hour telephone followup period.[121] Sixty-two patients had initial pulmonary symptoms that quickly resolved. One of the 62 patients (1.6%) developed progressive pulmonary toxicity. This patient was hospitalized and had resolution of symptoms within 24 hours without complications.

It is clear that the vast majority of patients exposed to a hydrocarbon do not need hospitalization.[9,121] A number of investigators have suggested protocols for determining which patients can be safely discharged.[9,12,106,119,121] None of these protocols has been prospectively validated. However, rational guidelines for hospitalization can be recommended. Those patients who have clinical evidence of toxicity, and most individuals with intentional ingestions, should be hospitalized. Patients who do not have any initial symptoms, have normal chest radiographs obtained at least 6 hours after ingestion, and who do not develop symptoms during the 6-hour observation period can be safely discharged. Care should be individualized for patients who are asymptomatic but who have radiographic evidence of hydrocarbon pneumonitis, and for patients who have initial respiratory symptoms but quickly become asymptomatic during medical evaluation. Reliable patients may be considered for possible discharge with next-day followup.

Summary

Hydrocarbons are a diverse group of xenobiotics that can cause toxicity by inhalation, ingestion, or dermal absorption. Most hydrocarbons occur as mixtures of several to many chemicals. Ubiquitous use of hydrocarbons in our society means that exposures are extremely common. Populations at particular risk for toxicity include children who ingest hydrocarbon compounds, workers who are occupationally exposed by inhalation or dermal absorption, and youths who intentionally inhale volatile hydrocarbons.

Toxicity is largely determined by the route of exposure, and is xenobiotic specific. Aspiration pneumonitis is the primary concern after hydrocarbon ingestion. Many hydrocarbons are poorly absorbed

from the gastrointestinal tract and unlikely to produce systemic poisoning. Acute systemic toxicity is unlikely to occur in the absence of CNS effects such as excitation or sedation. Most hydrocarbons are capable of producing profound CNS depression, even general anesthesia if absorbed systemically.

Specific hydrocarbons may demonstrate specific organ toxicity: the halogenated hydrocarbons are cardiotoxic, hepatotoxic, and nephrotoxic. Most are also acutely toxic to the CNS and some are also peripheral neurotoxins. Diagnosis is predominantly clinical. Diagnostic studies are rarely specific, and hydrocarbon-specific studies are seldom helpful in the acute setting. Skin decontamination is important in massive dermal exposures. Gastrointestinal decontamination, as well as the use of prophylactic antibiotics or corticosteroids, remain controversial. Management is largely supportive, and no specific antidotes are available.

Figure. No Caption Available.

A 56-year-old man was brought to the hospital by ambulance after being of â€œantifreezeâ€• was also brought. The patient had a history of diabe rosiglitazone. He had appeared normal when he was last seen, several ho that he had been upset after losing his job. Upon initial evaluation, the p but withdrew to pain. There was no sign of trauma. Initial vital signs wer 68 beats/min; respirations, 18 breaths/min; and temperature 98.4Â°F (3(saturation of 100% on room air, and rapid bedside glucose was 114 mg/d and reactive to light, and a funduscopic examination was normal. A gag were moist, the lungs were clear to percussion and auscultation, and a c sounds were present, the bladder was not distended, the skin was warm a clubbing, cyanosis, or edema of the extremities. The neurologic examinatio

consciousness, but was otherwise without focal findings.

An intravenous line was established with 0.9% NaCl solution, and the pat Empiric thiamine and naloxone were administered with no response. A sc arterial blood gas revealed a metabolic acidosis with respiratory compensa 94 mm Hg. The blood lactate concentration was 0.7 mEq/L. Serum electr mEq/L; CL^- , 108 mEq/L; HCO_3^- , 16 mEq/L; Ca^{2+} , 8.8 mEq/L. Other si mg/dL; creatinine, 1.2 mg/dL; glucose 116 mg/dL; ethanol 0 mg/dL; urir osmolality, 421 mOsm/kg. Acetaminophen and salicylates were undetectab mEq/L and the calculated osmolarity was 292 mOsm/L, giving an osmol ga with a Woods lamp and did not fluoresce; the sediment did not contain a

The patient was treated with fomepizole (15 mg/kg IV, followed by 10 mg IV every 6 hours), folate (50 mg IV every 6 hours), and pyridoxine (50 m the medical intensive care unit (ICU), and nephrology consultation reques dialyzed for 4 hours. Initial toxic alcohol levels had not been requested, b recovered and sent for analysis. In the serum, ethylene glycol and isopro methanol was 95 mg/dL. Fomepizole and folate were continued after hem was 119 mg/dL. The patient was dialyzed again, with a subsequent metha (about 48 hours after presentation), his mental status had gradually retur increased to 15 mg/kg every 12 hours. After a third course of hemodialys therapy was discontinued except for folate. The patient was transferred to evaluation. The can brought with the patient by the family contained au

Chemistry

Alcohols are hydrocarbons that contain a *hydroxyl* (-OH) group. The term alcohols other than ethanol, that is, those alcohols not intended for inges all alcohols are toxic, causing inebriation and end-organ effects, such as l The most common toxic alcohols encountered clinically are methanol and glycol contains 2 hydroxyl groups; molecules with this characteristic are

termed *diols* (also known as *glycols* because these molecules generally ha alcohols include isopropanol (or isopropyl alcohol or 2-propanol), benzyl glycol (1,3-propanediol). *Primary* alcohols, such as methanol and ethanol, the molecule (the *terminal* carbon), whereas *secondary* alcohols, such as

bound to nonterminal carbons.

Glycol ethers are glycols with a hydrocarbon chain bound to one or more structure R_1 O-CH_2 -CH_2 -O-R_2 or R_1 O-CH_2 -CH_2 -CH_2 -OR_2). Poisoning resemble toxic alcohol poisoning. Glycol ethers commonly encountered inc known as 2-butoxyethanol, ethylene glycol monobutyl ether, or butyl cell methoxyethanol), and diethylene glycol (2,2â€²-dihydroxydiethyl ether). T uses, and are found in household and automotive products, such as hydr cleaner, paints, lacquers, and fog machine liquid. Use of the E-series gly has dramatically declined over the past few decades, as they have been ethers (derivatives of propylene glycol).[7 , 25] However, butoxyethanol is s equivalents with the necessary physical properties.[25] Polyethylene glycol (polymer of ethylene glycol with the structure H(OCH_2 CH_2)$_n$ OH. High mo soluble in water, but not absorbed by the gastrointestinal tract when inge osmotic laxative. Different chain lengths have different physical properties texturizer in many medicinal and food products.

History and Epidemiology

Methanol was a component of the embalming fluid used in ancient Egypt. 1661 by distillation of boxwood, calling it *spirit of box.* The molecular cor Dumas and Peligot, who coined the term *methylene* from the Greek roots production began in 1923, and today most methanol is used for the synt containing consumer products that are commonly encountered include mo solid cooking fuel for camping and chafing dishes (eg, Sterno cans), phot antifreeze (â€œdry gasâ€•). Methanol is also used as a solvent by itself, alcohol. Most reported cases of methanol poisoning in the United States in products by individuals, with more than 60% caused by ingestion of wind review.[23] However, there have been sporadic epidemics of mass methano tainted fermented beverages.[8 , 70] These epidemics are a continuing prob

Ethylene glycol was first synthesized in 1859 by Charles Wurtz, and first during World War II, when its precursor, ethylene oxide, became readily as an engine coolant (antifreeze used in car radiators, as opposed to anti contains methanol).

Isopropanol is primarily available as rubbing alcohol. Typical household p

[, 79 , 129] Most reported cases of toxic alcohol poisoning by this route inv
greater surface-area-to-volume ratio in these patients), and likely also i
glycol ethers have high percutaneous absorption, and it appears that absc
water.[66 , 76]

Once absorbed, alcohols are rapidly distributed to total body water (Table
small oral dose of methanol on an empty stomach, the measured volume
distribution half-life of about 8 minutes.[42] Although peak concentrations c
investigation, anecdotal experience suggests that peak concentrations may
ingestions.

Without intervention, toxic alcohols are eliminated primarily through succ dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), each of whic to the reduction of NAD^+ (oxidized form of nicotinamide adenine dinucleot nicotinamide adenine dinucleotide) and H^+ (hydrogen ion). Methanol is r acid (Fig. 103-1). Ethylene glycol has two hydroxyl groups that are seria in turn, glycoaldehyde, glycolic acid, glyoxylic acid, and finally oxalic acid

This metabolism, like ethanol metabolism by the same enzymes, is zero-or about 10 mg/dL/h.[21 , 61 , 90] This rate is apparently unchanged in chronic

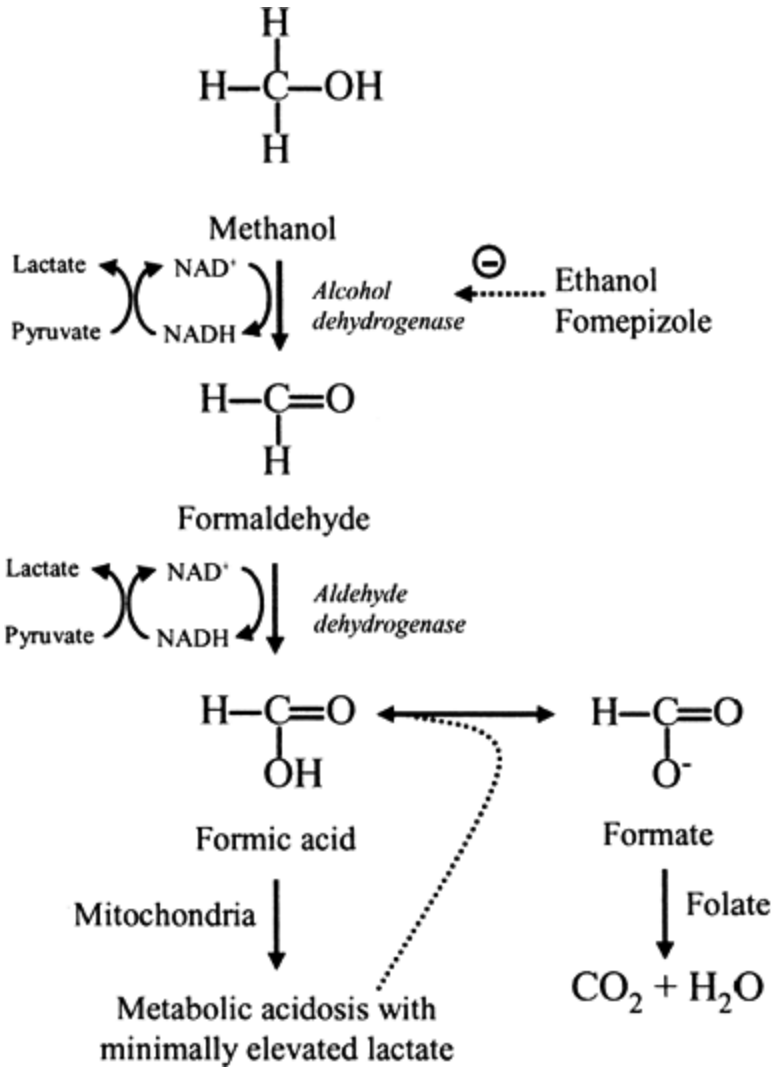

Figure 103-1. Major pathways of methanol metabolism. Metabolic acidos equilibrium to favor the more toxic formic acid.

Alternate minor metabolic pathways, such as catalase, exist for methanol ingestion, the formate metabolite is bound by tetrahydrofolate and then formyltetrahydrofolate dehydrogenase to carbon dioxide and water. Ethyle and glycine using thiamine and pyridoxine as cofactors. Because of the lo normally minor metabolic pathways are attractive targets for potential th

Methanol and ethylene glycol may also be eliminated from the body as u function is normal, ethylene glycol is slowly cleared by the kidneys, with [19 , 123] Methanol does not have significant renal elimination, and is cleare

glycol as a vapor in expired air (half-life 30â€“54 hours).[13 , 106]

Clinical Manifestations and Pathophysiolog

Central Nervous System Effects

All alcohols may cause inebriation, depending on the dose (Table 103-2) higher-molecular-weight alcohols are more intoxicating than lower-mole

alcohols (eg, isopropanol â‰ˆ ethylene glycol > ethanol > methanol).[13] inebriation does not exclude toxic alcohol ingestion, particularly if the pa quantities of ethanol and is tolerant of its CNS effects. This is intuitively of 25â€“50 mg/dL are potentially associated with toxicity, although in mo car with a serum ethanol concentration of up to 93 mg/dL (equivalent to as measured by breathalyzer).

TABLE 103-2. Signs and Symptoms of Toxic Alcohol Exposures

The CNS manifestations of toxic alcohol poisoning are incompletely unders alcohol inebriation is similar to ethanol inebriation, in which case effects GABAergic tone (both directly and through inhibition of presynaptic Î³-am receptors) and inhibition of the *N* -methyl-D-aspartate (NMDA) glutamate CNS effects of other alcohols are clinically similar, there is no direct evid same.

Metabolic Acidosis

Metabolic acidosis with an elevated anion gap is a hallmark of toxic alcoh metabolism of these alcohols to toxic organic acids. The acids have no ra elimination (unlike acetic acid from ethanol metabolism, which can enter t accumulate. In methanol poisoning, formate is responsible for the acidosi in ethylene glycol poisoning, glycolic acid is the primary acid responsible making a minor contribution. Among the toxic alcohols,

isopropanol is unique in that it is not metabolized to an acid metabolite b Acetone is a ketone, not an aldehyde, and therefore cannot be further me isopropanol has no organic acid metabolite and does not cause metabolic is the defining characteristic of isopropanol poisoning.

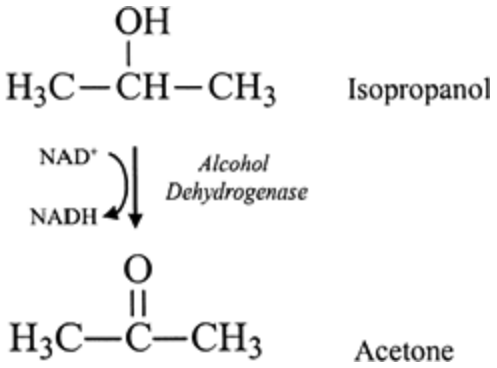

Figure 103-3. Isopropanol metabolism.

Specific End-Organ Effects

Additional end-organ effects depend on which alcohol is involved. Methan blurry or hazy vision or defects in color vision, to â€œsnowfield visionâ€ On physical examination, central scotoma may be present on visual field the optic disc, and papilledema are described as characteristic findings.[8] methanol is a mitochondrial toxin, inhibiting cytochrome oxidase (much li oxidative phosphorylation.[31 , 98 , 99] Although it is unclear why this resul are relatively spared, retinal pigmented epithelial cells and optic nerve ce [86 , 126 , 127]

Interestingly, neurons in the basal ganglia appear to be similarly suscepti lesions (particularly putamen and, less commonly, caudate nucleus) char computerized tomography or magnetic resonance imaging after methanol lesions of this type are nonspecific and can occur in other disease states monoxide exposure), they may occur in the absence of hypotension and suggesting a direct toxic mechanism. Rarely, injury to other tissues may pancreatitis are reported after methanol poisoning.[52 , 73] For unclear reas incidence of pancreatitis (50%).[52] Myoglobinuria and resultant acute renal severe methanol poisoning.[46]

The most prominent end-organ effect of ethylene glycol is nephrotoxicity. complex with calcium to precipitate as crystals in the renal tubules, leadi addition, the intermediate products of ethylene glycol metabolism are direc mechanism yet to be described, causing acute tubular necrosis and there [, 112] Furthermore, although oxalic acid has long been recognized as a tox not cause glomerular injury;[67] thus the presence of necrotic lesions to th some pathology specimens provides indirect evidence that oxalic acid is r nephrotoxicity of ethylene glycol.[35]

Ethylene glycol can occasionally affect other organ systems. In severe po present in sufficient amounts to cause hypocalcemia by precipitation with of the QTc interval on the electrocardiogram and dysrhythmias.[120] Precipi brain has also been found on autopsy after severe ethylene glycol poison multiple cranial nerve abnormalities that occasionally develop,[124] althoug

causation. A leukemoid reaction may also occur in the setting of severe mechanism remains unclear.[96]

Hemorrhagic gastritis has been reported in association with isopropyl alcc assumed to be caused by a local irritant effect, one reported case of he isopropanol exposure suggests that this is not the only mechanism, and, i effect.[29]

Diagnostic Testing

Toxic Alcohol Concentrations

Actual serum methanol, ethylene glycol, and isopropanol concentrations ar when toxic alcohol poisoning is suspected shortly after exposure. Howeve commonly measured by gas chromatography with or without mass-spect are not available in most hospital laboratories on a 24-hour basis, if avail these are only available as â€œsend-outâ€• tests, so results arrive too Enzymatic assays for methanol, formic acid, ethylene glycol, and glycolic and these may lead to more readily available clinical tests, but a comme veterinary use only. A group in Finland described a point-of-care breath t transform infrared (FT-IR) analyzer similar to the â€œbreathalyzersâ€• u Although analyzers like this are used to check for methanol as a combust approved for medical use in the United States. Once approved, they woul analysis because they are easy to use and provide a rapid result. They a concentrations, a feature that would be very helpful during hemodialysis be used to detect ethylene glycol because of its low volatility.

Patients presenting late after ingestion may already have metabolized all and thus may have low or no measurable toxic alcohol concentrations. An more helpful in late cases of ethylene glycol ingestion. Some authors hav glycolic acid in addition to testing for the parent compound when ethylen Similarly, a formic acid concentration may be valuable when a patient pr Clearly, a low or undetectable toxic alcohol concentration must be interpre other clinical data, such as the presence of acidosis and end-organ toxicit concentrations as potentially valuable additions.

Samples must be handled correctly for accurate toxic alcohol results. Par
methanol and isopropanol, concentrations may be falsely low if the sampl

are not airtight. This loss of volatile alcohol commonly results in low cor
done as â€œadd-onâ€• tests to samples already opened for electrolyte

Other alcohols, such as benzyl alcohol and propylene glycol, as well as th
assessed by gas chromatography. Thus, these xenobiotics present a muc
methanol and ethylene glycol. Enzymatic assays for methanol or ethylene
alcohol and propylene glycol, although false-positive ethylene glycol tests
Consequently, a high index of suspicion is critical to making the diagnosis
of history, specific toxic alcohol testing should be performed.

Once alcohol concentrations are obtained, their interpretation represents
Traditionally, a methanol or ethylene glycol level greater than 25 mg/dL l
evidence supporting this as a threshold is often questioned. In a case se
the 1950s, a methanol level of 52 mg/dL was the lowest associated with
origin of the 25 mg/dL threshold, incorporating a 50% reduction as a ma
the 52-mg/dL concentration presented 24 hours after his initial ingestion,
poisoned than suggested by his serum concentration at that point. In fact
poisoning involve late presenters with metabolic acidosis.[74] The only repo
presenting early with only an elevated methanol concentration (45.6 mg/d
acidosis or end-organ toxicity.[12 , 74] However, until better data is availabl
mg/dL as a threshold for treatment.

Because of the problems with obtaining and interpreting actual serum co
have been used to assess the patient with suspected toxic alcohol poisor
should include serum electrolytes (including calcium), blood urea nitroge
serum osmolality, and a serum ethanol concentration. An arterial blood g
also helpful in the initial evaluation of ill-appearing patients.

Anion Gap and Osmol Gap

For a full discussion of the anion gap concept, see Chap. 17 . As discusse
of toxic alcohol poisoning. In fact, the possibility of methanol or ethylene
when patients present with an anion gap acidosis of unknown etiology, fr

Unless other clinical information suggests otherwise, it is important to e ketoacidosis in these patients (the most common causes of anion gap ac This is because of the extensive evaluation and expensive, potentially inva individual would be committed. However, elevated lactate concentrations m methanol and ethylene glycol poisoning.

The unmeasured anions in toxic alcohol poisoning are the dissociated org The acidosis takes time to develop, sometimes as long as 24 hours for m gap elevation early after reported toxic alcohol ingestion does not exclude the body, the development of acidosis will not begin to occur until the rat below a number that varies by alcohol.

A potential early surrogate marker of toxic alcohol poisoning is an elevat 17). However, it is important to recognize that osmol gap elevation is n alcohol poisoning. Because a baseline osmol gap is generally not available osmol gap ranges from -14 to +10, so-called normal osmol gaps cannot example, in a patient with a baseline osmol gap of -10, a gap of +5 repr mg/dL, or an ethylene glycol concentration of 93 mg/dL, concentrations a moderately elevated osmol gap (+10 to +20) is not necessarily diagnos many other disorders, such as alcoholic ketoacidosis and lactate-associate However, a markedly elevated osmol gap (>50) is difficult to explain by

Further complicating matters, the anion gap and osmol gap have a recipr because soon after ingestion, the alcohols present in the serum raise the gap, because metabolism to the organic acid anion has not yet occurred. organic acid anions, the anion gap, rises while the osmol gap falls, becau particles that have already been accounted for in the calculated osmolarity theory patients who present early after ingestion may have a high osmol who present later may have the reverse.[59 , 60] Figure 103-4 depicts a m process.

Ethanol Concentration

A serum ethanol concentration is an important part of the assessment of poisoning. As discussed in Chap. 17 , the ethanol concentration is necess addition, because ethanol is the

preferred substrate of alcohol dehydrogenase (4:1 over methanol, and 8: concentration would be protective if coingested with a toxic alcohol. In fa mg/dL virtually preclude toxic alcohols as the cause of an unknown anion presence of such a concentration should have prevented metabolism to th ingested several hours after significant amounts of a toxic alcohol.[56]

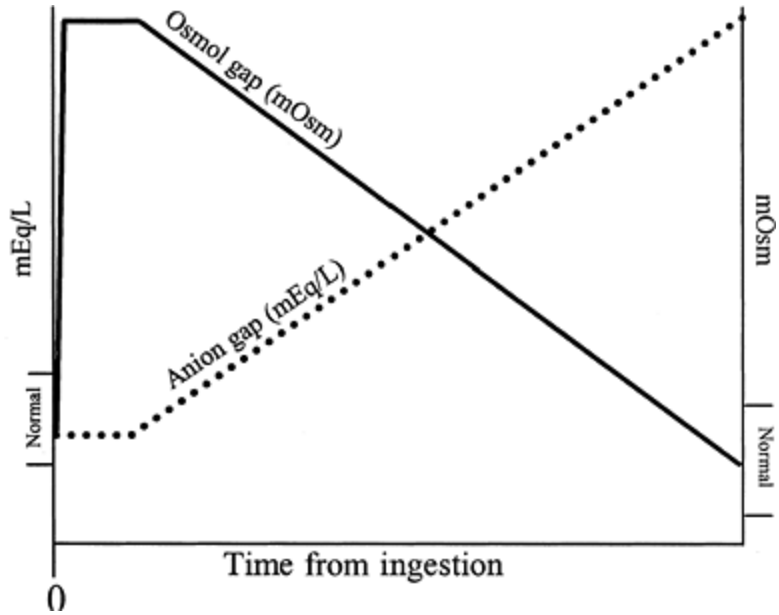

Figure 103-4. The reciprocal relationship of anion gap and osmol gap ov shortly after an ingestion may have a normal anion gap, whereas patients normal osmol gap.

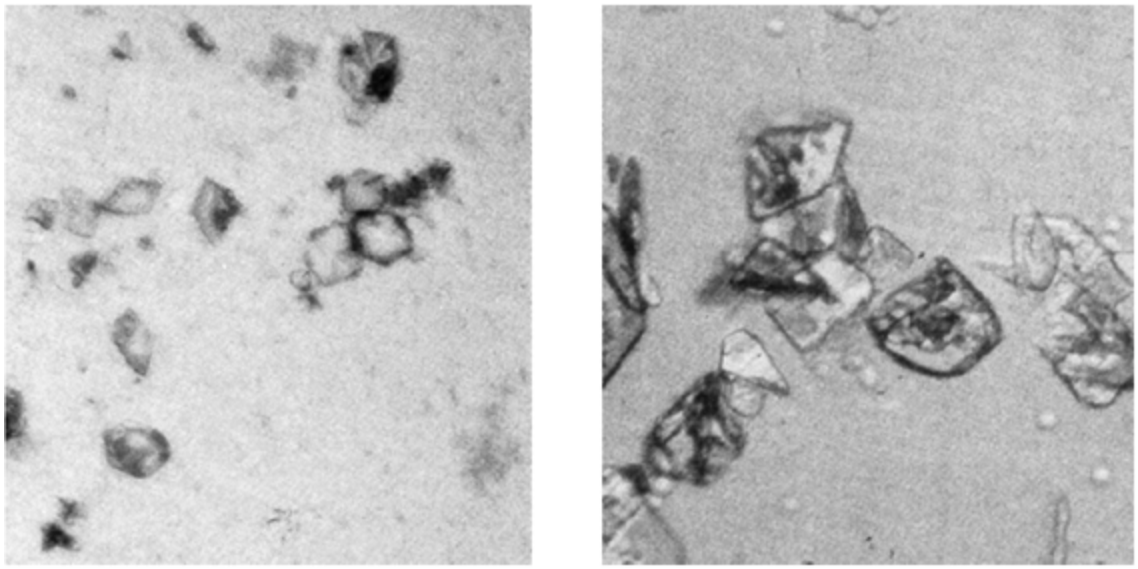

Figure 103-5. Calcium oxalate crystals (dehydrate forms) under low (A) of a patient following the ingestion of ethylene glycol.

Lactate

Both methanol and ethylene glycol can result in elevated lactate concent Formate, as an inhibitor of oxidative phosphorylation, can lead to anaero elevation. Additionally, metabolism of all alcohols results in an increased production of lactate from pyruvate. Furthermore, hypotension and organ also result in elevated lactate concentrations. Lactate production by these concentrations less than 5 mmol/L.

In ethylene glycol poisoning, the glycolate metabolite may also cause a measured by some analyzers, particularly those that analyze whole-blood implicated include ABL 625, Beckman LX 20, Chiron 865, Bayer (formerly Hitachi 911 analyzers, but not the Vitros 950.[93, 111, 138] The artifact res lactate oxidase enzyme used in these machines,[93, 111, 138] although dire anode has also been suggested as a possible mechanism.[121] The presence used to diagnose ethylene glycol poisoning in hospitals where multiple lac and without sensitivity to glycolate.[121]

Other Diagnostics

The urine may provide information in the assessment of the patient with Calcium oxalate monohydrate (spindle-shaped) and dihydrate (envelope-sh urine sediment is examined by microscopy, although this finding is neithe one series, calcium oxalate crystals were present in the urine of only 63% ethylene glycol ingestion.[14]

Some brands of antifreeze contain fluorescein to facilitate the detection of is ingested and the urine is examined with a Woods lamp within the first fluorescence.[137] False-positive fluorescence may result from examining th because of the inherent fluorescence of these materials, so if this test is be poured onto a piece of white gauze or paper. Recent work suggests th children had urinary fluorescence in one study.[18]

The evaluation of patients with known or suspected ethylene glycol poisor concentration and a creatinine concentration. Patients with methanol poisc assessment of liver enzymes and serum lipase and/or amylase concentrat associated hepatitis and pancreatitis.

Management

As always, immediate resuscitation of critically ill patients starts with ma circulation. Because alcohols may cause respiratory depression and coma are commonly necessary for patients with severe poisoning. Alcohol-indu often lead to hypotension, and many patients will require fluid resuscitat Gastrointestinal decontamination is rarely, if ever, indicated for toxic alcc and limited binding to activated charcoal. However, placement of a nasog contents is probably worthwhile

in intubated patients, as absorption may sometimes be delayed after a la

Alcohol Dehydrogenase Inhibition

The most important part of the initial management of patients with know (after initial resuscitation) is blockade of ADH. This allows for the establis

arrangement for hemodialysis while preventing the formation of toxic me
blockade may itself serve as definitive therapy.

Teleologically, ADH exists for the purpose of metabolizing ethanol, so it is
higher affinity for ethanol than for other alcohols. In fact ADH has an affi
vitro than its affinity for methanol, and 67 times greater than its affinity
[109] Thus significant concentrations of ethanol prevent metabolism of othe

absent. In addition, any patient with an anion gap acidosis without anoth
osmol gap should also be treated. Once concentrations are available, ther
concentration is below 25 mg/dL, although as discussed above, this numb
than on data.

Hemodialysis

The definitive therapy for patients poisoned by toxic alcohols is hemodial and their toxic metabolites from the blood, and can correct the acidâ€“ba hemodialysis have become more controversial with the advent of fomepiz with its low incidence of adverse effects. Ethylene glycol can generally be once ADH is blocked and the glomerular filtration rate (GFR) is normal, ar an invasive procedure like hemodialysis are not warranted, except for a patients with end-organ toxicity or severe acidosis have significant amoun addressed by ADH blockade, and acidosis is associated with poor prognos failure will not eliminate the parent compound once ADH is blocked, excep of methanol. Therefore, there is a consensus that metabolic acidosis, sign and seizures), and renal failure are indications for hemodialysis. A â€œtox osmol gap are more relative indications for hemodialysis, and decisions mu physician for the specific clinical scenario, taking into account the availab advocated using toxic metabolite concentrations (if available) as additiona case series, an elevated formate concentration appears to be a better pr clinically important toxicity.[105] Similarly, glycolic acid concentrations are concentrations of death and renal failure.[112] However, although clearance substantial,[64 , 65 , 72] the overall clearance in one case series did not ap endogenous concentrations in patients also treated with folate and bicarb quality in this series.[140]

The American Academy of Clinical Toxicology (AACT) practice guidelines a methanol concentration for hemodialysis in the absence of acidosis, renal clinical status.[4] The AACT guidelines for ethylene glycol actually advise a alone, without any of these clinical indications.[5] Clearly, there is still insu concentrations of alcohols or their metabolites where dialysis is absolutely a subjective one based on the overall clinical scenario.[57] However, until m concentration of 25 mg/dL remains a reasonable indication for hemodialys mg/dL in the absence of alcohol dehydrogenase blockade or abnormal ren reasonable indication.

Although hemodialysis effectively clears isopropanol and acetone from the this purpose. Because isopropanol does not cause a metabolic acidosis an organ effects, the risks of hemodialysis likely outweigh the benefits.

Many patients will require multiple courses of hemodialysis to clear the to

nephrologists to estimate the dialysis time required.[54] Pharmacokinetically and will decrease the toxic alcohol concentration by half in about 2Â½ ho blockade should be continued during and after hemodialysis until a subse xenobiotic is confirmed to be nontoxic. Ethanol infusion rates must be inc therapeutic serum concentration as the ethanol is cleared (see Antidotes redosed every 4 hours during hemodialysis to maintain therapeutic serum

Adjunctive Therapy

There are several therapeutic adjuncts to ADH blockade with or (especial considered for these patients. One difference that has been invoked to ex methanol in some species is the relative abundance of hepatic folate store Folate and leucovorin enhance the clearance of formate in animal models metabolism of ethylene glycol to ketoadipate, and pyridoxine enhances its to hippuric acid). Although all of these modalities offer theoretical advanta change outcome in humans. However, there is one human case report sh folinic acid therapy.[63] Additionally, some authors have suggested that an clearance by hemodialysis was because it was dwarfed by the effectivenes study group and the control group.[72] Because of the safety of vitamin su outweighs the risk of therapy (see Antidotes in Depth: Thiamine Hydroch and Leucovorin [Folinic Acid]).

Formate (dissociated formic acid), is much less toxic than the undissociat undissociated formic acid has a much higher affinity for cytochrome oxida target site for toxicity.[81] In addition, the undissociated form is better able Alkalinization with a bicarbonate infusion shifts the equilibrium to favor th accordance with the Henderson-Hasselbalch equation. This also enhances f trapping.[65] Uncontrolled case series data have shown that patients treate expected outcomes after severe methanol poisoning,[97] but the results are ADH blockade and hemodialysis.[13 , 62 , 91] Additionally, the severity of th poisoning is a good predictor of severe neurologic effects such as coma a not been proven to prevent these effects. However, in the absence of co (eg, hypokalemia, volume overload), alkalinization should be used in the poisoning and a significant acidosis. A blood pH greater than 7.20 is a r

also be considered for patients with ethylene glycol poisoning and signifi

Other Alcohols

Propylene Glycol

Propylene glycol is commonly used as an alternative to ethylene glycol It is also used as a diluent for many pharmaceuticals (such as phenytoin successively metabolized by ADH and ALDH to lactate, lactic acidosis resu result in extremely high lactic acid levelsâ€”levels that would be incompat disease process. In other disease states associated with lactate accumulat reflection of underlying anaerobic metabolism, a marker of severe illness pathophysiology. Lactic acidosis from propylene glycol is surprisingly well more sinister than itself, and it is rapidly cleared by oxidation to pyruvat carbohydrate metabolism. (Chapter 53 further discusses propylene glycol

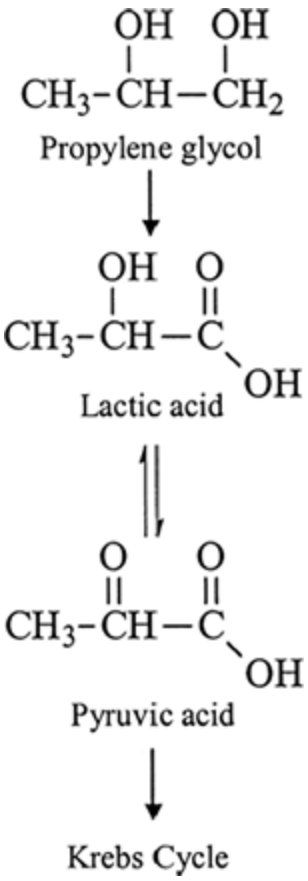

Figure 103-6. Propylene glycol metabolism to lactic acid. Under normal pyruvate which, following decarboxylation, enters the Krebs cycle.

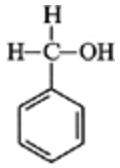
Benzyl Alcohol



Benzyl alcohol

Benzyl alcohol used as a preservative for intravenous solutions. It is no it was responsible for â€œneonatal gasping syndrome,â€• involving mu acidosis, and death from its metabolism to benzoic acid and hippuric acid benzyl alcohol.)

Glycol Ethers

Diethylene Glycol

Diethylene glycol's toxicity in humans was first recognized in 1937 after manifestations typically begin with abdominal pain, nausea, and vomiting acidosis, acute renal failure, and progressive mental status depression ov poisoning in children is also manifested by liver failure, respiratory failu optic neuritis, and paresthesias.[10 , 103 , 122] Two cases of adults with

intentional diethylene glycol ingestions resulted in peripheral neuropathy peripheral demyelination and axonal degeneration at autopsy.[28] Despite the only reported patient to have nerve conduction studies performed af evidence of an axonopathy.[53] The patient developed total quadriplegia, th course of several months.[53]

It is unclear whether toxicity is caused by the diethylene glycol parent co

the ether linkage is stable in the body; ethylene glycol was not detectabl glycol poisoning,[53] nor could it be detected in a rat model of diethylene hydroxyethoxyacetic acid was an identified metabolite.[136] It is also uncle hydroxyethoxyacetic acid occurs in humans, or whether this metabolism aldehyde dehydrogenase. In rats, fomepizole blocks this metabolism.[136] I minimal toxicity after diethylene glycol ingestion when treated with fome suffered severe toxic effects despite early fomepizole therapy.[115]

Based on the limited currently available evidence, it is reasonable to initi hemodialysis, in patients who present early after diethylene glycol ingesti ingestion are likely to need hemodialysis for renal failure.

Butoxyethanol

Most cases of butoxyethanol poisoning involve adults with intentional ing Unintentional exposures in children to household glass cleaners containing adverse effects.[25, 132] Cases of butoxyethanol poisoning are likely to con physical properties as an amphiphilic solvent with a low evaporation rate replacement in industry has not yet been found.[72] The disposition of buto entirely clear, but Figure 103-7 summarizes what is known. It does not occurs in humans, but this remains controversial.

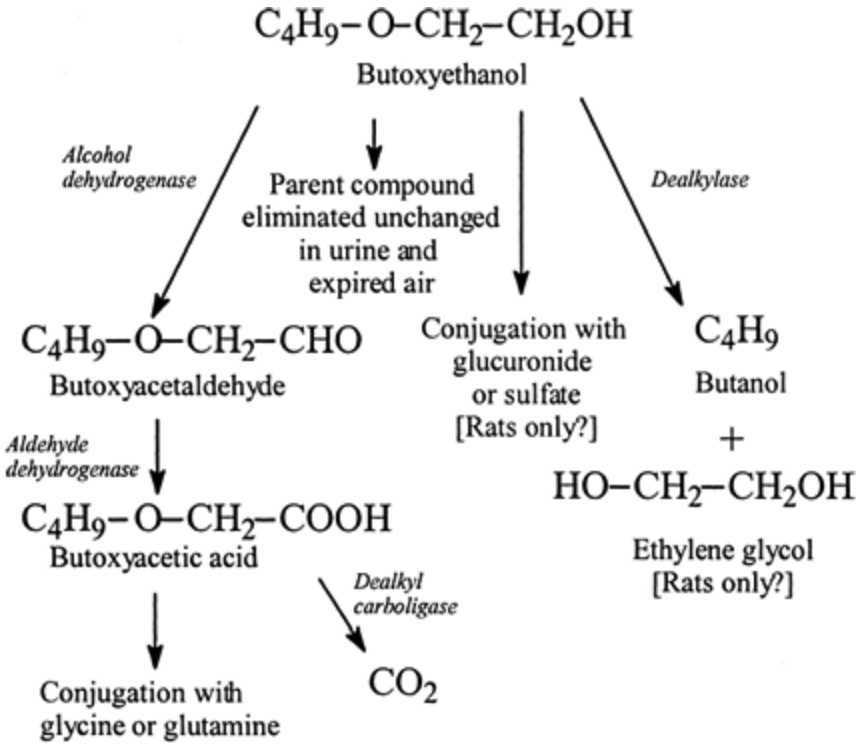


Figure 103-7. Elimination of butoxyethanol. It is still not certain whethe formation occur in humans.[39]

Clinical manifestations of acute butoxyethanol toxicity may include menta hyperchloremic metabolic acidosis, acute renal failure, hemolysis, nonhem injury, and mild elevation of the aminotransferases.[6, 16, 41, 47, 87, 11 cause adverse effects. Although butoxyethanol does not increase cancer ra hemangiosarcomas in male mice and forestomach tumors in female mice. Protection Agency has said that it could not yet determine whether butox effects on fetal development are also unclear.[33, 40, 80, 95]

Partly because its metabolism and mechanism of toxicity are incompletely acute butoxyethanol poisoning is still controversial. Good outcomes have alone,[87] and after ethanol and bicarbonate therapy with hemodialysis.[47] did not appear to hasten butoxyethanol elimination and persistent neurol alcohol dehydrogenase inhibition with ethanol or fomepizole is a reasonal considered in patients with severe acidosis.

Ethylene Glycol Monomethyl Ether

Ethylene glycol monomethyl ether poisoning should be increasingly rare ir substantial toxicity has greatly limited its use. For example, in Sweden, it in 1993 to 19 tons per year in 1997.[68] In the United States, production ha past 20 years.[135] After exposure, 86% of ethylene glycol monomethyl etl and excreted in the urine.[44 , 68] Ethanol and pyrazole completely block th that this metabolism involves alcohol dehydrogenase.[94 , 116] Clinical man with only 3 cases reported. One man developed hemorrhagic gastritis and ultimately proved fatal.[141] Two men recovered after developing confusion metabolic acidosis, tachycardia, tachypnea, and renal failure in one case. ethylene glycol monomethyl ether metabolism, acute toxicity should be t blockade, although there are not yet human outcome data to support the

Chronic hematologic effects, typically after inhalation or dermal exposure resulting in anemia, leucopenia, or pancytopenia in severe cases.[135] Repr azoospermia in men[134] and increased frequency of spontaneous abortions occurred in animal models of ethylene glycol monomethyl ether exposure, known exposure (eg, workers in the semiconductor industry).[135] Obviously important element of clinical management for these patients.

Summary

Toxic alcohol poisoning is complex and may result in consequential toxicit inebriation, and subsequent toxicity results from metabolism to organic a and end-organ effects. The time required

for this metabolism results in a delay before toxicity clinically manifests available, the serum anion gap and osmol gap may help with decision mal history is concerning. Therapy consists of ADH antagonism with fomepizole therapy with bicarbonate, folate or folinic acid, pyridoxine, and thiamine. because it removes the alcohol and the toxic metabolites while correcting abnormalities. However, hemodialysis may have a more limited role in th poisoning, because of the safety and efficacy of fomepizole.

Antidotes in Depth

Fomepizole

Mary Ann Howland

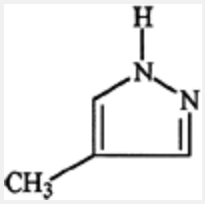

Figure. No Caption Available.

Fomepizole is a competitive inhibitor of alcohol dehydrogenase (ADH) that prevents the formation of toxic metabolites from ethylene glycol and methanol. It may also have a role in halting

the disulfiramâ€“ethanol reaction, and in limiting the toxicity from a variety of xenobiotics that rely on alcohol dehydrogenase for metabolism to toxic metabolites. In addition, as both an inducer and an inhibitor of certain cytochrome P450 (CYP) isoenzymes, the presence of fomepizole may lead to drug interactions.

History

In 1963, Theorell and associates described the inhibiting effect of pyrazole on the horse ADH-NAD^+ (nicotinamide adenine dinucleotide) enzymeâ€“coenzyme system.[71] They noted that pyrazole appeared to block ADH by complexation, and that the administration of pyrazole to animals poisoned with methanol and ethylene glycol improved survival.[72] However, pyrazole also inhibited other liver enzymes, including catalase and the microsomal ethanol-oxidizing system.[50] Additional adverse effects of pyrazole administration resulted in bone marrow, liver, and renal toxicity, and these effects increased in the presence of ethanol and methanol.[61] These factors led to the search for less-toxic compounds with comparable mechanisms of action.

In 1969, Li and Theorell found that both pyrazole and 4-methylpyrazole (fomepizole) inhibited ADH in human liver preparations.[49] Studies in rodents found that fomepizole was relatively nontoxic regardless of the presence or absence of ethanol.[10] Subsequent studies of fomepizole in monkeys and humans poisoned with methanol and ethylene glycol demonstrated both the inhibitory effect and relative safety of fomepizole.[15,16,61]

Pharmacology

Fomepizole has a molecular weight of 82 daltons and a pKa of 2.91 at low concentrations and a pKa of 3.0 at high concentrations. The freebase is used in the United States, whereas the salts are used in Europe. The freebase is chemically equivalent to the chloride

and sulfate salts at physiologic pH.[20]

Values for K_m (Michaelis-Menten dissociation constant) have been estimated for the toxic alcohols, along with the value for K_I (dissociation of enzyme-inhibitor complex inhibition constant) with fomepizole. The smaller the K_m, the higher the affinity of the substrate (alcohol) for the enzyme, and the lower the concentration of the substrate that is needed to half saturate the enzyme. Studies in monkey and human livers demonstrate that fomepizole is a competitive inhibitor of alcohol dehydrogenase.[53,68] In monkey liver, fomepizole demonstrated very similar K_Is for both ethanol and methanol at 7.5 and 9.1 Âµmol, respectively.[53] In this same model, the K_m was 3.2 for ethanol and 20.1 Âµmol for methanol, demonstrating a 6 times higher affinity of ethanol for alcohol dehydrogenase than methanol.[53] The affinity was 15 times higher when human liver was used.[67] Studies in monkeys demonstrate that a fomepizole concentration of 9â€“10 Âµmol/L (0.74â€“0.8 Âµg/mL) is needed to inhibit the metabolism of methanol to formate.[10,61] In human liver, the level needed to achieve inhibition is about 0.9â€“1 Âµmol/L.[49,67] The most recent trial that used intravenous fomepizole attempted to maintain a serum fomepizole concentration above 10 Âµmol/L. Current dosing calls for a serum fomepizole concentration of 100â€“300 Âµmol/L to insure a margin of safety.[1]

The CYP2E1 isozyme oxidizes ethanol and a number of other xenobiotics to toxic metabolites, including acetaminophen, carbon tetrachloride, nitrosamines, and benzene. Fomepizole, like ethanol and isoniazid, has dual effects on this isozyme. Fomepizole induces this isozyme in rat liver and kidney, but not in the lung, through a posttranscriptional mechanism not involving increased mRNA. However, when fomepizole is present, the isoenzyme is inhibited. It is not until after fomepizole is eliminated, that the consequences of induction are manifest.[13,76,77] In hepatocyte culture, fomepizole stabilizes and maintains the induced metabolic activity of the

isoenzyme for about 1 week.[78]

Pharmacokinetics

The volume of distribution of fomepizole is about 0.6â€“1 L/kg; it is metabolized to 4-carboxpyrazole, an inactive metabolite that accounts for 80â€“85% of the administered dose.[58] In healthy human volunteers, oral doses of fomepizole were rapidly absorbed and demonstrated saturation and nonlinear kinetics.[37] The K_m (concentration at which the maximum elimination rate is 50%) was estimated to be 75 Âµmol/L.[37,56] First-order kinetics were exhibited at concentrations below the K_m, whereas zero-order elimination occurred at concentrations 100â€“200% of the K_m.[37] Thus elimination of fomepizole at doses of 10 mg/kg, 20 mg/kg, 50 mg/kg, and 100 mg/kg was 3.66, 5.05, 10.3, and 14.9 Âµmol/L/h, respectively.[37] Classical Michaelis-Menten kinetics would predict that the elimination rate should be the same at the two higher doses, but this is not the case. The authors speculate that multiple metabolic pathways with different affinities exist and predominate at different fomepizole concentrations. At a dose of 20 mg/kg, the half-life of fomepizole calculated from the linear portion of the curve was 5.2 hours and occurred when serum concentrations were less than 100 Âµmol/L. Peak concentrations after oral administration were achieved within 2 hours and were 132, 326, 759, and 1425 Âµmol/L following 10, 20, 50, and 100 mg/kg doses, respectively. Every increase of 10 mg/kg in the oral dose of fomepizole raised the serum concentration

130â€“160 Âµmol/L.[37] The renal clearance was low (0.016 mL/min/kg), and only 3% of the administered dose was excreted unchanged in the urine.[37]

In a pharmacokinetic study in healthy volunteers, oral administration produced similar serum concentrations to IV fomepizole.[55] The pharmacokinetics of intravenous fomepizole

were studied in 14 patients being treated for ethylene glycol toxicity.[45] A mean peak concentration of 342 Âµmol/L (200â€“400 Âµmol/L) was achieved following a loading dose of 15 mg/kg (183 Âµmol/kg).[58,69] A significant weakness of the study affecting toxicokinetic data is that the effect of simultaneous plasma ethanol concentrations was not analyzed. The lowest fomepizole plasma concentration of 105 Âµmol/L was present at 8 hours after the loading dose. The rate of elimination was determined to be zero order at 16 Âµmol/L/h as compared with a first-order elimination half-life of 3 hours during hemodialysis. Other authors have reported similar fomepizole clearances (12.99 Âµmol/L/h).[17] A recent pharmacokinetic analysis in patients poisoned with methanol or ethylene glycol demonstrated a mean peak fomepizole concentration of 19 Âµg/mL (226 Âµmol/L), an apparent half-life of 14.5 hours (in presence of methanol or ethylene glycol), and an apparent half-life of 40 hours in the presence of ethanol along with methanol or ethylene glycol. In the sole death, hepatic tissue contained 12 Âµg/g of fomepizole, even when the plasma concentration was <1 Âµg/mL (12 Âµmol/L).[75]

The plasma clearance of fomepizole during hemodialysis was 230 mL/min. Previous analysis using determinations of dialysis fluid revealed an extraction ratio of approximately 75% and a dialysance of 117 mL/min, which was very similar to a simultaneous ethylene glycol determination.[26] The dialysance of fomepizole was similar to urea in a pig model and suggests no significant protein binding of fomepizole.[38]

The pharmacokinetic interactions between fomepizole and ethanol were studied in a double-blind crossover design in healthy human volunteers.[42] Fomepizole was given orally in doses of 10, 15, and 20 mg/kg 1 hour prior to oral ethanol at 0.5â€“0.7 g/kg as a 20% solution in orange juice. Fomepizole decreased the elimination rate of ethanol by approximately 40%, from 12â€“16 mg/dL/h to about 7â€–9.5 mg/dL/h. When intravenous fomepizole was administered at 5 mg/kg over 30 minutes and ethanol was administered orally

at doses to achieve a concentration of 50â€“150 mg/dL for 6 hours beginning at the end of the fomepizole infusion, the elimination of fomepizole was decreased by approximately 50%.[42] This decrease occurred without a change in the amount or fraction of unchanged fomepizole appearing in the urine. The authors suggested that the ethanol probably inhibited the metabolism of fomepizole to 4-carboxypyrazole by the cytochrome P450 system. A single low dose of fomepizole given to humans had a maximal effect on ethanol metabolism at 1.5â€“2 hours.[9] Thus ethanol and fomepizole mutually inhibit the elimination of each other, prolonging their respective plasma concentrations. Methanol also decreases the elimination of fomepizole by approximately 25% in the monkey.[61]

Methanol

In Vitro and Animal Studies

Studies using human livers demonstrate the inhibitory effect of fomepizole on alcohol dehydrogenase.[67] Studies in monkeys, the animal species that most closely resembles humans in metabolizing methanol, also clearly demonstrate the inhibitory effect of fomepizole in preventing the accumulation of formate.[8,61,62]

Human Experience

The largest fomepizole case series to date involved 11 patients who were given IV fomepizole in the approved US dosing regimen.[16] Following administration, formate concentrations in all patients fell and the arterial pH increased.[16] Case reports demonstrate similar findings.[17,28,32]

Effect of Fomepizole on Methanol and

Formate Concentrations

Methanol exhibits dose-dependent kinetics.[41] At low doses (0.08 g/kg), which achieve serum concentrations of about 10 mg/dL, methanol elimination is first order, with a half-life of about 2.5â€“3 hours.[45,48] In concentrations of about 100â€“200 mg/dL, methanol exhibits zero-order kinetics and is eliminated at about 8.5â€–9 mg/dL/h in untreated humans[41] and 4.4â€–7 mg/dL/h in untreated monkeys.[24,64] When monkeys were given 3 g/kg of methanol with resultant serum concentrations of about 500 mg/dL, the elimination of methanol exhibited apparent first-order kinetics. This alteration is likely caused by the greater contribution of other first-order pathways, such as pulmonary and urinary elimination, which may account for a greater fraction of the total body clearance under these circumstances.[41] Once fomepizole is administered, the elimination of methanol becomes first order in humans, and the half-life of methanol is about 54 hours.[16] When the metabolism of methanol to formate by alcohol dehydrogenase is blocked, formate is eliminated with a half-life dependent on dose and the uncertain effect of folate and bicarbonate therapies. When formate was administered to monkeys in the absence of methanol, formate half-life was 30â€“50 minutes.[21] In monkeys given methanol followed by fomepizole, the formate levels decreased by more than 80% in 2 hours.[8] A recent analysis of formate concentrations in 6 patients with methanol poisoning treated with fomepizole, folate, and sodium bicarbonate revealed a formate half-life of 235 Â± 83 minutes.[46]

Ethylene Glycol

In Vitro and Animal Studies

Monkeys given 3 g/kg of ethylene glycol intraperitoneally, recovered without treatment, whereas those given 4 g/kg died without therapy. All those given 4 g/kg of ethylene glycol with

fomepizole survived.[21]

Human Experience

The first 3 patients treated with oral fomepizole improved clinically and tolerated the therapy.[4] Subsequent case reports and case series using fomepizole orally or IV, with or without hemodialysis, have also demonstrated effectiveness of fomepizole in preventing glycolate accumulation.[5,11,15,31,34,44,63,69]

Effect of Fomepizole on Ethylene Glycol and Glycolate Concentrations in Humans

Renal function is essential in the elimination of ethylene glycol. With normal renal function, the half-life of ethylene glycol is about 8.6 hours.[69] Based on pooled human data, the half-life of ethylene glycol after alcohol dehydrogenase is blocked by fomepizole is about 14â€“17 hours in those patients with normal renal function, and about 49 hours in patients with impaired renal function.[4,31,69] Based on a limited number of determinations, the renal clearance

of ethylene glycol averaged 31.5 mL/min during the first 2 days; the corresponding creatinine clearance was 112 mL/min, and estimated total-body clearance during fomepizole therapy was 57 mL/min.[5] These calculations suggest that the renal clearance of ethylene glycol accounted for only 55% of estimated total body clearance. In a study where neither renal function was defined nor the amount of glycolate (MW = 76 daltons) excreted unchanged by the kidneys described, glycolate had a mean half-life of 10 Â± 8 hours in patients treated with fomepizole before hemodialysis, and a mean half-life of less than 3 hours during hemodialysis.[63]

Safety and Adverse Effects

Retinol dehydrogenase, which is responsible for converting retinol to retinal in the eye, is an isozyme of ADH. As such, it was essential to study whether fomepizole would inhibit this enzyme and subsequently produce retinal damage.[61] Studies in several animal species demonstrate that fomepizole is relatively nontoxic, with no demonstrable signs of ophthalmic toxicity.[8] Two of the largest case series, and 2 recent case reports confirm the lack of retinal toxicity with fomepizole and demonstrate the reversibility of methanol-induced visual toxicity when patients are treated with fomepizole and hemodialysis before permanent ophthalmic toxicity developed.[15,16,25,70]

The LD_{50} (median lethal dose for 50% of test subjects) of fomepizole in mice and rats is 3.8 mmol/kg after IV administration, and 7.9 mmol/kg following oral administration.[52] An oral placebo-controlled, double-blind, single-dose, randomized, sequential, ascending-dose study was performed in healthy volunteers to determine fomepizole tolerance at 10â€“100 mg/kg.[41] There were no adverse effects in the 10 and 20 mg/kg groups, whereas at 50 mg/kg, 3 of 4 subjects experienced slight to moderate nausea and dizziness within 2.5 hours of fomepizole administration. All subjects reported comparable symptoms at 100 mg/kg, which lasted for 30 hours in 1 individual without vital sign or laboratory abnormalities noted. The most common adverse effects of the use of fomepizole reported by the manufacturer (in a total of 76 patients and 63 volunteers) were headache 12%, nausea 11%, and dizziness 7%. Other less commonly observed adverse effects include phlebitis, rash, fever, and eosinophilia. Similarly, divided daily doses of fomepizole up to 20 mg/kg for 5 days have been administered without any demonstrable toxicity.[60] The most common laboratory abnormality after fomepizole administration is a transient elevation of aminotransferase levels, which was reported in 6 of 15 healthy volunteers.[40] In the 2

largest case series of patients treated with fomepizole for toxic alcohol poisoning, there were no adverse events classified as â€œdefinitelyâ€• or â€œprobablyâ€• related to fomepizole.[15,16] Fomepizole is not approved for use in children, but has been used successfully in children who have ingested ethylene glycol and methanol.[6,12,18,22,23,33,75]

Fomepizole is pregnancy category C and thus should be utilized appropriately as indicated.

Disulfiram and Other Xenobiotics

Fomepizole successfully terminated the adverse reactions resulting from the use of disulfiram administered to volunteers pretreated with a small dose of ethanol and those reactions occurring in a chronic alcoholic surreptitiously given disulfiram by his wife.[51] Pretreatment with oral fomepizole was also successful in preventing the facial flushing and tachycardia typically associated with ethanol administration in ethanol-sensitive Japanese subjects.[35,36]

Limited animal studies and a few case reports suggest that fomepizole may be effective in limiting the toxicity secondary to diethylene glycol, triethylene glycol and 1,3-difluoro-2-propanol.[11,27,73] The role of fomepizole in overdoses secondary to 2-butoxyethanol (ethylene glycol monobutyl ether, butyl cellosolve) is unclear, but fomepizole may be useful if administered within several hours of ingestion and before rapid metabolism of butoxyethanol to butoxyacetic acid occurs.[57] Isopropanol is probably metabolized at least in part by alcohol dehydrogenase, but fomepizole therapy is not indicated, as this intervention would prolong the metabolism of isopropanol to acetone.[1]

Comparison to Ethanol

Ethanol has been used for many years to inhibit the metabolism of methanol and ethylene glycol to their respective toxic metabolites. Although very inexpensive, ethanol has many disadvantages, compared to fomepizole. Ethanol causes central nervous system depression that is at least additive to that of the methanol or ethylene glycol; dosing difficulties occur as a result of the rapid and often unpredictable rate of ethanol metabolism, and prolonged ethanol administration causes tolerance to ethanol to develop; an intravenous formulation of ethanol is not readily available; the serum concentrations of ethanol must be closely monitored; a 5 or 10% intravenous preparation of ethanol is hyperosmolar;[79] and there is a great potential for hyponatremia and hypoglycemia or other ethanol-related adverse effects, such as pancreatitis and hepatitis. In contrast to all of these problems associated with ethanol administration, fomepizole has the advantage of being a very potent inhibitor of alcohol dehydrogenase without producing central nervous system (CNS) depression. Fomepizole dosing is much easier without a need for serum concentration monitoring, thus allowing for every-12-hour dosing except during hemodialysis, when dosing should occur every 4 hours. Limited adverse effects of fomepizole include local reactions at the site of infusion when concentrations exceeding 25 mg/mL are employed, nausea, dizziness, anxiety, headache, rash, transiently elevated aminotransferases, and eosinophilia.

Fomepizole is preferred to ethanol for all of the above reasons. Ethanol should only be used when fomepizole is not readily available. Hospitals should be encouraged to stock fomepizole.

Dosing

The loading dose of fomepizole is 15 mg/kg IV, followed in 12 hours by 10 mg/kg every 12 hours for 4 doses. If therapy is necessary beyond 48 hours, the dose is then increased to 15 mg/kg every 12 hours, for as long as necessary. This increase is

recommended because fomepizole stimulates its own metabolism. Patients undergoing hemodialysis require additional doses of fomepizole to replace the amount removed during hemodialysis.

The manufacturer recommends dosing fomepizole every 4 hours during hemodialysis. Fomepizole should be administered at the beginning of hemodialysis if the last dose was more than 6 hours earlier. At the completion of hemodialysis, administer the next scheduled dose if more than 3 hours has transpired on one-half of the dose if 1â€“3 hours has passed.

The fomepizole dose must be diluted in 100 mL of 0.9% sodium chloride solution or D_5W (dextrose 5% in water) prior to IV administration, and then infused over 30 minutes to avoid venous irritation

and phlebosclerosis. Once diluted, fomepizole remains stable for 24 hours when stored in the refrigerator or at room temperature.[1]

Fomepizole therapy should be continued until the methanol or ethylene glycol is no longer present in sufficient concentrations to produce toxicity. Although these concentrations are not precisely known, 25â€“50 mg/dL of either ethylene glycol or methanol is a conservative estimate that can be lowered in the presence of acidâ€“base disturbances.[1,2 and 3]

The threshold concentrations for hemodialysis of methanol or ethylene glycol can be based on measurements when analyses can be done in a timely fashion. The duration of fomepizole therapy in the absence of hemodialysis can be estimated based on the assumption of half-life of the toxic alcohol when blocked with fomepizole. The half-life of methanol is approximately 54 hours in the presence of fomepizole.[11] The half-life of ethylene glycol in the presence of fomepizole is approximately 14â€“17 hours in patients with normal renal function, and 49 hours in patients with impaired renal function.[4,34,69]

Availability

Fomepizole is marketed as Antizol injection by Orphan Medical in a tray pack containing 4 vials (1.5 mL vials of 1 g/mL). Temperatures of <77Â°F (25Â°C) cause the contents of the fomepizole vials to solidify. Warming reliquifies the product without adversely affecting its potency.

Summary

Fomepizole is a potent competitive inhibitor of alcohol dehydrogenase that is useful in inhibiting the metabolism of methanol, ethylene glycol, and other xenobiotics that use alcohol dehydrogenase in the formation of toxic metabolites. Once alcohol dehydrogenase is blocked, the decision to use hemodialysis depends on how much damage has occurred to the organs of elimination, and how well the body can eliminate both the parent compound and the toxic metabolites formed prior to fomepizole administration. Fomepizole appears to be safe and, although it has been used successfully orally, only an intravenous dosing regimen is approved and available. Although the price of fomepizole is higher than ethanol, its many advantages over ethanol, including the ability to often deliver care ouside the ICU, make fomepizole the preferable antidote. Hospitals should be encouraged to stock fomepizole.

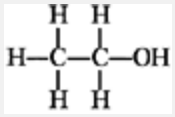
Ethanol

Mary Ann Howland



Ethanol

Ethanol is used therapeutically as a competitive substrate to xenobiotics metabolized by alcohol dehydrogenase, thus limiting the metabolism of those xenobiotics to toxic metabolites. Methanol

and ethylene glycol[7] are the two most lethal xenobiotics when metabolized by this pathway. Other xenobiotics whose metabolism may be inhibited by the presence of ethanol include short-chain polyethylene glycols, such as di- and triethylene glycol,[42] and monofluoroacetate and fluoroacetamide. Ethanol also affects the cytochrome P450 enzyme system, especially 2E1, for which it has biphasic properties as an inhibitor/inducer similar to fomepizole and isoniazid. Only the competitive relationships of ethanol with potentially toxic xenobiotics are used to therapeutic advantage, while the effect on the cytochrome P450 system often leads to unwanted drug interactions and pharmacokinetic tolerance after several days of administration.

Affinity for Alcohol Dehydrogenase

The dose of ethanol necessary to achieve competitive inhibition depends on the relative concentrations of the toxic alcohols and their affinity for the enzyme. An affinity constant, K_m, is used to express the degree of affinity: the lower the K_m value, the stronger the affinity. A summary of in vitro experiments using human liver demonstrated a K_m of 30 mM for ethylene glycol, 7 mM for methanol, and 0.45 mM for ethanol.[22,33,34] This means that the affinity of ethanol for alcohol dehydrogenase is 67 times that of ethylene glycol and 15.5 times that of methanol. Studies in methanol-poisoned monkeys revealed that when ethanol was administered at a molar ethanol-to-methanol (E/M) ratio of 1:4, the metabolism of methanol was reduced by 70%; at a 1:1 E/M ratio, metabolism was reduced by >90%.[24] In these experiments, the dose of methanol was kept constant at about 1 g/kg (31 mmol/kg), whereas the dose of ethanol was varied. Although the methanol serum concentration was not measured, a calculation using this dose and a volume of distribution of 0.6 L/kg would predict a serum concentration of about 166 mg/dL. Even in molar ratios as high as 8:1, methanol did not inhibit ethanol metabolism. When ethylene glycol and methanol are administered together,

ethylene glycol did not inhibit methanol metabolism.[24] Smaller amounts of ethanol are required to block the metabolism of ethylene glycol, compared to the amount of ethanol required to block the metabolism of methanol, as the affinity of ethylene glycol for alcohol dehydrogenase is even less than that of methanol.[16,22,33,34,36,40] Most authors[1,16,40] recommend either a serum ethanol concentration of 100 mg/dL, or at least a 1:4 molar ratio of ethanol to methanol or ethylene glycol, whichever is greater. One hundred mg/dL (~22 mmol/L) ethanol protects against 88 mmol/L (286 mg/dL) of methanol or 88 mmol/L (546 mg/dL) of ethylene glycol. Inhibiting the metabolism of methanol and ethylene glycol, impedes the formation of toxic metabolites and prevents the development of metabolic acidosis.[9,12,15,40] After this toxic metabolic pathway is blocked with ethanol, renal, pulmonary, and extracorporeal routes of toxic alcohol removal become the sole mechanisms for elimination.

Case reports attest to the efficacy of ethanol in preventing the sequelae of methanol and ethylene glycol poisoning when administered in a timely fashion after the toxic alcohol ingestion and before the accumulation of the toxic metabolites.[4,6,18,39,44] In the presence of sufficient blocking concentrations of ethanol, the half-life of ethylene glycol in 2 patients with normal kidney function was 17.5 hours, which was comparable to 17 hours in a case series of patients receiving fomepizole alone with normal kidney function.[4,31,38] A half-life of 46.5 hours for methanol was reported in a patient with methanol poisoning who had received a sufficient quantity of ethanol. Again, this half-life for methanol in the presence of ethanol was quite similar to the 54 hours reported in a case series of methanol poisoned patients treated only with fomepizole.[2,18]

Pharmacokinetics and Dosing

Ethanol can be given either enterally or intravenously (Tables A29-

1 and A29-2). Concentrations of 20â€“30% orally and 5â€“10% IV are well tolerated. Intravenous administration has the advantage of complete absorption,[20] avoidance of gastrointestinal symptoms, and ability to be administered to an unconscious or uncooperative patient. The disadvantages of IV ethanol include difficulty in obtaining and preparing an intravenous ethanol solution, the hyperosmolarity of a 5% ethanol solution (about 950 mOsm/L), the possibility of osmotic dehydration, hyponatremia, and venous irritation. Ethanol administered enterally is rapidly absorbed and achieves peak concentrations in about 1â€“1.5 hours.[5,11,23,41] The amount of ethanol absorbed after oral administration is variably dependent on a number of factors, such as fasting, nutritional status, accelerated gastric emptying, female gender, genetics, chronic alcoholism, lean body mass, and increasing age, as well as the presence of certain H_2 antihistamine receptor antagonists.[3,6,11,19,21,43,45] Sufficient concentrations are generally achieved when 0.8 g/kg of ethanol is given orally over 20 minutes.[3,5,6,11,21,41]

Regardless of route, the objective is to rapidly achieve and maintain a level of at least 100 mg/dL of ethanol, which is adequate for enzyme inhibition in most cases. Inhibition is best achieved by administering a loading dose of ethanol, followed by a maintenance dose. The volume of distribution for ethanol is approximately

0.6 L/kg.[46] The loading dose of ethanol is obtained by the following formula:

$$\begin{aligned}\text{Loading dose} &= C_p \times Vd \\ &= 1\ \text{g/L (100 mg/dL)} \times 0.6\ \text{L/kg} \\ &= 0.6\ \text{g/kg}\end{aligned}$$

C_p = plasma concentration which for this agent is comparable to the serum concentration

TABLE A29-1. Intravenous Administration of 10% Ethanol

Loading Dose[c]	Volume (mL)[b] (given over 1 hour as tolerated)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 10% ethanol (infused over 1 hour as tolerated)	80	120	240	400	560	800
Maintenance Dose[a]	Infusion Rate[b] (mL/h for various weights)[d]					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Normal						
80 mg/kg/h	8	12	24	40	56	80
110 mg/kg/h	11	16	33	55	77	110
130 mg/kg/h	13	19	39	65	91	130
Chronic Alcoholic						

150	mg/kg/h	â€”	â€”	â€”	75	105	150
During Hemodialysis							
250	mg/kg/h	25	38	75	125	175	250
300	mg/kg/h	30	45	90	150	210	300
350	mg/kg/h	35	53	105	175	245	350

[a]Infusion to be started immediately following the loading dose. Concentrations above 10% are not recommended for IV administration. The dose schedule is based on the premise that the patient initially has a zero ethanol level. The aim of therapy is to maintain a serum ethanol level of 100â€“150 mg/dL, but constant monitoring of the ethanol level is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the infusion rate of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia.
[b]For a 5% concentration, multiply the amount by 2.
[c]A 10% V/V concentration yields approximately 100 mg/mL. [d]Rounded to the nearest mL.
Reprinted, with permission, from Roberts JR, Hedges J, eds: Clinical Procedures in Emergency Medicine. Philadelphia, WB Saunders, 1985, pp. 1073â€“1074.

For a 70-kg person, the loading dose would be 42 g (70 kg Ã— 0.6 g/kg) of ethanol, or 420 mL of 10% V/V (volume-to-volume) ethanol. However, an 0.8-g/kg or 8-mL/kg loading dose of a 10%

ethanol solution is recommended in order to provide a margin of safety because of the inconsistencies in bioavailability and the ongoing metabolism that occurs during administration.[20,35] The IV loading dose should be administered over 20â€“60 minutes, as tolerated by the patient. The 10% ethanol concentration is preferable to the 5% concentration in order to limit the volume of fluid administered. It is also preferred over the more concentrated solutions in order to limit local venous irritation and avoid postinfusion phlebitis. Because of the free water content and significant hypertonicity of the 10% solution, the patient should be closely observed for the development of hyponatremia.

To maintain an ethanol concentration of 100 mg/dL, enough ethanol has to be administered to replace the ethanol that is undergoing elimination (66â€“130 mg/kg/h). The average hourly dose for a 70-kg person is 4.6 g, but higher doses are required in chronic alcoholics (100â€–154 mg/kg/h) or others who may have induced enzymes, and in those undergoing hemodialysis (250â€–350 mg/kg/h; Chap. 10.[8,16,26,31,32]

Because ethanol elimination varies in each individual, frequent serum ethanol determinations should be made to ensure adequate dosing while also monitoring blood glucose and fluid and electrolyte status. Also, any increase in the anion gap or decrease in bicarbonate concentration implies that the ethanol dose is inadequate to achieve blockade of alcohol dehydrogenase and the ethanol dosing should be increased.

Problems encountered with the administration of ethanol include further risk of central nervous system depression[10,27,30] or ethanol-related toxicities, such as hepatitis and pancreatitis, hypoglycemia, dehydration, and fluctuating serum concentrations, and potential drug interactions resulting in disulfiramlike reactions.[47]

Availability

A more practical problem often involves finding or preparing the ethanol to be given. Hospital pharmacies and emergency departments should stock ethanol for such a purpose, but frequently do not. Commercial preparations of 5% ethanol in 5% dextrose are available for IV administration. Alternatively, sterile ethanol USP (absolute ethanol) can be added to 5% dextrose to make a solution of approximately 10% ethanol concentration; 55 mL (not 50 mL) of absolute ethanol is then added to 500 mL of 5% dextrose to produce a total end volume of 555 mL (10% = 10 mL in 100 mL, in this case, 55 mL in 555 mL or 55/555). If oral administration is chosen, it is important to remember that the â€œproofâ€• number on the label is double the concentration; that is, â€œ100-proofâ€• ethanol is 50% ethanol. If there will be any delay in obtaining ethanol for intravenous use, oral therapy with ethanol should be initiated immediately.

Comparison to Fomepizole

Although ethanol has been used as an antidote for toxic alcohols for many years in adults and children[37] and has the advantages

of easy access and low cost, fomepizole is a very potent inhibitor of alcohol dehydrogenase with many favorable attributes.[13,14,17,25,28,29] Fomepizole does not produce central nervous system (CNS) depression, is easier to dose, and does not require serum concentration monitoring. Although the price of fomepizole is higher than ethanol, its many advantages over ethanol make fomepizole the preferable antidote. Hospitals should be encouraged to stock fomepizole.(see Antidote in Depth: Fomepizole and Chap. 103).

TABLE A29-2. Oral Administration of 20% Ethanol

Loading Dose[c]	Volume (mL)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 20% ethanol, diluted in juice. May be administered orally or via nasogastric tube	40	60	120	200	280	400
Maintenance Dose[a]	mL/h for various weights[c,d]					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Normal						
80 mg/kg/h	4	6	12	20	28	40
110 mg/kg/h	6	8	17	27	39	55
130 mg/kg/h	7	10	20	33	46	66
Chronic Alcoholic						
150 mg/kg/h	8	11	22	38	53	75

During Hemodialysis						
250 mg/kg/h	13	19	38	63	88	125
300 mg/kg/h	15	23	46	75	105	150
350 mg/kg/h	18	26	53	88	123	175

[a]Concentrations above 30% (60 proof) are not recommended for oral administration. The dose schedule is based on the premise that the patient initially has a zero ethanol level. The aim of therapy is to maintain a serum ethanol level of 100â€“150 mg/dL, but constant monitoring of the ethanol level is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the dose of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia.
[b]A 20% V/V concentration yields approximately 200 mg/mL.
[c]Rounded to the nearest mL.
[d]For a 30% concentration, multiply the amount by 0.66.
Reprinted, with permission, from Roberts JR, Hedges J, eds: Clinical Procedures in Emergency Medicine. Philadelphia, WB Saunders, 1985, pp. 1073â€“1074.

Summary

When administered appropriately, ethanol is an excellent first step in preventing further metabolism of methanol and ethylene glycol. The disadvantages of ethanol compared to fomepizole are making

ethanol an outmoded antidote. However, neither fomepizole nor ethanol affect the toxic metabolites that are already present in the body. Once alcohol dehydrogenase is blocked, the decision whether to use hemodialysis depends on how much end-organ damage has occurred, how well the body can eliminate the parent compound without the benefit of hemodialysis, and how much toxic metabolite is already present. With the use of either ethanol or fomepizole, the increase in hospital length of stay in an ICU or on a medical floor may be substantial, particularly for methanol-poisoned patients without the benefit of hemodialysis.

Chapter 104

Pesticides: An Overview with a Focus on Principles and Rodenticides

Neal E. Flomenbaum

A 35-year-old Hispanic man with a past psychiatric history was brought to the emergency department after claiming to have ingested an unidentified rodenticide called â€œTres Pasitos.â€• His vital signs were: blood pressure 120/70 mm Hg; pulse 45 beats/min; respiratory rate 28 breaths/min; and temperature 97.8Â°F (36.6Â°C). The patient was lethargic, diaphoretic, incontinent of urine and stool, and had no evidence of trauma or seizure. The patient had prominent fasciculations of his face and extremities, 3-mm pupils, and profuse oropharyngeal secretions requiring frequent suctioning. His pulmonary examination revealed scattered rales, and his abdomen had hyperactive bowel sounds. His neurologic examination was significant for symmetric decrease in muscle strength and garbled speech, but he was fully oriented. The patient immediately received atropine, 2 mg IV, which elevated his heart rate and decreased his oropharyngeal secretions. Over the first 30 minutes,

the patient required 10 mg of atropine to achieve and maintain a normal level of consciousness, and subsequently a continuous infusion of IV atropine was initiated at 4 mg/h. Pralidoxime IV at 500 mg/h was started simultaneously. The patient was admitted to the critical care unit and was fully recovered by 36 hours. An initial red blood cell cholinesterase level was reported as slightly decreased (3414 U/L; normal 5300â€“10,000 U/L).[66]

Introduction to Pesticides, Rodenticides and Herbicides: Definition, Regulation, and Epidemiology

Pesticides are substances or mixtures of substances intended to prevent, destroy, repel, or mitigate any pest and any substances or mixture intended for use as a plant regulator, defoliant, or desiccant.[29] â€œPestsâ€• are insects, fungi, herbs, rodents, and worms. Beginning with the 2000 annual report, the American Association of Poison Control Centers, Toxic Exposure Surveillance System (AAPCC-TESS) has listed 5 subcategories of pesticides: fungicides (nonmedicinal), herbicides, insecticides, repellents, and rodenticides. Other types of pesticides not specifically listed by TESS include desiccants, defoliants, and nematocides.

The total number of yearly pesticide exposures reported by TESS has risen steadily to a current level of almost 100,000 annual exposures, as has the number of exposures involving children younger than 6 years of age, who continue to represent more than 50% of the total. The annual number of deaths reported to TESS that are attributed to all pesticides each year remains less than 50 (Chap. 130).

Since 1947, the production, use, and distribution of all pesticides in the United States has been regulated by the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and its subsequent amendments in 1972, 1975, and 1978. The Environmental Protection Agency (EPA) was given the authority to administer and enforce FIFRA regulations in 1970.

Currently under FIFRA all pesticides must be registered with the EPA and are classified for either general use or restricted use by licensed or certified applicators. The EPA and the FDA together establish pesticide tolerance levels for agricultural products and foods. Under the 1978 amendment, FIFRA allows individual states to regulate and enforce pesticide regulations and some states have now established even more stringent requirements and lower acceptable levels than the EPA. The EPA, however, maintains the authority to act when states are unable or unwilling to do so. The EPA also regulates pesticides under several other Acts: The Federal Environmental Pesticide Control Act, the Resource Conservation Recovery Act of 1972 (RCRA), the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA, also called the â€œsuperfundâ€• Act), the Toxic Substance Control Act (TSCA), the Clean Water Act and the Safe Drinking Water Act.[98]

TABLE 104-1. EPA Toxicity Classifications

According to FIFRA, both the pesticide and its manufacturer must be registered with the EPA. The pesticide must be sold exactly as formulated, registered, and labeled. Failure to comply with these regulations can result in civil and criminal penalties, product recalls, product seizures, or banning a product from future sales.[98] Of more immediate concern however, is the authority granted by FIFRA to protect the health of the population. When evidence indicates that a pesticide may be a significant health hazard, one or more of the following actions may be taken: permissible workplace exposure limits may be issued, a product may be removed from sale, or its registration may be canceled, restrictions on use or application of a product may be ordered and tolerance levels for pesticide residue on food stuffs or water contamination may be set.[98] Since 1978, demonstration of efficacy of a pesticide may be waived, unless the product affects public health. The Food Quality Protection Act of 1996 requires that EPA establish tolerances based in part on the higher vulnerability of children to pesticide residues, and on the aggregate exposures from residues from all sources and from all agents with the same mechanism of toxicity.[80]

Table 104-1 summarizes the EPA's toxicity classifications and the significance of oral median lethal dose for 50% of test subjects (LD_{50}) is discussed under rodenticides below. The remainder of this chapter deals

with the clinical problems posed by rodenticide poisoning. Some of the oldest and most toxic rodenticides are discussed individually in Chap. 104 , 105 , 106 , 107 and 108 whereas others are discussed in Chaps. 85 (Arsenic) and 96 (Thallium). Chap. 109 and Chap. 110 discuss insecticides. Chap. 111 discusses herbicides and Chap. 112 discusses fumigants.

Epidemiology: Rodenticides

Reported rodenticide exposures in the United States are most commonly associated with young children. About 20,000 rodenticide exposures are reported annually to AAPCC-TESS and over 85% involve children younger than 6 years of age (Chap. 130). Remarkably, despite the very large number of exposures, no more than 5 deaths are reported each year from rodenticide poisoning. Beginning with the 2001 report, TESS added three types of rodenticides to the specific rodenticide categories that are tracked: bromethalin, cholecalciferol, and zinc phosphide. TESS continues to track Î±-naphthyl thiourea (ANTU), warfarin and â€œsuperwarfarinsâ€• (or long-acting types of anticoagulants), barium carbonate, monofluoroacetate, strychnine, Vacor, â€œother,â€• and â€œunknown,â€• but since 2001, cyanide, which was previously listed both as a rodenticide and as a â€œchemical,â€• has been listed only as a chemical.

Of the 20 deaths caused by rodenticides reported by AAPCC-TESS between 1999 and 2003, long-acting anticoagulants accounted for 9, strychnine 5, and zinc phosphide 1; the combination of â€œotherâ€• and â€œunknownâ€• rodenticides accounted for a total of 5 deaths. However, in considering the human toll of rodenticide exposures, it is important to note that the TESS database does not specifically list as a rodenticide exposure any encounter with a pesticide that is used as a rodenticide, but not marketed or officially labeled as a rodenticide.

The case at the beginning of this chapter is an example of an insecticide used as a rodenticide and is one of a series of 35 such cases referred to the New York City Poison Control Center between 1994 and 1997; all of

the cases involved an insecticide illegally imported and sold as Tres Pasitos rodenticide primarily within the Dominican community in New York City.[66] The active ingredient of Tres Pasitos is aldicarb, a carbamate cholinesterase inhibitor. Used legally in some parts of the United States as an insecticide, aldicarb is not registered for use as a rodenticide but is sold covertly for such use in local shops.

Although children constitute the largest group of patients exposed to rodenticides, suicidal persons, potential homicide victims, pest control operators, and intoxicated, psychiatric, and impaired older adult persons are also at substantial risk of intentional or unintentional rodenticide exposures. The large number of unintentional ingestions of rodenticides placed in food containers or dishes, with or without added bait such as peanut butter, illustrates the danger of marketing toxic substances in such dishes or transferring toxic substances to other containers. Additional epidemiologic data on pesticides, herbicides, fumigants, and specific rodenticides are found in the corresponding chapters.

The Definition and Classification of Rodenticides

A rodenticide is any product commercially marketed to kill rodents, mice, squirrels, gophers and other small animals. Rodenticides are a heterogeneous group of chemicals bearing little or no relationship to one another, apart from their current or historic use as rodenticides. The â€œperfect rodenticide,â€• one that effectively kills rodents but is not toxic to humans or nonrodent pets, has yet to be discovered or synthesized. Instead, a wide variety of less-than-perfect rodenticides are commercially available differing from one another in chemical composition, mechanism for killing rodents, and toxicity to humans.[38, 54, 55, 65, 75] Purportedly â€œeffective and harmlessâ€• products are periodically introduced, only to be subsequently withdrawn when the true human toxicities become known. Some of

these products may remain in basements, on hardware store shelves, or

in use by professional pest control operators long after they are officially withdrawn from sale.

Rodenticides have been classified in several different ways: (a) as inorganic and organic compounds; (b) by animal selectivity; (c) by nature and onset of symptoms; and (d) according to their LD_{50} in rats.[5] Classification by LD_{50} is emphasized in this chapter and used to organize all of the consequential rodenticides in Table 104-2 .

Inorganic and Organic Compounds

Inorganic compounds include the salts of arsenic (Chap. 85), thallium (Chap. 96), phosphorus (Chap. 107), barium (Chap. 105), and zinc phosphide (Chap. 112). Organic compounds include sodium fluoroacetate (Chap. 106), ANTU, warfarin (Chap. 57), red squill (Chap. 114), strychnine (Chap. 108), norbormide, and Vacor.[5]

Animal Selectivity

The cardioactive steroid red squill was promoted as a safe rodenticide because humans and other animals presumably would vomit the highly emetogenic poison prior to experiencing any cardiotoxic effects; rats do not vomit and therefore would be expected to experience the cardiotoxic effects of red squill. Norbormide, an irreversible smooth-muscle constrictor, causes widespread ischemic necrosis and death in rats, but does not appear to affect other animals or humans because it acts on a specific norbormide receptor found only in the smooth muscle of rats. ANTU, a relatively selective rodenticide, is a derivative of phenylthiourea without the bitter taste characteristic of the thiourea. ANTU causes pulmonary edema in rats that have not developed tolerance to it. ANTU, however, is only relatively selective: although rats are more sensitive to it than other animals, large doses (>4 g/kg) can also be lethal to primates.

All of the rodenticides classified as inorganic, and organic rodenticides such as strychnine and sodium fluoroacetate, are nonselective and of

extreme concern when ingested by humans and domestic animals. Use of this entire group of rodenticides is restricted to commercial pest control operators and government agencies.

Nature and Onset of Symptoms

Although a rodenticide classification system based purely on the nature and onset of symptoms seems very appealing, such a system may be unreliable, may create a false sense of security, and may result in inappropriate management and/or inadequate followup. Many different rodenticides cause neurologic and/or gastrointestinal signs and symptoms, whereas characteristic or pathognomonic signs such as â€œrisus sardonicusâ€• from strychnine, or alopecia from thallium, may not be recognized, do not always occur consistently (especially after ingesting small amounts), or, as in the case of thallium-induced alopecia, will not occur until days after an acute ingestion. Classifying rodenticides by the time of onset of symptoms may similarly lump together within a late-onset group some of the least toxic (regular warfarin type, cholecalciferol) and most toxic, (long-acting warfarin type, thallium) rodenticides.

LD_{50} in Rats

Probably the most clinically useful way of classifying rodenticides at present is by toxicity based on LD_{50} data in rats. With a few noteworthy exceptions, the relative degree of toxicity per kilogram and the characteristic adverse effects generally hold among different mammals, allowing the healthcare provider the opportunity to consider a combination of historical and characteristic physical evidence to diagnose or exclude various rodenticides and to decide on an optimal management plan. The limitations of this classification system, however, must be understood to use it appropriately: (a) in rare cases, the LD_{50} may vary unpredictably among species (eg, Vacor); and (b) repeated ingestions of less toxic rodenticides (eg, short-acting anticoagulants, cholecalciferol) may, in fact, make them highly toxic (Table 104-2).

Highly Toxic Rodenticides (Signal Word: â€œDangerâ€•)

According to FIFRA highly toxic rodenticides are those substances with a single-dose LD_{50} of less than 50 mg/kg body weight. The label â€œDangerâ€• is the strongest warning issued by the Consumer Product Safety Commission for a potential toxic hazard. Lower hazard levels are denoted by â€œWarningâ€• and â€œCautionâ€• (Table 104-1). The highly toxic â€œDangerâ€• group includes thallium (Chap. 96), sodium monofluoroacetate (SMFA, compound 1080) and fluoroacetamide (compound 1081) (Chap. 106), strychnine (Chap. 108), zinc phosphide (Chap. 112), elemental phosphorus (Chap. 107), arsenic (Chap. 85), barium carbonate[51 , 62 , 78 , 87 , 93 , 94 , 106] (Chap. 105) and Vacor (*N* -3-pyridylmethyl-*N* â€²-*p* -nitrophenyl-urea) (see Table 104-2 and previous editions of this text for an extensive discussion of Vacor).

Moderately Toxic Rodenticides (Signal Word: â€œWarningâ€•)

Moderately toxic rodenticides, those with an LD_{50} of 50â€“500 mg/kg body weight, include the â€œselectiveâ€• rodenticide ANTU and cholecalciferol (vitamin D_3), one of the newest and increasingly popular rodenticides.

Î±-Naphthyl-Thiourea (ANTU)

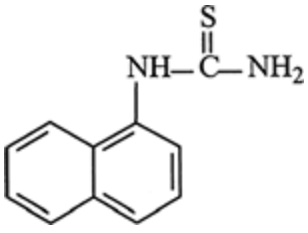

Figure. No Caption Available.

ANTU kills rats by causing acute lung injury and pleural effusion, probably because of damage to the lung capillaries resulting in increased permeability.[11, 86] Young rats and rats exposed initially to small, nonlethal doses are relatively resistant to the lethal effects of ANTU, possibly by developing pulmonary cell hyperplasia.[9] The heart appears to be unaffected by ANTU.[11, 86] There are no well-documented cases or series of human ANTU exposures from which human toxicity can be accurately determined. In several older series of combined ANTU plus chloralose ingestions, it appears that the respiratory symptoms were more severe from the combination than from chloralose alone, suggesting pulmonary effects of ANTU in humans. Of the 14 patients poisoned by the

P.1472

P.1473

P.1474

combination, 11 required intubation because of tracheobronchial hypersecretion.[33, 38] Recommended treatment for ANTU ingestions is administration of activated charcoal (AC).[65] Supportive and symptomatic care should be provided as there is no known antidote.

Toxin Name	Physical Characteristics	Toxic Mechanism	Estimated Fatal Dose	Diagnostic Presenting Signs and Symptoms	Onset	Antidote and/or Treatment*
Indandiones						
Pindone (Pival)	Moldy, acrid odor, fluffy yellow powder, concentrations 0.005–2.5%	Anticoagulation via interference with clotting factors II, VII, IX, X; death from hemorrhage	?	Chronic ingestion possibly produces cardiac and neurologic symptoms as well as bleeding with elevated INR	Delayed several days	Vitamin K_1, fresh frozen plasma (FFP) as indicated Activated factor VII
Pivalyn	0.5%					
Diphacinone	0.005–2.0%					
Chlorophacinone	0.005–2.5%					
Valone	0.005–2.5%					

[a] The LD_{50} values used in this table are derived from data on acute oral ingestions of the commercial product by rats. In some cases the commercial product contains a very small percentage of active ingredient. The signal words that appear on labels of registered products may differ from the signal word assigned to the acute oral LD_{50} test because the label may also reflect another study (acute dermal or inhalational LD_{50}) requiring a more severe signal word. See Table 104–1 for the Consumer Product Safety Commission definitions and use of signal words as indicators of potential hazard of toxicity. Peacock D, Biologist, Registrations Division Office of Pesticide Programs, EPA, Washington, DC.

*Gastrointestinal decontamination should be provided as appropriate (Chap. 8); only unique or controversial aspects are discussed in this table.

TABLE 104-2. Management of Specific Rodenticide Ingestions

Cholecalciferol

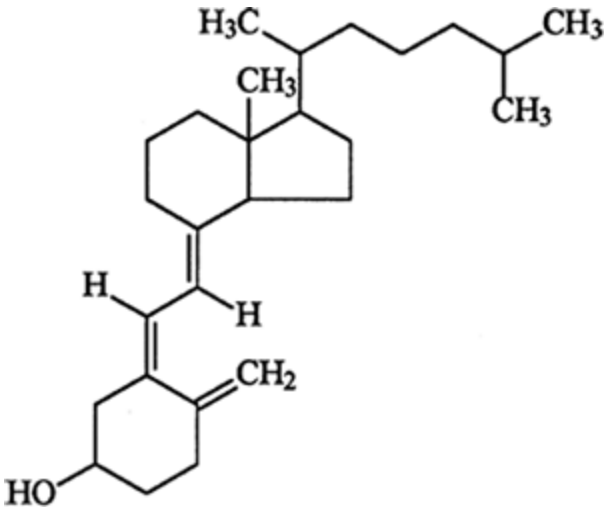

Figure. No Caption Available.

Cholecalciferol (vitamin D_3) was first registered and marketed in the United States in 1984. It is now used by professional pest control operators as Quintox, and by the general public as Rampage. Cholecalciferol mobilizes calcium from the bones of rodents and rabbits and in toxic doses produces hypercalcemia, osteomalacia, and metastatic calcification of the cardiovascular system, kidneys, stomach, and lungs; death typically occurs in 2â€“5 days.[58 , 59 and 60] Although all animals are susceptible to the effects of cholecalciferol, rats and mice succumb to much lower doses than do larger animals such as cats and dogs.[59 â€“60] Cholecalciferol appears to be an effective rodenticide either when a large amount is consumed in one meal or when smaller amounts are consumed over a 2â€“3-day period.[59 , 60 , 83] Because death is not immediate and the cholecalciferol does not impart unusual characteristics to the bait, the bait shyness that occurs with zinc phosphide, ANTU, strychnine, and other rodenticides does not occur with cholecalciferol.[58 , 59 and 60] The closely related vitamin D_2 (or ergocalciferol) has been used as a rodenticide in Europe and Canada since 1978, without the development of resistance reported to date.[58 , 59 and 60]

Although rats manifest the signs of severe acute hypercalcemia, including lethargy and ultimately death from myocardial infarction in 2â€“5 days,[83] no serious human toxicity or death from the rodenticide form of

cholecalciferol are reported to date. It is important to note that all of the advice for managing human ingestions of cholecalciferol rodenticide is based on experience with treating therapeutic forms of vitamin D poisoning and hypercalcemia. One case of cholecalciferol poisoning in an industrial setting may be particularly relevant because, as in the case of a child who might repeatedly ingest small amounts of rodenticide, the exposure described was to small doses over a 32-day period and resulted in prolonged hypercalcemia.[43]

Although calciferol levels are not readily available, a normal serum calcium level obtained 48 hours after an acute ingestion almost certainly excludes any significant toxicity. Immediate intervention after a large acute ingestion may include gastric emptying by emesis or orogastric lavage, followed by gastric decontamination with AC and possibly sorbitol Repetitive dosing of AC has been recommended, but data are insufficient to confirm usefulness of either approach.

Treatment for moderate to severe degrees of hypercalcemia (greater than 11.5 mg/dL) includes IV fluid therapy with 0.9% sodium chloride solution if the patient is hypovolemic and can tolerate a fluid load. Potassium and magnesium levels should be monitored and maintained. Furosemide should be administered.

Low-Toxicity Rodenticides (Signal Word: â€œCautionâ€•)

The remaining rodenticides, with one exception, are of low toxicity (LD_{50}, 500â€“5000 mg/kg). This category includes red squill (*Urginea maritima*)[89, 102] (Chap. 114), norbormide, bromethalin, and the anticoagulants (Chap. 57). The â€œwarfarin-typeâ€• anticoagulant rodenticides and the long-acting â€œsuperwarfarinâ€• forms are responsible annually for more than 80% of the reported exposures and approximately 50% of the deaths attributed to rodenticides. Norbormide and bromethalin are discussed below.

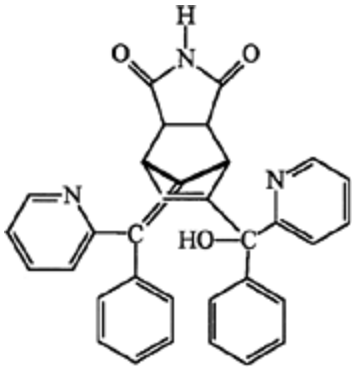

Figure. No Caption Available.

Norbormide

Norbormide, an irreversible smooth-muscle constrictor, appears to be specific for rats and has no known human toxicity. Rats die as a result of intense generalized vasoconstriction, resulting in tissue anoxia.[65] In vitro, norbormide promotes calcium entry into smooth muscle cells, inducing a myogenic contraction, selective for the small vessels in rats, whereas in the arteries of other mammals (and in the rat aorta), norbormide behaves like a calcium channel blocker.[12] Following exposure it is sufficient to achieve gastric decontamination with AC.

Bromethalin

The commercial product formulation of bromethalin, is considered to be of low toxicity defined above. Bromethalin was registered with the EPA in 1982, became available in 1986, and is currently available commercially in the United States primarily in the form of green pellets mixed with cornmeal (which gives it a fresh corn odor) and denatonium benzoate Bitrex. Bromethalin is marketed under trade names such as Assault or Vengeance.

From the time that bromethalin first became available, concern was expressed about its potential toxicity.[58] However, the first possible

bromethalin-induced case of human toxicity was not reported until 1996,[15] perhaps because as late as 1997, bromethalin had been registered in only 6 states and in 2 of these states, California and New York, bromethalin first became available in 1996. Since 2001, TESS has been reporting between 333 and 581 annual exposures, including 275 to 461 in children younger than 6 years old. The outcome of the exposures have been noted as â€œmoderateâ€• or less (most frequently â€œnoneâ€•) in all cases, with no deaths reported to date.

Bromethalin is considered to be a highly effective, single-feeding rodenticide with a mode of action reportedly involving the uncoupling of oxidative phosphorylation in the mitochondria, resulting in decreased adenosine triphosphate (ATP) production, increased fluid accumulation, and consequent increased pressure on nerve axons interrupting nerve impulse conduction.[59]

The pathologic changes resulting from a 1.5-mg/kg oral dose of bromethalin administered to cats, included spongy changes, hypertrophied fibrous astrocytes, and hypertrophied oligodendrocytes in the white matter of the cerebrum, cerebellum, brainstem, spinal cord, and optic nerve.[26, 28] Prior to sacrifice of the animal, the clinical manifestations of bromethalin poisoning in these cats included ataxia, focal motor seizures, decerebrate posture, decreased proprioception, and depressed level of consciousness. Dogs given oral doses of 6.25 mg/kg of bromethalin developed hyperexcitability, tremors, seizures, depression, and death within 15â€“63 hours of exposure.[27] Death in animals is also usually preceded by paralysis and loss of tactile sensation.[103, 104]

Because there is no known antidote for bromethalin, symptomatic and supportive care should be provided.

Dangerous Old, New, and Unusual Rodenticides: The Worldwide Problem

The confusion caused by other types of pesticides inappropriately used as rodenticides is compounded occasionally when a dangerous rodenticide

favored in one part of the world is introduced and used in a different area, or when a highly toxic, previously abandoned rodenticide is â€œrediscovered.â€• All 3 types of problems are being increasingly reported. Accessibility to the products and global travel may explain part of the problem.

Tetramethylene Disulfotetramine (Tetramine, TETS, TEM)

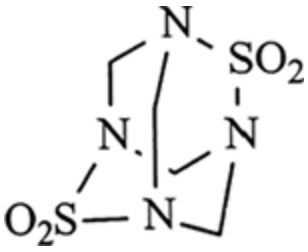

Figure. No Caption Available.

During the past decade, several reports have appeared in the medical literature describing the toxicity of the illegal Chinese rodenticide tetramine.[8 , 22] First patented as a rodenticide in the United States in 1953, tetramine was eventually banned in China in 1984.[8] This quick-acting, single-dose poison nevertheless, is still produced in many parts of China and is occasionally responsible for unintentional or deliberate poisonings. In September 2002, a deliberate adulteration of restaurant food with tetramine by a competing restaurant owner poisoned 300 people and caused 42 deaths, all in schoolchildren. In that same year, the first known case of tetramine poisoning in the United States resulted from a 15-month-old infant playing with the white powder brought back from China by her parents and applied to a kitchen corner;[8] the child developed convulsive status epilepticus that was refractory to lorazepam, phenobarbital, and pyridoxine. The child required intubation and was left with multiple neurologic deficits including persistent absence seizures, possible cortical blindness, multiple epileptogenic foci months later, and developmental delay 1 year later.

Tetramine is an indirect acting Î³-amino butyric acid (GABA) antagonist similar in some respects to picrotoxin with an LD_{50} of 0.1â€“0.3mg/kg.[32] Tetramine is more lethal than the World Health Organization's (WHO) most toxic registered pesticide, sodium fluoroacetate. Tetramine is also suggested to be 100 times more toxic (on a g/kg basis)[8] to humans than potassium cyanide.[8] As little as 5â€“10 mg/kg of tetramine may be lethal.[22] Because of its high stability in water, tetramine is a relatively persistent environmental contaminant that theoretically could cause secondary poisonings.[22]

In addition to its most common manifestation of toxicity, which is refractory seizures, tetramine also causes coma and possibly coronary ischemia. Symptoms are said to begin from 30 minutes to 13 hours after exposure and fatality may occur within 3 hours of onset. A variety of methods have been used to treat tetramine poisoning in China, including AC hemoperfusion and hemodialysis, but none have proven to be uniformly successful

and there are no proven antidotes for tetramine. Management includes the standard approach to gastrointestinal decontamination with AC and the standard approach to seizures with benzodiazepines, and with effective airway protection.

Î±-Chloralose (Glucochloral, Chloralosane)

Î±-Chloralose is a crystalline powder (usually colored pink or blue) that is formed by the condensation of glucose with trichloroacetaldehyde (chloral). Î±-Chloralose is a central nervous system depressant, still used as a veterinary anesthetic. Its effects in humans include sedation, anesthesia, spontaneous myoclonic movements, and generalized convulsions.[33 , 48] Most human exposures are nonfatal and most current reports appear to emanate from France and Europe. Management in this case is also supportive, with the use of airway protection and the administration of AC.

Salmonella -Based Rodenticides

Salmonella enteritides , a human pathogen, is an active ingredient in rodenticides still produced and used in Central America and Asia. Biorat, currently available in several countries, is made by coating rice grains with a combination of *S. enteritides* and warfarin. The strain of *Salmonella* â€”phage type 6aâ€”found in Biorat is similar to the strain of *Salmonella* that was in Ratin, a rodenticide used in Europe until the 1960s, which caused human illness and deaths.[71] In 1954 and 1967, the WHO recommended not using *Salmonella* -based rodenticides because of their threat to human health. Since 1980, *S. enteritides* has been responsible for a global pandemic of foodborne illness associated with eggs and poultry.[71] In addition to inadvertent exposures, *Salmonella* -based rodenticides have been used intentionally to cause human illness.

Managing the Patient Exposed to an Unknown Rodenticide

For the patient exposed to an unknown rodenticide, the approach is more complicated than for a patient who ingests a known common commercial rodenticide such as warfarin or cholecalciferol. First, as always, adequate breathing and circulation must be assured, as the patient is briefly examined. If the patient is initially stable, the next priority is to make every effort to fully identify the type and quantity of rodenticide ingested

If the rodenticide and its package material are not brought with the patient, someone should be sent to get them because identifying a harmless rodenticide ingestion early on is more cost-effective and less traumatic to the patient than treating for an unknown ingestion. If the rodenticide container is labeled, and the information is telephoned back to the health care provider, care should be taken to obtain the full name, not just the brand name. The names are frequently used interchangeably by manufacturers. For example, until 1986, there was a line of rodenticides all carrying the â€œPied Piperâ€• name on a variety of very different products: Pied Piper for Rats and Mice contained ANTU and

warfarin; whereas Pied Piper Kwik-Kill Mouse Seed contained strychnine; and Pied Piper Rodenticide contained red squill. Many manufacturers still use similar names for dissimilar poisons.

Although full identification of the rodenticide is important, a careful physical examination should be performed in any case, searching for toxic signs that indicate specific rodenticides:

- Gastrointestinal symptomatology, paresthesias, and the late onset of hair loss are characteristic of thallium (Chap. 96).[10 , 23 , 24 , 39 , 44 , 56 , 64 , 67 , 74]
- Irritability or â€œapprehensionâ€• followed by seizures, coma, and death from respiratory failure or ventricular tachycardia and fibrillation are produced by SMFA, fluoroacetamide[17 , 18 , 19 , 20 , 36 , 70 , 77 , 84 , 96 , 99] (Chap. 106) and tetramine.
- Central nervous system stimulation, opisthotonos, prolonged recurrent motor seizures, and medullary paralysis followed by death suggest strychnine poisoning (Chap. 108).[6 , 14 , 30 , 41 , 46 , 50 , 53 , 68 , 69 , 72 , 76 , 85 , 91 , 97 , 101 , 105]
- Hypotension, vomitus with a rotten or â€œfishyâ€• odor, cardiopulmonary collapse, coma, renal damage, and leukopenia suggest various metal phosphide poisonings (Chap. 112).[1 , 2 , 4 , 16 , 21 , 35]
- Oral and skin burns, luminescent â€œsmokingâ€• vomitus, and stools with a garlic odor, and gastrointestinal and biliary damage characterize yellow phosphorus poisoning (Chap. 107).[25 , 57 , 79 , 88 , 95 , 100]
- Dysphagia, muscle cramps, seizures, hematemesis, and bloody diarrhea followed by cardiovascular collapse suggest arsenic (Chap. 85).[49 , 92]
- The combination of striking hyperglycemia with or without ketoacidosis, and severe postural hypotension, autonomic and

peripheral neuropathies, ileus, and esophageal or GI perforation characterize Vacor poisoning (see Goldfrank's Toxicologic Emergencies, 7th ed., Chap. 90).[3 , 31 , 34 , 37 , 40 , 42 , 45 , 47 , 52 , 61 , 63 , 81 , 82 , 90]

- Muscle tremors, myoclonic jerks with flexion of major muscle groups, and unresponsiveness may be the human manifestations of bromethalin poisoning (Chap. 104).
- Dyspnea, crackles, acute lung injury, pleural effusions, and hypothermia are seen with massive ingestions of ANTU (Chap. 104).
- Nausea, vomiting, diarrhea, and abdominal pain will probably be the only effects of ingesting red squill, but when those effects are combined with signs of ventricular irritability (premature ventricular contractions and ventricular fibrillation), then this potent emetic and cardioactive steroid is certainly identified (Chap. 114).[73 , 89 , 102]
- Signs or symptoms of a bleeding disorder and abnormal coagulation or international normalized ratio (INR), or low levels of coagulation factors, point to either a large acute ingestion of a superwarfarin rodenticide, such as brodifacoum, or repeated (chronic) ingestion of a regular warfarin-type rodenticide (Chap. 57).[13]
- Finally, evidence of hypercalcemia following (massive or chronic) rodenticide ingestion suggests cholecalciferol (vitamin D_3).

If a toxic syndrome is identified, aggressive management, including the use of specific antidotes, may be necessary (see Table 104-2). Immediately following an ingestion and prior to the development of signs and symptoms of toxicity, there is no rodenticide currently in use for which orogastric lavage followed by AC, and possibly an intestinal evacuant cathartic, is contraindicated, although they may be unnecessary. After the patient is symptomatic however, orogastric lavage, AC, and catharsis must be individualized according to the specific toxin and the patient's clinical condition.

If every effort to identify the rodenticide fails, the following diagnostic

evaluation may be indicated: A complete blood cell count (CBC) or hemoglobin (Hgb)/hematocrit (Hct) determination and

INR will help diagnose and manage repetitive ingestions of the older warfarin-type rodenticide, chronic ingestions of the newer superwarfarin anticoagulant rodenticides, and a large single ingestion of a superwarfari a few days after ingestion. Following acute ingestions, the CBC and INR will not be useful until 48 hours later. Repetitive ingestions of the otherwise harmless older warfarins is an important consideration for children who have pica, and for institutionalized, emotionally disturbed adults who may nibble grainlike rodenticides repeatedly. Serum glucose, potassium, and bicarbonate determinations will identify hyperglycemia and ketoacidosis caused by Vacor, and an elevated serum calcium concentration suggests cholecalciferol (vitamin D_3) ingestion. Liver enzymes, BUN, and creatinine are useful baseline determinations for rodenticides that cause hepatic or renal damage, respectively (eg, zinc phosphide, yellow phosphorus, cholecalciferol). A serum sample and 50 mL of urine should be obtained and sent to the toxicology laboratory with the request to hold it for possible heavy metals screening, especially if the patient is vomiting. Finally, if indicated by history or symptomatology, additional specimens may be collected for specific rodenticide determinations (eg, thallium, strychnine); a digoxin level may offer a clue to Red Squill ingestion. Chest and abdominal radiographs ma be useful because of the radiopaque nature of some of the uncommonly used rodenticides (Chap. 6).

If there is any doubt about either the nature of the rodenticide or the reliability of the patient (or parents) after the diagnostic evaluation, the patient should be admitted for observation. No matter what type of rodenticide was ingested, a determination should be made regarding whether the ingestion was unintentional, a suicide gesture or attempt, or a manifestation of abuse or neglect.[7] A psychiatric assessment is, of course, indicated for any possible suicide attempt.

Summary

As developed and underdeveloped parts of the world continue to experiment with and use a variety of exotic and very toxic or lethal rodenticides, it will be even more important to be able to discriminate between expected sequela of known or suspected rodenticides and unexpected sequela from other pesticides or xenobiotics used inappropriately as rodenticides. The key to managing the patient who ingested a rodenticide is to identify the rodenticide, the quantity ingested, its potential toxicity, and any available specific antidote. Toxic ingestions should be excluded or treated immediately; conversely, patients with the most common acute anticoagulant, bromethalin or cholecalciferol exposures should not be overtreated.

Chapter 105
Barium

Andrew Dawson

Barium (Ba)

Atomic number	=	56
Atomic weight	=	137.33
Normal concentrations Serum	=	< 0.2 mg/L

A 34-year-old woman was brought to the emergency department by her husband after she stated that she unintentionally ingested his hair care product. Her complaints included abdominal pain, diarrhea, palpitations, and weakness. Initial vital signs were: blood pressure 140/90 mm Hg; pulse 100 beats/min; respiratory rate 16 breaths/min; and rectal temperature 98.6Â°F (37Â°C). Oxygen saturation by pulse oximetry was 96% on room air. Physical examination was only remarkable for diffuse and symmetrical muscle weakness. An ECG demonstrated sinus tachycardia with U waves and intermittent runs of ventricular tachycardia. An arterial blood gas was obtained while the patient

was breathing room air, and showed: pH, 7.34; PCO_2, 46 mm Hg; PO_2, 90 mm Hg.

The patient was attached to continuous ECG monitor, given 100% oxygen via a nonrebreather mask, and an intravenous bolus of lidocaine (100 mg) was administered. Her dysrhythmia transiently improved, but recurred. Subsequently, electrolytes were notable for sodium, 138 mEq/L; potassium, 2.4 mEq/L; chloride, 95 mEq/L; bicarbonate, 20 mEq/L; glucose, 110 mg/dL; BUN, 18 mg/dL; and creatinine, 1.2 mg/dL.

The patient was given potassium chloride (40 mEq) by mouth and an intravenous infusion of 10 mEq/h was started. Her serum potassium and ECG were checked hourly. After the first hour, during which a total of 50 mEq of potassium chloride was administered, her serum potassium rose to 2.8 mEq/L, and she continued to have some ectopy on her ECG. A total of 180 mEq/L of potassium chloride was administered (with combined oral and IV therapy) over 10 hours before her ECG returned to normal and her weakness resolved. She was observed for another 24 hours, and before being transferred to the psychiatry service for further evaluation of her behavior and rationale for ingestion of this xenobiotic. At that time her serum potassium was 3.8 mEq/L and she was asymptomatic.

Chemistry

Barium is a soft metallic element with an atomic weight of 137.327 that is located at number 56 in the periodic table (between Cesium and Lanthanum). The metal oxidizes easily when exposed to water or alcohol and has a melting point of 1341Â°F (727Â°C) and a boiling point of 3398Â°F (1870Â°C). Elemental barium is not found in nature; it normally occurs as an oxide, dioxide, sulphate (barite), or carbonate (witherite). It was first isolated by Sir Humphry Davy in 1808. Chemically, barium resembles calcium more than any other element. Although some salts occur naturally,

most salts used for commercial purposes are produced from the more commonly found carbonate or oxides. Barium salts may be either water-soluble or insoluble. The solubility of all barium salts increases as pH is lowered. The soluble salts: acetate, chloride, hydroxide, oxide, nitrate, and (poly)sulfide, are the most commonly associated with toxicity (Table 105-1). Barium (poly)sulfide may also produce toxicity through the formation of hydrogen sulfide when it combines with the acid normally present in the stomach. Insoluble salts such as the arsenate, chromate, fluoride, oxalate, and sulfate are rarely associated with toxicity. However, the solubility of barium carbonate is low at a normal pH, but increases significantly when the pH is lowered. Additionally, in gastric acid, barium conversion to the highly soluble barium chloride occurs.

History and Epidemiology

Barium poisoning is rare, with less than 100 exposures reported annually to the Toxic Exposure Surveillance System (TESS) database (Chap. 130). Toxicity has been reported for most forms of barium, although it is most commonly reported following the intentional ingestion of soluble salts found in rodenticides,[8] insecticides, or depilatories.[9] Toxicity has also followed occupational exposure to barium salts by ingestion or inhalation. An explosion of the propellant barium styphnate caused extensive burns and trauma in a 50-year-old man who also developed significant barium toxicity within 2 hours of exposure which persisted for at least 4 days.[12] Barium carbonate has an appearance that is similar to that of flour and has been responsible for most unintentional barium poisonings. Despite the fact that barium sulfate is insoluble,

rare cases of unintentional toxicity have been reported during radiographic procedures and include complications associated with oral[18] and rectal administration.[11,16,20] Toxicity and death

occurred when soluble barium salts unintentionally contaminated contrast solution[2] and flour.[7]

TABLE 105-1. Available Barium Salts

Barium Salt	Solubility*	Common Uses
Acetate	58.8	Textile dyes
Carbonate	0.02 Solubility increases markedly in an acid pH. Also conversion to barium chloride	Rodenticide, welding fluxes, pigments, glass, ceramics, pyrotechnics, electronic devices, welding rods, ferrite magnet materials, optical glass, manufacture of caustic soda and other barium salts
Chloride	375 (26Â°C)	Textile dyes, barium salts, pigments, boiler detergents, in purifying sugar, as mordant in dyeing and printing textiles, as water softener, in manufacture of caustic soda and chlorine, polymers, stabilizers

Fluoride	1.2 (25Â°C)	Welding fluxes
Nitrate	87	Optical glass, ceramic glazes, pyrotechnics (green light), fireworks, explosives, antiseptic preparation
Oxide	34.8	In glass, ceramics, refining oils and sugar, as an additive in petroleum products and also as materials of plastics, pharmaceuticals, polymers, glass and enamel industries.
Styphenate		Propellent used in manufacture of explosive detonators
Sulfate	0.002	Radiopaque contrast media, manufacture of white pigments, paper making
Sulfide	0.9	Depilatories, manufacture of fluorescent tubes

*In g/L at 68Â°F (20Â°C); where the solubility was not measured at 68Â°F (20Â°C), the temperature (Â°C) used is shown in parentheses.

Toxicokinetics

Toxicity can occur from ingestion of as little as 200 mg of barium salt, although oral lethal doses are reported to range from 1 to 30 g barium salt. In ambient air, inhaled concentrations greater than 250 mg/m^3 are considered dangerous.

Following ingestion, 5â€“10% of soluble barium salts are absorbed,[15] with the rate of absorption dependent on the degree of water solubility of the salt. The time to peak plasma concentrations is 2 hours.[13]

Toxicokinetics are characterized by a rapid redistribution phase, followed by a slow decrease of plasma barium levels with a reported half-life ranging between 18 hours and 3.6 days.[13,21] Renal elimination of the absorbed dose accounts for 10â€“28% of total barium excretion, with the feces being the predominant route of elimination.

Deaths are most commonly reported following ingestion, but have also occurred from inhalation, intraperitoneal exposure, vaginal exposure, or by extravasation.[14] Death from an ingestion of barium chloride was associated with the following barium levels at autopsy: blood, 9.9 mg/L; bile, 8.8 mg/L; urine, 6.3 mg/L; and gastric contents, 10 gm/L.[14]

Pathophysiology

Clinical Manifestations

At a cellular level, barium induces hypokalemia by two synergistic mechanisms. Barium is a competitive blocker of the potassium rectifier channel, which is responsible for the efflux of intracellular potassium out of the cell. It may also directly increase cell

membrane permeability to sodium. This causes a secondary increase $Na^{+}â€“K^{+}$ pump electrogenesis, leading to a shift of extracellular potassium into the cell.

Intracellular trapping of potassium leads to depolarization and paralysis.[15] Additionally, the inhibition of potassium channels increases vascular resistance and reduces blood flow[3,5] and is the likely mechanism for hypertension and lactic acidosis.

Although severe hypokalemia is a major contributor to paralysis, some authors have found that muscle weakness is better correlated with barium concentration than with potassium concentration.[19,22] This suggests a possible direct effect of barium on either skeletal muscle or neuromuscular transmission.

Abdominal pain, nausea, vomiting, and diarrhea commonly occur within 1 hour of ingestion. Esophageal injury[1] and hemorrhagic gastritis are also reported.[14] Severe hypokalemia is the cardinal feature of barium toxicity and can occur within 2 hours following oral or parenteral exposure. Hypokalemia may be exacerbated by blood transfusions, suggesting that fresh red blood cells provide a new reservoir for K^{+} sequestration.[12] Progressive hypokalemia is associated with severe ventricular dysrhythmias, hypertension, profound flaccid muscle weakness, and respiratory failure.

Other less commonly reported effects include lactic acidosis, hypophosphatemia, and rhabdomyolysis.[13] Altered level of consciousness and seizures[5] and basal ganglia manifestations are reported.[10] It is unclear whether these later findings are a result of direct toxicity or secondary to tissue ischemia.

Diagnostic Studies

Barium can be measured by a variety of techniques. Mass spectrometry can quantitate barium in blood and urine. Graphite furnace atomic absorption spectrometry (GF-AAS) has also been used.[15] Serum barium levels are not readily available, but values

greater than 0.2 mg/L are considered abnormal.[4]

Following acute exposures, patients should have serum electrolytes (particularly potassium and phosphate) measured hourly while performing continuous ECG monitoring. Creatine phosphokinase (CPK), acidâ€“base status, and renal function should also be measured. A plain abdominal radiograph may show barium, but the sensitivity and specificity of radiography has never been determined for barium poisoning.[15]

Differential Diagnosis

Other causes of acute hypokalemia (Chap. 17) associated with paralysis, such as periodic hypokalemic paralysis, toluene toxicity, and diuretic use, should be considered if there is no history or laboratory confirmation of barium exposure. Likewise, toxicological etiologies for flaccid paralysis such as hypermagnesemia, botulism, and the administration of neuromuscular blockers should also be considered.

Management

Patients should be admitted to a monitored bed with full respiratory support readily available. Patients who are asymptomatic at 6 hours with normal potassium concentrations can be discharged.

Decontamination

Activated charcoal (AC) is unlikely to be effective. Orogastric lavage should be considered in patients who present early after ingestion, but is unlikely to provide extra benefit in patients who are already symptomatic or who have had spontaneous emesis. Oral sodium sulfate administration may prevent absorption by precipitating unabsorbed barium ions to insoluble, nontoxic barium

sulfate. Oral magnesium sulfate has also been used with success.[17] The oral dose of magnesium sulfate is 250 mg/kg for children and 30 g for adults. Intravenous magnesium sulfate or sodium sulfate is not advised, because it may lead to renal failure as a result of precipitation of barium in the renal tubules.[19,24]

Patients in respiratory failure should receive assisted ventilation. Aggressive correction of hypokalemia is important to minimize the risk or to treat cardiac dysrhythmias. Large doses of potassium replacement (400 mEq in 24 hours) are reported to be required to correct serum potassium, but may still not improve muscle strength (Chap. 17).[15] As hypokalemia is a result of intracellular sequestration of potassium, potassium supplementation increases the total body potassium load. In this situation, rebound hyperkalemia may occur when barium is eliminated, especially in the setting of a patient with impaired renal function, and the necessity of observation should be anticipated.

Enhancement of Elimination

Correction of hypokalemia alone may not reverse weakness and would not be expected to completely restore the resting membrane potential. In this setting, hemodialysis can be considered. Hemodialysis for the management of severe barium toxity has been reported in three cases.[21,23] Additionally, in a case report, continuous venovenous hemo(dia)filtration (CVVHDF) tripled the measured barium elimination, reduced serum barium half-life by a factor of 3, stabilized serum potassium levels, and rapidly improved motor strength, with complete neurological recovery within 24 hours.[15] Either method of enhanced elimination should be considered in any severely symptomatic patient who does not respond to correction of hypokalemia.

Summary

Although poisoning by barium salts is rare, these salts are widely used in industry and therefore represents a substantial risk for human exposure. The ingestion of barium salts is typically followed by a rapid onset of symptoms and can result in life-threatening toxicity. In addition to good supportive care the mainstay of treatment is rapid correction of hypokalemia.

Chapter 106

Sodium Monofluoroacetate and Fluoroacetamide

Fermin Barrueto

A previously healthy 23-year-old woman arrived at the emergency department (ED) after drinking a â€œshotâ€• of liquid in a bottle marked â€œSMFA solution (1%).â€• She was actively vomiting and complaining of abdominal pain. She was taking no prescription medications, had no allergies, and denied ingesting any non prescription medications or using any illicit drugs. After 30 minutes of evaluation, she had a single generalized tonic-clonic seizure.

Her vital signs were: blood pressure 95/50 mm Hg; pulse 136 beats/min; respiratory rate 28 breaths/min; temperature 100.1Â°F (37.98Â°C); and pulse oximetry 95% on room air. There was no drooling or stridor. Head and neck examination revealed no burns on the face or within the oropharynx. Her lungs were clear to auscultation, and cardiovascular examination revealed tachycardia with delayed capillary refill of 4 seconds. The abdominal examination was benign, and the neurologic examination done

before the seizure revealed an agitated but alert and oriented woman with no focal deficits.

Laboratory analysis of a blood sample drawn before her seizure occurred revealed a hematocrit of 36.4%, a hemoglobin of 11 g/dL, a white blood cell count of 12,100/mm^3, and a platelet count of 275,000/mm^3. The electrolyte analysis revealed: sodium, 143 mEq/L; chloride, 101 mEq/L; potassium, 3.0 mEq/L; bicarbonate, 18 mEq/L; blood urea nitrogen, 49 mg/dL; creatinine, 2.9 mg/dL; glucose, 105 mg/dL; and calcium, 8.0 mg/dL, and an anion gap of 24. Arterial blood gas analysis revealed a pH of 7.30; PCO_2 of 25 mm Hg: and PO_2 of 75 mm Hg. Serum lactate concentration was 6.2 mmol/L. ECG revealed sinus tachycardia with occasional premature ventricular contractions and a prolonged QTc interval of 501 milliseconds. Chest radiograph was normal.

After the seizure resolved spontaneously, the patient was given 2 mg of lorazepam intravenously. She became hypotensive, with a blood pressure of 75/40 mm Hg despite a 2-L bolus of 0.9% sodium chloride. The patient was intubated and a norepinephrine infusion was started. Twelve hours after arrival in the ED and 24 hours from the estimated time of ingestion, the patient experienced cardiac arrest and died despite maximal supportive care.

History and Epidemiology

Sodium monofluoroacetate (SMFA) is synthesized by plants such as gifblaar (*Dichapetalum cymosum*), native to Brazil, Australia, and South and West Africa.[10] The highest concentration of the compound is reportedly in the seeds of a South African plant, *Dichapetalum braunii*, at a concentration of 8.0 mg/g.[10] The compound was developed by the Denver Research Station in the 1940s as a means of controlling rodent populations. When SMFA (CAS No. 62-74-8) was developed, it was assigned the compound number 1080, which was registered as its trade name.

Fluoroacetamide, a similar pesticide, is known as Compound 1081. Use of either was banned in the United States in 1972, except in the form of collars intended to protect sheep and cattle from coyotes. These collars, imbedded with SMFA, are placed around the neck of the livestock, which is the typical point of attack for coyotes. It is an effective poison against most mammals and some amphibians.[20]

Currently, SMFA is used extensively in New Zealand and Australia to control the possum population and other animal species considered pests that have no natural predators. During 2004 the New Zealand National Poisons Center received 91 inquiries regarding SMFA, of which only one concerned possible human exposure (personal communication).

Pharmacokinetics and Toxicodynamics

Sodium monofluoroacetate is an odorless and tasteless white powder with the consistency of flour. When it is dissolved in water, it is said to have a vinegar-like taste. Sodium monofluoroacetate and fluoroacetamide (CAS No. 640-19-7) are well absorbed orally, and poisoning has also occurred from inhalation.[9,10,11] Detailed toxicokinetic data are lacking in humans, but in sheep, up to 33% can be excreted unchanged in the urine over 48 hours. Glucuronide and glutathione conjugates have also been isolated.[9] Substantial defluorination is not thought to occur in vivo. The plasma half-life is estimated to be 6.6â€“13.3 hours in sheep.[9] Sodium monofluoroacetate has an LD_{50} of 0.06 mg/kg in dogs; the extrapolated LD_{50} in humans is 2â€“5 mg/kg.

Pathophysiology

Sodium monofluoroacetate, a structural analog of acetic acid (Figure 106-1), is an irreversible inhibitor of the tricarboxylic acid

cycle within the mitochondria (Figure 13-3). Monofluoroacetic acid enters the mitochondria when it is converted to monofluoroacetyl-coenzyme A (CoA) by acetate thiokinase. Once inside the mitochondria, citrate synthase joins the monofluoroacetyl-CoA complex with oxaloacetate to form fluorocitrate. Fluorocitrate then covalently binds aconitase, preventing the enzyme from any further interaction in the tricarboxylic acid cycle.[14] Thus fluorocitrate acts as a â€œsuicide-inhibitorâ€• of aconitase, producing a biochemical dead end. The subsequent increase in citrate, which chelates divalent cations, causes hypocalcemia. This sequence was well demonstrated in an animal model in which citrate was administered intrathecally, resulting in seizures that were attenuated with calcium administration.[12]

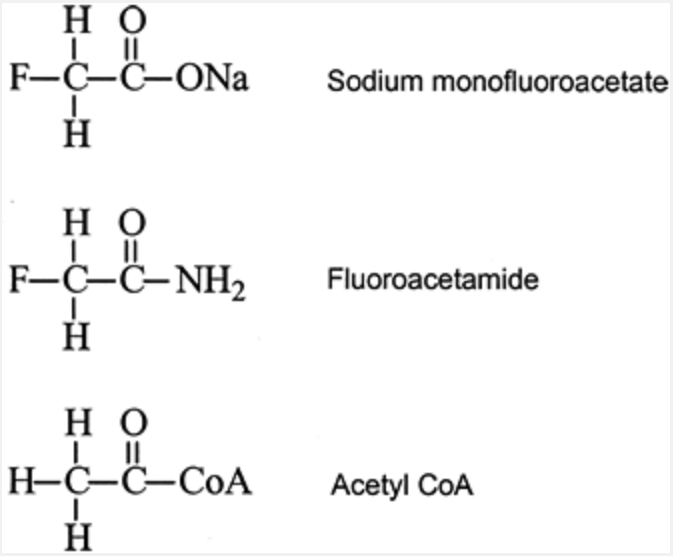

Figure 106-1. Structural similarities among acetyl-CoA, sodium monofluoroacetate, and fluoroacetamide.

Suicide inhibition of aconitase impairs energy production, leading to metabolic acidosis with an elevated lactate concentration. Additionally, other tricarboxylic acid cycle intermediates increase

in concentration, contributing to the toxicity. Fluoride toxicity, from enzymatic defluorination of sodium monofluoroacetate and fluoracetamide, does not occur substantially in vivo and is of minor significance.

Clinical Manifestations

The majority of the clinical experience with SMFA is associated with intentional self-poisoning; fluoroacetamide poisoning is presumed to have a similar presentation.[1,2,13,22] Most patients will develop symptoms within 3â€“6 hours from the time of exposure. In the largest case series, 38 Taiwanese patients ingested SMFA; 7 died.[6] The most common symptoms of exposure recorded at the time of ED presentation were nausea and vomiting (74%), diarrhea (29%), agitation (29%), and abdominal pain (26%).[6] The mean time to presentation to the hospital was 10.9 Â± 5.7 hours for those who died and 3.4 Â± 0.6 hours for the survivors. All deaths occurred within 72 hours of admission to the hospital. The presence of respiratory distress and/or seizures was statistically a poor prognostic indicator of death. All 7 patients who died had systolic blood pressures less than 90 mm Hg on presentation to the ED, compared with 16% of the survivors.[6] One published case report describes the survival of an unresponsive patient with episodic hypertension after SMFA exposure.[19]

The physiologic effects of impaired energy production were described in two patients: one survivor and one fatality.[7] Invasive hemodynamic monitoring revealed persistent low systemic vascular resistance and increased cardiac output, despite adequate fluid resuscitation.[7]

In summary, the common clinical presentation of SMFA exposure is the presence of nausea, vomiting, agitation, abdominal pain, and diarrhea. Signs and symptoms associated with severe poisoning are seizures, respiratory distress, and hypotension. Neurologic sequelae such as cerebellar dysfunction may be permanent.[23]

Diagnostic Testing

The presence of SMFA and fluoroacetamide can be confirmed with gas chromatography-mass spectrometry and thin-layer chromatography.[3,5,15] Simultaneous analysis for rodenticides that can induce seizure, for example, fluoroacetamide and â€œtetramine,â€• has been performed by gas chromatography in China, where exposure to these xenobiotics is more probable.[4,25] An elevated serum citrate concentration has been proposed as a useful marker for exposure to SMFA. However, none of these studies can be performed in a clinically relevant time period. A combination of history, signs, symptoms, and common laboratory tests can assist with the diagnosis.

A complete blood cell count may reveal leukocytosis. Electrolyte abnormalities include hypokalemia and hypocalcemia. Creatinine, liver enzymes, and bilirubin level may also be elevated. Hypokalemia, an anion gap metabolic acidosis, and an elevated creatinine level[8] are associated with severe poisoning but are very nonspecific.[6] An electrocardiogram is valuable in the diagnosis of SMFA exposure: a prolonged QTc interval, atrial fibrillation with a rapid ventricular response, ventricular tachycardia, and other dysrhythmias may be present. An initial computed tomography scan of the brain may be normal, but subsequent scans may reveal brain atrophy if the patient survives the exposure.[23]

Treatment

Initial decontamination should include removal of clothes and cleansing of skin with soap and water. Because there is no antidote for SMFA or fluoroacetamide poisoning, orogastric lavage should be considered for exposed patients who present to the ED prior to significant emesis. Appropriate patients should receive activated charcoal (AC), however, there is a study in rats that showed colestipol was more effective in binding SMFA than AC.[16]

Although there are no human data to support this, the use of colestipol, if available, should also be considered in life-threatening cases.

In animal models, the ethanol and glycerol monoacetate (monacetin) are thought to be antidotes, acting as acetate donors for ultimate incorporation into the tricarboxylic acid cycle.[23] Both of the xenobiotics are converted to acetyl-CoA and compete for binding of citrate synthase with monofluoroacetyl-CoA. This may prevent the â€œsuicide-inhibitionâ€• of aconitase, subsequent increase in citrate, and the formation of the toxic metabolite fluorocitrate.[23]

Ethanol has been used in human cases, although the appropriate dose is unknown.[6,7,18] A reasonable therapeutic dose that is considered safe is the amount of ethanol required to obtain and sustain an ethanol serum concentration of 100 mg/dL as must be achieved in the treatment of ethylene glycol or methanol poisoning (Antidotes in

Depth: Ethanol). In smaller mammals, the dose is estimated to be 1.5â€“8.0 mL/kg of 50% ethanol administered orally. One patient who ingested 240 mg, which is typically a lethal dose of SMFA, mixed the SMFA with a Taiwanese wine (30% ethanol) and survived.[6] Although not sufficiently investigated, it is possible that the ethanol effectively decreased or delayed the full toxic effect of the SMFA.

In a mouse model,[17] use of a combination of calcium salts, sodium succinate, and Î±-ketoglutarate resulted in improved survival. The rationale of using these antidotes is to provide tricarboxylic acid cycle intermediates that are distal to the inhibition by the toxin of aconitase in an attempt to improve energy production. Of particular note, these antidotes were not effective unless calcium was co-administered, emphasizing the importance of replenishing electrolytes, particularly the divalent cations that are chelated by

citrate.[22]

If a patient develops hypotension and shock, rapid administration of intravenous fluids should be followed by a vasopressor, such as norepinephrine. Supportive care, correction of electrolyte abnormalities (calcium and potassium), ethanol infusion and monitoring for dysrhythmias and seizures are the mainstays of treatment.

Summary

Sodium monofluoroacetate and fluoroacetamide are potent pesticides that inhibit the tricarboxylic acid cycle disrupting cellular energy production. Patients who are exposed to SMFA typically present with nausea, vomiting, agitation, and abdominal pain which may be followed by hypotension, respiratory distress, shock, seizures, and death. Hypokalemia, hypocalcemia, metabolic acidosis, and elevation of serum creatinine also occur. Treatment of SMFA and fluoroacetamide poisoning involves replenishing electrolytes, correcting hypotension with intravenous fluids and vasopressors if necessary, monitoring for dysrhythmias, and treatment of seizures. Ethanol, although not a perfect antidote, is typically available and can be administered rapidly and safely. The efficacy of other experimental antidotes is unknown.

Chapter 107
Phosphorus

Heikki E. Nikkanen
Michele Burns Ewald

Phosphorus (P)		
Atomic number	=	15
Atomic weight	=	30.97
Normal concentrations Serum	=	3â€“4.5 mg/dL (1â€“1.4 mmol/L)

A 3-year-old girl was brought to the emergency department by her parents immediately after she was found eating rat bait containing Stearns' Electric Brand Paste, which contains 2.5% elemental phosphorus. Initially, the girl was unconscious and her vital signs were: blood pressure 50/30 mm Hg; pulse 160 beats/min; respirations 44 breaths/min; and temperature 98.6Â°F (37.0Â°C). Physical examination revealed an irregular cardiac rhythm without murmur, a soft abdomen, cyanotic skin, and a garlic odor to the

breath. An intravenous line of 0.9% sodium chloride (NaCl) was established and blood was drawn for laboratory analysis. The physicians performed an orogastric lavage and recovered a small amount of grain-like material. The child was transferred to a pediatric intensive care unit at regional pediatric hospital, where on arrival she only responded to painful stimuli. Her vital signs were: systolic blood pressure 50 mm Hg; pulse 160 beats/min; respirations 44 breaths/min; and temperature 94.1Â°F (34.5Â°C). Laboratory data was unremarkable except for an inorganic phosphorus level of 5.2 mg/dL (normal 3â€“4.5 mg/dL). An electrocardiogram showed premature atrial contractions.

The child was treated with a gastric lavage of potassium permanganate 1:5000 solution, followed by administration of a cathartic. Supportive measures improved her vital signs, but 2 hours after her admission she had a cardiopulmonary arrest, and could not be resuscitated.

History and Epidemiology

The word phosphorus comes from the ancient Greek â€œphos,â€• which means light, and â€œphorus,â€• which means bringing. Phosphorus was initially identified in specimens of distilled urine by an alchemist named Hennig Brandt in Hamburg in about 1669. The clinical use of phosphorus first appeared in a medical text in 1720. It was touted as a treatment for colic, tetanus, apoplexy, and gout. Phosphorus also gained a popular reputation as a tonic and aphrodisiac, and its use was promoted by traveling medicine shows which impressed gullible onlookers with the phosphorescent and explosive nature of the â€œmedicine.â€• Despite its highly toxic nature, it remained in the British Pharmacopoeia until 1932 and was available without prescription in Great Britain until the 1950s.

White phosphorus gained public notoriety as the main ingredient in â€œlucifers,â€• or strike-anywhere matches. Invented by French

chemist Charles Sauria in 1830. Over 3 trillion of these matches were struck per year by the end of the 19th century. However useful these matches were to the population, the history of their production epitomizes workers' struggles with safety during the industrial revolution. Workplace exposure to phosphorus produced â€œphossy jaw,â€• or mandibular osteonecrosis first documented in Germany in 1838. The incidence of this disease was approximately 1% among the young women who worked in match factories at that time. Accounts of patients suffering from phossy jaw describe loss of teeth, softening or destruction of the mandible, and formation of abscesses discharging foul-smelling pus.

Because of the fire hazard presented by strike-anywhere matches, and the health risks posed to their makers, the Berne Convention of 1906 prohibited the use of white phosphorus in matches among its signatories. Although the United States failed to ratify this multinational treaty, the Match Act of 1912 was subsequently passed by Congress. It effectively taxed these matches out of existence. Today, matches are markedly safer and use red phosphorus in the striking pad on the matchbook rather than white phosphorus in the match head.

Phosphorus incendiary bombs were responsible for a large portion of the destruction unleashed on Europe during World War II, typified by the London Blitz of 1940. Numerous murders were attempted or committed in the 19th and early 20th centuries using phosphorus. Although it was readily available, it had the dual disadvantages of a strong garlic odor and a luminescence, which alerted both intended victims and suspicious coroners.

TABLE 107-1. Exposure Limits to White Phosphorus

Agency	Exposure Measure	Value
NIOSH	IDLH	5 mg/m^3
ACGIH	TLV TWA	0.1 mg/m^3
NIOSH	REL TWA	0.1 mg/m^3
OSHA	PEL TWA	0.1 mg/m^3

White phosphorus is used commercially today to manufacture insecticides (organic phosphorus compounds) and fertilizer (phosphoric acid).[14,15,22,23,28,31] White phosphorus itself is used as an incendiary and may be found in hand grenades, mortar rounds, shells, smoke generators, tracer rounds, and fireworks.[21,22,24,28] White phosphorus is used in many countries to create homemade fireworks known as totes, *diablitos*, or Watusi that are commonly used in suicides and occasionally homicides. These fireworks typically weigh about 300 mg, containing up to about 10% white phosphorus, and also include up to 40% potassium chlorate. Quality control is poor and the exact contents are unpredictable.

Elemental phosphorus, primarily the red allotrope, is a key component in the synthesis of illicit methamphetamine, and its sale is now tightly controlled by the Drug Enforcement Administration (DEA). Workplace exposure limits exist for the many industrial applications for which elemental phosphorus is

critical (Table 107-1).

Chemistry

Phosphorus (P) is the 15th element on the periodic table, with an atomic weight of 30.97 Daltons. Elemental phosphorus exists in three allotropes: black phosphorus, a nontoxic compound that does not ignite spontaneously; red phosphorus, a fairly innocuous phosphorus intermediate in reactivity between black and white phosphorus; and white phosphorus, a highly reactive and dangerous element. White phosphorus is a tetramer, P_4, which is a waxy paste, insoluble in water. It has a melting point of 111.2Â°F (44Â°C) and an ignition temperature of 86Â°F (30Â°C) in moist air. It may emit a pale green glow in some circumstances because of low-level reactivity with the surrounding oxygen. The presence of impurities in white phosphorus account for the general description of white phosphorus as yellow phosphorus. White phosphorus undergoes rapid oxidation on contact with oxygen, with the resultant liberation of heat, light, and dense white smoke. The chemical equation which describes this process is as follows:

$4P + 5O_2$ â†’ $2P_2O_5$

This reaction continues until the phosphorus or the oxygen is consumed. Phosphorus pentoxide generates phosphoric acid when dissolved in water:

$P_2O_5 + 3H_2O$ â†’ $2H_3PO_4$

Thus, following the explosion of white phosphorus, not only is white phosphorus broadly disseminated, but it also creates a dense cloud of white smoke with a garlic odor. The smoke is phosphoric acid, which can produce pulmonary, ophthalmic, and dermal irritation.

Red phosphorus differs from the white allotrope by its crystalline form, its lack of phosphorescence, and its markedly reduced reactivity with oxygen. Red phosphorus will slowly degrade to

highly toxic phosphine gas (PH_3) and phosphorous acids. Phosphine is reactive and usually undergoes rapid oxidation (Chap. 112). Black phosphorus is produced by heating white phosphorus with a mercury catalyst, forming a graphite-like sheet of phosphorus atoms. Black phosphorus is the least reactive, does not readily ignite and has little commercial value.

TABLE 107-2. Distribution of White Phosphorus by Various Body Tissues

UPTAKE	High	Moderate	Low
Tissue	Adrenal cortex	Adrenal medulla	Bone
	Bowel mucosa	Endometrium	Brain
	Epidermis	Lung	Fat
	Hair follicles	Myocardium	Myometrium
	Liver	Ovary	Skeletal muscle
	Pancreas	Renal medulla	
	Renal cortex	Spleen	
		Thymus	

Because the majority of toxicity reported from elemental phosphorus is a result of the white allotrope, when phosphorus is mentioned in this chapter, it refers to the white allotrope, unless otherwise specified.

Toxicokinetics

White phosphorus is rapidly absorbed from the intestinal tract. After systemic absorption, it is taken up primarily by the tissues of the liver, renal cortex, bowel mucosa, epidermis, hair follicles, pancreas, and adrenal cortex. Within several hours of ingestion 69â€“73% of the total ingested dose is identified concentrated in the liver.[40] Other tissues absorb the toxin to lesser degrees (Table 107-2).[8]

In rat models, a subcutaneous lethal dose is approximately 10 mg/kg[37] and the intraperitoneal median lethal dose (LD_{50}) is approximately 9 mg/kg.[17] A review of 56 cases of human white phosphorus poisoning suggested a lethal dose of 1 mg/kg, which is the commonly accepted value.[11] This study predates the introduction of intensive care units, so the lethal human dose in the modern day may be significantly higher, although a later prospective study suggests a lower lethal dose.[22]

White phosphorus is highly lipid-soluble, and significant absorption can occur after skin or mucosal exposure. Penetrating wounds and dermal burns enhance the systemic absorption of white phosphorus.

Pathophysiology

Hepatic

White phosphorus increases oxygen consumption in the hepatocyte. Uncoupling of oxidative phosphorylation is the likely mechanism, and there is a decrease in intrahepatocyte adenosine

triphosphate (ATP) levels.[37] Mitochondrial injury, visible as swelling, can be seen on electron microscopy. White phosphorus may affect the transformation of triglycerides into Î²-lipoproteins or the secretion of the latter into the bloodstream, accounting for the increase in observed cytoplasmic fat that is noted.[37] Massive hepatic steatosis is a hallmark of white phosphorus toxicity, with a rise in hepatic triglycerides beginning within 2 hours and peaking in 36 hours. Hepatic necrosis may be prominent, particularly in zone 1, in distinction to most other classic hepatotoxins, such as acetaminophen

and carbon tetrachloride, that produce zone 3 necrosis. Hepatic glycogen stores are decreased, and blood glucose levels fall. Hepatic glucose-6-phosphatase activity increases.[37] A massive increase of rough endoplasmic reticulum may not be pathognomonic for phosphorus-induced liver injury, but it is seen universally in this poisoning and is rarely produced by other xenobiotics.[17,33]

A rat model of chronic white phosphorus exposure showed development of hepatic edema, and hepatitis, followed by fibrosis and cirrhosis.[33]

Skin, Mucous Membranes, and Gastrointestinal Tract

White phosphorus can cause both thermal and chemical injury. The exothermic reaction described earlier is the major mechanism of injury to the skin. There are no data about direct chemical toxicity to the skin of either white phosphorus or phosphorus pentoxide. Phosphoric acid penetrates the skin, but the significance relative to the thermal burn is unclear.[10,21] In exposures involving penetrating dermal injury, subcutaneous tissue damage as a result of generation of phosphoric acid may occur, albeit more slowly than on the exposed skin. The gastrointestinal tract similarly may

be relatively spared compared to equivalent exposure of the skin, likely a result of the low concentration of oxygen in the gastrointestinal tract.[31] The mucous membranes may similarly be affected by white phosphorus, much of it mediated by phosphoric acid.

Cardiovascular

Some postmortem cardiac examinations of victims of phosphorus poisoning revealed no morphologic changes.[5] One report notes interstitial edema and vacuolated cytoplasm with pale linear areas on microscopic examination. The same researchers noted an experimental decrease in rat myocardial protein synthesis after phosphorus poisoning.[41] The likely mechanism of phosphorus-induced dysrhythmias is profound electrolyte abnormalities, including hypocalcemia and hyperkalemia.

Nervous System

The uptake of radiolabeled phosphorus into neural tissue is minimal[8] and there is no information regarding histopathological changes in brain tissue following phosphorus exposure. Nervous system manifestations of white phosphorus poisoning appear to be more related to the development of hypocalcemia than to direct toxic effect on the tissues.

Electrolyte Homeostasis

Hyperphosphatemia is a direct result of absorption and conversion to phosphoric acid and subsequent deproteination. Calcium complexes with phosphate causing hypocalcemia and may precipitate within tissues in forms such as hydroxyapatite. Hyperkalemia may result from the profound hypocalcemia (as in hydrofluoric acid poisoning) or it can occur as a result of renal failure.

Renal

White phosphorus causes injury to the glomerulus following systemic absorption.[1] Microscopic analysis of renal tissue shows fatty degeneration in some cases[8] but in others is described as fatty deposition and necrosis.[37]

TABLE 107-3. White Phosphorus Poisoning

Stage	Characteristics
I Day 1:	GI tract injury, cardiac dysrhythmias, neurologic manifestations, hypocalcemia.
II Days 2â€“3:	Fulminant hepatic failure.
III Days 4â€“8:	Death from liver failure and delayed cardiac toxicity.
IV Day 8:	Recovery

Clinical Manifestations

Overall, the mortality from ingestion ranges from 20â€“50%.[22,29] Indicators of a poor prognosis include ingestion of greater than 1 mg/kg; signs of severe electrolyte disturbance, such as reversal of Ca^{2+}-to-PO_4^{-3} ratio, mental status changes, prolongation of QTc interval, and ST-T wave abnormalities; tenfold or greater increase in alanine aminotransferase (ALT); severe coagulopathy; and peak liver enzymes reached within 36 hours of ingestion.[5,15]

Previous literature describes the course of oral white phosphorus poisoning in 3 stages.[23] The first, which lasts for hours to days, is marked by irritation and injury of the gastrointestinal tract. In the second stage, the gastrointestinal symptoms may resolve. This period can last for several days. In the third stage, patients develop cardiac, hepatic, or renal toxicity. Recovery, if it occurs, takes place over days to weeks.[29] (See Table 107-3.) However, review of 41 fatal reported cases of white phosphorus ingestion suggests a clinical course that differs from this description.[22,23,28,31] Over half the deaths occurred in the first day, and the cause of death, when known, was cardiac in nature, presumably dysrhythmic as a result of electrolyte abnormalities. Deaths as a result of fulminant hepatic failure occur within the first week. Some delayed cardiac deaths occurred between 5 and 8 days after exposure. No additional deaths are reported after day 8.

Hepatic

White phosphorus produces hepatotoxicity in a predictable and dose-dependent manner.[7,18] Abnormal aminotransferases occur in approximately half of phosphorus poisoned patients,[23] and in most patients they begin to rise within 24 hours of exposure. The time to aminotransferases peak levels and the magnitude of the elevation differed significantly between the patients who died and patients who lived. The group which died had an average ALT peak of 16 times normal level, reached in 36 hours. In the survival group, ALT rose to 8 times normal, reaching this peak in 6 days. Coagulopathy was observed in only 17% of patients.[15] The serum triglyceride level may fall as the hepatic toxicity develops, and there may be an increase in serum and urinary ketones.

Skin, Mucous Membranes, and

Gastrointestinal Tract

White phosphorus skin burns are very painful, with a necrotic appearance, yellowish color, and garlic odor.[4] As in the case of chemical burns, they heal slowly and require longer hospital stays than do simple thermal burns.[24] Human experience and animal models suggest that a second or third degree burn of 10â€“15% body surface area may result in death from phosphorus absorption.[4,5] One epidemiological study of military personnel showed an average third-degree burn size of 11.2% and a mortality rate of 4.1%.[24]

Mucosal surfaces that are directly affected by phosphorus suffer the same chemical burns noted on the skin. Following exposure

to phosphorus smoke membranes in exposed areas, such as the mouth, nose and eyes, may develop swelling, injection and other signs of irritation.

Oropharyngeal burns, nausea, vomiting, diarrhea, abdominal pain, and gastrointestinal hemorrhage may occur following ingestion of white phosphorus. Hematemesis occurs in about 30% of patients who ingest phosphorus, and post mortem examinations of the intestines do show diffuse hemorrhages.[37] The vomitus and stool are typically described as having a garlic odor. Nine case reports describe that the effluent emitted smokeâ€”the famous â€œsmoking stoolâ€•â€”and was phosphorescent.[15,30,31]

Cardiovascular System

Early death following white phosphorus exposure is commonly because of cardiovascular collapse.[31] In one case, this was found to be because of decreases in cardiac contractility and systemic vascular resistance.[41] Electrocardiographs performed during the first 12 hours showed abnormalities in 70% of the subjects.[19,36] These included bradycardia, atrial fibrillation, QTc interval

prolongation, ST segment depression, T-wave changes, bradycardia, atrial fibrillation, and low-voltage QRS complexes. These manifestations likely reflect electrolyte abnormalities, such as severe hypocalcemia.[19,36] Cardiac arrest may occur within several hours of oral or dermal exposure. Death from cardiac causes generally occurs in the period from 3â€“8 hours after systemic absorption.[5,23,31] However, some late cases of cardiac death are reported. Cardiovascular collapse, cardiac arrest without dysrhythmias and morphologic myocardial injury are also described.[30] Hypocalcemia may cause cardiomyopathy, heart failure, and mimic myocardial infarction.[9,16,20,26]

Nervous System

Central nervous system signs, which include irritability, anxiety, agitation, confusion, lethargy, delirium, hallucinations, seizures and coma, are often the first manifestations of toxicity. Patients, who develop CNS signs or symptoms before other organ systems are affected, have a mortality rate of 73%.[23] In the peripheral nervous system, hypocalcemic manifests as paresthesias, carpopedal spasm, tetany, and even laryngeal stridor or opisthotonus.[27,23]

Renal

Renal failure and hyperkalemia are not prominent elements of white phosphorus poisoning, but are noted in some cases.[34] In a series of 41 cases reported in the 1970s, nearly half of the patients had an abnormal BUN and creatinine, but only 3 developed transient renal failure.[23] No cases of chronic renal failure are described. Two hypotheses for renal failure are a direct toxic effect of white phosphorus on the kidney, and acute tubular necrosis because of the shock state.[8]

Electrolytes

Rabbits that died from white phosphorus burns within the first 24 hours had profound elevations of serum phosphorus and depressions of serum calcium. The clinical findings of patients with white phosphorus poisoning are suggestive of acute hypocalcemia.

Chronic Exposure

Workers engaged in the early years of white phosphorus production developed an unusual mandibular osteonecrosis known as â€œphossy jawâ€• and cachexia, anemia, and fatigue.[2] A case-controlled study of workers at a white phosphorus plant in China from 1973 to 1984 showed that 22 of 58 had osteolytic or osteosclerotic lesions on radiography of the mandible. Ten years later, 13 of the 22 had complete resolution of their lesions, 2 had remaining lesions that were improved, and 7 had no changes in their previous abnormalities. Hepatomegaly was noted in 6â€“9%, leukopenia in 18â€“20%, and pulpitis or tooth decay in 20â€“57%. The concentration of white phosphorus measured in the factory air was 0.13 mg/m^3. Longer employment was associated with increased incidence of pathology, with an exponential rise at year 5.[35]

Assessment and Management

Protection of Healthcare Personnel

Care must be taken to prevent exposure of healthcare personnel. White phosphorus contained in vomitus or stool can be hazardous; one case report of a suicide by white phosphorus ingestion contains a picture of a hole burned through a bed sheet by a patient's feces.[30] Given the low melting point, white phosphorus may be present in the liquid phase in a patient's clothing, and may ignite spontaneously at room temperature.[21,24] Personnel must

wear protective equipment to prevent direct contact with phosphorus. As discussed below, patients must be decontaminated and thoroughly wetted.

Supportive and Standard Care

Life support measures, such as airway protection and fluid resuscitation, should be provided. A complete blood count, hepatic enzymes, PT, PTT, electrolytes, bun, creatinine, serum phosphate, and serum calcium should be measured. Hypocalcemia, hyperphosphatemia, and hyperkalemia should be expeditiously treated using standard modalities. Frequent measurement of vital signs and continuous cardiac monitoring are essential. Renal function and urine output, must be evaluated. Most patients with white phosphorus exposure should be admitted to hospital. Ophthalmic irrigation should be performed if eye irritation is present.

Skin Decontamination

The patient with a cutaneous exposure should be immediately doused with, or immersed in, water. Irrigation is the only treatment shown to decrease burn size, length of hospital stay, and mortality.[10,12,13] Any areas where white phosphorus may remain must be kept wet at all times, as the substance may re-ignite if it is exposed to ambient oxygen.[21]

Copper sulfate solutions are occasionally recommended for conversion of particulate phosphorus to the less harmful copper phosphate, which is black, making debridement easier.[3] However, copper sulfate can inhibit glucose-6-phosphate dehydrogenase, leading to lethal hemolysis[34] and raising a significant concern about its potential benefit. Remaining particulate phosphorus may be identified using a Woods lamp, as phosphorus fluoresces easily. Alternatively, the application of silver nitrate may prevent ignition

of the phosphorus by depositing a film of silver on the surface of the phosphorus.[32] After combustion has been prevented and particles identified, a thorough debridement must be performed as any remaining phosphorus can be systemically toxic.

Gastrointestinal Decontamination

Early lavage of the stomach has been recommended without supporting data.[38] Given the high mortality associated with exposure to

white phosphorus and the lack of effective antidotes, lavage should be considered, with appropriate precautions. One case report describes an explosion and fire, which occurred after a nasogastric tube was inserted into the stomach of a phosphorus poisoned patient.[39] This was likely because of entrance of oxygen into the stomach through the tube or exit of phosphorus from the tube. Regardless of the exact circumstance, precautions can be taken to minimize this risk. Connect the external end of the tube to a syringe filled with water; prime the tube itself with water; confirm placement by instilling water rather than air, or by withdrawing gastric contents.

There are no data evaluating the ability of activated charcoal (AC) to adsorb phosphorus, nor of any known clinical benefit.[31] However, white phosphorus is highly toxic in small amounts, no effective antidote exists, and esophageal burns are not prominent. The administration of oral AC therefore is appropriate for patients who have ingested phosphorus.

Whole-bowel irrigation with polyethylene glycol may decrease the absorption of phosphorus by mixing the xenobiotic in a nonabsorbable carrier and removing it from the GI tract.[31,38] Given the highly toxic nature of white phosphorus, this treatment should be attempted for consequential exposures.

Instillation of 1:5000 potassium permanganate solution into the stomach will theoretically convert ingested white phosphorus to a less harmful oxide.[6] This treatment has been used on many patients, but no clinical trial has demonstrated a benefit.[11,14,28] This therapy is not readily available, is high risk from a chemical perspective, has no sound clinical basis, and is therefore not indicated.

N-Acetylcysteine

In another study, a standard intravenous *N*-acetylcysteine (NAC) regimen was given to 9 of 15 patients who had ingested fireworks. Although there was no significant benefit identified in this small, uncontrolled trial, all patients who received the full course survived. As NAC is a benign therapy and may be of benefit, we recommend it in cases of white phosphorus poisoning.

Other Antidotal Therapy

A prospective human study reached the conclusion that corticosteroids are not helpful in reducing the hepatotoxic effects of white phosphorus.[22] In small-animal studies, ubiquinone, cysteine, and sulfate treatments were shown to prevent liver damage to some degree. No human data evaluates these therapies.[33,37]

Enhanced Elimination

The correction of hyperphosphatemia, hyperkalemia, and hypocalcemia can be most rapidly done through the use of hemodialysis. However, its use for these electrolyte disturbances in the setting of acute phosphorus poisoning is not reported. Exchange transfusion is reported in humans, but too few data were collected to draw a conclusion about its value in this situation.[22] However, whole blood cross circulation appears to have a

significant positive effect on survival in a controlled animal study. In the control arm, the mortality was 90%, compared to 20% in the treatment arm.[7] This result suggests that exchange transfusion may be beneficial.

Summary

White phosphorus is used in military and industrial applications, and in fireworks. Poisoning carries a mortality of greater than 20%. Early death is generally due to cardiac dysrhythmias, secondary to electrolyte abnormalities, such as hypocalcemia and hyperkalemia. Death after the first 24 hours is generally due to hepatic failure. Management must include protection of healthcare personnel, as any remaining exposed phosphorus may ignite or explode. Patients with dermal exposure must be doused with water and kept wet to prevent spontaneous ignition of white phosphorus. Treatment of patients with oral exposure includes gastric lavage and administration of AC. Intensive supportive care is required, the mainstay of which is electrolyte homeostasis. Intravenous *N*-acetylcysteine may be of benefit in preventing hepatic injury.

Chapter 108
Strychnine

Yiu-Cheung Chan

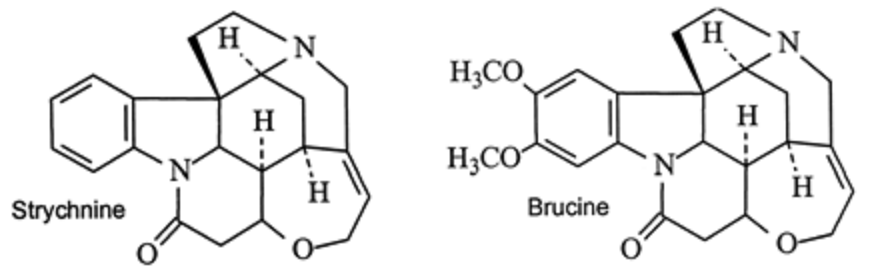

Figure. No Caption Available.

A 45-year-old woman who had been injecting heroin for a long period of time presented to an emergency department (ED) shortly after self-injecting heroin, complaining of generalized muscular

aches and twitching. Over a short period of time she developed repeated episodes of uncomfortable diffuse muscular twitching, but remained alert. She was otherwise in good health, although her tetanus vaccination status was unknown.

On arrival in the ED, her vital signs were: blood pressure 134/58 mmHg; pulse 97 beats/min; respiratory rate 22 breaths/min; temperature 100Â°F (37.2Â°C), and oxygen saturation by pulse oximetry 100% on room air. Respiratory and cardiovascular examinations were unremarkable. The abdomen was rigid and the neck was stiff during the muscular contractions, but both examinations were normal in between the contractions. Her cranial nerve and sensory examinations remained intact and there were no focal signs. The remainder of her neurologic examination revealed involuntary muscular contractions in all limbs and an increased reflex jerk. Clinical investigations revealed normal ECG, chest radiograph, and CT scan of the brain. Blood tests, including glucose, electrolytes, arterial blood gas, renal function, and liver function were also all within normal limit. A complete blood count was remarkable only for mild leukocytosis.

Either strychnine poisoning or tetanus was considered the most likely diagnosis, and the patient was treated with 5-mg diazepam intravenously, tetanus immunoglobulin (Hypertet), and other general supportive measures. Over the next few hours in the ICU, the muscular spasms gradually improved and her hemodynamic status remained stable. This rapid improvement made tetanus unlikely and strychnine the probable etiology for the patient's spasm. After 4 days, the patient was discharged from the hospital with a normal examination and no sequelae. A urine specimen was positive for strychnine.

History

Strychnine alkaloid can be found naturally in *Strychnos nux vomica*, a tree native to tropical Asia and North Australia, and in

Strychnos ignatii and *Strychnos tiente*, trees native to South Asia. The alkaloid was first isolated in 1818 by Pelletier and Caventou.[5,17] It is an odorless and colorless crystalline powder that has a bitter taste when dissolved in water. Besides strychnine, the dried seeds of *Strychnos nux vomica* contain brucine, a structurally similar, although less potent, alkaloid.[88] In addition to the naturally occurring alkaloidal form, strychnine is available from commercial sources in its salt form, usually as nitrate, sulfate, or phosphate.

Strychnine was first introduced as a rodenticide in 1540, and was subsequently used medically as a cardiac, respiratory, and digestive stimulant,[49] as an analeptic,[92] and as an antidote to barbiturate[91] and opioid overdoses.[60] Nonketotic hyperglycemia,[9,40,80] sleep apnea,[75] and snake bites[17] were all once also considered indications for strychnine use. In 1982, at least 172 commercial products were found to contain strychnine, including 77 rodenticides, 25 veterinary products, and 41 products for human use.[82] Currently, strychnine is used mainly as a pesticide and rodenticide (for moles, gophers, and pigeons),[82] and a research tool for the study of glycine receptors. Most commercially available strychnine-containing products contain about 0.25â€“0.5% strychnine by weight.[82]

Epidemiology

In the past, strychnine poisoning caused significant mortality, especially in children. Between 1926 and 1928, strychnine killed more than three Americans every week.[5,30] In 1932, it was the most

common cause of lethal poisoning in children[5,82,98] and one third of the unintentional poison-related deaths in children younger than 5 years were attributed to strychnine.[85] Currently, strychnine poisoning is rare in United States, but deaths are still reported.

The Toxic Exposure Surveillance System (TESS) data of the American Association of Poison Control Centers (AAPCC) reports 1601 strychnine exposures during the past 10 years with 0â€“3 deaths annually (Chap. 130).

Strychnine poisoning has resulted from deliberate exposure with suicidal and homicidal intent,[12,30] from unintentional poisoning by a Chinese herbal medicine (Maqianzi),[18] a Cambodian traditional remedy (slang nut),[52,56,86] and adulteration of street drugs.[14] Maqianzi is used to treat limb paralysis, severe rheumatism, and inflammatory disease, whereas slang nut is used to treat gastrointestinal illness. The bitter taste of strychnine allows it to be substituted for heroin,[46] and cocaine.[14,25,64] There are also reports of strychnine poisoning from adulterated amphetamines,[25] ecstasy (MDMA, 3-4 methylenedioxymethamphetamine),[28] Spanish fly,[13] and from the ingestion of gopher bait.[54]

Toxicokinetics

Standard references list the lethal dose of strychnine as approximately 50â€“100 mg[20,36,37,70,94] (1â€“2 mg/kg). However, mortality resulting from doses as low as 5â€–10 mg[6] and, alternatively, survivals following ingestions of 3.75 g and 15 g of strychnine are reported.[20,97] Some of this variation may be attributed to the route of administration, with parenteral administration being more toxic than oral, and the limitations of self reports of exposure quantities.

Strychnine is rapidly absorbed from the gastrointestinal tract, mucous membranes, and via the parenteral route. There is also one case report of poisoning as a result of dermal absorption of strychnine from an alkaline solution, in which strychnine exists in the nonionized, alkaloid form.[38] Protein binding is minimal and strychnine is rapidly distributed to peripheral tissues[93] with a large volume of distribution (13 L/kg).[43] Based on postmortem findings, the highest concentrations of strychnine are found in the

liver,[58,70,78] bile,[70] blood,[70] and gastric contents.[70,78] Relatively less strychnine is identified in kidney, urine, and brain.[78]

Strychnine is metabolized by hepatic P450 microsomes[1,61] producing strychnine-N-oxide as the major metabolite,[1] and this metabolism is increased by P450 induction.[47,51] Several urinary metabolites are identified,[65] and 1â€“30% of strychnine is excreted unchanged in urine,[10,69] in decreasing proportions when larger amounts are ingested.[81,93] In human case reports, strychnine follows first order elimination kinetics with a half-life of 10â€“16 hours.[29,69,96]

Pathophysiology

The pharmacologic effects of strychnine are well understood. Glycine, one of the major inhibitory neurotransmitters in the spinal cord, mediates its effects by opening a ligand-gated chloride channel, thus allowing the inward flow of Cl^-[21] (Chap. 14). As Cl^- moves into the cell, it becomes hyperpolarized or inhibited. Strychnine competitively inhibits the binding of glycine to the Î±-subunit of the glycinergic chloride channel.[14,95,98] Although strychnine affects all parts of the central nervous system in which glycine receptors are found, the most significant effect is in the spinal cord. With the loss of the glycine inhibition to the motor neurons in the ventral horn, there is a loss of inhibitory influence on the normally suppressed reflex arc. The result is increased impulse transmission to the muscles producing generalized muscular contraction. Rabbits pretreated with glycine were found to have a 40% increase in the strychnine â€œseizureâ€• threshold, illustrating the competitive nature of strychnine and glycine activity on the glycinergic chloride channel.[77] For comparison, tetanus toxin (tetanospasmin) causes the identical clinical syndrome of muscular contractions, although tetanospasmin prevents the release of presynaptic glycine and does not function as a competitive antagonist. In dogs, strychnine

also has positive chronotropic and inotropic effects on the heart,[83] but this effect is unlikely to exert a major effect in human poisoning.

Clinical Manifestations

Strychnine poisoning is characterized by a rapid onset of signs and symptoms. Symptoms begin within about 15â€“60 minutes of ingestion,[35] and although less well documented, are expected to occur even sooner after parenteral or nasal administration. Delayed onset of clinical effects are rarely reported.[26,37] The typical symptoms of poisoning are involuntary, generalized muscular contractions resulting in neck, back, and limb pain. The contractions are easily triggered by trivial stimuli (such as turning on a light) and each episode usually lasts for 30 seconds to 2 minutes[82] with the period of recurrent episodes lasting as long as 12â€“24 hours. Differences in the strength of various muscle groups result in the classic signs of opisthotonus, facial trismus, and risus sardonicus, with flexion of the upper limbs, and extensions of lower limbs. Hyperreflexia, clonus, and nystagmus[11,62] are also evident on examination. Because strychnine affects glycine inhibition mainly in the spinal cord, the patient typically remains fully alert until metabolic complications arise. The combination of convulsive motor activity involving both sides of the body in the conscious patient has often resulted in imprecise descriptions such as â€œconscious seizureâ€• or â€œspinal seizure.â€• Hemodynamically, hypotension,[27,29,64] or hypertension[14,32,63] in the presence of bradycardia[16,27,29,64] or tachycardia[14,16] are all reported. Hyperthermia, presumably from increased muscular activity, is typical, and temperatures as high as 109.4Â°F (43Â°C) are reported.[14] Other nonspecific signs and symptoms include dizziness, vomiting, and chest and abdominal pain.[62]

Early in the course of strychnine poisoning, mortality is mainly due

to hypoventilation and hypoxia secondary to muscular contractions.[32] Later, life-threatening complications include rhabdomyolysis with subsequent myoglobinuria and acute renal failure,[16] hypoxia- or hyperthermia-induced multiorgan failure, aspiration pneumonitis,[84] anoxic brain injury, and pancreatitis.[45] Rarely, local neuromuscular sequelae such as weakness, myalgia, and anterior tibial compartment syndrome are reported.[14] As might be expected, the prognosis is related to the duration and extent of the episodes of muscle contractions.[34]

Differential Diagnosis

The diagnosis of strychnine poisoning is mainly established on clinical grounds, although several differential diagnostic etiologies need to be considered. Tetanus produces similar muscular hyperactivity, but with less rapid onset and lasting much longer than strychnine poisoning. Frequently, the diagnosis of tetanus is suggested by a history of recent injury, or the finding of an obvious wound. In general, patients with tetanus have a deficient record of tetanus immunization.

Strychnine poisoning can be differentiated from generalized seizures by the presence of a normal sensorium during the period of diffuse convulsions. That is, most patients with bilateral convulsions

are having generalized seizures, which by definition involve the reticular activating system, producing unconsciousness. It is conceivable, although extraordinarily rare, to have bilateral focal seizures producing apparent â€œgeneralizedâ€• convulsions; in this case because the reticular activating system may not be involved, the patient's mental status may be preserved. The diagnostic utility of the presence of consciousness in a patient with a generalized convulsion for diagnosing strychnine poisoning or tetanus is true at least in the time period of the clinical course. At

later times this finding may be obscured by metabolically induced alterations in sensorium. When this occurs an electroencephalogram may be helpful, if it documents an absence of focal neurological deficits. A CT can help to exclude structural brain lesions, and a lumbar puncture is helpful to exclude meningitis or encephalitis. Hypocalcemia, hyperventilation, and myoclonus secondary to renal or hepatic failure are evaluated by appropriate routine laboratory testing. Although a drug-induced dystonic reaction should be considered when there is a relevant drug history, dystonic reactions are usually static, and strychnine poisoning results in dynamic muscular events. Serotonin syndrome, malignant hyperthermia, neuroleptic malignant syndrome, and stimulant use should be considered, if the medical history is supportive.

Diagnostic Testing

Both respiratory and metabolic acidosis are commonly found in strychnine-poisoned patients. Metabolic acidosis correlates with serum lactate levels,[14] whereas respiratory acidosis is secondary to hypoventilation resulting from diaphragmatic and respiratory muscle failure. Survival is well documented in patients with serum pHs in the range of 6.5â€“6.6.[14,32,33,35,55,96] The lowest pH and highest lactate reported in a patient who subsequently had full recovery was 6.5 and 32 mmol/L,[14,196] respectively. Thus, profound acidosis in strychnine poisoning is not necessarily associated with poor prognosis. One proposed reason is that the serum pH does not correlate with the intracellular pH in the vital organs, namely the brain and heart.[7,8,14,73] In contrast to the lactic acidosis seen in shock, the lactic acidosis of strychnine poisoning results from overactivity of the muscle instead of undersupply or underutilization of oxygen and nutrients.

Besides acidosis, other laboratory abnormalities expected from prolonged muscular activity include evidence of rhabdomyolisis,[14]

hyperkalemia,[14] and acute renal failure. There is also stress induced leukocytosis,[14,45] elevated liver enzymes,[45,62,90] hypocalcemia,[14,43] hypernatremia,[35] and hypokalemia.[31,62,84] The electrocardiogram is expected to remain normal or reflect changes consistent with the above electrolyte disturbances.[43] Chest radiography may show evidence of aspiration pneumonia or acute lung injury.

Strychnine can be detected by various methods such as thin layer chromatography,[48,67,89] high performance liquid chromatography,[2,23] ultraviolet spectrometry,[67] a simple colorimetric reaction,[67] gas chromatographyâ€"mass spectrometry,[15,16,58,69,78] gas chromatographyâ€"flame ionization detector,[94] and capillary electrophoresis.[99] With the exception of the bedside colorimetric reaction, none of these tests are routinely available in a time frame useful to assist in clinical decisions. Strychnine is also detectable in amounts as low as 0.01 ppm in tissue,[2,24,59,72] and it resists postmortem putrefaction. Additionally, even when available, quantitative levels do not correlate with clinical toxicity. Reported blood strychnine levels in fatal poisoning ranged from 0.5 to 61 mg/L.[94] Conversely, the highest initial blood level associated with survival was 4.73 mg/L from blood drawn at 1.5 hours postingestion;[96] a level as low as 0.06 mg/L was found in a patient reported to have muscular irritability.[29]

Management

Induced vomiting is absolutely contraindicated because of the risk of aspiration and loss of airway control following rapid onset of muscle contractions in strychnine poisoning. Orogastric lavage should be considered on an individual basis after evaluating potential benefits and risks.[3] When gastric lavage is thought to be indicated, it may be important to protect and secure the airway with an endotracheal tube before attempting lavage. Activated

charcoal (AC) binds strychnine effectively at a ratio of near 1:1; 1 g of AC will bind 950 mg of strychnine.[4,88] In animal models, pre-[66] and post-[71] treatment with AC increases the median lethal dose of 50% of test subjects (LD_{50}) for strychnine. Clinical evidence of the effectiveness of AC on strychnine dates back to 1831, when in front of the French Academy of Medicine Professor Touery took a lethal dose of strychnine with AC and survived.

Currently, there is no evidence to recommend the use of multiple-dose AC or whole-bowel irrigation in strychnine poisoning. Although forced diuresis was once suggested as an effective means of enhancing the elimination of strychnine,[88] subsequent data failed to demonstrate an increase in drug clearance[81] and it is therefore no longer recommended. Peritoneal dialysis, hemodialysis, and hemoperfusion have not been extensively studied. Because strychnine is rapidly distributed out of the blood[93] into a large volume of distribution (13 L/kg), extracorporeal drug elimination procedures are unlikely to be useful and therefore not justified given their risks.

Supportive treatment remains the most important aspect of management in the majority of cases. The focus of care is to stop the muscular hyperactivity as soon as possible to prevent the metabolic and respiratory complications. At all times, unnecessary stimuli and manipulation of the patient should be avoided, as these activities trigger muscle contractions. Benzodiazepines remain the first-line treatment for strychnine-induced muscular hyperactivity.[82,96] Although much of the evidence concerning the efficacy of benzodiazepines is based on diazepam,[41,50,53,64] any of the commonly used benzodiazepines (diazepam, midazolam, lorazepam) would likely have similar effects. The initial dose of the benzodiazepine chosen should be the standard dose used for other indications, although doses of more than 1 mg/kg diazepam or its equivalent may be needed.[44,57] In case of failed intravenous access, lorazepam or midazolam can be given intramuscularly. Dosing should be repeated until the patient's muscles relax and

the contractions cease. Besides benzodiazepines, barbiturates (phenobarbital, pentobarbital) are also effective in stopping the strychnine induced hyperactivity[42,56,74,87] and are considered second-line treatment if benzodiazepines fail. Both benzodiazepines and barbiturates work through agonism of Î³-aminobutyric acid (GABA) receptor chloride complexes to increase the inhibitory neurotransmission to the spinal cord from the brain, and thus raise the reflex arc threshold.[79] If these measures fail to control the muscular hyperactivity, a nondepolarizing neuromuscular blocking (NMB) agent should be administered. Only nondepolarizing NMB agents should be used, as succinylcholine itself induces muscle contractions.[14,29,56,64,81] It is important to remember that strychnine has no direct effects on consciousness, so that sedation must always accompany attempts at neuromuscular blockade. Generally, therapy is continued for about 24 hours, at which time the medications are slowly withdrawn, as tolerated.

The most important therapy for the metabolic complications of strychnine poisoning is to stop the further production of metabolic products by terminating the muscular hyperactivity as soon as possible. Hyperthermia should be treated aggressively by active cooling with ice water immersion, cooling blanket or mist and fan,

depending on the degree of temperature elevation. Means to prevent rhabdomyolysis-induced acute renal failure includes adequate fluid administration to ensure good urine output (>1 mL/kg/hr), the potential use of urinary alkalinization with sodium bicarbonate,[76] and temporary renal replacement therapy, if acute renal failure occurs. Metabolic acidosis rapidly resolves when muscular activity is controlled.[14,68]

Thus, effective management in the first few hours of strychnine poisoning is crucial for survival. If the patient can be supported adequately for the first 6 hours, this may be considered a good prognostic sign.[14,37] All significantly poisoned patients should be

managed in an intensive care unit with the help of a regional poison control center or medical toxicologist. For those patients unintentionally exposed to strychnine who remain asymptomatic, an observation period of 12 hours is sufficient to exclude significant risk.

Summary

Strychnine is a lethal poison not frequently encountered, except in areas that favor its use to exterminate small animals. A â€œconscious seizureâ€• is the characteristic presentation of strychnine toxicity, and is rapidly followed by life-threatening metabolic and respiratory consequences. The mainstay of treatment is supportive care with the goal of rapidly terminating muscular contractions, providing adequate airway management, and rapidly treating hyperthermia, and or metabolic abnormalities. Although benzodiazepines are generally sufficient, neuromuscular paralysis with a nondepolarizing NMB agent may be required. Generally, the prognosis of strychnine poisoning is good, if the patient can be adequately supported and survives the first few hours of toxicity.

Chapter 109

Insecticides: Organic Phosphorus Compounds and Carbamates

Richard F. Clark

A 40-year-old suicidal man was brought by relatives to the emergency department (ED) after drinking two sips of 50% malathion about 3 hours earlier. The patient was awake but confused and extremely diaphoretic. He had the odor of hydrocarbons on his breath; however, there was no evidence that the liquid had spilled onto his clothes. His initial vital signs in the ED were: blood pressure 210/120 mm Hg; pulse 100 beats/min; respiratory rate 22 breaths/min; temperature 98.6Â°F (37Â°C); and oxygen saturation 95% on room air. Physical examination demonstrated midsized pupils, minimal crackles in all lung fields, and copious vomiting and diarrhea. The patient was drooling between episodes of vomiting.

Initial evaluation demonstrated the patient's airway was patent and he was not in immediate respiratory distress. He was administered oxygen by face mask, placed on a cardiac monitor, an intravenous (IV) line was inserted and 2 mg atropine administered. Additional atropine was

obtained and placed at the bedside.

Even with supplemental oxygen and atropine given, the victim's oxygen saturation on pulse oximeter began to fall soon after arrival in the ED. His heart rate also rapidly increased to 120 beats/min, and an electrocardiogram demonstrated a prolonged QTc interval (560 msec). A portable chest radiograph showed bilateral pulmonary edema with normal heart size. The poison center was contacted immediately on his arrival, and recommended administration of more atropine and pralidoxime. After administration of an additional 3 mg atropine and pralidoxime 1 g intravenously, his breath sounds improved. But, despite therapy, his oxygenation continued to fall to 87%, and he began coughing up pink-tinged, frothy sputum. He continued to have large amounts of vomiting and diarrhea. A pralidoxime bolus of 1 g was administered intravenously, over 15 minutes and an infusion at 500 mg/h was initiated. The poison center also advised giving additional 2-mg atropine doses every 5â€“15 minutes as needed to control his secretions.

Although the emesis, diarrhea, and bronchorrhea diminished after a total of 20 mg of atropine, the clinicians elected to intubate the patient. He was sedated with 3 mg IV midazolam and paralyzed with 10 mg IV vecuronium. His oxygen saturation following intubation was 98% on 100% FIO_2 at an intermittent mandatory ventilation (IMV) rate of 16/min, and his vital signs were: blood pressure, 175/90 mm Hg; and pulse, 125 beats/min. A nasogastric tube was inserted and lavage of the stomach contents performed, followed by administration of 75 g of activated charcoal (AC). He was transferred to the intensive care unit (ICU).

In the ICU, the pralidoxime infusion was continued at 500 mg/h, and atropine was administered intermittently throughout the first 24 hours of admission for a total dose of 30 mg. Hematologic studies were normal except for a white blood cell count (WBC) of 19,000/mm^3. His other laboratory studies were remarkable for a glucose of 195 mg/dL, potassium of 3.2 mEq/L, and bicarbonate of 20 mEq/L. The chest

radiograph dramatically improved over the first 24 hours, and by the second day was only remarkable for a right-upper-lobe infiltrate. The patient was kept sedated with midazolam and intubated for another 24 hours to better monitor his pulmonary status. His ECG gradually improved by the second day, with a heart rate of 105, and normalization of his QTc interval.

On hospital day 2, because oxygenation was normal on room air, his sedation was terminated and he was extubated. His nausea and vomiting had largely improved, and no further frothy sputum was observed. The diaphoresis and diarrhea had resolved, but he continued to smell of solvents. Cholinesterase measurements sent initially showed virtually no detectable red blood cell (RBC) or butyrylcholinesterase (plasma) activity. All other laboratory results had normalized by the second day. He was transferred to a step-down unit for observation, and did not require any further atropine that day. The pralidoxime infusion was maintained at 500 mg/h, and penicillin started for presumed aspiration pneumonia after his sputum turned purulent. In view of the persistent presence of a hydrocarbon odor, the PC advised to wash the victim's skin and hair at least on a daily basis.

On hospital day 3, the patient reported feeling much better. His pralidoxime infusion was stopped and he was evaluated by the psychiatric service. That afternoon, he reported 2 episodes of diarrhea and some nausea; as a result, atropine 2 mg IV was administered and the pralidoxime infusion was restarted with resolution of symptoms once again.

The patient required no further atropine during his hospitalization. Pralidoxime infusion was stopped on hospital day 5, and he was discharged to a psychiatric facility on hospital day 7.

History

The first potent synthetic organic phosphorus anticholinesterase was

tetraethylpyrophosphate (TEPP), which was synthesized by Clermont in 1854. Clermont's report described the taste of the compound, a remarkable achievement because a few drops should be rapidly fatal.[69] In 1932, Lange and Krueger wrote of choking and blurred vision following inhalation of dimethyl and diethyl phosphorofluoridates.[78] This account inspired Schrader in Germany to begin investigating these agents, initially as pesticides, and later for use in warfare (Chap. 126). During this research, Schrader's group synthesized hundreds of compounds, including the popular pesticide parathion and the chemical warfare agents sarin, soman, and tabun. Allied scientists were also motivated during the same period by the work, and independently discovered other extremely toxic compounds such as diisopropylphosphofluoridate (DFP).[165] Since that time, it is estimated that more than 50,000 organic phosphorus compounds have been synthesized and screened for pesticidal activity, with dozens being produced commercially.[18]

The history of carbamates was first recorded by Westerners in the 19th century when they observed that the Calabar bean (*Physostigma venenosum Balfour*) was used in tribal cultural practice in West Africa.[164] These beans were imported to Great Britain in 1840, where, by 1864, Jobst and Hesse isolated an active alkaloid component they named â€œphysostigmine.â€• [164] VÃ©e and Leven (1865) claimed to have obtained it in crystallized form, and named it *eserine*, from Ã©sÃ©re, the African term for the ordeal bean. Physostigmine was first medicinally used to treat glaucoma in 1877.[70,79] In the 1930s, the synthesis of aliphatic esters of carbamic acid led to the development and introduction of carbamate pesticides, marketed initially as fungicides.[169] In 1953 the Union Carbide Corporation developed and first marketed carbaryl, the insectivide being prepared at the plant in Bhopal, India, during the catastrophic release of methyl isocyanate in 1984 (Chap. 2).[102]

Epidemiology

Organic phosphorus compounds and carbamates are the two groups of cholinesterase-inhibiting pesticides that commonly produce human toxicity. Although the term organophosphate is traditionally used in clinical practice and in the literature to refer to all phosphorus-containing pesticides that inhibit cholinesterase, phosphates are compounds in which the P atom is surrounded by four O atoms, and there are other derivatives of phosphoric and phosphonic acids such as phosphonates that can exhibit cholinesterase inhibition. Some chemicals, such as parathion, contain thioesters, whereas others are vinyl esters. Those cholinesterase-inhibiting (anticholinesterase) insecticides that contain phosphorus will be collectively termed organic phosphorus compounds in this chapter. Those that contain the OC=ON linkage will be termed carbamates.

During the 5-year period of 1998â€“2002, the American Association of Poison Control Centers (AAPCC) recorded more than 55,000 exposures to organic phosphorus compounds and more than 25,000 exposures to carbamates. Although these totals are large, the number of reported organic phosphorus compound exposures reported to the AAPCC in the last 2 years of this period declined by almost 20%, perhaps owing to mass marketing and use of less toxic pesticides. However, the number of fatalities reported to by the AAPCC remained constant, during this time averaging about 8 per year. These insecticides still rank as the most frequent lethal insecticides in use in the United States, and among the most lethal poisonings (Chap. 130). In Taiwan, where insecticides are often more accessible than medications in rural areas, fatality rates recorded with exposures to these compounds are as high as 23%.[150] Similarly, organic phosphorus insecticides were responsible for as much as high as 50% of all poisonings deaths in India in the past 25 years,[153] and may account for up to 75% of all poisonings in that country today.[130] The World Health Organization (WHO) estimates that at least one million unintentional poisonings and two million suicide attempts occur annually worldwide from these insecticides.[19] However, these figures undoubtedly omit numerous unreported and possibly unrecognized illnesses resulting from lower level

environmental exposure to these chemicals.

Typically patients present following unintentional or suicidal ingestion of anticholinesterase insecticides or after working in areas recently treated with these compounds.[67] Children and adults can develop toxicity while playing in or inhabiting a residence recently sprayed or fogged with organic phosphorus insecticides by a pesticide applicator.[183] Direct dermal contact with certain types of these insecticides may be rapidly poisonous.[105] Outbreaks of mass poisoning have occurred from contamination of crops or food.[19,34,43,118,144,145,167] Recently, epidemics of cholinergic toxicity have been reported among groups illegally importing and using the potent carbamate aldicarb.[124,132] Organic phosphorus agents have also been used for homicide.[118,119]

Pharmacology

Organic Phosphorus Compounds

Poisoning from organic phosphorus compounds results in a rise in the concentration of acetylcholine (ACh) at muscarinic and nicotinic cholinergic receptors, which, in turn, leads to the syndrome of cholinergic excess. Figure 109-1 shows the basic formula for cholinesterase-inhibiting organic phosphorus compounds. The â€œXâ€• or â€œleaving groupâ€• determines many of the characteristics of the compound and provides a means of classifying organic phosphorus insecticides into four main groups (Table 109-1). Group 1 compounds contain a quaternary nitrogen at the X position, and are collectively termed phosphorylcholines. These chemicals originally developed as weapons of war[51] are powerful cholinesterase inhibitors and can also directly stimulate cholinergic receptors, presumably because of their structural resemblance to Ach. Group 2 compounds are called fluorophosphates because they possess a fluorine molecule as the leaving group. Like group 1 compounds, these compounds are volatile and highly toxic, making them well-suited for

chemical warfare. The leaving group of group 3 compounds is a

cyanide molecule or a halogen other than fluorine. The most well-known agents in this group are cyanophosphates such as tabun. The fourth group is the broadest and comprises various subgroups based on the configuration of the R_1 and R_2 groups, with the majority falling into the category of either a dimethoxy or diethoxy compound. Most of the insecticides in use today fall into this last class.[51]

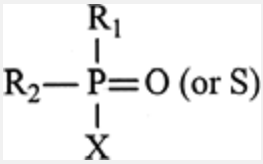

Figure 109-1. General structure of organic phosphorus insecticides. X represents the leaving group. R_1 and R_2 may be aromatic or aliphatic groups that can be identical.

Group 1–phosphorylcholines
Leaving group: substituted quarternary nitrogen
Echothiophate iodide

Group 2–fluorophosphates
Leaving group: fluoride
Dimefox, sarin, mipafox

Group 3–cyanophosphates, other halophosphates
Leaving group: CN, SCN, OCN, halogen other than fluoride
Tabun

Group 4–multiple constituents
Leaving group:
Dimethoxy
Azinphos-menthyl, bromophos, chlorothion, crotoxyphos, dicapthon, dichlorvos, dicrotophos, dimethoate, fenthion, malathion, mevinphos, parathion-methyl, phosphamidon, temephos, trichlorfon

Diethoxy
Carbophenothion, chlorfenvinphos, chlorpyriphos, coumaphos, demeton, diazinon, dioxathion, disulfoton, ethion, methosfolan, parathion, phorate, phosfolan, TEPP

Other dialkoxy
Isopropyl paraoxon, isopropyl parathion

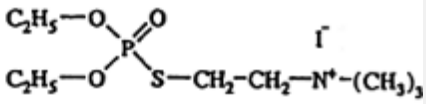
Diamino
Schradan

Chlorinated and other substituted dialkoxy
Haloxon

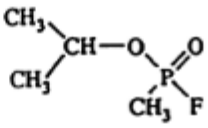
Trithicalkyl
Merphos

Triphenyl and substituted triphenyl
Triorthocresyl phosphate (TOCP)

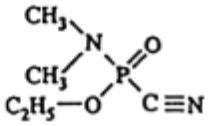
Mixed substituent
Crufomate, cyanofenphos



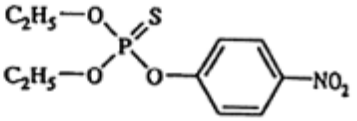
Echothiophate iodide



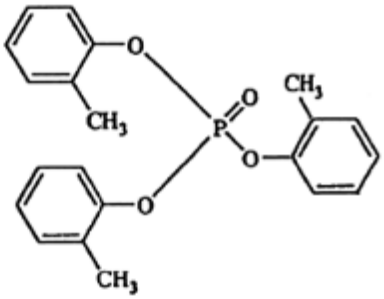
Sarin



Tabun



Parathion



Triorthocresyl phosphate (TOCP)

TABLE 109-1. The Classification of Organic Phosphorus Compounds by Groups. Leaving Groups and Examples of Each Group are Included

â€œDirectâ€•-acting organic phosphorus insecticides can inhibit acetylcholinesterase (AChE) without being structurally altered by the body. However, many of the more popular pesticides, such as parathion and malathion, are â€œindirectâ€• inhibitors or prodrugs requiring partial metabolism (to paraoxon and malaoxon, respectively) within the body to become active. Most of the indirect inhibitors undergo desulfuration in the intestinal mucosa and liver following absorption to form the more active phosphate or â€œoxonâ€• metabolites.[87] The active form is a more potent cholinesterase inhibitor. The covalent bond is completed as the leaving group of the organic phosphorus insecticide is split off by AChE, resulting in a stable but reversible bond between the remaining substituted phosphate of the

organic phosphorus agent and AChE, effectively inactivating the enzyme (Figure 109-2, normal metabolism; Figure 109-3, inactivation, see Figure 12-6 for a more detailed analysis). Although the splitting of the choline-enzyme bond in normal ACh metabolism is completed within microseconds, the severing of the organic phosphorus compoundâ€“enzyme bond can be prolonged.[51,154] In organic phosphorus compound poisoning, the complex becomes irreversibly bound during the next 24â€“72 hours when one of the R groups leaves the phosphate molecule. This step is termed â€œaging.â€•[142] De novo synthesis of AChE is required to replenish its supply once aging has occurred.[136,164,176]

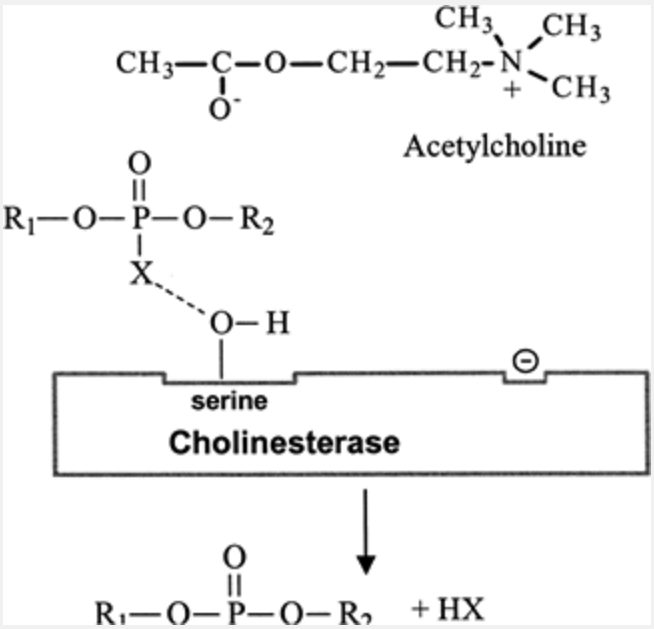


Figure 109-2. Normal metabolism of acetylcholine by acetylcholinesterase to choline and acetic acid.

Carbamates

Carbamate insecticides are *N*-methyl carbamates derived from carbamic acid (Figure 109-4). Medicinal carbamate compounds include physostigmine, pyridostigmine, and neostigmine. Medications such as meprobamate and various urethanes are carbamate derivatives, but do not inhibit cholinesterase.[164] Thiocarbamate fungicides and herbicides (eg, Maneb, Zineb, Nabam, Mancozeb) also do not inhibit AChE and do not produce the cholinergic toxidrome (Chap. 111).

When exposed to carbamate compounds, AChE undergoes carbamylation in a manner similar to phosphorylation by organic phosphorus agents, allowing ACh to accumulate in synapses.[177] Aging cannot occur and the carbamate-AChE bond hydrolyzes spontaneously, reactivating the enzyme. As such, the duration of symptoms in

carbamate poisoning is generally less than 24 hours.

Pharmacokinetics

Organic Phosphorus Compounds

Organic phosphorus insecticides are extremely well absorbed from the lungs, gastrointestinal tract, skin, mucous membranes, and conjunctiva following inhalation, ingestion, or topical contact,[51,99] unlike some xenobiotics percutaneous exposure may cause severe toxicity.[21,59,179] The presence of broken skin and dermatitis and higher environmental temperatures further enhances cutaneous absorption.[51]

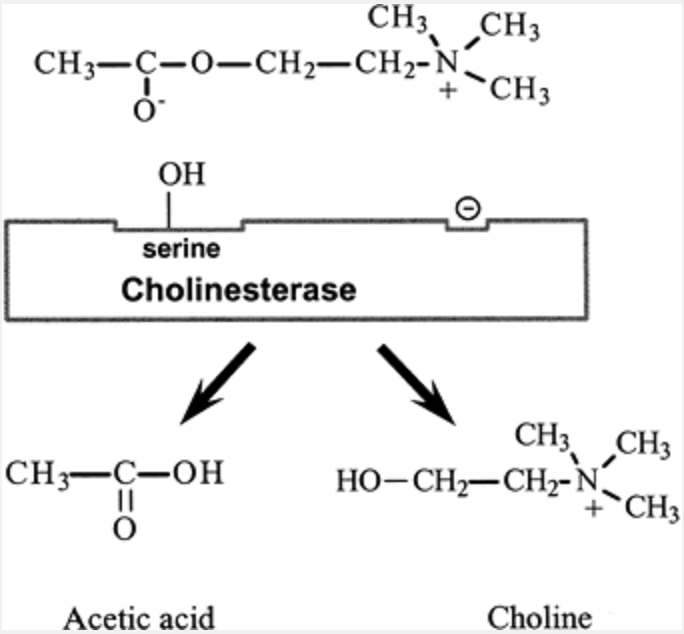

Figure 109-3. Mechanism of inhibition of acetylcholinesterase by an organic phosphorus compound. The X is the leaving group. A serine residue at the active site of the enzyme gives up a hydrogen atom to combine with the leaving group while the active site undergoes phosphorylation and inhibition. This initial inhibition is reversible with pralidoxime. However, as the inhibited

phosphorylated enzyme â€œages,â€• one of the R groups is lost. The aged phosphorylated enzyme is unable to be rejuvenated by pralidoxime.

Cholinesterase-inhibitor poisonings can be chronic or acute, although the differentiation has little clinical relevance. The difficulty in removing these compounds from the skin and clothing may explain some chronic poisonings[21] and inadequate skin and respiratory protection during pesticide application is responsible for most of the remainder.

Most organic phosphorus insecticides are lipophilic.[164] Radiolabeled parathion injected into mice distributes most rapidly into the cervical brown fat and salivary glands, with high levels also measured in the liver, kidneys, and ordinary adipose tissue.[46] Adipose tissue gradually accumulates the highest levels. Cholinergic crisis may recur in patients when unmetabolized organic phosphorus agents are mobilized from fat stores.[50,51] The more lipophilic compounds such as fenthion and chlorfenthion are particularly likely to cause this phenomenon.[173]

Peak levels of most organic phosphorus insecticides are measured around 6 hours after oral ingestion in man.[126] Although serum half-lives of these compounds range from minutes to hours,[78] prolonged absorption or redistribution from fat stores may allow for

measurement of circulating insecticide concentrations for up to 48 days.[25,52,78,140]

Figure 109-4. General structure of carbamate insecticides.

Organic phosphorus insecticides are thought to be metabolized by various mixed function oxidases in the liver and intestinal mucosa, but the exact pathways are not yet well understood.[51,87,159] The phosphorylating ability of these substances is lost when any of the side chains are hydrolyzed. Certain indirect-acting compounds are activated to a more toxic compound by this initial metabolism. Particularly lipophilic organic phosphorus compounds may be protected from metabolism by fat storage, markedly prolonging their elimination half-life.[25,51,107] Inactive metabolites of these compounds are excreted in the urine.[51]

Recently, studies have investigated possible relationships between human serum paraoxonase (PON) activity and susceptibility to acute and chronic effects of organic phosphorus poisoning.[4,22,49,155] Paraoxonase is an A-esterase that can hydrolyze the active (oxon) metabolites of some organic phosphorus insecticides. Activity differs significantly among animal species. Some animal models of organic phosphorus poisoning demonstrate protection from toxicity when exogenous PON is administered, and greater susceptibility to poisoning when enzyme-deficient animals (such as genetically engineered knockout mice) are exposed.[49,155] Some authors have postulated that

genetic polymorphisms in human PON activity may lead to variations in interindividual susceptibility to some organic phosphorus insecticides.[49]

Carbamates

Carbamate insecticides are well absorbed across skin and mucous membranes, and by inhalation and ingestion. Peak serum levels of some compounds are measured 30â€“40 minutes following ingestion.[16] Most carbamates undergo hydrolysis, hydroxylation, and conjugation in the liver and intestinal wall, with 90% excreted in the urine within 3 days.[127] There are two main pharmacokinetic characteristics that distinguish carbamates from organic phosphorus compounds. First, carbamate insecticides do not easily cross into the central nervous system.[51] CNS effects of carbamates are thus limited, although CNS dysfunction may still occur in massive poisonings or may result from hypoxia secondary to pulmonary toxicity and paralysis. Second, the carbamate-cholinesterase bond does not â€œageâ€• as in organic phosphorus compound poisoning; thus it is reversible, with spontaneous hydrolysis occurring usually within several hours.

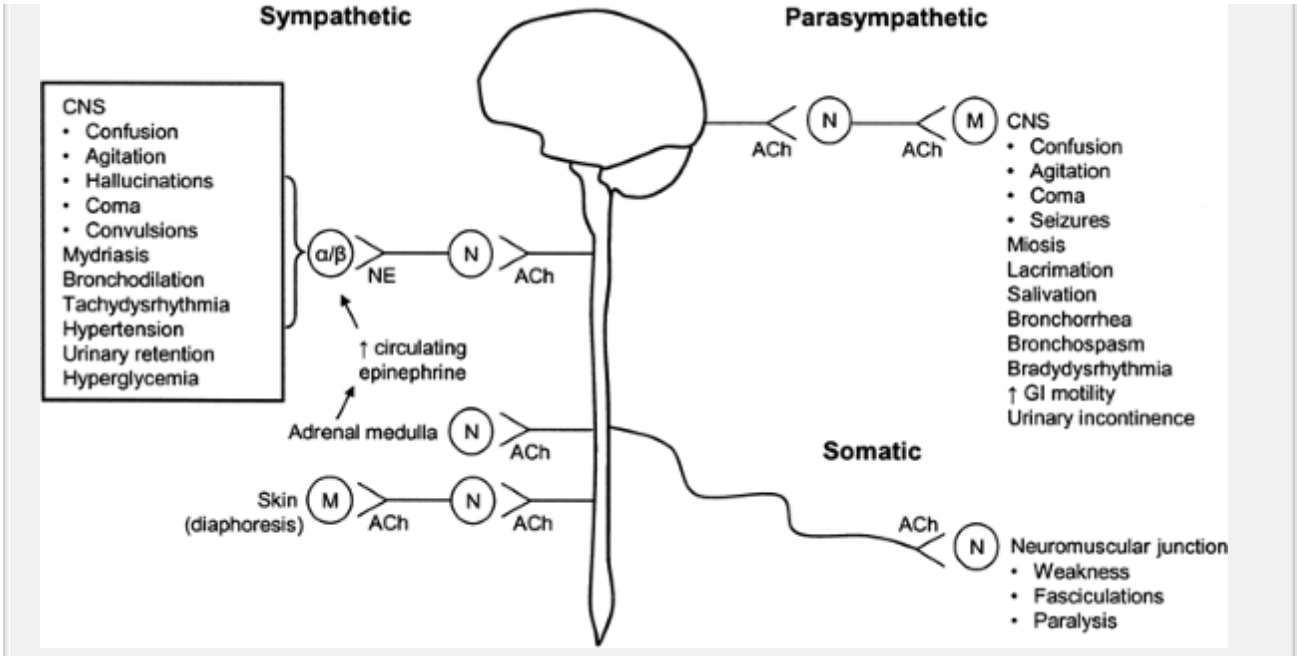

Figure 109-5. Pathophysiology of cholinergic syndrome as it affects the autonomic and somatic nervous systems.

Pathophysiology

Acetylcholine is a neurotransmitter found at both parasympathetic and sympathetic ganglia, skeletal neuromuscular junctions, terminal junctions of all postganglionic parasympathetic nerves, postganglionic sympathetic fibers to most sweat glands, and at some nerve endings within the central nervous system (Figure 109-5).[51] As the axon terminal is depolarized, vesicles containing ACh fuse with the nerve terminal, releasing ACh into the synapse or neuromuscular junction. Acetylcholine then binds postsynaptic receptors leading to activation (G proteins for muscarinic receptors and ligand-linked ion channels for the nicotinic receptors). Activation alters the flow of K^+, Na^+, and Ca^{2+} ionic currents on nerve cells, and alters membrane potential of the postsynaptic membrane, resulting in propagation of the action potential.[15]

Acetylcholinesterase (AChE) is an enzyme that hydrolyzes ACh into two inert fragments: acetic acid and choline. Under normal circumstances, virtually all ACh released by the axon is hydrolyzed almost immediately, with choline undergoing reuptake into the presynaptic terminal and used to resynthesize ACh.[51,128,164] Organic phosphorus insecticides and carbamates are inhibitors of carboxylic ester hydrolases within the body, including variably chymotrypsin, AChE, plasma or butyrylcholinesterase (pseudocholinesterase), plasma and

hepatic carboxylesterases (aliesterases), paraoxonases (A-esterases), and other nonspecific proteases. Acetylcholinesterase is found in human nervous tissue and skeletal muscle, and on erythrocyte (RBC) cell membranes. RBC cholinesterase activity levels correlate best with the function of nervous system AChE. Butyrylcholinesterase is a hepatic-derived protein that is found in human plasma, liver, heart, pancreas, and brain. Although the function of this enzyme is not well understood, its activity can be easily measured and has important clinical implications in anesthesia (Chap. 66).

Clinical Manifestations

Acute Toxicityâ€”Organic Phosphorus Compounds

Clinical findings of toxicity from these compounds derive from excessive stimulation of muscarinic and nicotinic cholinergic receptors by ACh in the central and autonomic nervous systems, and at skeletal neuromuscular junctions (Figure 109-5). Although the classically described patient with organic phosphorus insecticide poisoning is one who is unresponsive with pinpoint pupils, muscle fasciculations, diaphoresis, emesis, diarrhea, salivation, lacrimation, urinary incontinence, and an odor of garlic or solvents, most presentations are not so typical. The onset of symptoms varies according to the compound, the route, and the degree of exposure. Patients suffering

massive ingestions can become symptomatic as quickly as 5 minutes following ingestion, and deaths have occurred within 15 minutes of ingestion.[51,95] Most victims of acute poisonings become symptomatic within 8 hours of exposure, and nearly all are symptomatic within 24 hours.[118] The longest delays may occur with compounds requiring metabolic activation, such as malathion, or very lipid-soluble agents such as fenthion. Symptoms may last for variable lengths of time, again based on the agent and the circumstances of the exposure. For example, the more lipophilic compounds, such as dichlofenthion, can cause cholinergic effects for several days following oral ingestion.[25]

A variety of CNS findings are reported after exposure. Many patients present awake and alert, complaining of anxiety, restlessness, insomnia, headache, dizziness, blurred vision, depression, tremors, or other nonspecific symptoms.[118] The level of consciousness may deteriorate rapidly to confusion, lethargy, and coma, and patients may display inappropriate behavior or convulsions.[118]

The effects of excessive ACh on the autonomic nervous system may be variable because cholinergic receptors are found in both the sympathetic and parasympathetic nervous systems (Figure 109-5). Excessive muscarinic activity can be characterized by several mnemonics, including â€œSLUDâ€• (salivation, lacrimation, urination, defecation) and â€œDUMBBELSâ€• (defecation, urination, miosis, bronchospasm or bronchorrhea, emesis, lacrimation, salivation). Of these, miosis may be the most consistently encountered sign. Bronchorrhea can be so profuse that it mimics pulmonary edema.[118]

Although muscarinic findings are emphasized in these mnemonics, muscarinic signs usually are not clinically dramatic or initially predominant, except in very severe poisonings. In many cases, parasympathetic findings are offset by excessive autonomic activity from stimulation of nicotinic adrenal receptors (resulting in catecholamine release) and postganglionic sympathetic fibers.[164] Mydriasis is reported in as many as 13% of cases, presumably from nicotinic stimulation of sympathetic receptors.[43] Bronchodilation and

urinary retention can occur as a result of sympathetic activity on smooth muscle.[164] Excessive adrenergic influences on metabolism cause glycogenolysis with hyperglycemia and ketosis that are occasionally mistaken for diabetic ketoacidosis.[106] Hypoglycemia can also occur, although the mechanism is unclear.[72] Increased sympathetic activity usually precipitates white blood cell demargination, resulting in leukocytosis.[118] Hyperamylasemia is occasionally reported in cases of severe organic phosphorus pesticide poisoning, and although pancreatitis may result from spasm of the sphincter of Oddi,[101] hyperamylasemia is most often the result of salivary gland stimulation and not the result of pancreatic dysfunction.[93] Elevations of hepatic enzymes can also occur following organic phosphorus pesticide exposures.[51,131]

The cardiovascular manifestations also reflect mixed effects on the autonomic nervous system.[98] Increased sympathetic tone is often initially present, and most patients manifest a sinus tachycardia,[98,118] and sometimes hypertension. As toxicity becomes more severe, bradycardia with a prolonged PR interval and atrioventricular blocks of various degrees occur because of excessive parasympathetic tone, and possibly because of reduced coronary blood flow.[86,98,118] Unequal sympathetic stimulation of myocardial cells, and interactions with potassium channels and the Na^{+}/Ca^{++} exchanger in the myocardial cell membrane are probably responsible for the occasional prolonged QTc interval.[2,98,114,123] This prolongation in QTc interval can be associated with polymorphic ventricular tachycardia (torsades de pointes).[83,98,123,171] Finally, hypotension may occur because of stimulation of vascular receptors by excessive circulating ACh.

The most common pulmonary complications of these compounds are bronchorrhea and bronchoconstriction. Additionally, because liquid preparations are usually dissolved in a hydrocarbon aspiration frequently results following ingestion in severe poisoning and can lead to hydrocarbon pneumonitis.[123] Respiratory depression is common, and is in part centrally mediated.[118]

Acetylcholine stimulation of nicotinic receptors also governs skeletal muscle activity. The effects of excessive cholinergic stimulation at these sites are similar to that of a depolarizing neuromuscular blocker agent (succinylcholine) initially resulting in fasciculations or weakness. This effect is considered by some to be the most reliable sign of toxicity.[119] Cranial nerve abnormalities are uncommon. As the severity of poisoning progresses, paralysis ensues. Paralysis of the respiratory muscles in combination with bronchorrhea, bronchoconstriction, and CNS depression leads to hypoxemia and respiratory arrest, the most common cause of death.[118,162] Rarely, patients may present only with paralysis from nicotinic effects without any other initial signs and symptoms suggestive of organic phosphorus compound toxicity.[45,54] This is more common with nerve agent weapons of mass destruction. Extrapyramidal effects such as rigidity and choreoathetosis occur uncommonly after severe anticholinesterase poisoning but can persist for several days after cholinergic features have resolved.[11,76]

Acute Toxicityâ€”Carbamates

The effects of poisoning from carbamate insecticides appear identical to those of organic phosphorus insecticides except for the relative inability of the carbamate to penetrate the CNS and the rapid hydroxylation of the carbamate-AChE bond. However, as noted previously, CNS abnormalities may occur in victims of severe carbamate poisonings, especially aldicarb.[166] Some of these CNS effects may result from hypoxia caused by respiratory insufficiency or severe bronchorrhea.

Chronic Toxicity

Illness may also result from chronic exposure to excessive amounts of organic phosphorus insecticides. Chronic exposure most commonly occurs in workers who have regular contact with these compounds, but may also occur in individuals who have repeated contact with excessive

amounts of insecticides in their living environments. Cholinergic ophthalmic preparations can also lead to toxicity in this manner.[100] Although tolerance to acute cholinergic systemic effects of organic phosphorus insecticides (including death in rats) may be observed with long-term exposures,[51] persons who have such repeated contact may begin to describe symptoms after substantial lengths of time. These effects can range from vague neurologic complaints, such as weakness and blurred vision, to miosis, nausea, vomiting, diarrhea, diaphoresis, and other cholinergic effects.[100,109,135,156] Much of the literature on this topic is retrospective. Red blood cell cholinesterase activity is the most sensitive measure of exposure, and workers in contact with these chemicals should have baseline cholinesterase testing for comparison and monitoring.[51,68]

Recent literature has linked Parkinson disease with chronic exposure to pesticides including organic phosphorus insecticides.[11,157] The structures of some pesticides are similar to that of known neurotoxins like 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Some individuals may have a possible genetic susceptibility. Additionally, significant acute exposures to organic phosphorus insecticides can lead to self-limited movement disorders resembling Parkinson that resolve over weeks to months.[11,115] Although statistics derived from some epidemiologic studies suggest the connection,[41,63] others studies have failed to a find an association between organic phosphorus compounds and Parkinsonism.[163]

Delayed Syndromes

Intermediate Syndrome

Delayed muscle weakness often without fasciculations or cholinergic features can occur 24â€“96 hours after acute organic phosphorus compound poisoning.[62,78,129,137,146,158] This phenomenon was first described in 1987, and is termed the â€œintermediate syndromeâ€• because it occurred in between the periods of acute and delayed

toxicity.[146] The majority of reported cases of intermediate syndrome presented initially with cholinergic signs and symptoms that improved with atropine and oxime therapy over the first 1â€“2 days after exposure. Relapse with peripheral neurologic impairment developed about 48 hours after presentation. Intermediate syndrome occurs more often in patients poisoned with parathion, methyl parathion, diazinon, malathion, fenthion, monocrotophos, dimethoate, and methamidophos.[62,146] Redistribution of these lipophilic pesticides and their metabolites from adipose tissue may be responsible,[27,28,29,30,31 and 32,50,148,158] and the syndrome may resolve when the body burden of these metabolites diminish and cholinesterase levels normalize. There is growing speculation that intermediate syndrome may result from inadequate oxime therapy,[26,27,29] although more recent case reports question this theory.[82,158] One recent study suggested that the occurrence of intermediate syndrome strongly correlated with the initial degree of cholinergic crisis, and seemed to be a continuum with the neuromuscular paralysis resulting from the early stages of poisoning.[73] The authors and others propose that muscle injury during early cholinergic crisis may progress to intermediate syndrome.[73,181]

The most frequently encountered clinical findings of intermediate syndrome include upper body weakness, cranial nerve palsies, and areflexia. Fasciculations occur rarely. Level of consciousness is rarely affected. The muscle weakness in these patients can progress to respiratory distress and paralysis.[62,129,137,146] The most commonly affected muscles are the facial, extraocular, palatal, respiratory, and proximal limb muscles.[62,137,146]

Clinical examination remains the most reliable means of identifying the occurrence of intermediate syndrome.[21] Electromyograms will often show tetanic fade in these patients, and suggest both pre- and postsynaptic involvement.[78] However, repetitive nerve stimulation may not always accurately predict the occurrence or severity of intermediate syndrome, but may be beneficial in determining the need for mechanical ventilation.[29]

The treatment of intermediate syndrome is largely supportive with airway protection and ventilatory assistance. There are no substantial data demonstrating that pralidoxime or atropine is effective in the treatment of this disorder, although patients may require these medications to control the cholinergic symptoms resulting from persistent effects at nicotinic receptors on motor nerves proximal to the neuromuscular junction. However, because some reports correlating pralidoxime dose and intermediate syndrome suggest that insufficient dosing may play a part we therefore recommend reinstituting pralidoxime infusion at 500 mg/h when intermediate syndrome is suspected. The weakness and paralysis commonly resolve in 5â€“18 days.[14,62,73,78]

Encephalopathy and Peripheral Neuropathies

Peripheral neuropathies can occur either with chronic organic phosphorus pesticide exposures or days to weeks following acute exposures. This disorder appears to result from inhibition of an enzyme within nervous tissue named neurotoxic esterase or neuropathy target esterase.[74,78] Symptoms seem to be initiated by the phosphorylation of this enzyme, or perhaps of some related compound, followed by aging of the complex.[182] Such neuropathies may even result from exposure to organic phosphorus compounds that do not inhibit red blood cell cholinesterase or produce clinical cholinergic toxicity.[17] The more commonly implicated chemicals include triaryl phosphates, such as triorthocresyl phosphate (TOCP), and dialkyl phosphates, such as mephosfolan, mipafox, and chlorpyrifos.[75,105,118] Pathologic findings demonstrate effects primarily on large distal neurons, with axonal degeneration preceding demyelination.[117]

Contaminated foods and beverages were responsible for epidemics of organic phosphorus compoundâ€“induced delayed polyneuropathies and encephalopathy. In the 1930s, thousands of individuals in the United States became weak or paralyzed after drinking a supplement containing TOCP an outbreak nicknamed â€œGinger Jake

paralysis.â€• [5,108,112,113] Contaminated cooking and mineral oils were responsible for outbreaks of delayed polyneuropathies in Vietnam and Sri Lanka.[34,144,145] Vague distal muscle weakness and pain are often the presenting symptoms and may progress to paralysis.[45,58] The administration of atropine or pralidoxime may not alter the onset and clinical course of these symptoms.[45,118,170] Pyramidal tract signs can appear weeks to months after acute exposures.[78,170] Electromyograms and nerve conduction studies may be helpful in diagnosing this disorder by identifying the type of neuropathy (such as axonopathy, myelinopathy or transmission neuropathy) and differentiating it from similar presentations such as Guillain-BarrÃ© syndrome.[1,148] Recovery of these patients is variable and occurs over months to years, with residual deficits common.[8,113,147]

Delayed neuropathies are not usually associated with carbamate insecticides. One reason for this difference is presumed to be that

aging of the neuropathy target esterase pesticide complex is a requirement for neuronal degeneration. Paradoxically, studies suggest that subgroups of carbamates may actually bind neuropathy target esterase and exert a protective effect against more toxic organic phosphorus compounds.[3] However, several cases of possible delayed neuropathy associated with carbamates are reported.[35,169,182] These cases involve ingestions of carbaryl, *m*-tolyl methyl carbamate, and carbo furan, include both sensory and motor tracts, and tend to resolve over 3â€“9 months. EMG findings in these subjects are variable.

Behavioral Toxicity

Behavioral changes may also occur after acute and chronic exposure to organic phosphorus compounds.[78] Signs and symptoms include confusion, psychosis, anxiety, drowsiness, depression, fatigue, and irritability.[51,107,143,161] Electroencephalographic changes may be noted and can last for weeks.[51,57,68] Single photon emission computed

tomography (SPECT) scanning revealed morphologic changes in the basal ganglia of one child following poisoning.[13] Although no specific treatment is effective, most psychological abnormalities resolve within a year.[53] Behavioral toxicity following carbamate exposure is extremely rare.

Diagnostic Testing

Organic Phosphorus Compounds

When confronted with a patient in cholinergic crisis who presents with a history of acute excessive exposure to an organic phosphorus cholinesterase inhibitor insecticide, the diagnosis is frequently straightforward. However, when the history is unreliable or does not suggest poisoning, the physician must turn to other means to confirm the diagnosis of organic phosphorus or carbamate insecticide poisoning.

The most reliable and appropriate laboratory test for confirming cholinesterase inhibition by insecticides is a test that measures specific insecticides and active metabolites in biologic tissues. Unfortunately, although urine and serum assays for organic phosphorus compounds and their metabolites are being investigated,[7,60,88,122] such testing is rarely obtainable within a few minutes or hours. Moreover â€œnormalâ€• ranges and toxic levels are not established for most compounds. Another useful research tool is the measurement of AChE activity in neuronal tissue, but this requires CNS or neuronal tissue biopsies and, even then this test is not very helpful unless the baseline activity is known. Currently, the only practical diagnostic study for verifying cholinesterase inhibitor poisoning is a measurement of cholinesterase activity in readily accessible tissue, such as the plasma and erythrocytes.[51,118]

Butyrylcholinesterase (plasma cholinesterase) is able to metabolize various xenobiotics, including succinylcholine and cocaine.

Erythrocytes contain a form of AchE that is structurally similar to the enzyme found in neuronal tissue.[20] Inhibition of either red blood cell cholinesterase or butyrylcholinesterase only serves as markers for cholinesterase inhibitor poisoning, as inhibition of these enzymes do not contribute to signs and symptoms of poisoning.

There is tremendous interindividual and interchemical variability in the degree and duration with which the organic phosphorus insecticides affect various cholinesterases. After a significant exposure, butyrylcholinesterase activity usually falls first, followed rapidly by a decrease in red blood cell cholinesterase activity. The sequence may be highly variable, but by the time patients present with acute symptoms, levels of both cholinesterase activities have usually fallen well below baseline values, and often have fallen below detectable limits.[118]

Butyrylcholinesterase activity usually recovers before red blood cell cholinesterase activity often returning to normal within a few days in the absence of a repeat exposure to the inciting agent.[23] However, butyrylcholinesterase activity is less specific for exposure than is red cell cholinesterase activity.[51] Low butyrylcholinesterase activity can be found in patients with a number of disorders, including hereditary deficiency of the enzyme, malnutrition, hepatic parenchymal disease, chronic debilitating illnesses, and iron deficiency anemia.[51,125] Additionally, day-to-day variation in the activity of this enzyme in healthy individuals may be as high as 20%.[51]

Red blood cell cholinesterase activity is thought to more accurately reflect nervous tissue AChE activity than does butyrylcholinesterase because the AChE in red blood cells is true AChE. Some authors suggest that clinical organic phosphorus pesticide poisoning occurs when red blood cell cholinesterase activity falls to below 50% of baseline values.[111,118] Although these statements are generally true, there are several potential pitfalls in interpreting cholinesterase laboratory values. First, it is AChE inhibition in nervous tissue that causes toxicity, and red blood cell and butyrylcholinesterase activity

may not always reflect neuronal enzyme activity. Organic phosphorus insecticides vary in their ability to inhibit butyrylcholinesterase or red blood cell cholinesterase. Because these tests are only markers of neuronal enzyme inhibition, this variation may lead to some patients presenting highly symptomatic after minimal reductions in red blood cell or butyrylcholinesterase, although others can be asymptomatic after losing 50% activity.[23,67,110] The wide normal range of red blood cell and butyrylcholinesterase activity also allows for patients with high normal values to suffer significant falls in cholinesterase activity, yet still register near normal levels of cholinesterase activity on laboratory assay.[23,67,110]

Red blood cell cholinesterase regenerates more slowly than AChE found in neurons.[118] To completely replenish the RBC AChE supply, the red blood cells in circulation at the time of the organic phosphorus insecticides exposure must be replaced, or pralidoxime administered. An average of 66 days may be necessary for red blood cell cholinesterase activity to recover following severe inhibition[23] (assuming no treatment with pralidoxime), and activity may take up to 120 days to return to normal. The patient may have completely recovered neuronal activity of AChE and resolved all cholinergic symptoms, yet still have low red blood cell cholinesterase laboratory values. For this reason, in subacute poisoning with organic phosphorus agents, it is difficult to accurately predict the actual time of onset or duration of exposure when only the red blood cell cholinesterase activity is known. In fact, the ability of red blood cell cholinesterase activity to serve as a historical marker for excessive exposure to organic phosphorus insecticides provides the basis for monitoring red blood cell cholinesterase activity in pesticide workers.[24,33,91,133]

Depressed red blood cell cholinesterase activity may be the result of exposures or conditions other than insecticide poisoning, such as in therapy with antimalarial agents such as chloroquine and pernicious anemia. Genetic and circadian variations are also common, with daily fluctuations within the same individual as high as 10%.[180] Additionally, levels are normally slightly lower in children younger than 4 months of

age, probably increasing as hepatic function matures.[81] Oral contraceptives raise red blood cell cholinesterase activity.

TABLE 109-2. Interpreting Cholinesterase Values

	Red Blood Cell Cholinesterase	Butyrylcholinesterase
Advantage	Better reflection of synaptic inhibition	Easier to assay, declines faster
Site	RBC (reflects CNS gray matter, motor end plate)	CNS white matter, plasma, liver, pancreas, heart
Regeneration (untreated)	1%/day	25â€“30% in first 7â€“10 day
Normalization (untreated)	35â€–49 day	28â€–42 day
Use	Unsuspected prior exposure with normal plasma cholinesterase	Acute exposure
False depression	Pernicious anemia, hemoglobinopathies, antimalarial treatment, oxalate blood tubes	Liver dysfunction, malnutrition, hypersensitivity reactions, drugs (succinylcholine,

		codeine, morphine), pregnancy, genetic deficiency

The most important aspect to consider when interpreting the cholinesterase activity as reported by a laboratory is how it compares with baseline values in that individual (Table 109-2). Because baseline values are usually unavailable in most cases, laboratories report out a â€œreference rangeâ€• of activity. This range is based on the central 95% of values of cholinesterase activity for the general population.

Blood samples for cholinesterase activity must be obtained in the appropriate blood tubes. Tubes containing fluoride will permanently inactivate the enzyme, yielding falsely low activity levels, and should not be used. Specimens for red blood cell cholinesterase are usually drawn into tubes containing a chelating anticoagulant such as ethylenediaminetetraacetic acid (EDTA) to prevent clot formation. Butyrylcholinesterase does not require an anticoagulant and can be drawn into a tube without chelators or anticoagulants. Because laboratory color coding systems for blood tubes vary, laboratory personnel should be contacted to determine the appropriate venipuncture container.

Carbamates

Carbamates inhibit neuronal and red blood cell AChE, and butyrylcholinesterase. The relative ease with which spontaneous decarbamylation of cholinesterase takes place may result in the measurement of relatively normal red cell cholinesterase activity despite severe cholinergic symptoms if the assay is not performed within several hours of sampling.[39,124] As in the case with organic phosphorus pesticide poisoning, the wide â€œnormalâ€• range of cholinesterase values may make interpretation of cholinesterase

activity difficult at times when the patient's baseline values are unknown. Unlike organic phosphorus insecticides, carbamates generally do not produce persistent depressed red blood cell and butyrylcholinesterase activities.

Atropine Challenge

An atropine sulfate challenge may be helpful in diagnosing cholinergic poisoning in a patient who presents with findings suggestive of this disorder, but in whom no history is available to suggest excessive exposure to an organic phosphorus or carbamate insecticide. In an individual not exposed to significant amounts of insecticide a test dose of 1â€“5 mg of atropine in adolescents or adults, or 0.05 mg/kg in children up to an adult dose, should produce classic antimuscarinic findings such as mydriasis, tachycardia, and dry mucous membranes. Conversely, the persistence of cholinergic signs and symptoms after an atropine challenge strongly suggests the presence of organic phosphorus compound or carbamate poisoning.[118] However, some patients suffering from mild-to-moderate anticholinesterase poisoning may respond to these doses of atropine. Therefore, the reversal of cholinergic findings does not exclude poisoning by one of these compounds.

Electromyogram (EMG) Studies

Although measuring cholinesterase levels is the test most often used to estimate tissue and neuronal AChE activity, studies support the use of repetitive nerve stimulation testing as an accurate method of quantifying AChE inhibition at the neuromuscular junction.[9,10,27] Spontaneous repetitive potentials or fasciculations following single-nerve stimulation resulting from persistent ACh at nerve terminals can be a sensitive indicator of AChE inhibition at the motor endplate, and may be useful in the early diagnosis of anticholinesterase poisoning.[10] This type of evaluation may also be of benefit in early detection of rebound cholinergic crisis caused by continued insecticide absorption

or redistribution from adipose, or onset of an intermediate syndrome.[9,27]

Differential Diagnosis

The differential diagnosis for cholinergic poisoning includes 3 main categories (Table 109-3). The first comprises insecticides and other noninsecticidal cholinesterase inhibitors including the medicinal anticholinesterases neostigmine, pyridostigmine, physostigmine, and echothiophate iodide. The most common patients to suffer cholinergic

poisoning syndrome from medicinal cholinesterase inhibitors are patients with myasthenia gravis who are given excessive doses of pyridostigmine. This entire group of xenobiotics should produce low butyrylcholinesterase and low red blood cell AChE activity. Newer agents used to treat Alzheimer disease, such as tacrine, may inhibit ACh, but symptomatic overdose of these agents has not yet been reported.

TABLE 109-3. Categories of Cholinergic Poisoning

Cholinesterase inhibitors
Organic phosphorus insecticides
Organic phosphorus ophthalmic medications
Carbamate insecticides
Carbamate medicinals
Cholinomimetics
Pilocarpine
Carbachol
Aceclidine
Methacholine
Bethanechol
Muscarine-containing mushrooms

Nicotine alkaloids
Coniine
Lobeline
Nicotine

The second category of compounds that produce a syndrome of cholinergic poisoning include agents with cholinomimetic activity. These compounds directly stimulate muscarinic or nicotinic cholinergic receptors, but do not inhibit AChE. In individuals exposed to these compounds butyrylcholinesterase and red blood cell cholinesterase activity should be normal. Cholinomimetic medications include preparations of carbachol, methacholine, pilocarpine, and bethanechol. Non pharmaceutical agents such as muscarine-containing mushrooms can be cholinomimetic (Chap. 113). Finally, a third group of xenobiotics nicotine alkaloids (eg, nicotine, lobeline, and coniine) cause CNS, autonomic, and skeletal muscle symptoms similar to those occurring in organic phosphorus and carbamate toxicity (Chap. 82).

Management

Organic Phosphorus Insecticides

The first cause of death results from respiratory failure and hypoxemia that may result from coma and convulsions, nicotinic effects on skeletal muscles, (weakness and paralysis) and muscarinic effects on the cardiovascular and pulmonary system (bronchospasm, bronchorrhea, aspiration, bradydysrhythmias, or hypotension.) Therefore initial treatment for a patient exposed to organic phosphorus compounds is directed at ensuring an adequate airway and ventilation, and at reversing excessive muscarinic effects. Seizures not secondary to hypoxemia are treated with standard anticonvulsants such as benzodiazepines or barbiturates.

Maintenance of the patient's airway is best assured by early

endotracheal intubation and positive pressure ventilation in patients who are comatose, have significant weakness, or who are unable to handle copious secretions that may accompany the poisoning. Only a neuromuscular blocking agent that is not primarily metabolized by cholinesterases should be used to induce pharmacologic paralysis. The duration of action of the depolarizing agent succinylcholine and the nondepolarizing agent mivacurium, for example, will be extended in the presence of low butyrylcholinesterase activity, resulting in paralysis that can be prolonged up to 24 hours or more.[143,149]

The second management priority is to control excessive muscarinic activity. Atropine sulfate competitively antagonizes ACh at muscarinic receptors to reverse excessive secretions, miosis, bronchospasm, vomiting, diarrhea, diaphoresis, and urinary incontinence.[14,78,118] For adolescents and adults, intravenous doses should begin with boluses of 1â€“5 mg and for children at 0.05 mg/kg up to adult doses depending on the severity of symptoms. Many authors state that repeat doses of 1â€“2 mg should be given every 2â€“3 minutes or more rapidly until atropinization occurs.[51,118,183] We suggest that during the initial resuscitation the dose of atropine should be doubled on each subsequent administration until symptoms such as bronchorrhea are under control. â€œAtropinizationâ€• has been accomplished when the patient exhibits dry skin and mucous membranes, decreased or absent bowel sounds, tachycardia, reduced secretions, no bronchospasm (in absence of other causes such as aspiration), and usually, mydriasis. An improvement in pulmonary secretions is the most important target in atropine therapy and can be guided by following lung sounds and oxygenation. Tachycardia is not a contraindication to atropine therapy. Although the pupils are often helpful in gauging the need for atropine, the miosis encountered in severe ingestions and by direct ocular exposure to organic phosphorus insecticides may respond only to topical ophthalmic atropine.[139] Conversely, a positive pupillary response alone should not be used to discontinue further therapy. Isolated pulmonary manifestations may respond to administration of nebulized atropine or ipratropium, and this treatment can accompany

parenteral administration of these medications.

Large doses of atropine may be needed to reverse the bronchospasm, bronchorrhea, bradycardia, and heart block associated with severe organic phosphorus pesticide toxicity.[51,59,61,99,119] Some patients with mild symptoms need only 1 or 2 mg of atropine to reverse cholinergic toxicity, but the moderately poisoned adolescent or adult commonly requires total doses as large as 40 mg.[38,76] Severe poisonings may necessitate even higher doses. Some adults have received over 1000 mg of atropine in 24 hours (with adequate pralidoxime dosing) without demonstrating antimuscarinic effects,[38,172] and total doses as high as 11,000 mg during the course of treatment have been reported.[71] Children have been managed with continuous infusions of atropine starting at 0.025 mg/kg/h,[13,92,123] and adult infusions of atropine can begin at 0.5â€“1 mg/h and titrated as needed. Continuous infusions have been used for as long as 32 days in severely poisoned patients.[52]

Atropine does not reverse nicotinic effects. Therefore, the patient who improves after receiving atropine must still be closely monitored in an intensive care setting for impending respiratory failure.

When antimuscarinic CNS toxicity becomes evident, yet peripheral cholinergic findings necessitate the administration of more atropine (eg, bradycardia, bronchorrhea, vomiting), glycopyrrolate bromide can be substituted for atropine because its quaternary ammonium structure limits CNS penetration.[134] The initial intravenous dose of glycopyrrolate for adults and adolescents is 1â€“2 mg, repeated as needed or in children 0.025 mg/kg up to adult doses. As with atropine, much higher doses of glycopyrrolate may be required to stabilize patients with severe poisonings. Although scopolamine has also been used in place of atropine,[134] it may cause more pronounced CNS effects. A urinary catheter should be inserted in all atropinized patients to prevent urinary retention. If atropine supplies are exhausted during therapy, other antimuscarinic agents like diphenhydramine may be used.

Pralidoxime

Although phosphorylated AChE undergoes hydrolytic regeneration at a very slow rate, this process can be markedly enhanced by using an oxime such as pralidoxime hydrochloride (2-PAM) (Fig. 109-6).[175] In addition to rejuvenating AChE, pralidoxime may also reverse toxicity by directly inactivating free organic phosphorus molecules and by exhibiting an apparent antimuscarinic effect on nervous tissue.[51,85] Regeneration of AChE lowers ACh concentrations to normal levels, reversing both muscarinic and nicotinic effects. An immediate rise in red blood cell cholinesterase activity, presumably paralleling a rise in neuronal AChE activity, is often noted after the administration of pralidoxime.

Most phosphorylated AChE will presumably be aged within 24â€“48 hours of exposure.[51,164] Pralidoxime is unable to rejuvenate active enzyme from the organic phosphorus compoundâ€“AChE complex that has undergone aging.[38,66] Therefore, pralidoxime therapy is

most effective if started early in the course of toxicity.[37,142,158] The actual rate of aging however, varies significantly among organic phosphorus insecticides. Additionally, circulating organic phosphorus pesticide concentrations have been measured for as long as 48 days after exposure,[25,52] either because of prolonged absorption from the GI tract or, more likely, because of redistribution from fat stores.[13,38,51,52,118] Therefore, some AChE may still be undergoing new inhibition for days or weeks after exposure in symptomatic patients, and such inhibition may be reversible by pralidoxime.[173] Case reports support this reasoning by noting dramatic effects in reversing paralysis, weakness, and cholinergic symptoms even after late administration of pralidoxime.[26,27 and 28,30,107,118,121]

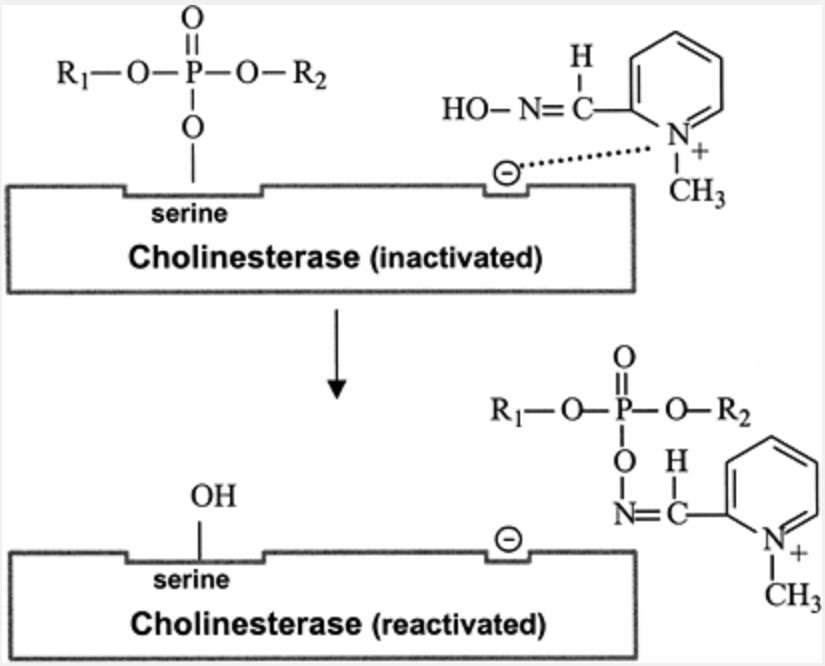

Figure 109-6. Mechanism of reactivation of acetylcholinesterase by pralidoxime. The positively charged aromatic nitrogen of pralidoxime is â€œattractedâ€• to the anionic site of acetylcholinesterase, allowing the reactive oxime portion of the molecule to position itself over the phosphorylated active site of the enzyme. Pralidoxime then becomes phosphorylated, reactivating acetylcholinesterase.

The initial dose of pralidoxime for adolescents and adults is 1â€“2 g intravenously over 10â€“15 minutes and for children 20â€“40 mg/kg IV up to adult doses over 10â€“15 minutes.[78,141] Although minimal serum concentrations of 4 Âµg/mL are estimated to be necessary for maintenance of enzyme reactivation,[158,160] the degree of reactivation may be dependent on the specific identity and concentrations of both oxime and organic phosphorus compound.[173] Bolus dosing of pralidoxime every 4â€“8 hours is ineffective in maintaining these levels,[104] and therefore a constant infusion appears to be more

appropriate. Present recommendations for adults are to begin the maintenance infusion at 250â€“500 mg/h, titrating to symptoms.[78] Alternative dosing by weight reported in other studies suggests using 4â€“5 mg/kg as a loading dose over 15â€“30 minutes, followed by a continuous infusion of 2â€“4 mg/kg/h to maintain serum concentrations.[104,174] WHO-sponsored recommendations note that pralidoxime infusions of up to 8 mg/kg/h or more may be required in some cases.[40] Based on these data, it seems prudent in adults requiring pralidoxime to administer an initial IV loading dose of 1â€“2 g over 15 minutes, and then begin an IV infusion at 500 mg/h. Pharmacokinetics of pralidoxime in children are extremely variable and different from adults.[141] Reports suggest that loading doses for children should be 20â€“40 mg/kg of pralidoxime intravenously over 15â€“30 minutes (up to adult bolus doses), followed by a continuous infusion of 10â€–20 mg/kg/h. This regimen is effective in treating symptoms associated with organic phosphorus pesticide poisoning and does not result in pralidoxime-associated toxicity.[44,141] Of interest, recent research in animals suggests that oral dosing of pralidoxime and atropine (obviously not practical in the majority of severe intoxications) may also improve survival.[14]

Side effects of pralidoxime are usually minimal at normal doses.[56,120] Severely poisoned patients have received 500 mg/h for weeks without adverse effects.[52,118] Rapid infusion can cause mild cholinergic effects because of transient blockade of AChE[118] and has resulted in neuromuscular blockade and central respiratory depression.[78,164] Occasional visual complaints are also reported in patients receiving pralidoxime.

Some effects of pralidoxime are not well understood. The quaternary ammonium compound structure of pralidoxime largely prevents it from crossing the bloodâ€“brain barrier.[105] However, case reports of organic phosphorus compound toxicity describe pralidoxime-induced reversal of convulsions and improvements in mental status and electroencephalograms not attributable to improved ventilation or perfusion.[42,48,64,65,80,96,97,125] These findings could also result from a

neuroprotective effect of antimuscarinic agents.[12,168]

Pralidoxime is not equally effective in reversing cholinergic symptoms in all types of organic phosphorus compound poisonings.[78,118] It is particularly effective in reversing toxicity from parathion, diazinon, methyl parathion, TEPP, dimethoate, and dichlorvos but[51] dimethoxy compounds, such as malathion and methyl demeton, may be more resistant to reversal.[51]

Diazepam

Diazepam may improve survival in victims of severe organic phosphorus pesticide poisoning. Animal studies demonstrate that administering diazepam along with oximes in the treatment of organic phosphorus nerve agents (sarin, soman, tabun, VX) or dichlorvos can increase survival and decrease the incidence of seizures and neuropathy.[36,85,90,97,116,138] Diazepam can also decrease cerebral morphologic damage resulting from organic phosphorus compoundâ€“related seizures.[103,152] One study also suggests that diazepam may help attenuate organic phosphorus-induced respiratory depression,[36] postulating that the benzodiazepines may attenuate the overstimulation of central respiratory centers caused by organic phosphorus insecticides.

Decontamination

Rapid and continuous cutaneous absorption of organic phosphorus pesticides and carbamates necessitates removal of all clothing as soon as possible. Medical personnel should avoid self-contamination by wearing neoprene or nitrile gloves. Double-gloving with standard vinyl gloves may be protective for short intervals. Skin should be triple-washed with water, soap, and water, and rinsed again with water. Although alcohol-based soaps are sometimes recommended to dissolve hydrocarbons,[47] these products can be difficult to find, and expeditious skin cleansing should be the primary goal. Cutaneous absorption can

also result from contact with organic phosphorus and carbamate compounds in vomitus and diarrhea if the initial exposure was by ingestion. Oily insecticides may be difficult to remove from thick or long hair, even with repeated shampooing, and shaving scalp hair may be necessary. Exposed leather clothing or products should be discarded because decontamination is very difficult once impregnation has occurred.

Military institutions are now experimenting with cholinesterase sponges for cutaneous organic phosphorus decontamination.[55] The sponge consists of a cholinesterase enzyme covalently linked and immobilized in a polyurethane matrix. The sponge reportedly is effectively in removing organic phosphorus compounds from skin and surfaces.[55]

In acute ingestions, if emesis has not occurred, evacuation of stomach contents by lavage is recommended. Because the onset of coma, seizures, and paralysis can be rapid, airway protection may be necessary to perform the procedure safely. Although there are data suggesting that AC may adsorb some organic phosphorus insecticides, there are no studies evaluating whether repeat administration of AC changes the outcome or clinical course of these patients and also ileus may develop during atropine therapy. Thus, the present recommendation is that patients with anticholinesterase poisoning receive a single dose of 1 g/kg AC. Healthcare providers must always maintain caution when coming into contact with stomach contents or other body fluids when managing these cases. Individuals have been poisoned by providing mouth-to-mouth resuscitation to a victim of an intentional ingestion of diazinon.[84]

Disposition

Even after atropinization, patients with cholinesterase inhibitor poisoning should be continuously observed for evidence of deteriorating neurologic function and potential paralysis. Patients commonly develop confusion and agitation following large doses of

atropine as a consequence of the central antimuscarinic effects.

Red blood cell cholinesterase and butyrylcholinesterase activities should be measured intermittently after the institution of pralidoxime therapy.[6,77,90,151,173,178] In most case, checking enzyme activity every 12â€“24 hours will be sufficient in symptomatic patients, and can be reduced to once a day testing or less when cholinergic effects have resolved. Butyrylcholinesterase may not normalize with pralidoxime therapy because this enzyme does not contain an anionic site to attract the compound[82] and red blood cell cholinesterase activity may be markedly depressed long after neuronal AChE levels have returned to normal. Therefore, an individual who remains asymptomatic may be discharged home with subnormal cholinesterase activity. However, a significant fall in cholinesterase activity may reflect redistribution of insecticide from fat stores or prolonged absorption and may be accompanied by the redevelopment of cholinergic symptoms 3 or 4 days after initial resolution of symptoms.[38,51,107] Further deterioration of cholinesterase activity should be treated by reinstituting a pralidoxime infusion, even though the patient may still be asymptomatic. After an additional 24 hours of pralidoxime, if the patient remains asymptomatic, pralidoxime can be halted again, and red blood cell cholinesterase and butyrylcholinesterase activities monitored. When available, electromyographic studies to detect signs of motor endplate dysfunction and early AChE inhibition may be a more sensitive method for identifying recurrent cholinergic toxicity.[10]

A patient who becomes asymptomatic, has not needed pralidoxime or atropine for 1â€“2 days, and who has cholinesterase activity documented to be stable, may be discharged. The patient should not be allowed to go home wearing clothing that was worn when the poisoning occurred. (The clothing should be disposed of as medical waste and destroyed.)

Carbamates

The treatment of patients with carbamate poisoning is identical to that of organic phosphorus compound poisoning with two exceptions. First, the use of pralidoxime in monomethyl carbamate exposure is controversial and many providers will not administer it because animal data imply that pralidoxime may increase AChE inactivation in carbaryl poisoning.[51,89,94] However, other studies and subsequent anecdotal experience have found that pralidoxime is useful in treating poisoning from the dimethyl carbamates such as isolan,[51] and may not adversely impact treatment for monomethyl carbamate poisoning in humans. Recent reports suggest aldicarb poisoning may also benefit from oxime therapy.[132] Comparative human data investigating the use of pralidoxime in carbamate poisonings are currently lacking. Fortunately, because of the rapid hydrolysis of the carbamate-AChE complex, symptoms, including weakness and paralysis, usually resolve within 24â€“48 hours without pralidoxime therapy. However, administering pralidoxime to a poisoned patient in a cholinergic crisis is appropriate when it is not known whether the patient is suffering from organic phosphorus or carbamate pesticide poisoning. If the poisoning is from a carbamate pesticide, pralidoxime therapy may not be necessary, but if used, should not prove detrimental.

Second, significant inhibition of red blood cell cholinesterase and butyrylcholinesterase by carbamates generally does not last for more than 1â€“2 days, assuming absorption is complete. Patients exposed to carbamates usually have normal red blood cell and butyrylcholinesterase values by the time of discharge. There are no reported cases of recurrent or delayed poisonings following carbamate insecticide poisoning. Therefore, repeating cholinesterase tests after patients are asymptomatic is usually unnecessary.

Summary

Cholinesterase inhibitors are commonly used pesticides. As the use of these compounds expands, instances of both acute and chronic exposure are likely to become more common. The clinical presentation

of toxicity from these compounds relates to their ability to stimulate the parasympathetic, and, to a lesser extent, the sympathetic branches of the autonomic nervous system. The early clinical findings of cholinesterase inhibitor poisoning may be mixedâ€”a mixture of muscarinic and nicotinic with signs and symptoms that can include weakness, fasciculations, tachycardia, hypertension, vomiting, diaphoresis, diarrhea, salivation, small (or less often large) pupils, and either micturition or urinary retention. As acetylcholine concentrations continue to rise, the clinical course usually changes to reflect mainly muscarinic, skeletal muscle, and CNS abnormalities, with bradycardia, heart block, hypotension, bronchorrhea, bronchospasm, salivation, diaphoresis, lacrimation, vomiting, diarrhea, urinary incontinence, miosis, fasciculations and paralysis, hyperglycemia, and ketosis. Secretions from every orifice may become copious and hinder resuscitation efforts. With supportive care and antidotal therapy, some patients with cholinesterase inhibitor poisoning improve rapidly, signs and symptoms resolving within 2 or 3 days. In other cases, redistribution and absorption of these chemicals may continue for days, leading to prolonged or recurrent cholinergic symptoms and lengthy hospitalizations. Although measuring cholinesterase activity can be helpful when the diagnosis of cholinesterase inhibitor poisoning is unclear or questionable, most laboratories are unable to perform these tests rapidly enough to be useful. Expeditious recognition of the cholinergic syndrome followed by therapy with atropine to control muscarinic activity and an oxime to regenerate acetylcholinesterase coupled with supportive care will improve clinical outcome.

Asoxime (HI6)

Figure. No Caption Available.

Pralidoxime (2-hydroxyiminomethyl-1-methyl pyridinium chloride; 2-PAM) is the only cholinesterase-reactivating agent currently available in the United States.[45] It is employed together with atropine in the management of patients poisoned by organic phosphorus insecticides. Administration should be initiated as soon as possible after exposure, but pralidoxime may remain effective for days after an exposure, and should be administered to all symptomatic patients independent of delay. Continuous infusion is preferable to intermittent administration for patients with serious toxicity and a prolonged therapeutic course may be required.

Chemistry

Pralidoxime is a quaternary pyridinium oxime with a molecular weight of 173 daltons. The chloride salt exhibits excellent water solubility and physiologic compatibility.

Reactivation of Cholinesterases Following Organic Phosphorus Compound Poisoning

Organic phosphorus pesticides are powerful inhibitors of carboxylic esterase enzymes, including acetylcholinesterase (true cholinesterase, found in red blood cells, nervous tissue, and skeletal muscle) and plasma cholinesterase or butyrylcholinesterase (found in plasma, liver, heart, pancreas, and brain).[41] The organic phosphorus compound binds firmly to the serine-containing esteratic site on the enzyme, inactivating it by phosphorylation (Figure 109-2, 109-3 and 109-4).[25,42,63] This reaction results in the accumulation of acetylcholine at muscarinic and nicotinic synapses in the peripheral

and central nervous systems, leading to the clinical manifestations of organic phosphorus poisoning. After the organic phosphorus pesticide binds to cholinesterase, the enzyme is inactivated and can undergo one of three processes: endogenous hydrolysis of the phosphorylated enzyme; reactivation by a strong nucleophile, such as 2-PAM; and aging, which involves biochemical changes that render the phosphorylated molecule inactive.

Endogenous hydrolysis of organic phosphorus compounds can be extremely slow and, for the most part, is considered insignificant in contrast to the rapid hydrolysis of many carbamates. Studies in the 1950s demonstrated the ability of oximes to reactivate cholinesterase bound to organic phosphorus compounds.[71,73] The positively charged quaternary nitrogen of pralidoxime is attracted to the negatively charged anionic site on the phosphorylated enzyme, bringing it in close proximity to the phosphorous moiety (Figure 109-2, 109-3 and 109-4). Pralidoxime then exerts a nucleophilic attack on the phosphate moiety, successfully competing for it and releasing it from the acetylcholinesterase enzyme.[70] This action liberates the enzyme to a variable extent and restores enzymatic function. Organic phosphorus compounds with small substituted side chains are more easily reversed by oximes because of better steric positioning, allowing easier access to the oximes.[73]

The understanding of the pathophysiology of the intermediate syndrome is inadequate to determine whether pralidoxime can prevent the development of the syndrome.[61] Additionally, certain organic phosphorus pesticides may lead to the development of delayed onset neurotoxicity that cannot be prevented by pralidoxime treatment.[15,36]

Efficacy Related to Time of Administration After Poisoning

Early in vitro evidence suggested that the successful use of

cholinesterase reactivators depended on administration within 24â€“48 hours of exposure to the organic phosphorus compounds; afterwards, the acetylcholinesterases would be irreversibly inactivated. However, according to currently available information there is no absolute time limitation on reactivator function. The 48-hour limit was derived from in vitro experiments using a small number of tightly bound compounds and reactivators and data from plasma cholinesterase

enzyme activity, which is now recognized to be relatively resistant to oxime-nucleophilic attack. The early data was accepted without consideration of relevance to human systems, the use of newer and less tightly bound compounds, temperature and pH variation, blood flow, fat solubility, active metabolites, and species specificity. Fat-soluble organic phosphorus compounds redistribute from fat stores over time, acting similarly to sustained-release products. Even if they have not aged, they continue to reinhibit acetylcholinesterase for days. An in vitro experiment assessed the effect of aging on the ability of pralidoxime to regenerate rat erythrocyte and brain cholinesterases using three different organic phosphorus compounds.[67] The rate of reactivation of erythrocyte and brain cholinesterases was significantly decreased over time for fenitrothion and methyl parathion, with no reactivation occurring at 48 hours. This is partly because demethylated organophosphorus pesticides age more quickly than diethylphosphorylated agents.[15] In contrast, a very high reactivation rate for ethyl parathion was still apparent at 48 hours. This demonstrates that the structure of the organic phosphorus compound is important in the rates of aging and reactivation with pralidoxime. Fenitrothion and methyl parathion are both O'O dimethyl organic phosphorus compounds as is dimethoate, whereas ethyl parathion is an O'O diethyl organic phosphorus compound.[67] Other studies also suggest that 2-PAM and obidoxime are effective long after the previously suggested 48-hour window of therapy.[2,4,7,11,14,15,15a,39,69]

Carbamates

Acetylcholinesterases inactivated by most carbamates spontaneously reactivate with half-lives of 1â€“2 hours, and typical clinical recovery occurs in several hours. However, in severe cases, cholinergic symptoms may persist for 24 hours.[9,19] Pralidoxime is rarely indicated for carbamate poisoning, but it is not generally contraindicated as was previously suggested. The conclusion that pralidoxime was contraindicated after a carbamate exposure was based solely on data derived from the study of a single carbamate (carbaryl). This conclusion was inappropriately applied to all carbamates. In vitro experiments had demonstrated that pralidoxime had no effect on the reactivation of erythrocyte acetylcholinesterase carbamylated by aldicarb, methomyl, and carbaryl.[30] However, Pralidoxime decreased the rate of carbamylation of 16 insecticidal carbamates and only modestly increased the rates for 3, 1 of which was carbaryl.[13] Animal studies demonstrated the beneficial effects of pralidoxime and obidoxime in decreasing the lethality of several carbamate insecticides.[43,60] In contrast, obidoxime and pralidoxime worsened the toxicity of carbaryl possibly because the carbamate-oxime complex may actually be a more potent cholinesterase inhibitor than carbaryl alone.[19,43,60] Even in the presence of carbaryl, however the combination of atropine plus an oxime resulted in survival data comparable to that of atropine alone.[19] This evidence suggests that although pralidoxime is not usually a necessary adjunct to atropine in a pure carbamate overdose, it may at least occasionally improve morbidity and mortality.[9] Pralidoxime should not be withheld in a seriously poisoned patient out of concern that a cholinergic xenobiotic may be a carbamate.[30] However, pralidoxime should always be used in conjunction with atropine and should never be the sole therapeutic agent.

Pharmacology

Pralidoxime is most important at nicotinic sites where atropine is

ineffective, often improving muscle strength within 10â€“40 minutes after administration.[42,63] This effect is vital to maintaining the functioning of the muscles of respiration. Pralidoxime is synergistic with atropine and in addition liberates cholinesterase enzyme so that additional acetylcholine can be metabolized. This suggests that 2-PAM should rarely if ever be used alone.[16,42] Some organic phosphorus compounds respond much better to 2-PAM than do other compounds depending on the affinity of pralidoxime for the particular type of phosphorylated enzyme and its reactivating ability and whether ageing has occurred prior to administration.[74]

The CNS benefits of 2-PAM are controversial, as the molecule is a quaternary nitrogen compound not expected to cross the bloodâ€“brain barrier.[35,42] Animal studies suggest conflicting results.[38] Rat studies using radiolabeled pralidoxime demonstrated a lack of any radioactivity in the CNS after IV administration.[66] Following exposure to IV fenitrothion, intravenous administration of pralidoxime in rats failed to improve survival or to reactivate brain cholinesterase, whereas intramedullary pralidoxime partially restored brain cholinesterase and eliminated fatalities.[66] A recent rat experiment using a microdialysis technique demonstrated only 10% CNS penetration of 2-PAM.[54]

Clinical observations however have certainly suggested a CNS action of 2-PAM with a prompt return of consciousness reported in some cases.[41,42,49,70] A 3-year-old child who was comatose from parathion was given 500 mg of 2-PAM IV over 15 minutes with continuous electroencephalographic (EEG) monitoring. Within 2 minutes there was a dramatic response on the EEG, followed rapidly by normalization of consciousness.[31]

Early work with cats led to a proposal that a plasma concentration of â‰¥4 Âµg/mL was a desired therapeutic concentration for pralidoxime.[62] Recent in vitro work with human erythrocytes and a mouse hemidiaphragm model suggests that higher serum concentrations are actually needed.[74] Twenty percent reactivation

was achieved in 5 minutes with serum concentrations of 10 Âµg/mL.[74] A recent simulation and analysis suggests that plasma concentrations between 10 and 15 Âµg/mL (50â€“100 Âµmol/L) are necessary for optimal treatment of severely poisoned patients.[15a] These recommendations await validation in poisoned patients.

Other Reversal Agents

To improve the central effect of pralidoxime, the dihydropyridine derivative of pralidoxime was synthesized.[5] This derivative, known as pro-2-PAM, acts as a â€œprodrug,â€• or drug carrier, which allows passage through membranes such as the bloodâ€“brain barrier. Once across the membranes, spontaneous in vivo oxidation converts pro-2-PAM to the active species, demonstrating a 13-fold higher level of 2-PAM in the brain than when 2-PAM itself is administered under similar conditions. Further experiments support the significantly increased central effects of pro-2-PAM.[53]

The use of sugar oximes (the molecular combination of glucose with 2-PAM derivatives) to promote CNS penetration also appears promising.[50] Obidoxime (Toxogonin) is an oxime used outside the United States that contains two active sites per molecule and is considered by some to be more effective than 2-PAM.[16,74] An in vitro study using human erythrocyte acetylcholinesterase supported the superiority of obidoxime to pralidoxime in reactivating acetylcholinesterase inhibited by the dimethyl phosphoryl and diethyl phosphoryl organic phosphorus compounds paraoxon, mevinphos, and malaoxon. On a molar basis, obidoxime is approximately 10â€“20 times more effective in reactivating acetylcholinesterase than is pralidoxime.[74]

The H series of oximes (named after Hagedorn) were developed to act against the chemical warfare nerve agents. These oximes have superior effectiveness against sarin, VX and certain types of newer pesticides (eg, methyl-fluorophosphonylcholines).[10,26,29,32,52,74,75]

Unfortunately, they are less efficacious for traditional organic phosphorus insecticide poisoning, and their toxicity profile is inadequately defined.[10,26,29,32,52,74,75] In addition to reactivating acetylâ€“cholinesterases, the Hagedorn oximes demonstrate direct central and peripheral anticholinergic effects at supratherapeutic concentrations.[52]

Duration of Treatment

The signs and symptoms of organic phosphorus compound poisoning are usually manifest from within minutes up to 24 hours.[42] Delayed manifestations occur with the fat-soluble organic phosphorus compounds, such as fenthion or chlorfenthion. The route of exposure may also influence the onset of systemic symptoms; for example, there may be a delay following dermal contact, which does not occur following ingestion or inhalation. When either symptoms are delayed or prolonged, or when treatment is delayed, extended therapy with 2-PAM may be indicated.[1,7,39] In one case of poisoning with the fat-soluble organic phosphorus compound fenthion 5 days elapsed before cholinergic symptoms appeared, and some symptoms then persisted for 30 days.[39] Pralidoxime and atropine were administered continuously in varying doses for the time that the patient was symptomatic.

Pharmacokinetics and Pharmacodynamics

Pralidoxime pharmacokinetics are characterized by a two-compartment model. Pharmacokinetics values vary depending on whether calculations are determined in healthy volunteers or poisoned patients. In volunteers, the steady-state volume of distribution is about 0.8 L/kg and the half-life is 75 minutes.[24,47] Pralidoxime is renally excreted, and within 12 hours, 80% of the dose is recovered unchanged in the urine.[59]

A dose of 10 mg/kg of 2-PAM IM to volunteers results in peak plasma concentrations of 6 Âµg/mL (reached 5â€“15 minutes after IM injection) and a plasma half-life of approximately 75 minutes.[59] Following a standard IV 30-minute infusion dose of 1 g of 2-PAM in a 70-kg man, the plasma level fell to less than 4 Âµg/mL at 1.5 hours. In a simulated model, a continuous infusion of 500 mg/h of 2-PAM led to a level greater than 4 Âµg/mL after 15 minutes, which could be maintained throughout the infusion.[64] In a human volunteer study, an intravenous loading dose of 4 mg/kg over 15 minutes followed by 3.2 mg/kg/h for a total of 4 hours maintained pralidoxime serum concentrations greater than 4 Âµg/mL for 4 hours. The same total dose, 16 mg/kg, administered over 30 minutes only maintained those concentrations for 2 hours.[37]

In poisoned patients receiving continuous infusions of pralidoxime as opposed to intermittent infusions, both the volume of distribution and the half-life are increased. A volume of distribution of 2.77 L/kg, an elimination half-life of 3.44 hours, and a clearance of 0.57 L/kg/h were reported in poisoned adults given a mean loading dose of 4.4 mg/kg followed by an infusion of 2.14 mg/kg/h.[70] In poisoned children and adolescents, the volume of distribution varied with severity of poisoning from 8.8 L/kg in the severely poisoned patients to 2.8 L/kg in moderately poisoned patients.[56] After a mean loading dose of 29 mg/kg followed by a continuous infusion of about 14 mg/kg/h, a steady-state serum concentration of 22 Âµg/mL, a half-life of 3.6 hours, and a clearance of 0.88 L/kg/h were calculated.[56]

Oral administration of salts of 2-PAM (not used clinically because of anticholinesterase poisoningâ€“induced vomiting) demonstrated a peak concentration at 2â€“3 hours, a biologic half-life of 1.7 hours, and an average urine recovery of 27% of unchanged 2-PAM in humans, and clinical efficacy in a mice model.[8,28]

Autoinjector administration of 600 mg of pralidoxime chloride in an adult man (9 mg/kg) produced a concentration above 4 Âµg/mL at 7â€“16 minutes, a maximum plasma concentration of 6.5 Âµg/mL at

about 28 minutes, and a half-life of 2 hours.[47,58] Using traditional needle and syringe IM administration requires longer time to achieve comparable plasma concentrations. The autoinjectors more widely disperse the medication in the tissues resulting in faster absorption.[51]

Adverse Effects

At therapeutic doses of 2-PAM in humans, adverse effects are minimal.[17,18,40,41 and 42,49,64] Transient dizziness, blurred vision, and elevations in diastolic blood pressure may be related to the rate of administration.[24,37] Doses of 45 mg/kg produce blood pressure elevations that may persist for several hours, but may be reversed with IV phentolamine.[58] Rapid IV administration has produced sudden cardiac and respiratory arrest because of laryngospasm and muscle rigidity.[44,57,72] Following IM administration, other adverse effects reported to occur in normal volunteers include diplopia, dizziness, headache, drowsiness, nausea, tachycardia, increased systolic blood pressure, hyperventilation, decreased renal function, muscular weakness, and pain at the injection site.[47] Elevations in liver enzymes were observed in volunteers administered autoinjector doses of 1200â€“1800 mg; LFTs returned to normal in 2 weeks.[47]

Pralidoxime is pregnancy category C and should be used as clinically indicated for women.

Dosing and Administration

The optimal dosage regimen for pralidoxime is unknown. Traditionally, the recommended initial adult dose is 1â€“2 g in 100 mL of 0.9% sodium chloride solution given intravenously over 15â€“30 minutes.[48] The pediatric dose is 20â€“40 mg/kg up to a maximum of 2 g as a loading dose given intravenously over 30-60 minutes.[51] These initial doses can be repeated in 1 hour if muscle weakness and fasciculations are not relieved. Thereafter, additional

doses may be needed every 3â€“8 hours as long as signs of poisoning recur.[48]

Patients with reduced renal function may require dosage adjustment, but there are no specific recommendations on how to accomplish this.[45] Alternatively, a loading dose followed by a continuous maintenance infusion has been reported to be safe and effective in a limited number of adults and children.[40,42,56,65,67,70] Serious cholinergic poisoning may require a continuous 2-PAM infusion of 500 mg/h in adults and 10â€“20 mg/kg/h up to 500 mg/h in children. One author suggests a loading dose of 25â€“50 mg/kg (up to a maximum dose of 2 g) in children, depending on the severity of the poisoning, to be followed via continuous infusion of 10â€“20 mg/kg/h.[51,56] In patients with acute lung injury the dose can be given as a 5% solution by a slow IV injection over at least 5 minutes.[45,59]

Although IV administration is preferred, IM administration is acceptable using a 1-g vial of 2-PAM reconstituted with 3 mL of sterile water for injection or 0.9% sodium chloride for injection to provide a solution containing 300 mg/mL (concentrations above 35% weight/volume produce muscle necrosis in animals).[45,59]

Depending on the severity of a nerve agent exposure, 1â€“3 injections with the autoinjector of both atropine and pralidoxime should be administered. The number of autoinjector doses administered to a child depends on the child's age and weight.[20,34] For children ages 3â€“7 (13â€“25 kg), one autoinjector of atropine and one autoinjector of pralidoxime should be administered, which should result in a projected pralidoxime dose of 24â€“46 mg/kg. For ages 8â€“14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered. These injections should result in a projected pralidoxime dose of 24â€“46 mg/kg. For patients older than 14 years of age, three autoinjectors of atropine and pralidoxine should be administered. This results in a projected dose of pralidoxime of less than 35 mg/kg. For children younger than 3 years

during an emergency, one autoinjector of atropine and one of pralidoxime may be administered in accordance with a risk-benefit analysis. If time permits and only autoinjector doses are available, its contents after isopropyl alcohol swabbing may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.[21]

In most cases, pralidoxime is continued for a minimum of 24 hours after symptoms have resolved. Extended dosing may be necessary, depending on the patient's clinical condition and the nature of the organic phosphorus compound.[68] Alternatively, if serial determinations of red blood cell cholinesterase activity can be obtained in a timely fashion, restoration of a normal value seems a reasonable endpoint of therapy with the exception of rapidly aging organic phosphorus compounds where a normal AchE cannot be achieved. In all cases, patients should be observed for recrudescent toxicity after termination of pralidoxime. If symptoms return, therapy should be continued for a minimum of an additional 24 hours.

Availability

Pralidoxime chloride (Protopam) is supplied in 20-mL vials containing 1 g of powder, ready for reconstitution with sterile water for injection.[45,48]

The addition of 20 mL of sterile water for injection to the 1-g vial of 2-PAM results in a 5% solution (50 mg/mL). Following reconstitution, the 2-PAM should be used within several hours. This solution can be further diluted to a volume of 100 mL of normal saline for IV infusion.

As noted above pralidoxime chloride is also available for IM administration by an autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 20 mg benzyl alcohol and 11.26 mg glycine. The 2-PAM autoinjector also is packaged in a kit containing 600 mg of pralidoxime in 2 mL of sterile water for

injection with 40 mg benzyl alcohol and 22.5 mg glycine accompanied by an autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This kit is called a â€œMark 1 Nerve Agent Antidote Kit (NAAK)â€• and is designed to be used IM by first responders in case of a nerve agent attack. The needles are approximately 1 inch in length.

Summary

Pralidoxime is an effective reactivator of acetylcholinesterase in many organic phosphorus compound poisonings. It primarily reverses neuromuscular manifestations but has some CNS effects. New oximes may improve CNS penetration and efficacy. Pralidoxime and atropine are synergistic and should be used together in the management of patients with organic phosphorus poisonings. If a patient requires multiple doses of atropine for muscarinic symptoms, then the use of 2-PAM is indicated. In symptomatic patients, acetylcholinesterase is partially inactivated and will remain so until new enzyme is synthesized or inactivated enzyme is reactivated. The resolution of all signs or symptoms with atropine alone indicates only that acetylcholinesterase inactivation is less than 50% and that endogenous hydrolysis by nonphosphorylated enzyme is sufficient to eliminate symptoms. This clinical response by no means indicates however, that the enzyme systems are fully active; patients may still benefit from enzyme regeneration with the safe and effective antidote pralidoxime.

Finally, because newer fat-soluble organic phosphorus pesticides are currently available, it may be necessary to administer atropine and 2-PAM for more prolonged periods of time than previously indicated based on the clinical manifestations and the predicted kinetics of the highly fat soluble pesticides.[7]

Antidotes in Depth

Atropine

Mary Ann Howland

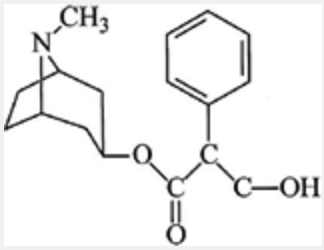

Figure. No Caption Available.

Atropine is the prototypical antimuscarinic drug. It is a competitive antagonist at both central and peripheral muscarinic receptors, used to treat symptomatic exposures to muscarinic agonists and

acetylcholinesterase inhibitors such as carbonate and organic phosphorous pesticides and organic phosphorus chemical warfare nerve agents.

History

Many plants contain the alkaloids atropine and/or scopolamine. One notable example is *Atropa belladonna*, named by Linnaeus after Atropos, the goddess of fate in Greek mythology who could cut short a person's life. Belladonna means beautiful woman in Italian and comes from the practice by Italian women of placing belladonna extract in their eyes, to produce aesthetically pleasing dilated pupils.[6] In the early 1800s, atropine was isolated and purified from plants and in the 1860s, Fraser experimented with the dose response relationship between atropine and physostigmine involving various organs such as the heart and the eye.[12] Experiments in the 1940s with cholinesterase inhibitors demonstrated the ability of atropine to reverse many of the effects of these xenobiotics and to protect against doses 2â€“3 times the LD_{50}s in animals.[34]

Chemistry

Atropine (dl-hyoscyamine), like scopolamine (l-hyoscine), is a tropane alkaloid with a tertiary amine structure that allows CNS penetration. Quaternary amine antimuscarinic agents such as glycopyrrolate, ipratropium, and tiotropium do not cross the bloodâ€“brain barrier into the CNS.[6]

Pharmacology

Centrally acting muscarinic antagonists include atropine scopolamine and homatropine. Glycopyrrolate, ipratropium, and tiotropium act peripherally. Scopolamine is about 10 times more potent than atropine.[20]

Cholinesterase inhibitors (eg, organic phosphorous insecticides, carbamates chemical warfare nerve agents) prevent the breakdown of acetylcholine by acetylcholinesterase thereby increasing the amount of acetylcholine available to stimulate cholinergic receptors. Cholinergic receptors are made up of muscarinic and nicotinic receptors. Muscarinic agonists (eg, muscarine, methacholine, and pilocarpine) stimulate muscarinic receptors. They do not have any effect on nicotinic receptors.

Atropine is a competitive antagonist of acetylcholine primarily at muscarinic receptors (M_1â€“M_5).[7] Muscarinic receptors are coupled to G proteins and either inhibit adenylyl cyclase (M_2, M_4) or increase phospholipase C (M_1, M_3, M_5). Muscarinic receptors are widely distributed throughout the peripheral and central nervous systems. The competitive blockade of muscarinic receptors in normal individuals results in dose dependent effects which occur in a hierarchy dependent on the importance of parasympathetic tone.[6] In adults low doses (0.5 mg) of atropine cause a paradoxical bradycardia, and some drying of the mouth and sweat glands. Higher doses of atropine (2 mg) produce noticeable dryness, subjective feeling of warmth, slight flushing, slight tachycardia, reactive slightly dilated pupils blurred near vision, mild drowsiness, some postural hypotension, and urinary hesitation. At higher doses of 3â€“4 mg of atropine all the aforementioned symptoms are exaggerated, hyperthermia, tachycardia, and drowsiness are present. At doses of 5 mg of atropine all of previously noted symptoms are even more marked and in addition the patient has difficulty voiding and GI transit time and tone are decreased. By the time doses of â‰¥10 mg of atropine are employed patients are incapacitated with hot, dry, flushed skin, dilated pupils, blurred vision, very dry mouth, tachycardia, urinary retention, constipation, increased drowsiness or disorientation, hallucinations, stereotypical movements, bursts of laughter, delirium, and finally, coma.[6,14] The duration of action of atropine is dose-dependent and may last as long as 12â€“24

hours.

Miosis from the topical instillation of an cholinesterase inhibitor into the eye will not be reversed by the systemic administration of atropine.[14] The systemic administration of 354 mg of atropine made one patient floridly anticholinergic but did not counteract the ophthalmic effects of a previously instilled topical cholinesterase inhibitor.[14]

This paradoxical bradycardia produced at low doses of atropine is thought to be a consequence of the inhibition of peripheral M_1 presynaptic postganglionic parasympathetic neurons: stimulation of these receptors by acetylcholine inhibits the further release of acetylcholine, and atropine interferes with this negative feedback.[6,33]

Pharmacokinetics and Pharmacodynamics

Atropine is absorbed rapidly from most routes of administration including inhalation, oral, and IM.[2] Oral ingestion of 1 mg of atropine produced maximal effects on heart rate and on salivary secretions at 1 and 3 hours respectively.

The distribution half-life of atropine following IV administration is approximately 1 minute. The apparent volume of distribution (Vd) is about 2â€“2.6 L/kg.[19] As a result of the rapid distribution, 10 minutes after IV administration less than 5% of the dose remains in the plasma. The plasma concentrations of atropine are similar at 1 hour following either 1 mg IV or IM in adults.[2,5] The elimination half-life is 6.5 hours.[27]

Following IM administration of 0.02 mg/kg in adults the absorption rate and elimination rates were comparable for the racemic d,l-hyoscyamine and the active l-hyoscyamine at 8 minutes and 2.5

hours respectively. The mean peak plasma concentration and the area under the curve (AUC) were higher for the racemic mixture indicating a stereochemical difference in metabolism.[19] Renal elimination accounts for 34% of the dose and the majority of renal elimination occurred within 6 hours. Other studies suggest as much as 57% may be eliminated unchanged in the urine.[2] Plasma concentrations of l-hyoscyamine correlate with effects on heart rate and the antisialagogue effects. Plasma concentrations below 0.5 Âµg/L caused bradycardia, whereas higher concentrations caused tachycardia.[19]

Atropine autoinjectors are now given to first-responders for use during chemical terrorist attacks. The administration of 2 mg of atropine by autoinjector was compared to 2 mg administered by conventional needle and syringe into the deltoid of 6 adult subjects.[31] The onset of tachycardia and the time to maximal increase in heart rate occurred sooner with the autoinjector (16 minutes vs. 23 minutes and 34 minutes vs. 41 minutes respectively). An analysis of radiographs of contrast material injected by autoinjector or conventional IM administration into a dog's leg, demonstrated that the autoinjector appeared to â€œsprayâ€• the material into a larger tissue area accounting for a faster rate of absorption.[31]

Ocular instillation of atropine causes mydriasis by blocking the M_3 muscarinic receptor on the iris sphincter muscle.[23] The peak mydriatic effect occurs within 30â€“40 minutes and persists for 7â€“10 days. Ophthalmic atropine also causes cycloplegia by blocking the M_3 muscarinic receptor on ciliary muscle. Peak cycloplegia occurs within 1â€“3 hours and persists for 6â€“12 days.

In contrast, the effects of topical homatropine on the eye occur sooner than topical atropine (10â€“30 minutes for mydriasis and 30â€“90 minutes for cycloplegia) and are shorter in duration (6â€“48 hours).

An investigation of the bioavailability of atropine eye drops in healthy adults revealed on average 65% systemic absorption, but with a wide individual variability.[18] The time to maximum serum concentration was 30 minutes and the elimination half-life was 2.5 hours.

The pharmacokinetics of 3 inhaled doses of atropine was compared to 2 mg of IM atropine in healthy adults.[15] Peak concentrations were comparable for the 2 mg inhaled and 2 mg IM atropine doses. The time to peak concentration following inhalation averaged 1.3 hours.

Clinical Use

One of earliest descriptions of the effectiveness of atropine in parathion and tetraethylpyrophosphate insecticide poisoning was published in 1955.[13] The report emphasized the improvement in survival when atropine was administered early and continued with adequate maintenance doses in conjunction with intubation and ventilation. The report also found that after parathion and tetraethyl pyrophosphate exposure, dogs were more likely to develop heart block and bronchoconstriction, whereas humans were more likely to develop a relative rather than absolute bradycardia. Additionally, humans were more likely to die from respiratory causes stemming from central apnea, diaphragmatic weakness and bronchorrhea.

In 1971, a landmark case series and review of organic phosphorus insecticide poisonings were published. Included in this report was a table classifying the severity of poisoning along with treatment protocols for each level of severity.[24] This regimen served as the foundation of treatment regimens for many years.

In the 1930s and 1940s, the Germans synthesized organic phosphorous insecticides (acetylcholinesterase inhibitors) that were further developed as chemical warfare nerve agents (Chap.

126).[30] Although these agents inhibit acetylcholinesterase in a manner similar to that of traditional organic phosphorous insecticides such as parathion, these so called â€œnerve agentsâ€• also affect other cholinesterases, and at high doses, directly affect nicotinic and muscarinic receptors. Atropine was chosen in the late 1940s as the standard antidote for these nerve agents. The dose of atropine needed to antagonize these nerve agents is much less than that needed to effectively antagonize traditional organic phosphorous insecticides, largely because of differences in pharmacokinetics. The benefits of adding pralidoxime to atropine were noted in the 1950s, and in the 1960s, pralidoxime was established as a standard antidote in addition to atropine for these agents (Antidotes in Depth: Pralidoxime).

Adverse Effects and Toxicity

When atropine is used in the absence of a xenobiotic that increases or mimics acetylcholine, these effects begin at 0.5 mg IV in the adult. However, in the presence of a muscarinic agonist or an anticholinesterase agent, the effects may not occur until many milligrams of atropine are administered.

IV doses of greater than 10 mg of atropine and oral doses of 500â€“1000 mg have been administered with full recovery. Deaths from atropine use, are usually correlated with hyperthermia.

An unintentional atropine dose of 1 g orally resulted in typical manifestations of anticholinergic poisoning which began within a short time and lasted 4 days.[1] In 2 hours the patient went from feeling hot and flushed with blurred vision to stuporous. Over the ensuing 24 hours he became tachycardic, hyperthermic, and comatose with dilated unreactive pupils and shallow respirations. By 40 hours he started to respond to his name and his temperature had normalized, but he remained dry with dilated and nonreactive pupils. He went from comatose to restless,

hallucinating, and paranoid. At 4 days he regained a normal mental status with amnesia for the previous 4 days.

A survey of pediatric emergency departments in Israel reported on 240 children who were unintentionally injected with atropine autoinjectors during the Persian Gulf crisis.[3] Half of the children developed systemic effects that correlated with the doses of atropine administered. Eight percent of effects were serious but there were no seizures or deaths.

Systemic atropine toxicity may occur when too large a dose of atropine is instilled in the eye, especially in children.[26] Excessive absorption from other routes of administration (eg, rectal, inhaled) would also be expected to result in toxicity.[29] In the event of an atropine overdose, physostigmine, a reversible, CNS active, cholinesterase inhibitor, is the antidote of choice (Antidotes in Depth: Physostigmine). Psychiatric patients in the 1950s were often given atropine as a remedy. Within 15â€“20 minutes of getting 32 to 212 mg of IM atropine, patients become restless and often confused. This progresses to muscular incoordination, ataxia, weakness and garbled speech.[11] The patients then pass from being disoriented, with illusions, visual hallucinations, and delirium to being comatose. The coma often lasted for 4â€“6 hours and then patients recovered in a manner that in some respects is the reverse of intoxication. Regardless of the dose of atropine required to induce

the coma, physostigmine 4 mg IM completely reversed it within 20 minutes but the reversal only lasted for 30â€“45 minutes.

Atropine is classified by the Food and Drug Administration (FDA) as pregnancy category C. Atropine crosses the placenta and may cause tachycardia in the fetus near term.[32]

Administration and Dosing

The dosage regimen of atropine for an organic phosphorous pesticide poisoning in adults has never been studied in a randomized controlled trial and there is considerable variation in textbook recommendations.[9] However experience suggests that atropine should be initiated in adults in doses of 1â€“2 mg IV for mild-to-moderate poisoning and 3â€“5 mg IV for severe poisoning with unconsciousness.[24] This dose can be doubled every 3â€“5 minutes.[10] The editors believe that the most important endpoint for adequate atropinization is clear lungs, and the reversal of the muscarinic toxic syndrome. Some authors suggest clear lungs, heart rate â‰¥80 beats/min, and systolic blood pressure â‰¥80 mm Hg as most important, and dry axillae and wider than pinpoint pupils as additional goals.[10] Once these endpoints have been achieved, a maintenance dose of atropine needs to be started. One group suggests administering 10â€“20% of the loading dose as an IV infusion every hour as a starting point with meticulous frequent reevaluation and titration.[9] When too much atropine is administered, the patient demonstrates classic signs of peripheral anticholinergic toxicity: hot dry flushed skin, urinary retention, absent bowel sounds, tachycardia, mydriasis and central anticholinergic activity including restlessness, confusion, and hallucinations or CNS depression.

In the event that a person is exposed to a chemical warfare nerve agent atropine should be administered in a dosage suitable for both the severity of the poisoning and the age of the patient. In a conscious adult patient with mild to moderate cholinergic effects 2 mg of atropine IV or IM should be administered every 5â€“10 minutes until shortness of breath and drying of secretions occurs.[30] One adult autoinjector contains 2 mg of atropine and therefore multiple injectors are often required. Total doses of 2â€“4 mg of atropine are usually all that is needed. Patients who are unconscious or apneic require higher total doses with 5â€“15 mg usually sufficing.[30]

The appropriate total autoinjector doses for children depend on

age and weight.[16,21] For ages 3â€“7 (13â€“25 kg), 1 autoinjector (2 mg) of atropine and one autoinjector of pralidoxime (600 mg) should be administered resulting in a projected atropine dose of 0.08â€“0.15 mg/kg. For ages 8â€“14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered resulting in a projected atropine dose of 0.08â€“0.15 mg/kg. For patients older than 14 years of age, three autoinjectors of atropine and pralidoxime should be administered. This results in a projected dose of atropine of less than 0.11 mg/kg. In an emergency for children younger than 3 years of age a risk-benefit analysis would suggest injecting one autoinjector of atropine and one of pralidoxime. If time permits and only one autoinjector is available for use, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.[17]

Availability

Atropine sulfate injection, is available in many different strengths, with the following concentrations in each 1 mL vial or ampule: 50 Âµg, 300 Âµg, 400 Âµg, 500 Âµg, 800 Âµg and 1 mg.

The AtroPen Auto-Injector is a prefilled syringe designed for IM injection by an autoinjector into the outer thigh.[4] It is available in 4 strengths: 0.25 mg, 0.5 mg (Blue Label), 1 mg (Dark Red Label), and 2 mg (Green Label).

Atropine is also packaged in a kit with a second autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg benzyl alcohol and 22.5 mg glycine. The pralidoxime injector is accompanied by an atropine autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This particular combination kit is called a â€œMark 1 Nerve Agent Antidote Kitâ€• (NAAK) and is designed for IM use in case of a nerve agent attack. The needles are approximately 1 inch in

length.[22]

Atropine is available orally in 300-Âµg, 400-Âµg, and 600-Âµg tablets.

In case of a shortage during an emergency, in vitro evidence suggests that outdated atropine retains its potency and that an extemporaneously prepared atropine solution from powder is stable for at least 3 days.[8,28]

Summary

Atropine has many clinical uses as a competitive antagonist at both central and peripheral muscarinic receptor sites. The use of atropine is extensive for patients with bradycardias, in advanced cardiac life support and those exposed to acetylcholinesterase inhibitors in the workplace, in the home, and potentially on the battlefield.

Insecticides: Organic Chlorines, Pyrethrins/Pyrethroids, and DEET

Michael G. Holland

A 2-1/2-year-old (14-kg) boy got into the medicine cabinet and swallowed lindane shampoo (150 mg, or 10.7 mg/kg). Shortly thereafter his mother tonic-clonic seizures. When emergency medical services arrived, the child by the time he arrived at the emergency department (ED) he was more a vomited once.

On examination he was lethargic with no seizure activity. Vital signs were heart rate 110 beats/min; respiratory rate 24 breaths/min, and temperat were clear to auscultation. The poison center was called and the poison recommended achieving IV access, observation, and the administration c should seizures recur. The child was admitted to the pediatric intensive c postictal confusion rapidly cleared, and his mental status remained norma subsequent seizures. His vital signs remained normal. He was discharged completely asymptomatic. His parents received poison prevention educat

Organic Chlorine Pesticides

History and Epidemiology

Until the 1940s, commonly available pesticides included highly toxic arse and nicotine.[100] When Nobel Prize-winning chemist Paul MÃ¼ller demons of dichlorodiphenyltrichloroethane (DDT) in the early 1940s, a whole new introduced.[32] The organic chlorine insecticides were inexpensive to proc stable, and had relatively low acute toxicity when compared to previous chlorines have a negative temperature coefficient, making them more ins and less toxic to warm-blooded organisms (Table 110-1).[125] Widespread occurred from the 1940s until the mid-1970s. They were highly effective agriculture, allowing unprecedented crop output from each acre of arable organic chlorines were used extensively in structural protection and soil health applications of DDT and its analogues were also found in the contr malaria by eliminating the mosquito vector.[25] By 1953, DDT alone was c 50 million lives, and with averting one billion cases of human disease.[33] I this consequential impact on human health, DDT is the single most impor explosion that occurred between 1950 and 1970.[33]

However, the properties that made these chemicals such effective insectic environmental hazards: they are slowly metabolized, lipid soluble, chemi persistent. In her 1962 book, *Silent Spring* , Rachel Carson, a biologist w Service, demonstrated that organic chlorines are bioconcentrated and bior She alleged that this persistence could eventually lead to increases in car publications since then have stated that organic chlorine residues in pred peregrine falcons, bald eagles, and pelicans, caused eggshell thinning an success.[32] However, these theories were not actually demonstrated when administered in high concentrations to experimental birds. Testing on dor Japanese quail,[16 , 18 , 90] chickens,[4] and mallard ducks[120] showed little o before the Environmental Protection Agency (EPA) regarding DDT registrat disproved fear of placing future generations at risk of cancer. This, and t residues in humans, led to the severe restriction or total ban of DDT and North America and Europe.[25] There is considerable evidence that since D replacements have placed many more millions at risk for malaria, and is

millions of deaths from this disease.[70 , 88 , 89] Not surprisingly, DDT is st mosquito control agent with a low order of acute toxicity, and is very ine replacement insecticides. For these reasons, the World Health Organizatior list of banned pesticides, and it is still widely used for malaria control pr will likely be for the foreseeable future.

Organic chlorine pesticides are complex, cyclic polychlorinated hydrocarb generally in the range of 300â€“550 Da. They are nonvolatile solids at ro central nervous system stimulants.

TABLE 110-1. Classification of Organic Chlorine Pesticides

In contrast, chlorinated hydrocarbon solvents and fumigants are low mol that are volatile liquids or gases, and that generally have CNS-depressant

The organic chlorine pesticides are grouped into four categories based on similar toxicities: (a) DDT and related analogues; (b) cyclodienes (the re endrin; and heptachlor, endosulfan), and related compounds (toxaphene, hexachlorocyclohexane (lindane, the Î³ isomer; with the commonly used hexachloride), the primary organochlorine pesticide still in common clinica United States. Isomerism is important, because the Î² and Î´ isomers are insecticidal properties.[1,23,81] and (d) mirex and chlordecone (Table 11 compounds differ

substantially, both between and within groups, with respect to toxic dose metabolism, and elimination.[25] The signs and symptoms of toxicity in hu similar within each group.

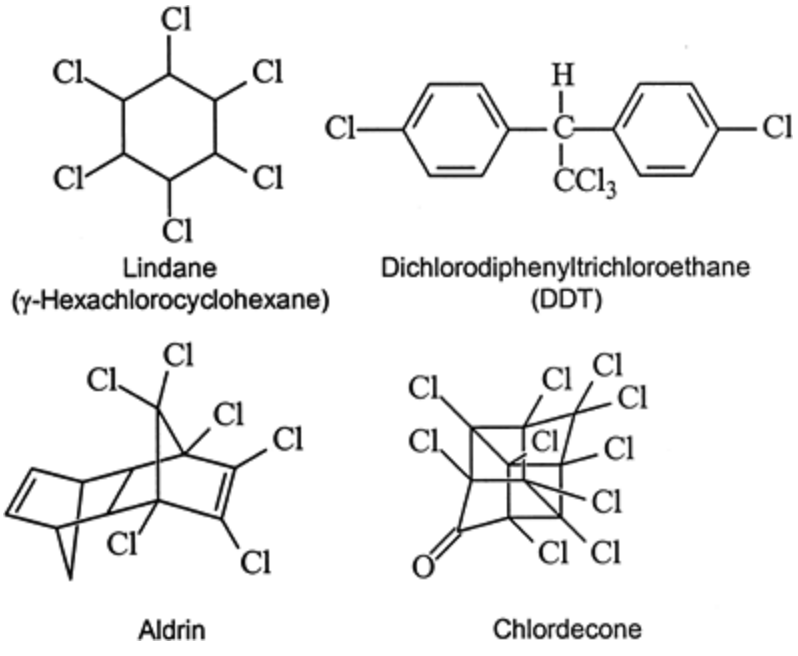

Figure 110-1. Structures of various organic chlorine pesticides.

Toxicokinetics

Absorption

All of the organic chlorine pesticides are well-absorbed orally and by inh variable, depending on the particular compound. Absorption by any route and the physical state (solid or liquid) of the pesticide. None of the orga and are usually either dissolved in organic solvents or manufactured as p

DDT and its analogues methoxychlor, dicofol, and chlorobenzilate are ve unless the pesticide is dissolved in a suitable hydrocarbon solvent.[87] DDT concentrations are usually low, and toxicity by the respiratory route is u

All of the cyclodienes have significant transdermal absorption rates. Cuta approximately 50% that of the oral route.[25] Oral absorption of the cyclod poisonings have occurred when foodstuffs were contaminated with these absorbed through the skin in both acute and chronic exposures.[99]

Lindane is well absorbed after skin application, and in adults has a docu rate of 9.3% of a topically applied dose over 24 hours.[36] Anatomic sites v capacities: axillary rates are 3.6 times greater, although scrotal absorptior of forearm rates.[11 , 40 , 53 , 107] Animal studies and case reports suggest malnourished, and those who receive repeated topical doses may have ir increased toxicity.[82] Hot baths, occlusive clothing or bandages the vehicle cutaneous integrity, such as eczema, fissures and other violations of the penetration.[107 , 108] The state of hydration of the skin also affects the a just prior to application can enhance absorption and increase the likelihoc stable compound, and volatilizes easily when heated. It was used extensiv vaporizers, and toxicity was common via inhalation, and when vaporizer ingested by children.[25] Review of data when lindane was ingested therap demonstrates that 40 mg/d for 3â€“14 days generally produced no symp

Mirex and chlordecone are efficiently absorbed via skin, by inhalation, an

Distribution

All organic chlorines are lipophilic, a property that allows penetration to t serum ratios at equilibrium are high, in the range of 660:1 for chlordane; 150:1 for dieldrin.[26] Central nervous system redistribution of the organic to fat may account for the apparent rapid CNS recovery despite the pers burden. In the rat model, there is a direct correlation between the concer brain and the clinical signs produced after a single dose of the insecticide

Serum lindane levels peak at 6 hours, and have a half-life of 18 hours a

Metabolism

The high lipid solubility and very slow metabolic disposition of DDT, DDE dichloroethylene, metabolite of DDT), dieldrin, heptachlor, chlordane, mir significant adipose tissue storage and increasing body burdens in chronic Organic chlorines that are rapidly metabolized and eliminated, such as en endosulfan, lindane, methoxychlor, dienochlor, chlorobenzilate, dicofol, and persistence in body tissues, despite being highly lipid soluble.[87]

Most organic chlorines are metabolized by the hepatic microsomal enzym oxidation, with subsequent conjugation. However, metabolism may result i metabolite with more toxicity than the parent compound, such as heptacl chlordane to oxychlordane, and aldrin to dieldrin.

In animals, most organic chlorine pesticides are capable of inducing the systems.[24 , 100 , 128] Enzyme induction changes the biodegradation of the certain animal models the acute toxicity of organic phosphorus compounds reduced by the administration of organic chlorines. This protective effect hepatic microsomal metabolism of the organic phosphorus compound beca administering piperonyl butoxide, an inhibitor of the liver microsomal enz induction of hepatic enzymes has not been described in man, except in ra with concomitant neurologic findings.[35 , 44]

Elimination

The half-lives of fat-stored compounds and poorly metabolized organic chl

chlordecone are measured in months or years. The elimination half-life of The primary route of excretion of the organic chlorines is in the bile, but urinary metabolites. However, as with other compounds excreted in bile, have significant enterohepatic or enteroenteric recirculation such as mire of the lipophilic compounds are excreted in maternal milk.[91]

Mechanisms of Toxicity

The same neurotoxic properties that make the organic chlorines lethal to potentially toxic to higher

forms of life. The organic chlorines exert their most important effects in Electrophysiologic studies demonstrate that the organic chlorine insecticid membrane by either interfering with repolarization, by prolonging depolar maintenance of the polarized state of the neuron. The end result is hype system and repetitive neuronal discharges.

DDT primarily affects the axon, by causing the voltage-dependent Na^+ ch depolarization, allowing repetitive action potentials.[74, 109] Low-level stim responses, seen clinically as prominent tremors and abnormal startle refle Evidence of this mechanism of action is the amelioration of DDT-induced phenytoin, a sodium channel blocker, which reduces the ability of voltag recover from inactivation.[51, 118]

The cyclodienes and lindane act as Î³-aminobutyric acid (GABA) antagonis the $GABA_A$ -receptor-chloride ionophore complex in the CNS, by interactir site.[1, 7, 23, 38, 43, 46, 75, 81] In fact, the degree of binding at this sit amount of Cl^- influx inhibited and the relative neurotoxicity of each insec , and 110-2). Indeed, development of cyclodiene resistance seems to be $GABA_A$ -receptor-chloride ionophore complex in these affected insects.[9] , of GABA agonists, such as benzodiazepines and phenobarbital, in treating of the cyclodienes[47] and lindane.[130] Toxaphene also inhibits GABA bindin chloride ionophore complex.[99]

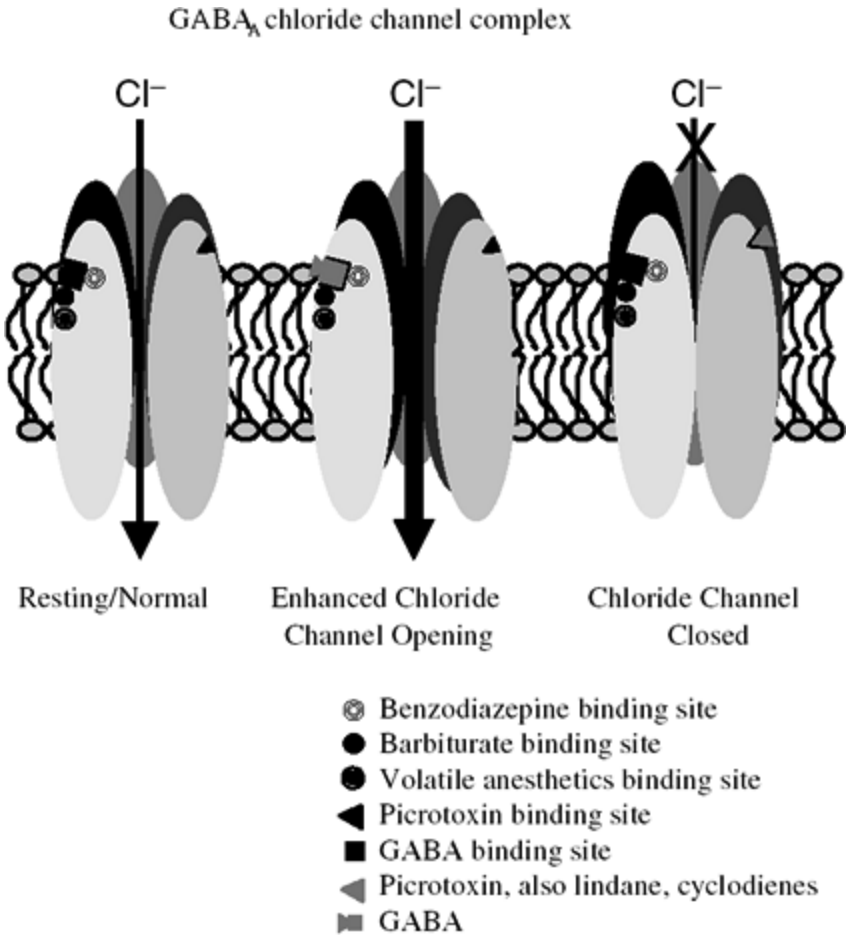

Figure 110-2. Chloride channel. Under resting conditions, a tonic influx cell in a polarized state. Binding of GABA or an indirect-acting GABA ag volatile anesthetic) opens the chloride channel. The subsequent chloride membrane, making the neuron less likely to propagate an action potential GABA antagonists, such as picrotoxin, close the chloride channel, reducin decreased membrane polarity causes the neuron to become hyperexcitable normally subthreshold in nature (Chap. 14).

The mechanisms of action of mirex and chlordecone are not as well unde ATPase, and Ca^{+2} -ATPase. However, lindane, DDT, and the cyclodienes a produce very different symptoms of toxicity, suggesting that these effects clinical manifestations seen in mirex/chlordecone toxicity. Phenytoin and the prominent tremor seen with chlordecone intoxication, but conversely poisoning, which further supports a different mechanism than the sodium

and chlordecone are poor inhibitors of GABA binding at the $GABA_A$ -recep therefore their mechanism of action is likely not at this site.[8] Seizures are chlordecone.

Organic chlorines sensitize the myocardium to endogenous catecholamines dysrhythmias, presumably in a fashion similar to the chlorinated hydrocar

Drug Interactions

There are theoretical consequences of liver enzyme induction, such as er therapeutic drugs and/or reduced efficacy. Dysfunctional uterine bleeding contraceptive metabolism induced by chlordane, but this was in a single exposure to chlordane.[44] A large group of workers poisoned by chlordecon increased hepatic microsomal activity, but no evidence of drug interaction Thus, induction of the hepatic microsomal enzyme system by organic chlo extended, substantial exposure.[87] There are no definitive reports of enha drugs or adverse reactions because of microsomal enzyme induction in m

Clinical Manifestations

Acute Exposure

In sufficient doses, organic chlorines lower the seizure threshold (DDT ar agents) or remove inhibitory influences (antagonism to GABA effects) and resultant seizures, respiratory failure, and death.[15, 17, 21, 32, 46, 47, exposure, tremor may be the only initial manifestation. Nausea, vomiting, face, paresthesias of face, tongue, and extremities, headache, dizziness, agitation, and confusion may subsequently occur. Seizures only occur afte only after ingesting large amounts.[32, 47, 58] Single, acute, oral doses of usually necessary to produce symptoms.[47] However, with lindane, the cy often are no prodromal signs or symptoms, and more often than not, the a generalized seizure.[15, 17, 32, 33, 47, 58, 93, 111] If seizures develop, hours of ingestion when the stomach is empty, but may be delayed as mu ingestion follows a substantial meal.[47]

Seizures related to dermal application of 1% lindane for treatment of ect

following a single inappropriate application,[63, 82, 116] or, more common exposures.[59, 84] The time from application to seizure onset can vary fror are often self-limited, but

may recur or result in status epilepticus. An epidemic of lindane poisonin substitution of lindane powder for sugar in coffee demonstrated a delay of the onset of nausea, vomiting, dizziness, facial pallor, severe cyanosis of collapse, convulsions, and hyperthermia. Affected patients ingested an ave a single dose.[25]

The cyclodienes are also notable for their propensity to cause seizures tha following an acute exposure. If the seizures are brief and hypoxia has no complete. Electroencephalographic (EEG) abnormalities have been recorde seizures.[58] Hyperthermia secondary to central mechanisms, increased mu pneumonitis is common.[33]

The ingestion of combinations of xenobiotics may result in significantly ir synergy. This has been demonstrated for DDT and lindane.[48]

Lindane: Specific Risks

Patients are at risk for developing central nervous system toxicity from i such as exceeding recommended application times or amounts, repeated following hot baths, and use of occlusive dressings or clothing shortly af occurs after unintentional oral ingestion of topical preparations. Young ch possibly because of greater skin permeability, increased ratio of body surf liver enzymes.[48] The elderly may also be at increased risk because of in atrophic skin, and perhaps age-related increased sensitivity. Preexisting of seizures include chlorpromazine treatment, CNS disease, or skin abso [, 77, 82, 84, 107, 108, 115, 116]

Despite the availability of safer and equally or more effective treatments continues to be used because of its low cost and generally good safety p English-language case reports and those submitted to the U.S. Food and toxicity into those associated with concentrations of lindane greater than cases could be considered probably related to 1% lindane;[4] of these, 6 c

or inappropriate skin application. The sale of lindane-containing products f banned in California because of its toxicity and environmental concerns.[1

Chronic Exposure

Chlordecone (Kepone), unlike the other organic chlorines, produces an in related to its extremely long persistence in the body. Because of poor inc makeshift chlordecone factory in Hopewell, Virginia, 133 workers were hea 1974â€“1975. They developed a clinical syndrome which became known a epidemic,â€• which consisted of a prominent tremor of the hands, a fine trembling of the entire body, known as the â€œKepone Shakes.â€• Othe opsoclonus (rapid, irregular, dysrhythmic ocular movements), ataxia, mer loss, and elevated liver enzymes.[35] Idiopathic intracranial hypertension, sperm motility were also found in some of these workers.[22] Severely affec exaggerated startle response, remarkably similar to that seen in animal s intense that some workers went home covered with chlordecone, and sev neurologic symptoms, presumably from exposures while laundering their

DDT and Breast Cancer

DDT and other organic chlorine insecticides have estrogenic effects.[28 , 1 estrogenic compounds adversely affect birds because differentiation of the estrogen-dependent.[41] Breast cancer incidence rates in the United States year since the 1940s, coinciding with, among many other factors, the wor lifetime exposure to excess estrogen is a known risk factor for human bre postulated that women who have higher levels of estrogenic organic chlo polychlorinated biphenyls [PCBs]) may be at risk for developing breast c

Several small case-control studies of women with breast cancer showed th higher average body burdens of DDT, DDE, and PCBs than their age-mat implicated the organic chlorines as a possible cause of human breast can larger studies have shown no increased risk of breast cancer because of and that currently accepted hereditary and lifestyle risk factors were pres cancer.[52 , 60 , 96 , 97] Additionally, other natural dietary estrogens such a and fungal metabolites are present in the human diet, and the organic c minimal by comparison.[42]

Organic Chlorines and Other Malignancies

The organic chlorines can induce liver tumors in mice, but have not been s hamsters.[48] Some reports suggest an association between long-term exp pesticides and blood disorders such as aplastic anemia, leukemia, and c purpura.[47 , 85 , 94] However, there is no convincing evidence that any of humans. Workers heavily exposed to DDT and dieldrin do not have an in Epidemiologic evidence suggests that the incidence of deaths from liver c since 1930, which includes the more than 50 years since the introduction is some evidence that DDT can be a facilitator of carcinogenesis induced aflatoxin, and that chlordane may have the same facilitative character recent comprehensive review found no evidence of human cancer risk fro dieldrin.[112]

Diagnostic Information

The history of exposure to an organic chlorine pesticide is the most critic exposure is otherwise rare. By law, the package label of these products r concentrations, and the vehicle. The EPA-registered use of the insecticide which agent is involved (Table 110-2). The presence of an unusual odor on the skin may be helpful. Toxaphene, a chlorinated pinene, has a mild endosulfan has a unique â€œrotten eggâ€• sulfur odor (Table 110-1). radiograph may reveal the presence of a radiopaque chlorinated pesticide radiopacity of the xenobiotics (Chap. 6).[30] A large number of other xeno first manifestation of toxicity, and must be considered in the differential c 14 and 19).

Laboratory Testing

Gas chromatography can detect organic chlorine pesticides in serum, adip confirmation is necessary for legal purposes, it may be necessary to mea chlorines. If the patient's history and toxidrome are obvious, then labora as this determination will not alter the course of management, and these an emergent basis. At present, there are no data correlating health effec Routine surveillance of serum levels in the occupationally exposed is not

Most humans studied have measurable levels of DDT in adipose tissue. In

very large exposure to DDT, serum DDT levels increased proportionally w were not associated with any apparent adverse health effects, but there v increasing levels of the liver enzyme Î³-glutamyltransferase (GGT), but s seen.[61] Serum lindane levels document exposure, and most laboratories exposed workers with chronic neurologic symptoms showed a blood lindan limited series of patients with acute lindane ingestion suggests that a ser with sedation, and that 0.20 mg/L is associated with seizures and coma.[3] lindane levels in the CNS are 3â€“12 times higher than serum levels.[31] , with a prolonged exposure to chlordecone, clinical signs and symptoms o levels.[22]

Management

As with any patient who presents with an altered mental status, the adm thiamine should be considered. Skin decontamination is essential, especial Clothing should be removed and placed in a plastic bag disposed of appr waste, and the skin washed with soap and water. Healthcare providers sh gloves and aprons. Because these pesticides are almost invariably liquids, to suction and lavage gastric contents, if clinically indicated. This is most recent ingestion (Chap. 8). Activated charcoal (AC) can be used after or lavage is not indicated.[47] , [68] However, the ability of AC to adsorb the va adequately studied, and mixtures containing petroleum distillates would pr the organic chlorines are all neurotoxins, the risk of complications associ outweighs the risk of any of the GI decontamination strategies in most ac lindane toxicity following intragastric administration showed a trend, but benefit, of AC.[56] The use of cholestyramine, a nonabsorbable bile acid-bi the same murine model did show a statistically significant benefit by raisi the lethal dose.[56] Oil-based cathartics should never be used, as they ma some evidence that sucrose polyester (olestra, a nonabsorbed synthetic c increase excretion of a wide variety of fat-soluble organic chlorine chemi inexpensive and more palatable alternative to cholestyramine to increase increased body burdens from chronic toxicity.

Seizures should be controlled with a benzodiazepine followed by pentobar if necessary, neuromuscular blockade to control the peripheral manifestat

preventing metabolic acidosis and rhabdomyolysis. Phenytoin is much less particularly with the GABA-chloride ionophore antagonists lindane, toxaph , [97] Hyperthermia should be managed aggressively with external cooling.

Cholestyramine should be administered to all patients symptomatic from organic chlorines. Chlordecone undergoes both enterohepatic and enteroe be interrupted by cholestyramine at a dosage of 16 g/d.[22] Cholestyramine of chlordecone 3â€“18-fold in industrial workers exposed during the Hope clinical improvement.[22]

Pyrethrins and Pyrethroids

The pyrethrins are the active extracts from the flower *Chrysanthemum* insecticides are important historically, having been used in China since th developed for commercial application by the 1800s. They are produced b ground Chrysanthemum flowers. The resulting concentrates have greater first pyrethrin identified, consists of 6 esters derived from chrysanthemic insecticides are highly effective contact poisons, and their lipophilic nature penetrate insect chitin (exoskeleton), and paralyze their nervous systems blockade.[20 , 73 , 87 , 109] When applied properly, they have essentially no because of their rapid hydrolysis. Pyrethrins break down rapidly in light a no environmental persistence or bioaccumulation. This fact makes them m must be constantly reapplied.

The pyrethroids are the synthetic derivatives of the natural pyrethrins (Ta They were developed in an effort to produce more environmentally stable pyrethroids were divided into two groups based on the intoxication syndro animals. The T syndrome

(for tremor seen in rats) was produced by intravenous administration of p the pyrethroids that did not contain a cyano group at the central ester lin syndrome (for choreoathetosis and salivation) was produced by 12 of the cyano group at the ester linkage. Pyrethroid Class	Generic Name, CAS #	Brand Names	Generation of

TABLE 110-3. Synthetic Pyrethroids in Common Use

A newer classification scheme was developed that predominates in the lite the structure of the pyrethroid, their clinical manifestations in mammalia on insect nerve preparations and their insecticidal activity. Type I pyrethr the central linkage without a cyano group. Commonly used type I pyreth allethrin, tetramethrin, and fenothrin. The type II pyrethroids have a cyan ester linkage. Type II pyrethroids in common use include cypermethrin, fluvalinate, and fenvalerate. The Î± cyano group greatly enhances neurot in both mammals and insects, and type II agents tend to produce the CS are generally considered more potent and toxic than the type I pyrethroid [106 , 86]

The development of the pyrethroids can be divided into â€œgenerations,â of introduction.[126] The first generation began in 1949, with the developm generation began in 1965, with the introduction of tetramethrin. The majo generation was a dramatic increase in potency compared with the pyreth introduced in the 1970s and including fenvalerate and permethrin, were agricultural use. They were more potent, and more environmentally stabl lasting 4â€“7 days. The current fourth generation includes mostly type II greater insecticidal activity, and environmental stability for nearly 10 day

There are more than 1000 pyrethroids, of which 6â€“10 are in widespread and pyrethroids are found in more than 2000 commercially available prod rapid paralytic effect (â€œknock downâ€•) on insects.

Most mammalian species are relatively resistant, because the pyrethrins c cleavage and oxidation.[80] Toxicity of the pyrethrins and pyrethroids is en

with microsomal enzyme inhibitors such as piperonyl butoxide or *N* -octy

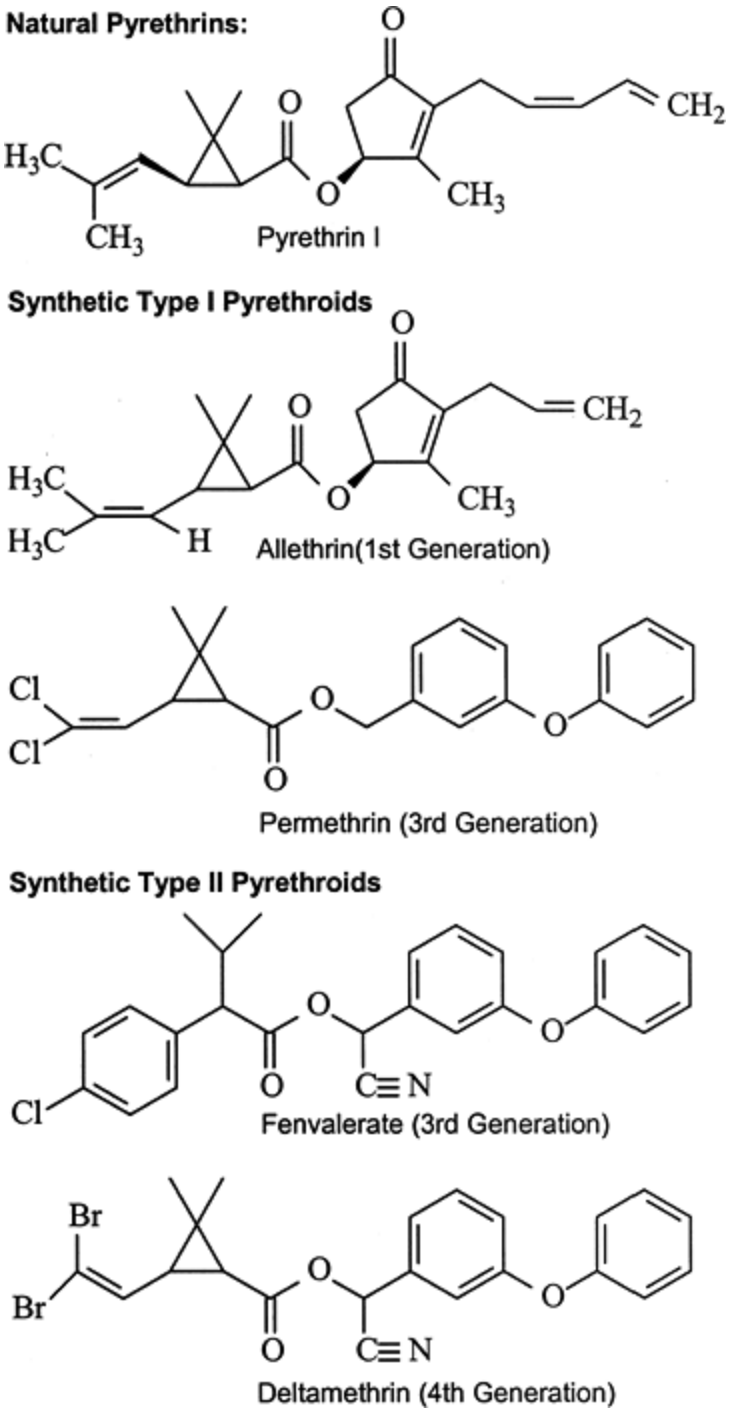

Figure 110-3. Representative structures of pyrethrin and pyrethroids.

Permethrin, a type I pyrethroid, is used medicinally for topical treatment humans, and impregnated in clothing for its insect repellant properties. It with approximately 2% or less absorbed systemically through the skin.[67] have confirmed that 5% permethrin is the drug of choice for scabies trea versus safety profile of topical treatments for scabies and lice.[92 , 125] The resistance to the 1% over-the-counter product, but comparison trials still lindane.[13]

Since West Nile Virus was first identified in the United States in 1999, the most U.S. states. Outbreaks of encephalitis caused by West Nile virus (WI summer and early autumn months annually in New York City since 1999. and transmission to humans occurs via mosquito vectors. Many states ha in an effort to control mosquitoes, the vector of this disease. Most spray insecticides because of their favorable safety profile, and their efficacy ag widespread spraying programs have increased the potential for human ex Centers for Disease Control and Prevention study of pyrethroid spraying d detectable pyrethroid metabolites in the general public living in the spray asthma surveillance showed no increases in emergency department visits conditions for the periods after pyrethroid spraying.[55]

Toxicokinetics

Absorption

The oral toxicity of pyrethrins in mammals is extremely low, because they inactive compounds. Their dermal toxicity is even lower, owing to their s metabolism.[33 , 80]

The pyrethroids are more stable than the natural pyrethrins, and systemi ingestion.[49] Absorption probably also occurs through the oral mucosa, as Chinese insecticide sprayers who frequently used their mouths to clear c exposures are from dermal absorption, the rate of which may vary depen Direct absorption of pyrethroids through the skin to the peripheral senso the facial paresthesias that occur in these cases, as symptoms were prom contact.[19 , 64] The pyrethroids are also absorbed via inhalation; however, sprayers, inhalation was not found to be a clinically significant route of e

zone assays.[19]

Distribution

The pyrethroids and pyrethrins are lipophilic and as such are rapidly distr system.[33] Because they are rapidly metabolized, there is no storage or chronic toxicity.[32]

Metabolism

The pyrethroids are readily metabolized in animals and man by hydrolase dependent microsomal system. The metabolites are of lower toxicity than Piperonyl butoxide, a P-450 inhibitor, enhances the potency of pyrethroid insects. It is often added to insecticide preparations to ensure lethality, a effect of a pyrethroid alone is not always lethal to the insect.[32]

Elimination

There is no evidence that the pyrethroids undergo enterohepatic recircu from the urine of exposed workers within 12 hours, and fenvalerate disap compounds, and metabolites of the pyrethroids, are found in the urine.[87] is used in population-based studies for pesticide exposures. However, a r studies revealed that commonly assayed pyrethroid metabolites also occur natural degradation. These metabolites included 3-phenoxybenzoic acid (of multiple pyrethroids), cis-3-(2,2-dichloroethenyl)-dimethyl cyclopropane metabolite of cis-permethrin, cypermethrin, cyfluthrin], trans-DCCA (met

cypermethrin, cyfluthrin), and 3-(2,2-dibromovinyl)-2,2-dimethyl-cyclopro metabolite of deltamethrin). Therefore the detection of these metabolites i subject's exposure to the parent compound or from its metabolite in the

Pathophysiology

Like DDT, pyrethrins and pyrethroids prolong the activation of the voltag binding to it in the open state, causing a prolonged depolarization[38 , 73 , voltage-sensitive sodium channels is responsible for the insecticidal activity

pyrethroids to nontarget species. Natural pyrethrins and type I synthetic â€œburst dischargesâ€• following a single stimulus, but they have little potential. Type II pyrethroids cause the Na^+ channel to remain open long depolarization of the resting membrane potential.[109, 124] Type II pyrethr lead to significant after-potentials and eventual nerve conduction block. dependent sodium channel, unlike the insect, has many isoforms, and ma resistance in mammalian species. Different pyrethroids have varied effect channels, and the effects are not additive, and in fact may be antagoni is important as well, because some pyrethroid trans isomers at the ester the cis isomers are, and some isomers are insecticidal but lack mammalia isomerism.[105] Pyrethroids also have activity at certain isoforms of the v which may explain the neurotransmitter release that occurs in pyrethroi pyrethroids block voltage-sensitive chloride channels in test animals, prod CS syndrome. These effects may contribute to enhanced CNS toxicity.[105] interference of the type II pyrethroids with the GABA-mediated inhibitory high concentrations.[20, 73] Suppression of the GABA chloride channels like pyrethroid toxicity.[73]

Type I pyrethroids have a negative temperature coefficient, similar to DD to nonâ€“warm-blooded target species. Type II pyrethroids have a positi makes them more insecticidal at higher ambient temperatures.[126] This pr greater mammalian toxicity of type II pyrethroids as compared to type I.

Clinical Manifestations

Pyrethrum probably has an LD_{50} of well over 1 g/kg in man, as extrapola of toxicity associated with the pyrethrins are the result of allergic reactio allergic reactions are patients who are sensitive to ragweed pollen, 50% chrysanthemums (ragweed and chrysanthemum are in the same botanica actually may result from other natural components present in the extract generally do not induce allergic reactions.[12, 80]

In animals, type I pyrethroid poisoning most closely resembles that of DI twitching, increased metabolic rate, and hyperthermia. Excluding the rare allergy, the type I pyrethroids are unlikely to cause systemic toxicity in h are generally more potent, and cause profuse salivation, ataxia, coarse

seizures in animals. In humans, type II pyrethroids cause paresthesias (s effects in sensory nerves), salivation, nausea, vomiting, dizziness, fascic coma, seizures, and acute lung injury.[49 , 64] A review of more than 500 poisoning from China highlights some similar manifestations between a m overdose and an organic phosphorus compound overdose.[49] However, ser has resulted when poisoning from a type II pyrethroid was mistaken for and treatment was directed at these seemingly cholinergic signs.[49] Featur may be because of solvents and surfactants present in the agricultural p pyrethroids contain a cyanide moiety, cyanide poisoning does not occur a not indicated.

Most exposures are dermal, and local symptoms predominate in the majo feature is local paraesthesias in the areas of contact. Ocular contact caus including immediate pain, lacrimation, photophobia, and conjunctivitis.[6]

Treatment

Initial treatment should be directed toward skin decontamination, as mos exposures by this route. Patients with large oral ingestions of a type II p a single standard dose of AC, provided the diluent of the pyrethroid does Contact dermatitis and acute systemic allergic reactions should be treated corticosteroids and Î²-adrenergic agonists as clinically indicated.

Treatment of systemic toxicity is entirely supportive and symptomatic, be Benzodiazepines should be used for tremor and seizures. Topical vitamin especially effective in preventing and treating the cutaneous paresthesias exposures.[25 , 80]

DEET

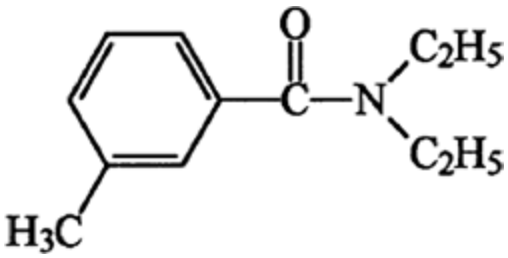

Figure. No Caption Available.

The topical insect repellant, *N* ,*N* -diethyl-3-methylbenzamide (DEET, for *m* -toluamide), was patented by the U.S. Army in 1946, and commercially since 1956. Currently, it is used worldwide by more than 200 million pers that 38% of the U.S. population uses DEET each year. With the spread of 1999, reducing the incidence of mosquito bites has become a public healt of an annoyance arthropod. Mosquito repellants therefore have become im most effective repellant available.[39]

DEET can be purchased without prescription in concentrations ranging from formulations of solutions, creams, lotions, gels, and aerosol sprays. DEET interfering with the chemoreceptors that attract the insects to their hosts

Toxicokinetics

DEET is extensively absorbed via the gastrointestinal tract.[83] Skin absorp the vehicle and the concentration. It does not bind to stratum corneum, a remains in the skin 8 hours after application.[83] DEET is lipophilic, and sk within 2 hours, although it is eliminated from plasma within 4 hours. The in the range of 2.7â€“6.21 L/kg in animal studies. DEET is extensively m hydroxylation by the hepatic microsomal enzymes, primarily by the isozyr 2A6.[121] DEET is excreted in the urine within 12 hours, mainly as metabol as the parent compound.[38 , 83]

Pathophysiology

The exact mechanism of DEET toxicity is unknown. A recent review of ad 26 cases with major morbidity including encephalopathy, ataxia, convuls hypotension, anaphylaxis, or death, particularly after ingestion or dermal [76 , 78 , 117 , 122] These primarily neurologic adverse reactions occurred m involved prolonged use and excessive dosing beyond what is currently re involved a child who was known to be heterozygous for ornithine carban and death was because of a Reye-like syndrome with hyperammonemia.

episodes of hyperammonemia unrelated to DEET use, and DEET does not by, OCT activity in humans.[79] There is currently no evidence that enzyme metabolism or influences individual susceptibility to toxicity.

Although single, large, acute oral doses (1â€“3 g/kg) in rats produced se smaller acute doses (500 mg/kg and less) and chronic multigenerational c produced no obvious toxicity.[101] Teratogenicity studies in rats and rabbits except at the highest doses,[102 , 131] and DEET was not found to be carci of applications, the number of reports of toxicity appears exceedingly sm wide margin of safety.[38 , 45 , 79 , 83]

Clinical Manifestations

Most calls to poison control centers regarding DEET exposures involve mir symptomatic exposures occur primarily when DEET is sprayed in the eyes suicidal ingestions, most serious reactions consist of seizures in children route; in fact, some of these cannot be definitely attributed to DEET.[45 , without treatment and the majority of patients with serious toxicity recov

Treatment

DEET exposures are treated with supportive care aimed at the primarily r dermal exposures skin decontamination should be a priority to prevent f intentional oral ingestions should receive a single dose of AC if clinically

Avoiding the overuse of DEET seems prudent. The American Academy of DEET concentrations of 10% or less for use on children,[104] and most cor for use on children are approximately 5â€“7%. One application lasts 4â€“ reapplication is unnecessary. Soaking the skin is not more effective and r should be applied only to exposed skin. One should avoid abraded skin, o be taken to avoid exposure to eyes and sensitive skin areas. Avoid use or child does not wipe on eyes, mouth, genitalia, and so on. Adults should a and then wipe onto the child's face, rather than spraying onto a child's f most active for a few hours preceding and following dusk, DEET should b skin when protection is no longer needed. Avoid using combination produc DEET, when the repellant component is not needed. Other options for pr

means, such as mosquito netting.

Chapter 111
Herbicides

Rebecca L. Tominack

A 39-year-old 60-kg man came to the emergency department (ED) about 6 hours after intentionally drinking 120 mL of a 41% glyphosate isopropyl amine salt and surfactant herbicide concentrate. He vomited immediately after the ingestion and again after he drank a few sips of water. He complained of a burning mouth, sore throat, and substernal burning chest pain. His vital signs were: blood pressure 110/72 mm Hg; pulse 90 beats/min, respiratory rate 12 breaths/min; and temperature 98.3Â°F (36.8Â°C) and oxygen saturation was 95% on room air. The electrocardiogram showed sinus rhythm without evidence of ischemia. Physical examination was normal except for significant pharyngeal erythema with ulceration and epigastric tenderness. An intravenous line was inserted and volume replacement begun, which was successful in raising blood pressure. Maintenance fluids were then substituted to avoid volume overload. No gastrointestinal decontamination was attempted because of the late presentation. He was transferred to the intensive care unit.

The admission chest radiograph was normal. The only laboratory abnormality was moderate leukocytosis. An upper gastrointestinal endoscopy was performed. The pharynx was edematous and inflamed. There were erythema and superficial ulcerations in the esophagus and stomach. The treatment plan was supportive care for GI tract injury, intravenous H_2 antagonists, and close observation for hypotension, respiratory compromise, and complications of the GI injury. Repeat endoscopy 1 week later showed satisfactory healing of the superficial erosions and ulcers. The patient was discharged on the 9th day after admission.

The term pesticides includes insecticides, herbicides, fungicides, and rodenticides. Herbicides are intended to kill unwanted vegetation or regulate some aspect of the growth cycle of plants. Most of the developed world operates stringent approval and registration systems for herbicides and other pesticides. Because of this intense, ongoing regulatory oversight, herbicides are among the best-studied chemicals in modern society.

History and Epidemiology

In the late 1800s, farmers had few options for weed control. Often there was no attempt to control weeds at all; crop seeds were scattered in a field, nature took its course, and separation of mature weeds from crop was done at the harvest. Smothering weeds before planting by turning the soil with a plow was a standard agricultural practice that only recently is being replaced with an alternative â€œno-tillâ€• practice. In the early 1700s, farmers began sowing seed in rows to facilitate mechanical weed removal after the crop emerged. However, pulling weeds by hand or chopping them with a hoe are prohibitively labor-intensive solutions, particularly for field crops. The first serious attempts to find chemical agents for weed control culminated in the success of Bordeaux mixture (copper sulfate and lime) and Paris Green (copper acetoarsenite) in controlling fungal diseases affecting the French

vineyards. Heavy metal salts such as iron sulfate, copper nitrate, and arsenates and various inorganic chemicals such as borates and chlorates were investigated and found marginally acceptable, primarily to control broadleaf weeds among cereal grain crops on small, intensively cultivated farms. Thus, before the second World War, only a limited number of chemicals were available as herbicides, and these were of relatively low potency, relatively high toxicity to nontarget species, and undesirably persistent in the environment.

In the 1940s, the first herbicidal chemical based specifically on plant physiology was discovered, 2,4-dichlorophenoxyacetic acid (2,4-D). This xenobiotic interferes with growth-regulating compounds called auxins produced by the plant. It was a great success because of its effectiveness against broadleaf weeds in crops, its low cost, higher potency, lower toxicity, and lack of persistent residues. The period since the 1940s has been characterized by the steady introduction of a large number of active herbicide ingredients into the marketplace. Over 200 chemicals are currently registered for use as herbicides in the United States and approximately 500 chemicals in use worldwide; nearly half of these have been introduced in the last 15 years.

In 2001, 1.87 billion pounds of herbicide active ingredients were used worldwide representing 37% of the 5.05 billion pounds of all pesticides used worldwide. In that same year US use of herbicide active ingredients totaled 553 million pounds, or 46% of the 1.2 billion pounds of conventional pesticides used in the United States that year. US herbicide use is currently 5-fold higher than insecticide usage and 8-fold higher than fungicide usage. The largest sector of US use is agriculture, accounting for 78% of total herbicide poundage applied, followed by 13% in home and garden sectors, and 9% in industrial and commercial market sectors. Herbicide use in both agricultural and industrial/commercial sectors has actually decreased over the last 20 years, whereas home usage has nearly doubled over the same time. The highest-use agricultural

herbicides in pounds for 2001 were glyphosate, 88 million pounds; atrazine, 77 million; metolachlor, 41 million; acetochlor, 33 million; and 2,4-D, 31 million pounds. Although the number of

pounds used in the home and garden market, are much smaller, the potential for human exposures is probably greater.[31]

Chemistry

Typical classification schemes organize herbicides by mechanism of action on the plant and subcategorize them by general chemical structure. Herbicides within the same chemical group usually share qualitatively similar toxicologic profiles. About 10% of herbicides have unique structures and are therefore unclassified.

Most contemporary herbicides are organic chemicals, and some of the behavior of a herbicide in plants, animals, and the environment can be predicted from its organic chemistry. Aliphatic chain structures with polar, nonhalogen substitutions (N, O, P, S) tend to be readily degraded in the environment by microbiota. Conversely, aromatic structures, particularly if halogenated, tend to be more difficult to degrade and may persist in the environment. Although some degree of herbicide persistence may be desirable for crops with a long growing season, persistence from one growing season to another or any bioaccumulation is generally undesirable.

Many herbicide structures include an organic acid or other polar groups that can participate in salt formations. The parent acids are often not sufficiently water-soluble for water-based application. Organic salts, often amine, ammonium, sodium, or potassium ionize in water and are more often encountered commercially. Salts are also relatively nonvolatile, which prevents loss to the atmosphere and adds an increased margin of safety against inhalation exposure by the human applicator. In dermal or eye exposure, the primary concern will be local irritation. Allergic contact dermatitis is possible if the formula contains a sensitizing active or adjuvant ingredient or

an ethoxylated surfactant that has formed sensitizing aldehydes and other oxidation products.[30] Because most herbicide active ingredients are water-soluble, their penetration through the skin is usually minimal.

In potential spray exposure, the droplet size generated by the equipment is a primary consideration in evaluating the extent of airborne exposure. Spray equipment and nozzles used in agriculture are intended to deliver relatively large droplets, which fall quickly to minimize spray drift onto nontargeted plants. Generally more than 95% of droplets generated are larger than 100 Âµm and are not considered respirable particles, capable of being retained by the lung.[19] Most particles over 10 Âµm are filtered out by impacting in the nasopharynx and large airways. However, during heavy, prolonged, or overhead spraying, sufficient numbers of large mist droplets can enter the nose and mouth and may result in symptoms such as bad taste and irritated nose and throat. These symptoms are usually self-limiting.

Ingestion of most herbicides that have been diluted with water for use is unlikely to cause severe toxicity, even in relatively large quantity, although notable exceptions include paraquat and diquat. Because most active ingredients based on plant physiology show a reduced level of toxicity to mammals, the toxicity of any particular formulation may not be related to the active ingredient. Instead, the surfactants and other adjuvants may pose the higher risk of toxic effect. Ingestion of concentrated formulations that carry high loads of active ingredient, solvent, surfactant, and other adjuvants may result in significant toxicity that may be life-threatening. Local and systemic surfactant effects must be anticipated and any target organ damage inherent to the active ingredient.

Because of the nature of the commercial herbicide industry, active ingredients and different salts are introduced, combined in a nearly endless series of product formulations and names, and then withdrawn from the market. Formulations also vary by country. Risk

of toxicity depends on the amount and concentration of active ingredient and formulation adjuvants in the preparation to which the patient was actually exposed. Once a concentrated product is diluted with water for use, the label and safety data sheet information likely overstate the hazard of exposure.

Glyphosate

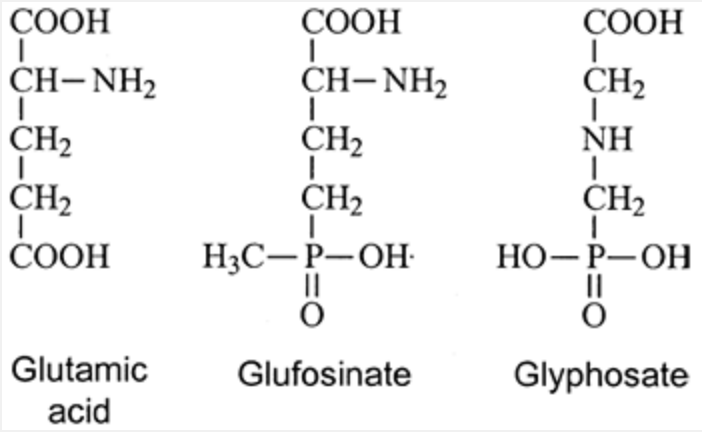

Figure. No Caption Available.

Glyphosate is the classic example of an active ingredient of low human toxicity that is formulated and sold with other, more toxic ingredients that are primarily responsible for the acute health effects. In serious exposures such as intentional ingestions, the healthcare provider tends to ascribe the toxic effects to the active ingredient. This assumption is generally applicable to other types of pesticides such as insecticides and rodenticides whose active ingredients are quite toxic to humans because they affect specific targets in insects or rodents which are present and affected in humans also. Glyphosate targets synthesis of chlorophyll-related molecules in plants, and has no target in humans. Human toxicity of glyphosate formulations is not dependent on the glyphosate content

primarily, but on the type and concentration of the surfactant, the preservative, the salt partner of glyphosate, and other adjuvants.

Large volume ingestions of the original glyphosate formulation concentrate (41% isopropyl amine salt of glyphosate, 15% polyethoxylated tallow amine surfactant, and water) were characterized by risk of severe irritant damage to GI mucosa, shock, and acute lung injury with 7â€“15% mortality. This is likely systemic surfactant toxicity. Although formulations are in constant flux regarding adjuvants, the need for some sort of surfactant or surfactant system remains a constant. Therefore, the basic toxic effects of significant acute exposure to concentrated formulations will likely be similar, but with somewhat unpredictable changes in dose-response relationship and timing of onset.

Characteristics

Glyphosate [*N*-(Phosphonomethyl)glycine] has been commercially available nearly 35 years and is now the most common herbicide in US and worldwide agriculture.[28,41] A related chemical is glyphosine [*N*,*N*-Bis(phosphonomethyl)glycine], which is a dimer of glyphosate used a plant growth regulator.

Glyphosate is a â€œpostemergentâ€• herbicide that is applied after the plant has emerged from the soil and is nonselective in its action,

killing any green plant. It inhibits the enzyme 5-enolpyruval shikimic acid 3-phosphate (EPSP) synthetase, which is important in the biosynthesis of aromatic amino acids. The lethal effects in the plant can be reversed by supplying L-phenylalanine and L-tyrosine.

There is no equivalent enzyme in animal systems; thus, this is the mechanism of its selective toxicity to plants and relative lack of effect in animals. Additionally, it has limited activity as a nonspecific metal chelator, an effect that does not appear important

clinically.

Current Use and Formulations

Glyphosate is registered for use in over 130 countries. The original glyphosate formulation concentrate (Roundup Herbicide, Monsanto) contained the isopropyl amine salt of glyphosate (41% w/v), a polyethoxylated tallow amine surfactant (15.4% w/v), and water. Glyphosate is now available as a generic ingredient, and there are thousands of products containing it marketed under various names by many large and small companies worldwide. There are many differences among the products in addition to differences in glyphosate concentration. Most products contain the original isopropyl amine salt, but some contain the mono-ammonium, di-ammonium, sodium sesqui-, potassium, trimethyl sulfonium (trimesium) or other salts of glyphosate, some of which appear to have different toxicity. Some products are dry formulations; some contain different surfactant systems, or greater or lesser amounts of total surfactant, or no surfactant at all. Glyphosate is also sold in combination with other herbicide active ingredients including diquat, various chlorophenoxy compounds, simazine, linuron, and picloram or with a fertilizer to boost plant growth, which enhances plant lethality. These variations affect the risks of exposure and complicate assessment of the effects of an exposure on a particular patient, and hinder application of published clinical literature to new exposure cases.

Mechanism of Toxicity of Glyphosate and Formulations

The glyphosate molecule itself has a relatively favorable acute toxicity profile in animals. Its acute oral toxicity is relatively low (rat oral LD_{50} = 5600 mg/kg), as is its systemic toxicity from dermal exposure. It is not a contact sensitizer. It is noncarcinogenic

(US EPA category E), nonmutagenic, and devoid of developmental toxicity. There is no serious chronic toxicity in 2-year animal feeding studies. Because glyphosate is used commercially in salt form, and with various surfactants and other adjuvants, the acute toxicity profile of the particular formulation is more important than the profile of glyphosate alone. An animal oral LD_{50} can be obtained from the material safety data sheet (MSDS) of every formulation registered in the United States, and should be compared with the oral LD_{50} of the original glyphosate formulation. This comparative toxicity measure will permit an estimate of the dose-response range of the formulation in question compared to the formulation represented in the published literature.

Because of the selective toxicity of glyphosate to plant life and corresponding low mammalian toxicity, as contrasted with the formulation adjuvants, the surfactant is suspected to be the primary culprit of the toxic syndrome described in large series of ingestions of concentrated glyphosate formulation (<41% isopropyl amine salt and â‰¥15% polyethoxylated tallow amine surfactant). The relative contribution of the surfactant, the glyphosate, and its salt to the toxic syndrome remains controversial. Many of the clinical features identified in glyphosate-surfactant poisonings occur regularly with reported cases of large-volume ingestion of herbicide concentrates irrespective of the active ingredient. The common factor is the presence of surfactant. This is observational evidence that a systemic surfactant syndrome accompanies many serious herbicide ingestion poisonings and is a primary determinant of the toxic symptoms in the early phase of acute poisoning.[71] Although the original surfactant paired with glyphosate is described as nonionic, its tertiary nitrogen is largely protonated at physiologic pH, and it clinically produces effects more traditionally associated with a cationic surfactant. Clinical descriptions of ingestion of benzalkonium chloride, a quaternary ammonium cationic surfactant, share striking similarities with those of the tallow amine-containing original brand name formulation.[16] These include superficial

necrosis of mucous membranes, severe GI tract irritation with erosions, glottic edema, acute lung injury, profound hypotension, oliguria, renal failure, and cardiovascular collapse.

An in vivo intravenous study in dogs confirmed the role of surfactant in causing hypotension through myocardial depression at exposure levels comparable to human poisonings.[69] It compared the cardiovascular physiologic effects of infusions of equivalent doses of isopropyl amine glyphosate alone, polyethoxylated tallow amine surfactant alone, or the two combined as in the formulated herbicide. The endpoint of infusion was a 50% fall in mean arterial pressure. Both the surfactant alone and the combination reduced mean arterial pressure, heart rate, cardiac output, and left ventricular stroke work index and elevated peripheral vascular resistance, whereas the glyphosate infused alone did not. These findings suggest that the hypotension produced was primarily related to myocardial depression and was caused by surfactant.

It is theoretically possible that isopropyl amine itself may exhibit cardiac or other actions. It represents 30% by weight of the isopropyl amine salt of glyphosate, is used as an emulsifying agent and wax remover, and has a rat oral LD_{50} of 820 mg/kg.

Issues of relative contribution of various formulation ingredients to the clinical effects have not been fully investigated and current understanding remains limited. Soon after the first large series of cases of suicidal ingestions was published, the amount of surfactant in the original brand name formulation sold in the United States was significantly reduced; thus, the published literature probably overstated the toxic potential to humans who might have ingested this revised formula. The myriad of different glyphosate formulations currently sold as options to the original formulation share this tenuous connection to the literature. Publications based on a particular archaic glyphosate formulation are becoming irrelevant to contemporary clinical information needs on glyphosate because the marketed formulations continue to change and

diversify. However, as clinical descriptions of agrochemical surfactant poisonings, the literature will have enduring applicability.

The moderate skin irritation of the original brand name formulation is caused by the polyethoxylated tallow amine surfactant. One hundred percent surfactant solution is corrosive to skin in animal tests, and progressively less irritating as the concentration is lowered. Similarly, as the surfactant content is progressively reduced in the concentrated formulation or by dilution of the concentrate in preparation for use, the potential for irritation declines.

Toxicokinetics

Absorption

Glyphosate kinetics and metabolic fate have been extensively characterized in animals, and human clinical data appear

to follow the same general patterns. Approximately 20â€“30% is absorbed orally, and there is evidence of an enhanced absorption ratio at higher doses.

Dermal absorption of glyphosate is poor, less than 2.5%. Water or soap and water washing removes glyphosate from skin; 50% can still be removed by washing delayed 24 hours after exposure.

Elimination

Glyphosate is not metabolized in mammalian systems but a minor metabolite, amino methyl phosphonic acid, may be detected in amounts â‰¤0.5% of glyphosate. It is theorized to originate from colonic bacterial metabolism. Glyphosate is rapidly excreted unchanged in the urine. Experience in human poisoning suggests an elimination half-life from the blood of 2â€“3 hours, assuming renal function is normal. Half-life becomes prolonged as renal function

progressively deteriorates. The absorption, distribution, and disposition of the polyethoxylated tallow amine or other surfactants are not known. They are generally composed of related assortments of large molecules that are unlikely to be well-absorbed intact from the normal gut, with possibly increased absorption occurring after it damages the mucosal surface.

Clinical Manifestations

The range of clinical effects produced by ingestion of the original glyphosate formulation include irritation, edema, and erosions of the oropharynx and GI tract; nausea, vomiting, diarrhea, and midchest and abdominal pain; leukocytosis, metabolic acidosis, elevated salivary amylase, tachypnea, hypoxia, acute lung injury, and volume-responsive hypotension followed by cardiovascular hypotension unresponsive to fluids and pressor amines. Secondary organ dysfunction may occur in the CNS, liver, and kidneys. Aspiration pneumonitis is a potential complication. Fatality rates in the large published series of large volume ingestions of formulations with high concentrations of glyphosate and surfactant range from 7.5 to 16%. Those who ingest large volumes of highly concentrated herbicide (>200 mL of 41% glyphosate isopropylamine and â‰¥15% surfactant) and those developing acute lung injury or cardiogenic shock are at more risk of a fatal outcome. Endoscopic evaluation shows esophageal injury and gastric injury in 70% of patients, and duodenal injury in fewer than 20%. Laryngoscopy shows significant laryngeal injury in the majority of patients, and this correlates with longer hospital stay and risk of aspiration pneumonitis.[27]

Oral and gastrointestinal irritation (burning of mouth and throat, vomiting, abdominal pain) develop rapidly after ingestion. Hypotension may develop within hours of very large ingestions. Some patients may appear to be relatively stable for the first 8â€“12 hours and then develop hypotension and respiratory

distress.

Recent case reports of ingestion of the trimesium salt describe dramatically accelerated fatality, and the reason is not clear. A 6-year-old who unintentionally drank a mouthful of glyphosate-trimesium died within minutes. An adult who ingested 150 mL intentionally also collapsed and died rapidly. Autopsy findings in the child included severe irritation of the gastrointestinal tract and airways, acute lung injury, cerebral edema, and dilated right atrium and ventricle; and in the adult included irritant injury of the pharynx, esophagus, and duodenum and acute lung injury.[65] Obviously it is important to recognize this particular herbicide in a clinical setting. The common name by which this herbicide is described is in flux. It may appear as glyphosate-trimesium, â€œsulfonate,â€• trimethyl sulfonium glyphosate, trimesium salt of glyphosate, and â€œsulfonium, trimethyl-salt with *N*-(phosphonomethyl)glycine (1:1).â€• The latter is the current US EPA nomenclature.

It is difficult to correlate ingested amount with severity of clinical effect because of the unmeasured loss through vomiting. However, in general, severity follows a dose-related trend. In one large series, there were 11 fatalities among 41 cases (27%) of patients who ingested an estimated 150 mL or more of concentrated formulation (41% isopropyl amine glyphosate, â‰¥15% surfactant) but none among 51 who ingested <150 mL.[75] In another large series, an average ingestion of 17 Â± 16 mL (range 5â€“50 mL) produced no symptoms; 58 Â± 52 mL (5â€“150 mL), mild symptoms; 128 Â± 114 mL (20â€–500 mL), moderate symptoms; and 184 Â± 70 mL (85â€–200 mL), severe symptoms or death.[59] Risk of death appears to be higher in older patients.

Once diluted for use to glyphosate concentrations around 1% and surfactant concentration around 0.4%, the various glyphosate formulations offer little risk of adverse effects except temporary, minor eye, membrane, or skin irritation, and systemic effect after

ingestion. Some dry formulations may contain sodium sulfite, which could cause bronchospasm in sulfite-sensitive patients. Allergic contact dermatitis is possible if a sensitizing preservative such as 3-iodo-2-propanyl butyl carbamate or a benzisothiazolone is contained in the particular formulation. The latter preservatives are also phototoxic. Additionally, ethoxylated surfactants undergo decomposition with time to release a variety of aldehydes including formaldehyde. This is known to be a potent contact sensitizer and may account for many skin rashes previously judged to be unrelated to glyphosate herbicide formulations.[69]

Laboratory

In some fatal cases serum glyphosate levels have been reported to exceed 3000 mg/L, although many are significantly lower.[69] However, serum levels are not useful clinically in assessing the severity of exposure or poisoning. Furthermore, glyphosate levels are not readily available. Surfactant analysis is not feasible because the surfactant itself is a complicated mixture of compounds, which vary by carbon-chain size and ethoxy chain size. Patient status can be assessed by determinations of oxygenation status, renal and hepatic function, electrolytes, and acidâ€“base balance. Leukocytosis and increased serum amylase and lipase may be noted. The chest radiograph may be normal or show evidence of acute lung injury or aspiration. The electrocardiogram shows no abnormalities specific to the ingestion but may document possible abnormalities in patients with severe cardiorespiratory compromise.

Treatment

Gastric Decontamination

Ingestion of less than 2 mouthfuls of concentrated herbicide in an adult is unlikely to cause serious illness, and ingestions of nearly any amount of dilute (<2% glyphosate) solution are inconsequential

other than risk of bad taste, nausea, and perhaps vomiting. After significant ingestions of herbicide concentrate, spontaneous vomiting usually occurs rapidly and obviates the need for the induction of emesis or lavage. The potential risk to the patient who may have suffered severe mucosal damage to the esophagus and stomach and the timing of the procedure relative to ingestion must be considered before lavage is attempted.

Activated charcoal (AC) apparently adsorbs the principal toxic component in formulated herbicide, whether it be glyphosate, the surfactant or both. Pretreatment of rats with activated charcoal

before administration of an LD_{100} oral dose of the original glyphosate formulation or an equivalent dose of surfactant prevents mortality. Likewise, in vitro mixing of either with activated charcoal and administration of the supernatant is not lethal. This suggests that the primary toxic component is adsorbed by AC and that it is probably the surfactant. The binding characteristics of glyphosate and AC are unknown.

Extracorporeal Removal

Hemodialysis is effective in removing glyphosate from blood. AC hemoperfusion of cow blood in an in vitro system failed to remove glyphosate.[59] It is not expected that hemodialysis would remove surfactant because of its large molecular size. Because of the rapid elimination of glyphosate by normal kidneys and its uncertain role in the toxic syndrome, there is no proven benefit to accelerating glyphosate removal by hemodialysis. This should be reserved for renal indications. Although, theoretically, hemoperfusion may remove surfactant, this has not been proven experimentally or in patients, largely because the surfactant composition does not permit analysis. Additionally, improved clinical outcome has not been demonstrated for hemoperfusion; therefore, this technique cannot be recommended.

Supportive Care

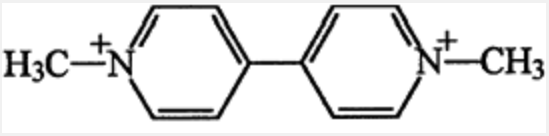
There are no specific therapies or antidotal measures for glyphosate-surfactant poisoning. Fluids and electrolytes should be administered IV in sufficient volume to replace GI tract losses and maintain high normal urine output and normal hemodynamics. However, in severe poisoning, hypotension from cardiovascular compromise may supervene; fluid overload may precipitate or worsen hypoxemia and respiratory distress. In such cases, hemodynamic monitoring may be necessary to optimize management.

Hypoxemia occurs frequently even in the absence of abnormal chest radiograph and should be monitored and corrected; patients should be endotracheally intubated and mechanically ventilated if necessary.

Prognosis

Fatalities generally occur in the first 2 days after ingestion, and possibly very rapidly when sulfonium, trimethyl-salt with N-(phosphonomethyl)glycine (1:1) is involved. Development of respiratory distress severe enough to require intubation, renal failure severe enough to require dialysis, and shock are poor prognostic signs.[42] In survivors recovery is complete.

Paraquat



Paraquat

Paraquat is the classic example of a herbicide that is safe when used as directed on plants but is capable of extreme toxicity when misused. Because of its low cost, rapid action, and favorable environmental characteristics, paraquat remains a widely used herbicide throughout the world. The combination of ready availability and severe toxicity results in continued appearance of serious and fatal poisonings, many with suicidal intent. Paraquat induces pulmonary fibrosis mediated by free radicals; once initiated, even heroic medical interventions cannot save a the patient. Poor worker-protection practices are also problematic in subacute and chronic toxicity.

Characteristics

Paraquat (1,1â€²-dimethyl-4,4â€²-bipyridylium dichloride, CAS 1910â€“42â€“5) is a growth regulator primarily used on field crops, fruit and nut crops, and nonagricultural areas such as airports, commercial buildings, and storage yards. It rapidly damages and kills plants on contact by intercepting electrons moving through photo system I, the photosynthesis pathway in plants that

generates reducing equivalents. In the presence of light, paraquat generates reactive oxygen radicals including hydrogen peroxide that disrupt cell membrane integrity. The above-ground portion of the plant collapses rapidly (â€œburn down,â€•) although regrowth can occur from the roots of perennials. It is rapidly inactivated by adsorption to soil.

Paraquat dichloride is marketed most commonly as an aqueous solution concentrate containing 200 g paraquat dichloride/L (20% w/v), sometimes in combination with diquat or other herbicides. In the United States, paraquat is registered as a restricted use pesticide available in concentrations from 23â€“43.5% dichloride salt. Spray dilutions are typically in the range of 1â€“5 g/L (0.1 to 0.5% w/v). The aqueous concentrates also contain appropriate adjuvant agents as described above and sometimes deterrent adjuvants to prevent or mitigate unintentional ingestion. If no blue dye is added, the concentrate is colored dark brown like cola, for which it can be mistaken, especially if decanted into a soft drink bottle.

Epidemiology

Most cases of paraquat poisoning result from the deliberate ingestion of one of the liquid formulations containing 20â€“40% paraquat. Thousands of deaths have been reported since paraquat was first marketed in 1962, mostly in adults with intentional ingestions. Unintentional ingestions can occur, particularly when the product has been handled or stored incorrectly. Death has also been reported from homicidal use, massive dermal exposure, intravenous administration, and prolonged occupational spraying. Suicidal ingestion of paraquat has been a particular problem in some countries. Measures taken by the manufacturer and by regulatory agencies have curbed the incidence of unintentional ingestions and reduced the mortality rate. These measures include marketing thickened or gel formulations with reduced paraquat concentration,

capping the maximum concentration allowed in commerce and for spray application, placing restrictions on open sale and availability, designing improved product labeling, providing education programs discussing correct use, using marker blue dyes, adding pyridine stenchants to make the product smell bad and taste worse, and including emetics in the formulations. In the 4-year period immediately after the 1988 institution of the color change from brown to blue and the addition of both a stenchant and an emetic to paraquat formulations in the United States, there was a nearly 50% decline in the proportion of all pesticide exposures represented by paraquat ingestion compared with the number of cases in the four years preceding these changes in the formulation. This indicates that such measures indeed have an impact on unintentional exposures. However, they are unlikely to influence those truly intent on suicide.

Toxicokinetics

Absorption

Splash or diluted spray mist exposure to skin, eyes, and upper airways leads to minimal systemic absorption despite

the risk of local tissue damage. Repeated or continuous dermal contact, especially with a concentrated solution, may lead to some absorption into the bloodstream if the integrity of the stratum corneum is impaired.[2] Dermal exposure to burned skin and chronic occupational exposure are reported to have resulted in sufficient paraquat absorption to cause death. Following ingestion, systemic absorption of paraquat is rapid but incomplete (<30% of the dose). Absorption occurs predominantly from the small intestine and is facilitated by active transport of the herbicide across the mucosal cells. If the GI mucosa is compromised, the percentage absorbed is likely to be higher because of additional absorption by passive

diffusion. Peak plasma concentrations of paraquat generally occur within 2 hours after ingestion. Paraquat's volume of distribution is about 1â€“2 L/kg. It distributes rapidly to most tissues, with highest concentrations in the kidneys and the lungs. Higher renal concentrations reflect the role of the kidney in the elimination of paraquat. The high concentrations in the lung result from time- and energy-dependent uptake of paraquat by type I and II alveolar epithelial cells via the polyamine uptake pathway. The uptake results from the structural similarity between paraquat and endogenous diamines and polyamines such as putrescine and spermidine. These are taken up actively into the lung by a membrane transport system[15] that has specificity for molecules with two positively charged quaternary nitrogen atoms separated by a distance of approximately 0.6â€“0.7 nm (Figure 111-1).

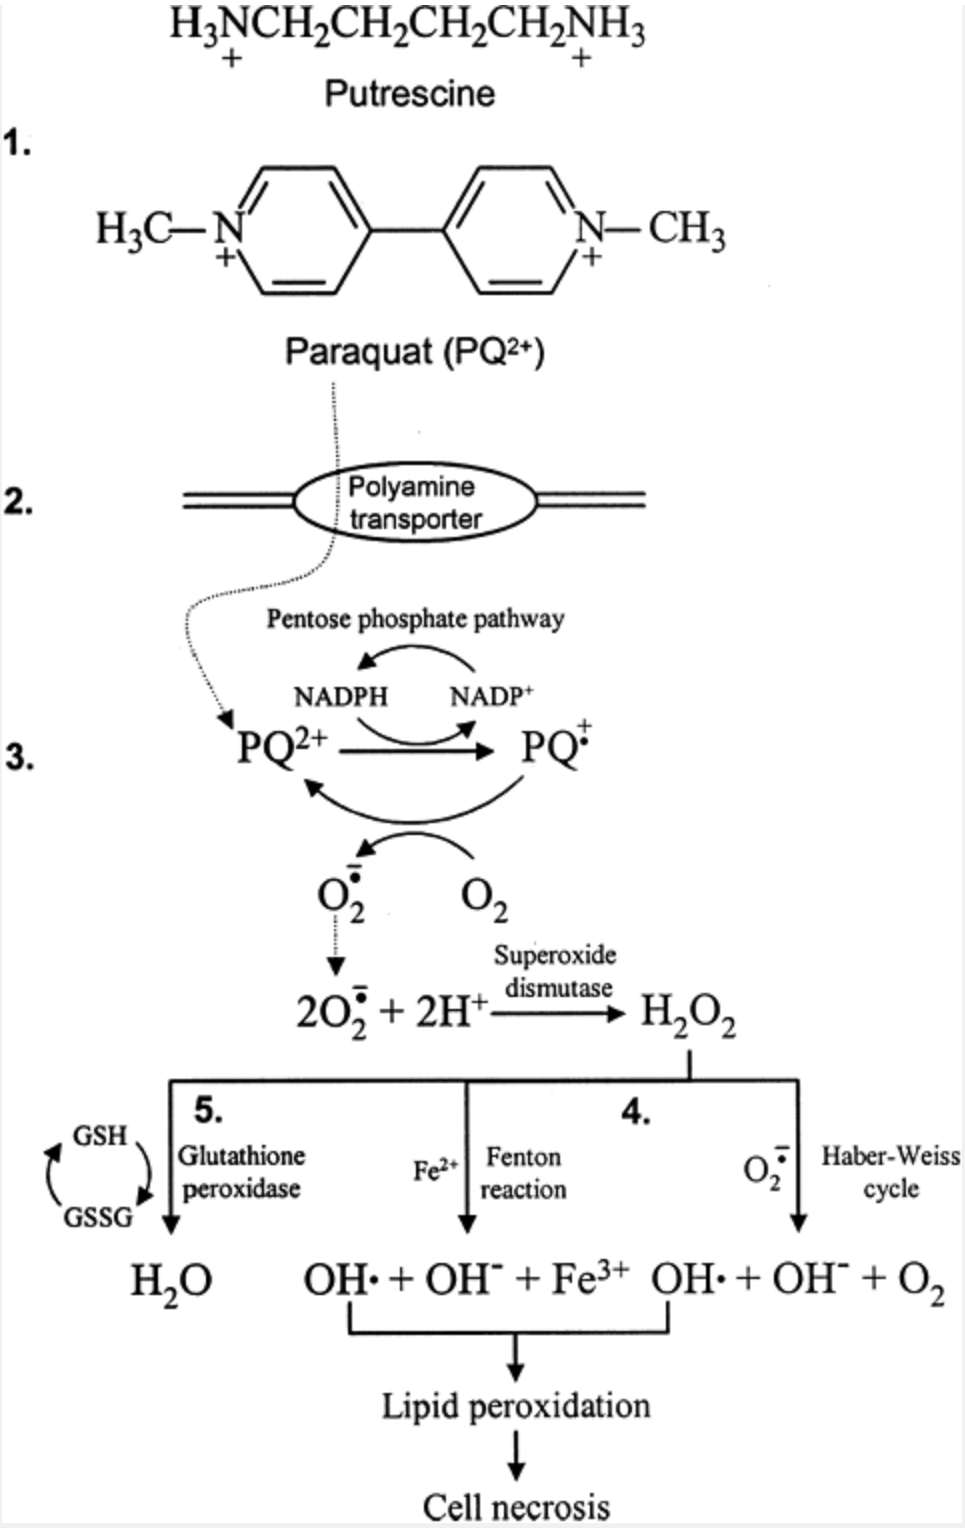


Figure 111-1. Mechanisms of toxicity of paraquat in the type II

alveolar epithelial cell. 1. Structure of paraquat and putrescine, showing the distance between the 2 nitrogen atoms of each. 2. Putative receptor responsible for the active uptake of paraquat by the alveolar epithelial cells. 3. Redox cycling of paraquat and oxygen. 4. Formation of the OHâ€¢ radical. 5. Detoxification of hydrogen peroxide (H_2O_2). *(Reprinted, with permission, from Smith LL: Mechanism of paraquat toxicity in lung and its relevance to treatment. Hum Toxicol 1987;6:31â€“36).*

Elimination

More than 90% of the absorbed dose of paraquat is eliminated by the kidneys as the parent compound within the first 12â€“24 hours after the ingestion. Even in patients who have ingested a toxic dose, renal function and paraquat clearance remain unaffected for several hours. When renal function is normal, the renal clearance of paraquat is higher than that of creatinine because of net tubular secretion of the molecule. As renal function deteriorates as a result of the poisoning, clearance of paraquat falls concurrently, and the half-life becomes prolonged, from about 12 hours to more than 24 hours. Redistribution from lung and muscle into the bloodstream is slow, with a half-life of about 24 hours, and accounts for the detection of low concentrations of paraquat in the urine for several days after the ingestion.

Mechanism

Paraquat produces tissue damage in the mouth and upper GI tract. Damage to organs such as kidney, heart, liver, pancreas, and muscle is assumed to be related to redox cycling and oxygen toxicity, but this has not been proven. The mechanism of toxicity has been determined most clearly in the lung when it is exposed to lower concentrations consistent with an ingested dose of 20–40 mg cation/kg (equivalent to 27–54 mg/kg of the dichloride salt found in 10–20 mL of the 20% concentrate). Once actively transported inside the pneumocyte, paraquat is reduced by an nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reaction to the mono-cation radical ($PQ^{+\bullet}$; Figure 111–1). This radical spontaneously reacts with molecular oxygen to form a superoxide radical ($O_2^{-\bullet}$) and regenerating the original paraquat dication, which now can undergo the reduction–oxidation cycle again. The nearly inexhaustible supply of electrons and oxygen in the lung sustain this redox cycling. It is further augmented over time by an increasing supply of paraquat molecules as they are accumulated from the blood against a concentration gradient and sequestered in the lung.

The recycling participation of paraquat in activating molecular oxygen explains why oxygen enhances the toxicity of paraquat and paraquat enhances the toxicity of oxygen. Like many superoxide radicals initially formed in the reaction of oxygen with PQ^+, paraquat can transfer its free electrons, forming other free radicals and resulting in chain reactions that are very damaging to cellular structures. For example, two superoxide radicals can be catalyzed by superoxide dismutase to hydrogen peroxide (H_2O_2), which in turn can be detoxified by catalases or peroxidases to nontoxic water molecules. On the other hand, in the presence of iron both the initial superoxide and hydrogen peroxide can also be catalyzed to yield the potent hydroxyl radical (•OH), which is thought to be the ultimate toxic free radical species derived from paraquat. The OH• generates additional free radicals by interacting with biomolecules such as proteins or membrane fatty acids. For example, OH• can take a hydrogen atom from polyunsaturated fatty acids, forming a lipid radical and subsequently lipid peroxides or hydroperoxide. These in turn pass on the free electron to other lipids, and a chain reaction of lipid damage occurs. This process, known as lipid peroxidation, leads to degradation of cell membranes. The reactive oxygen species formed by the initial interaction with $PQ^{\ddagger}$ interact with molecular sites on DNA, proteins, and cell membranes, disrupt cellular functions, and cause cell death. Cascading free radical production explains why the cellular injury from paraquat and other free radical generators far exceeds that produced by the initial reaction products.

NADPH is consumed during the initial reduction of paraquat to $PQ^{\ddagger}$ and by the glutathione peroxidase and reductase enzyme systems as they detoxify the superoxide radicals and their products. In response, the pentose phosphate and fatty acid synthesis pathways are activated to regenerate NADPH. Restoration of NADPH cellular reducing equivalents promotes the continuous redox reaction involving paraquat and oxygen and thus the continuous generation of more toxic oxygen species.

Antioxidant systems, such as the enzymes superoxide dismutase, catalase, and glutathione peroxidase and vitamins C and E, cannot respond in the same way, and so their capacity to extinguish the runaway free radical chain reaction is limited. This imbalance explains why the doseâ€“response curve for paraquat toxicity is very steep. Once a threshold dose is attained that begins to overwhelm the antioxidant defense system and damage cells, it requires very little increase in dose to attain the maximum toxic effect in a test population.

Clinical Manifestations

The clinical features of paraquat poisoning are summarized in Table 111-1. Ocular exposure causes gradually developing irritation that reaches a maximum about 12â€“24 hours after exposure as a result of stripping of the superficial epithelium of the cornea and conjunctiva. The severity of the injury is directly proportional to the concentration of the formulation. Dermatitis and nail damage can follow dermal contact with paraquat, particularly if it is not washed off quickly. The nails can become deformed by white bands, ridging, disruption of the nail bed, and impaired growth. Spray mist droplets impacting on the upper respiratory tract mucosa can produce inflammation, epistaxis, cough, and chest pain.

The severity and course of paraquat ingestion poisoning can be divided into three categories that broadly reflect dose-response.[76] Mild-moderate poisoning usually results from an ingestion of 10 mL

or less of 20% paraquat dichloride concentrate in a 70-kg person, equivalent to 20 mg paraquat cation/kg or 28.6 mg paraquat dichloride salt/kg. The possible effects include none/asymptomatic, oral mucosal ulceration, nausea and vomiting, and transient impairment of renal, hepatic or respiratory function. Recovery is expected and is complete.

TABLE 111-1. Clinical Features of Paraquat Poisoning by Organ System

Cardiovascular Hypovolemia, shock, dysrhythmias Central nervous Coma, convulsions, cerebral edema Dermatologic Corrosion of skin, nails, cornea, conjunctiva, and nasal mucosa Endocrine Adrenal insufficiency caused by adrenal necrosis as part of multiple organ failure Gastrointestinal Oropharyngeal ulceration and corrosion; nausea, vomiting, hematemesis, diarrhea, dysphagia,	Genitourinary Oliguric or nonoliguric renal failure caused by acute tubular necrosis; proximal tubular dysfunction Hematopoietic Leukocytosis early, anemia late Respiratory Cough, aphonia, prominent pharyngeal membranes (pseudodiphtheria), mediastinitis, pneumothorax, hemoptysis, acute lung injury, hemorrhage, pulmonary fibrosis

perforation of esophagus, pancreatitis, centrilobular hepatic necrosis, cholestasis	

Moderate-severe poisoning occurs in patients who ingest between 20 and 40 mg paraquat cation/kg (10â€“20 mL of the 20% concentrate in a 70-kg person). They characteristically exhibit early development of upper GI tract corrosion, acute renal tubular necrosis and hepatic injury. CNS involvement may appear as headache, dizziness, drowsiness, and incoordination, and as respiratory failure and coma if severe. Patchy infiltrates may appear on chest radiograph. Patients generally survive the acute phase and experience delayed but progressive pulmonary inflammation, fibrosis, and profound hypoxemia, which is the cause of death. Mortality occurs 5 days to several weeks after the ingestion. The proliferative lesion may not become evident until a week or more after the ingestion. However, cellular damage from free radicals begins immediately and initiates the destructive phase characterized by loss of both type I and II alveolar cells and of surfactant, infiltration by inflammatory cells, and hemorrhage. Hemorrhagic acute lung injury may occur. The subsequent proliferative phase is characterized by loss of alveolar integrity, proliferation of fibroblasts, and deposition of collagen in the interstitium and alveolar spaces. The fibrosis, which is in part cytokine mediated, is not specific for paraquat-induced injury but is seen in response to acute alveolitis induced by many pulmonary toxins. Survival is possible but residual restrictive lung disease may be a long-term sequelae.

A fulminant course of poisoning occurs in patients who ingest more than 40 mg paraquat cation/kg (>20 mL of 20% concentrate in a 70-kg person.) They do not survive long enough to demonstrate pulmonary fibrosis. Patients exhibit severe vomiting and diarrhea,

oropharyngeal and gastrointestinal ulceration, renal and hepatic failure, acute pulmonary injury and alveolitis, cardiac dysrhythmias, shock, and coma. They usually die within 1â€“4 days after ingestion from multiorgan failure, shock, or corrosive destruction of the GI tract. Death from esophageal perforation and mediastinitis can occur within 2â€“3 days of the ingestion.

The diagnosis can be missed if paraquat ingestion is unsuspected. Sudden appearance of rapidly progressive pulmonary fibrosis in the 2 weeks following an illness characterized by oral ulceration and upper GI symptoms must include surreptitious paraquat ingestion in the differential diagnosis.

Diagnostic Testing

Urine and plasma should be sent to the laboratory promptly for qualitative and, if available, quantitative determination of paraquat concentrations. If possible, specimens should be placed in plastic containers because paraquat binds to glass. Rapid, qualitative analysis in urine is performed by reducing paraquat to its blue mono-cation radical with sodium dithionite under alkaline conditions and comparing the result with appropriate positive and negative controls. A fresh alkaline sodium dithionite solution is made by adding 100 mg of sodium dithionite (nonoxidized) to 5 mL of 5 M NaOH. An aliquot sample (250 ÂµL) of this solution is added to 1 mL urine. If paraquat is present in a concentration of 2 Âµg/mL or greater, a concentration-dependent blue to black color is evident. Diquat is reduced similarly to form a yellow-green color.

Plasma or urine paraquat concentrations can be measured quantitatively by a variety of techniques, the most common being radioimmunoassay, gas chromatography, spectroscopy, and high-performance liquid chromatography. It is usually relatively easy to identify a laboratory that can perform the spot test but more difficult to find one to do the quantitative measurements. Many

manufacturers support a 24-hour emergency service that should provide this information for each country. The telephone number for the service in countries in which it is available can be found either on the product label or via a poison center or other emergency facility. In many areas, quantitative assay results are not available in a timely manner to assist with management of the patient. In this case, the management must be guided by the clinical and other laboratory findings. Clinical chemistry abnormalities reflect the developing necrosis of the renal tubules, liver, lung, pancreas, and muscle.[68] Hematologic abnormalities, if any, are usually nonspecific and related to bleeding, infection, or stress. If paraquat concentrations in blood exceed about 10 mg/L, measured values of creatinine and lactic acid dehydrogenase (LDH) may be elevated artificially because of interference with the colorimetric methods used to measure them.[11]

Tissue destruction of the esophagus and mediastinum can be associated with pneumomediastinum and pneumothorax. Typically the resultant changes in the lung parenchyma are obvious on the chest radiograph, first as cystic and linear opacities and later as consolidation, particularly in the perihilar regions. Figure 111-2 shows a chest radiograph, taken on the ninth day after the ingestion of paraquat in a patient who died 3 days later. It shows diffuse consolidation most marked in the perihilar regions.

Management

Early treatment is a very important determinant of survival in paraquat-poisoned patients. The â€œwindow of opportunityâ€• for any effective treatment of paraquat poisoning is very short, only a few hours at most. Therefore, any patient who has been exposed to paraquat, particularly if a concentrated liquid formulation is involved, should be treated as a medical emergency, even if there are no symptoms or signs of toxicity at the time of presentation. All attempts should be made to obtain an accurate history for any

agrochemical ingestion.

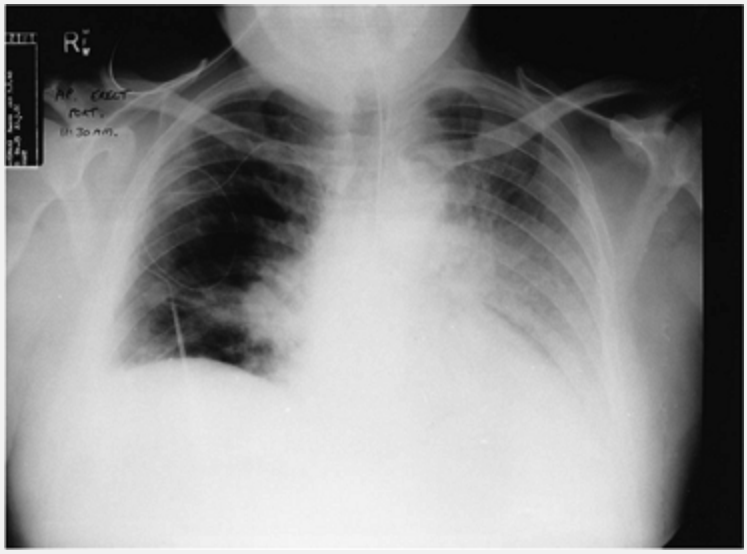

Figure 111-2. Chest radiograph taken 9 days after the ingestion of 70 mL of 20% paraquat, demonstrating diffuse alveolar consolidation, most marked in the perihilar regions.

If there has been dermal exposure, either primarily or secondarily from contact with contaminated vomitus, the clothing should be removed immediately and the skin washed gently but thoroughly with soap and water. Harsh scrubbing should not be conducted because the resultant skin abrasion could actually increase the transdermal absorption of paraquat. If the eyes have been splashed, ocular irrigation with copious amounts of water should continue for 15 minutes. These patients should be seen by an ophthalmologist for further management.

Gastric Emptying

If paraquat was ingested only minutes earlier, measures to remove it or prevent its absorption from the gastrointestinal tract should be

instituted immediately. Spontaneous vomiting is a near certainty in significant ingestions because both the irritant effects of paraquat and the emetic added to many formulations. Induced emesis should not be attempted. Even if the patient has already vomited, further gastrointestinal decontamination should be considered. As a first aid measure, in the field, a slurry of AC, Fuller earth, bentonite, or garden clay can be considered, especially if there will be a substantial delay in reaching a medical facility. In most developed countries, resorting to nonpharmaceutical clay will not need to be seriously considered. Naso- or orogastric lavage may have applicability only in patients who present immediately after ingestion. However, substantial mucosal damage in the esophagus and stomach caused by paraquat formulation places these structures at risk for perforation by the large-bore lavage tube. A better alternative is administering an oral adsorbent as quickly as possible.[47]

Adsorbents

Oral adsorbent options include 1 to 2 g/kg of AC, 1 to 2 g/kg of Fuller earth in a 15% (w/L) aqueous suspension, or 1 to 2 g/kg bentonite in a 7% (w/v) aqueous slurry. All three adsorbents bind and retain paraquat effectively; ready availability determines the choice of adsorbents.[9] If the patient vomits the first dose, another should be given, through a nasogastric tube if necessary. Rapid control of repeated vomiting with antiemetics and promotility agents is essential when the patient cannot retain the adsorbent.

Extracorporeal Removal

Methods to maintain or increase the rate of elimination of paraquat from the body should be considered. Hemoperfusion across a cartridge containing AC enhances elimination of paraquat from the blood. Although significant reduction in mortality can be

demonstrated in dogs 2â€“12 hours after an LD_{50} or LD_{100} dose of paraquat,[20,79] there is no clinical evidence that hemoperfusion is efficacious in humans. Many factors may account for this. Most patients ingest much more than a potentially fatal dose; even if hemoperfusion removes an amount equivalent to several fatal doses, many fatal doses may remain in the body. Many patients present hours after ingestion during which time the paraquat is actively removed from the blood and sequestered in the lung, where it is inaccessible to hemoperfusion. When renal function is normal, hemoperfusion contributes very little additional clearance, so it has proportionately less effect on survival. Likewise, because most of the absorbed dose is eliminated by the kidneys during the first 12 hours after the ingestion; hemoperfusion after this time has little proportional effect on total clearance. Last after the initial plasma phase the slow redistribution phase from the muscles and lungs back to plasma limits the removal rate of paraquat.[51,52] Because of these factors, charcoal hemoperfusion should be begun only if it can be initiated within 4 hours of ingestion and continued for 6â€“8 hours. Based on current clinical and experimental evidence, there is no indication for repeated hemoperfusion. Although hemodialysis can equal or exceed renal clearance of paraquat, particularly when renal function is impaired, it has not reduced mortality. Hemodialysis therefore should only be considered for paraquat removal when hemoperfusion is not available.

Continuous arteriovenous hemofiltration can reduce the marked rebound in plasma paraquat concentrations that occurs after hemoperfusion as a result of redistribution of paraquat from the tissues but no clinical benefit from this procedure has been demonstrated. Forty-four patients receiving continuous venovenous hemofiltration (CVVH) after hemoperfusion had the same overall mortality rate as 36 patients not receiving CVVH (67% vs 64%). However, death was delayed an average of 2.5 days and was a result of respiratory failure rather than circulatory collapse in those receiving CVVH.[35]

Supportive Care

Supportive and palliative care are the most important components of the management of paraquat-poisoned patients. Fluids and electrolytes should be administered IV in sufficient volume to replace GI tract losses and maintain normal hemodynamics and high-normal urine output. Analgesia may be needed for the pain associated with the mucosal ulceration. Patients should be monitored frequently for the development and progression of renal and respiratory failure. Supplemental oxygen is a double-edged sword in that it accelerates paraquat-induced oxygen radical toxicity as it temporarily relieves the distress of hypoxia.[5,6] Generally, supplemental oxygen should be withheld until the arterial oxygen tension falls below 50 mm Hg and/or the patient expresses respiratory distress. The potential contribution of oxygen to the pathologic process and the ultimate decline of the patient should always be considered.

Investigational Treatments

Although many treatments have been proposed and attempted empirically based on the pathologic mechanism of toxicity, none are supported by convincing clinical efficacy.[3] Some authors claim success based solely on the results achieved in a single patient. Few controlled trials of these interventions have been performed, and results of published case series are inconsistent. Major deficits in assessing clinical benefit from various interventions and their combinations include the lack of a uniformly used prognostic indicator that reliably predicts risk of death at an early stage in the poisoning; and small numbers of patients receiving a particular intervention.

Partially evaluated treatments include those that could reduce circulating paraquat (Fab or recombinant single-chain antibody),[8] prevent the accumulation of paraquat by the lung (various

polyamines, *d*-propranolol), increase efflux of paraquat from the lung (cyclophosphamide, *d*-propranolol), reduce or prevent the consequences of the redox cycling (reduction of inspired oxygen FIO_2, vitamin E, superoxide dismutase, ascorbic acid, deferoxamine, selenium, niacin, *N*-acetylcysteine (NAC), or S-carboxy methylcysteine), or reduce the extent or consequences of pulmonary fibrosis (corticosteroids, immunosuppressive agents, fibrinolytic agents, colchicine, radiotherapy, and inhaled nitric oxide).[4]

Two studies with promising preliminary results found reduced mortality in severely poisoned patients given pulse therapy with cyclophosphamide and high-dose methylprednisolone compared to conventionally treated control patients comparable in age, gender, urine dithionite results, and time since ingestion. In the first study series of nonrandomized patients, mortality in the pulse therapy group (n = 16) was reduced compared to the control group (n = 17) (25% vs. 71%).[43] In a prospective, randomized follow-up study by the same authors,[44] all patients received gastric lavage followed by AC instillation, two 8-hour hemoperfusion sessions against activated charcoal, and 10 mg intravenous dexamethasone every 8 hours for 14 days. The patients randomized into the treatment group also received at the end of hemoperfusion 1 g of intravenous methylprednisolone daily for days 1, 2, and 3 and cyclophosphamide 15 mg/kg daily for days 2 and 3 of pulse therapy. Patients with mild poisoning as predicted by a light blue or clear color on the admitting urine dithionate test (n = 21), and those retrospectively assessed as having fulminant poisoning (n = 71) were not included in the data analysis. Exclusion of the latter is a point which has received some criticism.[10] The pulse treatment group had reduced mortality (4/22, 18%) compared to the conventionally treated control group (n = 16/28, 57%). When an intention to treat analysis is done to include those retrospectively excluded as fulminant poisoning, a trend for increased survival is present but does not reach statistical significance. This treatment strategy addresses acute pulmonary

inflammation as the key pathophysiologic target in fatal hypoxemia rather than subsequent fibrosis. The cause of death in fulminant poisoning is not pulmonary inflammation or fibrosis; therefore, salvage of such patients with pulse therapy seems medically doubtful. In a single case reported separately, recovery was achieved in a severely poisoned paraquat patient by a second pulse of methylprednisolone on day 30 when pulmonary inflammation and hypoxemia emerged despite steady daily therapy of dexamethasone after the first pulse therapy. More study of a larger number of severely poisoned patients must be performed to confirm or refute benefit of this approach before it can be recommended as a standard treatment.

Lung Transplantation

Lung transplantation has been performed in a few patients, but only one survival is reported in the literature. In that case, a single

lung was transplanted 44 days after paraquat ingestion; recovery was complicated by subsequent removal of the other poisoned native lung, and severe myopathy prevented weaning from mechanical ventilation.[77] Therefore, single or bilateral lung transplantation can be considered if a patient survives for 3 weeks or longer with end-stage respiratory failure and otherwise meets criteria for transplantation. In this context of prolonged medically supported survival, other serious, long-term effects of paraquat are revealed. For example, patients given lung transplants who survived for several months after paraquat exposure have developed progressive toxic myopathy, which proved fatal in one case.

Prognosis

Survival is dose-dependent. Not all patients who ingest paraquat die, but the mortality has been as high as 75% in some series of patients. Typically a patient who survives does not develop

significant pulmonary injury and has no or few residual effects. Some of the few survivors with residual pulmonary fibrosis have progressively improved over time. Patients who ingest paraquat intentionally usually take a higher dose than those who ingest it unintentionally and therefore typically have a worse prognosis. Similarly, the incidence of death is higher the more concentrated the formulation ingested.

There are proposed prognostic tools to estimate the chance of survival or mortality using serum paraquat concentration or urine dithionate assay results along some time axis following ingestion. Others use physiologic parameters such as APACHE scoring. They all share a major limitation in that they have not been adequately validated in a prospective manner. This hampers the interpretation of studies that investigate the effect of various treatments on survival. An example of such a prognostic tool is presented in Figure 111-3.[22,54] Plasma concentrations of paraquat measured within 28 hours after the ingestion are useful in estimating the prognosis according to the nomogram. This nomogram was derived empirically from clinical data and not by statistical means, and is not infallible. Patients with higher concentrations than those predicted from the nomogram to be associated with survival, have nevertheless survived; conversely, some patients with lower concentrations have died.[54] When experience with the nomogram in 166 cases was reviewed, it correctly predicted the outcome in 93% of cases who died and in 64% who survived.[54] Therefore, reports in the literature of unexpected survival in individual patients based on the nomogram should be attributed only with caution to one or another innovative treatment because of the somewhat inadequate nature of the predictive values. The extension of this nomogram beyond 28 hours has similar predictive efficacy. It appears that whenever the initial plasma concentration of paraquat exceeds 3 mg/L, mortality is 100%. The mode of death is cardiogenic shock within 24 hours of the ingestion in those whose paraquat levels exceed 10 Âµg/mL.

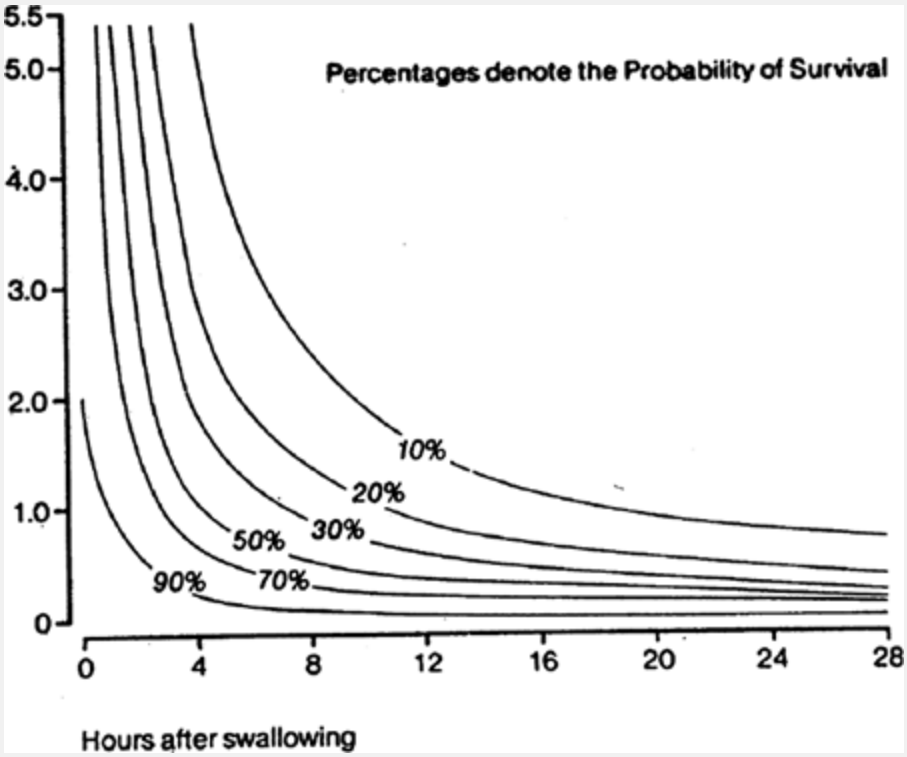

Figure 111-3. Nomogram showing the relationship among the plasma concentrations of paraquat on the ordinate (Âµg/mL), time after ingestion on the abscissa, and the probability of survival. *(Reprinted, with permission, from Hart RB, Nevitt A, Whitehead A: A new statistical approach to the prognostic significance of plasma paraquat concentrations [Letter]. Lancet 1984;2: 1222â€“1223.)*

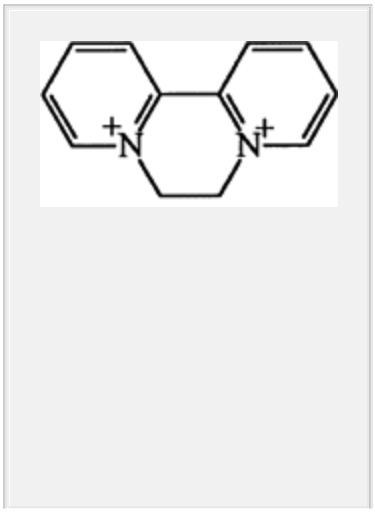
Concentrations of paraquat in urine obtained within the first 24 hours of ingestion can also be used to estimate prognosis.[61,62] Of 53 patients studied, 15 who had urinary concentrations of paraquat below 1 Âµg/mL within the first 24 hours, survived. Urinary concentrations in those who died within 24 hours ranged from approximately 10â€“10,000 Âµg/mL; concentrations in those who died later from pulmonary fibrosis were between 1 and 1000

Âµg/mL.[61,62]

Several indices using physiologic and clinical data have been proposed.[54,67] Examples include predicting the risk of mortality or change of survival based on rate of increase in plasma creatinine over a 5-hour period[55] and abnormal alveolar permeability found by lung scintigraphy.[29] Several factors can moderate the amount of paraquat absorbed and thus decrease the plasma and urinary concentrations. When paraquat is swallowed on a full stomach, its absorption is reduced because of delayed gastric emptying and the adsorption of the herbicide by the food. The presence of ulceration in the upper gastrointestinal tract is a poor prognostic sign because it may reflect the concentration and the dose of paraquat in the formulation. In one series of patients who had upper GI endoscopy between 3 hours and 3 days after the ingestion, 9 of 14 patients with gastric and esophageal ulcerations died. Conversely, all 6 who had no gastric ulcerations survived.[5] The development of renal failure heralds a poor prognosis. In the same report, 19 of 20 patients developed renal failure died.[5]

Diquat



Diquat

Diquat (1,1â€²-ethylene-2,2â€²-dipyridylium dibromide) is used agriculturally for the same purposes as paraquat and for the control of aquatic weeds. It is sometimes combined with paraquat. Recently, it has also been combined in dilute formulations with glyphosate to provide complementary herbicidal actions of rapid burn-down and elimination of viable root remnants. Diquat is similar to paraquat in terms of acute oral toxicity as measured by LD_{50} in rats (150â€“250 mg ion/kg), caustic local effects, kinetics, and

mechanism of toxicity, with one important exception. Diquat lacks the structural features necessary for active transport by the polyamine uptake pathway into the lungs. Therefore, the extent of pulmonary injury and fibrosis following the ingestion of toxic doses of diquat is much less than paraquat. Instead, the predominant target organ is the kidney. Ingestion of diquat rapidly causes nausea, vomiting, watery diarrhea, and pain. Because of severe irritation or ulceration of the oropharynx, esophagus, and gastrointestinal tract. Progression of toxicity may include airway compromise, hemodynamic collapse, respiratory failure, seizures, and renal failure with attendant clinical complications. Intracranial hemorrhage and brainstem infarction have also been reported in several severe poisonings. In comparison to paraquat, there have been relatively few cases of diquat poisoning. Among 11 adult cases, the lethal dose of diquat was 6â€“12 g.[5] Fatalities occurred despite treatment such as forced diuresis, hemoperfusion, and antioxidants. In one fatal case, the serum diquat level 4 hours was 64 Âµg/mL after ingestion of 60 g of diquat cation. The patient exhibited progressive anuria, coma, and seizures and died 26 hours after ingestion from cardiovascular collapse. Extracorporeal removal techniques yielded 1.09 g of diquat. Postmortem findings included marked renal tubular and some glomerular damage.[21] Another

patient ingested 200 mL of diquat dibromide diluted to 1.84% and remained asymptomatic for 8 hours afterward. Subsequently he developed esophagitis, epiglottitis, and acute renal failure, from which he slowly recovered.[74] In another case, intravaginal instillation of 20 mL of concentrated diquat formulation resulted in local corrosion, renal failure, diffuse slowing on EEG, and spastic quadaparesis lasting 3 months.[57]

Local effects of dermal exposure include chemical burn and injury to nail beds. The dermal LD_{50} of diquat dibromide in rabbits is also of the same magnitude as paraquat dichloride (both approximately 200â€“300 mg/kg). Although as an ionized molecule diquat is poorly absorbed through intact skin, it can itself damage skin after repeated or prolonged contact and facilitate its own absorption. Skin exposure has been experimentally shown to be capable of causing systemic poisoning and death in test animals. Ocular exposure to diquat causes irritation and delayed superficial tissue injury. Damage is mediated by oxygen radicals and may cause visual impairment that takes weeks to resolve. This risk can be substantially mitigated by rapid and thorough rinsing of the eyes with water.

Treatment of diquat-exposed patients is similar to the treatment provided to those exposed to paraquat and includes gastric decontamination, adsorbents, hemodialysis and perfusion, and supportive care. Extracorporeal removal techniques remove diquat from the circulation as renal failure ensues, but they have not appeared to affect mortality among the small number of reported cases. Diquat can be detected qualitatively in the urine by the same colorimetric dithionite test for paraquat, in this case producing a yellow-green color instead of purple-blue. At extremely high serum levels, diquat may also introduce an artifact into certain laboratory assays for serum creatinine.

2,4-D and Chlorophenoxy Herbicides

Characteristics

2,4 dichlorophenoxyacetic acid (2,4-D) was introduced as the first selective herbicide in 1946 and remains one of the most widely used agents worldwide. It is the prototype and representative of a large group of related agents including diclofop, MCPA (methyl chlorophenoxy acetic acid), MCPB (methyl chlorophenoxy butyric acid), MCPP (mecoprop, methyl chlorophenoxy propionic acid) and silex. This group is composed of chlorinated and methyl-substituted phenoxyl acetates, butyrates and propionates and their various salts, amines, and ester forms. The chlorophenoxy herbicides are selectively toxic to broad-leaf plants (eg, clover, dandelion) and not to monocotyledonous species such as grass, wheat, barley, oats, sorghum, corn, and sugarcane. Thus they find great applicability for suppressing weeds in cropland, rangeland, and residential lawns; 2,4-D is the â€œweedâ€• in weed-and-feed formulations. The chlorophenoxy herbicides are synthetic plant hormones, which mimic natural auxins involved with growth responses such as cell elongation and cell division. Growth becomes deranged with cupped leaves and twisted stems appearing before plant death. The exact mechanism of lethality to plants is not known but it appears to involve inhibition of nucleic acid synthesis.[64] Monocotyledons are resistant because they have enhanced ability to glycosylate the herbicide after absorption, which inactivates it.

Use on home lawns provides more opportunity for exposure of both adults and children to 2,4-D than herbicides confined to agriculture or industrial markets. Despite this general availability, reports of poisoning are rare and largely confined to intentional ingestions. The role of chronic or recurrent exposures to chlorophenoxy herbicides in farm work or Vietnam-based exposure to 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) in Agent Orange as the etiology of certain cancers and other adverse health effects is still uncertain. Of the latter, much evidence points to contaminating dioxin as the responsible agent.[12]

Toxicokinetics

Absorption

2,4-D is rapidly and nearly completely absorbed after ingestion (>90%) under experimental conditions. The actual dose absorbed after ingestion is very difficult to estimate because there is typically loss as a result of rapid vomiting. After ingestion, peak tissue concentrations occur in 4â€“12 hours.[34,58] 2,4-D is poorly absorbed through the skin (2â€“6%) and is influenced by the salt or ester form of the chlorophenoxy acid and formulation parameters, occlusion, ambient temperature, and the integrity of the stratum corneum. A radiolabeled skin absorption study showed a standard deviation of 50% of the mean value, suggesting wide interindividual variability in dermal transport. Slow continued absorption through the skin continues over 5â€“7 days following a single topical application, despite removal of the deposit residue by external skin washing. Dermal absorption can be significantly increased by the active ingredients in many sunscreen and sunscreen-insect repellent formulations because these act as penetration enhancers.

Distribution

Once absorbed, the toxicity of the various salt and ester forms is represented by the parent acid as rapid hydrolysis of the ester linkage occurs in serum. Experimentally, 2,4-D appeared in brain tissue within 30 minutes of administration, at concentrations slightly lower than in the serum. Onset of toxicity occurred concurrently, implying that the primary target site of poisoning is the CNS. As an organic acid, 2,4-D is highly protein bound. In high-dose situations when protein binding is saturated the free acid distributes

throughout the body. Distribution of the parent acid into the brain,

which should be hindered by the bloodâ€“brain barrier, may have some connection to its transport by a specific organic acid transporter (OAT). In the choroid plexus, its uptake into cells is inhibited by benzylpenicillin, implicating OAT.[3]

Elimination

2,4-D is excreted in the urine mainly unchanged with only a few percent found as a conjugated metabolite. Excretion becomes less efficient at higher serum concentrations, implying saturation of at least some component of renal elimination, probably organic acid tubular secretion. The half-life of elimination appears to be 12 or more hours, with a terminal elimination half-life of approximately 33 hours. Alkaline manipulation of urine pH increases clearance and shortens half-life. The actual mechanism is uncertain, as the â€œion trappingâ€• explanation would be inconsequential at a urine pH range of 5â€“8 given the low pKa of 2,4-D.

Mechanism of Toxicity

Mammals and insects do not respond hormonally to plant hormones or analogs. The toxic mechanisms of chlorophenoxy compounds in humans and animals are not understood but they appear to have multiple effects in biologic systems. Experimental results implicate interference with membrane-based organic acid transporters and exchangers that carry neuronal metabolic substrates. Oxidative membrane stress, apoptosis, and selective regional neurotransmitter interference have also been proposed. Some chlorophenoxy compounds block chloride membrane conductance in striated muscle. Through structural mimicry, these agents appear to be false substrates of both acetyl coenzyme A (CoA) synthase and choline acetyltransferase, producing substituted acetyl-CoA and acetylcholine. Chlorophenoxy false cholinergic messengers are formed at nicotinic and muscarinic sites in nerves and muscles and at extraneuronal sites. The chlorophenoxy herbicides are also weak

uncouplers of oxidative phosphorylation and impede energy metabolism.

Clinical Manifestations

2,4-D is severely irritating to eyes. It is not considered irritating to skin but applicators of chlorophenoxy herbicide formulas report burning eyes, nose and throat that persists for several days following exposure. It is not a sensitizer.

Organs that bear most of the symptoms of chlorophenoxy poisoning appear to be the central nervous system and the neuromusculature.[64] Adverse effects of poisoning are compatible with neurotoxicity, uncoupling of oxidative phosphorylation, and skeletal muscle toxicity. Ingestion produces rapid onset of oral and abdominal distress characterized by burning pain in mouth, throat and esophagus/chest, nausea, vomiting that may persist for 12 or more hours, dysphagia, and diarrhea. Patients may then demonstrate hypotension, tachypnea, tachycardia or tachydysrhythmias, hyperthermia, diaphoresis, flushing, dizziness, lethargy, confusion, ataxia, and in severe poisoning, seizures or coma. Direct cardiac effects are suggested by various ECG changes and dysrhythmias; ventricular fibrillation is often the terminal event experimentally. Peripheral neuromuscular effects have included increased or decreased reflexes, hypotonia, weakness, muscle aching and tenderness, and fibrillatory twitching. Electromyograms are abnormal. Dyspnea and hypoxia secondary to mechanically inadequate respiration may occur. Myotonia (delayed muscle relaxation after contraction) is a characteristic effect of 2,4-D in animals but only rarely reported in human poisonings.

In 1962, observations on the empiric use of 2,4-D for potential therapeutic response in a patient with disseminated coccidiomycosis were reported. Over a period of 34 days, the patient received 12.7 g of the sodium salt of 2,4-D, most of it intravenously. The most frequently administered daily doses were 800 or 960 mg; however,

the last dose was 2,000 mg IV. This 2-g dose produced no complaints from the patient and resulted in no changes in the physical examination. On the following day 3,600 mg of 2,4-D was given intravenously and the patient developed toxicity at the end of the infusion. Observations included depressed consciousness, diffuse myofibrillations that persisted for several hours. Coma responsive to painful stimuli hyporeflexia, and urinary incontinence ensued. No other neuromuscular manifestations developed in the 2 weeks prior to his death from the fungal disease.

There is still considerable controversy whether exposure to 2,4-D can result in peripheral neuropathy.[13,14] It is not a consistent sequela in patients who survive large-volume ingestions. Most case reports follow relatively minor skin exposure. Because a dose-response relationship is not evident, and there is no plausible mechanism for this specific toxicity, no conclusion can be made causally linking peripheral neuropathy to chlorophenoxy herbicide exposure, unless it be an uncharacterized or rare idiosyncratic response.

Laboratory

Analysis of biologic specimens for chlorophenoxy herbicide is not readily available and not needed for managing the patient. Elevated creatine phosphokinase, and myoglobinuria may occur as a result of muscle damage. Myoglobin release from substantial rhabdomyolysis may jeopardize renal function beyond some minor proteinuria which may occur as a direct toxic effect. Minor-to-moderate injury to liver may be manifest as elevation of hepatic aminotransferases.

Similarly to salicylic acid, another organic acid uncoupler of oxidative phosphorylation, sufficiently high dose may produce complex acidâ€“base disturbances, which include one or more elements of respiratory alkalosis and metabolic acidosis.

Management

Initial treatment consists of removing herbicide from the body and supportive care. AC may be considered in patients with significant ingestions.

Urinary Alkalinization

There is some anecdotal evidence supporting the claim that alkalinization of the urine enhances the excretion of chlorophenoxy herbicides. In one case, renal clearance of 2,4-D rose nearly 5-fold for every unit increase in urine pH.[6,53] Clinical improvement of the patient appeared to follow decline of the serum concentration. Effectiveness of this intervention in removing the herbicide is increased by concurrent high urine flow. Urinary alkalinization may be shown to be of limited value, but is unproven, whereas hemodialysis is a better option in severely poisoned individuals if it is available. Because of striated muscle toxicity, rhabdomyolysis represents an independent indication for urinary alkalization to preserve renal tubule integrity.

Extracorporeal Removal

Hemodialysis is effective in removing chlorophenoxy herbicides from the blood. It should be considered in all patients who manifest CNS or neuromuscular toxicity.

Other Treatment

A single case report observed relief of muscle tenderness with the administration of quinidine sulfate given every 4â€“6 hours to treat an unspecified cardiac dysrhythmias. In a separate case report, quinidine administered to treat intermittent nodal tachycardia also relieved muscular hypertonia. These reports constitute inadequate

evidence to recommend quinidine or quinine as effective in treating the muscle symptoms of chlorophenoxy poisoning.

Glufosinate and Bialaphos

Description

The soil fungus *Streptomyces hygroscopics* produces the tripeptide phosphinothricin-alanine-alanine, also known as bialaphos, and this is metabolized in plants and animals to phosphinothricin, also known as glufosinate. Glufosinate is a unique amino acid (2-amino-4-hydroxymethylphosphinyl butanoic acid) that is an analogue of glutamic acid. It exerts a nonselective herbicidal action by inhibiting glutamine synthetase, an enzyme important in amino acid metabolism, nitrogen transformation, and detoxification of ammonia. The accumulation of ammonium is phytotoxic. The parent molecule bialaphos has limited commercial use as an herbicide. Its active moiety, glufosinate, is synthesized and used in many areas around the world for control of weeds and weedy grasses, especially among permanent crops as in plantations, forests, orchards, and vineyards. It is also used to desiccate certain crops to facilitate harvest. Glufosinate is marketed as the ammonium salt in various products including Basta, Ignite, Challenge, and Finale. The surfactant included with Basta has been characterized as anionic, sodium polyoxyethylene alkyl ether sulfate.

Toxic Mechanism

Glufosinate inhibits mammalian glutamine synthetase in various tissues but causes accumulation of ammonia and glutamate only when administered at near-lethal levels.[18] The mammalian system, unlike plants, apparently can compensate to some degree for inhibition of glutamine synthetase by other metabolic pathways. Glufosinate also inhibits glutamate decarboxylase, leading to a decrease in Î³-aminobutyric acid (GABA). Glufosinate and bialaphos

are centrally neurotoxic in humans. Both seizures and profound CNS depression can occur concurrently. Clinical improvement lags behind the physical elimination of the compound, implying prolonged effect at the target site(s). In one case of bialophos poisoning, serum glutamate levels were followed and found to be abnormally high on day 5 of the poisoning and did not return toward normal until day 26.[49] This finding is in keeping with the clinical observation. The circulatory failure noted in patients with severe acute oral poisoning may be because of systemic surfactant syndrome. This was experimentally demonstrated in an in vivo and in vitro animal model by induction of the characteristic vasodilatation and cardiac depression effects caused by either the surfactant alone or the formulated herbicide containing the surfactant but not by glufosinate alone.[37]

Toxicokinetics

Glufosinate and bialaphos are partially absorbed orally. Onset of serious CNS symptoms is delayed many hours to more than a day after a large volume ingestion of herbicide concentrate. Glufosinate is excreted renally unchanged. The serum glufosinate concentration was measured every 3â€“6 hours in a 65-year-old man who ingested an estimated 60 g as 300 mL of a 20% w/v concentrate. Total urinary excretion was measured every 24 hours. The distribution half-life ($t_{1/2}$ Î±) was 1.84 hours and the elimination half life ($t_{1/2}$ Î²) was 9.6 hours. The apparent volume of distribution was estimated to be 1.4 L/kg. Renal clearance was calculated at 78 mL/min, and represented nearly all of the whole body clearance.[23] Because glufosinate is a racemic mixture of D and L enantiomers, some analytic work has been attempted to distinguish the enantiomers in poisoned patients. In the single patient reported to date, the D enantiomer kinetics best fit a 1-compartment model, but the L enantiomer best fit a 2-compartment model and had a longer half-life of elimination.[25] Both enantiomers were found in the CSF at the time of onset of significant CNS depression at

concentrations approximately one third of the concurrent serum levels. Existence of a specific uptake mechanism is postulated as the ionic nature of this small molecule would normally exclude it from crossing the bloodâ€“brain barrier.[24] More work must be accomplished to evaluate the clinical significance of this finding.

Clinical Manifestations

Early symptoms of the systemic surfactant syndrome may appear very soon after ingestion of concentrate and include oral irritation, nausea, and vomiting. Death from cardiovascular failure has occurred in at least 2 patients who ingested at least 300 mL of the surfactant-formulated herbicide. Onset of CNS symptoms is delayed for 4â€“8 hours after large ingestion with significant symptoms such as coma and respiratory depression usually delayed for 24 hours or longer. One author reports a delay in onset of 60 hours after ingestion.[38] CNS symptoms may continue to progress for 24â€“48 hours. Typical CNS symptoms include drowsiness, ataxia, disordered eye movement, disorientation, tremor, stupor, deep coma, and central apnea and respiratory arrest.[38,39,70,73] Convulsions are a late manifestation of poisoning and appear in only approximately 50% of those seriously poisoned. There may be seizure onset from 7.5â€“29 hours after ingestion.[36,70,72] Seizures are always preceded by loss of consciousness and in fact may begin after the patient begins to awaken from deep coma. Seizures are repetitive and can be prolonged; status epilepticus is possible. Secondary organ damage that may result from seizure activity includes fever, rhabdomyolysis, and myopathy.

During the recovery period, the patient may experience loss of short-term memory (both retrograde and anterograde amnesia).[78] This effect is also a feature of amnestic shellfish poisoning, which involves domoic acid, another excitatory amino acid neurotransmitter. Recovery from glufosinate poisoning is prolonged and extubation may need to be delayed for a week or more.

Normalization of higher functions may require weeks. Some patients have required discharge to a rehabilitation facility. Diabetes insipidus developed approximately 14 hours after admission in one reported case of glufosinate poisoning.[70] The peak urine output was >300 mL/h, serum sodium was 167 mEq/L, plasma osmolality 332 mOsm/kg, urine osmolality 200 mOsm/kg, and plasma antidiuretic hormone was abnormally low.

The patient responded to intranasal desmopressin given 40 hours after admission, with normalization of affected physiologic parameters within 48 hours.[70]

Ingestions of the related chemical bialaphos are less frequent because of its limited commercial availability. In one documented case of ingestion of 100 mL of 32% w/v bialaphos plus ethanol, the patient exhibited early vomiting, respiratory distress, and metabolic acidosis. Ten hours after ingestion he developed nystagmus, which lasted for 19 days. Respiratory arrest occurred 36 hours after ingestion.[44] Hours after ingestion, seizure episodes lasting 80 seconds, followed by 40 hours of complete apnea, developed. The patient recovered and was discharged without apparent sequelae.[46] In another case of intentional ingestion of formulated bialaphos, the patient rapidly developed nystagmus, coma, respiratory arrest, and convusions.[49]

In one series, 5 patients who reportedly ingested 0.3â€“1.8 mL/kg (~20â€“100 mL) of 18.5% glufosinate ammonium formulation remained asymptomatic, but 6 who ingested 1.7â€“9.1 mL/kg (100â€–500 mL) developed CNS dysfunction 8â€–34 hours later. The acute neurotoxic dose of glufosinate was thereby estimated to be approximately 300 mg/kg. Ingestion in adults of more than 1 or 2 mouthfuls of concentrate should be evaluated in a healthcare facility because the onset of CNS dysfunction may occur 24 hours or more later.

Laboratory

There is no readily available laboratory test to document ingestion of glufosinate or bialaphos or determine serum levels. High-performance liquid chromatography (HPLC) has been used in research settings to measure glufosinate in plasma, urine, and CSF. Serum should be monitored for elevations of lipase and hepatic aminotransferases, and creatine phosphokinase monitored in patients with multiple seizures. Clinicians should be aware of the potential for diabetes insipidus and suspect it if the urine output, serum sodium, and serum osmolarity become abnormally high without attendant concentration of urine. There are no clinical data on serum ammonia levels.

Management

Gastric Decontamination

Orogastric or nasogastric lavage and AC may be indicated for particular patients with substantial exposures. Spontaneous vomiting commonly occurs after significant ingestions of formulated herbicides because of the surfactant content; and may therefore make it unnecessary to attempt gastric lavage. Particular attention must be exercised in protecting the airway because of the obtundation and coma that may develop many hours after ingestion. Gastric lavage plus extracorporeal removal failed to prevent progression of CNS effects to coma and seizures in two patients who presented 30 minutes and 3.5 hours after ingestion.[72]

Extracorporeal Removal

Hemodialysis is superior to AC hemoperfusion in eliminating glufosinate from blood in vitro.[73] However, several clinical authorities perform both procedures in tandem in an herbicide-poisoned patient.[63,70,72] In theory, any circulating surfactant would

more likely be removed by hemoperfusion, and any water-soluble herbicide is more likely to be removed by dialysis. Improved clinical outcome has not been demonstrated for this practice. Early hemodialysis/hemoperfusion resulting in documented significant reductions in plasma glufosinate levels, failed to avert the progression of CNS pathology or hasten recovery. In one case the serum glufosinate level was reduced from 3.11 Âµg/mL to 0.91Âµg/mL. In the other case it was reduced from 1.56 Âµg/mL to 0.68 Âµg/mL. Midpoint in this dialysis, the concentration was 0.75 Âµg/mL at the inlet and 0.10 Âµg/mL at the outlet.[72] Onset and resolution of clinical symptoms lag behind serum glufosinate levels.[23,72] Thus, serum levels appear to underestimate the degree of toxic effect at the tissue target level.

Supportive Care

Central respiratory failure and arrest may develop suddenly and require emergent intubation and ventilation. Prophylactic intubation is indicated for any glufosinate- or bialaphos-poisoned patient who becomes stuporous. Additionally, hypotension, airway edema, or acute lung injury may develop in patients with large-volume herbicide ingestion as a result of systemic surfactant syndrome. Patients should be carefully monitored for adequate organ perfusion, respiratory effort, and oxygenation. Seizures respond to intravenous benzodiazepines. A single case of diabetes insipidus responded to intranasal desmopressin.[70]

Prognosis

There were 6 fatalities among 34 cases of glufosinate poisoning reported by the Japanese Poison Center.[73] Recovery may be prolonged, but other than anterograde memory loss, appears to be complete. More clinical experience is required to better understand this poisoning.

Inorganic Herbicides

Inorganic herbicides were generally introduced prior to WW II and include sodium chlorate, arsenicals, dinitrophenols, cyanates, and ammonium sulfamate. Because of nonspecific mechanism of toxicity they tend to have more mammalian toxicity than later herbicides based on plant physiology. Many are still in use.

Nitrophenolic Herbicides

Dinitrophenol (DNP) and substituted nitrophenolic compounds (Binapacryl, dinitroorthocresol [DNOC]) and salts, dinoterb, dinoterb, dinoseb, and salts, dinofen) inhibit cellular energy production in plants, fungi, and insects as the basis for their use as herbicides, miticides, fungicides, and wood preservatives. Because elements of this fundamental biochemistry are also shared by mammals, nitrophenylic compounds are predictably toxic to humans and animals. 2,4-Dinitrophenol is the prototype and classic example of a chemical that uncouples oxidative phosphorylation, the process by which the electron transport system in mitochondria creates an electrochemical gradient that allows the production of adenosine triphosphate (ATP). There are no current registrations for any of these compounds for any pesticidal purpose in the United Sates, although opportunity for exposure still exists in other parts of the world, through leftover products, and through environmental contamination in some unregulated chemical waste sites.

History and Current Use

In the July 1893 edition of *The Manufacturer and Builder: A Practical Journal of Industrial Progress*, 4,6-dinitro-o-cresol was introduced by the name antinonnin (derived from the German name for the gypsy moth, Nonnenraupe) for which â€œâ€¦extraordinary virtues are claimed as an exterminator

of insects destructive to plants or vegetation, parasites on animals, mice and rats and other vermin, and as an effectual protector of wood or lumber against mildew and dry rot. It is interesting and important to note that fact that antinonnin, when used in the state of correct dilution, is quite safeâ€¦â€• From this beginning came an entire class of pesticidal nitrophenolic compounds, of which Dinocap, the last one remaining on the US market in the 1990s, underwent voluntarily cancellation of its FIFRA registration in 2004. Therefore, there are no current legal pesticidal uses of dinitrophenol compounds within the United States, although tolerances remain for some specific uses for imported food (e.g., Dinoseb on apples). Dinitrophenol pesticides have included the prototypes dinitroorthocresol and dinitrophenol (DNP), Dinobuton, Dinocap, dinopenton, dinoprop, dinosam. Dinoseb, dinosulfon, and Dinoterb. Those still in use in the United States in the 1980s were subject to emergency suspension, cancellation or data call-in by the EPA in response to new studies showing developmental toxicity and imperiled male fertility/sperm damage, in addition to acute toxic risks.

Another use which exploits the toxic mechanism of DNP is that as a weight loss agent (Chap. 39). Following its introduction in the 1930s toxic reactions and deaths were rapidly reported, the FDA had no authority to act but only to warn the public under the existing Pure Food and Drug Act of 1908. An epidemic of bilateral cataracts, primarily in women who had taken dinitrophenol, cooled most of the remaining enthusiasm in the medical community, although the agent was still available in over-the-counter (OTC) products. It was not until the 1937 elixir of sulfanilamide epidemic focused congressional attention on the need for drug safety was the revamped FDA ability to put dinitrophenol on a list of agents too toxic for any medical use, and act on it as mislabeled. Use in weight loss clinics re-emerged in the early 1980s. FDA has subsequently reaffirmed the prohibited classification of this chemical for therapeutic use, as have most other countries. However, internet

sites for weight control and body-building provide detailed information on obtaining and using dinitrophenol, in some cases describing how to measure wetted, industrial material to pack one's own capsules.

Mechanism of Toxicity

Dinitrophenol (DNP) is considered the classic uncoupler of mitochondrial oxidative phosphorylation, one of the key processes contributing to mitochondrial ATP formation. The electron transport system reoxidizes NADH and $FADH_2$ formed during the tricarboxylic acid cycle and conserves the energy released from the glucose molecule, by pumping protons across the inner mitochondrial membrane. This creates an electrochemical gradient of protons, which is then used to synthesize ATP. There is a â€œcouplingâ€• of the two processes: electron transport requires ATP generation and ATP generation requires electron transport. If the gradient is lessened by loss or leakage of protons back through the membrane, the production of ATP will diminish. DNP is a weak acid that dissociates into DNP^- and H^+. The extra electron of DNP^- delocalizes over the entire molecule; thus it remains relatively hydrophobic and can readily pass the mitochondrial inner membrane. It picks up a proton on one side of the membrane, diffuses across the membrane, and releases the H^+ on the other side. Net movement of H^+ occurs in the direction of the concentration gradient, which of course, is the gradient created by pumping of protons by the electron transport system. The net effect is reduction of both the proton gradient and subsequent ATP synthesis. Salicylic acid, another hydrophobic weak acid, uncouples by the same mechanism of increasing the permeability of the inner mitochondrial membrane to protons by carrying them across it, and thereby dissipating the electrochemical gradient. The electron transport system proceeds to maximum activity but ADP is not phosphorylated to ATP. No work is done, and the excess energy is liberated as heat. Increased glycolysis ensues to provide substrate for the ineffective system.

Serum glucose may be normal, elevated or low, but does not reflect cellular stores and energy production. Metabolic acidosis may occur as lactate generating anaerobic metabolism attempts to provide cellular energy.

Toxicokinetics

DNP and other nitrophenylic herbicide compounds are rapidly absorbed through oral and inhalation routes, and of significant but lesser degree through skin. Maximum increase in basal metabolic rate occurred in 1 hour after ingestion of DNP in human subjects. Peak plasma levels of DNP were attained within 0.5â€“4 hours in dogs. Toxicity may be somewhat delayed by transcutaneous absorption. Serious illness is possible from breathing dusts or overspray during mixing, loading and application of nitrophenylic herbicides. Cumulative toxicity of small, frequent doses is possible. DNP is primarily excreted in the urine as glucuronide conjugates of hepatic reduction metabolites, principally 2- amino-4 nitro phenol. Some is excreted unchanged. A two compartment kinetic model is proposed after study in animals, in which the terminal half-life is 8â€“10 hours. Elimination from renal tissue may have a half-life of days. Intervening hepatic injury may prolong the elimination half-life. The illness runs a rapid course: death or recovery occurs within 24 to 48 hours. If production of heat exceeds the capacity for its dissipation, fatal hyperthermia may result. These compounds may cross the placenta.

Clinical Effects

Dinitrophenol and substituted derivatives such as Dinoseb and Dinocap, are quite toxic with rodent oral LD_{50}s of approximately 30â€“50 mg/kg. As little as 1 g cumulative dose of DNP over several days has been fatal in humans. The classic clinical presentation of uncoupled oxidative phosphorylation is that of hypermetabolism and energy failure: increased body temperature, increased respiratory

and heart rates, intense fatigue, profuse sweating, thirst, flushed skin, malaise, dyspnea, headache, dizziness, anxiety, confusion, cardiovascular collapse, convulsions, and coma.[13] Pulmonary edema is possible. If death occurs it may be sudden, and rigor mortis appears sooner than expected. In nonfatal exposures, renal and hepatic damage may occur within days after symptom onset. The threshold for increased metabolic rate in humans is around 1 mg/kg of DNP. Hypermetabolism is evident at approximately 4 mg/kg.

Systemic immunologic hypersensitivity reactions have occurred in some 10â€“20% of patients from small doses of DNP used for weight reduction. Such reactions have included isolated pruritus, urticarial or maculopapular eruptions, severe desquamating dermatitis, and generalized edema. Reactions subside with cessation of exposure. Chemically induced bilateral cataracts have occurred in women taking small doses of DNP for weight reduction. Risk of cataracts does not correlate with duration of exposure, but may be a manifestation of a genetically determined vulnerability. Cataract development may occur rapidly; most reported epidemic cases occurred within a year of exposure.[26] Bone marrow toxicity of neutropenia and agranulocytosis are reported. Interference with synthesis and pituitary feedback control for thyroid hormones have been reported.[14]

Local effects of ingestion exposures may also cause irritation or corrosion of oropharyngeal and upper GI mucosa, salivation, nausea, vomiting, and bright yellow stools. Local skin effects include yellow staining, erythema, irritation, and blisters. Many nitrophenylic herbicides are sensitizers, repeated or prolonged exposure may result in allergic contact dermatitis. Local eye exposure effects may include burning pain, lacrimation, and eyelid inflammation and present risk of systemic absorption and toxic effects.

Laboratory

Analysis of serum or urine for dinitrophenolics or metabolites may be possible to confirm exposure, but will likely be unavailable in time to guide clinical management. Serum glucose, electrolytes, hepatic enzymes and renal function should be monitored.

Management

Externally contaminated patients pose a risk of secondary contamination to others. Gentle but thorough soap and water washing of potentially exposed body areas including hair, ears, fingernails should be done with protective gloves and apron. Decontamination will not remove any yellow staining; attempts to do so will damage the skin and perhaps increase absorption of the toxin. Aggressive supportive care may be necessary, including large-volume fluid replacement if hypovolemia is present. Hyperpyrexia, which may be life-threatening, must be rapidly corrected by mechanical means as would be done for heat stroke, for example, cooling blanket. Do not use salicylates for fever reduction. If the exposure was oral, AC may be considered. The hypermetabolic illness runs its course rapidly, usually within 24â€“48 hours. Illness beyond this time in survivors is a consequence of organ damage. Although pharmacologic treatment of hyperpyrexia with dantrolene has been anecdotally reported, there are insufficient information and lack of support mechanistically to recommend its use in dinitrophenolic poisoning. Likewise there is no support for the use of Î²-receptor antagonists, haloperidol, and antithyroid medication.

Sodium Chlorate (NaClO3) (Chap. 98)

Chlorate is the chlorine analog of nitrate and kills all green plants by oxidizing and inactivating a critical nitrate reductase complex. It is phytotoxic by both foliar and soil application, and is also used to sterilize soil, where it may persist for months to years.[66] Recent

research shows a potential application for gut sterilization in cattle prior to slaughter to reduce cross-contamination of meat with *Escherichia coli* and other enteric bacteria. Its major herbicidal uses are control of roadside vegetation and to desiccate crops before harvest. It is a strong oxidant, having three oxygen molecules to donate. Although not itself combustible, it reacts violently with reducing and combustible materials such as clothing, wood, and dried foliage. Formulations usually carry a fire suppressant such as urea or sodium borate to counter this fire hazard. Sodium chlorate is sold alone or in combination with atrazine, 2, 4-D, bromacil, diuron, or sodium metaborate. Minor amounts are also produced when chlorine dioxide is used to disinfect drinking water.

Mechanism of Toxicity

As a potent oxidizer, sodium chlorate oxidizes hemoglobin to methemoglobin causing inadequate oxygen transport. Oxidant stress may also denature and precipitate hemoglobin as Heinz bodies, which prompts removal of these damaged red cells from the circulation by the spleen and liver. Severe acute intravascular hemolysis may occur with its consequent hyperkalemia and risk of acute tubular necrosis. Induced hemolytic anemia in concert with methemoglobin in the remaining red cells produces catastrophic hypoxia. Chlorate action on hemoglobin may be somewhat delayed in a concentration dependent manner, unlike nitrite, which rapidly oxidizes hemoglobin. After the prolonged presence of chlorate, methemoglobin becomes unresponsive to reduction by methylene blue. Red cell membrane enzymes are cross-linked and inactivated by chlorates, including glucose-6 phosphate dehydrogenase, which must be intact for successful methylene blue action. Loss of maintenance enzyme activity makes erythrocyte cell membranes rigid, permeable to cations and fragile. Adding to the pathogenic potential, the chlorate ion itself is not inactivated as it oxidizes hemoglobin, as are other methemoglobin formers such as nitrites, and can therefore continuously produces methemoglobin

autocatalytically until it is excreted.[48] Sodium chlorate is irritating to eyes, skin, and membranes; ingestions are characterized by severe gastrointestinal distress.

The lowest fatal doses in adults are reported to be 100â€“200 mg/kg (10â€“15 g), although typical fatal doses are on the order of 50â€“100 g and higher. Conversely, patients have survived 100-g doses with aggressive care. A two-gram dose was fatal in a child.

Toxicokinetics

As a water-soluble salt, sodium chlorate is not well-absorbed through skin, and ingestion is the primary route of poisoning. Animal data with small doses show a half-life of absorption of about 1.5 hours, and a half-life of elimination of 36 hours. It is excreted in the feces and urine.

Clinical Manifestations

Ingestion produces vomiting, abdominal pain, methemoglobinemia and its cyanotic coloring, severe acute intravascular and extravascular hemolytic, hyperkalemia, renal failure, and disseminated intravascular coagulation (DIC).[17,32] Attendant clinical complications of hypoxia include shock, acidosis, cardiac dysrhythmias and arrest, respiratory failure, and central nervous system dysfunction. Because of a slight delay in onset of hematologic events, do not dismiss patients who do not initially appear severely ill as not being severely poisoned.

Treatment

Ingestions of sodium chlorate are potentially life-threatening, and gastric decontamination by lavage should be considered according to accepted guidelines. AC is not effective in binding small inorganic molecules like chlorate.

Once toxicity is underway, patient stabilization may become

challenging and must incorporate multimodal therapy including standard treatments for shock with fluids and vasopressors, and intubation for respiratory failure. One hundred percent oxygen following intubation will maximize oxygen dissolution in plasma. Acute hemolytic anemia and methemoglobin concurrently will catastrophically reduce oxygen carrying capacity of blood, and consideration must be given to red cell transfusions and possible plasma exchange. Rapid development of acute renal failure is likely in severe poisoning. Robust urine flow and urinary alkalinization should be considered. Hemodialysis should be considered early to compensate for loss of urinary chlorate excretion as renal failure develops and will restore electrolyte balance, and provide renal replacement. Other complications should as DIC should be managed by existing standards of care.

Specific Antidotal Therapy

Methylene blue therapy must be used early in the poisoning when methemoglobin first appears, or

not at all, Because of inactivation of G6PD and consequent loss of methylene blue effectiveness with time. Methylene blue will not reverse Heinz body formation and extravascular hemolysis. If initially successful, repeated doses may be necessary as methemoglobin may re-form. Once therapeutic effect diminishes, or evidence of hemolysis appears, methylene blue should be stopped as it may add to the oxidant stress on hemoglobin instead of reversing it.

Oral or IV administration of 25% sodium thiosulfate solution has been proposed as therapy to convert chlorate ion into chloride ion. Ascorbic acid, vitamin E, and NAC have been suggested as a supplemental antioxidant treatment for chlorate-induced methemoglobin. Actual experience with these proposed antidotes seems lacking, and they cannot then be recommended as standard

effective therapy.

Laboratory

Chlorate measurements are not readily available. A qualitative colorimetric test for chlorate using aniline as the reagent has been used to detect its presence in gastric contents. Ion chromatography has been used to measure chlorate concentrations in blood and urine.

Herbicidal Borates

Boric acid and borates are used as algaecides, fungicide/wood preservative, insecticides (ants, roaches grain weevils, silverfish), and herbicides. Although necessary micronutrients in plants, in excessive amounts of borates are desiccating and interrupt photosynthesis. The primary herbicidal borates are sodium metaborate tetrahydrate and sodium tetraborate. Herbicidal borates are usually found in combination with other active ingredients such as monuron, bromacil and trichlorobenzoic acid. A common use is vegetation control along rights of way, especially in concert with sodium chlorate for which it also provides a fire retardant action. Sodium tetraborate is corrosive to the eyes and irritating to respiratory mucous membranes. Workers exposed to airborne dusts or spray droplets report eye irritation, dryness of the eyes, nose and throat, and cough. Chronic high-dose exposure is selectively toxic to testes; workers exposed to dusts during manufacturing have reduced sperm counts and motility. Acute low-dose ingestions as typically occurs nonintentionally are often asymptomatic but may result in vomiting, diarrhea, and abdominal pain. Symptoms of mild CNS depression such as headache, lethargy, and lightheadedness may follow. Very high-dose ingestion may result in pronounced toxicity involving CNS depression and seizures, metabolic acidosis, shock renal failure, and hepatic injury. Nonspecific cellular toxicity may be due in part to enzyme inhibition (Chap. 98).

Arsenicals

Arsenic compounds are legacy pesticides in long use against various types of pests including fungi/mold, plants, insects, and animals because of the nonspecific mechanism of toxicity that affects life at all levels of organization (Chap. 85). In addition to arsenic trioxide, pesticidal arsenic compounds include a variety of trivalent salts (various arsenites, derived from arsenic trioxide in water) and pentavalent salts (various arsenates, derived from arsenic pentoxide in water). Compounds better suited against mold or insects include arsenic trioxide, copper acetoarsenite (Paris Green) lead arsenate, lead hydroxy arsenate (basic lead arsenate) and calcium arsenate.

Compounds suitable for herbicidal use in the United States have included organic arsenicals such as cacodylic acid (dimethylarsinic acid, Agent Blue) and sodium cacodylate, calcium hydrogen methane arsenate, disodium methane arsenate, monosodium methane arsenate, monomethylarsonic acid (MMA^{+5}), and monoammonium methane arsenate. Many are still have U.S. registrations to kill weedy grasses such as crabgrass and nut grass and to defoliate cotton before harvest. In mid-1988, the EPA canceled the registrations for most inorganic arsenicals used for purposes other than wood preservation. Exceptions included lead arsenate for use as a growth regulator in grapefruit, and calcium arsenate in flowable form for turf use. Inorganic arsenicals such as sodium arsenite and other organic arsenicals may still be used in other world areas as herbicides. Various nonherbicidal pesticide uses of inorganic compounds may continue as well.

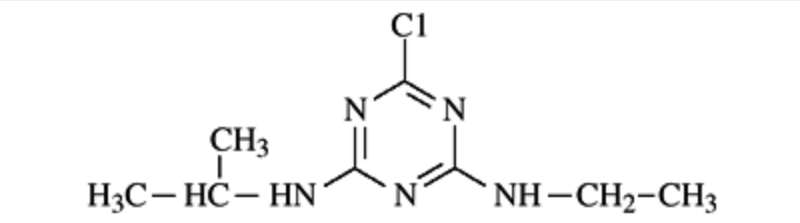
Chromated Copper Arsenate (CCA) Wood Preservative

The contemporary issue about lumber treated with CCA is that of long-term environmental exposure and risk of cancer. Wood for use

in outdoor areas is preserved by pressurized saturation with a solution of chromated copper arsenate against degradation by dry rot, mold, termites, and other pests. Studies suggest that arsenic slowly leaches from CCA-treated wood but the rate varies by amount of CCA applied, local climate conditions, and age of the wood product. Although no unacceptable risk has yet been identified, as of 2004 CCA-treated wood is no longer permitted in new construction in residential areas such as in decks, walkways, fences, gazebos, picnic tables, and playground equipment. Nonresidential uses including highway noise barriers, sign posts, utility posts, and retaining walls are still permitted. Structures already in place are not affected, but as an extra precaution, regular application of certain penetrating coatings such as oil-based, semitransparent stains will minimize potential exposure.

For all pesticidal arsenicals refer to Chapter 85 for details regarding toxic properties and treatment.

Atrazine and Other Chlorotriazines



Atrazine 6-chloro N^2 ethyl N^4 isopropyl-1,3,5-triazine-2,4-diamine

The chloro-S-triazine herbicides, including atrazine, simazine, cyanine, and others, comprise one of the most extensively used herbicide class in the United States.[45] Their primary uses are to control broadleaf and grassy weeds in crops such as corn, sugar cane, and conifers and for nonselective weed control in noncrop rights of way and industrial land. There are few reports of acute human toxicity related to any of these agents.

There are many types of formulations, some with very high loads of actives (80â€“90%) and multiple-active products. Liquid formulations are likely to contain a hydrocarbon solvent.

Kinetics and Clinical Effects

The chlorotriazines are slowly and incompletely absorbed through skin: experimentally less than 5% in 20 hours, but are well absorbed orally (80%).[1] Metabolism is by cytochrome P450 and metabolites,[40] including a glutathione conjugate, are excreted renally.[7]

These herbicides can induce cell-mediated hypersensitivity after prolonged or repeated contact with the skin, and are mildly to moderately irritant to skin, eyes, and mucous membranes. A single case report is published of intentional atrazine ingestion of 500 mL of a concentrate containing 100 g atrazine, 25 g amitrole, and 25g ethylene glycol plus an uncharacterized amount of surfactant.[50] The patient developed coma, shock, metabolic acidosis, gastrointestinal bleeding, renal failure, hepatic necrosis, and DIC, and died on the third day. Much of this is compatible with surfactant toxicity except kidney and liver damage.[33]

Management

The toxic dose of atrazine or other triazene herbicides in their various formulations is unknown, but is apparently relatively high.

Gastric decontamination may be indicated in any particular patient according to accepted guidelines.[33] Because liquid formulations are likely to be emulsifiable concentrates containing both surfactant and a hydrocarbon solvent, precautions must be taken to avoid both aspiration and esophageal trauma.

Hemodialysis removed only 120 mg of atrazine in 4 hours in the man who had ingested a total of 100 g.[50] Unless renal impairment intervenes, it is unlikely that hemodialysis will materially affect the clinical course. Experience with acute toxicity is too limited to permit adequate characterization of effects or treatment. There are no antidotes or specific treatment measures.

Hypotension, airway edema, or acute lung injury may develop in patients with large-volume herbicide ingestion as a result of systemic surfactant syndrome. Patients should be carefully monitored for adequate organ perfusion, respiratory effort, and oxygenation.

Analysis of atrazine in biologic specimens is not routinely available.

Summary

The expanding diverse worldwide agricultural role of herbicides has led to increasing availability and risk as suicidal agents or unintentional exposures of great potential concern.

The exposure of various populations to paraquat and diquat has led to highly lethal complex toxicologic emergency often encountered in developing countries. Glyphosate and glufosinate are additional examples of high-risk herbicides. Evaluation of the supposedly inert components of these formulations has been emphasized. The increasing interest in the toxic potential of these agents is timely, particularly as society attempts to assess the risks and benefits of these agents.

Chapter 112
Methyl Bromide and Other Fumigants

Keith K. Burkhart

A 46-year-old healthy man employed in a nursery was brought to the em complained of nausea, vomiting, and dizziness. The supervisor reported th been exposed to gas used to fumigate the greenhouse. He had transporte to the greenhouse in the morning, about 2â€“3 hours prior to admission. I canisters into the cab of his pick-up truck and then driving them to the g be used. When he went to unload them, he noticed that one of them see Concerned that it may have leaked during transport, he lifted the canister anything. Because he felt fine, he did not mention the event to his super he started to feel ill.

Physical examination revealed a well-developed and well-nourished man wh appeared to be in mild discomfort. Vital signs were: blood pressure 120/7 and regular; respirations 16 breaths/min; and temperature 99Â°F (37.2Â° at 80 kg. The skin was moist, and there was erythema noted on his neck the shirt collar. His neck was otherwise normal. Examination of the head, was only remarkable for mild conjunctival injection. The chest was remarl rhonchi. Cardiac examination revealed normal S1 and S2 and no murmurs were normal. The abdomen was mildly tender in the epigastrium, without

hepatomegaly were noted. Neurologic examination revealed a normal mer nerves, symmetrical reflexes, and normal sensory and motor examinations reached out to steady himself.

The 12-lead ECG demonstrated normal sinus rhythm with a normal QRS c laboratory assessment including CBC, electrolytes, BUN, creatinine, glucos amylase, lipase, and arterial blood gases were normal.

In the emergency department (ED) the patient had a generalized tonic-clo respond to 20 mg of diazepam. The patient underwent rapid-sequence in mg/kg as an IV loading dose. Two hours later the patient remained coma activity.

On the second day in the ICU, he developed acute respiratory distress sy FiO_2 . His seizure activity returned and required higher doses of phenoba insufficiency complicated his clinical course, but these all resolved with st week ICU stay. He made a partial neurological recovery that left him whe induced myoclonus and difficulty performing activities of daily living. Fum rodents, nematodes, insects, weed seeds, and fungi anywhere in the soil, commodities.[29] Many different chemical classes have been used historically remain in use today in the United States. Most fumigants were abandoned of which were halogenated solvents. The list of discontinued halogenated tetrachloride, chloroform, dibromochloropropane, 1,2-dichloropropane, eth dichloride. Chapter 99 discusses paradichlorobenzene and naphthalene. Cl halogenated fumigant often added in mixtures because of its warning pro in its role as a lacrimator (Chap. 126). For the last few decades methyl prominently, although the Montreal Protocol banned its use beginning in phosphides are also used extensively in the United States.[10] Many reports reported from India and the Middle East.[1 , 16 , 67]

Although fumigants exist in all 3 physical states, they are most commonly explaining why inhalation is the most common route of exposure (Table 1 fumigants are generally heavier than air. Several, such as methyl bromid colorless and the toxic concentrations are below the odor threshold, mak Methyl bromide evaporates from soil after a liquid application. Phosphides although the resultant phosphine gas may have a garlic odor. Metam sodi

A number of sulfur containing compounds are also used as fumigants. Su fumigant used in some regions of the United States. Sulfur dioxide (Chap. fumigant, whereas carbon disulfide use was discontinued. The dithiocarba Metam sodium is one of the most frequently used members of this class ethylene oxide, formaldehyde, oxirane, and paraformaldehyde are aldehyd used as fumigants, but they will not be reviewed in this chapter.

Methyl Bromide

History and Epidemiology

Methyl bromide (CH_3 Br) was used as an anesthetic in the early 1900s, It was employed as a fire retardant during World War II, a role that pers

in Europe.[37] Like many other halogenated xenobiotics, methyl bromide wa methylating agent, chemical precursor, and in fruit packaging.[36 , 66] Indu occurring environmental production in oceans have lead to low levels of r water, and food.[42]

**Commodity fumigant, wihich is a class term used by the Environmental fumigation of a food or agricultural product.

TABLE 112-1. Physical Properties and Industrial Use of Fumigants

Hazardous materials incidents are reported for methyl bromide, both duri Residents and plant employees, living or working adjacent to agricultural applied, are occasionally exposed secondary to inadvertent releases.[10, 2] possibly other fumigants have also escaped from fumigated structures to resulting in severe illness and fatalities.[38, 49] Underground pipes adjoinin have led to exposures.[39] Fatalities have occurred when workers entered residues.[45] The transfer of methyl bromide between containers has resul sequelae.[21] Defective or leaking canisters of methyl bromide are another Europe, indoor and outdoor exposures to old fire extinguishers have caus fatalities.[7, 37, 70, 75] Rarely, intentional exposure to fumigants by inhal been used as a means of suicide.[34, 50, 65] Most symptoms reported by t chloropicrin, which is usually formulated as 2% of the methyl bromide co irritant and nonspecific symptoms of methyl bromide and chloropicrin mal differentiate at the time of the exposure.[29]

Diets high in marine products and fruits may cause an increased environ bromide.[42] The 1987 Montreal Protocol was an international agreement to

chemicals. Methyl bromide was scheduled to be phased out in 2005, but applied for and were granted exemptions.[58] Historically, stored or importe by the public, despite restricted use or bans.[61]

Occupational Exposure

Methyl bromide fumigation may expose workers to high concentrations at Methyl bromide can be detected at the joint connections to the vaporizer of 50 parts per million (ppm) have been recorded. Depending on ventila to 55 ppm occurred when the plastic sheets were removed 7 days after a exposures may occur during application secondary to employee error or rubber gloves may absorb methyl bromide. Tight-fitting clothing may trap Because of these properties, leather and rubber should be avoided for all should be changed after the application.

Methyl bromide is listed in the International Agency for Research on Canc classifiable as to its carcinogenicity in humans. One small human cohort s cancer in which the expected number was 0.11. Animal studies have pro mice, gavage produced fore-stomach squamous cell carcinomas, but then show an increased rate. One rat study showed increased pituitary adenom

The American Conference of Governmental Industrial Hygienists (ACGIH) TWA (time-weighted average) of 3.9 mg/m^3 for methyl bromide; 1 mg/m^3

Toxicokinetics

The dermal absorption of methyl bromide appears to contribute to its tox dermal exposure developed persistent peripheral motor neuropathy, highl systemic toxicity after dermal exposure.[47]

Significant individual variability exists for methyl bromide metabolism. P transferase is believed responsible for some of this variability.[9] Pharmacog pharmacogenomics may ultimately explain individual variability. Three of high hemoglobin adduct levels despite performing the same job.[40] S-meth hemoglobin adducts may persist for weeks.[9] Cysteine residues number 104 Î² chain appear to be preferentially methylated.[25] Which biomarker will pr determined.

Bioactivation and then alkylation also appear to be responsible for toxicity ethylene dibromide. The antifertility effects and toxicity of ethylene dibro alkylating, mustard-like, activity.[23] Human in vitro and rat liver models v assessment of ethylene dibromide carcinogenicity.[59] Ethylene dibromide

both conjugative metabolism via glutathione S-transferase and oxidative CYP 2E1, 2A6, and 2B6. The conjugative pathway produces an episulfoniu a carcinogen.

Pathology/Pathophysiology

Pathologic examinations demonstrate the neurotoxic potential for methyl of a man who died 30 days after methyl bromide exposure from a corrod demonstrated that the inferior colliculi and the cerebellar dentate nuclei h gliosis. The brain stem and spinal cord were normal, although the dorsal neuronal loss. The peripheral nerves showed axonal and myelin loss with lesions to the inferior colliculi and the dentate nucleus were also described 5 years after severe poisoning.[32] The cerebral lesions are reportably simi Wernicke encephalopathy. Methylation of the sulfhydryl groups of metaboli common mechanistic pathway.[46 , 70]

Clinical Manifestations

Exposure to high concentrations of methyl bromide may lead to immedia including a rapid loss of consciousness followed by seizures, dysrhythmias symptoms may be delayed for days following low-level exposure.[36] Cardio neurological toxicity may develop following toxicity from methyl bromide a fumigants (Table 112-2).

Some individuals may initially manifest irritant symptoms of the eye, na These irritant symptoms may help differentiate upper respiratory and ga from methyl bromide exposure. In more severe poisonings pulmonary sym shortness of breath that may rapidly progress to bronchitis, pneumonitis, hemorrhage. In some cases, the initial symptoms of methyl bromide pois influenza or a viral-like illness such as gastroenteritis.[49 , 66]

TABLE 112-2. Comparison of Clinical Effects of Fumigants

The neurologic effects of methyl bromide poisoning are most consequentia
demonstrate these irritant effects, yet present later with neurological syn

nervous system symptoms may include headache, vomiting, dizziness, d diplopia, dysmetria, dysarthria, and mood disorders or inappropriate affec ataxia, psychotic delirium, intention tremor, fasciculations, myoclonus, sei reported case of methyl bromide poisoning, the initial diagnosis was Rey

Six patients developed skin lesions including erythema, vesicles, and bulla predominantly in moist areas or pressure points, including groin, axilla, an wristband.[80] In another report, erythema and multiple vesicles developed who used protective respiratory gear.[47] This patient's skin lesions healed persistent peripheral neuropathy.

Patients with chronic exposures may present with varied neurologic featu nystagmus, paresthesias, dysesthesias, hyporeflexia and hyperreflexia.[14] with optic nerve degeneration may be permanent.[14] One chronically expos presentations for psychosis before the underlying etiology of methyl bron determined.[79]

Chronic exposure to methyl bromide is associated with hepatotoxicity an that acute poisoning produces similar effects and that critically ill patients manifest fulminant hepatic failure. Autopsy findings have included acute degenerative nephritis.[49 , 75] Recovery is typical in survivors.[53]

Diagnostic Testing

Standard baseline laboratory tests should be obtained although they will following poisoning. Hepatic

dysfunction should be assessed with serum hepatic aminotransferases and bromide levels are not readily available in most laboratories. Although a s facilitate the clinical management of a methyl bromide poisoned patient, t diagnosis.[50] Serum bromide levels may remain elevated for a week or m The elevation of the serum bromide, however, does not always correlate v exposure.[27 , 39] An elevated serum bromide level may also cause a false when assayed using an ion selective electrode meter.[54 , 77] Alternatively, bromide exposure, the residual air concentration of methyl bromide can b

Treatment

Treatment for methyl bromide poisoning relies on general and supportive for management of dysrhythmias, coma, seizures, ALI, and hepatic and r common and difficult to control with traditional anticonvulsants such as Pentobarbital coma and neuromuscular blockade have been required for r

Decontamination should include the removal of clothing, as methyl bromid including rubber and leather. Irrigation of the eyes with saline and skin c water should be performed. Because of the systemic toxicity of the halog reasonable to administer at least one dose of oral activated charcoal (AC

Extracorporeal removal of bromide by hemodialysis can rapidly clear seru neurological improvement is described, but severe disabilities may still re following fumigant exposure occurs as the bromide is released into the se methylation of neuronal proteins has already occurred and that hemodialy outcome.

Chelators and *N* -acetylcysteine (NAC) have been proposed as antidotes, to be effective. The use of NAC as a sulfhydryl donor and antioxidant to insult, needs further study, as does the role of NAC to help recovery fron Injury, especially neurological, most likely occurs shortly after exposure an manifestations.

Prognosis

Most patients who develop seizures and coma will not survive. The few s exposure described in the literature, with rare exception, will have neur These sequelae may or may not be permanent and have included cogniti depression, anxiety, mood disorders with rapid behavioral swings, and su [36 , 62 , 66]

Nine months after an acute exposure to methyl bromide complicated by c woman had severe sequelae that included ataxia with action-induced my therapy.[66] A 46-year-old fumigator wearing a defective face mask had m exposures to methyl bromide that led to status epilepticus.[62] His recovery ataxia and action myoclonus interfering with his activities of daily living.

epilepticus that developed several hours after exposure to methyl bromide neuromuscular blockade after the failure of diazepam, phenytoin, nitrous administration. This patient also had ataxia, intention tremor, and fasciculu and died from a pulmonary embolus.[7] A young girl had electrophysiologic the conclusion that it was multifocal and generalized, occurring spontan stimuli and during voluntary movements demonstrated on the EEG by gia somatosensory evoked potentials (SEPs).[73] The myoclonus was refractory intensity did decrease during a 2-year follow-up. A 12-year-old girl deve and dysarthria after exposure to leaking fire extinguishers, but made a d that became complete after a year.[37] Recovery from peripheral neuropath

Dichloropropene

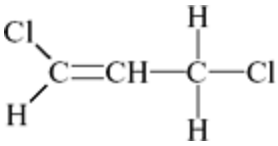

Figure. No Caption Available.

History and Epidemiology

Dichloropropene was introduced in 1945 and is primarily used as a soil f Exposures are reported both during production and also by ingestion. Trac D.

Occupational Exposure

Chronic subclinical changes have been reported in soil fumigators using bulb occupations.[8] Hematologic cancers including lymphoma and histiocyti firemen after dichloropropene exposure.[48] The TLV for dichloropropene is exposure limit is 5 mg/m^3 .[8]

Toxicokinetics

The metabolism of dichloropropene probably is similar to that of other c

such as carbon tetrachloride and chloroform. Glutathione depletion has be model.[26]

The dose and route correlate with toxicity and outcome in rodent models At 100 mg/kg in mice, hepatotoxicity occurs by the intraperitoneal route, 700 mg/kg administered by the intraperitoneal route hepatic failure and correlated with a 130-fold increase in dichloropropene epoxide formation isozymes. In a rat hepatocyte model, pretreatment with the antioxidant, hepatotoxicity.[71]

The inhalational route is the primary method of toxicity for dichloroproper dermal absorption of dichloropropene was only 2â€“5% of inhalational a

Clinical Manifestations

There are a few reports of systemic dichloropropene toxicity. A patient d ingestion of dichloropropene.[34] The victim drank a glass of dichloroproper Immediately recognizing that it was not water; he vomited. Within 2 hou tachypnea, hypotension, sweating, and abdominal pain, followed by hema death at only 38 hours postingestion. The ingestion also produced rhabd and hyperglycemia.[34]

A hazardous materials incident exposed nine firemen to dichloropropene. neck pain, nausea and difficulty breathing.[48] Individuals may develop cor allergies to dichloropropene.[19] Healing of the skin lesions may leave pig

Diagnostic Testing

Hepatic and renal function should be monitored following acute poisoning, extensive necrosis after ingestion.[34] No additional tests are recommended supportive care.

Biomonitoring for exposure to dichloropropene is being developed.[8] Hepat fumigators but the increase was not statistically significant. This finding, enzyme induction. Erythrocyte GST (glutathione S-transferase) and GSH controls, fumigators had increased serum creatinine and increased urine

retinol binding protein.

Management

The patient's clothes should be removed and bagged to avoid continued of the patient and the healthcare worker. If ingestion occurs, one dose of There are no data to support specific therapies beyond supportive care, a therapy and NAC warrant further study.

Phosphides

History and Epidemiology

Phosphides are usually found as powders or pellets, usually in the form o (Zn_3P_2 and Al P, respectively). Calcium and magnesium phosphides are (PH_3) is formed from phosphides after contact with water, particularly if moisture may react with tablets to decrease their potency after the packa tablets are often placed in grain stores, such as ships, allowing the phosp storage sites are sealed. Phosphine is also available as a compressed gas exposures and toxicity, both from phosphide salts or from compressed ga fumigation in both transport and storage areas, particularly if entry to the proper ventilation.[28,78] Phosphine poisoning was also reported when the shop to another business in the same building.[61]

Many reports of serious phosphide poisoning including fatalities originate countries.[56] The consumption of aluminum phosphide is a common choice

Clandestine methamphetamine laboratories that use the ephedrine/hydric manufacturing method may generate phosphine gas at high reaction tem venue are reported, and first responders have also been exposed to high

Toxicokinetics and Pathophysiology

Phosphides produce toxicity rapidly, generally within 30 minutes of ingesti less than 6 hours.[2] The ingestion of fresh unopened tablets consistently r phosphine gas results in nearly instant toxicity.

Phosphine disrupts mitochondrial function by blocking cytochrome c oxidas energy failure in cells, free radical generation increases, resulting in lipid Phosphine also inhibits cholinesterases in rats.[52] Phosphide ingestions ove

Clinical Manifestations

Phosphides are potent gastric irritants; profuse vomiting and abdominal pa symptoms.[16] Respiratory signs and symptoms include tachypnea, hyperpn tightness that may progress to ALI over days. Tachycardia, hypotension, develop.[3,22,51,68] Phosphine-induced dysrhythmias include atrial fibrill and ventricular tachycardia and fibrillation.[69] Central nervous system tox and delirium.[2,51]

Diagnostic Testing

The diagnosis is usually made from the history. Further laboratory testing supportive care. Phosphine tissue concentrations are not routinely availa

Management

Patients who ingest phosphine frequently vomit from the irritant effects o emesis, theoretically, may expose healthcare workers to phosphine fumes in sealed containers and disposed of properly, as wet phosphides will cor gas. A physician performing an autopsy became symptomatic when the st containing phosphide was exposed.[41]

Vomiting makes AC administration difficult and raises the risk of aspiration what extent AC would bind phosphides,[16] the likely effectiveness of gastri the lack of clinical outcome data for AC, aggressive administration of oral

Comprehensive supportive care is recommended. Dilution with bicarbonate recommended,[30] as bicarbonate is believed to decrease the gastric hydr assists in the conversion of phosphides to phosphine gas. Also unproven i permanganate to oxidize the phosphides.[30] Trimetazidine is used for the as it may diminish the oxidant stress caused by phosphine.[17] Trimetazidine States. Preliminary research using rat models in India suggests possible

survival time with the use of NAC and pralidoxime.[4 , 52] These therapies,

Sulfuryl Fluoride

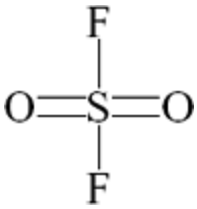

Figure. No Caption Available.

History and Epidemiology

Sulfuryl fluoride (Vikane) has been used as a structural fumigant insectici insects such as termites in homes since 1957. Although it is commonly u Washington, a recent 5-year review of fumigant illness did not contain ar toxicity.[10] Structure or tent fumigation is performed by completely enclos in plastic or a tarpaulin; the sulfuryl fluoride is pumped in as a compress sulfuryl fluoride with chloropicrin added as a warning agent, are the mos

Toxicokinetics and Pathophysiology

Little is known about the toxicokinetics of sulfuryl fluoride in humans. At 4000 ppm) rats developed seizures followed by respiratory arrest.[55] At lo chronic exposure, rats and rabbits developed respiratory inflammation, re vacuolation.[24] The mechanism of toxicity is not understood. The measura suggests that the release of fluoride may be a major pathophysiologic m of chronic, low concentration exposures fluorosis developed.

The TLV-TWA (Threshold Limit Value-Time Weighted Average) for SF is 5 Term Exposure Limit) is 10 ppm; IDLH (Immediately Dangerous to Life ar fluoride was not found to be teratogenic in rats nor rabbits.[31]

Clinical Manifestations

Case reports of sulfuryl fluoride exposure describe acute and subacute co similarities to methyl bromide. Initial symptoms may be gastrointestinal, diarrhea and abdominal pain, or respiratory, including cough and dyspnea may produce salivation, lacrimation with conjunctivitis, and nasopharyngitis studies, severe exposures in humans affect the cardiopulmonary and ner

A husband and wife reentered their home after it was cleared by the fum residual sulfuryl fluoride levels were not provided.[57] Within 24 hours both husband complained of dyspnea and cough that became severe. Approxim exposure, he had a seizure followed by cardiopulmonary arrest. His wife vomiting. Over 3 days she became progressively weaker and unable to w dyspnea followed by ventricular fibrillation. She had a plasma fluoride leve exposure began. Autopsies listed the cause of death as pulmonary edema

Another report describes suspected suicide by sulfuryl fluoride inhalation. second person reentered a tented structure while a worker was found nea tank. A 19-year-old woman who reentered apparently to retrieve some p She was found unconscious, but became alert after removal from the hor coughing and chest pain. Approximately 6 hours later she developed carp cardiac dysrhythmias followed by death. Her serum fluoride level was 20 remarkable for pulmonary edema.

Neurotoxicity may also result from low level acute or chronic exposures. applicator developed nausea, vomiting, and abdominal cramps along with transient.[72] On three subsequent evaluations he complained of difficulty memory and dexterity testing were noted in structural fumigation workers bromide and sulfuryl fluoride.[12]

Diagnostic Testing

Patients with sulfuryl fluoride exposure require frequent monitoring of ser calcium complexes with the fluoride ions (See chapter 101). Continuous the QTc interval, as hypocalcemia may precipitate dysrhythmias. Serum f helpful for the acute management, may help with confirmatory diagnostic

Management

After removal from the scene to fresh air, the patient should be disrobed gassing of any sulfuryl fluoride gas. In treating sulfuryl fluoride poisoning hypocalcemia may be needed. Patients should have ECGs performed and cardiac monitoring to observe for QTc prolongation. Similar to the manag supportive care may be needed for the seizures, cardiac dysrhythmias and bronchospasm.

Metam Sodium

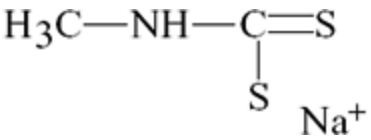

Figure. No Caption Available.

Metam sodium, which breaks down into methyl isothiocyanate, is a potent more common causes of occupational exposure to fumigants.[10] In Sacram derailment resulted in a metam sodium release with persistent air concer exposed individuals developed irritant-induced asthma or reactive airways following the spill.[18] In the cleanup, prolonged exposure to water with 20 caused dermatitis.[44]

Summary

The search for the ideal fumigant continues. It is likely that the use of p bromide use declines during its phase out period. Iodomethane or methyl by the Environmental Protection Agency (EPA). A few reports from Europe methyl iodide may be similar to that of methyl bromide.[33 , 63]

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 113
Mushrooms

Lewis R. Goldfrank

A 58-year-old woman presented to the emergency department (ED) with severe, crampy, abdominal pain and profuse diarrhea. She had spent the summer morning picking wild mushrooms in a local park, as she had done for many years. She found numerous edible species and ate quite a few while picking them. Her symptoms began within 1 hour of returning from the park.

She explained that she was an expert in selecting edible mushrooms, that she picked at the same place every year, and that she never previously had trouble. Prior to coming to the United States she had foraged in the woods of Poland for years without difficulty. She insisted that the mushrooms could not be at fault because they were found growing on dead wood and that slugs had mutilated several of the mushrooms.

The patient had no known allergies and did not drink alcohol. No other family members had been ill recently. Physical examination revealed a pale, diaphoretic, dyspneic, and anxious woman who was persistently gagging. Her vital signs were: blood pressure, 110/60 mm Hg; pulse,

120 beats/min supine; respiratory rate, 24 breaths/min; temperature 98.6Â°F (37Â°C).

The patient's head was atraumatic. Her pupils were 4 mm, equal, and reactive. Sclerae were anicteric; and conjunctivae were pink. Her mucosa was moist with no excessive lacrimation or salivation, and her throat was unremarkable. There were no cutaneous abnormalities. Lungs were clear, heart sounds were normal, and abdominal examination revealed diffuse tenderness with hyperactive bowel sounds. Liver and spleen were unremarkable. The extremities were normal.

The patient was vehemently resistant to the suggestion that she stay in the hospital. However, her dizziness upon standing convinced her to remain. Blood samples were drawn, and an IV was started with 0.9% sodium chloride solution at 300 mL/h. The patient was admitted for observation and volume repletion.

As the patient prepared herself for admission, she gave her belongings and clothing to her daughter. At that point the staff noticed a large bag filled with mushrooms. The patient was so convinced of the quality of these mushrooms that she wanted to give them to her daughter to take home, but eventually she was persuaded to leave the mushrooms in the ED for further examination.

Her hematocrit was 42%, white blood cell count (WBC) was 8300/mm^3 (72% polymorphonuclear leukocytes, 20% lymphocytes, 4% monocytes, 4% eosinophils), and prothrombin time was 13 seconds. Blood glucose was 220 mg/dL; blood urea nitrogen (BUN) was 21 mg/dL; sodium was 140 mEq/L; potassium was 3.7 mEq/L; chloride was 101 mEq/L; and bicarbonate was 30 mEq/L. The chest radiograph was normal, and abdominal radiographs showed a nonspecific ileus pattern.

Despite the patient's certainty that the mushrooms were edible, her presentation persuaded the staff to have the mushrooms investigated. Microscopic spore assessment methods to identify toxic mushrooms

conducted by a mycologist confirmed that the patient had mistakenly picked the jack-o'-lantern (*Omphalotus illudens*), an orange, bioluminescent mushroom,[3] believing it was the edible species of chanterelle (*Cantharellus cibarius*). This error is frequently reported.[38,92]

Epidemiology

Unintentional exposures to mushrooms represent a small but relatively constant percentage of consultations requested from Poison Control Centers (see citations for American Association of Poison Control Centers [AAPCC] data in Chap. 130) A summary of the 19 years of AAPCC data reveals that mushrooms represent less than 0.5% of the reported exposures to poisons. Combined data accumulated by the AAPCC and the Mushroom Poisoning Registry of the North American Mycological Association indicates that approximately 5 patient exposures to toxic mushrooms per 100,000 population occur per year. Some variations result from geographic and climatic conditions and mycologic habitats.[90] Although the methods of analysis of patients with mushroom exposures have changed over the past 19 years, cumulative AAPCC Toxic Exposure Surveillance System (TESS) data consistently demonstrate the relative benignity

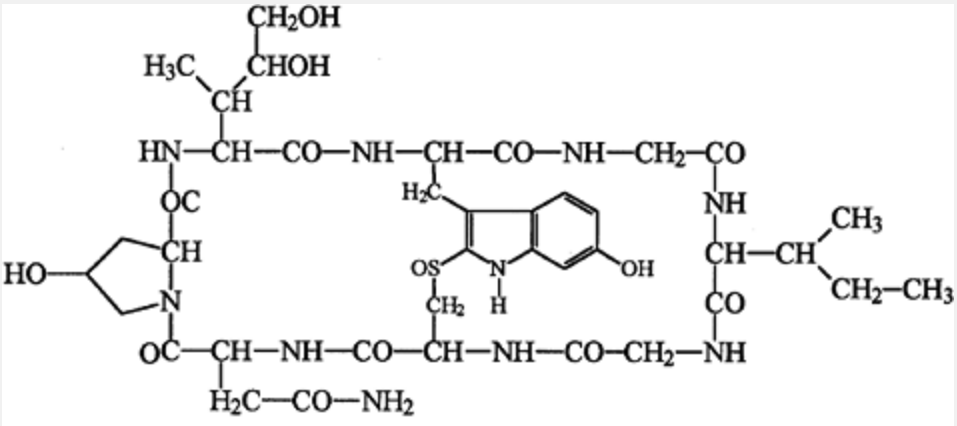
of the vast majority of exposures. The inability of most healthcare providers to correctly identify the ingested mushroom and the rarity of lethal ingestions are demonstrated by the accumulated data. In more than 95% of cases, the exact species was unidentified,[90] and only approximately 10% of the mushroom groups ingested were known. More than 50% of exposed individuals had no symptoms. Twenty-five percent of the patients were treated in healthcare facilities annually; of these 10â€“15% had minor toxicity, less than 5% had moderate toxicity, and approximately 0.3% had major toxicity. During the 19-year period covered by TESS, only 22 of the patients died of their ingestions. Of the mushrooms associated with a death, 14 probably were *Amanita* spp, 2 hallucinogens, 1 *Boletus* spp, 1 presumed

gyromitrin-containing mushroom, and 4 unidentified. All reported deaths occurred in adults. Of the mushroom groups identified in intentional abuse and poisonings, hallucinogens and gastrointestinal (GI) toxins were the most common, yet accounted for less than 10% of ingestions. All other groups represented less than 2% of the total number of identified. Because 90% of mushrooms involved in exposures are never identified, a strategy for making significant decisions with incomplete data is needed.

Classification and Management

Because mushroom species vary widely with regard to the toxins they contain and because identifying them with certainty is difficult, a clinical system of classification is more useful than a taxonomic system (Table 113-1). In many cases, management and prognosis can be determined with a high degree of confidence from the history and initial symptoms.[41,54,55] Ten groups of toxins are identifiable: cyclopeptides, gyromitrin, muscarine, coprine, ibotenic acid and muscimol, psilocybin, general GI irritants, orellinine, allenic norleucine, and myotoxins.[41,54]

Group I: Cyclopeptide-Containing Mushrooms



Î±-Amanitin

Most mushroom fatalities in North America and worldwide are associated with cyclopeptide-containing species.[4,24,102] These mushrooms include a number of *Amanita* species, including *A. verna, A. virosa*, and *A. phalloides*, *Galerina* spp, including *G. autumnalis, G. marginata*, and *Galerina venenata*, and *Lepiota* species, including *L. helveola*, *L. josserandi*, and *L. brunneoincarnata*. (See ILAMANITAPHALLOIDS and ILAMANITAVIROSA in the Image Library at http://www.goldfrankstoxicology.com)

Early differentiation of cyclopeptide poisonings from other types of mushroom poisoning is difficult. Patients poisoned with cyclopeptides may present to an ED with a seemingly innocuous picture of nausea, vomiting, abdominal pain, and diarrhea, which often is attributed to other causes. Such patients may be sent home, only to return moribund on a subsequent day. The delayed onset of more serious symptoms is typical of cyclopeptide poisoning and is a critical consideration in assessing any potential poisoning.

Amanita phalloides contains 15â€“20 cyclopeptides with an approximate weight of 900 daltons. The amatoxins (cyclic octapeptides), phallotoxins (cyclic heptapeptides), and virotoxins

(cyclic heptapeptides) are the best studied.[27,51,97] Of these three chemically similar cyclopeptide molecules, phalloidin (the principal phallotoxin) appears to be a rapid-acting toxin, whereas amanitin tends to cause more delayed manifestations.[79] Phalloidin crosses the sinusoidal plasma membranes of hepatocytes by a carrier-mediated process. This process is shared by bile salts and can be prevented in the presence of extracellular bile salts, suggesting a competitive inhibition. A sodium-independent bile salt transporting system may be responsible for phalloidin hepatic uptake, elimination, and detoxification.[61] Phalloidin interrupts actin polymerization and impairs cell membrane function, but because of its limited oral absorption it appears to have minimal toxicity, restricted mostly to GI dysfunction. There is no evidence for the toxicity of virotoxins in humans.

The amatoxins appear to be the most toxic of the cyclopeptides, leading to hepatic, renal, and central nervous system (CNS) damage. These polypeptides are heat stable, insoluble in water, and lose activity over a period of years upon desication.[27] Î±-Amanitin is the principal amatoxin responsible for human toxicity following ingestion. Approximately 1.5â€“2.5 mg amanitin can be obtained from 1 g dry *A. phalloides*, and as much as 3.5 mg/g can be obtained from some *Lepiota* spp.[66,70,97] A 20-g mushroom contains well in excess of the 0.1 mg/kg amanitin considered lethal for humans.[25]

Î±-Amanitin absorption appears to be facilitated by a sodium-dependent bile acid transporter. Several studies demonstrate that the sodium taurocholate cotransporter polypeptide facilitates hepatocellular Î±-amanitin uptake.[40] In vitro studies show that Î±-amanitin is cytotoxic based on its interference with RNA polymerase II, preventing the transcription of DNA.[59,83] The LD_{50} of Î±-amanitin in mice is 0.1â€“0.75 mg/kg, and the LD_{50} of Î²-amanitin in mice is 0.2â€“0.4 mg/kg,[25] suggesting the two amanitins have comparable toxicity.

In animals, cimetidine (a potent cytochrome P450 system inhibitor) may have a hepatoprotective effect against Î±-amanitin by inhibiting

metabolism,[77] but it shows no protective effect against phalloidin toxicity.[79] Cimetidine is proposed as a therapeutic intervention,[78] but no available human data support its use. The amanitins are poorly but rapidly absorbed from the GI tract,[45] and Î±-amanitin may be enterohepatically recirculated. Target organs are those with the highest rate of cell turnover, including the GI tract epithelium, hepatocytes, and kidneys. Amatoxins do not appear to cross the placenta, as demonstrated by the absence of fetal toxicity in severely poisoned pregnant women.[6,11,88]

Amatoxins show limited protein binding and are present in the plasma at low concentrations for 24â€“48 hours.[45] In an intravenous radiolabeled amatoxin study in dogs, 85% of the amatoxin was recovered in the urine within the first 6 hours, whereas <1% was found in the blood at that time.[26] Amatoxins can be detected by high-performance liquid chromatography,[45] thin-layer chromatography, and radioimmunoassay in gastroduodenal fluid,

serum, urine, stool, and liver and kidney biopsies for several days following an ingestion.[25,27,50]

Genus/Species	Toxin	Time of Onset of Symptoms	Primary Site of Toxicity	Symptoms	Mortality	Specific Therapy[a]
I. *Amanita phalloides, A. tenuifolia, A. virosa* *Galerina autumnalis G. marginata, G. venenata* *Lepiota josserandi, L. helveola*	Cyclopeptides Amatoxins Phallotoxins	5–24 h	Hepatic	Phase I: GI toxicity-N V D Phase II: Quiescent, Phase III: Gastroenteritis, jaundice, ↑ AST, ↑ ALT	10–30%	Activated charcoal Hemoperfusion Penicillin G Silibinin
II. *Gyromitra ambigua, G. esculenta, G. infula*	Gyromitrin (metabolite: monomethylhydrazine)	5–10 h	CNS	Seizures, abdominal pain, N/V, weakness, hepatorenal failure	Rare	Benzodiazepines, Pyridoxine, 70 mg/kg IV
III. *Clitocybe dealbata, Omphalotus olearius* Most *Inocybe* spp	Muscarine	0.5–2 h	Autonomic nervous system	Muscarinic effects-salivation, bradycardia, lacrimation, urination, defecation, diaphoresis	Rare	Atropine: Adults: 1–2 mg Children: 0.02 mg/kg with a minimum of 0.1 mg
IV. *Coprinus atramentarius*	Coprine (metabolite: 1-aminocyclopropanol)	0.5–2 h	Aldehyde dehydrogenase	Disulfiramlike effect with ethanol, tachycardia, N/V	Rare	—
V. *Amanita gemmata, A. muscaria, A. pantherina*	Ibotenic acid, muscimol	0.5–2 h	CNS	GABAergic effects, rare delirium, hallucinations, dizziness, ataxia	Rare	Benzodiazepines during excitatory phase
VI. *Psilocybe caerulipes, P. cubensis* *Gymnopilus spectabilis* *Psathyrella foenisecii*	Psilocybin, psilocin	0.5–1 h	CNS	Ataxia, N/V, hyperkinesis, hallucinations	Rare	Benzodiazepines
VII. *Clitocybe nebularis* *Chlorophyllum molybdites, C. esculentum,* *Lactarius* spp *Paxillus involutus*	Various GI irritants	0.5–3 h	GI	Malaise, N/V/D	Rare	—
VIII. *Cortinarius orellanus, C. speciosissimus, C. rainierensis*	Orelline, orellanine	>24 h Days-weeks	Renal	Phase I: N/V Phase II: Oliguria, renal failure	Rare	Hemodialysis for renal failure
IX. *Amanita smithiana*	Allenic norleucine	0.5–12 h	Renal	Phase I: N/V Phase II: Oliguria, renal failure	None	Hemodialysis for renal failure
X. *Tricholoma equestre*	Unidentified myotoxin	24–72 h	Muscle (skeletal and cardiac)	Fatigue, nausea, muscle weakness, myalgias (↑CPK), facial erythema, diaphoresis, myocarditis	25%	—

D = diarrhea; N = nausea; V = vomiting.
[a]Supportive care (fluids, electrolyes, and antiemetics) as indicated.

TABLE 113-1. Mushroom Toxicity

Some of the toxicokinetic analyses following unquantified ingestions demonstrate 12â€“23 Âµg amatoxin excretion in the urine over 24â€“66 hours, of which 60â€–80% occurred during the first 2 hours of collection. The extreme variabilities of the type and quantity of ingestant, the host, and the management make interpretations exceedingly difficult.[93] In another series, total maximal urinary Î±- and Î²-amanitin excreted over 6â€“72 hours were 3.19 and 5.21 mg, respectively. Two thirds of the patients had total amanitin toxin excretion >1.5 mg.[45] Urinary amanitin excretion concentrations differ by several orders of magnitude. Whether the variation results from exposure dose, time following ingestion, or laboratory technique is unclear. Several techniques for evaluating urinary amanitin presence qualitatively and quantitatively are under investigation. The sensitivity and specificity of these determinations are under investigation.[14,15,70,87] Most studies suggest that no circulating amatoxins are present by the time the need for transplantation is evident.[23]

Clinical

Phase I of cyclopeptide poisoning resembles severe gastroenteritis, with profuse watery diarrhea not occurring until 5â€“24 hours after ingestion. Supportive fluid and electrolyte replacement leads to transient improvement during phase II, which occurs between 12 and 36 hours after ingestion.[70,102] However, despite such supportive care, phase III, manifested by hepatic and renal toxicity and death, may ensue 2â€–6 days after ingestion.[4] Pancreatic toxicity may rarely occur.[32] The initial hepatotoxicity begins within the second phase, but clinical hepatotoxicity (Chap. 26) with elevated concentrations of bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT), hypoglycemia, jaundice, and coma are not

manifest until 2â€“3 days after ingestion. Pathologic manifestations include steatosis, central zonal necrosis, and centrilobular hemorrhage, with viable hepatocytes remaining at the rims of the larger triads. Lobular architecture remains intact.[4]

Cyclopeptide poisoning alters the hormones that regulate glucose, calcium, and thyroid homeostasis, resulting in widespread endocrine abnormalities.[48] Insulin and C-peptide concentrations are elevated at a stage of poisoning prior to hepatic and renal compromise.[22,48] These findings are suggestive of direct toxicity to pancreatic Î² cells, resulting in release of preformed hormone or induction of hormone synthesis. This insulin release necessitates vigilance for hypoglycemia prior to hepatocellular damage. Serum calcitonin concentrations may be elevated, and hypocalcemia may be present. Thyroxine concentrations may be depressed and triiodothyronine concentrations undetectable, whereas thyroid-stimulating hormone concentrations may not be elevated. These thyroid-related findings were reported in a single study and merit further investigation.[48]

In a series of 10 patients poisoned by diverse *Lepiota* spp, 50% developed a mixed sensory and motor polyneuropathy. Most of the patients spontaneously recovered within 1 year, although a single patient developed progressive clinical and electromyographic deterioration.[72] These neuropathic findings have not been recognized in other case reports.

Treatment

The search for treatments has been vigorously pursued in Europe because of the persistently large number of amatoxins victims each year.[31] Thioctic (Î±-lipoic) acid initially was reported to be beneficial in treating the amatoxin-induced liver toxicity in several different animal models, and a number of uncontrolled clinical trials in humans followed.[4] Because of its potential effects as a coenzyme in the tricarboxylic acid cycle or as a free radical scavenger, thioctic acid, was credited for the survival of 39 of 40 patients reportedly poisoned

by *A. phalloides*.[52] Hypoglycemia is a common feature of thioctic acid therapy for *Amanita* poisoning, but whether hypoglycemia results from direct toxicity of the drug or is secondary to hepatic damage is not clear.

Despite the initial success, thioctic acid was not effective in various other studies.[33,34] Survival rates of patients poisoned by *A. phalloides* who received any of the following: supportive care, fluid and electrolyte repletion, high-dose penicillin G, dexamethasone, and thioctic acid are between 70% and 90%.[31,44,63,64,102]

Several laboratory investigations in mice and rats suggest that 1 g/kg penicillin G (l g = 1,600,000 units) may have a time- and dose-dependent protective effect.[35,36] These results are limited because the amatoxins were administered intraperitoneally, resulting in the death of untreated animals 12â€“24 hours later. Additional investigations demonstrated that 1 g/kg penicillin G administered 5 hours after sublethal doses of Î±-amanitin decreased clinical and laboratory toxicity.[35] The mechanisms suggested include displacing Î±-amanitin from albumin, blocking its uptake from hepatocytes, binding circulating amatoxins, and preventing Î±-amanitin binding to RNA polymerase. None of these mechanisms is substantiated. Although the hepatoprotective effects of penicillin remain unclear,[24] a dose of 1,000,000 units of penicillin G/kg/d IV is recommended as safe and possibly efficacious.[49,50,81]

The active complex of milk thistle (*Silybum marianum*) is silymarin, which is a lipophilic extract composed of 3 isomeric flavonolignans: silibinin, silychristin, and silydianin. Silibinin represents approximately 50% of the extract, but is 70â€“80% of the marketed product.[43] Silibinin may modify or occupy cell membrane receptor sites, thereby inhibiting hepatocellular penetration by Î±-amanitin. Use of silibinin 50 mg/kg in dogs, 5 and 24 hours following exposure to Î±-amanitin, suppressed chemical evidence of hepatotoxicity and lethality. Although silibinin is routinely available in health food stores and appears to be safe and well tolerated in patients with chronic liver disease, no

reduction in mortality, improvement in histology at liver biopsy, or biochemical marker has been identified in a systematic review and meta-analysis.[43] Silibinin 20â€“50 mg/kg/d is recommended for use in humans, even though this xenobiotic is not approved by the FDA for use in the United States.[50,96] Activated charcoal both adsorbs the amanitins and improves survival in laboratory animals.[25] Emesis, lavage, and catharsis are not necessary unless the patient is seen shortly after the ingestion, because the toxin usually induces emesis and catharsis. Activated charcoal is safe, logical, and a valuable therapeutic strategy. Although the clinical presentation often is delayed, 1 g/kg body weight of activated charcoal should be given orally every 2â€“4 hours (if the patient is not vomiting) or by continuous nasogastric infusion. Fluid and electrolyte repletion and treatment of hepatic compromise are essential. Intravenous 0.9% sodium chloride solution and electrolytes usually are necessary because of substantial fluid loss due to vomiting and diarrhea. Dextrose repletion may be necessary because of nutritional compromise, hepatic failure, or glycogen depletion. Because of its hepatoprotective effects, *N*-acetylcysteine is also suggested as an antidote, but no evidence for any specific benefit has been demonstrated.

Forced diuresis, hemodialysis, plasmapheresis,[46,47] hemofiltration, and hemoperfusion[29] may be effective shortly after ingestion, but most studies neither offer clinical evidence of benefit nor supportive

pharmacokinetic data for any of these therapies.[50,69,70,93,95] Plasmapheresis, which is dependent on effective clearance, high plasma protein binding, and a low volume of distribution, does not remove more than 10 Âµg amatoxin. Because of the absence of prospective controlled studies of exposure to amatoxins in addition to the extreme variability of success with many regimens, multiple-dose activated charcoal and supportive care remain the standard therapy. Early recognition of exposure to amanitin is an indication for hemoperfusion, but most patients likely will not have the potential for

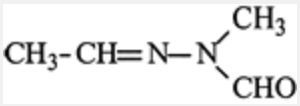
benefit at the time they develop clinical manifestations of toxicity.[47] Future therapeutic interventions may be dependent on improved understanding of the hepatocellular bile acid transporter system.[40,53]

Extracorporal albumin dialysis[28] and molecular absorbent regenerating system[19] are variant detoxification techniques used in patients with fulminant hepatic failure to remove water soluble and albumin bound toxins while providing renal support. These two techniques permit time for hepatic regeneration or sufficient bridging time to orthotopic liver transplantation. The criteria and timing for liver transplantation in this setting are far less established than for fulminant viral hepatitis, where grade III or IV hepatic encephalopathy, marked hyperbilirubinemia, and azotemia are the well-established criteria for transplantation[68] (Chap. 26). When fulminant hepatic failure is present, *N*-acetylcysteine should be administered until the patient recovers from the encephalopathy because of its presumptive benefits under these circumstances (Antidotes in Depth: *N*-Acetylcysteine). Successful transplantations were performed in individuals whose resected livers showed 0â€“30% hepatocyte viability. In these cases, the authors did not wait for progression past grade II encephalopathy or for development of azotemia or marked hyperbilirubinemia.[68] Criteria for patient selection are essential to avoid unnecessary risk while offering the potential for survival to appropriate candidates who have no functional liver. The grim prognosis associated with hepatic coma secondary to *Amanita* poisoning has led several transplant groups to consider hepatic transplantation for encephalopathic patients with prolonged INRs, persistent hypoglycemia, metabolic acidosis, increased concentrations of serum ammonia and AST, and hypofibrinogenemia.[39,49,68] There are now case reports of successful liver transplantation for fulminant hepatic failure from presumed *Amanita ocreata*,[49,101] *A. phalloides*[45,68] *Amanita vivosa*,[13] *Lepiota helveola*,[62] and *Lepiota brunneoincarnata* poisoning.[72]

To enhance the likelihood of success, several authors suggest that individuals who manifest symptoms suggestive of hepatotoxic *Amanita, Galerina*, or *Lepiota* spp exposure should be told of the potential need

for transplantation and, with their consent, rapidly transferred to a regional liver transplantation center.

Group II: Gyromitrin-Containing Mushrooms



Gyromitrin

Members of the gyromitrin group include *G. esculenta, G. californica, G. brunnea*, and *G. infula. Gyromitra esculenta* is a good example of a mushroom with a â€œJekyll and Hydeâ€• personality, enjoying a reputation of being edible in the western United States but of being poisonous in other areas. These mushrooms are found commonly in the spring under conifers and are easily recognized by their brainlike appearance. Poisonings with these mushrooms are exceptionally uncommon in the United States, representing <1% of all recognized events, whereas these poisonings are considered more common in Europe. Certain cooking methods may eliminate the toxin, but inhalation of the fumes while cooking may cause poisoning. Because of the potential for toxicity, all members of this mushroom family should be avoided. The most common error occurs in the spring, when an individual seeking the nongilled brainlike *Morchella esculenta* (morel)

finds the similar *Gyromitra esculenta* (false morel). (See ILGYROMETRA in the Image Library.)

Gyromitra mushrooms contain gyromitrin (*N*-methyl-*N*-formyl hydrazone), which on hydrolysis splits into acetaldehyde and *N*-methyl-*N*-formyl hydrazine. Gyromitrin is unstable and therefore unlikely to exist in its free form. Subsequent hydrolysis, yields monomethylhydrazine (CH_3NHNH_2). The hydrazine moiety reacts with pyridoxine, resulting in inhibition of pyridoxal phosphate-related enzymatic reactions. This interference with pyridoxal phosphate disrupts the function of the inhibitory neurotransmitter Î³-aminobutyric acid (GABA).[54] The implications of this decrease in GABA, which is thought to contribute to intractable seizures associated with isoniazid or gyromitrin toxicity in a fashion identical to isoniazid toxicity, is discussed in Antidotes in Depth: Pyridoxine.

The initial signs of toxicity for these mushrooms occur 5â€“10 hours after ingestion and include nausea, vomiting, diarrhea, and abdominal pain. Patients manifest headaches, weakness, and diffuse muscle cramping. Most patients improve dramatically and return to normal function within several days. Rarely, early in the clinical course patients develop delirium, stupor, convulsions, and coma. Infrequently, patients develop a hepatorenal syndrome and require extensive in-hospital care.

Activated charcoal 1 g/kg body weight should be given. Benzodiazepines such as diazepam or lorazepam are appropriate for initial management of seizures. Under most circumstances, supportive care is adequate treatment. Pyridoxine in doses of 70 mg/kg IV may be useful in limiting seizures (Antidotes in Depth: Pyridoxine).

There are no rapid diagnostic strategies in the laboratory, although thin-layer chromatography, gas-liquid chromatography, and mass spectrometry can be used for subsequent (delayed) identification of the various hydrazine and hydrazone metabolites.

Group III: Muscarine-Containing Mushrooms

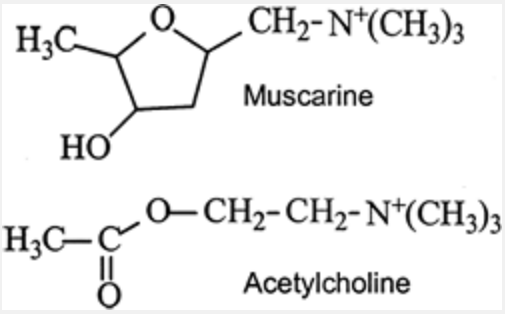


Figure. No Caption Available.

Mushrooms that contain muscarine include numerous members of the *Clitocybe* genus, such as *C. dealbata* (the sweater) and *C. illudens* (*Omphalotus olearius*), and the *Inocybe* genus, that in turn include *I. iacera* and *I. geophylla. Amanita muscaria* and *Amanita pantherina* contain limited quantities of muscarine. (See ILCLITOCYBEDEALBATA and ILOMPHALOTUSOLEARIUS in the Image Library.)

Muscarine and acetylcholine are similar structurally and have comparable clinical effects at the muscarinic receptors. Peripheral manifestations typically include bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic manifestations do not occur because muscarine, a quaternary ammonium compound, does not cross the bloodâ€“brain barrier (Chap. 14). No nicotinic manifestations occur.

The effects of muscarine often last longer than those of acetylcholine. Because muscarine lacks an ester bond, it is not susceptible to

acetylcholinesterase hydrolysis. Clinical manifestations, which typically are mild, usually develop within 0.5â€“2 hours and last several additional hours. Significant toxicity is uncommon, limiting the need for more than supportive care. Rarely, atropine (1â€“2 mg given IV slowly for adults or 0.02 mg/kg with a minimum of 0.1 mg IV for children) can be titrated and repeated as frequently as indicated to reverse symptomatology.

No current, clinically available, analytic techniques can identify muscarine, although high-performance liquid chromatography would be appropriate for investigative purposes.

Group IV: Coprine-Containing Mushrooms

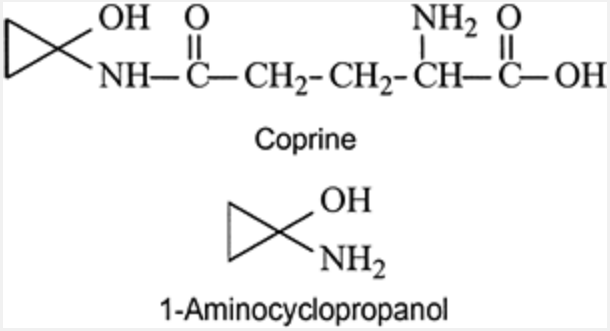

Figure. No Caption Available.

Coprinus mushrooms, particularly *C. atramentarius*, contain the toxin coprine. (See ILCOPRINUSATRAMENTARIUS in the Image Library.) These mushrooms grow abundantly in temperate climates in grassy or woodland fields. They are known as â€œinky capsâ€• because the gills that contain a peptidase autodigest into an inky liquid shortly after picking. The edible member of this group, *Coprinus comatus* (shaggy mane) is nontoxic, and probably its misidentification results in

collectors' errors. Coprine, an amino acid, its primary metabolite, 1-aminocyclopropanol,[17,60,89] or, more likely, a secondary in vivo hydrolytic metabolite, cyclopropanone hydrate, has a disulfiramlike effect.[100] Although both of these metabolites appear to inhibit aldehyde dehydrogenase, the most stable in vivo inhibitory effect is present in cyclopropane hydrate.[100] Inhibition of acetaldehyde dehydrogenase results in buildup of acetaldehyde and its accompanying adverse effects, which occur if the patient ingests alcohol concomitantly or for as long as 48â€“72 hours after the mushroom ingestion. Within 0.5â€“2 hours of ethanol ingestion, an acute disulfiram effect is noted, with tachycardia, flushing, nausea, and vomiting. Interestingly, alcohol ingested simultaneously does not result in clinical manifestations because inhibition of aldehyde dehydrogenase is slightly delayed during coprine metabolism. Treatment is symptomatic with fluid repletion and antiemetics such as metoclopramide, although clinical manifestations usually are mild and resolve within several hours. Prophylactic use of fomepizole immediately following ingestion of ethanol and coprine-containing mushrooms has a theoretical basis, but no case reports or studies are published. This group of mushrooms rarely causes fatalities (disulfiram is discussed further in Chap. 77).

Group V: Ibotenic Acid- and Muscimol-Containing Mushrooms

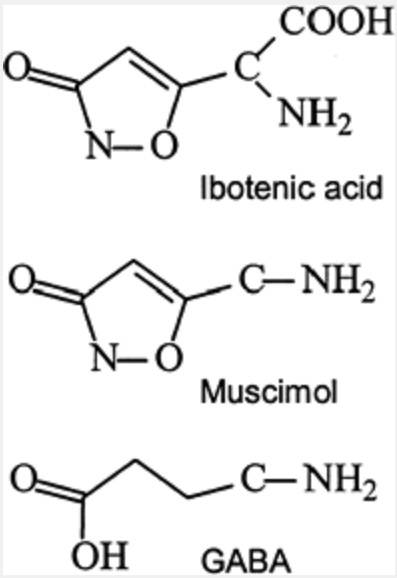

Figure. No Caption Available.

Most of the mushrooms in this class are primarily in the *Amanita* genus, which includes *A. muscaria*, (fly agaric) *A. pantherina*, and *A. gemmata*. (See ILAMANITAMUSCARIA1, ILAMANITAMUSCARIA2 and ILAMANITAMUSCARIA3 in the Image Library.) They exist singly and are scattered throughout the US woodlands. The brilliant red or tan cap (pileus) is that of the mushroom commonly depicted in children's books and is easily recognized in the fields during summer and fall.

Small quantities of the isoxazole derivatives ibotenic acid and muscimol are found in these mushrooms, which have been used in religious customs throughout history. Ibotenic acid is structurally similar to the stimulatory neurotransmitter glutamic acid. The stereochemistry of muscimol is very similar to that of the neurotransmitter GABA and may act as a GABA agonist.

Most patients who develop symptoms intentionally ingested large quantities of these mushrooms while seeking an hallucinatory experience. Within 0.5â€“2 hours of ingestion, these compounds

produce the GABAergic manifestations of somnolence, dizziness, hallucinations, dysphoria, and delirium in adults, whereas the excitatory glutamatergic manifestations of myoclonic movements, seizures, and other neurologic findings predominate in children.[7]

Treatment is invariably supportive. Most symptoms respond solely to supportive care, although a benzodiazepine such as diazepam or lorazepam is appropriate for excitatory CNS manifestations.

Group VI: Psilocybin-Containing Mushrooms

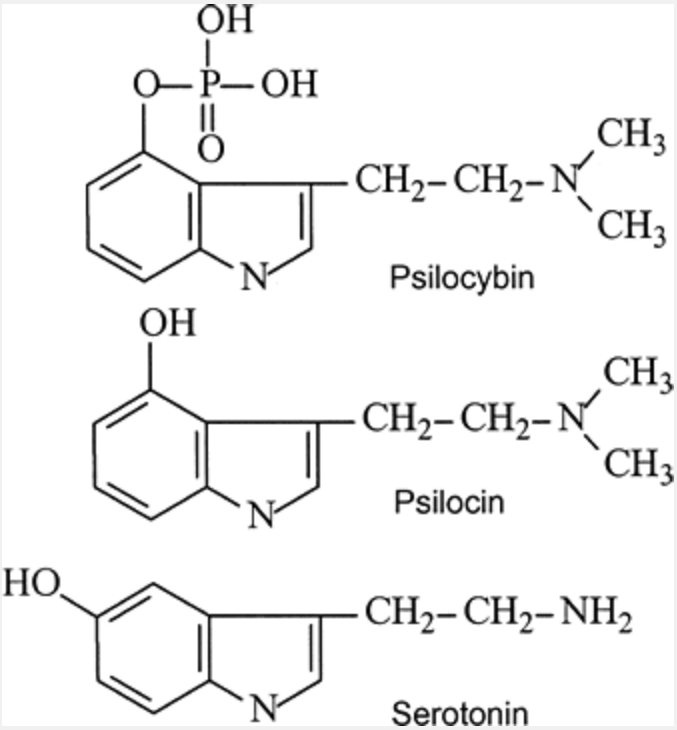

Figure. No Caption Available.

Psilocybin-containing mushrooms include *Psilocybe caerulescens*,

Psilocybe cubensis, *Conocybe cyanopus*, *Panaeolus foenisecii, Gymnopilus spectabilis,* and *Psathyrella foenisecii.* (See ILPSILOCYBECYANESCENS, ILPSILOCYBECAERULIPES, and ILGYMNOPILUSSPECTABILIS in the Image Library.) These mushrooms have been used for native North and South American religious experiences for thousands of years. They grow abundantly in warm, moist areas of the United States. Drug culture magazines and Internet sources advertise mail-order kits containing *P. cubensis* spores to grow â€œmagic mushroomsâ€• domestically.

Toxicity from this group is common because of the popularity of hallucinogens.[9] The quality, quantity, and variety of mushroom ingested may or may not be related to the hallucinogenic effects. Psilocybin is rapidly and completely hydrolyzed to psilocin in vivo. Serotonin, psilocin, and psilocybin are very similar structurally and presumably act at a similar 5-HT_2 receptor site. The effects of psilocybin as a serotonin agonist and antagonist are discussed in Chaps. 14 and 80.

The psilocybin and psilocin indoles, like those of lysergic acid diethylamide (LSD), rapidly (within 1 hour of ingestion) produce CNS effects, including ataxia, hyperkinesis, visual hallucinations, and illusions.[42] Rare cases of renal failure,[37,71] seizures, and cardiopulmonary arrest[9] are associated with psilocybin-containing species. However, such associations should always be questioned when reported in a substance-using population potentially simultaneously exposed to other toxins.

Some patients manifest tachycardia, anxiety, hallucinations, tremor, agitation, and mydriasis. Anxiety and light-headedness may develop quite rapidly (<1 hour), and most manifestations are recognized within 4 hours of ingestions with a return to normalcy within 6â€“12 hours. A single patient who intravenously administered an extract of *Psilocybe* mushrooms experienced chills, weakness, dyspnea, headache, severe myalgias, vomiting associated with hyperthermia, hypoxemia, and mild methemoglobinemia.[20]

Treatment for hallucinations usually is supportive, although a benzodiazepine such as diazepam or lorazepam may be necessary when reassurance proves inadequate.

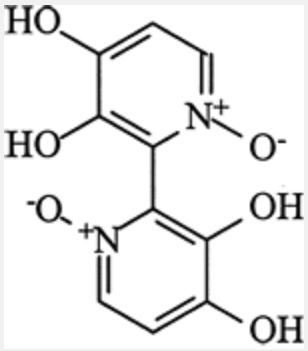
Group VII: Gastrointestinal Toxin-Containing Mushrooms

By far the largest group of mushrooms is a diverse group that contains a variety of ill-defined GI toxins. Many of the hundreds of mushrooms in this group fall into the â€œlittle brown mushroomâ€• category. Some *Boletus, Lactarius* spp, *Omphalotus olearius, Rhodophyllus* spp, *Tricholoma* spp, *Chlorophyllum molybdites*, and *Chlorophyllum esculentum* are mistaken for edible or hallucinogenic species. (See ILRUSSULAEMETICA and ILCHLOROPHYLLUMMOLYBDITES in the Image Library.) The toxins associated with this group are not identified. The malabsorption of proteins and sugars such as trehalose and the ingestion of a mushroom infected or partially digested by microorganisms or allergy may be responsible for symptoms. GI toxicity occurs 0.5â€“3 hours after ingestion when epigastric distress, malaise, nausea, vomiting, and diarrhea are evident. Treatment with regard to fluid resuscitation, vomiting, and diarrhea is supportive. The clinical course is brief and the prognosis excellent.

Others have described a *Paxillus* syndrome, which may be associated with involutin, one of the constituents of *Paxillus*.[50] A small number of patients with ingestions of *Paxillus involutus*, and possibly *Clitocybe claviceps* and *Boletus luridus*, develop a mild GI syndrome followed by an immune-mediated hemolytic anemia, hemoglobinuria, oliguria, and renal failure. IgG antibodies to a *Paxillus* extract were detected by a hemagglutination test in these patients.[98,99]

Rarely, clinical presentations are life threatening, with hypovolemic shock necessitating fluids and vasopressors.[84] Resolution of symptoms usually occurs within 6â€“24 hours. The clinical courses associated with specific mushroom ingestions are variable.[7] Death is rare.

Group VIII: Orellanine-and Orellinine-Containing Mushrooms



Orellanine

Cortinarius mushrooms, such as *Cortinarius speciosissimus.* (See ILCORTINARIUSSPELIOSISSIMUS in the Image Library.) and *Cortinarius orellanus*, are commonly found throughout Europe. *Cortinarius rainierensis* is a common North American species.[16,80] The *C. orellanus* toxin orellanine is reduced by photochemical degradation to orellinine, another bipyridyl agent that is further reduced to the nontoxic orelline.[2,65,74] The toxic compound orellanine is a hydroxylated bipyridine compound activated by its metabolism through the P450 system. Toxicologically, these molecules are similar to paraquat and diquat and may have comparable mechanisms of action, although precise knowledge is limited (Chap. 111). Other nephrotoxins, such as cortinarines, are isolated from certain *Cortinarius* species[87] and result in tubular damage, interstitial nephritis, and fibrosis.

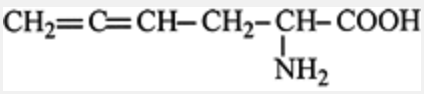
Initial symptoms occur 24â€“36 hours after ingestion and include headache, chills, polydipsia, anorexia, nausea, vomiting, and flank and abdominal pain. The largest case review demonstrated that numerous

patients repetitively ingested the *Cortinarius* spp prior to diagnosis.[21] Oliguric renal failure may develop several days to weeks after initial symptoms.[10] The only initial laboratory abnormalities may be hematuria, leukocyturia, and proteinuria. Nephrotoxicity is characterized by interstitial nephritis with tubular damage and early fibrosis of injured tubules with relative glomerular sparing.[16,80] Hepatotoxicity is rarely reported.[10] Hemoperfusion, hemodialysis, and renal transplantation are used for treatment.[10,21] No evidence suggests that secondary detoxification by plasmapheresis or hemoperfusion is of any benefit in preventing chronic renal failure even when initiated in the first 48 hours.[21,50,73] The data are inadequate to define management or prognosis precisely, as many patients improve rapidly, while some require acute hemodialysis and others require chronic therapy for renal failure.[10] No laboratory or clinical parameters to assist in predicting the individual reactions to the toxins are available. Although case reports in the literature commonly lack definitive proof of ingestion or confirmation of toxin presence, the more

rapid the onset of GI and renal manifestations, the greater the risk of both acute and chronic renal failure appear to be.[21]

Orellanine is rapidly removed from the plasma within 48â€“72 hours and concentrated in the urine in a soluble form. It can be detected in the plasma at the time of clinical symptoms by some investigators[73] but not by other investigators.[75] Thin-layer chromatography on renal biopsy material can detect orellanine long after clinical exposure.[73,75]

Group IX: Allenic Norleucine-Containing Mushrooms



Allenic norleucine

This relatively new diagnostic group is associated with ingestion of *Amanita smithiana*. (See ILAMANITASMITHIANA in the Image Library.) The 13 cases of *A. Smithiana* poisoning reported have all occurred in the Pacific Northwest.[56,91,94] Because the mature specimen often lacks any evidence of a partial or universal veil, these mushrooms are not recognized as *Amanita* species. It appears that all of the poisoned individuals were seeking the edible pine mushroom matsutake (*Tricholoma magnivelare*), a highly desirable look-alike. (See ILTRICHOLOMAMAGNIVELARE in the Image Library.) The *A. smithiana* and *A. abrupta* possess 2 amino acid toxins: allenic norleucine (amino-hexadienoic acid) and possibly l-2-amino-4-pentynoic acid.[18,67,103] In vitro renal epithelial tissue cultured with allenic norleucine developed morphologic changes similar to those that occur following *A. smithiana* ingestion.[67] In mice the extract of *Amanita abrupta* was also hepatotoxic, which suggests that other toxic agents in addition to the two described amino acids were present.[103]

Initial symptoms were noted from 30 minutes to 12 hours following ingestion of either raw or cooked specimens. GI manifestations, including anorexia, nausea, vomiting, abdominal distress, and diarrhea, occurred frequently, accompanied by malaise, sweating, and dizziness.

In some cases, vomiting and diarrhea persisted. The patients were oliguric or anuric upon presentation. Acute renal failure manifested 4â€“6 days following ingestion with marked elevation of BUN and creatinine. ALT and lactate dehydrogenase concentrations frequently were elevated, whereas amylase, AST, alkaline phosphatase, and bilirubin were only infrequently abnormal.

Risk of toxicity was greatest in older patients and in patients with underlying renal insufficiency. Patients who required hemodialysis underwent the procedure 2â€“3 times per week for approximately one month. None of the patients in the three series died.

There is no known antidote for these nephrotoxins. Activated charcoal, although of no proven benefit, should be used in standard doses when a patient in the northwest United States presents with early GI manifestations after mushroom ingestions. The clinician will be forced to consider the circumstances of ingestion to assess the probability of *A. smithiana* ingestion as opposed to ingestion of mushrooms containing a GI toxin.

In view of the substantial morbidity associated with *A. smithiana* ingestions, historic, clinical, and/or temporal evidence of this ingestion should lead to activated charcoal hemoperfusion or hemo-dialysis as a strong consideration when the patient presents in the early phase of exposure. When a patient presents with renal compromise several days, as opposed to weeks, following mushroom ingestion and with a history of early, as opposed to delayed, GI manifestations, the clinician may be able to differentiate *A. smithiana* from *Cortinarius* spp exposure.

Group X: Rhabdomyolysis-Associated Mushrooms

Twelve patients who ingested *Tricholoma equestre* (*T. flavovirens*) mushrooms for three consecutive days developed severe rhabdomyolysis that was lethal in three cases.[5] All patients developed

fatigue, muscle weakness, and myalgias 24â€“72 hours following the last mushroom meal. The individuals also developed facial erythema, nausea without vomiting, and profuse sweating. The mean maximal creatine phosphokinase (CPK) was 226,067 units/L in women and 34,786 units/L in men, with some values >500,000 units/L. Electromyography revealed muscle injury with myotoxic activity. The biopsies showed myofibrillar injury and edema consistent with an acute myopathy.

Dyspnea, muscle weakness, pulmonary congestion, acute myocarditis, dysrhythmias, cardiac failure, and death ensued in three patients. Autopsy demonstrated myocardial lesions identical to those found in the peripheral muscles. Although muscle toxicity was reproduced using *T. equestre* extracts in a mouse model, the etiology of the toxicity is not defined.[5] All the triterpenoids, sterols, indoles, and acetylenic compounds extracted from these mushrooms previously were assumed to be without toxicity. Currently all the clinical experience originates from Europe; no cases are reported in the United States.

Management

Because ingestion of certain mushrooms may lead to toxicity with substantial mortality, patients with suspected mushroom ingestions require rigorous management. A serious effort at precise identification of the genus and species involved will make assessment, management, and followup easier and more logical. The basic regimen of adsorption should be initiated if potentially toxic mushrooms are ingested. If nausea and vomiting persist, an antiemetic can be used to ensure that the patient can retain activated charcoal 1 g/kg. Appropriate life support measures should be instituted as necessary. Fluid, electrolyte, and glucose repletion are essential.

There is a wide variability in quantity and type of toxin present in mushrooms according to geography, local conditions, and individual susceptibility. The clinical course for *A. smithiana* poisoning has led us to suggest an alteration in the initial approach to patients in the

northwest United States who have early onset (0.5â€“3 hours) of GI distress following mushroom ingestion. Until recently, all patients who had early onset of nausea, vomiting, diarrhea, and abdominal cramps were presumed to be poisoned by a member of the groups containing either the GI toxins or muscarine. However, a better understanding of *A. smithiana* led us to limit the use of an algorithm we and others frequently used in the past (see Goldfrank's Toxicologic Emergencies, 6th edition, Figure 75-1). The routine use of specific antidotes should be avoided because they usually are unnecessary.

Disposition

It is important to remember that many patients with mushroom ingestions present with signs and symptoms suggestive of mixed

poisonings. Whereas some ingestions produce â€œpurerâ€• symptom complexes than others, some ingestions, such as those of *A. muscaria*, produce GI and CNS effects, and still other ingestions, such as of *Cortinarius* spp, have acute GI and delayed renal manifestations. Treatment or partial treatment may further confound the assessment. In addition, it is essential to remember that any acute GI disorder actually may be the manifestation of mushroom toxicity. In the spring and fall, in areas with moderate weather and humidity, it is particularly important to consider intentional or unrecognized exposure to mushroom toxins, although a logical approach to management is impossible in the absence of a precise history.

Because the clinical course of mushroom poisoning can be deceptive, all patients who manifest early symptoms (<3 hours) and remain symptomatic despite supportive care (Tables 113-1 and 113-2) should be admitted to the hospital. In this group of patients inhabiting the Pacific Northwest, *A. smithiana* should be of particular concern. Patients whose delayed initial presentation (â‰¥5 hours) is suggestive of amatoxin exposure should be hospitalized, as should any patient postingestion who cannot be followed safely or reliably as an

outpatient. Tables 113-1 and 113-2 list the characteristic times of appearance and evolution of symptoms caused by mushroom toxins and groups. Confusion may result from atypical clinical manifestations or, commonly, ingestion of several different mushrooms species, some of which may produce early symptoms and others delayed toxicity. Patients with certain types of ingestions may appear to improve initially with only supportive care. This latency period, which is characteristic of *Amanita* spp, may not be appreciated when several different species are eaten simultaneously. However, because hepatotoxicity leading to death may not appear until 2â€“3 days after ingestion (amatoxins) and nephrotoxicity may not appear for 3â€“21 days (orellanine and allenic norleucine), all patients with symptoms require subsequent followup.

Visualizing and analyzing the gross, microscopic, or chemical characteristics of the ingested mushroom remain vital strategies that are infrequently used. When the whole mushroom or parts are unavailable, the diagnosis must be based on the clinical presentation. No rapidly available studies in emergency departments or clinical chemistry laboratories are available to assist with management. The development of a rapid clinical test for amatoxins,[14,15,50] gyromitrin, orellanine, and allenic norleucine would be useful and permit early use of hemoperfusion and greater vigilance with regard to use of hemodialysis. We have not yet achieved the ability to use thin-layer chromatography, high-performance liquid chromatography, gas chromatography, or gas chromatography-mass spectrometry for clinically relevant circumstances.

TABLE 113-2. Mushroom Toxicity: Correlation Between Symptomatology and Time of Onset of Symptoms

	Early <3 h	Middle 5â€“24 h	Late >24 h
Gastrointestinal	Muscarine	Amatoxin	Orelline and orellanine
	Gastrointestinal toxins	Allenic norleucine	
	Allenic norleucine	Gyromitrin	
Hepatic			Amatoxin Gyromitrin
Neuropsychiatric	Ibotenic acid and muscimol Psilocybin	Gyromitrin	
Renal			Orelline and orellanine Allenic norleucine

Lycoperdonosis

Lycoperdonosis is not related to either the toxic or hallucinogenic

characteristics of a mushroom. This syndrome occurs in patients following acute inhalation of spores as a folk medical therapy for epistaxis[85] and in adolescents for various experimental reasons.[86] Puffball mushrooms (*Lycoperdon perlatum*, *Lycoperdon pyriforme*, or *Lycoperdon. gemmatum*), which are edible in the fall and can (upon decay or drying) release large numbers of spores by compression or agitation. (See ILLYCOPERDONPYRIFORME and ILLYCOPERDONPERLATUM in the Image Library.) Massive inhalation, insufflation, and chewing of spores can lead to the development of nasopharyngitis, nausea, vomiting, and pneumonitis within hours. Over a period of several days, cough, shortness of breath, myalgias, fatigue, and fever develop. Rarely patients require intubation because of pulmonary compromise associated with diffuse reticulonodular infiltrates.[86] Lung biopsy demonstrates an inflammatory process with the presence of *Lycoperdon* spores.[85] Patients treated with prednisone and antifungal agents such as amphotericin B recovered within several weeks without sequelae.

Identification

General

Although mushroom identification is a difficult science, this section may be helpful to the clinician dealing with a suspected case of mushroom toxicity. However, it is generally best to rely on symptomatology, not mushroom appearances, to confirm a diagnosis. As a general rule, positive identification of the mushroom should be left to the mycologist or qualified toxicologist. Digital images sent over the Internet with verbal descriptions to a mycologist have enhanced diagnostic potential, although definitive identification could not be achieved in a limited study.[30]

The most important anatomic features of both edible and poisonous mushrooms are their pileus, stipe, lamellae or gills, and volva.

- *Pileus:* Broad, caplike structure from which hang the gills (lamellae), tubes, or teeth.
- *Stipe:* Long stalk or stem that supports the cap; the stipe is not present in some species.
- *Lamellae:* Platelike or gill-like structures on the undersurface of the pileus that radiate out like the spokes of a wheel. The spores are found on the lamellae. Some mushrooms have pores or toothlike structures on their pili, which contain the spores. The mode of attachment of the lamellae to the stipe is noteworthy in making an identification.
- *Volva:* Partial remnant of the veil found around the base of the stipe in some species.
- *Veil:* Membrane that may completely or partially cover the lamellae, depending on the stage of development. The â€œuniversalâ€• veil covers the underside, the spore-bearing surface of the pileus.

- *Annulus:* Ringlike structure that may surround the stipe at some point below the junction, with the cap that is a remnant of the partial veil.
- *Spores:* Microscopic reproductive structures that are resistant to extremes in temperature and dryness, produced in the millions on the spore-bearing surface (see Lamellae). Of all the characteristics of a particular mushroom species, spores are the least variable, although many mushrooms have similar-appearing spores. A spore print is helpful in establishing an identification. (See ILSPOREPRINT 1 and ILSPOREPRINT 2 in the Image Gallery.) A spore print viewed microscopically is comparable to a bacterial Gram stain. Spore colors range from white to black and include shades of pink, salmon, buff, brown, and purple. Spore color in general is constant for a species.

The Unknown Mushroom

- The most important determinant is whether the ingested mushroom is one of the deadly varieties, especially *Amanita.* Outside of the Pacific Northwest, the onset of GI symptoms within 3 hours of ingestion does not result from amatoxin poisoning. In the Pacific Northwest, symptoms may represent *A. Smithiana* (allenic norleucine) poisoning (Tables 113-1 and 113-2).
- Attempt to obtain either the collected mushrooms or a detailed description of their features. Arrange for transport of the mushroom in a dry paper bag (not plastic). Ensure that the mushroom is neither moistened nor refrigerated, either of which will alter its structure. Remember that gastric contents may contain spores that can be crucial for analysis.
- If the mushroom cap is available, make a spore print by placing the pileus spore-bearing surface side down on a piece of paper for at least 4â€“6 hours in a windless area. The spores that collect on the paper can be analyzed for color. White spore prints can be visualized more easily on white paper by tilting the paper and looking at it from an angle.
- Concomitant with step 3, contact a mycologist and use the best resources available for identification. A botanical garden usually has expert mycologists on staff, or a local mycology club can locate a mycologist. Alternatively, the North American Mycological Association through its Internet site (http://www.namyco.org/) can furnish this information. A regional poison control center almost always can provide this expertise or locate an expert.
- If none of the resources in step 4 is accessible, Melzer reagent can be useful in differentiating look-alike species and defining the presence of an amatoxin. A positive reaction is indicated by the development of a dark blue color upon contact with Melzer reagent.[58] Melzer reagent is a solution of 20 mL water, 1.5 g

potassium iodide, 0.5 g iodine, and 20 g chloral hydrate. Staining a sample of the spores with 1 drop of reagent and then viewing the sample under a microscope helps to determine whether the mushroom is a deadly *Amanita*, with bluish-black â€œamyloidâ€•-reacting round spores.

- An additional test used by some is the Meixner reaction. Several drops of 10â€“12N hydrochloric acid are applied to an amatoxin-containing mushroom sample squeezed onto newspaper, resulting in a blue reaction.[50] The reliability of this test is doubtful, and most mycologists prefer to use Melzer reagent. Although the Meixner test is sensitive, false-negative and false-positive tests are of concern.[8]

Poisoning Principles: Myths and Science

Differentiating myths from science is a difficult task in any field of medicine. This effort is even more complex when discussing mushrooms. The following principles are of great value in developing a logical approach to a potential ingestion.

- Wild mushrooms should never be eaten unless an experienced mycologist can absolutely identify the mushroom. Even experts have trouble identifying some mushrooms, yet some foragers boldly indicate that distinguishing edible from toxic mushrooms is â€œas easy as telling brussels sprouts from broccoli.â€• Remember the saying, â€œThere are old mushroom hunters, and bold mushroom hunters; but there are no old, bold mushroom hunters.â€•
- The toxicology of any species can vary, depending on geographic location.
- If poisoning is suspected, attempt to obtain samples of the mushrooms eaten and identify them. Every ED should have a readily available resource on mushrooms, such as one of the major

mycology field guides.[1,12,57,58,76,82] In any case, identification is best made with the aid of the poison center's consultant mycologist.

- Mushrooms often are implicated as the cause of an illness when, in fact, infections or other diseases are responsible. Other etiologies include the mode of preparation (the sauce or wine) or the cooking utensil.
- There are no absolute generic approaches for evaluating the potential toxicity of a mushroom. Myths suggesting the safety or lack of safety by staining of silver, presence of insects or slugs, peeling off the mushroom cap, or the area of mushroom growth are unreliable or false. Neither odor nor taste is a good predictor of toxicity. Pure white mushrooms, little brown mushrooms, large brown mushrooms, and red- or pink-spored boletus (a mushroom without lamellae) should be considered potentially toxic.
- Cooking may inactivate some toxins but not others. In general, no wild mushroom should be eaten raw or in large quantities. Examples of toxicity associated with lack of cooking include *Armillariella mellea* (honey mushroom), which usually is well tolerated when cooked but not raw, and *Verpa bohemica* (a morel-like mushroom), which is edible but causes illness if eaten in excess.
- Associated phenomena may be responsible for or contribute to toxicity. Could insecticides have been sprayed on the mushrooms? Is it an alcohol-related response? Besides the well-known disulfiram reaction involving *C. atramentarius*, other good edibles, including the black morel *(Morchella angusticeps)* and the sulfur polypore (*Laetiporus sulfureus*), can cause adverse reactions if consumed with alcohol. The etiology of these adverse reactions is not understood.
- â€œEdibleâ€• mushrooms that are allowed to deteriorate become toxic. Therefore, only young, recently matured specimens should

be eaten when adequate mycologic support is available.

- The finding that only some people who ate a mushroom species manifested characteristic toxicity should not exclude the diagnosis of mushroom poisoning. The degree of toxicity may be dose related or genetically determined, or a person may have a pathologic predisposition to toxicity.

- Mushroom allergy can manifest as anaphylaxis.
- Most poisonous mushrooms resemble edible mushrooms at some phase of their growth. For this reason, even careful examination of the ring, cap, consistency, form, and color may not reliably identify the edible species. Also, characteristic features of specific toxic mushrooms may not be present under certain conditions. Although the deadly *A. phalloides* and *A. virosa* usually have remnant patches of tissue from the universal veil that envelops the mushroom in its â€œbuttonâ€• stage, rain may wash these remnants away. Similarly, a subterranean basal cup may not be noticed if the mushroom is cut at the ground level by a novice forager (Figure 113-1).
- Even the new in-vogue â€œwild mushroomsâ€• in the fanciest markets may not be entirely safe.

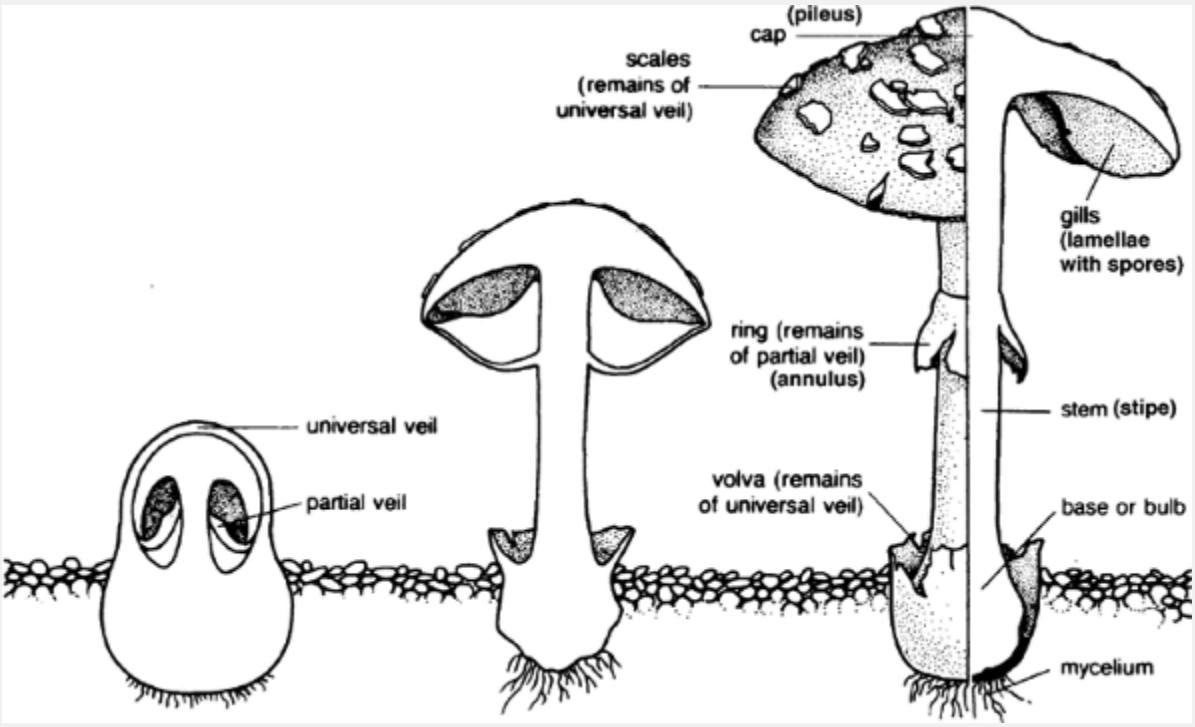


Figure 113-1. In the more highly specialized and evolved mushrooms, various protective tissues cover the fruit body and its constituent parts during its development. In the toadstool shown, an *Amanita* species, 2 veils of tissue are involvedâ€”one an outer enclosing bag, the universal veil, which ruptures as the fruit body expands to leave a volva at the base and fragments on the cap, the other an inner partial veil covering the developing gills, which is pulled away as the cap opens to leave a ring on the stem. Chapter 114
Plants

Mary Palmer

Joseph M. Betz

A 25-year-old man was found unconscious with sustained ventricular tachycardia. He was found with a printout from a web page describing the use of *Aconitum* spp (monkshood) from horticultural sources as a means of committing suicide. His vital signs were: blood pressure, 60 mm Hg palpable; pulse, 120â€“170 beats/min; respiratory rate, 22 breaths/min; temperature 99Â°F (37.3Â°C); and oxygen saturation 100% by pulse oximetry breathing 28% oxygen. His dysrhythmia was responsive to sodium bicarbonate and 100 mg lidocaine IV bolus followed by a 2-mg/min infusion. Urine toxicology for cocaine, amphetamine, salicylate, and acetaminophen was negative. Upon awakening, he would not describe what he had done. Although both urine and serum specimens were obtained, local public health and medical examiner laboratories and 3 commercial natural product laboratories were unable to analyze these specimens for aconitine, one of the active ingredients presumed responsible for his symptoms.

Classification of Plant Xenobiotics

Aconitine, from monkshood, exemplifies the rich history of plant toxicology. It was believed by the Greeks to be the first poisonâ€”â€œlycotonumâ€• â€”created by the goddess Hecate from foam of the river Cerebrus.[18] Alkaloid constituents are responsible for its toxic (and therapeutic) effects. â€œAlkaloidâ€• is one of several classes of organic molecules found in plants as defined by the science of pharmacognosy. The pharmacognosy approach is consistent with the literature of plant efficacy and is applied here to their toxicity (Table 114-1). Unfortunately, the â€œscienceâ€• of pharmacognosy is not always straightforward and varies depending on the pharmacognosist. Hence our approach borrows primarily from two groups of authors[107,296] to keep the classification as consistent as possible. The major groups are as follows:

- *Alkaloids:* Molecules that react as bases and contain nitrogen, usually in a heterocyclic structure. Alkaloids typically have strong pharmacologic activity that defines many major toxidromes.
- *Glycosides:* Organic compounds that yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The aglycone is the basis of subclassification into saponin or steroidal glycosides (also called cardioactive steroids, Chap. 62), cyanogenic glycosides, anthraquinone glycosides, and others such as atractyloside and salicin.
- *Terpenes and resins:* Assemblages of 5-carbon units (isoprene unit) with many types of functional groups (eg, alcohols, phenols, ketones, and esters) attached. These are the largest group of secondary metabolites; approximately 20,000 are identified. Most essential oils are mixtures of monoterpenes, and the terpene name depends on the number of assemblages. Monoterpenes have 2 units ($C_{10}H_{16}$), sesquiterpenes have 3

isoprene units (C_{15}), diterpenes have 4 isoprene units (C_{20}), triterpenes have 6 (C_{30}), etcâ€¦ These molecules have an active role in plant defense mechanisms.

- *Proteins, peptides, and lectins:* Proteins consist of amino acid units with various side chains, and peptides consist of linkages among amino acids. Lectins are glycoproteins classified according to the number of protein chains linked by disulfide bonds and by binding affinity for specific carbohydrate ligands, particularly galactosamines. The toxalbumins (eg, ricin) are lectins. These components tend to be neurotoxins, hemagglutinins, or cathartics.
- *Phenols and phenylpropanoids:* Phenols have phenyl rings. Phenylpropanoids consist of a phenyl ring attached to a propane side chain. They are devoid of nitrogen, even though some are derived from phenylalanine and tyrosine. They constitute a major group of secondary metabolites and among plant toxins consist of *coumarins* (lactone side chains), *flavonoids* (built upon a flavan 2,3-dihydro-2-phenylbenzopyran nucleus, eg, naringenin and rutin), *lignans* (2 linked phenylpropanoids, eg, podophyllin), *lignins* (complex polymers of lignans that bind cellulose for woody bark and stem), and *tannins* (polymers that bind to protein and can be further hydrolyzed or condensed).

Plant chemistry is complex. Our simplified presentation of one toxin class per plant, per symptom group (Table 114-1) overlooks the fact that plants contain multiple chemicals and chemical classes that work independently or in concert. Additionally, different plant families may contain similar, if not identical, xenobiotics (a form of convergent evolution). In some cases, xenobiotics remain unidentified and are grouped in the section on Unidentified Toxins.

Dissimilar molecules from diverse pharmacognosy classes that

share effects are grouped together for pragmatic purposes in the section on Effects Shared Among Diverse Classes of Xenobiotics. They are further categorized into Plantâ€“Drug Interactions, Sodium Channel Effects, Antimitotic Alkaloids and Resins, and Plant-induced Dermatitis.

TABLE 114-1. Primary Toxicity of Common Important Plant Species

P.1578

P.1579

P.1580

P.1581

P.1582

P.1583

Our focus is on exposures to flowering plants (angiosperms) related to foraging, dietary, or occupational contact, except for some gymnosperms or algae and, rarely, medicinal contact (medicinal use as herbals is discussed in Chap. 43).[222] Because our understanding of plant toxicity is poor relative to that of pharmaceutical agents, we include animal research to provide a more comprehensive foundation for comparison to human experiences that may otherwise go unrecognized without such precedent or may likewise prove incorrect in time. The science of plant toxicology formally began in the United States as a response to significant poisonings of livestock.[360,361] The overall quality of literature for human exposures is poor and primarily available as case reports.[276]

P.1584

Many of these cases lack clear links between toxin exposure and illness, and qualitative serum concentrations often are unavailable.[157] Uncertainty is compounded by the fact that plants

themselves are inherently variable, and potency and type of toxin depend on the season, geography, local environment, plant part, and methods of processing.[6,126]

Identification of Plants

Positive identification of the plant species should be attempted whenever possible, especially when the patient becomes symptomatic. Communication with an expert botanist or poison center is highly recommended and can be facilitated by transmission of digital images or a fax.[243] Provisionally, simple comparison of the species in question with pictures or descriptions from a field guide or flora may help exclude the plant's identity from among the most life-threatening in Table 114-1. A plant identification also can be compared with those searched in the PLANTOX database (http://www.vm.cfsan.fda.gov/~djw/readme.html) managed by the Food and Drug Administration.[75,359,361] Laboratory analysis is not timely enough to be useful except as a tool in an investigatory or forensic analysis.[133]

In cases where expert identification cannot be immediately achieved, crude recognition of taxonomic families of poisonous plants is the simplest first step to identify or exclude poisonous plants but is most easily achieved when the plant is in flower or fruit. For instance, if the flower is described or looks like a flower from a tomato or potato, it probably is in the Solanaceae family. Plants of this family typically produce gastroenteritis or anticholinergic findings following ingestion. It then would be prudent to begin expectant management (eg, prepare for use of physostigmine). This approach will be less useful for those xenobiotics (eg, pyrrolizidine alkaloids) that occur in numerous different families.

Approach to the Exposed Patient and

Understanding Risk

Faced with the care of an individual who comes seeking medical care, health care givers must determine whether or not the patient needs treatment interventions. Potential symptoms listed in Table 114-1 are organized by plant name but with their *major* organ system effects for quick reference to types of symptoms and whether they might be life threatening.[35] For instance, life-threatening symptoms such as dysrhythmias or seizures can be searched by â€œcardi-â€• or â€œneuro-â€• in the first column and compared with the plant(s) in question. The plants and xenobiotics that present life-threatening symptoms are so noted. Exposures associated with one of these plants or xenobiotics or major organ system symptoms dictates the need for possible prompt gastric emptying, decontamination, individualized therapy, and hospitalization. Note that nonspecific symptoms such as nausea and vomiting are listed only when they are the sole cause of morbidity or mortality (toxalbumins such as ricin), but nausea and vomiting are nearly ubiquitous among acute poisonings of clinical consequence.

Identified plant species most frequently reported during a decade of Poison Center experience are indicated in Table 114-1. In most cases, these species provide reassurance because most offer benign outcomes, and only 2 among these can be life threatening depending on the circumstances of the exposure. Given the relatively poor understanding of toxins and in the absence of complete information about an exposure, expectant management and supportive care are the rule. Even if a plant is not marked as life threatening or commonly reported, the patient should undergo a period of observation and followup given the relatively immature science of plant toxicology relative to that of pharmaceuticals.

The difficult task in human plant toxicology is the lack of adequate data to determine risk (see examples in Chap. 124). Typically, evaluations of risk are based on poison center data and usually

cite the numerous calls without clinical consequence as a part of the risk equation (Chap. 130).[208,209,210,211,212 and 213,260,363] However, poison center data are dominated by pediatric cases and other cases with unsubstantiated clinical manifestations (Chap. 130).[157] These cases often represent small or nonexistent exposures, and their inclusion in the database may mask real risks by diluting â€œtrueâ€• hazardous exposures with trivial or nonexistent exposures. Furthermore, misidentification of the plant may occur because of either similar appearance or similar nomenclature.

In summary, basic decontamination and supportive care should be instituted as fits the situation, with appropriate consultation to a poison center. The most consequential and dangerous plant xenobiotics for humans are discussed here and those that can produce life-threatening signs acutely are denoted in Table 114-1.

Toxic Constituents in Plants, Taxonomic Associations, and Selected Symptoms

Alkaloids: Toxic Manifestations

The term *alkaloid* refers to nitrogen-containing basic xenobiotics of natural origin and limited distribution. They figure prominently in the history of humanâ€“plant interaction, ranging from epidemics of poisoning caused by ergot-infested rye bread in the Middle Ages, to addictions to cocaine, heroin, and nicotine in contemporary time. Numerous examples of toxic constituents of these families are given in the following discussion, which begins with a description of every major toxidrome that involves alkaloids. See also Sodium Channel Effects under Effects Shared Among Diverse Classes of Xenobiotics later in this chapter for description of additional life-threatening alkaloids.

Anticholinergic Effects: Belladonna Alkaloids

The belladonna alkaloids are all from the family Solanaceae and can be identified as members of this family by their characteristic flowers (most familiar from nightshade, potato, or tomato flowers). The belladonna alkaloids have potent antimuscarinic effects. Ingestion produces classic signs of this toxidrome: tachycardia, hypertension, hyperthermia, dry skin and mucous membranes, skin flushing, diminished bowel sounds, urinary retention, agitation, disorientation, and hallucinations (Chap. 3). Since the 1970s, the quest for recreational â€œhighsâ€• has surpassed unintentional ingestions as the main source of toxicity. Hallucinatory effects are sought in seeds and teas, especially in late summer, when jimsonweed *(Datura stramonium)* seeds (see ILDATURASTRAMONIUM1 and ILDATURASTRAMONIUM2 in the Image Library at http://www.goldfrankstoxicology.com) become available.[46,48,71,72,149,152,320] One hundred of these seeds contain up to 6 mg atropine and related alkaloids, and an ingestion of this amount can be fatal.[27]

Although various species and plants within species bear differing concentrations of diverse xenobiotics, the clinical manifestations usually are similar.[290,347] Onset of symptoms typically occurs 1â€“4 hours postingestion, or more rapidly if the plants are smoked or consumed as a tea infusion. The duration of effect is partly dose dependent and may last from a few hours to weeks.[152] The course of anticholinergic poisoning is altered by use of physostigmine, which when consequential may require repetitive dosing, necessitating observation and hospitalization.[307] Moreover, physostigmine may be lifesaving in patients with seizures or agitated delirium (Antidotes in Depth: Physostigmine Salicylate). Anticholinergic toxicity may be produced without detectable

atropine, scopolamine, or hyoscyamine concentrations and is better left as a clinical and not a laboratory diagnosis.[320]

Solanine is contained in other members of the Solanaceae family, but it is not a belladonna alkaloid. It inhibits cholinesterase in vitro, although cholinergic symptoms are not noted clinically. Nonetheless, reports of solanine-induced central nervous system (CNS) toxicity includes hallucinations, delirium, and coma.[244,278] However, most symptomatic patients typically develop nausea, vomiting, diarrhea, and abdominal pain that begins 2â€“24 hours after ingestion, which, like CNS toxicity, may persist for several days.[80,278] Although solanine is present in most of the 1700 species in the genus *Solanum*, solanine toxicity in humans is uncommonly encountered. Green potatoes and green potato tops are most commonly associated with symptoms, which is not surprising because the alkaloids are most concentrated in those items. Most reports of death come from the older literature,[4,162] and consumption of 2â€“5 g of green components per kilogram body weight per day is not predicted to cause acute toxicity.[284]

Nicotine and Nicotine-like Alkaloids: Nicotine, Lobeline, Sparteine, *N*-Methylcytisine, Cytisine, and Coniine

Nicotine toxicity (other than from inhaled sources) occurs via ingestion of leaves of *Nicotiana tabacum*, cigarette remains, organic products and insecticides, and transdermally among farm workers harvesting tobacco (green tobacco sickness).[137,139,289] A dose as little as 1 mg/kg can be lethal to an adult.[238,282] Overstimulation of the nicotinic receptors by high doses of nicotine produces a toxidrome that progresses from gastrointestinal (GI) symptoms to diaphoresis, mydriasis, fasciculations, tachycardia, hypertension, hyperthermia, and seizures, respiratory depression, and death (Chap. 82). Wearing of protective clothing by tobacco farm workers best prevents green tobacco sickness.

These manifestations are also produced by alkaloids other than nicotine.[355] There are no recent reports of nicotinic toxicity from lobeline (found in all parts of *Lobelia inflata)*, but its overenthusiastic use in the 18th century resulted in morbidity and mortality.[44]

Sparteine from broom *(Cytisus scoparius)*[349] and *N*-methylcytisine from blue cohosh *(Caulophyllum thalictroides)*[291] provide additional examples of nicotinelike alkaloids that may be teratogenic.[194] Laburnum or golden chain *(Cytisus laburnum)* contains cytisine, which reportedly is responsible for mass poisonings and fatalities in children and adults who eat the plants or parts thereof (even as little as 0.5 mg/kg, or a few peas).[138,259,293] Unfortunately, such reports have resulted in thousands of unnecessary hospital admissions for patients without morbidity and mortality after ingestion of this plant, demonstrating the difficulty in separating hazard from risk and in obtaining accurate doseâ€“response information in the setting of plant exposures and human variability.[30,121]

The most famous description of the end stages of nicotinic toxicity dates from approximately 2400 years ago by an observer of Socrates' fatal ingestion of a decoction of poison hemlock *(Conium maculatum)*:[342]

> â€¦the person who had administered the poison went up to him and examined for some little time his feet and legs, and then squeezing his foot strongly asked whether he felt him. Socrates replied that he did not and said to us when the effect of the poison reached his heart, Socrates would depart.

Birds do not experience coniine toxicity but provide a vector for poisoning. According to the book of Exodus, quail that fed on seeds

(presumably from poison hemlock) became toxic and passed the toxicity on to the Israelites who ate the fowl. In the 20th century, people have succumbed to hemlock poisoning following their avian repasts. This is especially well documented in Italy, where the toxic alkaloid coniine subsequently was detected in the bird meat, as well as in the blood, urine, and tissue of some victims.[294,314]

The age of the plant seems to be directly correlated with increasing concentrations of coniine, whereas the toxin Î³-coniceine occurs in greater amounts in new growth; hence, the plant remains toxic over the length of the growing season.[91,135] Fatal poisonings are reported on multiple continents,[91,34] and death may result from respiratory arrest.[23] Of 17 poisoned Italian patients, all had elevated liver aminotransferases and myoglobin concentrations, and 5 had acute tubular necrosis. Death developed 1â€“16 days following ingestion.[295]

Cholinergic Effects in Alkaloids: Arecoline, Physostigmine, and Pilocarpine

Betel chewing has been a habitual practice in the East since ancient times. The â€œquidâ€• consists of betel nut *(Areca catechu)* and other ingredients. The effects of acute exposure to arecoline, the major alkaloid, include sweating, salivation, and hyperthermia. Effects of acute use are rarely reported, but are associated with death, at least in susceptible patients.[87] Prolonged use is linked to dental decay and oral cancer.[64,85,90,106,316] Physostigmine is an alkaloid derived from the Calabar bean *(Physostigma venenosum)*, where it is present in concentrations of 0.15%. The miotic effects of physostigmine have been used to reverse mydriatic agents. Its efficacy as an anticholinesterase agent makes it a valuable antidote in anticholinergic poisoning (Antidotes in Depth: Physostigmine Salicylate). Pilocarpine is derived from *Pilocarpus jaborandi* from South America and possesses stimulatory effects on muscarinic receptors. It is of

value in treatment of glaucoma.[106] Reversal of toxicity can be achieved by atropine.

Psychotropic Alkaloids: Lysergic Acid and Mescaline

Hallucinations from the direct serotonin effects of lysergic acid diethylamide (LSD) and its derivatives and from the amphetaminelike serotonin effects of the mescaline alkaloids are reported following ingestion of morning glory seeds (*Ipomoea* spp) and peyote cactus *(Lophophora williamsii)*, respectively (Chap. 80). Ingestion of at least 150 morning glory seeds also produces nausea and vomiting.[68,179,369] Despite their chemical relatedness to LSD, molecules such as lysergacidamide and lysergacidethylamide, found in Hawaiian baby woodrose seeds *(Argyreia nervosa)* and sold for their hallucinogenic effects, produce a syndrome more similar to that of anticholinergic poisoning.[28]

Alkaloidal Central Nervous System Stimulants and Depressants: Ephedrine, Synephrine, Cathinone, and Narcotics

Use of ephedrine-containing *Ephedra* herbal products was banned by

the FDA in 2004 secondary to cardiovascular toxicity and deaths.[357] However, varieties of *Sida cordifolia* also contain ephedrine. Synephrine, another compound structurally related to ephedrine, occurs in *Citrus aurantium*, which is ingested as a plant or as a medicinal. Deaths are reported following ingestion of *C. aurantium* rinds by children.[240] Drug interactions can ensue from their use.[175] Another plant ingested for its CNS stimulant activity is khat *(Catha edulis).* The plant contains cathinone (Î±-

aminopropiophenone) and cathine [(+)-norpseudoephedrine]. In addition, narcotics derived from the poppy plant (*Papaver* spp) are prototypic CNS depressants and analgesics (Chap. 38).

Pyrrolizidine Alkaloids

Pyrrolizidine alkaloids are widely distributed both botanically and geographically. Approximately half of the 350 different pyrrolizidine alkaloids characterized to date are considered toxic. Pyrrolizidine alkaloids are found in 6000 plants and in 13 plant families but are most heavily represented within the Boraginaceae, Compositae, and Fabaceae families. Within these families, the genera *Heliotropium*, *Senecio*, and *Crotalaria*, respectively, are particularly notable for their content of toxic pyrrolizidine alkaloids.[332] These hepatotoxic alkaloids all contain an unsaturated 1-hydroxymethyl pyrrolizidine system.[370] The hepatic cytochrome P450 system converts these compounds to highly reactive pyrroles in vivo. Chronic exposures cause hepatic venoocclusive disease by stimulating proliferation of the intima of hepatic vasculature. Most poisonings occur as a result of contamination of food grain with seeds of pyrrolizidine alkaloid-containing plants or by use of pyrrolizidine alkaloid-rich plants for medicinal purposes. Acute poisoning probably is caused by an oxidant effect resulting in hepatic necrosis.[75,150] An estimated 20% of patients with acute pyrrolizidine alkaloid poisoning die, 50% recover completely, and the rest develop subacute or chronic manifestations of hepatic venoocclusive disease.[14] Pyrrolizidine alkaloids are teratogenic and are transmitted through breast milk.[301] Other types of plant-associated hepatic disorders are discussed in Effects Shared Among Diverse Classes of Xenobiotics.

Isoquinoline Alkaloids: Sanguinarine, Berberine, and Hydrastine

Sanguinarine was detected in 26 family members who consumed a

mustard oil contaminated with seeds of *Argemone mexicana*.[322] All patients suffered GI distress followed by peripheral edema, skin darkening, erythema, skin lesions, perianal itching, anemia, and hepatomegaly. Ascites developed in 12%, and myocarditis and congestive heart failure occurred in approximately a third of affected individuals.[371] Medicinally, sanguinarine is used for dental hygiene.[164] In North America, sanguinarine is found in blood root *(Sanguinaria canadensis)*, which, like *Argemone*, is in the Ranuculaceae family.

Berberine is structurally similar to sanguinarine and reportedly also has cardiac depressant effects. A number of medicinal plants contain berberine, including goldenseal *(Hydrastis canadensis)*, Oregon grape (*Mahonia* spp), and barberry (*Berberis* spp). It causes myocardial and respiratory depression and contraction of smooth muscle in vasculature and the uterus.[240] Strychninelike movement disorders are described following ingestion of hydrastine, which composes 4% of goldenseal.

Miscellaneous Other Alkaloids: Emetine/Cephaline, Strychnine/Curare, and Swainsonine

Emetine and cephaline are derived from *Cephaelis ipecacuanha*, a tropical plant native to the forests of Bolivia and Brazil. They are the principal active constituents in syrup of ipecac, which produces emesis. Chronic use of syrup of ipecac, typically by patients with eating disorders or Munchausen syndrome by proxy,[13,111] can lead to cardiomyopathy, smooth muscle dysfunction, myopathies, electrolyte and acidâ€“base disturbances related to excessive vomiting, and death [154,315] (Antidotes in Depth: Syrup of Ipecac). Poisoning in patients ingesting plant material is not reported.

Strychnine and curare are both derived from plants of the *Strychnos* genus but possess very different clinical effects. The

alkaloids strychnine and brucine result in muscular spasms and rigidity by antagonizing glycine receptors in the spinal cord and brainstem and are derived from the seeds of *Strychnos nux-vomica*. The plant is used as an herbal remedy for arthritis called â€œmaqianzi,â€• which if processed in error produces muscle spasm and weakness, including respiratory muscles[59] (Chap. 108).

Curare is the name given to the unstandardized extract of the bark of certain members of the genera *Strychnos* and *Chondodendron.* The physiologically active principal of curare is (+)-tubocurarine chloride, a competitive antagonist of acetylcholine at nicotinic receptors in the neuromuscular junction. The pharmacology and potential applications of curare are great, as it is the molecule from which most nondepolarizing neuromuscular blockers are derived (Chap. 66). Plant poisoning is recorded solely with its traditional use as a hunting poison.[24,226,286]

Swainsonine is isolated from *Swainsonia canescens*, *Astragalus lentiginosis* (spotted locoweed), *Sida carpinifolia*, other species of *Swainsonia* and *Astragalus*, as well as several species in the genera *Oxytropis* and *Ipomoea*, and several fungi.[69,70] After subsisting on seeds containing swainsonine for nearly 4 months, a naturalist forager manifested profound muscular weakness and died in the wilderness.[207] The compound is teratogenic and causes chronic neurologic disease called â€œlocoism,â€• with weakness and failure to thrive in livestock. Swainsonine inhibits the glycosylation of glycoproteins by Î±-mannosidase II of the Golgi apparatus, resulting in a lysosomal storage disease. Swainsonine was used with some success in clinical trials for treatment of advanced neoplasms. Adverse effects included hepatic, pancreatic, and respiratory manifestations, as well as lethargy and nausea.[148]

Glycosides

Glycosides yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The aglycone

group is the basis of subclassification. The nonsugar or aglycone group determines the subtype of glycoside. For instance, the cardioactive steroids have saponin (steroid) aglycone groups and are among the saponin glycosides.

Saponin Glycosides: Cardioactive Steroids, Glycyrrhizin, *Ilex* Saponins

Cardioactive Steroids

Poisoning by virtually all *cardioactive steroids* is clinically indistinguishable from poisoning by digoxin (Chap. 62), which itself is derived from *Digitalis lanata*.[296] However, compared to toxicity from pharmaceutical digoxin, toxicity resulting from the cardioactive steroids found in plants has markedly different pharmacokinetic characteristics. For example, digitoxin in *Digitalis* species has a plasma half-life as long as 192 hours (average 168 hours).

The pharmacologic properties are true across taxonomic boundaries.[311] Poisonings by *Digitalis* spp,[267,292,324] squill (*Urginea* spp),[123,345] lily of the valley (*Convallaria* spp [see ILCONVALLARIAMAJALIS in the Image Library at http://www.goldfrankstoxicology.com]),[98,210,215] oleander (*Nerium* spp),[7,161,210,218,220] and yellow oleander (*Thevetia* spp [see ILTHEVETIAPERUVIANA1 and ILTHEVETIAPERUVIANA2 in the Image Library at http://www.goldfrankstoxicology.com]).[26,96,97,235,311,312] are clinically similar. The potency of these effects depends on the specific cardioactive steroid constituents and its dose. For instance, lily of the valley is rarely associated with morbidity or mortality,[98,219] whereas ingestion of only two seeds of yellow oleander by adults can produce severe symptoms, and expected outcome is grave if more than 4 seeds are consumed.[235,311]

Poisonings by oleander and yellow oleander occur predominantly in the Mediterranean and in the Near and Far East. These two plants are attractive ornamentals popular in the United States and Europe, commonly resulting in poisoning in some of these regions.[82]

Patients experience vomiting within several hours, followed by hyperkalemia, conduction delays, and increased automaticity (bradycardia and tachydysrhythmias). Interestingly, the cardiac manifestations may be difficult to distinguish from those produced by plants with sodium channel blockers (see Effects Shared Among Diverse Classes of Toxins). Activated charcoal was beneficial in preventing death after suicide attempts with yellow oleander in Sri Lanka and its use should not be delayed in the face of uncertain plant identity.[86] Antibody therapy reduces mortality 3-fold from yellow oleander poisoning but is too expensive for developing countries where oleander-induced mortality is highest. In addition, various cardioactive steroids respond differently to therapeutic use of digoxin-specific antibody fragments (Fab). Use of very large doses of digoxin-specific antibody (up to 37 vials reported in one case[292]) may be necessary to capitalize on the therapeutic cross-reactivity between antibody and the nondigoxin cardioactive steroids. The potential for success should lead to use of antibody therapy without delay when available.[81,306] Similarly, there is variable cross-reactivity among the individual plant cardioactive steroids with regard to the degree to which each elevates diagnostic polyclonal digoxin assay measurements in clinical laboratories. These measurements can be used only as qualitative proof of exposure but not as quantitative indicators of the exposure, because the elevations can result in marked *underestimation* of the â€œfunctional digoxin concentrations.â€• Until more is known, any positive digoxin concentration following exposure to a plant should be assumed to be significant and treated accordingly.

Because steroidal glycosides were found only in the stomach of a

patient who died after ingestion of common ivy *(Hedera helix)*, it was concluded that hederacoside C, Î±-hederin, and hederagenin did not cause death. Instead, the patient is believed to have asphyxiated on the leaves.[132]

Glycyrrhizin

Glycyrrhizin is a saponin glycoside derived from *Glycyrrhiza glabra* (licorice) and other *Glycyrrhiza* spp. Glycyrrhizin inhibits 11Î²-hydroxysteroid dehydrogenase, an enzyme that converts cortisol to cortisone. When large amounts of licorice root are consumed chronically, cortisol concentrations rise, resulting in pseudohyperaldosteronism because of its affinity for renal mineralocorticoid receptors.[109] Chronic use eventually leads to hypokalemia with muscle weakness, sodium and water retention, hypertension, and dysrhythmias[76,105,108,109,377] Assessment involves evaluation of the patient's fluid and electrolytes and electrocardiogram. Potassium replacement is the most common necessary intervention.

Ilex Species

Holly berries (from >300 *Ilex* spp) are a common and attractive ingestant among children, especially during winter holidays.[353] They contain a mixture of alkaloids, polyphenols, saponin glycosides, steroids, and triterpenes.[367] Saponin glycosides appear to be responsible for GI symptoms such as nausea, vomiting, diarrhea, and abdominal cramping that result from ingestion of the berries. Experimental data in animals describe hemolysis as well as cardiotonic effects similar to those of digoxin.[15,362] CNS depression was reported in a case in which a child consumed a â€œhandfulâ€• of berries; however, this child was also treated with syrup of ipecac.[298] The toxic dose has been suggested to be just two berries,[125] but one study suggested that no untoward effects are to be expected for ingestions of <6 berries.[362]

Symptoms may be expected to be restricted to GI effects, and treatment is supportive.

Cyanogenic Glycosides: *(S)*-Sambunigrin, Amygdalin, Linamarin, and Cyacasin

Cyanogenic glycosides yield hydrogen cyanide on complete hydrolysis. These glycosides are represented in a broad range of taxa and in approximately 2500 plant species.[354] The species that are most important to humans are cassava (*Manihot esculenta* [see ILMANIHOTESCULENTA in the Image Library at http://www.goldfrankstoxicology.com]), which contains linamarin, and *Prunus* spp, which contain amygdalin. Cycad toxins are neurotoxic or pseudocyanogenic. Rare reports of cyanide poisoning associated with *(S)*-sambunigrin in European elderberry *(Sambucus nigra;* sambunigrin) are more severe when these ingestions include leaves as well as berries.[39,49]

Many North American species of plants contain cyanogenic compounds, including ornamental *Pyracantha*, *Passiflora*, and *Hydrangea* spp, which either do not release cyanide or are rarely consumed in quantities sufficient to result in toxicity.[146] On the other hand, although the fleshy fruit of *Prunus* spp in the Rosaceae are nontoxic (apricots, peaches, pears, apples, and plums), the leaves, bark, and seed kernels contain amygdalin, which is metabolized to cyanide.[43] Amygdalin was the active ingredient of Laetrile, an apricot pit extract, promoted in the 1970s for its supposed selective toxicity to tumor cells. Its sale was restricted in the United States because it lacked efficacy and safety.[258] However, patients continued to travel to other countries for laetrile therapy, also marketed as â€œvitamin B-17,â€• and it once again is available through alternative medicine providers.[372] Ingestions of, and poisoning from, *Prunus* seeds continue today.[281,304,336] The manifestations of cyanide poisoning and treatment involving use of the cyanide antidote kit are detailed elsewhere (Chap. 121

and Antidotes in Depth: Nitrates, Sodium Thiosulfate, and Hydroxcobolanin).

Acute and chronic cyanide toxicity (including deaths) associated with consumption of inadequately prepared cassava (*M. esculenta* [see ILMANIHOTESCULENTA in the Image Library at http://www.goldfrankstoxicology.com]) are reported worldwide (Chap. 121).[2,303] Chronic manifestations include visual disturbances (amblyopia), upper motor neuron disease with spastic paraparesis, and hypothyroidism. These findings are associated with protein-deficient states and use of tobacco and alcohol. The ataxic neuropathy resembles that produced by lathyrism (see Proteins, Peptides, and Lectins). A unifying hypothesis about the etiology of these 2 similar diseases from seemingly very different sources is that thiocyanate accumulation may lead to degeneration of the Î±-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA)-containing neurons that are first stimulated and then destroyed in neurolathyrism.[326,329]

Similarly, seeds of cycads contain cycasin and neocycasin, which belong to the family of cyanogenic glycosides, as well as neurotoxins associated with consumption of indigenous food. The cyanogenic glycosides of cycads are considered pseudocyanogenic, with little potential to liberate hydrogen cyanide, but most typically produce violent vomiting 30 minutes to 7 hours after ingestion of 1â€“30 seeds.[58] On the island of Guam, indigenous peoples develop a devastating amyotrophic lateral sclerosis-parkinsonism dementia complex (ALS-PDC) that appears associated with ingestion of *Cycas circinalis* seeds or the flying foxas that feed extensively upon the cycads.[333] The implicated toxin originally was believed to be an amino acid[33] but more recently is identified as a sterol glycoside.[195] Research on the mechanism of this cycad-induced disease is ongoing, with the goal of understanding potential mechanisms of this disease and its links to ALS and Parkinson disease.[321]

Anthraquinone Glycosides: Sennoside and Others

Anthraquinone laxatives are regulated both as nonprescription pharmaceutical ingredients and as dietary supplements. These glycosides, such as sennoside, are metabolized in the bowel to produce derivatives that stimulate colonic motility, probably by inhibiting Na^{+}â€“K^{+}â€“ATPase in the intestine, which also promote accumulation of water and electrolytes in the gut lumen, producing fluid and electrolyte shifts that can be life threatening.[108]

Other Glycosides: Salicin and Atractyloside

Salicin is an inactive glycoside until it is hydrolyzed to produce salicylic acid (Chap. 35). The glycosidic bond is relatively resistant to stomach acid, and the hydrolysis must be accomplished by gut flora. The ability of individual human flora to produce the necessary enzymes varies significantly, resulting in variable clinical effects. However, sufficient hydrolysis to transform salicylic acid occurs in all individuals.

Atractylis gummifera was a favorite agent for homicide during the reign of the Borgias. Atractyloside, the active ingredient, decreases concentrations of cytochrome P450. It also inhibits oxidative phosphorylation in the liver by inhibiting the ADP/ATP antiporter blocking influx of adenosine diphosphate (ADP) into hepatic mitochondria and outflow of ATP to the rest of the cell (Chap. 13). Death or severe illness as a result of liver failure or hepatorenal disease following ingestion is reported.[156,166]

The effects of the glycosides sinigrin (from *Brassica nigra* seed and *Alliaria officinalis* [horseradish] root) and naringen (a polyphenolic glycoside from the grapefruit *Citrus paradisi*) are discussed in the sections on Plant-Induced Dermatitis and Plantâ€“Drug

Interactions, respectively.

Terpenoids and Resins: Ginkgolides, Kava Lactones, Thujone, Anisatin, Ptaquiloside/Thiaminase, and Gossypol

Ginkgolides in *Ginkgo biloba* are associated with antiplatelet aggregation effects. Three reports of spontaneous bleeding associated with ingestion of *Ginkgo* leaf products as an herbal medicine are perhaps explained by this property.[300,302,351] Another xenobiotic found only in the seed, 4-methoxypyridoxine (pyridine alkaloid), is associated with seizures. A mechanism similar to isoniazid-induced seizures is plausible.[129,188,255,358] These cases suggest treatment with pyridoxine phosphate (Chap. 55 and Antidotes in Depth: Pyridoxine). The dermal effects of *Ginkgo* are discussed in Plant-Induced Dermatitis.

Kava lactones are a family of terpene lactones found in kava kava *(Piper methysticum)* that causes central and peripheral nervous system effects or hepatotoxicity.[66] Kava kava has enjoyed a long ceremonial history among islanders of the South Pacific, and observers visiting Oceania have recorded its acute and chronic effects (both pleasant and unpleasant) over the centuries. Importation of kava kava to Australia in 1983 was a measure to assist Aborigines with alcohol abuse problems. However, the kava kava itself became abused, and its subsequent ban has resulted in the growth of a black market for kava kava.[12,45] Proposed mechanisms to explain the effects of kava lactones include effects at $GABA_A$ and $GABA_B$ receptors[83,186] or, more likely, local anesthetic effects.[38,142,275] Acute symptoms following ingestion include peripheral numbness, weakness, and sedation. Chronic use leads to kava dermopathy and weight loss.[36] More than 70 cases of hepatotoxicity, several requiring liver transplantation, are associated with both acute and chronic effects of the kava lactones

on cytochrome oxygenases or other yet to be defined etiologies and prompted regulatory health measures in Europe and North America.[47]

Thujone is one of many terpenes associated with seizures.[34] It is found in the wormwood plant *(Artemisia absinthium)* and its derivative absinthe, and in some strains of tansy *(Tanacetum vulgare).* The Î±- and Î²-isomers of thujone are believed to act much like camphor to produce CNS depression and seizures. Invoking the structural similarity of thujone to tetrahydrocannabinol (THC), one of the terpenoids of marijuana, to explain the psychoactive effects is controversial[250] (Chap. 81).

Absinthism is characterized by seizures and hallucinations, permanent cognitive impairment, and personality changes. Acute and chronic absinthism led to a worldwide ban of the alcoholic beverage absinthe, which contained thujone, in the early 1900s. The essential oil of wormwood is composed almost exclusively of thujone. Wormwood oil currently is available over the Internet and is responsible for at least 2 reports of adverse reactions in people seeking its hallucinatory or euphoriant effects[21,365]

Anisatin found in *Illicium* spp. This terpenoid produces seizures as a noncompetitive GABA antagonist. The Chinese star anise *(Illicium verum)* is sometimes used in teas and occasionally is confused or contaminated with other species of *Illicium*, particularly Japanese star anise *Illicium anisatum*.[140,180] These contaminations have resulted in small epidemics of tonicâ€“clonic seizures, particularly but not exclusively of infants after use of the tea to treat their infantile colic. Recently, in the United States, a case series of at least 40 individuals who had consumed teas brewed from â€œStar aniseâ€• experienced seizures, motor disturbances, other neurologic effects, and vomiting. These cases include at least 15 infants treated for infantile colic with this home remedy. This trend prompted the FDA to issue an advisory regarding the health risk from remedies sharing the common name â€œStar anise.â€•[180]

Ptaquilosides are found in the bracken fern *(Pteridium aquilinum)*, a plant that is extending its range and density worldwide. In foraging animals, consumption of ptaquilosides results in acute hemorrhage secondary to profound thrombocytopenia whereas thiaminases produce cerebral disease.[108,290] Although no acute human poisonings are reported, these xenobiotics are transmitted through cow's milk and are associated with increased prevalence of gastric and esophageal cancer in areas where fern is endemic and consumed by cows whose milk is not diluted. Chronic toxicity through spore inhalation also produces pulmonary adenomas in animals [325,374] More recently, research defined links between alimentary cancer in humans who previously consumed bracken fiddleheads.[5]

Gossypol is a sesquiterpene that is derived from cottonseed oil. It is used experimentally as a reversible male contraceptive. The mechanism for its spermicidal effect is unclear,[75] but the effects have been attributed to inhibition of plasminogen activation and plasmin activity in acrosomal tissue.[337] These effects are not currently reported to produce systemic bleeding. Gossypol also inhibits 11Î²-hydroxysteroid dehydrogenase, as does glycyrrhizin, but typically results in only isolated hypokalemia.[74]

Proteins, Peptides, and Lectins: Ricin and Ricinlike, Pokeweed, Mistletoe, Hypoglycin, Lathyrins, and Microcystins

Lectins are glycoproteins that are classified according to their binding affinity for specific carbohydrate ligands, particularly galactosamines, and by the number of protein chains linked by disulfide bonds. Toxalbumins such as ricin and abrin, are lectins that are such potent cytotoxins that they used as biologic weapons

(Chap. 126). Ricin, extracted from the castor bean (*Ricinus communi* [see ILRICINUSCOMMUNIS1 and RICINUSCOMMUNIS2 in the Image Library at http://www.goldfrankstoxicology.com]), exerts its cytotoxicity by 2 separate mechanisms. The compound is a large molecule that consists of 2 polypeptide chains bound by disulfide bonds. It must enter the cell to exert its toxic effect. The B chain binds to the terminal galactose of cell surface glycolipids and glycoproteins. The bound toxin then undergoes endocytosis and is transported via endosomes to the Golgi apparatus and the endoplasmic reticulum.[309] There the A chain is translocated to the cytosol, where it stops protein synthesis by inhibiting the 28S subunit of the 60S ribosome. In addition to the GI manifestations of vomiting, diarrhea, and dehydration, ricin can cause cardiac, hematologic, hepatic, and renal toxicity. All contribute to death in humans and animals.[7,52,189,203,274] Despite the obvious toxicity of this compound, death probably can be prevented by early and aggressive fluid and electrolyte replacement after oral ingestion (but not injection or inhalation, Chap. 126). Allergic reactions to some of these lectin-bearing plants are noted, particularly to *R. communis*.[265] Occupational exposures to castor oil are a particular hazard,[84,346] and the plant's pollen may be a pneumoallergen.[135]

Just how lethal are ingestions of the ornamental seeds? The highest concentration of xenobiotic is in the hard, brown-mottled seeds. These seeds are both tempting and available, even to children in the United States, because they are attractive enough to be used to make jewelry, and their parent plants are showy enough to have been exported for horticultural purposes outside of their native India (including to the United States).[199] Although mastication of one seed by a child liberates enough ricin to produce death,[203] this outcome (or even serious toxicity) is uncommon, even if the seeds are chewed, probably because GI absorption of the xenobiotic is poor and supportive care is effective.[9,52] Activated charcoal should be administered promptly.

Other *ricinlike lectins* are found in *Abrus precatorius* (jequirity pea,

rosary pea [see ILABRUSPRECATORIUS in the Image Library at http://www.goldfrankstoxicology.com]),[17,82] *Jatropha* spp,[221] *Trichosanthes* spp (eg, *kirilowii* or Chinese cucumber),[187] *Robinia pseudoacacia* (black locust),[73,248] *Phoradendron* spp (American mistletoe), *Viscum album* (European mistletoe),[94,102] and *Wisteria* spp (wisteria).[171,299] These all produce at least one double-chain lectin that binds to galactose-containing structures in the gut or inhibits protein synthesis in a manner similar to ricin.

Pokeweed mitogen of *Phytolacca americana* (pokeweed [see ILPHYTOLACCAAMERICANA in the Image Library at http://www.goldfrankstoxicology.com]) is a single-chain protein that inhibits ribosomal RNA by removing purine groups.[16,177] Given their mechanism, it is not surprising that the lectins are capable of producing GI symptoms, and they otherwise have toxic profiles with variable degrees of overlap in pattern and severity with ricin in humans and animals.

The most commonly ingested toxic plant lectins in the United States are from pokeweed, which is eaten as a vegetable but rarely causes toxicity or death. *Phytolacca* toxin and pokeweed mitogen are found in all plant parts, but the highest concentrations are found in the plant root. The mature deep purple berries are less toxic.[16] Pokeweed leaves are consumed after boiling without toxic effect if the water is changed between the first and second boiling (parboiling). When this detoxification technique is not followed, as in preparation of poke salad or pokeroot tea, violent GI effects can ensue 0.5â€“6 hours after ingestion. Nausea, vomiting, abdominal cramping, diarrhea, hemorrhagic gastritis, and death may occur. In addition, bradycardia and hypotension, perhaps induced by an increase in vagal tone, may be associated with nausea and vomiting.[159,297] More often than not, toxicity is limited to the GI tract. The mitogen produces a lymphocytosis 2â€“4 days after ingestion that may take up to 10 days to clear, but this is without clinical consequence.[16]

Mistletoe berries, both American and European, can produce severe gastroenteritis, especially when delivered as teas or extracts, or particularly as parenteral antineoplastic medicinal agents in Europe.[95] As festive holiday plants they become seasonally available for children. Poison Center data suggest that ingestion of 3â€“5 berries or 1â€“5 leaves of the American species may not cause toxicity, but these suggestions are based on limited evidence. (See Chap. 130.)[214] Despite single reports of seizure, ataxia, hepatotoxicity, and death,[156,327] most authors performing such retrospective examinations[155,219,327] conclude that mistletoe exposures are not a highly consequential risk.

Hypoglycin A (Î²-methylene cyclopropyl-L-Î±-aminopropionic acid) and *hypoglycin B* (dipeptide of hypoglycin A and glutamic acid) are found in the unripe ackee fruit and seeds of *Blighia sapida* (Euphorbiaceae). (See ILBLIGHIASAPIDA in the Image Library at http://www.goldfrankstoxicology.com.) The tree is native to Africa but was imported to Jamaica in 1778 by the botanist Thomas Clarke. The scientific name of the plant derives from Captain William Bligh, the British explorer.[32] The tree is also naturalized in Central America, southern California, and Florida. Epidemics of illness (Jamaican vomiting sickness) associated with consumption of the unripe ackee fruit (raw and cooked) occur in Africa but are more common in Jamaica, where ackee is the national dish.[50,246] The most toxic part is the yellow oily aril of the fruit, which contains three large shiny black seeds.[53] Cases in the United States usually are associated with canned fruit.[245] Hypoglycin A is metabolized to methylene cyclopropyl acetic acid, which competitively inhibits the carnitineâ€“acyl coenzyme (CoA) transferase system.[1,31,32] This prevents importation of long-chain fatty acids into the mitochondria, preventing their Î²-oxidation to precursors of gluconeogenesis. Î²-Oxidation and gluconeogenesis are further arrested by inhibition of various enzymes,[31,101] such as glutaryl CoA dehydrogenase, which blocks the malate shunt (Chap. 13). In addition, increased concentrations of glutaric acid may

inhibit glutamic acid decarboxylase, which produces GABA from glutamic acid. This not only depletes GABA but also increases concentrations of excitatory glutamate to produce seizures.[1,193] Insulin concentrations remain unaffected by hypoglycin and metabolites.[253] Carboxylic and other organic acid substrates build up in the urine and serum as a

result of these metabolic perturbations. Detection of these acids can help corroborate the diagnosis.[143]

Jamaican vomiting sickness is characterized by epigastric discomfort and the onset of vomiting starting 2â€“6 hours after ingestion. Convulsions, coma, and death can ensue, with death occurring approximately 12 hours following consumption. Laboratory findings are notable for profound hepatic aminotransferase and bilirubin abnormalities, and aciduria and acidemia without ketonemia. Cholestatic hepatitis can occur and is reported with chronic use.[219] Autopsy reveals fatty degeneration of liver, particularly microvesicular steatosis, and other organs with depletion of glycogen stores.[170] Left untreated, patient mortality reaches 80%, with 85% of the fatal cases suffering seizures. Treatment with glucose and fluid replacement is essential. Benzodiazepines can control seizures, perhaps directly if the seizures are related to depletion of GABA. L-Carnitine therapy may exert a theoretical therapeutic role similar to that noted with valproic acid toxicity,[104,223] whereas glycine therapy shows some beneficial effects in rats (Chap. 47).[319]

The *lathyrins* Î²-*N*-oxalylamino-L-alanine (BOAA) and Î²-aminopropionitrile (BAPN) are peptides from the grass pea *(Lathyrus* sativus) found in the seeds and leaves, respectively. BOAA produces neurolathyrism (seeds) and BAPN produces osteolathyrism (leaves) in individuals with a dietary dependence on this plant. Neurolathyrism is clinically indistinguishable from spastic paresis associated with consumption of improperly prepared cassava (see Cyanogenic Glycosides: *(S)*-Sambunigrin,

Amygdalin, Linamarin, and Cyacasin). Thiol oxidation with depletion of nicotinamide adenine dinucleotide (NADH) dehydrogenase at the level of neuronal mitochondria (ie, excitatory AMPA receptors) may be the common etiology.[246,273,326] Epidemics occur in Bangladesh, Ethiopia, Israel, and India.[137,226] Exposure to BOAA results in degeneration of corresponding corticospinal pathways that becomes irreversible if consumption of undetoxified grass peas is not stopped early. BOAA stimulates the AMPA class of glutamate receptors to provide constant neuronal stimulation, eventual degeneration, and hence spasticity. BAPN affects bone matrix and leads to bone pain and skeletal deformities that develop in adulthood.[163] These diseases occur in areas where the plants are endemic, the food is consumed for two months or more, and when diets are otherwise poor in protein and possibly in zinc.[214]

Microcystins are found in several cyanobacteria (blue-green algae) belonging to various species of the genera *Microcystis, Anabaena*, *Nodularia*, *Nostoc*, and *Oscillatoria*. [42] They elaborate a series of peptide xenobiotics called microcystins and nodularins *(Nodularia spumigena).* These xenobiotics produce hepatotoxicity by causing deterioration of the microfilament function in hepatocytes, leading to cell shrinkage and bleeding into the hepatic sinusoids. Evidence indicates that these peptides are carcinogenic to humans.[90] Although most cases of untoward effects from blue-green algae occur in animals, the potential for harm was demonstrated by use of microcystin-contaminated water in a dialysis unit in Brazil.[184] Unfiltered water was identified as the risk factor for liver disease in 100 patients who attended the dialysis center (Chap. 10). Fifty of these patients died of acute liver failure following early signs of nausea, vomiting, and visual disturbances. The concern for poisoning is heightened because certain species of *Cyanobacteria* are harvested and consumed as health foods[43,142,191] or may be consumed secondarily in fish.[231] In addition to the sodium channel and acetylcholinesterase effects, ingestion of the genus *Microcystis*

produces photosensitivity.[119]

Phenols and Phenylpropanoids: Coumarins, Capsaicin, Karwinskia Toxins, Naringenin and Bergamottin, Asarin, Nordihydroguaiaretic Acid, Podophyllin, Psoralen, and Esculoside

Phenols and phenylpropanoids represent one of the largest groups of secondary metabolites.[107,296] Coumarins and their isomers are phenylpropanoids that are discussed in Chap. 57. Some coumarins are warfarinlike in their activity and are capable of producing a bleeding diathesis when plants are consumed in sufficiently large quantities.[174,216] Lignans are formed when phenylpropanoid side chains react to form bisphenylpropanoid derivatives. Lignins are high-molecular-weight polymers of phenylpropanoids that bind to cellulose and provide strength to cell walls of stem and bark. Tannins are polymers that bind to proteins and divide into 2 groups: hydrolyzable and condensed (called *proanthocyanidins*, eg, karwinol).

Capsaicin is derived from *Capsicum annuum* or other species of chile or cayenne peppers. It is a simple phenylpropanoid that causes release of the neuropeptide substance P from sensory C-type nerve fibers. The immediate response to capsaicin is intense local pain and is the rationale for its use in pepper spray. Eventual depletion of substance P prevents local transmission of pain impulses from these receptors to the spinal cord, blocking perception of pain by the brain, explaining its use in postherpetic neuralgia.[364]

Painful exposures to capsaicin-containing peppers are among the most common plant-related exposures presented to poison centers. They cause burning or stinging pain to the skin. If

ingested in large amounts by adults or small amounts by children, they can produce nausea, vomiting, abdominal pain, and burning diarrhea.[89,364] Eye exposures produce intense tearing, pain, conjunctivitis, and blepharospasm.[344]

Skin irrigation, dermal aloe gel, analgesics, and oral antacids are therapeutic agents that may be helpful as appropriate, but patients can be reassured that the effects are transitory and produce no long-term damage. Irritated eyes can be treated with irrigation and local analgesia, but generally resolve without sequelae within 24 hours.[185]

Karwinskia toxins from plants commonly named Buckthorn, coyotillo, tullidora, wild cherry, or capulincillo *(Karwinskia humboldtiana)*. These xenobiotics are identified by their molecular weights (T-514, T-496, T-516, T-544). Toxicity has been known for more than 200 years. In 1920, an epidemic of deaths was reported after 20% of 106 Mexican soldiers died following ingestion of foraged *Karwinskia* fruits.[196,234] The fruits are attractive to children; epidemic poisonings have been reported in Central America[11] and are possible wherever the shrub is found (in semidesert areas throughout the southwestern United States and Caribbean, Mexico, and Central America). Recently, poisonings from this plant in Mexico have increased from a total of 72 cases reported between 1990 and 1994 to 40 cases per year currently reported in northern Mexico.[234,264] Uncoupling of oxidative phosphorylation or dysfunction of peroxisome assembly and integrity is described for Schwann cells.[353,368] Each xenobiotic exhibits similar cytotoxic effects at the cellular level, but with trophism for different organs in animal models.[234]

Within a few days of ingestion, a symmetric motor neuropathy ascends from the lower extremities to produce a bulbar paralysis that may lead to death. Deep-tendon reflexes are abolished in affected areas, but cranial nerve findings are absent. Distinction of this demyelinating motor neuropathy from Guillain-BarrÃ©

syndrome,

poliomyelitis, solvent, and other polyneuropathies is best assisted by detection of T-514 in the blood of affected patients.[29,196,234] The other recognized toxins are not detected in blood. Occasionally, axonal damage is observed, but demyelination is the predominant finding on biopsy. Nerve conduction studies always demonstrate loss or abolition of function in fast-conducting axons. Cerebrospinal fluid demonstrates normal protein, glucose, and cytology. Treatment is supportive, with mechanical ventilation as needed, and recovery typically is slow.

Naringenin and *bergamottin* are phenylpropanoids derived from grapefruit that inhibit CYP3A4 in gut and liver.[128] Grapefruit juice consumption can increase circulating concentrations of drugs reliant on 3A4 for metabolic elimination, including terfenadine, carbamazepine, and felodipine. These effects are maximally achieved by a single glass of grapefruit juice.[228]

Hyperforin is another phenylpropanoid found in St. John's wort *(Hypericum perforatum)* and is associated with plantâ€“drug interactions.

Asarin is found in the sweet flag plant tuber *(Acorus calamus).* Putative euphoric and hallucinogenic effects that motivate ingestion are in contrast to confirmed reports of unpleasant GI effects.[352]

Nordihydroguaiaretic acid (NDGA) is associated with hepatotoxicity after ingestions of chaparral *(Larrea tridentata)*.[317] Podophyllin and psoralens are phenylpropanoids discussed in Antimitotic Alkaloids and Resins and in Plant-Induced Dermatitis, respectively.

Esculoside (also called *esculin* or *aesculin)* has triterpene saponin side chains and is believed to be the toxic component in horse chestnut *(Aesculus hippocastanum).* Horse chestnut extracts are used medicinally in patients with venous insufficiency. Its

therapeutic use at high doses (>340 Âµg/kg) is associated with renal failure or a lupuslike syndrome.[151,168] Leaves, twigs, or horse chestnuts ingested by children or infused as teas result in a syndrome that resembles nicotine intoxication. The syndrome consists of vomiting, diarrhea, muscle twitching, weakness, lack of coordination, dilated pupils, paralysis, and stupor.[262] The mechanism of toxicity is not defined, but ingestion of chestnut approximately 1% of a child's weight is suggested to be poisonous to a child.

Carboxylic Acids: Oxalic Acid and Oxalate Raphides

Oxalic acid is the strongest acid among the carboxylic acids found in living organisms. It forms poorly soluble chelates with calcium and other divalent cations. Higher plants have varying ability to accumulate these products of metabolism. Oxalates are mainly found in certain plant families, such as the Araceae, Chenopodiaceae, Polygonaceae, Amaranthaceae, and several of the grass families. Human dietary sources include rhubarb, spinach, strawberries, chocolate, tea, and nuts.[236] Human consumption of soluble oxalate-rich foods correlates with kidney stone formation.[169]

The insoluble calcium oxalate raphides that are present in certain plants, usually in the Araceae family, are found in conjunction with a protein toxin that increases the painful irritation to skin or mucous membranes. This special manifestation is discussed in greater detail in Plant-Induced Dermatitis.

Alcohols: Cicutoxin

Cicutoxin, a diacetylenic diol, is found in the water hemlock *(Cicuta maculata)* and other *Cicuta* spp. Ingestion of any part of the plant constitutes the most common form of lethal plant ingestion in the

United States. In a series of 83 ingestions from 1900â€“1975, the case fatality rate was 30%, and it dominated plant-related fatalities among the most recent 10-year reviews of the Toxic Exposure Surveillance System (TESS) and Centers for Disease Control (CDC) plant-poisoning records (Chap. 130).[213,252] In contrast to most plant exposures in humans (which tend to involve children), these ingestions usually involve adults who incorrectly identify the plant as wild parsnip, turnip, parsley, or ginseng. All plant parts are poisonous at all times, but the tuber is especially toxic, and more so during the winter and early spring.[145,252] Absorption of cicutoxin is rapid and occurs through the skin as well as through the gut.[200] Ingestion of as little as a 2-cm section of the sweet-tasting root of *Cicuta* can produce fatal status epilepticus, the mechanism of which remains unclear.[25,41,165,270,335]

Symptoms of mild or early poisonings consist of GI symptoms (nausea, vomiting, epigastric discomfort) and begin as early as 15 minutes after ingestion. Emesis may diminish the toxic load in the gut. Diaphoresis, flushing, dizziness, excessive salivation, bradycardia, hypotension, bronchial secretions with respiratory distress, and cyanosis occur and rapidly progress to violent seizures. Complications include rhabdomyolysis with renal failure and severe acidemia.[41] Immediate gastric evacuation should be performed, and benzodiazepines should be administered for seizures. Case reports recommend diverse treatments such as hemodialysis, anticholinergic therapy, and sodium thiopentone infusion as potential lifesaving measures.[205,270,294,330]

Unidentified Toxins

Consistent with the inherent complexity of plants and the relatively early stage of the science, identification of the active ingredient(s) involved in poisoning is not always possible. An epidemic of the irreversible lung disease bronchiolitis obliterans developed in

1994. It involved more than 200 dieters who had been eating *Sauropus androgynous* as a weight-loss vegetable. The effects were dose related (usually~100 g/d) and manifested by month 7 after approximately 10 weeks of use.[176] The cases were associated with at least 4 deaths and, in addition to pulmonary disease, included 3 cases of torsade de pointes.[54,227] This last complication is consistent with the plant's high concentration of papaverine, a toxin that produces dysrhythmias in animals, but papaverine does not cause the lung disease.[375] Steroid and bronchodilator therapy consistently failed to improve pulmonary symptoms, and lung transplantation remains the only effective treatment for advanced cases.[227]

Milk sickness is an historic poisoning described by pioneer farmers. It was caused by transmission of the nontoxic ketone tremetone to humans via milk of animals grazing on white snakeroot plants *(Eupatorium rugosum)*.[242,318] Tremetone is transformed into an unknown, unstable toxin by hepatic microsomal enzymes.[19,20] Toxicity is cumulative. Milk sickness can be fatal in 1â€“21 days or is associated with a slow recovery marked by weakness for months or years, relapsing sometimes to death. A delay in the lactating animal's symptoms provided a lag time when xenobiotic-laden milk was taken from presymptomatic animals and thereby transmitted to humans before the problem was detected. Reports in animals but not humans may be found in the literature.

Breynia officinalis,[224] black cohosh *(Actaea racemosa)*,[341] and the yam *(Dioscorea bulbifera)*[338] are implicated as agents producing hepatotoxicity. Unidentified components of the plant

Achyranthes aspera are associated with production of hypotension and bradycardia.[161] Additional studies are needed to verify these effects.

Consumption of the food star fruit *(Averrhoa carambola)* and preexisting renal insufficiency are associated with development of

intractable hiccups, vomiting, motor disabilities, paresthesias, confusion, seizures, and death unless patients receive supportive care and hemodialysis.[61,266,348] The unidentified toxin appears to be neuroexcitatory and active in the thalamus and right temporooccipital cortex.[57]

Effects Shared Among Different Classes of Xenobiotics

Plantâ€“Drug Interactions

By increasing the metabolic rate of CYP enzymes,[302] hyperforin in St. John's wort *(H. perforatum)* decreases concentrations of (1) cyclosporin, (2) digoxin, (3)warfarin, (4) theophylline, (5) oral contraceptives, and (6) indivir. Activity of some of these 6 drugs and others (eg, amitriptyline and theophylline) may be reduced by flavonoids in St. John's wort, which increases drug elimination by increasing the activity of P-glycoprotein.[181] On the other hand, bergamottin and naringenin from grapefruit reduce activity of the CYP system enzymes and increase drug concentrations. Other *Citrus* species also appear to increase drug concentrations.[175]

Additive effects may be responsible for serotonin excess or mild serotonin syndrome when St. John's wort is used concurrently with tryptophan or serotonin reuptake inhibitors. Additive effects also appear to be responsible for increased prothrombin time in patients taking *Ginkgo biloba* and various dugs to affect coagulation (eg, warfarin or aspirin) because the ginkgolides have antiplatelet activity.[79,127,181,251] Hawthorn (*Crataegus* spp), used medicinally for cardiac disorders, may produce an additive effect when taken concomitantly with digoxin, producing bradycardia.[173] Excessive intake of broccoli provides enough vitamin K to competitively inhibit the negative effects of warfarin on vitamin K activation.[79]

Sodium Channel Effects: Aconitine, Veratridine, Zygacine, Taxine, and Grayanotoxins

Several unrelated plants produce xenobiotics that affect the flow of sodium at the sodium channel. For instance, aconitine and veratrum alkaloids tend to open the channels to influx of sodium, whereas others (eg, taxine) tend to block the flow, and grayanotoxins both increase and block sodium flow. The sodium channel opener aconitine from *Aconitum* spp or.(See ILACONITUMRAPELLUS in the Image Library at http://www.goldfrankstoxicology.com) *Delphinium* spp has the most persistent toxicity and the lowest therapeutic index among the many active alkaloid ingredients of the toxin called aconite. Some of these related alkaloids are controlled medicinal substances in the People's Republic of China and Taiwan.[88] Aconite has been abused for its psychoactive â€œout of bodyâ€• effects[110,343] and for suicide and homicide.[101,106] Properly processed aconite is supposedly less cardiotoxic than unprocessed material, because processing results in production of the less toxic dehydroaconitine. This xenobiotic should be suspected in potentially poisoned patients who manifest cardiac toxicity, paresthesias, and seizures.[60,110,256]

The mechanism of action depends on the individual alkaloid. Some compounds block and others activate sodium channels.[6,313] Aconitine itself opens the voltage-dependent sodium channel at binding site 2 of the Î±-subunit, initially increasing cellular excitability.[6] By prolonging sodium current influx, neuronal and cardiac repolarization eventually slows. It also has calcium channel-opening effects. Asian prescription medicines use the alkaloids to treat dysrhythmias and pain by reducing the excitability of the cardiac conducting system and sensory neurons, respectively. Enhanced activity of the vagus nerve results in

bradycardia, which is treated successfully by atropine.[197,283] Approximately one teaspoon (2â€“5 mg) of the root may cause death by paralyzing the respiratory center or cardiac muscle.

The aconitine alkaloids are rapidly absorbed from the GI tract. Cardiovascular symptoms typically progress from bradycardia and hypotension to tachydysrhythmias and cardiac arrest. CNS symptoms typically progress from paresthesias to CNS depression, respiratory muscle depression, paralysis, and seizures.[6] Nausea, vomiting, diarrhea, and abdominal cramping occur.[56,110,206,269,378] Cardiac toxicity resembles that caused by cardioactive steroids, with atrioventricular conduction blockade and increased ventricular automaticity resulting in a variety of rapid ventricular rates, from multifocal premature ventricular contractions to ventricular fibrillation and torsade de pointes. A history of paresthesias may be useful in differentiating aconitine toxicity from that caused by a cardioactive steroids, but empiric use of digoxin-specific antibody fragments should not be delayed if there is any doubt. These antibodies, however, are ineffectual against aconitine. Orogastric lavage, activated charcoal, and preparation for cardiac pacing, bypass, or balloon pump assist are warranted given the potential for rapid cardiovascular deterioration.[118,271] Success with amiodarone is reported.

Ingestion of veratridine and other veratrum alkaloids (from *Veratrum viride* and other *Veratrum* spp) generally results from foraging errors where the root appears similar to leeks *(Allium porrum)* and above-ground parts appear similar to gentian *(Gentiana lutea)* used for teas and wines in Europe.[40,115,120,125,287] The mechanism of action is like that of aconitine (sodium channel opening) but with shorter duration.[247,350] Although severe toxicity is reported, management is supportive with fluids, atropine, and pressors. Deaths are rare.[75,183,232]

Zygacine from *Zigadenus* spp (death camus) and other members of

the lily family produces the same toxic effects as veratridine alkaloids (vomiting, hypotension, and bradycardia). Symptoms begin 1â€“2 hours after ingestion[167,328] and usually result from errors while foraging for onions because of the plant's look-alike bulb. Treatment options are the same as above with Veratrum alkaloids. Fatalities among Native Americans in the western United States caused by *Zigadenus* were recorded after interviews conducted in the 19th century.

Taxine is another alkaloid mixture of sodium channel effectors that tend to close the channel.[340,373] It is derived from the yew (*Taxus baccata* [see ILTAXUS spp in the Image Library at http://www.goldfrankstoxicology.com]). Suicide using leaves is reported despite the large number of leaves required.[112,261,331,366,371] Toxic alkaloid is contained within the hard central seed but not in the surrounding fleshy red aril, which partly explains the low rate of toxicity in reported cases.[363]

Paclitaxel (Taxol) is an alkaloid component of the relatively rare Pacific yew *(Taxus brevifolia)* that is used as an antitumor chemotherapeutic agent because of its ability to promote the assembly of microtubules and to inhibit the tubulin disassembly

process in mitotic cells. Within 1 hour after ingestion, toxicity progresses from nausea, abdominal pain, bradycardia, and cardiac conduction delays to wide-complex ventricular dysrhythmias, paresthesias, ataxia, and mental status changes.[111,269] Four prisoners who drank an extract of yew experienced profound hypokalemia, and 2 died of cardiac arrest.[111,269] Animal models indicate that bradycardia is responsive to atropine,[289] but wide-complex tachydysrhythmia is unresponsive to sodium bicarbonate.[305]

Grayanotoxins (formerly termed *andromedotoxins*) are a series of 18 toxic diterpenoids present in leaves of various species of *Rhododendron*, *Azalea*, *Kalmia* (see ILKALMIA sp Image Library at

http://www.goldfrankstoxicology.com), and *Leucothoe* (Ericaceae). They exert their toxic effects via sodium channels, which they open or close, depending on the toxin.[263] Grayanotoxin I increases membrane permeability to sodium and affected calcium channels in a manner similar to that of veratridine (and batrachotoxin).[92,131,198] Grayanotoxins become concentrated in honey made from the plants, mainly in the Mediterranean. Accounts of poisoning by honey date back to at least 401 B.C., when Xenophon's troops were incapacitated after they consumed honey made from nectar of *Rhododendron luteum.* These accounts are echoed by modern accounts of toxic honey in the same region.[22,289,376] Bradycardia, hypotension, GI manifestations, mental status changes (â€œmad honeyâ€•), and seizures are described in patients or animals suffering grayanotoxin toxicity.[23,201,217,288,289,332,376]

Antimitotic Alkaloids and Resins: Colchicine, Vincristine, and Podophyllum

Consumption of colchicine from plant sources such as autumn crocus *(Colchicum autumnale)* produces a spectrum of symptoms, including nausea, vomiting, watery diarrhea, hypotension, bradycardia, electrocardiographic abnormalities, diaphoresis, alopecia, bone marrow depression, renal failure, hepatic necrosis, hemorrhagic acute lung injury, convulsions, and death.[130,147,202,249]

Colchicine-induced deaths from ingestion of *Gloriosa superba* are among the most common plant-associated fatalities in Sri Lanka.[114] Confusion of the bulbs or leaves of this plant with those of wild onions or garlic occur as a foraging error. Unintentional consumption by children, or ingestion with suicidal intent, accounts for the other cases involving morbidity or mortality.[3] The

mechanism of toxicity is disruption of microtubule formation in mitotic cells.

Vincristine and vinblastine are two other indole alkaloids that are used as antineoplastics and are both isolated from the Madagascar periwinkle *(Catharanthus roseus).* No reports of poisoning by these alkaloids following ingestion of the plant could be found (Chap. 52).

Podophyllum resin is the dry, alcoholic extract of the rhizomes and roots of mayapple (*Podophyllum peltatum* [see ILPODOPHYLLUMPELTATUM in the Image Library at http://www.goldfrankstoxicology.com]). The dry resin consists of up to 20% podophyllotoxin, Î±- and Î²-peltatin, desoxypodophyllotoxin, and dehydropodophyllotoxin. These xenobiotics are originally present in the plant as Î²-D-glucosides. Podophyllum resin containing podophyllin is available by prescription for topical treatment of venereal warts. Its medicinal derivatives (eg, etoposide) are used for a range of neoplastic diseases. It is used as a popular traditional Chinese medicine and may produce toxicity even in â€œtherapeuticâ€• doses.[191] Podophyllotoxins make up 20% of the resin from the roots of mayapple *(P. peltatum).* As a group, they disrupt tubulin formation, producing multisystem organ failure. Poisonings are caused by misidentification and adulteration, possibly because the list of common names by which it is known includes mayapple, as well as mandrake, wild mandrake, American mandrake, and European mandrake.[37,124] Catharsis is prominent after ingestion, but onset of symptoms may be delayed (10 hours in a fatal ingestion[44]). Acute severe sensorimotor neuropathy and bone marrow suppression following transient leukocytosis can occur even after one-time acute exposures and may be directly related to inhibition of microtubule assembly. Lethargy, confusion, encephalopathy, autonomic instability, sensory ataxia, and death are described following large exposures,[268] but poisoning also can occur after â€œtherapeuticâ€• doses of a popular traditional

Chinese medicine.[191] Glutamic acid has been used to prevent vincristine-induced peripheral neuropathy and would be a reasonable therapy following podophyllin ingestion.[182]

Plant-Induced Dermatitis

A large number of plants result in undesirable dermal, mucous membrane, and ocular effects (Chap. 29), the most common adverse effects reported to US poison centers and occupational health centers. Plant-induced dermal disorders can be categorized[106,254,310,334] into 4 mechanistic groups, that is, dermatis that results from (1) mechanical injury, (2) irritant molecules that penetrate the skin, (3) allergy, or (4) photosensitivity (direct and hepatogenous).

There is much overlap between these categories (some plants can produce all types). Clinicians may have difficulty distinguishing between plant-induced dermatitis and skin disorders[237,239] or between plant-induced dermatitis and pseudophytodermatitides caused by arthropods, pesticides, or wax (used in fruit and vegetable packaging).[334] Agents that cause adverse skin reactions can also cause eye and local gastric mucosal irritation.

Dermatitis from *mechanical injury* often is combined with primary or allergic contact dermatitis. Stinging nettles *(Urtica dioica* and other species) have a specialized apparatus in the form of an elongated silicious cell (glandular trichome) that acts like a hypodermic syringe to deliver irritant chemicals into the skin. Contact with these stinging hairs shears off the tip of the hair, producing micromechanical injury and releasing irritant contents: acetylcholine, histamine, and 5-hydroxytryptamine.[272] The proteinase mucunain is released from the barbed trichomes of *Mucuna* spp (cowhage),[105] and workers who handpick pineapples are subject to fissuring and loss of fingerprints after bromelain is introduced following dermal abrasion by raphides.[204]

Exposures to commonly available household plants such as dumbcane (*Dieffenbachia* spp), *Philodendron* spp,[241] and *Narcissus* bulbs can lead to mechanical injury and painful microtrauma produced by bundles of tiny needlelike calcium oxalate crystals called *raphides.* Packages of hundreds of raphides called *idioblasts* contain proteolytic enzymes. *Dieffenbachia* (>30 species [see ILDIFFENBACHIA sp. in the Image Library at http://www.goldfrankstoxicology.com]) exposures are commonly reported household or malicious plant exposures.[10,285] These exposures are rarely serious.[280] When the leaves are chewed, immediate oropharyngeal pain and swelling occur. Severe oral exposures can be excruciating and progress to profuse salivation, dysphagia, and loss of speech. Soothing liquids, ice, parenteral opioids, corticosteroids, and airway protection may be indicated, but antihistamines provide little relief. The edema and pain typically begin to subside after 4â€“8 days.[241] Ocular exposure to the sap may produce chemical conjunctivitis, corneal abrasions, and, rarely, permanent corneal opacifications.

Similar exposures to oxalate raphide-containing household plants in the same family *(Philodendron, Brassaia, Epipremnum aureum, Spathiphyllum*, and *Scheflera* spp) are not as painful as to dumbcane, presumably because the crystals are packaged differently and do not simultaneously deliver proteolytic enzymes.[204,260] One exception to their lower severity is a report of death in an 11-month-old following complications arising from esophageal lesions induced by philodendron.

Irritant dermatitis results from low-molecular-weight xenobiotics such as phorbol esters (Euphorbiaceae) that directly penetrate the skin without antecedent mechanical injury. Similar penetrance is achieved by products of glycoside hydrolysis. For instance, hydrolysis of ranunculin gives rise to anemonin in Ranunculaceae, the buttercup family, and hydrolysis of sinigrin in plants in the mustard family Brassicaceae yields allyl isothiocyanate. Although

one death is attributed to prolonged contact with sinigrin in mustard plaster,[254] exposures to primary irritants in Brassicaceae and Ranuculaceae usually are mild. Alternatively, dermatitis can occur without contact, as in cases of airborne contact dermatitis, in which typically exposed sites are the upper eyelids, neck, uncovered extremities, including antecubital fossae, and other skin folds[63,310] (Chap. 29).

Phorbol esters found in spurges (Euphorbiaceae) are contained in milky sap that is capable of producing erythema, desquamation, and bullae. The saps of some species are more irritating than others.[100] For instance, the manchineel tree *(Hippomane mancinella)*, found in the Caribbean and Florida, once was planted on graves to deter grave robbers, and juice from the tree has been used to brand animals and to blind people.[254] In addition to dermal and ocular injury, ingestion of some spurges can induce severe GI injury. Poinsettia *(Euphorbia pulcherrima)*, crown of thorns *(E. splendens)*, candelabra cactus *(E. lacteal)*, and pencil tree *(E. tirucalli)* are spurges found in the home as holiday or other ornamentation that rarely produce serious injury, despite reputations to the contrary. The poinsettia plant, for instance, gained a reputation of significant toxicity based on a single, inadequately documented case report from Hawaii in 1919, involving the death of a 2-year-old child. In a subsequent case, an 8-month-old child developed oral mucosal burns after chewing poinsettia.[99] Contact dermatitis, irritation of mucous membranes, and GI complaints (eg, nausea, vomiting, and abdominal pain)[78,99] are rare findings among the many reported exposures to poinsettia.[212]

Allergic contact dermatitis results from type IV hypersensitivity response and, unlike irritant dermatitis, requires repeat exposures to the agent before symptoms manifest. The most infamous of these xenobiotics are the urushiol oleoresins derived from catechols that are found in *G. biloba* (Ginkgoaceae) and members of the Proteaceae (eg, *Macadamia integrifolia*) and the

Anacardaceae.[105] The latter family is notable for inclusion of poison ivy *(Toxicodendron radicans)*, poison oak *(T. toxicarium, T. diversilobum)*, and poison sumac *(T. vernix)*,[67,116,117,233,339] as well as mango *(Mangifera indica)*, pistachio *(Pistacia vera)*, cashew *(Anacardium occidentale)*, and Indian marking nut â€œBhilawanolâ€• *(Semecarpus anacardium)*.[144] Upon first exposure, urushiol resins penetrate the skin and react with proteins to form antigens to which the body forms antibodies. Upon reexposure to urushiol resins, inflammatory mediators are released, leading to urticaria, itching, swelling, and pain. In extreme cases, these reactions can progress to type I hypersensitivity, as demonstrated by a 6% rate of anaphylaxis to mango among 580 patients who previously had mango-induced contact dermatitis.[8] Cross-reactivity between allergens is possible, and particular vigilance is required in sensitive individuals.[113,160,230] Prevention by removal of exposed objects that act as fomites for the oils and use of protective ointments are appropriate.[233,356] Therapy includes washing with soap and water and corticosteroid creams and, for those frequently exposed, desensitization (Chap. 29).[115,257]

Allergic contact dermatitis is the most common plant-induced occupational injury. In the United States, 33% of 462 floral shops surveyed reported that at least one employee had developed contact dermatitis.[310] Reactions are reported following exposure to tulips, *Narcissus*, Peruvian lily (*Alstroemeria* spp), and primroses (*Primula* spp). Exposure to the glycoside tuliposide A results in â€œtulip fingers,â€• the dry, painfully fissured hyperkeratosis of fingers observed in horticultural workers who chronically handle tulips.[172] Upon hydrolysis, this compound yields Î±-methylene-butyrolactone, the true allergen. Cross-reactivity is possible among some of these xenobiotics. *Alstroemeria* spp, a common ornamental called *Peruvian lily*, contain tuliposide A and thus can cross-react with antigens in those persons already allergic to tulips, producing an allergic contact dermatitis. Primin (2-methoxy-

6-*n*-pentyl-*p*-benzoquinone) from members of the Primulaceae[62,225] was responsible for the most frequently reported allergic plant dermatitis in northern Europe until workers refused to stock primroses. The â€œwood cutters dermatitisâ€• of loggers occurs with development of sensitivity to compounds in liverwort (*Frullania* spp), which is cross-reactive to ursinic acid in lichens and mosses found on the wood.[358] Cross-reactivity with common weeds such as ragweed (*Ambrosia* spp) or dandelion (*Taraxacum* spp) initiate the risk of hypersensitivity from members of the Composite family. A myriad of other types of plants are involved in producing occupational dermatitides.[134,189,190,279,308]

Sensitivity to Compositae (daisy family) involves more than 600 sesquiterpene lactones in at least 200 of the 25,000 species in the family and is as ubiquitous as the distribution of species. *Chrysanthemum* allergy is a common occupational hazard in Europe,[153,334]

Direct photosensitivity dermatitis is produced when compounds such as psoralen or other linear furocoumarins come into direct contact with the skin or is digested and becomes bloodborne to dermal capillary beds, where it interacts with sunlight.[65] These photosensitizing agents are activated by ultraviolet A (320â€“400 nm), producing singlet oxygen and DNA adducts. In addition to severe sunburnlike symptoms (erythema, epidermal bullae), hyperpigmentation lasting for several months may result from exposure to these compounds. The mechanism by which this reaction is produced is unknown, but depletion of glutathione is postulated to indirectly stimulate melanogenesis by disinhibiting the normally suppressant tyrosinase.[87,310] More than 200 of these xenobiotics have been identified in at least 15 plant families, including food sources, such as Apiaceae (anise, caraway, carrot, celery, chervil, dill, fennel, parsley, and parsnip), Rutaceae (grapefruit, lemon, lime, bergamot, and orange), Solanaceae (potato), and Moraceae (figs) family.[229,310] A 45-year-old woman died of complications of severe burns received in a tanning salon

following exposure to psoralen,[87] but most other human reactions are sequelae to handling crop plants or retail produce. Humans using St. John's wort *(H. perforatum)* may be susceptible to this syndrome.[93,139,202]

Hepatogenous photosensitivity is produced when a xenobiotic that normally is harmlessly ingested, absorbed, and hepatically excreted gains access to the peripheral circulation through failure of a liver excretion or detoxification mechanism. An example is

the photosensitivity that occurs when phylloerythrin, a product of chlorophyll digestion normally eliminated in the bile, accumulates in the blood as a result of liver dysfunction. The cyanobacterium *Microcystis aeruginosa*, as well as the plants *Lantana camara*, *Tribulus terrestris*, and *Agave lecheuilla*, reportedly cause this type of photosensitization in animals.[119]

Summary

Plant xenobiotics, as well as therapeutic ingredients, can be organized using a pharmacognosy approach. Examples are provided in which the toxin has therapeutic use (colchicine, taxine, physostigmine, pilocarpine, and others). Some xenobiotics act directly or are metabolized to toxic principals (tremetone), whereas others are toxic through secondary contact in animal meat or milk (coniine, tremetone, nitrates, pyrollizidine alkaloids, and ptaquiloside).[192,277,323]

This analysis should not lead to the false conclusion that all toxic plants, all xenobiotics in plants, or all toxic mechanisms are known. Some reassurance can be achieved by excluding exposure to most life-threatening plants and plant xenobiotics or ascertaining whether a common exposure is toxic. This determination can be aided by basic taxonomy while awaiting expert input. Management should balance the relative risks of using invasive gastric emptying and use of activated charcoal if the

plant induces sedation or vomiting or is nontoxic. Potentially fatal ingestions warrant gastric emptying in addition to standard decontamination with activated charcoal and supportive measures. Xenobiotics from sodium channel effectors, cicutoxin, or high-dose belladonna alkaloids necessitate expert toxicologic care and consultation for cardiac support devices and hemodialysis, respectively. Physostigmine should be at hand for serious anticholinergic toxicity. Seizures can be controlled with benzodiazepines, with knowledge that some plants may require pyridoxine (Ginkgo seeds) or possibly thiamine (ginkgolides, ptaquilosides). Hepatotoxicity should be treated empirically with *N*-acetylcysteine. Other xenobiotic-specific measures are noted throughout this chapter, but most patients require supportive management, the intensity of which is dictated by the patient's condition and plant identification. Laboratory diagnostic assays are published for many plant xenobiotics but in most cases are impractical to perform.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 115
Arthropods

In-Hei Hahn

Neal A. Lewin

A 24-year-old man presented to the emergency department (ED) with a chief complaint of a â€œbiteâ€• on his right hand that occurred several hours earlier. He was unpacking a crate of vegetables in his grocery store when he initially felt the bite on his hand and noted several small brown spiders in the bottom of the empty crates. Within 2 hours, the bite became painful and blistered. His vital signs were: blood pressure, 130/80 mm Hg; pulse, 74 beats/min; respiratory rate, 12 breaths/min; temperature, 100Â°F (37.2Â°C). The only remarkable finding was a painful blister surrounded by erythema on the dorsal aspect of his right thumb. The lesion was cleansed with soap and water. Two hours later, the wound became slightly ulcerated and painful. Based on the history and physical findings, the presumptive diagnosis was a cutaneous reaction to a brown recluse spider bite. The patient was shown a picture of the suspected spider, and he identified the brown recluse as his presumed attacker. Dapsone and erythromycin were administered, and the patient was discharged for followup with a dermatologist. He was told to return if systemic

symptoms developed.

The majority of arthropods are benign and environmentally beneficial. Some clinicians regard bites and stings as inconsequential and more of a nuisance than a threat to life. However, some spiders and ticks produce toxic venoms that can produce dangerous painful lesions or significant systemic effects. Important clinical syndromes are produced by bites or stings from the phylum Arthropoda, specifically the classes Arachnida (spiders, scorpions, and ticks) and Insecta (bees, wasps, hornets, and ants) (Table 115-1). Infectious diseases transmitted by arthropods, such as the various encephalitides, Rocky Mountain spotted fever, human ehrlichiosis, babesiosis, and Lyme disease, are not discussed in this chapter.

Arthropoda is the largest phylum in the animal kingdom. At least 1.5 million species are identified, and half a million are yet to be classified. It includes more species than all other phyla combined (Figure 115-1).[2] Arthropoda means â€œjoint-footedâ€• in Latin and describes their jointed bodies and legs connected to a chitinous exoskelelton.[2] Araneism or arachnidism results from the envenomation caused by a spider bite. â€œBitesâ€• are different from â€œstings.â€• Bites are defined as purposeful biting from the oral pole by species for either catching prey or blood feeding, and not inadvertent biting by plant-feeding species.[76,170] â€œStingsâ€• occur from a modified ovipositor at the aboral pole that is no longer able to function in egg laying. Stinging behavior typically is used for defense. Most spiders are venomous, and the venom enables them to secure, neutralize, and digest their prey. They are not aggressive toward humans unless they are provoked. The chelicerae (jaws) of many species are too short to penetrate human skin.

Spiders can be divided into categories based upon whether they pursue their prey as hunters or trappers. Trappers snare their prey by spinning webs, feed, and enshrine excess victims in a cocoon for a later feast. Although capable of producing silk, hunters do not spin such intricate webs; rather, they forage or lie in wait for their insect

prey.

The order of spiders (Araneae) differs from other members of the class because of various anatomic differences best assessed by an entomologist. Simplistically, the arachnids have 4 pairs of joined legs whereas insects have 3 pairs. The arachnid's body is divided into cephalothorax, pedicle, unsegmented abdomen, and 3 or 4 pairs of spinnerets from which silk is spun. Two pedipalps are attached anteriorly on the cephalothorax on either side of their chelicerae and are used for sensation. Spiders have 8 eyes but are quite myopic. Prey is localized by touch as they land in the spider's web. Most spiders are venomous (except for the family Uloboridae) and use their venom to kill or immobilize their prey. The remaining species of medical importance in the United States include the widow spiders (*Latrodectus* spp), the violin spiders (*Loxosceles* spp), and the hobo spider (*Tegenaria agrestis*). In Australia, the funnel web spider (*Atrax robustus*) can cause serious illness and death. In South America, the Brazilian Huntsmen (*Phoneutria fera*) and Arantia Armedeira (*Phoneutria nigriventer*) are threats to humans.

Most information on the clinical presentation of spider bites continues to be unreliable, based on case reports and case series. Frequently the cases do not have any expert confirmation of the actual spider involved, which can lead to propagation of misinformation about different spiders, particularly with necrotic arachnidism. For example, the white tail spider (*Lampona* spp) was suspected for more than 20 years to cause necrotic lesions. Only recently has a prospective study of confirmed spider bites refuted this myth by reporting more than 700 confirmed spider bites in Australia.[103,104] Because most arthropod-focused research involves characterizing the structure of spider toxins rather than verifying clinical presentations, it is important to focus on clinical studies that have definite bites confirmed by the actual presence of the spider and are defined by an expert to avoid spreading these myths. Definite spider bites or stings are defined as the following:[100] (1) evidence of a bite or sting soon after the incident or the creature

can be seen to bite or sting, (2) collection of the particular creature, either alive or dead, and (3) identification of the creature by an expert biologist/taxonomist in the field relating to the creature. Prospective studies using rigorous standards such as confirmed bites and stings, collection of the creature, complete data collection, recruitment of sufficient cases, and followup can only enhance the promotion of accurate information and expose the myths of necrotic arachnidism.

TABLE 115-1. Insects and Other Arthropods that Bite, Sting, or Nettle Humans

Arthropod	Description
Honeybee (*Apis mellifera*)	Hairy, yellowish brown with black markings
Bumblebee and carpenter bee (*Bombus* spp and *Xylocopa* spp)	Hair, but larger than honeybees and colored black and yellow
Vespids (yellow jackets, hornets, paper wasps)	Short-waisted, robust black and yellow or white combination
Schecoids (thread-waisted wasps)	Threadlike waist
Nettling caterpillars (browntail, Io, hag, and buck moths, saddleback and	Caterpillar shaped

puss caterpillars)	
Southern fire ant (*Solenopsis* spp)	Ant-shaped
Spiders (*Arachnida*) black widow, brown recluse	Body with 2 regions, cephalothorax, and abdomen; 8 legs
Scorpions (*Centruroides*)	Eight-legged, crablike, stinger at the tip of the abdomen; pedipalps (pincers) highly developed (not a true insect)
Centipedes (*Chilopoda*)	Elongated, wormlike, with many jointed segments and legs; 1 pair of poison fangs behind head

History and Epidemiology

Since the time of Aristotle, spiders and their webs were used for medicinal purposes. Special preparations were concocted to cure a fantastic array of ailments, including earache, running of the eyes, â€œwounds in the joints,â€• warts, gout, asthma, â€œspasmodic complaints of females,â€• chronic hysteria, cough, rheumatic afflictions for the head, and stopping blood flow.[201]

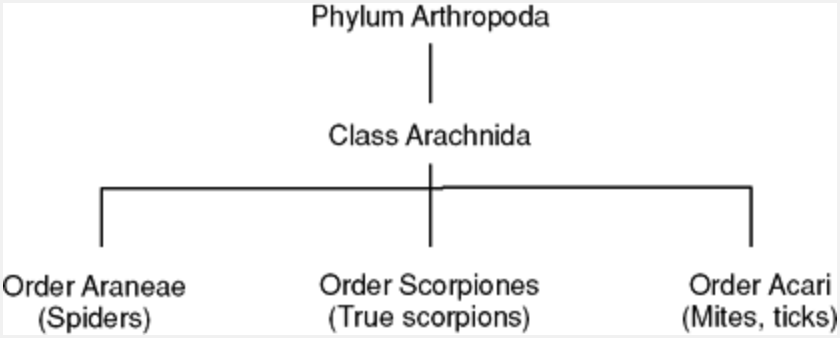

Figure 115-1. Taxonomy of the phylum Arthropoda.

The *Latrodectus* species has an infamous history of medical concern, hence the name *mactans*, which means â€œmurdererâ€• in Latin.[160] Hysteria regarding spider bites peaked during the 17th century in the Taranto region of Italy. The syndrome tarantism, which is characterized by lethargy, stupor, and a restless compulsion to walk or dance, was blamed on *Lycosa tarantula*, a spider that pounces on its prey like a wolf. Deaths were associated with these outbreaks. Dancing the rapid tarantella to music was the presumed remedy. The real culprit in this epidemic was *Latrodectus tredecimguttatus*.[160] Other epidemics of arachnidism occurred in Spain in 1833 and 1841.[133] In North America, there was a rise of spider exposures during the late 1920s, Rome reported large numbers in 1953, and Yugoslavia reported a large number of cases between 1948 and 1953.[28,133] These epidemics may be related to actual reporting biases as well as climactic variations.[160] Spider bites are more numerous in warmer months, presumably because both spiders and humans are more active during that season.

Approximately 200 species of spiders are associated with envenomations.[169,171] Eighteen genera of North America spiders produce poisonings that require clinical intervention (Table 115-2). In

one series of 600 suspected spider bites, 80% were determined to result from arthropods other than spiders, such as ticks, bugs, mites, fleas, *Lepidoptera* insects, flies, beetles, water bugs, and *Hymenoptera.* Ten percent of the presumed bites actually were manifestations of other nonarthropod disorders.[169,171]

From 1995â€“2003, an annual average of 22,000 spider exposures and 50,000 insect exposures were reported to US poison centers. No more than 4 fatalities were reported per year. In 2003, deaths resulted from *Hymenoptera, Solenopsis*, and *Loxosceles* exposures and a tick exposure[214] (Chap. 130). Arachnophobia by the public and by physicians is a perceived danger that far exceeds the actual risk. Often the misdiagnosis of spider bites results from the wide presentation of dermatologic conditions. For example, cutaneous anthrax can be mistaken for a cutaneous necrotic spider bite. In most cases, mortality is rare if supportive care is available and the healthcare provider addresses

the severe pain and associated catecholamine release that may affect the very young, the elderly, and those with underlying cardiopulmonary disease.

TABLE 115-2. North American Spiders of Medical Importance

Genus	Common Name
Araneus spp	Orb weaver
Argiope aurantia	Orange argiope
Bothriocyrtum spp	Trap door spider

Chiracanthium spp	Running spider
Drassodes spp	Gnaphosid spider
Heteropoda spp	Huntsman spider
Latrodectus spp	Widow spider
Liocranoides spp	Running spider
Loxosceles spp	Brown, violin, or recluse spider
Lycosa spp	Wolf spider
Misumenoides spp	Crab spider
Neoscona spp	Orb weaver
Peucetia viridans	Green lynx spider
Phiddipus spp	Jumping spider
Rheostica (*Aphonopelma*) spp	Tarantula
Steatoda grossa	False black widow spider
Tegenaria agrestis	Hobo spider

Ummidia spp	Trap door spider

Black Widow Spider (*Latrodectus Mactans;* Hourglass Spider)

Five species of widow spiders are found in the United States: *Latrodectus mactans* (black widow) (see ILLATRODECTUSMACTANS in the Image Library at http://www.goldfrankstoxicology.com), *Latrodectus hesperus* (Western black widow), *Latrodectus variolus* (found in New England, Canada, south to Florida and west to eastern Texas, Oklahoma, and Kansas), *Latrodectus bishopi* (brown widow of the South), and *Latrodectus geometricus* (brown widow or brown button spider) (see ILLACTRODECTUSGEOMETRICUS in the Image Library). Dangerous widow spiders in other parts of the world include *L. geometricus* and *L. mactans tredecimquttatus* (European widow spider found in southern Europe), *L. mactans hasselti* (red-back widow spider found in Australia, Japan, and India) (see ILLATRODECTUSHASSELTI in the Image Library), and *L. mactans cinctus* (found in South Africa). These spiders live in temperate and tropical latitudes in stone walls, crevices, wood piles, outhouses, barns, stables, and rubbish piles. They molt multiple times and as a result can change colors. The ventral markings on the abdomen are species specific, and the classic red hourglass-shaped marking is noted in only *L. mactans.* Other species may have variations on their ventral surface, such as triangles and spots. The female *L. mactans* typically is shiny, jet-black, and large (8â€“10 mm), with a rounded abdomen and a red hourglass mark on its ventral surface. Her larger size and ability to penetrate human skin with her fangs make her more venomous and toxic than the male spider, who is smaller, lighter in color, and has a more elongated abdomen and fangs that usually are too short to envenomate humans (Table 115-3). Black widow females are trappers and inhabit large untidy irregularly shaped webs. Webs are placed in or

close to the ground and in secluded, dimly lit areas that can trap flying insects, such as outdoor privies, barns, sheds, and garages.[2]

Pathophysiology

The venom is more potent on a volume-per-volume basis than the venom of a pit viper and contains 6 active components with molecular weights of 5000â€“130,000 daltons.[2] The 6 components are Î±-latrotoxin (Î±-LTX), 5 latroinsectotoxins (Î±-, Î²-, Î³-, Î´-, Îµ-LITs) affecting insects, and latrocrustatoxin (Î±-LCT) active only for crustaceans.[84] Î±-Latrotoxin binds, with nanomolar affinity, to the specific presynaptic receptors neurexin I-Î± and Ca^{2+}-independent receptor for Î±-latrotoxin (CIRL), otherwise known as *latrophilin*.[25,90,99] The binding triggers a cascade of events: conformational change allowing pore formation by tethering the toxin to the plasma membrane, Ca^{2+} ionophore formation, and translocation of the N-terminal domain of Î±-LTX into the presynaptic intracellular space, and intracellular activation of exocytosis from dense and clear vesicles containing norepinephrine, dopamine, neuropeptides, and acetylcholine, glutamate, and Î³-aminobutyric acid (GABA) respectively.[2,147,151] Neurexin I-Î± receptors, otherwise known as type I or calcium-dependent receptors, are from a family of neuron-specific cell membrane proteins with one transmembrane domain neuron-specific cell-adhesion molecule.[129,151] Neurexin I-Î± is not required for the excitotoxic action of Î±-LTX. Neurexin I-Î±â€“deficient mice were created and still were susceptible to Î±-LTX via stimulation of the CIRL receptor, or the type II receptor.[73] CIRL is a neuronal receptor that belongs to the family of 7-transmembrane domain G-proteinâ€“coupled receptors. Type II receptors bind to Î±-LTX independently of Ca^{2+} in the extracellular media. CIRL is thought to be coupled to phospholipase C, resulting in subsequent phosphoinositide metabolism that couples the function to secretion.[25,118] CIRL-1 and CIRL-3 are high-affinity neuronal receptors. CIRL-2 has 14 times less affinity to Î±-LTX than CIRL-1 but is expressed ubiquitously, specifically by placenta, kidney, spleen, ovary, heart, lung, and

brain.[99] The nervous system is the primary target for Î±-LTX, but cells from other tissues also are susceptible to the Î±-LTX because of the presence of CIRL-2.[99]

Clinical Manifestations

Widow spiders are shy and nocturnal. They usually bite when their web is disturbed or upon inadvertent exposure in shoes and clothing, although one patient developed latrodectism following the intentional intravenous injection of a crushed whole black widow spider.[34] A sharp pain typically described as a pinprick occurs as the victim is bitten. A pair of red spots may evolve at the site, although the bite is commonly unnoticed.[39,132] The venom is primarily a neurotoxin and does not usually cause a significant local reaction. The bite mark itself tends to be limited to a small puncture wound or wheal and flare reaction that often is associated with a halo (Table 115-3). However, the bite from *L. mactans* may produce *latrodectism*, a constellation of signs and symptoms resulting from systemic toxicity. Some cases do not progress; others may show severe neuromuscular symptoms within 30â€“60 minutes. The effects from the bite spread contiguously. For example, if a person is bitten on the hand, the pain progresses up the arm to the elbow, shoulder, and then toward the trunk during systemic poisoning. Typically, a brief time to symptom onset denotes severe envenomation. Several signs and symptoms are described with the bite of the female black widow spider. Adult male black widow spiders are half the size of the female and are considered harmless.

Hypertoxic myopathic syndrome of latrodectism involves muscle cramps that typically present 15 minutes to 1 hour after the bite. The muscle cramps initially occur at the site of the bite but later may involve rigidity of other skeletal muscles, particularly muscles of the chest, abdomen, and face. The pain increases over time and occurs in waves that may cause the patient to writhe. Large muscle groups are affected first. Classically, severe abdominal wall spasm occurs and may be confused with a surgical abdomen, especially in children who cannot

relate the history with the initial bite.[34] Muscle pain often subsides within a few hours but may recur for several days. Transient muscle weakness and spasms may persist for weeks to months.

Additional clinical findings include â€œ*facies latrodectismica*,â€• which consists of sweating, contorted, grimaced face associated with blepharitis, conjunctivitis, rhinitis, cheilitis, and trismus of the masseters.[133] A fear of death, *pavor mortis*, is described.[133] The following symptoms also are reported: nausea, vomiting, sweating, tachycardia, hypertension, muscle cramping, restlessness, and rarely priapism and compartment syndrome at the site of the bite.[2,47,95,189] Extreme restlessness occurs. Recovery usually ensues

within 24â€“48 hours, but symptoms may last several days with more severe envenomations.

TABLE 115-3. Brown Recluse and Black Widow Spiders: Comparative Characteristics

	Brown Recluse (*Loxosceles*)	Black Widow (*Latrodectus*)
Description	Female brown, 6â€“20 mm, violin-shaped mark on dorsum of cephalothorax; female greater toxicity than male	Female jet black, 8â€“10 mm, red hourglass mark on ventral surface, female greater toxicity than male
Major venom component	Sphingomyelinase D	Î±-Latrotoxin

Pathophysiology of envenomation	Vascular injury, dermonecrosis, hemolysis	Lymphatic, hematogenous spread neurotoxicity
Epidemiology	Bites more common in warmer months North America (southern and western states): *L. reclusa* South America: *L. laeta, L. gaucho* Europe: *L. rufescens* Africa (southern): *L. parrami, L. spiniceps, L. pilosa, L. bergeri* Asia/Australia: Rare	Bites more common in warmer months in subtropical and temperate areas; perennial in topics North America: *L. mactans, L. Hesperus, L. geometricus* Europe: *L. tredecimguttatus* Africa (southern): *L. indistinctus* Australia: *L. hasselti* Asia/South America: Rare
Clinical effects	Cutaneous	Cutaneous
	Initial (0â€“2 h after bite): painless, erythema, edema 2â€“8 h: Hemorrhagic, ulcerates, painful 1 week: Eschar Months: Healing	Initial (5 minâ€“1 h after bite): local pain 1â€“2 h: Puncture marks hours: Regional lymph nodes swollen, central blanching at bite site with

			surrounding erythema CVS: Initial tachycardia followed by bradycardia, dysrhythmias, initial hypotension followed by hypertension GI: Nausea, vomiting, mimic acute abdomen
		Hematologic Methemoglobinemia, hemolysis, thrombocytopenia, DIC	Hematologic: Leukocytosis Metabolic Hyperglycemia (transient) Musculoskeletal: Hypertonia, abdominal rigidity, â€œfacies latrodectismicaâ€• Neurologic CNS: Psychosis, hallucinations, visual disturbance, seizures PNS: Pain at the site ANS: Increase in all secretions; sweating, salivation,

		lacrimation, diarrhea, bronchorrhea, mydriasis, miosis, priapism, ejaculation
	Renal: Renal failure, secondary to hemolysis	Renal: Glomerulonephritis, oliguria, anuria Respiratory: Bronchoconstriction, acute lung injury
Treatment	Analgesia	Analgesia
	Wound care	Muscle relaxants
	Dapsone (?) Hyperbaric oxygen (?) Antivenom (?) not available universally Corticosteroids	Antivenom

Life-threatening complications include severe hypertension, respiratory distress, cardiovascular failure, and gangrene.[34,46,47,142,155,159] In the past 20 years, more than 40,000 presumed black widow spider bites have been reported to American Association of Poison Control Centers since its first publication in 1983. Death is rarely reported. There have been 2 fatalities in Madagascar from envenomation of the *Latrodectus geometricus*, one from cardiovascular failure and the other from

gangrene of the foot.[159] The most recent fatality reported from Greece resulted from toxic myocarditis secondary to envenomation of *L. mactans tredecimguttatus*,[155] confirmed by a local veterinarian. The patient developed severe dyspnea, hypoxemia, cyanosis, cardiomyopathy, and global hypokinesis of the left ventricle confirmed by echocardiography followed by death 36 hours later; antivenom was not available; on autopsy, diffuse interstitial and alveolar edema, with mononuclear infiltrate of the myocardium and degenerative changes, were noted and on toxicologic analysis for xenobiotics, as well as all blood, urine, bronchial, and serologic viral cultures, were negative. The paucity of mortalities is presumed to result from the improvement in medical care, the availability of antivenom, or the limited toxicity of the spider.

Diagnostic Testing

Laboratory data generally are not helpful in management or predicting outcome. According to one study, the most common findings include leukocytosis and increased creatine phosphokinase and lactate dehydrogenase concentrations.[46] Currently no specific laboratory assay is capable of confirming latrodectism.

Management

Treatment involves establishing an airway and supporting respiration and circulation, if indicated. Wound evaluation and local wound care, including tetanus prophylaxis, are essential.[213] The routine use of antibiotics is not recommended.

Pain management is a substantial component of patient care and depends on the degree of symptomatology. One grading system divides the severity of the envenomation into 3 categories.[46] Grade 1 envenomations range from no symptoms to local pain at the envenomation site with normal vital signs. Grade 2 envenomations

involve muscular pain at the site with migration of the pain to the trunk, diaphoresis at the bite site, and normal vital signs. Grade 3 envenomations include the grade 2 symptoms with abnormal vital signs, diaphoresis distant from the bite site, generalized myalgias to back, chest, and abdomen, nausea, vomiting, and headache. Using this grading system, grade 1 envenomations may require only cold packs and orally administered nonsteroidal antiinflammatory agents. Grade 2 and 3 envenomations probably require intravenous opioids and benzodiazepines to control pain and muscle spasm. Traditionally, 10 mL 10% calcium gluconate solution was given intravenously (IV) to decrease cramping. It was infused over 10 minutes and repeated at 30 minutes. A retrospective chart review of 163 patients envenomated by the black widow concluded that calcium gluconate was ineffective for pain relief compared with a combination of IV opioids (morphine sulfate or meperidine) and benzodiazepines (diazepam or lorazepam).[46,114] Another study found greater neurotransmitter release when extracellular calcium concentrations were increased, suggesting that administration of calcium is irrational in patients suffering from latrodectism.[167] The mechanism of action of calcium remains unknown and its efficacy anecdotal; therefore we do not recommend calcium administration for pain management. Although often recommended, methocarbamol (a centrally acting muscle relaxant) and dantrolene also are ineffective for treatment of latrodectism.[114,172] A benzodiazepine, such as diazepam, is more effective for controlling muscle spasms and achieves sedation, anxiolysis, and amnesia. Management should primarily emphasize supportive care, with opioids and benzodiazepines for controlling pain and muscle spasms, because the use of antivenom risks anaphylaxis and serum sickness.

Latrodectus antivenom is rapidly effective and curative. In the United States, the antivenom formulation is effective for all species but is available as a crude hyperimmune horse serum that may cause anaphylaxis and serum sickness. The morbidity of latrodectism is high, with pain, cramping, and autonomic disturbances, but mortality is low.

Hence controversy exists over when to administer the black widow antivenom. The antivenom can be administered for severe reactions (eg, hypertensive crisis or intractable pain), to high-risk patients (eg, pregnant women suffering from a threatened abortion), or for treatment of priapism.[95,160] Use of antivenom probably should not be considered for patients unless systemic symptoms otherwise designated as grade 3 are present because of the risk for anaphylaxis or anaphylactoid reactions.[46] The usual dose is 1â€“2 vials diluted in 50â€“100 mL 5% dextrose or 0.9% sodium chloride solution, with the combination infused over 1 hour (Antidotes in Depth: Scorpion and Spider Antivenoms). Skin testing may identify a highly allergic individual but does not eliminate the occurrence of hypersensitivity reactions; therefore we do not recommend skin testing. Pretreatment with histamine H_1- or H_2 -blockers and epinephrine may be beneficial in preventing histamine release and/or anaphylaxis, but their efficacy is unproven. Patients with allergies to horse serum products and those who have received antivenom or horse serum products are at risk for immunoglobulin IgE-mediated hypersensitivity reactions. Prevention consists of destroying the spider and taking precautions in areas inhabited by the spiders. When working in high-risk areas, gloves, heavy garments buttoned at the wrists and collars, and shoes should be worn.

In Australia, a purified equine-derived IgG-F(ab)$_2$ fragment antivenom for the red-back spider *Latrodectus hasselti* (RBS-AV) is available. A study showed that RBS-AV prevents latrodectism in mice envenomated with other widow spider venoms from the United States and Europe.[83] Inadvertent use of RBS-AV successfully treated envenomations from the comb-footed spider (*Steatoda* spp).[101] Hence RBS-AV may have a future role in treating black widow spider envenomations in the United States. The RBS-AV (CSL, Melbourne, Australia) is administered intramuscularly and given as first-line therapy to patients presenting with systemic signs or symptoms in Australia. Since its introduction in 1956, there have been no deaths, and the incidence of mild allergic reactions to RBS-AV is reported as 0.54% in 2144 uses.[198] However, a

prospective cohort study of confirmed red-back spider bites failed to show that intramuscular antivenom was better than no treatment when all patients were followed up over one week.[102] This study lacked the power to definitely demonstrate no difference between intramuscular treatment and no treatment, but the study found that only 17% of patients were pain-free at 24 hours with treatment. Therefore, intramuscular antivenom appears to be less effective than previously thought, and the route of administration requires review.

Brown Recluse Spider (*Loxosceles Reclusa*; Violin or Fiddleback Spider)

Loxosceles reclusa was confirmed to cause necrotic arachnidism in 1957, although reports of systemic symptoms following brown spider bites have appeared since 1872.[6] This spider has a brown violin-shaped mark on the dorsum of the cephalothorax, 3 pairs of eyes arranged in a semicircle on top of the head, and legs that are 5 times as long as the body. It is small (6â€“20 mm long), gray to orange or reddish brown (see ILLOXSCELESRECLUSA in the Image Library). *Loxosceles* spiders weave irregular white, flocculent adhesive webs that line their retreats.[71] Spiders in the genus *Loxosceles* have a worldwide distribution. In the United States, other species of this genus, which include *L. rufescens, L. deserta, L devia*, and *L. arizonica*, are prominent in the Southeast and Southwest.[4] They are hunter spiders that live in dark areas (wood piles, rocks, basements), and their foraging is nocturnal. They are not aggressive but will bite if antagonized (Table 115-3). These spiders live up to 2 years. They are resilient and can survive up to 6 months without water or food and tolerate temperatures from 46.4Â°Fâ€“109.4 Â°F (8Â°Câ€“43Â°C).[76] Like the black widow spider, the female is more dangerous than the male and bites only when provoked. *Loxosceles* venom has variable toxicity, depending on the species, with *L. intermedia* venom causing more severe clinical effects in humans.[11]

Pathophysiology

The venom is cytotoxic. Purification techniques have identified 8 subcomponents, including various enzymes, such as hyaluronidase, deoxyribonuclease, ribonuclease, alkaline phosphatase, lipase, and sphingomyelinase-D.[122] The two main constituents of the venom are sphingomyelinase-D and hyaluronidase. Hyaluronidase is a spreading factor that facilitates the ability of the venom to penetrate tissue but does not induce lesion development.[122] Sphingomyelinase-D, with a molecular weight of 32,000 daltons, is the primary constituent of the venom that causes necrosis and hemolysis. Sphingomyelinase-D causes human platelets to release serotonin and red blood cells to release hemoglobin.[122] Sphingomyelinase also reacts with sphingomyelin in the red blood cell membrane to release choline and *N*-acylsphingosine phosphate, which triggers a chain reaction releasing inflammatory mediators, such as thromboxanes, leukotrienes, prostaglandins, and neutrophils, leading to vessel thrombosis, tissue ischemia, and skin loss.[122] The rest of the constituents in the venom contain alkaline phosphatase, proteases, collagenase, esterase, ribonuclease, and deoxyribonuclease.[54,207]

An early study in experimental animals describes the pathogenesis of the skin lesion requiring polymorphonuclear leukocytes and complement infiltration of blood vessels at the bite site with resultant blood vessel injury as the pathologic basis for skin loss.[181] They demonstrated early perivascular collections of polymorphonuclear leukocytes with hemorrhage and edema progressing to intravascular clotting. Coagulation and vascular occlusion of the microcirculation occur, ultimately leading to necrosis.

Clinical Manifestations

The peak time for envenomation is from spring to autumn. Most victims are bitten in the morning. The clinical spectrum of loxoscelism can be divided into 3 major categories. The first category includes

bites in which very little, if any venom, injected. A small erythematous papule may be present that becomes firm before healing and is associated with a localized urticarial response. In the second category, the bite undergoes a cytotoxic reaction. The bite initially may be painless or have a stinging sensation but then blisters and bleeds, and ulcerates 2â€“8 hours later (Table 115-3). The lesion may increase in diameter, with demarcation of central hemorrhagic vesiculation, then ulcerate, and develop violaceous necrosis, surrounded by ischemic blanching of skin and outer erythema and induration over 1â€“3 days: This is also known as the â€œred, white, and blueâ€• reaction (see ILLOXOSCELESEVENOMATION in the Image Library).[115,217] Necrosis of the central blister occurs in 3â€“4 days, with eschar formation between 5 and 7 days. After 7â€“14 days, the wound becomes indurated and the eschar falls off, leaving an ulceration that heals by secondary intention. Local necrosis is more extensive over fatty areas (thighs, buttocks, and abdomen).[121] The size of the ulcer determines the time for healing. Large lesions up to 30 cm may require 4 months or more to heal.

The third category consists of systemic loxoscelism, which is not predicted by the extent of cutaneous reaction, and occurs 24â€“72 hours after the bite. The young are particularly susceptible.[94,173] The clinical manifestations of loxoscelism include fever, chills, weakness, edema, nausea, vomiting, arthralgias, petechial eruptions, rhabdomyolysis, disseminated intravascular coagulation, hemolysis that can lead to hemoglobinemia, hemoglobinuria, renal failure, and death.[22,36,68,131,177,216] Another extremely unusual presentation of loxoscelism is upper airway obstruction. This life-threatening complication was reported in a child who was bitten on his neck and subsequently developed progressive cervical soft tissue edema with airway obstruction and dermonecrosis 40 hours later.[80] There has been one other report of stridor and respiratory distress following a brown recluse envenomation of the ear. Although the presentation is rare, respiratory compromise should be considered when an envenomation occurs near the airway.[75] In North American, the incidence of systemic

illness is rare and mortality is low.[5]

Diagnostic Testing

Bites from other spiders, such as *Chiracanthium* (sac spider), *Phidippus* (jumping spider), *Argiope* (orb weaver), and *Tegenaria* (northwester brown spider), can become necrotic wounds. These spiders are often the actual culprits when the brown recluse is mistakenly blamed. Definitive diagnosis is achieved only when the biting spider is positively identified. No routine laboratory test for loxoscelism is available for clinical application, but several techniques are presently used for research purposes. The lymphocyte transformation test measures lymphocytes that have undergone blast transformation up to 1 month after exposure to *Loxosceles* venom. The lymphocytes incorporate thymidine into the nucleoprotein, providing a quantitative response.[3] A passive hemagglutination inhibition test (PHAI) has been developed in guinea pigs. The PHAI assay is based on the property of certain brown recluse spider venom components to spontaneously adsorb to formalin-treated erythrocyte membranes and the ability of the BRS venom to inhibit antiserum-induced agglutination of venom-coated red blood cells.[13] The test is 90% sensitive and 100% specific for 3 days postenvenomation and may prove useful for early diagnosis of brown recluse spider envenomation.[13] An enzyme-linked immunoassay (ELISA) specific for *Loxosceles* venom in biopsied tissue can confirm the presence of venom for 4 days postenvenomation.[13] The drawbacks of using a skin biopsy are the invasive nature of the procedure, which can result in further scarring with an increased potential for infection, and the lack of proof that skin biopsy can diagnose early envenomations prior to the development of dermatonecrosis. Another ELISA for detection of venom antigens has been developed that correctly discriminates the mice inoculated with antigens *Loxosceles intermidia* venom. The ELISA immunoassay, and antivenom may become useful early diagnostic tools if envenomation can be proved early, especially prior to the development of the purplish discoloration and blister formation that usually progresses to

cutaneous gangrene.[44] A venom-specific enzyme immunoassay that uses hair, skin biopsies, or aspirated tissue near a suspected lesion to detect the presence of venom up to 7 days after injury is under investigation.[120,137] In Brazil, ELISA is used to detect the venom of *L. reclusa* in wounds and patient sera, but the technique is not in widespread clinical use.[40]

Laboratory data may be remarkable for hemolysis, hemoglobinuria, and hematuria. Coagulopathy may be present, with laboratory data significant for elevated fibrin split products, decreased fibrinogen levels, and a positive D-dimer assay. Other tests may show increased prothrombin time (PT) and partial thromboplastin time (PTT), leukocytosis (up to 20,000â€“30,000 cells/mm^3),

spherocytosis, Coombs-positive hemolytic anemia, thrombocytopenia, or abnormal renal and liver function tests.[2,7,71,169,170 and 171,213]

Treatment

Optimal local treatment of the lesion is controversial. The most prudent management of the dermatonecrotic lesion is wound care, immobilization, tetanus prophylaxis, analgesics, and antipruritics as warranted (Table 115-4).[2,71,208,213] Early excision or intralesional injection of corticosteroids appears unwarranted.[164] Corrective surgery can be performed several weeks after adequate tissue demarcation has occurred. One case series used curettage of the lesion to remove necrotic and indurated tissue from the lesion, thus eliminating any continuing action of the lytic enzymes on the surrounding tissue with positive results.[93] These patients had wound healing without further necrosis and minimal scarring. Electric shock delivered via stun guns was not found to be useful in a guinea pig envenomation model.[13] Cyproheptadine, a serotonin antagonist, was not beneficial in a rabbit model.[153] A randomized control study evaluating the efficacy of topical nitroglycerin for envenomated rabbits showed no difference in preventing skin necrosis and suggested the possibility of increased

systemic toxicity.[127] Antibiotics should be used to treat cutaneous or systemic infection, but should not be used prophylactically.

Early use of dapsone in patients who develop a central purplish bleb or vesicle within the first 6â€“8 hours may inhibit local infiltration of the wound by polymorphonuclear leukocytes.[115] The dosage recommended is 100 mg twice daily for 2 weeks.[164] However, prospective trials with large numbers of patients are lacking. One study compared erythromycin and dapsone therapy, erythromycin and antivenom therapy, and erythromycin, dapsone, and antivenom therapy.[163] Although the treatment groups were very small, all groups showed wound healing at approximately 20 days. Use of dapsone in the management of a local lesion should be considered experimental until its use is validated by controlled randomized clinical trials. Hepatitis,[166] methemoglobinemia, and hemolysis (Chap. 122) are associated with dapsone use. If dapsone therapy is used, a baseline glucose-6-phosphate dehydrogenase and weekly complete blood counts should be performed.

TABLE 115-4. Management of Brown Recluse Spider Bite

General Wound Care
Clean
Tetanus prophylaxis as indicated
Immobilize and elevate bitten extremity
Apply cool compresses; avoid local heat
Local Wound Care
Serial observations
Natural healing by granulation
Delayed primary closure
Delayed secondary closure with skin graft
Gauze packing, if applicable
Systemic

Antipruritic/antianxiety and/or analgesic agents
Antibiotics for secondary bacterial infection
(?) Polymorphonuclear white blood cell inhibitors: dapsone, colchicine
Antivenom (experimental)
(?) Hyperbaric oxygen

An animal study evaluated the effects on the size of skin lesions induced by *Loxosceles* envenomation by treatment with hyperbaric oxygen therapy, dapsone, and combined hyperbaric oxygen therapy and dapsone.[91] However, the study design was limited and could find only a 100% difference in treatment groups. The study concluded that there was no clinically significant change in necrosis or induration by these treatment modalities. Further evaluation of these interventions remains appropriate. Another study using hyperbaric oxygen for treatment of *Loxosceles*-induced necrotic lesions in rabbits revealed no clinical improvement in the size of the lesion; however, the histology of the lesions improved. Whether this finding is of value in humans has not been determined.[191] Use of 1.2 mg colchicine, a leukocyte inhibitor, followed at 2-hour intervals with 0.6 mg for 2 days, then 0.6 mg every 4 hours for 2 additional days is sometimes recommended, but this treatment has substantial potential toxicity.[169,171]

Rabbit-derived intradermal anti-*Loxosceles* Fab (Î±-Loxd) fragments attenuated the dermatonecrotic inflammation of rabbits injected with *L. deserta* venom in a time-dependent fashion.[78] At time 0 after envenomation, lesion development was blocked. At 1 and 4 hours after envenomation, the Î±-Loxd Fab antivenom continued to suppress the lesion areas, although the longer the delay in treatment, the smaller the difference in treatment and control lesion areas. At 8 and 12 hours, there was no difference in lesion size. The typical 24-hour delay in lesion development makes the diagnosis difficult, and the antivenom would be useless if administered so late in the clinical course. Use of antivenom would be facilitated if the spider were caught and positively

identified or another test could be used to positively identify *Loxosceles* envenomation. Currently this antivenom is not available for commercial use. Patients manifesting systemic loxoscelism or those with expanding necrotic lesions should be admitted to the hospital. All patients should be monitored for evidence of hemolysis, renal failure, or coagulopathy. If hemoglobinuria ensues, increased IV fluids and urinary alkalinization an be used in an attempt to prevent acute renal failure. Hemolysis, if significant, can be treated with transfusions. Patients with a coagulopathy should be monitored with serial complete blood cell count, platelet count, PT, PTT, fibrin split products, and fibrinogen. Disseminated intravascular coagulopathy may require treatment, based on severity.

Hobo Spider (Tegenaria Agrestis, Northwestern Brown Spider, Walckenaer Spider)

The hobo spider is native to Europe and was introduced to the northwestern United States (Washington, Oregon, Idaho) in the 1920s or 1930s.[209] These spiders build funnel-shaped webs within wood piles, crawl spaces, basements, and moist areas close to the ground. They are brown with gray markings and 7â€“14 mm long. They are most abundant in the midsummer through the fall. They bite if provoked or threatened, but otherwise are reticent to bite and retreat quickly with disturbance.[18] The medical literature is sparse in reported hobo spider bites that are verified by a specialist. There is only one confirmed Hobo spider bite resulting in a necrotic lesion.[42] The case describes a 42-year-old woman with a history of phlebitis who felt

a burning sensation on her ankle, rolled her pants, and found a crushed brown spider, later confirmed to be *T. agrestis.* She complained of persistent pain, nausea, and dizziness, and a vesicular lesion developed within several hours. The vesicle ruptured and ulcerated the next day. The lesion initially was 2 mm, but over the

next 10 weeks enlarged to 30 mm in diameter and was circumscribed with a black lesion, at which time she sought medical advice. She was given a course of antibiotics, which did not limit the progression of this ulcer. Subsequently, the patient was unable to walk, and she was found to have a deep venous thrombosis. The other cases implicating Hobo spiders as a cause for dermatonecrotic injuries are based on proximity of the Hobo spider or other large brown spiders that are unidentified and on a rabbit model bioassay.[209,210] The Hobo spider from Europe is considered benign. When analyzing the venom from the European Hobo spiders and US Hobo spiders using liquid chromatography, little variability was found to account for the necrotic effects, which suggests that the Hobo spider toxicity syndrome needs to be revisited. New evidence suggests that Hobo spiders may have been falsely accused.[23] More investigation using large prospective studies must include verification of the spider by an expert arachnologist or definitive identification of an envenomed patient. *Tegenaria* spp is difficult to identify reliably, unless the arachnid's genitalia is examined microscopically.[211] These standards will allow for a more evidence-based approach rather than encouraging anecdotal information as a substitution for fact.

Pathophysiology

The toxin has been fractionated, with 3 peptides identified as having potent insecticidal activity, and no discernible effects in mammalian in vivo assays.[108] The peptide toxins TaITX-1, TaITX-2, and TaITX-3 exhibit potent insecticidal properties by acting directly in the insect central nervous system, and not at the neuromuscular junction.[108] Insects envenomated with *T. agrestis* venom and the insecticidal toxins purified from the venom developed a slowly evolving spastic paralysis. Currently, little is known about the toxin and its mechanism of action in humans.

Clinical Manifestations

The toxicity of Hobo spider venom is questionable; however, it occasionally causes necrosis secondary to infection. Other causes of dermatonecrotic lesions should be considered. The most common symptom associated with the spider bite is a headache that may persist for 1 week.[42] Other symptoms, including nausea, vomiting, fatigue, memory loss, visual impairment, weakness, and lethargy, are reported.[42,210]

Diagnostic Testing

No specific laboratory assay confirms envenomation with *T. agrestis* spider.

Treatment

Treatment emphasizes local wound care and tetanus prophylaxis, although systemic corticosteroids for hematologic complications may be of value. Surgical graft repair for severe ulcerative lesions may be warranted when there is no additional progression of necrosis.[42,157]

Tarantulas

Tarantulas, ancestors to the true spider, belong to the family Theraphosidae, a subgroup of Mygalomorphs (Greek word *mygale* for field mouse).[45,175] There are more than 1500 species, with approximately 40 species found in the deserts of western United States. Because of their great size and reputation, tarantulas are often feared. They are the largest and hairiest spiders, popular as pets, and can be found throughout the United States as well as tropical and subtropical areas (see ILAPHONOPELMASMITHI1 in the Image Library). The lifespan of the female can exceed 15â€“20 years. They have poor eyesight and detect their victims by vibrations. Their defense lies in either their painful bite with erect fangs or by spraying their victim with barbed urticating hairs that are released on provocation.[45]

Tarantulas bite when provoked or roughly handled. Based on the few

case reports, their venom has relatively minor effects in humans but can be deadly for canines and other small animals, such as rats, mice, cats, and birds.[33,105] A study from Australia covering a 25-year span reported only nine confirmed bites by theraphosid spiders in humans and seven confirmed bites in canines and two of which the spider then bit the human.[105] Four genera of tarantulas (*Lasiodora, Grammostola, Acanthoscurria*, and *Brachypelma*) possess urticating hairs that are released in self-defense when the tarantulas rub their hind legs against their abdomen rapidly to create a small cloud (see ILAPHONOPELMASMITHI2 in the Image Library).[76] There are 4 different types of hairs. Type 1 hairs are found on tarantulas in the United States and are the only hairs that do not penetrate human skin. Type 2 hairs are incorporated into the silk web retreat but are not thrown off by the spider. Type 3 hairs can penetrate up to 2 mm into human skin. Type 4 hairs belong to the South American *Grammostola* spider and cause severe respiratory inflammation. Tarantula hairs cause intense inflammation that may remain pruritic for weeks.

Pathophysiology

Tarantula venom, specifically the venoms of *Dugesiella henzi* (Arkansas tarantula) and members of the genus *Aphonopelma* (Arizona tarantula), contains hyaluronidase, nucleotides (adenosine triphosphate [ATP], adenosine diphosphate, and adenosine monophosphate), and polyamines (spermine, spermidine, putrescine, and cadaverine) that are used for digesting their prey from the inside out.[35,113,175] The role of spermine is unclear, but hyaluronidase is a spreading factor that allows more rapid entrance of venom toxin by destruction of connective tissue and intercellular matrix. ATP potentiates death in mice exposed to the *D. hentzi* venom and lowers the LD_{50} in comparison to venom without ATP.[43] Both venoms cause skeletal muscle necrosis when injected intraperitoneally into mice.[150] The primary injury results in rupture of the plasma membrane, followed by the inability of mitochondria and sarcoplasmic reticulum to maintain normal levels of calcium in the cytoplasm leading to cell

death. *Aphonopelma* venom is similar to scorpion venom in composition and clinical effects. Novel toxins have been discovered in the venom that can act on potassium channels, calcium channels, and the recently discovered

acid-sensing ion channels that may elucidate the molecular mechanism of voltage-dependent channel gating and their respective physiologic roles.[63,64]

Clinical Manifestations

Although relatively infrequent in occurrence, bites may or may not present with puncture or fang marks. They range from being painless to a deep throbbing pain that may last several hours without any inflammatory component.[105] Fever has been associated even in the absence of infection, suggesting a direct pyrexic action of the venom. Rarely, bites create a local histamine response with resultant itching, and hypersensitive individuals could have a more severe reaction and less commonly mild systemic effects such as nausea and vomiting.[76,105] Contact reactions from the hairs are more likely to be the health hazard than is the spider bite. The urticating hairs provoke local histamine reactions in humans and are especially irritating to the eyes, skin, and respiratory tract. Inflammation can occur at all levels from conjunctiva to retina. An allergic rhinitis can develop if the hairs are inhaled.[113] Tarantula hairs resemble sensory setae of caterpillars, both are type 3 that can migrate relentlessly and cause multiple foci of inflammation at all levels of the eye.[97] Ophthalmia nodosa, a granulomatous nodular reaction to vegetable or insect hairs, is reported with casual handling of tarantulas.[17,21] Other eye findings include spines in the corneal stroma, anterior chamber inflammation, migration into the retina, and secondary glaucoma and cataracts.[26]

Treatment

Treatment is largely supportive. Cool compresses and analgesics

should be given as needed. All bites should receive local wound care, including tetanus prophylaxis if necessary. If the hairs are barbed, as in some species, they can be removed by using adhesive or cellophane tape followed by compresses or irrigation with 0.9% sodium chloride solution. If the hairs are located in the eye, then surgical removal may be required, followed by medical management of inflammation. Urticarial reactions should be treated with oral antihistamines and topical or systemic corticosteroids.

Funnel Web Spiders

Australian funnel web spiders are a group of large mygalomorphs that can cause a severe neurotoxic envenomation syndrome in humans. The fang positions of funnel web spiders are vertical relative to their body, which requires the spider to rear back and lift the body to attack. The length of fangs can reach up to 5 mm. This spider can bite tenaciously and may require extraction from the victim.[139] The *Atrax* and *Hadronyche* species have been found along the eastern seaboard of Australia. *Atrax robustus*, also called the Sydney funnel web spider, is the best known and is located around the center of Sydney, Australia.[139] Funnel web spiders tend to prefer moist, temperate environments.[139] They are primarily ground dwellers and live in burrows, crevices in rocks, around foundations of houses. They build tubular or funnel-shaped webs.[76] At night, the spiders ascend the tubular web and wait for their prey. The Sydney funnel web spider is considered one of the most poisonous spiders. It was responsible for 14 deaths between 1927 and 1980, at which time the antivenom was introduced.[193]

Pathophysiology

Robustotoxin (atracotoxin or atraxin) is a protein with a molecular weight of 4854 daltons. It contains 42 amino acids and is the lethal component of *A. robustus* venom.[139] Robustotoxin produces an autonomic storm, releasing acetylcholine, noradrenaline, and

adrenaline. A 5 Âµg/kg intravenous infusion dose of robustotoxin from male *A. robustus* spiders causes dyspnea, blood pressure fluctuations leading to severe hypotension, lacrimation, salivation, skeletal muscle fasciculation, and death within 3â€“4 hours when administered to monkeys.[145] Versutoxin, a toxin from the Blue Mountain funnel web spider, is closely related to robustotoxin and has demonstrated voltage-dependent slowing of sodium channel inactivation.[148]

Clinical Manifestations

A biphasic envenomation syndrome associated with *A. robustus* is described in humans and monkeys.[195,196] Phase 1 consists of localized pain at the bite site, perioral tingling, piloerection, and regional fasciculations (most prominent in the face, tongue, and intercostals). Fasciculations may progress to more overt muscle spasm; masseter and laryngeal involvement may threaten the airway.[196] Other features include tachycardia, hypertension, cardiac dysrhythmias, nausea, vomiting, abdominal pain, diaphoresis, lacrimation, salivation, and acute lung injury, which often is the cause of death in phase 1.[215] Phase 2 consists of resolution of the overt cholinergic and adrenergic crisis; secretions dry up, and fasciculations, spasms, and hypertension resolve. The apparent improvement can be followed by the gradual onset of refractory hypotension, apnea, and cardiac arrest.[196]

Treatment

Pressure immobilization using the crepe bandage to limit lymphatic flow and immobilization of the bitten extremity may inactivate the venom and should be applied if symptoms of envenomation are present. Funnel web venom is one of the few animal toxins known to undergo local inactivation.[193,194] The patient should be transferred to the nearest hospital with the bandage in place. Monkey studies and a human case report suggest the utility of pressure immobilization.[81,197] Pressure immobilization should be removed when the patient is located at a facility that can administer antivenom. A purified IgG antivenom

protective against *Atrax* envenomations was developed in rabbits by Sutherland.[193] One ampule of the antivenom contains 100 mg purified rabbit IgG or 125 units of neutralizing capacity per ampule.[215] It has been effective for more than 40 humans bitten by the *Atrax* species.[194] The starting dose is 2 ampules if systemic signs of envenomations are present, and 4 ampules if the patient develops pulmonary edema or decreased mental status. Doses are repeated every 15 minutes until clinical improvement is seen.[215] Up to 8 ampules is common in a severe envenomation. Anaphylaxis has not been reported.[194] The manufacturer no longer recommends premedication. Even serum sickness seems to be rare after funnel web antivenom administration. There has been 1 case after the patient received 5 ampules of antivenom for an *A. robustus* envenomation.[138]

Scorpions

Scorpions are invertebrate arthropods that have existed for more than 400 million years.[48] Of the 650 known living species, most of the lethal species are in the *Buthidae* family (Table 115-7). The genera of the family *Buthidae* include *Centruroides, Tityus, Leuirus, Androctonus, Buthus*, and *Parabuthus*.[48] Unlike most spiders, scorpions envenomate humans by stinging rather than biting. Their 5-segmented tail contains a bulbous segment called the *telson* that contains the venom apparatus (see ILTITYUSSERRULATUS in the Image Library). More than 100,000 medically significant stings likely occur annually worldwide, predominantly in the tropics and North Africa.[1,20,56,85,106,119] According to American Association of Poison Control Centers data from 1995â€“2003, approximately 11,000â€“14,000 scorpion annual exposures occurred in the United States, mostly in the southwestern region, but no deaths have been reported. These members of the class *Arachnida* rarely cause mortality in victims older than 6 years.[165] The poisonous scorpions in the United States are *Centruroides gertschii.* The most important is *Centruroides exilicauda*, previously called *Centruroides sculpturatus Ewing* (bark scorpion; Table 115-5).

Pathophysiology

Components of scorpion venom are complex and species specific. Scorpions from the family Buthidae are the most harmful to humans.[88,158,165] The venom is thermostable and consists of phospholipase, acetylcholinesterase, hyaluronidase, serotonin, and neurotoxins. Components of *C. exilicauda* venoms are primarily neurotoxic. Four neurotoxins designated toxins Iâ€“IV have been isolated from *C. exilicauda*. Some of the toxins target excitable membranes, especially at the neuromuscular junction, by opening sodium channels. The results are repetitive depolarization of nerves in both sympathetic and parasympathetic nervous systems causing acetylcholine and catecholamine release, increased neurotransmitter release, catecholamine release from the adrenal gland, catecholamine-induced cardiac hypoxia, and action at the juxtaglomerular apparatus, causing increased renin secretion.[52,165] *Tityus* scorpion sting is related to elevated concentrations of interleukin (IL)-1Î², IL-6, IL-8, IL-10, and tumor necrosis factor (TNF)-Î±, which correlate with the severity of envenomation and hyperamylasemia.[62,70] The kinin system seems to participate in the pathogenesis of human *Tityus* envenomation.[69]

TABLE 115-5. Scorpions of Toxicologic Importance[85,105]

USA: *Centroides exilicauda*
Brazil, South America: *Tityus serrulatus*
Mexico: *Centroides sufusus*
India: *Buthus tamulus*
Spain: *Buthus occitanus*
Saudi Arabia: *Leirus quinquestriatus, Androctonus crassicauda*
Middle East: *Leirus quinquestriatus, Buthus minax, Androctonus* spp
North Africa: *Androctonus Australis, Buthus occitanus, Leirus* spp
South Africa: *Androctonus crassicauda*
Persian Gulf: *Androctonus crassicauda*
Australia: *Lychas marmoreus, Lychas* spp, *Isometrus* spp, *Cercophonius squama, Urodacus* spp

Clinical Manifestations

Scorpion stings produce a local reaction consisting of intense local pain, erythema, tingling or burning, and occasionally discoloration and necrosis without tissue sloughing (Table 115-7). Depending on the scorpion species involved, systemic effects may occur, including autonomic storm consisting of cholinergic and adrenergic effects. Cardiotoxic effects include myocarditis, dysrhythmias, and myocardial infarction.[55,66,86,87,135,174] ECG abnormalities may persist for several days and include sinus tachycardia, sinus bradycardia, bizarre broad notched biphasic T-wave changes with additional ST elevation or depression in the limb and precordial leads, appearance of tiny Q waves in the limb leads consistent with an acute myocardial infarction pattern, occasional electrical alternans, and prolonged QTc interval.[87,89] Other reported effects include pancreatitis, coagulation disorders, acute lung injury (ALI), massive hemoptysis, cerebral infarctions in children, seizures, and a shock syndrome that may precede but usually follows the hypertensive

phase.[19,59,66,86,87,174,184]

In the United States, *C. exilicauda* stings produce local paresthesias and pain that can be accentuated by tapping over the envenomated area (tap test) without local skin evidence of envenomation.[51,165] Symptoms begin immediately after envenomation, progress to maximum severity in 5 hours, and may persist for up to 30 hours.[48,165] Autonomic symptoms include hypertension, tachycardia, diaphoresis, emesis, and bronchoconstriction. The somatic motor symptoms reported include ataxia, muscular fasciculations, restlessness, thrashing, and opsoclonus; rarely, children require respiratory support[52,158] (Table 115-6).

Treatment

Because most envenomations do not produce severe effects, local wound care, including tetanus prophylaxis and pain management, usually is all that is warranted. In young children or patients who manifest severe toxicity, hospitalization may be required. Treatment

emphasizes support of the airway, breathing, and circulation. Corticosteroids, antihistamines, and calcium have been administered without any known benefit.[51]

TABLE 115-6. Envenomation Gradation for *Centruroides Exilicauda* (Bark Scorpion)

Grade	Signs and Symptoms
I	Site of envenomation Pain and/or paresthesias Positive tap test (severe pain increase with touch or percussion)
II	Grade I plus Pain and paresthesias remote from sting site (eg, paresthesias moving up an extremity, perioral â€œnumbnessâ€•)
III	One of the following: Somatic skeletal neuromuscular dysfunction: jerking of extremity(s), restlessness, severe involuntary shaking and jerking, which may be mistaken for seizures Cranial nerve dysfunction: Blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculation, upper airway dysfunction, slurred speech
IV	Both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction

Modified with permission from Curry SC, Vance MV, Ryan PJ, et al: Envenomation by the scorpion Centruroides sculpturatus. J Toxicol Clin Toxicol 1983â€“1984;21: 417â€“448; Allen C: Arachnid Envenomations. Emerg Med Clin North Am 1992;10:276.

The severity of envenomation dictates the need to use antivenom.

Continuous intravenous midazolam infusion has been used for *C. exilicauda* scorpion envenomation until resolution of the abnormal motor activity and agitation occurs.[74] Atropine has been used to reverse the excessive oral secretions in *C. exilicauda* scorpion envenomation, with some success in healthy children.[192] Routine use is not recommended and should be limited to species whose envenomations cause a prominent cholinergic crisis, such as *Parabuthus transvaalicus* in southern Africa.[192] The possibility of potentiating the adrenergic effects and causing cardiopulmonary toxicity is reported, so routine use of atropine is not recommended.[15] Atropine use to reverse the effects of stings from scorpions from India, South America, the Middle East, and Asia is contraindicated, because these scorpions cause an â€œautonomic stormâ€• with transient cholinergic stimulation followed by sustained adrenergic hyperactivity.[14,192]

One grading system suggests using antivenom for severe grade III and grade IV envenomations, which include somatic and/or cranial nerve dysfunction (Table 115-6).[51] A goat serum-derived anti-*Centruroides* antivenom is no longer available in Arizona, but was used successfully in a limited number of severe cases.[29] This approach is not universally accepted. Proponents believe antivenom may resolve symptoms sooner, whereas opponents cite serum sickness as a substantial concern (Antidotes in Depth: Scorpion and Spider Antivenoms).[29] A retrospective chart review of children younger than 10 years who experienced severe *Centruroides* scorpion envenomation found that anti-*Centruroides* antivenom resulted in rapid resolution of all symptoms in all 12 patients treated.[29] Of the patients treated with antivenom, 3% developed immediate hypersensitivity reactions and 58% had a delayed rash or serum sickness.[126] An equine-derived $F(ab)_2$ product called Alacramyn, developed in Mexico against the *Centruroides limpidus* venom, can be used to treat *C. exilicauda* bites, but US use of this foreign pharmaceutical is controversial.[16,183]

Scorpion envenomation can be prevented by wearing shoes when walking, particularly at night, because of the nocturnal nature of

scorpions. Shoes, sleeping bag, and tents should be shaken out prior to use. Cracks and crevices should be filled, wood piles and rubbish piles eliminated, and insecticides used in infested areas. The bark scorpion (*C. exilicauda*), which is fluorescent, can be demonstrated in the dark using a Woods lamp.

Ticks

In 1912, Todd[203] described a progressive ascending flaccid paralysis after bites from ticks. Three families of ticks are recognized: (1) *Ixodidae* (hard ticks), (2) *Argasidae* (soft ticks), and (3) *Nuttalliellidae* (a group that has characteristics of both hard and soft ticks). The terms *hard* and *soft* refer to a dorsal scutum or â€œplateâ€• that is present in the *Ixodidae* but absent in the *Argasidae.* Both types are characteristically soft and leathery, and both have clinical importance. *Ixodidae* females are capable of enormous expansion up to 50 times their weight in fluid and blood.[72] Ticks have 4 stages in their life cycle: egg, larva, nymph, and adult. The paralytic syndrome can occur during the larva, nymph, and adult stages and is related to the tick obtaining a blood meal. The following discussion focuses only on tick paralysis or tick toxicosis, and not on any of the infectious diseases associated with tick bites.

Most of the major tick-borne diseases in North America are transmitted by Ixodid ticks, except for relapsing fever, which is spread by the soft tick of the genus *Ornithodorus* or the louse. In North America, *Dermacentor andersoni* (North American wood tick) and *Dermacentor variabilis* are the most commonly implicated causes of tick paralysis.[79,204] While in Australia, the *Ixodes holocyclus* or Australian marsupial tick is the most common offender.[79,204]

Pathophysiology

Venom secreted from the salivary glands during the blood meal is absorbed by the host and systemically distributed. Paralysis results

from the neurotoxin â€œixovotoxin,â€•[1] which inhibits the release of acetylcholine at the neuromuscular junction and autonomic ganglia, very similar to botulinum toxin.[82,144] Both demonstrate temperature dependence in rat models and shows increased muscular twitching activity as the temperature is reduced.[49,128]

Clinical Manifestations

Usually the tick must remain on the person for 5â€“6 days in order to cause systemic symptoms. Several days must pass before tick salivary glands begin to secrete significant quantities of toxin. Once secreted, the toxin does not act immediately and may undergo binding and internalization, in a similar sequence to botulinum toxin.[49,110] Ticks typically attach to the scalp but can be found on any part of the body, including the ear canals and anus. Children, particularly girls, and adult men in tick-infested areas are predominantly affected. One large series of 305 cases in Canada reported that 21% were adults older than 16 years.[178] Among the children, 67% were girls; in adults 83% were male. The distribution was attributed to the difficulty of detecting ticks in long hair and the possible greater exposure of adult men to tick-infested environments. Children may appear listless, weak, ataxic, and irritable for several days before they develop an ascending paralysis that begins in the lower limbs. Fever usually is absent. Other manifestations include sensory symptoms such as paresthesias, numbness, and mild diarrhea. These symptoms are followed by absent or decreased deep-tendon reflexes and an ascending generalized weakness that can progress to bulbar structures involving speech, swallowing, and facial expression within 24â€“48 hours, as well as fixed dilated pupils and disturbances of extraocular movements.[82,178] If the tick is not removed, respiratory weakness can lead to hypoventilation, lethargy, coma, and death. Unlike the *Dermacentor* spp of North America, removal of the *I. holocyclus* tick does not result in dramatic improvement for several days to weeks. The maximal weakness may not be reached until 48 hours after the tick has been removed or drops off.[82] It is imperative to closely observe patients for

possible deterioration. The differential diagnosis includes Guillain-BarrÃ© syndrome (GBS), poliomyelitis, botulism, transverse myelitis, and spinal cord lesions. The cerebrospinal fluid remains normal and the rate of progression is rapid, unlike GBS and poliomyelitis.[65,176] The edrophonium test is negative. Nerve conduction studies in patients with tick paralysis may resemble those of patients with early stages of GBS: findings in both conditions include prolonged latency of the distal motor nerves, diminished nerve conduction velocity, and reduction in the amplitudes of muscle and sensory-nerve action potentials.[65]

Treatment

The most important aspect of treatment is considering tick paralysis in the differential diagnosis of any patient with ascending paralysis. Other than removal of the entire tick, which is curative, treatment is entirely supportive. The *I. holocyclus* of Australia is considerably more toxic and patients are more likely to deteriorate before they improve, so they must be closely observed for several days until improvement is certain.[82] Antitoxin, a hyperimmune serum prepared from dogs, is the usual treatment for paralyzed animals, and has been used sparingly in severely ill humans because of the risk of acute reactions and serum sickness.[82]

Prevention of tick bites includes wearing protective clothing and spraying clothes with insect repellant. Diethyltoluamide (DEET) repels ticks, but does not kill them. Permanone is a new tick aerosol spray repellant for use on clothing. It contains permethrin, which kills ticks on contact.[117] According to one study, permethrin in concentrations of 0.036â€“2.276 mg/m^2 induces 90â€“100% tick mortality, with 100% effectiveness for 1 month, and a decrease in effectiveness to 52% after the first washing.[117] Close inspection of all body parts and especially the scalp is important. Proper removal of the tick is very important, otherwise infection or incomplete tick removal may occur. The tick should be grasped as close to the skin surface as possible with

blunt curved forceps, tweezers, or gloved hands. Steady pressure without crushing the body should be used, otherwise expressed fluid may infect the patient. After tick removal, the site should be disinfected. Traditional methods of tick removal using petroleum jelly, topical lidocaine, fingernail polish, isopropyl alcohol, or a hot match head are ineffective and/or may induce the tick to salivate or regurgitate into the wound.[146]

Hymenoptera: Bees, Wasps, Hornets, Yellow Jackets, and Ants

Within the order *Hymenoptera* are three families of clinical significance: *Apidae* (honeybees and bumblebees), *Vespidae* (yellow jackets, hornets, and wasps), and *Formicidae* (fire ants). Insects of this subclass (Figure 115-2) are of great medical importance because their stings are the most commonly reported and can cause acute toxic and fatal allergic reactions (Table 115-7). An estimated 40 deaths per year are attributed to anaphylaxis secondary to hymenoptera stings.[12,182]

Apis Mellifera and *Bombus* species (honeybees and bumblebees) build nests away from humans and are passive unless disturbed. Apids can only sting once because their stinger is a modified ovipositor that resides in the abdomen. The structure is barbed and has a venom sac attached. Once the stinger embeds into the skin, the stinger disembowels the bee. Vespids, on the other hand, are more aggressive and build nests in trees and under awnings; yellow jackets inhabit the ground. They have smaller barbs that can be extracted from human skin and are able to sting multiple times.[76] The introduction of the Africanized honeybee in Brazil (because originally they were thought to be a more efficient honey producer) has caused significant economic and health issues. The bees have migrated toward the southern border of the United States, are less productive as a honey producer, and pose a greater threat to humans. African bees are characterized by large

populations, can make nonstop flights of at least 20 km, and have a tendency toward mass attack with little provocation.[140]

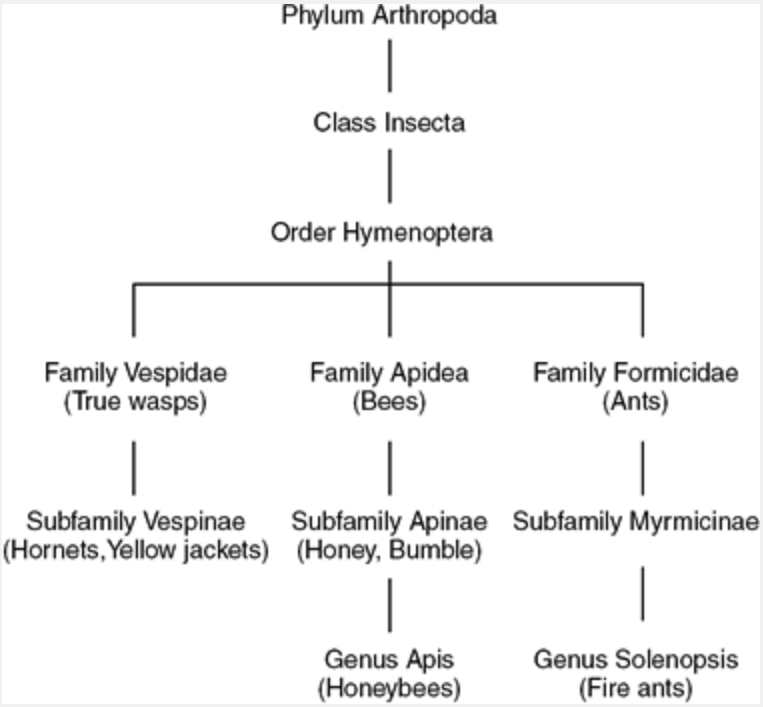

Figure 115-2. Taxonomy of the order Hymenoptera.

TABLE 115-7. Classification of Reactions to Hymenoptera Sting

Reaction	Clinical Presentation
Local	
Minimal	Localized pain, pruritus, swelling

	Lesion <5 cm Duration several hours
Large	Localized pain and pruritus Contiguous swelling and erythema Lesion >5 cm Duration 1â€“3 days
Systemic	
Minimal	Localized pain, pruritus, swelling Distant and diffuse urticaria, angioedema, pruritusand/or erythema, conjunctivitis Abdominal pain, nausea, diarrhea
Severe	Dermatologic Local: Pain, pruritus, and swelling Distant: Urticaria, angioedema, pruritus, and/or erythema Gastrointestinal Nausea, abdominal pain, diarrhea Respiratory Nasal congestion, rhinorrhea, hoarseness, bronchospasm, stridor, tachypnea, cough, wheezing Cardiovascular Tachycardia, hypotension, dysrhythmias, myocardial infarction Miscellaneous Seizures, feeling of impending doom, uterine contractions

Pathophysiology

Several allergens (Table 115-8) and pharmacologically active compounds are found in honeybee venom. The three major venom proteins for the honeybee are melittin, phospholipase A_2, and hyaluronidase.[125] Other proteins include apamin, acid phosphatase, and other unidentified proteins. Phospholipase A_2 is the major antigen/allergen in bee venom.[27]

Melittin is the principal component of honeybee venom. It acts as a detergent to disrupt the cell membrane and liberate potassium and biogenic amines.[10] Histamine release by bee venom appears to be largely mediated by mast cell degranulation peptide. Apamin is a neurotoxin that acts on the spinal cord. Adolapin inhibits prostaglandin synthase and has antiinflammatory properties that may account for its use in arthritic therapy.[179] Phospholipase A_2 and hyaluronidase are the chief enzymes in bee venom.

Vespid venoms contain 3 major proteins that serve as allergens and a wide array of vasoactive peptides and amines.[125] The intense pain following by vespid stings is largely caused by serotonin, acetylcholine, and wasp kinins. Antigen 5 is the major allergen in vespid venom.[141] Its biologic function is unknown. Mastoparans have action similar to mast cell degranulation peptide, but weaker.[10] One study found that phospholipase A_2 may be responsible for inducing coagulation abnormalities.[152]

Clinical Manifestations

Normally, the honeybee sting is manifested as immediate pain, a

wheal-and-flare reaction, and localized edema without a systemic reaction. Vomiting, diarrhea, and syncope can occur with a higher dose of venom resulting from multiple stings.[30] Rarely, a sting in the oropharynx produces airway compromise.[182] Toxic reactions occur with multiple stings (>500 stings are described as possibly fatal)[76] and include GI symptoms, headache, fever, syncope and, rarely, rhabdomyolysis, renal failure, and seizures.[30] Bronchospasm and urticaria are typically absent. This type of toxic reaction is different from the hypersensitivity reactions or anaphylactic reactions because it is not an IgE-mediated response, but rather a direct effect from the venom itself.

Hypersensitivity reactions, including anaphylaxis, occur to hymenoptera stings. These reactions are IgE mediated. The IgE antibodies attach to tissue mast cells and basophils in individuals who have been previously sensitized to the venom. These cells are activated, allowing for progression of the cascade reaction of increased vasoactive substances, such as leukotrienes, eosinophil chemotactic factor-A, and histamine. An anaphylactic reaction is not dependent on the number of stings. Patients who are allergic to hymenoptera venom develop a wheal-and-flare reaction at the site of the inoculum. The shorter the interval between the sting and symptom onset, the more likely the reaction will be severe. Fatalities can occur within several minutes; even initially mild symptoms may be followed by a fulminant course. Generalized urticaria, throat and chest tightness, stridor, fever, chills, and cardiovascular collapse can ensue.

Treatment

Application of ice at the site usually is sufficient to halt discomfort. The stinger should be removed by scraping with a credit card or scalpel, as opposed to pulling, which may release additional retained venom. Topical aspirin preparations or paste have not been proven to be effective in reducing swelling or pain with bee or wasp stings, and they significantly increased the duration of redness.[9] Therapy is aimed at

supportive care.

Prevention, especially in the allergic person, includes avoiding bright clothing, flowers, scented deodorants and shampoos, perfumes, and barefoot walks outdoors. An emergency kit containing a prefilled spring-loaded epinephrine syringe (EpiPen delivers 0.3 mg, EpiPen Jr. delivers 0.15 mg) with careful instructions from a physician, an antihistamine (diphenhydramine), and an emergency alert card or tag should be carried or worn by the sensitized individual. Individuals with a clear history of anaphylaxis should followup with an allergist for skin testing and venom immunotherapy for positive results. Immunotherapy significantly reduces the potential risk of anaphylaxis with subsequent stings.[77,98] Commercial preparations of venom from the honeybee, yellow jacket, white-faced hornet, yellow hornet, and wasp can be used for diagnosis and immunotherapy for patients with life-threatening reactions to stings. Several authors have discussed the indications and safety of immunotherapy.[125,218]

Fire Ants

There are native fire ants in the United States, but the imported fire ants *Solenopsis invicta* and *Solenopsis richteri* are the significant pests and have no natural enemies. They are native to Brazil, Paraguay, Uruguay, and Argentina, but were introduced into Alabama in the 1930s. They have spread rapidly throughout the southern United States, damaging crops, reducing biologic diversity, and inflicting severe stings to humans.[199] *Solenopsis*

invicta, the most aggressive species, now infests 13 southern states and has been introduced into Australia.[185,187] Allergic reactions to ant stings were limited to the jumper ant (*Myrmecia pilosula*, other *Myrmecia* spp) and the greenhead ant (*Rhytidoponera metallica; Odontomachs, Cerapachys*, and *Brachyponera* spp) in Australia until February 2001, when the red imported fire ant was identified at two sites in Brisbane.[185] The mode of introduction is unknown but may

have originated from the transport of infested sea cargo. The incursion is estimated to be 5 years old. Fire ants range from 2â€“6 mm in size and live in grassy areas and garden sites near still and flowing water. The nests are largely subterranean and have large, conspicuous, dome-shaped above ground mounds (up to 45 cm above the ground), with many openings for traffic. The mounds can contain 80,000â€“250,000 workers and one or more queens that live for 2â€“6 years and produce 1500 eggs daily.[212] Fire ants are named for the burning pain inflicted after exposure that can result in necrosis at the site. The imported fire ant attacks with little warning. By firmly grasping the skin with its mandibles, both the fire ant and the jumper ant can repeatedly inject venom from a retractile stinger at the end of the abdomen. Pivoting at the head, the fire ant injects an average of 7 or 8 stings in a circular pattern.[187] In the United States, residents of healthcare facilities who are immobile or cognitively impaired are at risk for fire ant attacks, especially when the facility lacks pest control techniques for fire ants.[58] Healthcare personnel often are unaware of the behavior of these insects, and the special measures required for their control.

Pathophysiology

The clinical sequelae from fire ant stings are related to the biologic activity of the venom. The venom inhibits sodium and potassium adenosine triphosphatases, reduces mitochondrial respiration, uncouples oxidative phosphorylation, adversely affects neutrophil and platelet function, inhibits nitric oxide synthetase, and perhaps activates coagulation.[107,109] Unlike the venoms of wasps, bees, and hornets that contain mostly aqueous containing proteins, the imported fire ant venom is 95% alkaloid, with a small aqueous fraction that contains soluble proteins.[130] Of the alkaloids, 99% is a 2,6-disubstituted piperidine that has hemolytic, antibacterial, insecticidal, and cytoxic properties.[57] These alkaloids do not cause allergic reactions, but produce a pustule and pain. The aqueous portion of the venom contains the allergenic activity of fire ant venom, *Sol i* I-

IV.[92,187] The proteins identified in the venom include a phospholipase, a hyaluronidase, and the enzyme *N*-acetyl-Î²-glucosaminidase.[57,187]

Clinical Manifestations

Three categories are suggested based on the reactions to the imported fire ant: local, large local, and systemic.[188] *Local reactions* occur in nonallergenic individuals. *Large local reactions* are defined as painful, pruritic swelling at least 5 cm in diameter and contiguous with the sting site. *Systemic reactions* involve signs and symptoms remote from the sting site. The sting initially forms a wheal that is described as a burning itch at the site, followed by the development of sterile pustules. In 24 hours, the pustules umbilicate on an erythematous base. Pustules may last 1â€“2 weeks.[76] Late cutaneous allergic reactions can occur in some persons who experience indurated pruritic lumps at the site of subsequent stings.[57] Large reactions may lead to tissue edema sufficient to compromise blood flow to an extremity. Anaphylaxis occurs in 0.6â€“6% of persons who have been stung.[187] Often, healing occurs with scarring in 10â€“14 days.

Diagnosis

Clinical clues such as pustule development at the sting site after 24 hours, species identification, and history may help to identify fire ant exposure. No laboratory assays to determine exposure are available. Fire ant allergy can be determined by correlating the clinical manifestation of fire ant sting reactions with imported fire antâ€“specific IgE determined by skin testing or radioallergosorbent test.

Treatment

Local reactions require cold compresses and cleansing with soap and water. Some authors recommend topical or injected lidocaine with or without 1:100,000 epinephrine and topical vinegar and salt mixtures to

decrease pain at the site of the bite and sting.[96,134] Topical application of aluminum sulfate and papain is not effective for reducing pain or pruritus.[32,168] Large local reactions can be treated with oral corticosteroids, antihistamines, and analgesics. Secondary infections should be treated with antibiotics. Systemic reactions should be treated with subcutaneous or intravenous epinephrine.

Butterflies, Moths, and Caterpillars

Butterflies and moths are insects of the order *Lepidoptera.* Several moth and butterfly families have species whose caterpillars are clinically important, that is, they contain spines or urticating hairs that secrete a poison that is irritating to humans on contact. *Lepidopterism* is a general term that describes the adverse effects to humans when they are exposed to moths and butterflies.[143] Caterpillar, which means *hairy cat* in Latin, is the larval stage for moths and butterflies. In the United States, several significant stinging caterpillars are of note. The puss caterpillar (*Megalopyge opercularis*) often is considered one of the most important and toxic of the caterpillars in the United States because it has been reported to be such a nuisance, especially in Texas.[190] Other names for the puss caterpillar are woolly/hairy worm, wooly slug, opossum bug, tree asp, Italian asp, and little perrito in Spanish.[190] The caterpillars look furry and are covered in silky tan to brownish hairs that hide short spines containing an urticarial toxin. The spines are yellowish with black tips, and the hairs vary in colors ranging from pale yellow and gray to brown.[24] Other significant stinging caterpillars in the United States are the flannel moth caterpillar (*Megalopyge crispata*), the Io moth (*Automeris io*), the saddleback caterpillar (*Sibine stimulata*), and the hickory tussock caterpillar (*Lophocampa caryae*).[123] In South America, especially Brazil, *Lonomia obliqua* caterpillars are notorious for causing severe pain and a hemorrhagic syndrome.[38,53] In Australia several caterpillars are of medical importance: mistletoe brown tail moth (*Euproctis edwardsi*), processionary caterpillars (*Ochrogaster lunifer*), cup moths (*Doratifera* spp), and the white-stemmed gum moth (*Chelepteryx*

collesi).[8] Pine processionary caterpillars (*Thaumetopoea pityocampa*) are the most important defoliator of pine forests in the Mediterranean and central European countries, with significant consequential economic and occupational repercussions for workers who frequent these pine forests.[205]

Pathophysiology

Little is known about the composition of the venom, which probably varies according to the different caterpillar species. Some toxins contain proteins that cause histamine release, such as thaumetopoien isolated from *Thaumetopoien pityocampa* or pine processionary caterpillar.[205,206] Another protein isolated from the *L. obliqua* caterpillar causes coagulopathy; its mechanism of action is not fully known but it somehow activates factors X and II.[61,112] The venom and hair structure of *Lagoa crispata*, which has often been confused with the southern Texas puss caterpillar, has been characterized.[124] The venom is stored at the base of the hollow setae (spines) where the poison sac and nervous tissue are located. Upon contact with these spines, the toxin is released. The toxin may be a protein or a substance that conjugates with proteins.[67] The varying differences of caterpillar venom and their clinical effects emphasize the importance of positive identification of caterpillars.

Clinical Manifestations

The clinical effects of caterpillar exposure can generally be separated into 2 typesâ€”stinging reaction and pruritic reactionâ€”although overlap may occur. Stinging caterpillars, such as *Megalopyge opercularis*, envenomate by contact with their hollow spines containing venom. The reaction is characterized as a painful, burning sensation with local effects and, less commonly, systemic effects. The area may become erythematous and swollen, and papules and vesicles may appear. The classic gridlike pattern develops within 2â€“3 hours of

contact. Reported symptoms include nausea, vomiting, fever, headache, restlessness, tachycardia, hypotension, urticaria, seizures, and even radiating lymphadenitis and regional adenopathy.[154] Another stinging caterpillar previously mentioned is the *L. obliqua* caterpillar, which causes the hemorrhagic syndrome that presents as a disseminating intravascular coagulopathy and as secondary fibrinolysis with skin, mucosal, and visceral bleeding, acute renal failure, and intracerebral hemorrhage.[38,112] Pruritic reactions occur upon exposure to the itchy caterpillars that have nonvenomous urticating hairs, which can produce a mechanical irritation, allergic reaction, or a granulomatous reaction from the chronic presence of the hairs. Several species that cause allergic reactions are the white-stemmed moth (*Chelepteryx collesi*), Douglas fir tussock moth (*Orgyria pseudotsugata*), and gypsy moth caterpillar (*Lymantria dispar*).[143] Caterpillar hairs can cause ocular trauma, otherwise known as *ophthalmia nodosa*.[186] The range of ocular pathology depends on the penetration factor and the effect of the released urticating toxins.[37] The ocular spectrum has been classified into 5 types by Cadera et al:[37]

- *Type 1:* Brief exposure time of 15 minutes. Symptoms of chemosis, inflammation, epiphora, and foreign body sensation may last for weeks.
- *Type 2:* Chronic mechanical keratoconjunctivitis (hairs in bulbar/palpebral conjunctivitis). Foreign body sensation is relieved by removal of hairs. Cornea abrasions may be present.
- *Type 3:* Gray-yellow nodules or asymptomatic granulomas.
- *Type 4:* Severe iritis with or without iritis nodules. Hairs in the anterior chamber and possible intralenticular foreign body.
- *Type 5:* Vitreoretinal involvement. Hairs may enter through the anterior chamber or iris lens or by transscleral migration. May cause vitreitis, cystoid macular edema, papillitis, or endophthalmitis.

Treatment

Treatment of ocular lesions depends upon the exposure classification. Most patients can be classified as type 1 or 2. Irrigation with saline should be followed by meticulous removal of setae, followed by topical steroids and antibiotics. Type 3 requires surgical excision of the nodules. Type 4 requires topical steroids with or without iridectomy for nodules or operative removal of setae. Type 5 requires local treatment with or without systemic steroids. Resistant cases may require vitrectomy with removal of setae. Treatment for dermal contact should be immediate, with removal of the embedded spines using cellophane tape and application of ice. Opioids may be necessary, if minor analgesics do not provide relief. If muscle cramps develop, benzodiazepines should be administered. One study recommended use of 10 mL 10% calcium gluconate administered intravenously, which provided pain relief.[136] Topical corticosteroids can be used to decrease local inflammation. Antihistamines such as diphenhydramine (25â€“50 mg for adults and 1 mg/kg, maximum 50 mg, in children) can be used to relieve pruritus and urticaria.[136,154] Nebulized Î²-agonists and epinephrine administered subcutaneously may be required for more severe respiratory symptoms and anaphylactoid/anaphylactic-type reactions. For hemorrhagic syndrome resulting from exposure to *L. obliqua* caterpillar, an antidote called the antilonomic serum (SALon) is available and is used for treatment of the hemorrhagic syndrome in Brazil.[60]

Blister Beetles

Blister beetles are plant-eating insects that exude a blistering agent for protection. They can be found in the eastern United States, southern Europe, Africa, and Asia. Most are from the order Coleoptera, family Meloidae. *Epicauta vittata* is the most common of more than 200 blister beetles identified in the United States.[111] When the beetles sense danger, they exude cantharidin by filling their breathing tubes with air, closing their breathing pores, and building up body fluid

pressure until fluid is pushed out through one or more leg joints.[76] Cantharidin is a potent blistering agent found throughout all 10 stages of life of the blister beetle.[41] Cantharidin is produced only by the male blister beetle and is stored until mating. The female loses most of her reserves as she matures. In the wild, the female repeatedly acquires cantharidin as copulatory gifts from her mates.[41] Cantharidin, also known popularly as *Spanish fly*, takes its name from the Mediterranean beetle *Cantharis vesicatoria.* It has been used as a sexual stimulant for millennia. The aphrodisiac properties are related to the ability of cantharidin to cause vascular engorgement and inflammation of the genitourinary tract, hence the reports of priapism and pelvic organ engorgement.[202] Cantharidin has been used for treatment of bladder and kidney infections, stones, stranguria (bladder spasm), and various venereal diseases.[111] In the last century, cantharidin was commonly used for treatment of pleurisy, pneumonia, arthritis, neuralgias, and various dermatitides. A topical 1% commercial preparation can be used for removal of warts and molluscum contagiosum.[50,180] Cantharidin poisoning has been reported by cutaneous exposure,[31] unintentional inoculation,[156] and inadvertent ingestion of the beetle itself.[200] Fewer than 30 cases of Spanish fly poisoning have been reported since 1900.[111]

Pathophysiology

Cantharidin is a natural defensive toxicant produced by blister beetles and shares a structural similarity with the herbicide Endothall.

Although the mechanism of action has not been elucidated, one mechanism based on an in vitro study suggests that cantharidin inhibits the activity of protein phosphatases type 1 and 2A. This inhibition alters endothelial permeability by enhancing the phosphorylation state of endothelial regulatory proteins and results in elevated albumin flux and dysfunction of the barrier.[116] Enhanced permeability of albumin may be responsible for the systemic effects of cantharidin, which lead to diffuse injury of the vascular endothelium

and resultant blistering, hemorrhage, and inflammation.

Clinical Manifestations

The clinical effects can mostly be attributed to the irritative effects on the exposed organ systems. The secretions cause an urticarial dermatitis that is manifested several hours later by burns, blisters, or vesiculobullae.[31] Symptoms may be immediate or delayed over several hours. In addition to the local effects, cantharidin can be absorbed through the lipid bilayer of the epidermis and cause systemic toxicity, with diaphoresis, tachycardia, hematuria, and oliguria from extensive dermal exposure.[202] If the periorbital region is contaminated, edema and blistering can evolve. Ocular findings from direct contact with the beetle or hand contamination include decreased vision, pain, lacrimation, corneal ulcerations, filamentary keratitis, and anterior uveitis.[156] When cantharidin is ingested, severe GI disturbances and hematuria can occur, described primarily as cantharidin toxicosis in horses.[161] Initial patient complaints may include burning of the oropharynx, dysphagia, abdominal cramping, vomiting, hematemesis followed by lower GI tract hematochezia, and tenesmus.[149] Although equids develop cantharidin toxicosis from their diet, there is one case of inadvertent blister beetle ingestion by a child who thought it was the edible *Eulepida mashona* or white grub; the child developed hematuria and abdominal cramping.[200] Genitourinary effects include dysuria, urinary frequency, hematuria, proteinuria, and renal impairment. Most symptoms resolved over several weeks. However, death from renal failure with acute tubular necrosis has been reported.[202] Most human exposures involve inadvertent contact with the beetle or its secretions, resulting in dermatitis, keratoconjunctivitis, and periorbital edema secondary to handâ€“eye involvement, also called the *Nairobi eye*.[156]

Diagnostic Testing

Cantharidin toxicosis has been identified for equine and ruminant

exposures by screening urine and gastric contents with high-performance liquid chromatography and gas chromatography-mass spectrometry.[161,162] This method has not been used in clinical practice.

Treatment

Treatment is largely supportive. Wound care and tetanus status should be assessed. For keratoconjunctivitis, an ophthalmologist should be consulted early in the clinical course and the patient treated with topical corticosteroids (prednisolone 0.125%), mydriatics (cyclopentolate 1%), and antibiotics (ciprofloxacin 0.3%).

Summary

Healthcare providers should have an extensive knowledge regarding bites and stings by arthropods and arachnids so that they can recognize the local and systemic reactions. Treatment of arthropod-borne disease rarely entails use of antivenoms. Proper hygiene to prevent secondary infections, avoiding contact with arthropods, decreasing the arthropod population mechanically and/or chemically, and use of repellents are important measures to decrease morbidity from arthropods. The patient should bring the arthropod to the hospital, if possible, to facilitate identification, and every attempt should be made to describe the evolution of the bite to assist in the differential diagnosis.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Antidotes in Depth

Antivenom (Scorpion and Spider)

Jeffrey N. Bernstein

The terms *antivenom* and *antivenin* often are used interchangeably. Wyeth, the maker of Crotaline and *Micrurus* antivenom, and Merck and Co., the makers of *Latrodectus* antivenom, adopted *antivenin* in the brand names for their products. Brand name recognition has largely been responsible for the use of the term *antivenin* in place of *antivenom.* Except where it refers to a specific brand name, the term *antivenom* is used in this Antidotes in Depth and throughout this textbook.

Antivenom for spiders and scorpions is prepared by immunizing animals with venom and then collecting the immune serum for administration.[4,37] Monkeys, horses, goats, sheep, chicken, camels, and rabbits have been used as sources of antivenom.[41] The animals are placed on an immunization schedule to allow production of immunoglobulins, mostly specific immunoglobulin IgG. Optimal antibody production typically takes approximately 6 weeks. The choice of animal used to make an immune serum is more often dictated by the availability of a species, financial considerations, and tradition than by scientific modeling. Horses are used

by the majority of antivenom producers. Horses are easy to maintain, and large volumes of serum can be obtained at one time without harming the animals. Although manufacturers may state that a specific animal gives a less immunogenic product, no studies have compared immune sera of different animals for human compatibility or tolerance. Varying efforts by the manufacturer are made to remove animal proteins such as albumin. The antidotal fraction of an antivenom exists as either whole IgG, or Fab, or $F(ab)_2$. Digestion of disulfide bonds of an IgG molecule with papain yields a mixture of Fab and Fc. The Fab component then can be isolated with affinity chromatography, and the highly antigenic Fc portion is discarded. Similarly, digestion of the IgG molecule with pepsin yields a mixture of $F(ab)_2$ and Fc. Although Fab and $F(ab)_2$ are more expensive to produce than their whole immunoglobin counterparts, they are generally regarded as less allergenic and therefore safer to use.

IgG is the easiest and most inexpensive to produce. It has a molecular weight of 150 kDa, the largest of the three antivenom types. Because of its size, it is less filterable at the glomerulus and has the smallest volume of distribution. IgG has a longer elimination half-life than either Fab or $F(ab)_2$.[27]

$F(ab)_2$ has an intermediate size (100 kDa) and elimination half-life. Because it lacks the Fc fragment of the IgG molecule, it has less potential to initiate anaphylaxis. The advantage of $F(ab)_2$ is that much of the allosteric configuration of the original IgG molecule is retained compared to Fab. This configuration theoretically allows for tighter binding to venom.

Fab is the smallest (50 kDa) in size and is eliminated renally. It has the largest volume of distribution and a greater ability to reach intracellular compartments. The pharmacokinetic properties of the venom have been suggested to define the development and characteristics of an antivenom.[27] Arachnid venoms with effects on the central nervous system tend to have low molecular weights and large volumes of distribution. Fab- and $F(ab)_2$ -based antivenoms with their larger volumes of distribution may be more suitable for binding these low-molecular-weight

centrally acting components of arachnid venom.[27]

Immunoglobulin-based antivenoms can be given by the intramuscular, intravenous, or subcutaneous route. Intravenous antivenom therapy is preferred for its ability to achieve rapid peak serum concentrations and the ability to withdraw the offending antivenom in the event of an allergic reaction.[28] Intramuscular injection has been used in instances where intravenous access is unobtainable. In a rabbit model, the elimination half-life of *Buthus occitanus* venom is reduced faster when antivenom is given by the intravenous route than are comparable doses given intramuscularly. Pharmacokinetic comparisons of venom and antivenom suggest that the lower-molecular-weight components of scorpion venom are absorbed and distributed faster than antivenom, when administered intramuscularly or given subcutaneously. Therefore intravenous antivenom is the preferred route for neutralization of venom.[30, 34, 35]

The unavailability of specific antivenoms necessitates symptomatic treatment or use of a comparable foreign antivenom. In the United States the specific goat-derived antivenom for *Centruroides* envenomation is no longer being produced. Clinical trials are underway for the use of Mexican equine $F(ab)_2$ for treatment of severe envenomation. In a study of 72 moderate scorpion stings in Para, Brazil, 32.7% who met criteria for antivenom administration did not receive treatment because of unavailability of the antivenom.[46] *Latrodectus* antivenom has been in short supply in the past, leading to the observation that *Latrodectus mactans* and *Latrodectus hesperus* could be neutralized by *Latrodectus hasseltii* antivenom.[18, 19, 39]

The exact identity of the species of arachnid is rarely known in the clinical setting. The spider or scorpion specimen usually is not available. The species usually is inferred more from the geographic region where the injury occurred than from the clinical presentation. For example, black widow envenomations that occur in southern Arizona are presumed to result from *L. hesperus* rather than *L. mactans*. Occasionally, stings or bites result from scorpions or spiders in imported foreign rugs and fruit. The clinician must also be aware that professional and amateur

entomologists may be exposed to bites or stings from exotic species. However, in these instances, the exact genus and species, or at least the common name, usually are known.

Centruroides Species

Centruroides exilicauda (formerly known as *Centruroides sculpturatus*) is the only scorpion of medical importance in the United States. It is indigenous to the deserts of Arizona but reportedly exists in Texas, New Mexico, California, and Nevada.[17] Occasionally, envenomations occur in nonindigenous areas of the country from â€œstowawayâ€• scorpions in the luggage of travelers.[59]

The two poison centers in Arizona receive between 8000 and 10,000 calls annually for scorpion exposures (Chap. 130).[40] In the past, the mortality from scorpion envenomation in the

United States was twice as high as that of all other venomous animals combined.[48] Although the incidence of envenomation remains high, no deaths associated with the toxic effects of scorpion venom have occurred for more than 40 years. However, the recent death of a 62-year-old woman likely was secondary to an anaphylactic reaction to scorpion venom.[10] The low incidence of fatalities most likely is attributable to better methods of supportive care, the use of antivenom, and the development of pediatric intensive care units.[32]

Antivenom for the *Centruroides* spp was produced in horses in Mexico as early as the 1930s.[17] In 1947, antivenom was produced from rabbits and cats immunized with *C. sculpturatus* and *Centruroides gertschi* .[52] The Antivenom Production Laboratory at Arizona State University (APL-ASU) began producing antivenom to *C. sculpturatus* in goats in 1965. This antivenom was used for treatment of scorpion stings in Arizona until November 2004. Production of the APL-ASU antivenom has ceased. All stockpiles have expired; however, several hospitals retain vials of antivenom in their inventory.[40] No FDA approval was ever granted for thi product; its use was restricted to the state of Arizona, where it was

supplied free of charge to hospitals for compassionate use. Transport across state lines was prohibited.

In view of the limited mortality from envenomation and the risk of seriou immediate hypersensitivity or serum sickness from administration of antivenom, there is rarely, if ever, an absolute indication for administration of *Centruroides* scorpion antivenom. Administration of antivenom, therefore, was reserved for patients with the most severe envenomations, typically in children younger than 6 years. A 4-level severity grading of scorpion envenomation is given in Table 115-7 .[17] Administration of antivenom is recommended for patients with grade III o IV systemic toxicity. However, these same symptoms also can be successfully managed in an intensive care setting with aggressive airway management, monitoring, and benzodiazepine infusions.

In Mexico, two antivenoms are primarily directed toward neutralizing the venom of *Centruroides* spp. The Mexico-Pharma Polyvalent Scorpion Antivenom may also be effective against North American *Centruroides* stings; however, there is no known reliable repository of this antivenom i the United States.[3] Although antibody fragments (Fab) were developed from immune goat serum for treatment of *Centruroides* envenomation, they are not commercially available.[8] In June 2000, Silanes Laboratory received orphan drug status for Alacramyn, an equine-derived $F(ab)_2$ fror *Centruroides limpidus* , *Centruroides noxius, Centruroides suffusus suffusus, and Centruroides meisei* (formerly known as *Centruroides elegans*). Currently, clinical trials of $F(ab)_2$ use in envenomed children are underway, stimulated by the absence of the ASU-APL product. One vi of Alacramyn contains sufficient $F(ab)_2$ to neutralize 150 mouse LD_{50} of *Centruroides* venom.[42] It is administered by slow IV infusion, 1 vial at a time with observation for 30 to 60 minutes before repeating. Dosing is similar in children and adults. It efficacy is documented in both animals and humans.[1 , 11 , 25] A prospective evaluation of serum venom concentrations in 14 clinically envenomed children was performed using enzyme-linked immunosorbent assay. After administration of antivenom, serum venom concentrations fell from 1000 to 4000 pg/mL to less than 200 pg/mL within 30 minutes and were unmeasurable within 2 hours.[25]

In a rabbit model, the total serum concentration of venom increased afte administration of $F(ab)_2$, suggesting that $F(ab)_2$ is capable of pulling venom from its site of action into serum.[11]

Cross-neutralization of the venom of 8 different species of *Centruroides* , including *C. exilicauda* , has been documented in vitro.[22]

The incidence of allergic reactions to Alacramyn is reported to be 2.7%, similar to the 3.4% reported for the APL-ASU goat serum.[9 , 38] The average duration of symptoms in treated patients was 1.4 hours. In a study of 15 children, the 12 patients who receive APL-ASU antivenom hac resolution of neurologic, respiratory, and cardiovascular symptoms within 3 hours of initiating therapy. In the 3 patients who did not receive antivenom therapy, symptoms lasted 15 to 24 hours.[9] If the current clinical trials of $F(ab)_2$ reveal the product to be safe and effective, the threshold to treat scorpion envenomation may be lowered by many clinicians. Alacramyn is tentatively set to be marketed under the name Anascorp in the United States.

Leiurus Species

The *Leiurus quinquestriatus* scorpion is indigenous to Africa, Asia, and th Middle East, including Egypt, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, and Turkey. Antivenom to *L. quinquestriatus* i made in France, Israel, and Turkey. The clinical effects of this scorpion are relatively resistant to treatment with antivenom. The manufacturer of Turkey antiscorpion antivenom recommends a dose of 1 mL antivenom fo treatment of envenomation. The usual dose for control of symptoms is 5 to 20 mL antivenom given intravenously.

In observational studies, an intravenous infusion of 5 to 20 mL was needed to control venom effects, and only patients given antivenom withi the first several hours demonstrated significant benefit.[2 , 31] The rate of allergic reactions for the Turkey antiscorpion antivenom is reported to be 1.6% to 6.6%.[31] The recommended dose of the Israeli *L. quinquestriatus* antivenom is 5 to 15 mL for intravenous use. Several authors report lack

of clinical efficacy of this antivenom.[6,26,53]

Leiurus quinquestriatus antivenom was successfully used to treat a 2-year-old boy with envenomation by *Androctonus crassicauda*. Symptoms resolved 2 hours after antivenom administration.[47]

Tityus Species

Tityus species of scorpions are endemic to South America, particularly Brazil. An $F(ab)_2$ for *Tityus serrulatus* antivenom is available from FundaÃ§Ã£o Ezequiel Dias (FUNED), in Belo Horizonte, Brazil. The usual dose of the antivenom is 20 mL as an intravenous infusion.[20]

In a series of 18 patients with *T. serrulatus* envenomation treated with antivenom, vomiting and local pain decreased within 1 hour, and cardiorespiratory manifestations disappeared within 6 to 24 hours in all patients except the 2 who presented with acute lung injury.[20] Sixteen patients recovered completely by 24 hours. Additionally, the Instituto Buntantan in Brazil produces Soro antiarachnidico and Soro antiscorpionico for treatment of *Tityus* spp.[44]

Androctonus Species

Scorpion antivenom in South Africa is an equine-derived antivenom available from the South African Vaccine Producers, formerly South African Institute for Medical Research (SAIMR), Johannesburg, South Africa.

Scorpifav, produced by Aventis Pasteur, is produced for treatment of *Androctonus* spp, *B. occitanus*, and *L. quinquestriatus*.

Buthus tamulus monovalent red scorpion antivenom serum produced by Central Research Institute of India is an equine-derived lyophilized antivenom for the venom of *Mesobuthus tamulus*. Although the manufacturer recommends a dosage of 1 vial, a dose of 5 vials reduced the mortality significantly in one study.[36,54]

In Pakistan, the treatment of scorpion stings was modified in 1991 to include the administration of 5 vials of antivenom. A retrospective case series of 950 patients treated with and without antivenom was compared to 968 cases after the 5-vial protocol was initiated. A statistically significant decrease in mortality occurred. The last recorded death resulting from a scorpion sting occurred in 1991 in a patient who did not receive antivenom.[54]

Parabuthus spp antivenom from South African Vaccine Producers is an equine-derived antivenom to *Parabuthus* spp. In one study antivenom became unavailable, allowing for a unique design of matched pairing of patients. Patients who received antivenom had a significant decrease in hospital stay after receiving 1 (5-mL) vial of antivenom. Pain, hypersalivation, fasciculation, tremor, and bladder distension responded best to serotherapy. Antivenom therapy did not significantly improve dysphagia, ptosis, or local swelling.[7]

Latrodectus Species (*L. Mactans, L. Hesperus, Latrodectus Bishopi, Latrodectus Geometricus, Latrodectus Indistinctus*)

Administration of the black widow spider antivenom is controversial. Although black widow envenomation is associated with severe muscle pain, cramping, and autonomic disturbances,[12 , 13 , 33] mortality is low. Symptomatic treatment almost always can be accomplished with muscle relaxants and opioids individually or in combination. Some authors believ that antivenom has too high a risk-to-benefit ratio to justify its use.[50] In selected patients, however, use of antivenom may reduce pain and suffering, shorten the course of envenomation, and reduce or eliminate the need for hospitalization.[45 , 55] We believe that indications for antivenom administration include severe muscle cramping, hypertension, diaphoresis, nausea, vomiting, and respiratory difficulty that is unresponsive to other therapy (Chap. 115). Pregnancy is suggested as a possible indication for antivenom administration.[5 , 51]

Antivenoms for a number of *Latrodectus* spiders are available worldwide (Table A32-1). *Latrodectus mactans* antivenom is produced by Merck and Co. in North America. The Australian red-back spider *L. hasseltii* antivenom is manufactured in horses by CSL Ltd. South Africa (SAFR) produces antivenom for both the black widow *(Latrodectus indistinctus)* and the brown widow *Latrodectus geometricus* . Aracmyn, a polyvalent $F(ab)_2$, is an equine-derived antivenom created for *L. mactans* in both Argentina and Mexico and for *Loxosceles* spp.

In North America Antivenin (Merck and Co.) for black widow venom (*L. mactans*) is made by immunizing horses. Each vial of antivenin contains 6000 antivenin units standardized by biologic assay in mice. Because the venoms of Latrodectus species are virtually identical by immunologic and electrophoretic mechanisms, antivenom created for *L. mactans* is presumed to be effective in other species of Latrodectus as well.[39] A recent shortage of antivenin (Merck and Co.) prompted the discovery that antivenom against *L. hasseltii* , the Australian red-back spider, also neutralizes venom of *L. mactans* in a mouse model.[19] In a review of 163 cases of presumed *L. hesperus* , envenomations antivenom reduced the duration of symptoms from a mean of 22 hours to a mean of 9 hours. Symptoms usually subsided within 1-3 hours of administration of the antivenom. Hospital admission rate fell from 52% in those who were managed with opioids and muscle relaxants to 12% in those patients receiving antivenom.[12] Administration of antivenom was also effective, even when given as late as 90 hours after envenomation.[45 , 55]

Dosage of antivenin (Merck and Co.) is usually one vial (2.5 mL) diluted in 50 mL of saline for intravenous administration. Black widow spider antivenom can also be given IM; however, this route carries the disadvantage of slower, more erratic absorption, less control over the rate of administration, and the inability to stop administration of the drug should an allergic reaction occur. For these reasons, the intramuscular route is not recommended.

Despite the apparent efficacy of antivenom, the decision to give horse serum for a disease with limited mortality is of great concern. Death from

bronchospasm and anaphylaxis is reported as a complication of antivenor administration, as is serum sickness.[13] Black widow antivenom is listed a a Pregnancy Category C agent.

In Australia, antivenom to the red-back spider (*L. hasseltii* , CSL Ltd.) is made by immunizing horses for production of $F(ab)_2$. Horse-derived $F(ab)_2$ has a lower reported incidence of allergic reactions, with early anaphylactoid reactions as low as 0.5% to 0.8%. The incidence of serum sickness is reported at less than 5%.[56 , 57]

In a report covering 1995 to 1996, only 20% of patients with *L. hasseltii* (red-back spider) bites required antivenom administration.[60] When treatment was given, 1 ampule was used in 76% of cases, 2 ampules wer used in 18% of cases, and 3 ampules were administered in only 6% of cases.[60] Three patients who required 6 to 8 vials of antivenom after failing to respond to the usual 1 to 2 vials are reported.[29] No antihistamine or epinephrine pretreatment was given, and no allergic or serum sickness complications occurred.

European widow spider *(Latrodectus tredecimguttatus)* antivenom is no longer produced.[29]

Funnel-Web Spider (Atrax and Hadronyche) Envenomation

A rabbit IgG-based funnel-web spider antivenom is available in Australia. Since the introduction of the antivenom, no deaths have been reported.[29] The initial dose should be 2 ampules in patients with any signs of envenomation. Patients with evidence of acute lung injury or decreased consciousness should receive 4 ampules.[43] The dosage for children is the same as for adults.[16]

In severe envenomations, the following protocol should be used.[43] Two ampules (each 5 mL of 2.0% [100-mg]) rabbit IgG) antivenom should be administered very slowly intravenously (adult or child). The dose can be repeated in 15 minutes if no improvement is seen. The dose should be

doubled for severe cases. A rapid response should occur. Administration o antivenom should be repeated until symptoms are completely reversed.[21] Not uncommonly, *Atrax robustus* envenomations require more than 3 ampules of antivenom.

TABLE A32-1. Worldwide Availability of Scorpion and Spider Antivenom [14, 16, 44, 58]

Loxosceles Species (*Loxosceles Reclusa, Loxosceles Laeta, Loxosceles Rufescens, Loxosceles Arizonica, Loxosceles Unicolor*)

Envenomation by the brown recluse spider *Loxosceles reclusa* , is associated with low, but significant, morbidity, particularly in the southeast United States. Anti-*Loxosceles* Fab blocks dermonecrosis in a rabbit model, but only if it is given within 24 to 48 hours of envenomatio in one study or as late as 48 hours in another study.[24, 49] However, comparisons do not reveal significant differences between dapsone- and antivenom-treated animals and suggest that a combination may be the best therapy.[15, 49] No commercially available antivenom exists in North America for treatment of *Loxosceles* envenomation. The late presentation of patients with necrotic lesions from a spider bite and the uncertainty of

the genus of the arthropod vector make antivenom use for *Loxosceles* difficult to study. The Instituto Butantan in Brasil has produced an antivenom for *L. reclusa* and *L. rufescens.*

Summary

The indications for antivenom administration in both spider and scorpion envenomations are controversial. The decision to use antivenom should b individualized to the patient, weighing the risk of giving a foreign immune serum, the level of available supportive care, the cost of supportive care, and the cost of obtaining or importing antivenom. The preferred route of administration is intravenous. One to two vials is the recommended dose for most antivenoms; higher doses may be needed to alleviate symptoms

Chapter 116
Marine Envenomations

D. Eric Brush

A 28-year-old man was stung on the lateral surface of his right hand by a lionfish when he reached into his tropical fish aquarium to adjust the aerator. Within seconds he experienced severe pain and swelling of his hand. En route to the hospital the patient applied an ice pack. In the emergency department he was awake, alert, and in considerable distress. His vital signs were: blood pressure, 150/90 mm Hg; pulse, 110 beats/min; respiratory rate, 18 breaths/min; oral temperature, 98.6Â°F (37Â°C).

Three small linear puncture marks, approximately 8 mm apart, were located on the lateral surface of the patient's right hand. The hand was swollen and erythematous. Neurovascular examination of the hand was normal. (See ILLIONFISH in the Image Library at http://www.goldfrankstoxicology.com.)

The hand was immersed in water that had been heated to 110Â°F (43.3Â°C). The immersion resulted in pain relief within 5 minutes. However, the pain recurred when the water cooled to room temperature. The patient received a diphtheria-tetanus toxoid

vaccination and was discharged 4 hours after arrival to the emergency department. No systemic signs had developed, and his pain was significantly relieved. He was instructed to take ibuprofen 400 mg every 6 hours, for pain and to have his hand examined by his private physician the next day.

Human encounters with venomous marine creatures are commonplace and may result in serious clinical effects. Injuries may arise from direct toxin effects and from mechanical destruction from the stinging apparatus. Significant morbidity and documented deaths have occurred following envenomation with spiny fish, cone snails, octopi, sea snakes, and several species of jellyfish. Despite significant advances in basic science research regarding the biochemical nature of marine toxins and their mechanisms of action, our knowledge of clinical effects in humans, and the optimal therapies for human envenomation, remain limited. Evidence for effective treatment is primarily derived from in vitro and in vivo animal research without the benefit of controlled human trials. However, current research in toxinology (the study of toxic proteins from microbial, plant, and animal origin) coupled with clinical observations provides information that can translate into reduced morbidity and mortality associated with these injuries.

Invertebrates

Cnidaria

The phylum *Cnidaria* (formerly *Coelenterata*) includes more than 9000 species, of which approximately 100 are known to cause injury in humans. They are commonly referred to as *jellyfish;* however, their phylogenetic designations separate â€œtrue jellyfishâ€• and other organisms into distinct classes (Table 116-1) (see ILJELLYFISH in the Image Library). All species possess microscopic cnidae (Greek knide = nettle), which are highly

specialized organelles consisting of an encapsulated hollow barbed thread bathed in venom. Thousands of these stinging organelles, called *nematocysts* (or *cnidoblasts*), are distributed along tentacles. A trigger mechanism called a *cnidocil* regulates nematocyst discharge. Pressure from contact with a victim's skin, or chemical triggers such as osmotic changes, stimulates discharge of the thread and toxin from its casing. Penetration of flesh leads to hypodermic venom delivery. Nematocysts of most *Cnidaria* are incapable of penetrating human skin, rendering them harmless. *Cnidaria* causing human envenomation, such as the box jellyfish, discharge threads capable of penetrating into the papillary dermis of human skin.[132]

Cubozoa

Members of the class *Cubozoa* are not true jellyfish. Animals in the *Cubomedusae* order have a cube-shaped bell with 4 corners, each of which supports between 1 and 15 tentacles. Species from this order produce the greatest morbidity and mortality of all *Cnidaria*. The order has two main families of toxicologic importance: *Chirodropidae* and *Carybdeidae*.

The *Chirodropidae* family is well known for the box jellyfish *Chironex fleckeri* (Greek cheiro = hand, Latin nex = murderer, is known as â€œassassin's handâ€•). The species was named in honor of Dr. Hugo Flecker, a physician from Cairns, Australia.[128] When full grown, its bell measures 25 to 30 cm in diameter, and 15 tentacles are attached at each corner of the bell. These tentacles may extend up to 3 m in length. Another member of this family is *Chiropsalmus quadrigatus*, the sea wasp. Its pale blue color makes detection in water nearly impossible.

The *Carybdeidae* family is most notable for *Carukia barnesi*, the Irukandji jellyfish. It is named in honor of Dr. Jack Barnes, who identified the species as the cause of a severe systemic syndrome following stings among a tribe of Aboriginal people (the Irukandji)

in the Cairns region of northern Australia.[59] Its small size, with a bell diameter of 2.5 cm, makes detection in the water difficult.

Hydrozoa

The *Hydrozoa* class, like the *Cubozoa*, are not true jellyfish; however, they are capable of inflicting considerable pain and even death in humans. The order *Siphonophora* (*Physaliidae* family) includes two unusual creatures of toxicologic concern:

Physalia physalis, the Portuguese man-of-war, and its smaller counterpart, *Physalia utriculus*, the bluebottle. They are pelagic (floating) colonial *Hydrozoa*, meaning they exist as a colony of multiple hydroids (*Cnidaria* is a polyp as the dominant life phase) in a formed mass. The easily recognizable blue sail that floats above the surface of the water is filled with nitrogen and carbon monoxide. Tentacles of *P. physalis* may reach lengths in excess of 100 ft and contain more than 750,000 nematocysts in each of its numerous tentacles (up to 40). *Physalia utriculus* has only one tentacle, which measures up to 15 m.

TABLE 116-1. Cnidaria

Latin Name	Common Name	Habitat[b]
Cubozoa class		
Chironex fleckeri[a]	Box jellyfish	Tropical Pacific Ocean, Indian Ocean, Gulf of Oman

Carukia barnesi[a]	Irukandji jellyfish	North Australian coast
Chiropsalmus spp[a]	Sea wasp or fire medusa	North Australian coast, Philippines, Japan, Indian
C. quadrigatus *C. quadrumanus*		Ocean, Gulf of Mexico, Caribbean, and Puerto Rico
Carybdea alata	Hawaiian box jelly	Hawaii
Carybdea rastoni	Jimble	Australia
Hydrozoa class		
Physalia physalis[a]	Portuguese man-of-war	Eastern US Coast from Florida to North Carolina, Gulf of Mexico, Australian coastal waters (rare reports)
Physalia utriculus	Bluebottle	Tropical Pacific Ocean, particularly Australia

Millepora alcicornis	Fire coral	Wide spread in tropical waters, including Caribbean
Scyphozoa class		
Chrysaora quinquecirrha	Sea nettle	Chesapeake Bay, widely distributed in temperate and tropical waters
Stomolophus meleagris	Cabbage head or cannonball jelly	Gulf of Mexico, Caribbean
Stomolophus nomura[a]		Yellow Sea between China and South Korea
Cyanea capillata	Lion's mane or hair jelly	Northwest US coast up to Arctic Sea, Norwegian and British coastlines
Pelagia noctiluca	Mauve stinger or purple-striped jelly	Caribbean

Linuche unguiculata	Thimble jelly	Florida, Mexico, and Caribbean
Anthozo[a] class		
Anemonia sulcata	European stinging anemone	Eastern Atlantic, Mediterranean, Adriatic Sea
Actinodendron plumosum	Hell's fire anemone	South Pacific
Actinia equina	Beadlet anemone	Great Britain, Ireland
[a]Well-documented human fatalities [b]Represents most common areas where stings are reported.		

The *Milleporina* order is well known for the sessile *Millepora alcicornis*, fire coral, which also exists as a colony of hydroids. It appears much like true coral and has a white to yellow-green lime carbonate exoskeleton. Small tentacles protrude through minute surface gastropores. The overall structure ranges from 10 cm to 2 m.

Scyphozoa

True jellyfish belong to the class *Scyphozoa* and are extremely diverse in size, shape, and color. Common varieties known to envenomate humans are *Cyanea capillata* (lion's mane or hair jelly), *Chrysaora quinquecirrha* (sea nettle), and *Pelagia noctiluca*

(mauve stinger). The mauve stinger is easily recognized; it appears pink in daylight and phosphorescent at night. Larvae of certain *Linuche linguiculata* cause sea bather's eruption (SBE). The larvae are pin-head sized and are seen only when they are grouped in large numbers near the surface of the water.

Anthozoa

The *Anthozoa* class has a diverse membership, including true corals, soft corals, and anemones. Only the anemones are of toxicologic concern. They are common inhabitants of reefs and tide pools and attach themselves to rock or coral. Armed with modified nematocysts known as *sporocysts* located on their tentacles, they can produce stings similar to those of organisms from other *Cnidaria* classes.

History and Epidemiology

Stings from *Cnidaria* represent the overwhelming majority of marine envenomations. In Australia, approximately 10,000 stings per year are recorded from *Physalia* spp alone.[54] Most *Cnidaria* stings occur during the warmer months of the year. Stings occur with greatest frequency on hotter-than-average days with low winds, particularly during times of low precipitation. â€œStinger netsâ€• are used in high-risk areas of the Australian coastline; however, one study reported that 63% of stings requiring medical attention occurred within netted waters.[84] Each stinger season, the Royal Darwin Hospital in Australia treats approximately 40 patients with stings.[40] A prospective evaluation of stings presenting to that hospital during a 12-month period from 1999â€“2000 revealed that 70% resulted from the box jellyfish. The remaining 30% involved other *Cubozoa* such as *C. barnesi*.[103] Although this finding may indicate a predominance of box jellyfish as the cause of stings, it also suggests that stings from box jellyfish are more severe and require medical attention with

greater frequently than stings from other *Cubozoa.*

Cases of sea bathers eruption (SBE) a stinging rash from *Cnidaria* larvae, occur in clusters. They display variation in intensity and frequency from year to year, as exemplified by a 25-year hiatus during which no cases were reported in Florida.[138] In 1992, more than 10,000 cases of SBE were seen in south Florida, with similar peaks in the 1940s and 1960s. Cases of SBE also are reported in Cuba, Mexico, the Caribbean, and occasionally in Long Island, New York.

Cnidaria common to the United States include the Portuguese man-of-war and sea nettle. Other species are widely distributed throughout the tropical and temperate waters of the globe (Table 116-1). Locations with documented deaths include the United States (Florida, North Carolina, Texas), Australia, the Indo-Pacific region (Malaysia, Langkawi Islands, Philippines, Solomon Islands, Papua New Guinea), and the coast of China. Since 1884 the estimated number of deaths in Australia attributed to *C. fleckeri* is approximately 70.[54,83] An estimated 2â€“3 deaths per year occur in Malaysia from an unknown species.[54] Approximately 20â€“40 deaths are reported yearly in the Philippines from an unidentified species of the *Chirodropidae* family.[54] Three deaths are well documented from *P. physalis* in the United States (Florida, North Carolina).[22,54,131] One death from *Chiropsalmus quadrumanus* occurred along the coast of Texas.[12] Eight fatalities in the Bohai waters of China (Yellow Sea) have been reported from *Stomolophus nomurai*.[54,151] Although *Chirodropidae* are found off the western coast of Africa, no fatalities in that region are documented.

Pathophysiology

Cnidaria venoms contain a variety of components that may induce dermanecrosis, myonecrosis, hemolysis, or cardiotoxicity,

depending on the particular species. In rats, *C. fleckeri* venom evokes transient blood pressure elevation, followed by hypotension and cardiovascular collapse within minutes.[107,109] Other effects in animals include decreased inotropy, cardiac conduction delay, ventricular tachycardia, and decreased coronary artery flow.[40] However, experiments using the most pure venom extracts without contamination from tentacle material demonstrate cardiovascular collapse without electrocardiographic changes.[109] *Chironex fleckeri* venom also possesses dermanecrotic and hemolytic fractions, although hemolysis in humans is not documented.[9] Two myotoxins from *C. fleckeri* cause powerful sustained muscle contractions in isolated muscle fibers.[44] Isolated heart models using *C. fleckeri* venom suggest its mechanism of action is nonspecific enhancement of cation conductance leading to increased Na^+ and Ca^{2+} entry into cells.[99] Other in vitro work confirms increased Na^+ permeability in cardiac tissue.[61]

Carukia barnesi, the Irukandji jelly, likely induces its dramatic vasopressor effects via catecholamine release. In rats the venom produces a pressor response that is blocked by $Î±_1$-adrenoreceptor antagonism.[108] The pressor response is not dose dependent; therefore, catecholamines in the venom would not explain this effect. No electrocardiographic abnormalities occurred in envenomated rats.

Venom from *Physalia* spp blocks neural impulses in isolated frog sciatic nerve[80] and produces ventricular ectopy, cardiovascular collapse, hyperkalemia, and hemolysis in dogs.[70] *Physalia* spp venom inhibits Ca^{2+} entry into the sarcoplasmic reticulum.[80] Similar mechanisms are proposed for *Chrysaora, Chiropsalmus*, and *Stomolophus. Chrysaora quinquecirrha* venom contains a 150-kDa polypeptide that induces atrioventricular block[18] and produces myocardial ischemia, hypertension, dysrhythmias, and nerve conduction block,[23,24] as well as hepatic and renal necrosis.[98] *Chrysaora quinquecirrha*â€“induced hepatotoxicity is believed to be a direct toxin effect not mediated by pore formation or Ca^{2+}

channel effects.[72] Equinatoxin II (EqtII), found in the venom of the anemone *Actinia equina*, induces pore formation in cell membranes, causing hemolysis.[1] This protein belongs to a group of anemone lysins, known as *actinoporins*, which bind to cell membranes and form pores via oligimerization.[88]

Symptoms resulting from stings may be partly immune mediated. Elevated serum antiâ€“sea-nettle immunoglobulin IgM, IgG, and IgE may persist for years in patients with exaggerated reactions to stings compared to controls.[19] A direct correlation between titers against *Chrysaora* and *Physalia* and severity of a visible skin reaction to envenomation, strongly suggests an allergic component.[120] Elevated IgG titers were demonstrated in one death from *P. physalis*.[131] Dermatonecrosis from *C. fleckeri* may involve the release of leukotrienes and other arachidonic acid derivatives and direct cell damage.[41] Postenvenomation syndromes may result from an exaggerated, prolonged, aberrant T-cell response.[25,26] Erythema nodosum has been reported following a sting from *P. physalis*, lending further support to a immunologic component to symptoms.[5] SBE displays a characteristic delay in onset of symptoms and can be effectively treated with steroids, suggesting a primary immune-mediated process for this entity. This is further supported by histopathology which shows the presence of perivascular and interstitial infiltrates with lymphocytes, neutrophils, and eosinophils.[148]

Clinical Manifestations

Most patients with stings are treated beachside and never require hospital treatment. The vast majority of patients with stings who seek medical care have severe pain, but are not systemically poisoned.[40] However, severe systemic manifestations may develop following stings from *C. fleckeri*, *C. barnesi*, *P. physalis*, and a few other *Cnidaria.*

Envenomation by *C. fleckeri* causes the most severe pain and is

frequently associated with systemic toxicity. Common symptoms include immediate severe pain, followed by an erythematous whiplike linear rash with a â€œfrosted ladderâ€• appearance. The pain often is excruciating and may require parenteral analgesia. Systemic symptoms include nausea, vomiting, muscle spasms, headache, malaise, fever, and chills. Pain generally abates over several hours, although the rash may persist for days. In a prospective series of *C. fleckeri* stings, 58% manifested delayed hypersensitivity reactions in the form of an itchy maculopapular rash at 7â€“14 days.[103] Most resolved spontaneously; some were treated with antihistamines and topical corticosteroids.

Some estimates cite a fatality rate following *C. fleckeri* envenomation of 15%â€“20%.[115] This likely represents a gross overestimation, given the low number of documented fatalities in the context of the extraordinary number of yearly stings. A prospective study of stings from *Cubozoa* over one year in Australia revealed no dysrhythmias, pulmonary edema, or death.[103] No patient received antivenom, and analgesia was the only pharmacotherapy implemented. Hospital admission was not required for any victim. Although most victims suffer only local severe pain, serious systemic toxicity occurs occasionally, and may include vertigo, ataxia, paralysis, delirium, syncope, and respiratory distress. Hypotension, dysrhythmia, pulmonary edema, hemolysis, and acute renal failure characterize the clinical findings. The last 10 reported deaths from *C. fleckeri* occurred in children, suggesting vulnerability due to lower body mass.[40] Fatality is documented following as little as 4 m of tentacle markings.[132] Death, when it occurs, typically is rapid leaving, many victims unable to reach shore. Cardiac arrest and pulmonary edema may develop in young healthy patients without prior cardiopulmonary disease.[76,87,147] Survival is possible with immediate cardiopulmonary resuscitation (CPR).[146] *Chiropsalmus quadrumanus*, a close relative of the box jellyfish, induces symptoms that parallel *C. fleckeri* stings, including pulmonary

edema and death.[12]

Irukandji syndrome is a particularly severe form of envenomation following *Cubozoa* stings. The causative species was isolated with brave self-experimentation by Dr. Jack Barnes using the *Cubomedusae* named *Carukia barnesi* in his honor. His conclusion that *C. barnesi* causes Irukandji was confirmed in a retrospective review of 50 cases, 39 of which had skin scrapings consistent with *C. barnesi*.[73] However, one patient who died had nematocysts that could not be identified, suggesting the possible existence of another causative species. This syndrome was thought to be isolated to Australia; however, three recent cases of Irukandjilike syndrome stemming from an unidentified organism were reported in the Florida Keys.[67]

Individuals afflicted with Irukandji syndrome often notice a mild sting while they are in the water; however, skin findings typically are absent. Severe systemic symptoms develop within 30 minutes and mimic a catecholamine surge: tachycardia, palpitations, hyperpnea, headache, pallor, restlessness, apprehension, sweating, and a sense of impending doom. A prominent feature is severe whole-body muscle spasms that come in waves and preferentially affect the back. Spasms are described as unbearable and frequently require parenteral analgesia. Symptoms generally abate over several hours. Admission rates in patients presenting to medical care can exceed 50%.[84] Hypertension is universal and may be severe, with systolic blood pressures well over 200 mm Hg. Two fatalities are described involving severe hypertension (systolic 280/150 mm Hg and 230/90 mm Hg) resulting in intracranial hemorrhage.[50,73] Hypotension frequently follows, requiring vasopressor support. Pulmonary edema results from myocardial dysfunction and is a potentially severe complication that can develop within 2 hours or be delayed several hours. Echocardiograms consistently reveal global ventricular dysfunction,[84,86,90] although focal hypokinesis may be present.[73]

Normal cardiac function typically returns after several days.[85] In a retrospective review of 116 cases presenting to Cairns Base Hospital, 22% of patients had elevated troponin I measurements,[73] although some reviews cite a frequency as high as 78%.[86] Nonspecific electrocardiographic changes were frequently noted in those reviews.

Physalia physalis envenomation typically causes severe pain, bullae, and skin necrosis (see ILJELLYFISH in the Image Library). Systemic symptoms include weakness, numbness, anxiety, headache, abdominal and back spasms, lacrimation, nasal discharge, diaphoresis, vertigo, hemolysis, cyanosis, renal failure, shock, and rarely death. Some patients experience local numbness and paralysis of the affected extremity that resolves spontaneously.[74] As with serious *C. fleckeri* stings, cardiovascular collapse and death occur within minutes of envenomation.[22] However, fatalities can be delayed several days following envenomation and may stem from complications such as myocardial infarction and aspiration pneumonia.[131] An unusual presentation is reported of a 4-year-old child who was stung along the North Carolina coast and developed massive hemolysis requiring red blood cell transfusions, followed by renal failure necessitating temporary dialysis.[68] In contrast to *P. physalis, P. utriculus* stings typically are mild and relieved with ice, although systemic toxicity occasionally develops.[56]

Millepora alcicornis (fire coral) is a common cause of stings in southern US and Caribbean waters. Although it belongs to the same phylogenetic class as *P. physalis*, it produces far less significant injuries. It is a nuisance to divers who touch what they perceive to be harmless coral and then suffer moderate burning pain for hours. Untreated pain generally lessens within 90 minutes, with skin wheals flattening at 24 hours and resolving within 1 week. Hyperpigmentation may persist up to 8 weeks.[15] The feather hydroid is the most numerous of the *Hydrozoa* and produces only mild stings.[92]

True jellyfish typically are less harmful to humans than *Cubozoa* or *Hydrozoa*. However, systemic toxicity and occasional deaths are reported from certain species such as *S. nomurai*, *C. capillata*, *C. quinquecirrha*, and *P. noctiluca*. *Stomolophus meleagris* is a common cause of stings; however, its weak venom produces only minor injury.[4]

Larvae of *Linuche unguiculata* are the primary cause of a pruritic papular eruption on the skin of sea bathers in Florida, occurring mostly in areas covered by a bathing suit as a result of larvae trapped under the garments. Cases were first noted in 1949 and referred to as SBE.[121] The larvae appear as pin-sized brown to green-brown spheres in the upper 2 inches of the water and typically go unnoticed. In a retrospective review, 50% of people reported a stinging sensation while they were in the water, and 25% reported itching upon exiting the water.[148] The remainder of patients developed symptoms within 11 hours. Skin lesions develop within hours of itching and appear as discrete, closely spaced papules, with pustules, vesicles, and urticaria. Most lesions occur in areas covered by the bathing suit; however, folds of skin such as the axilla, breasts, and neck may be affected. Itching often is severe and prevents sleep. New lesions may continue to develop over 72 hours. The average duration of symptoms is just under 2 weeks, and a small percentage of patients experience a recurrence of lesions several days later. Systemic symptoms such as chills, headache, nausea, vomiting, and malaise may occur. (See ILSEABATHERS in the Image Library.)

Following stings from sea anemones, victims may develop immediate or delayed pain. Skin findings range from mild erythema and itching to ulceration. A review of 55 stings from *Anemonia sulcata* presenting to a hospital in Yugoslavia (Adriatic Sea) revealed that, in addition to the local skin findings, many patients suffered nausea, vomiting, muscle aches, and dizziness.[89] Larvae of the anemone *Edwardsiella lineata* also cause SBE among

ocean swimmers in Long Island, New York. The hell's fire anemone *Actinodendron plumosum* is native to the South Pacific and causes significant local pain. One death occurred in the Virgin Islands following envenomation from an unknown species described as a â€œwhite anemone with blue tips.â€• The onset of hepatic and renal failure was rapid and required transplantation, after which the patient died.[63] Nonfatal elevation of hepatic enzyme concentrations following anemone sting also is reported.[16]

Diagnostic Testing

Laboratory evaluation may be warranted in patients suffering systemic toxicity following *Cnidaria* envenomation. Serial measurement of serum cardiac markers should be obtained from victims of Irukandji stings or others with consequential cardiovascular toxicity. Following severe stings from a variety of *Cnidaria*, urinalysis, hematocrit, and serum creatinine should be considered to detect the presence of hemolysis and subsequent renal injury. Chest radiography is indicated for complaints of dyspnea or abnormalities in oxygenation. Venom assays are not available, and serum antibody titers are not clinically useful.

Management

Initial interventions after *Cnidaria* envenomation should follow standard management strategies. Secondary measures are directed toward the prevention of further nematocyst discharge, which could intensify pain and enhance toxicity. Many topical agents have been used for this purpose, including

sea water, vinegar, Stingose, methylated spirits, ethanol, isopropyl alcohol, dilute ammonium hydroxide, urine, sodium bicarbonate, papain, shaving cream, and sand.

Vinegar is a common first-line treatment for topical application following *Cnidaria* stings. In vitro trials with *C. fleckeri* tentacles

demonstrate complete irreversible inhibition of nematocyst discharge following a 30-second application.[69] Additional study findings include massive nematocyst discharge with application of urine or ethanol, and no effect on discharge with use of sodium bicarbonate. Followup in vivo experiments demonstrate that vinegar is effective for other *Cubozoa*, including Morbakka (large *Cubozoan* in Australia),[49] *Carybdea rastoni*,[52] and *C. barnesi*.[53] Although massive nematocyst discharge occurs when vinegar is applied to *C. capillata* tentacles in vitro clinical exacerbation following this treatment is not reported in humans.[48] Massive discharge also occurs with *C. quinquecirrha*.[28] A smaller degree of discharge (30%) occurs with *P. physalis*,[56] whereas nematocysts of *P. utriculus* are unaffected by application of vinegar.[69]

Stingose is a commercially available product designed to counteract venom of insects, bees, stinging plants, and marine stingers. It is an aqueous solution of 20% aluminum sulfate and 1.1% surfactant. Its proposed mechanism of action is denaturing of proteins and long-chain polysaccharides via interaction with the Al^{3+} ion, as well as osmotic removal of venom. A human volunteer trial involving stings from live tentacles of *C. fleckeri* demonstrated pain relief within 5 seconds of Stingose application.[71] Similar results were achieved following treatment of stings from *C. quinquecirrha*. A field trial that included 17 *C. fleckeri* and 150 *P. utriculus* sting victims who were treated with Stingose immediately following injury was conducted. All victims reported rapid relief. However, placebo or alternative therapies were not used in this case series. The efficacy of treatment with vinegar, Stingose, methylated spirits, and salt water was measured in human volunteers following forearm application of *P. physalis* tentacles.[141] Vinegar demonstrated superior pain control compared to Stingose, whereas methylated spirits increased pain. The study assessed pain relief only and did not investigate the effects of the treatments on nematocyst discharge or systemic toxicity.

In many cases the identity of the â€œjellyfishâ€• causing injury is unknown. In those cases, therapy must be guided by geographic location. In the United States, where *P. physalis* and *C. quinquecirrha* are of greatest consequence, sea water should be used to aid in tentacle removal given that vinegar enhances nematocyst discharge. In the Indo-Pacific region, where *C. fleckeri* and *C. barnesi* are of greatest concern, vinegar should be the primary agent used. Following a 30-second application, adherent tentacles must be carefully removed. This can be accomplished with a gloved or towel-covered hand, or with sand and gentle scraping with a credit card or other blunt straight-edged tool.

In a nonrandomized trial, ice packs provided rapid effective relief for patients with mild-to-moderate pain from *Cnidaria* stings.[45] Patients with severe pain were less likely to benefit from ice packs. The venom of *C. fleckeri* and *C. quinquecirrha* is heat stable; therefore, hot water is ineffective for venom neutralization and may increase pain.[17]

Pressure immobilization bandaging is a technique that applies sufficient pressure to a wound to impede lymphatic drainage and prevent the entrance of toxin into systemic circulation. It typically has been used for snake bites, and its use following *Cnidaria* stings has sparked controversy. Given the rapid onset of symptoms, the utility of a technique that impedes lymphatic drainage is unlikely to provide benefit. Although the technique would be used only after tentacle removal, some microscopic nematocysts remain adherent to the skin after visible tentacle are removed. In vitro data investigating the effect of pressure on discharged nematocysts demonstrate not only that discharged nematocysts still contain venom, but that applying pressure forces more venom down the hollow tube.[105] This finding is correlated clinically as patients can deteriorate following pressure immobilization bandaging.[55] Given the lack of evidence suggesting benefit, coupled with clear, in vitro, evidence of increased venom delivery with this technique, it should not be used for treatment of

Cnidaria stings.

Box jellyfish antivenom is sheep-derived whole IgG raised against the â€œmilkedâ€• venom of *C. fleckeri.* It has been available in Australia since 1970. Combining *C. fleckeri* venom with box jellyfish antivenom prior to injection into pigs prevents all toxicity.[137] An isolated chick muscle experiment demonstrates that box jellyfish antivenom prevents the neurotoxicity and myotoxicity from *C. fleckeri* following pretreatment; however, there is no â€œrescue effect.â€•[106] Given that antivenom in humans is always used as a rescue therapy, this research raises concerns regarding efficacy in the clinical setting. Pretreatment of rats with box jellyfish antivenom prevented cardiovascular collapse in 40%, but did not blunt the initial hypertensive effect.[107] In vitro data demonstrate that box jellyfish antivenom neutralizes the dermonecrotic, hemolytic, and lethal fractions of venom from *Chiropsalmus* spp; however, the venom of *P. physalis* and *C. quinquecirrha* were not neutralized.[10] Other in vitro and in vivo data demonstrate incomplete neutralization of *Chiropsalmus* spp venom.[10,106]

There are no controlled studies in humans evaluating the efficacy of box jellyfish antivenom in the treatment of *C. fleckeri* envenomations, nor is there convincing evidence that its use has saved human lives. Despite the frequency of hospital visits for stings from *C. fleckeri* in Australia, the use of box jellyfish antivenom is rare.[40] Evidence for its efficacy stems from case reports suggesting that pain abates rapidly after administration.[14,147] Although box jellyfish antivenom may improve pain control, patients still may require parenteral narcotics for analgesia following antivenom administration.[11] Significant morbidity and mortality still occur despite antivenom use.[39,87,132] Case reports of box jellyfish antivenom use for *C. barnesi* stings demonstrate no apparent benefit.[47]

Many serious stings occur in the Northern Territory of Australia,

where stinger nets are not commonly used. Distance from medical care limits the ability to obtain antivenom in a timely fashion.[40] Although box jellyfish antivenom can be administered by paramedics via intramuscular (IM) injection,[55] poor IM absorption and incomplete venom neutralization with antivenoms, as well as delayed peak serum concentrations, limit the utility of this approach.[114] The amount of antivenom required to neutralize twice the lethal dose in humans, is estimated to be 12 vials.[40] The manufacturer recommends treating initially with 1 ampule intravenously (IV) diluted 1:10 with saline or 3 undiluted ampules (1.5â€“4 mL each) IM at 3 separate sites, if IV access is unavailable. Some authors who have treated multiple patients with antivenom suggest treating coma, dysrhythmia, or respiratory depression with 1 ampule IV, titrating up to 3 ampules with continuation of CPR in patients with refractory dysrhythmia until a total of 6 ampules have been administered.[103] For less serious envenomations, patients can be given 1 ampule if ice packs and parenteral analgesia prove ineffective.[103] Serious adverse events or delayed sequelae following the use of IV antivenom are uncommon, although allergic reactions are a consideration.[133]

Verapamil was considered a treatment for *C. fleckeri* stings based on evidence that calcium entry into cells is an important mechanism of toxicity. One animal model demonstrated synergy with use of verapamil in combination with box jellyfish antivenom,[27] whereas another showed verapamil pretreatment as well as rescue prolonged survival.[20] This is in contrast to other models demonstrating that verapamil negates the benefits of antivenom[107] and increases mortality.[137] Verapamil also has been tested in animals with *C. quinquecirrha* envenomation but demonstrated no benefit.[98] Interestingly, addition of magnesium to antivenom for treatment of *C. fleckeri* envenomation in rats prevented cardiovascular collapse in 100%, suggesting that magnesium may have a role in the treatment of stings from this

species.[107] Given that animal data are inconsistent with regard to verapamil and that hypotension may develop with severe envenomation, use of calcium channel blockers is not recommended for treatment of *C. fleckeri* stings.

Treatment for Irukandji syndrome should focus on analgesia and blood pressure control. Several modalities for control of severe hypertension have been suggested and include phentolamine, IV magnesium, and nitroglycerin.[38,51] No single therapy demonstrates superior efficacy, although titratable agents are preferred because hypotension may occur in later stages of toxicity.

Mollusca

The phylum *Mollusca* (Latin mollis = soft) includes the classes *Cephalopoda* (octopus, squid, and cuttlefish) and *Gastropoda* (cone snails). Of the cephalopods, only the blue-ringed octopus *Hapalochlaena maculosa* and the greater blue-ringed octopus *Hapalochlaena lunulata* are of toxicologic concern. Of the 400 species of cone snails that belong to the genus *Conus*, 18 are implicated in human envenomations.

History and Epidemiology

The blue-ringed octopus normally is yellow-brown in color, but it develops iridescent blue rings when it is threatened. It is not aggressive and only causes envenomation in humans when it is handled. A 1983 review of reported octopus envenomations uncovered a total of 14 cases, all of which occurred in Australia.[142] There were 2 deaths[60,130] and 4 serious envenomations. Other reviews suggest up to 7 deaths may have occurred prior to 1969, some outside Australia.[43] The blue-ringed and greater blue-ringed octopus are found in the Indo-Pacific region, primarily in Australian waters. (See ILBLUERING in the Image Library.)

Estimates of reported cone snail envenomations suggest only 15 deaths have occurred worldwide.[46] *Conus geographicus* (fish hunting cone) is the most common species implicated, although *Conus textile* may also cause death in humans. Cone snails are found predominantly in the Indo-Pacific, including all parts of Australia, New Guinea, Solomon Islands, and Philippines. Two deaths from *C. geographicus* occurred in Guam.[82]

Pathophysiology

The octopus salivary gland secretes a toxin that previously was called *maculotoxin.* The structure was later identified as tetrodotoxin.[125] The beak of the octopus creates small punctures in human skin through which venom is introduced. Tetrodotoxin blocks Na^+ conductance in neurons, leading to paralysis. Venom also contains 5-hydroxytryptamine (5-HT), hyaluronidase, tyramine, histamine, tryptamine, octopine, taurine, acetylcholine, and dopamine.[134] Rabbits subjected to bites develop rapid flaccid paralysis without cardiotoxicity and die from asphyxia.[134] Other animal models using venom gland extract demonstrate rapid onset of respiratory muscle paralysis and severe hypotension.[58] Death occurs despite artificial respiration and results from hypotension.

TABLE 116-2. Conus Peptide Targets

Receptor Type	Peptide	Mechanism
Ligand-gated ion channels		
Nicotinic	Î±-Conotoxin M1 M2	Competitive antagonism neuromuscular junction neuronal receptors

5-HT_3	Î±-Conotoxin	Noncompetitive antagonism
NMDA	Conantokins	Inhibits conductance
Voltage-gated ion channels		
Ca^{2+}	Ï‰-Conotoxin	Channel blockade
Na+	Âµ-Conotoxin	Channel blockade
	Î´-Conotoxin	Delayed channel activation
K+	Îº-Conotoxin	Channel blockade
G-protein linked		
Vasopressin receptor	Conopressin-G	Receptor agonism
Neurotensin receptor	Contulakin-G	Receptor agonism

Cone snails have a hollow proboscis that contains a tooth bathed in venom. Envenomation occurs when the shells are handled. The proboscis can extend the length of its shell, thereby envenomating

the hand of someone touching the opposite end of the shell. Any *Conus* species contains approximately 100 peptides or *conotoxins* in its venom. Targets include voltage- and ligand-gated ion channels as well as G-proteinâ€“linked receptors (Table 116-2).[102] Many of these peptides have been used extensively in laboratory research for their ability to selectively target a variety of specific calcium channel subtypes. *Conus imperialis* (worm hunter) has venom that contains a substantial amount of 5-HT, which is not found in any other *Conus* venom tested thus far.[94] This species also contains a vasopressinlike peptide.[100] *Conus* peptides with antinociceptive properties are being used in human trials of chronic pain. Ziconotide (Prialt, Elan Pharmaceuticals) has completed phase III human trials for control of chronic pain via intrathecal infusion pump.[93] Clinical trials with other peptides for treatment of chronic pain are underway.[136]

Clinical Manifestations

The blue-ringed octopus creates 1 or 2 puncture wounds with its chitinous jaws, causing only a small amount of discomfort. A wheal may develop with erythema, tenderness, and pruritus. Tetrodotoxin exerts a curareform effect that causes paralysis while retains normal mental status. Symptoms include perioral and intraoral paresthesias, diplopia, aphonia, dysphagia, ataxia, weakness, nausea, vomiting, flaccid muscle paralysis, respiratory failure, and death. Detailed case reports demonstrate rapid onset of symptoms.[142] Complete paralysis requiring intubation with findings of fixed and dilated pupils is followed within 24 to 48 hours by near-complete recovery of neuromuscular function.[142] In one reported death, a young man placed the octopus on his shoulder. He subsequently noted a small puncture wound, developed dry mouth, dyspnea, inability to swallow, and became apneic. He developed asystole 30 minutes after arrival at the hospital despite artificial ventilation.[60] Another similar bite resulted in symptom onset at 10 minutes, followed by

death at 90 minutes, despite bystander CPR.[134] With less severe envenomations, cerebellar signs may be present without paralysis. Near-total paralysis with intact mentation resolving over 24 hours is described in humans.[134]

Envenomation from cone snails occurs with careless handling or from rummaging through sand. Cone snails are nocturnal feeders, so they may present more of a hazard to night divers. Symptoms range from a slight sting to excruciating pain. Local symptoms include tissue ischemia, cyanosis, and numbness. Systemic symptoms include weakness, diaphoresis, diplopia, blurred vision, aphonia, dysphagia, generalized muscle paralysis, respiratory failure, cardiovascular collapse, and coma. Death is rapid and occurs within 2 hours. Based on military medical records of more than 30 cases predating 1970, the mortality rate approaches 25%, with *C. geographicus* being the most lethal.[82] Other estimates suggest that, without medical care, mortality may reach 70%.[150] Given the rarity of severe human envenomation from cone snails, it is unclear if death results purely from respiratory insufficiency, or if cardiovascular toxicity plays a significant role.

Diagnostic Testing

Laboratory testing following envenomation from octopi or cone snails should be directed by clinical findings. Coma, respiratory failure, and hypotension merit evaluation of serum metabolic parameters, chest radiography, and electrocardiogram. Tetrodotoxin can be detected in the urine or serum using high-performance liquid chromatography with subsequent fluorescence detection, but this assay is not readily available.[101]

Management

Primary interventions include, maintenance of airway, breathing, and circulation. Some authors recommend hot water

(45Â°â€“50Â°C, 113Â°â€“122Â°F) following cone snail stings for pain relief.[82] Unlike *Cnidaria* envenomations, where nematocysts full of venom can persist on the skin and lead to continued venom delivery, stings from the octopus and cone snail mirror those of snake bites, where venom delivery is an immediate and finite event. Therefore, pressure immobilization bandaging may help following octopus or cone stings by decreasing lymphatic spread of toxin without concern for worsening the envenomation.[46] Other measures include local wound care and tetanus prophylaxis. Antivenom is not available for octopus or cone snail venoms.

Echinodermata, Annelida, and Porifera

The *Echinodermata* phylum includes starfish, brittle stars, sea urchins, sand dollars, and sea cucumbers. *Annelida* are segmented worms that include the *Polychaetae* family of bristle worms. Sponges are classified in the *Porifera* phylum. One feature that all three phyla share is the passive envenomation of people who mistakenly handle or step on the animals. Most stings from these creatures are mild.

History and Epidemiology

Echinoderms, annelids, and sponges are ubiquitous ocean inhabitants. The crown-of-thorns starfish *Acanthaster planci* is found in the warmest waters of Polynesia to the Red Sea and is a particularly venomous species because of its sharp spines, which easily puncture human skin. Sea urchins are found in all oceans of the world. Bristle worms such as *Hermodice carunculata* typically are found in tropical waters such as those of Florida and the Caribbean. However, some species live in the frigid waters of Antarctica. The fire sponge *Tedania ignis* is a brilliant yellow-orange sponge found in large numbers in Hawaii and the Florida Keys. Other common American sponges are *Neofibularia nolitangere* (poison-bun sponge or touch-me-not sponge) and

Microciona prolifera (red sponge). *Neofibularia mordens* (Australian stinging sponge) is a common Southern Australian variety. In the Mediterranean, sponges are often colonized with sea anemones, which may be the cause of severe stings.[15]

Pathophysiology

Sea urchins are covered in spines and pedicellariae. The pedicellariae are pincerlike appendages used for feeding, cleaning, and defense. They generally contain more venom than the spines and are more difficult to remove from wounds. Urchins laden with pedicellariae can evoke more severe stings than urchins with less pedicellariae. Venom contained within the spines consists of steroid glycosides, 5-HT, hemolysin, protease, and acetylcholinelike substances. Some species harbor neurotoxins. The most venomous are species of *Diadema*, *Echinothrix*, and *Asthenosoma.* Starfish are less noxious because they generally have short, blunt spiny projections. The crown-of-thorns is the exception, with its longer sharp spines containing toxic saponins with hemolytic and anticoagulant effects as well as histaminelike substances.[135] Sea cucumbers excrete holothurin, a sulfated triterpenoid oligoglycoside, from the anus (organs of Cuvier) as a defense. The toxin inhibits neural conduction in fish, leading to paralysis. Some cucumbers eat *Cnidaria* and subsequently secrete their venom.

Bristle worms have many parapodia that have the appearance, but not the function, of legs. Several bristles extend from each parapodium, which gives the family *(Polychaeta)* its name (poly = many, chaetae = bristles). The bristles may penetrate human skin, leading to envenomation with an unknown substance.

Sponges have an elastic skeleton with spicules of silicon dioxide or calcium carbonate. They attach to the sea floor or coral beds. Toxins include halitoxin, odadaic acid, and subcritine, the nature of which is uncertain.[21] Dried sponges are nontoxic; however, on

rewetting they may cause toxicity even after several years.[129]

Clinical Manifestations

Most injuries from sea urchins are caused by inadvertently stepping on the spines or attempting to handle the animal. An intense burning with local tissue reaction occurs, including edema and erythema. Rarely, with multiple punctures, light-headedness, numbness, paralysis, bronchospasm, and hypotension may occur, although this is not documented in the medical literature.[3] Reports of death are not substantiated with evidence. The Pacific urchin *Tripneustes* has a neurotoxin with a predilection for cranial nerves.[15] Mild elevations of hepatic enzymes are reported in one patient with foot cellulitis from an urchin sting.[149] Small cuts on the skin from handling starfish may allow venom to penetrate, leading to contact dermatitis. The crown-of-thorns may cause severe pain, nausea, vomiting, and muscular paralysis.[92] Handling sea cucumbers leads to contact dermatitis, intense corneal inflammation, and even blindness. Bristle worms are covered in irritating bristles that can cause a reddened urticarial rash. Symptoms typically are mild and resolve over several hours to days.

Contact with the fire sponge, poison-bun sponge, or red-moss sponge causes erythema, papules, vesicles, and bullae, which generally subside within 3â€“7 days. Victims may develop fever, chills, and muscle cramps. Skin desquamation occurs at 10 days to 2 months,[4] with chronic skin changes lasting months.[21] Erythema multiforme and anaphylaxis are uncommon complications but may occur with *Neofibularia* spp.[15] Colonization of sponges with

Cnidaria can lead to dermatitis with skin necrosis, referred to as *sponge diver's disease.*

Management

The primary objective following envenomation from sea urchins and crown-of-thorns starfish is analgesia. Submersion of the affected extremity in hot water (105Â°Fâ€“115Â°F, 40.6Â°C â€“46.1Â°C) is commonly used and administration of oral analgesics generally are sufficient.[46,92] Puncture wounds require radiographic evaluation to locate potential foreign bodies. Spines frequently crumble when extraction is attempted. Intraarticular spines should be surgically removed. Decisions regarding spines in other locations should be influenced by ease of removal, presence of infection, and persistent pain. Tetanus prophylaxis should be addressed. Consideration of antibiotic prophylaxis should be based on degree of injury and patient factors such as diabetes or other immunocompromise. Although most infections likely are secondary to human skin flora, marine flora such as *Mycobacterium marinum* and *Vibrio parahaemolyticus* should be considered potential wound contaminants. Treatment of sponge exposures usually requires only removal of spicules using adhesive tape or the edge of a credit card. Use of antihistamines and topical steroids often provides no relief from stinging sponges.[21]

Vertebrates

Snakes

Sea snakes are members of the class *Reptilia* and are divided into 2 subfamilies: *Hydrophiinae* and *Laticaudinae*. They are close relatives of the cobra and krait. They are generally less than 1 m in length, have a flattened tail, and often are brightly colored. Distinction from eels is made by the presence of scales and the absence of fins and gills. There are 52 species of sea snakes, all of which are venomous. At least 6 species are implicated in human fatalities. The most common species cited in human envenomation is *Enhydrina schistosa*, the beaked sea snake. *Pelamis platurus*, the yellow-bellied sea snake, also is frequently implicated.

History and Epidemiology

The true incidence of sea snake envenomation is unknown because many bites go unreported. Worldwide the number of deaths per year may approach 150, with an overall mortality rate estimated at 3%.[46] In a review of 120 documented bites, 51.7% of victims were fisherman handling nets.[111] The remainder of victims were wading or swimming along the coast line. In another review of 101 bites occurring from 1957â€“1964 in North West Malaysia, more than 50% of bites were from the beaked sea snake, including 7 of the 8 fatal bites in that series, bringing the mortality to 8% prior to the availability of antivenom.[113] However, 31 â€œdry bitesâ€• were excluded, suggesting that the overall mortality is somewhat lower. Of the 20% of patients in that series suffering â€œserious envenomation,â€• half died despite supportive care.[113] A followup series of patients after the introduction of antivenom described 2 deaths out of 11 â€œserious envenomations,â€• suggesting a decreased mortality resulting from this intervention. These were all retrospective reviews of published or personally communicated cases, thereby limiting interpretation.

Sea snakes are common to the tropical and temperate Indian and Pacific Oceans, but also are found along the eastern Pacific Coast of Central and South America and the Gulf of California. In this eastern Pacific region, the yellow-bellied sea snake is the only species known. There are no sea snakes in the Atlantic Ocean. The majority of envenomations occur along the coasts of South East Asia, the Persian Gulf, and the Malay Archipelago (Malaysia). Snakes tend to inhabit the turbid coast lines and deeper reefs of these regions.

Pathophysiology

All sea snakes have small front fangs. Their venom is neurotoxic, myotoxic, nephrotoxic, and hemolytic. Known components of the venom include acetylcholinesterase, hyaluronidase, leucine

aminopeptidase, 5â€²-nucleotidase, phosphodiesterase, and phospholipase A. The neurotoxin is a highly stable 6000- to 8000-dalton protein similar to that of the cobra and krait. In mice, beaked sea snake venom is 4â€“5 times more potent than cobra venom based on a microgram/kilogram ratio; however, cobra venom yield is greater.[31] Venom homology exists across many species.[75] The neurotoxin acts postsynaptically via acetylcholine (ACh) receptor blockade at the neuromuscular junction and presynaptically causes initial release, followed by inhibition of ACh release.[97,116,143] In vitro cell research shows direct nephrotoxicity of crude venom, which may partially account for the nephrotoxicity seen clinically.[124] Renal failure likely is a combination of rhabdomyolysis and direct venom effects on the kidneys.

Clinical Manifestations

Sea snakes generally are docile, except when they are provoked, or during the mating season. Bites typically are painless or inflict minimal discomfort. Between 1 and 4 fang marks are common; however, up to 20 fang marks are possible as a result of multiple bites. The diagnosis can be obscured, because victims may not associate the slight prick following the bite with later onset of ascending paralysis. Symptom onset may occur within minutes, although a delay of up to 6 hours is possible. Although paralysis results from the neurotoxic fraction of the venom, muscle destruction stemming from myotoxic fractions causes painful, stiff muscle movements and myoglobinuria, which are hallmarks of sea snake myotoxicity. Myoglobinuria develops between 30 minutes and 8 hours after the bite. Other classic symptoms include ascending flaccid paralysis, dysphagia, trismus, ptosis, aphonia, nausea, vomiting, fasciculations, and ultimately respiratory insufficiency, seizures, and coma. Morbidity and mortality stem from respiratory paralysis, aspiration, rhabdomyolysis, and renal failure.

Diagnostic Testing

Laboratory diagnostics are directed toward identifying hemolysis, myonecrosis, hyperkalemia, and renal failure. Serum electrolytes, creatinine, and creatine phosphokinase, as well as hematocrit and urinalysis, should be obtained. Elevated concentrations of hepatic enzymes may indicate severe envenomation. Serial measurement of these parameters is recommended.

Management

Prehospital management of sea snake bites mirrors treatment of terrestrial snake bites and includes immobilization of the extremity and consideration of a pressure immobilization bandage to impede lymphatic drainage. Currently no data regarding the efficacy of this technique for sea snake envenomations are available. Tourniquets that impede venous or arterial flow are not recommended and may be detrimental. Airway and respiratory effort should be closely monitored because paralysis can develop rapidly.

The most commonly used antivenoms for sea snakes are equine IgG Fab fragments derived from the beaked sea snake (*E. schistosa*) or terrestrial tiger snake (*Notechis scutatus*) (Table 116-3). In vitro experiments demonstrate that sea snake antivenom is effective for neutralizing all species of sea snakes tested (*Praescutata*

viperina in Thailand, *Pelamis platurus* in Central America, *Laticauda semifasciata* in the Philippines, *Laticauda laticaudata* in Japan, *Hydrophis cyanocinctus*, *Lapemis hardwickii*).[140] Optimal neutralization occurs within the subfamily *Hydrophiinaem*, which contains *E. schistosa*; however, effective neutralization is demonstrated within the subfamily *Laticaudinae*. Terrestrial tiger snake antivenom also can neutralize sea snake venom in vitro. Based on the volume of antivenom required, tiger snake

antivenom was more effective for neutralization of all sea snake venoms tested except that of the beaked sea snake, for which sea snake antivenom was more effective.[7] This finding is expected because the beaked sea snake venom is the antigen used for producing sea snake antivenom. Based on units required, sea snake antivenom was more effective for all venoms tested. Another in vitro study comparing tiger snake and sea snake antivenom against venom *E. schistosa* demonstrated tiger snake antivenom was 10 times more effective in terms of milligram of venom neutralized per milliliter antivenom.[96] In the same study, the use of 17 different types of elapid antivenom resulted in poor neutralization of beaked sea snake venom.

TABLE 116-3. Antivenoms

Organism	Manufacturer	Derivation	Concentration
Box jellyfish			
C. fleckeri	CSL	Ovine, whole IgG	20,000 units/ampule
Sea snake			
E. schistosa (beaked sea snake)	CSL	Equine, IgG Fab	1000 units/ampule
N. scutatus	CSL	Equine, IgG Fab	3000 units/ampule

(terrestrial tiger snake)			
Stonefish			
S. trachynis	CSL	Equine, IgG Fab	2000 units/ampule
CSL = Commonwealth Serum Laboratories, Melbourne, Australia.			

In rescue experiments with mice using 11 different sea snake venoms and 4 different antivenoms (*E. schistosa*, *E. schistosa-N. scutatus*, *N. scutatus*, and polyvalent sea snake *Lapemis hardwickii, Laticauda semifasciata, Hydrophis cyanocinctus*), tiger snake antivenom was superior to all others with respect to volume amount required to prevent death.[8] The experiment compared effective dose 50 (ED_{50}) in milliliter amount of antivenom; however, the numbers of stated units per milliliter of antivenoms were not equivalent. One milliliter of tiger snake antivenom used in the experiments contained 380 units, which is 14 times the amount contained per milliliter of monovalent sea snake antivenom (27.3 units/mL). Another finding of the study was improved efficacy with early administration of antivenom.

No controlled human trials have evaluated the efficacy of sea snake antivenom, although case reports suggest improved outcomes and more rapid recovery with its use.[95,113] There are also well-documented cases of successful use of tiger snake antivenom.[2,62] Anecdotal experience in Malaysia using sea snake antivenom suggests slow recovery from myalgias and weakness over 48 hours, compared to resolution over 2 weeks without

antivenom (2 cases, 1 control).[112]

Based on in vitro and in vivo research, the optimal antivenom for treatment of sea snake bites is unclear. Both sea snake and tiger snake antivenom are effective in neutralizing a wide variety of sea snake venoms. Therefore, the most readily available antivenom should be used when needed. Commonwealth Serum Laboratories manufactures both monovalent sea snake and tiger snake antivenom for use in Australia. However, limited distribution to aquariums and zoos outside Australia does occur. The manufacturer's guidelines for use of monovalent sea snake antivenom recommend administration of 1 ampule (1,000 units) for systemic symptoms. However, because symptoms may be delayed and early administration is more likely to result in venom neutralization, any evidence of envenomation should prompt the administration of antivenom. The antivenom should be diluted 1:10 with 0.9% sodium chloride solution and administered IV over 30 minutes. A 1:5 dilution can be used for small children. Skin testing is not recommended. Epinephrine and antihistamines should be readily available. No upper limit is suggested for the number of vials to administer, although larger amounts are more likely to result in serum sickness. Patients have received up to 7000 units without adverse effect directly attributable to the antivenom.[95] One ampule (3000 units) of tiger snake antivenom can be used as an alternative, if sea snake antivenom is unavailable. Other treatments should focus on wound care, tetanus prophylaxis, analgesia, and fluid administration to minimize nephrotoxicity from myoglobinuria.

Fish

Stingrays are members of the class *Chondrichthyes* (Order *Rajiformes:* skates and rays). Families include *Dasyatidae* (whip ray or sting ray), *Urolophidae* (round ray), *Myliobatidae* (batfish or eagle ray), *Gymnuridae* (butterfly ray), and *Potamotrygonidae*

(river ray, freshwater). The order of toxicity is butterfly ray <eagle ray <stingray, and whip ray <round rays.[4]

The family *Scorpaenidae* is composed of a variety of venomous spiny fish (Table 116-4). Fish in the genus *Pterois* are commonly called *lionfish* (*P. volitans* and *P. lunulata*). Stonefish are grouped under the genus *Synanceja* and include *S. trachynis* (Australian estuarine stonefish), *S. horrida* (Indian stonefish), and *S. verrucosa* (reef stonefish). They are unattractively disguised to blend in with the rocky sea bottom. (See ILSTONEFISH1 and ILSTONEFISH2 in the Image Library.) Scorpionfish have a similar appearance and belong to the genus *Scorpaena* (eg, *S. guttata:* California sculpin). Other *Scorpaenidae* include *Notesthes robusta* (bullrout) and *Gymnapistes marmoratus* (cobbler). The European weeverfish causes toxicity similar to members of *Scorpaenidae* and is classified under the family *Trachinidae*. This includes *Trachinus vipera* (lesser weever) and *T. draco* (greater weever, aka adderpike, stingfish, seacat). These bottom dwellers are smaller and have fewer spines than *Scorpaenidae* and are much less ghoulish in appearance. Another cause of venomous fish stings is catfish. Although most live in freshwater, marine catfish such as *Plotosus lineatus* can cause human envenomation. Other venomous spiny fish include rabbitfish, stargazers, toadfish, ratfish, and even some sharks that have spines on their dorsal fins (Port Jackson shark, dogfish shark).

History and Epidemiology

Some estimates suggest 1500â€“2000 stingray injuries occur yearly in the United States. Most envenomations occur when the animal is inadvertently stepped on. In a review, a total of 17 fatalities resulting from trunk wounds, hemorrhage, or tetanus, were identified worldwide.[46] In a review of 603 cases of stingray injuries, only 2 deaths occurred, both as a result of intraabdominal trauma.[118] No deaths stemming solely from venom are recorded.

There are 11 different species of sting rays in

US costal waters (7 in the Atlantic, 4 in the Pacific). In the southeastern United States, *Dasyatis americana* is a common inhabitant. *Urolophus halleri* is the most common species on the western coast of the United States.

TABLE 116-4. Spiny Fish

Latin Name	Common Name	Habitat
Scorpaenidae family		
Pterois		
P. volitans	Lionfish (also zebrafish, turkeyfish, or red firefish)	Indo-Pacific region, coast of Florida to North Carolina (nonnative to US coast)
P. lunulata	Lionfish or butterfly cod	
Synanceja		
S. trachynis	Australian estuarine stonefish	Indo-Pacific region

S. horrida	Indian stonefish	
S. verrucosa	Reef stonefish	
Scorpaena		
S. cardinalis	Red rockcod, scorpionfish	Coast of Australia
S. guttata	California sculpin, scorpionfish	Coast of California
Notesthes robusta	Bullrout	Coast of Australia
Gymnapistes marmoratus	Cobbler	
Trachinidae family		
Trachinus		Coasts of Great Britain to Northwest Africa, throughout
T. vipera	Lesser weeverfish	Mediterranean and Black Seas

T. draco	Greater weeverfish (also adderpike, stingfish, or seacat)	

Three populations are at highest risk for spiny fish envenomation: fishermen sorting the catch from nets, waders, and aquarium enthusiasts. Only 5 deaths from *Scorpaenidae* have been reported; all resulted from stonefish and are poorly documented.[46] One death in 1915 occurred days after envenomation and likely resulted from infection.[37] No deaths from stonefish are reported in Australia, a country where they are commonly found in coastal waters.[40] The incidence of weeverfish stings is unknown, but they are a common occurrence in the summertime among Italian coastal towns.[30] A review of reported weeverfish stings between 1955 and 1962 identified approximately 12 cases per year resulting in â€œserious illness.â€•[127] Approximately 10 stings per year are reported in Denmark.[29]

Scorpaenidae are found throughout the tropical and temperate oceans. They exist as far north as the Gulf of Oman and Southern Japan and extend south beyond New Zealand. In the United States, *Scorpaenidae* stings occur in the Florida Keys, the Gulf of Mexico, off the coast of California, and Hawaii. Lionfish (genus *Pterois*) are common to home aquariums and account for most poison center calls involving spiny fish envenomation in the United States. The bullrout inhabits the eastern coast of Australia, along with the cobbler, which is found only in Australia. Weeverfish live in the shallow temperate waters with sandy or muddy bottoms in the eastern Atlantic and Mediterranean, including the European Coast extending to the southern tip of Norway. The marine catfish lives in the tropical Indo-Pacific waters.

Pathophysiology

Stingray tails possess tapered, bilaterally retroserrated spines covered by an integumentary sheath. The ventrolateral groove contains venom glands that saturate the spine with venom and mucus. The venom contains several amino acids, 5-HT, 5â€²-nucleotidase, and phosphodiesterase.[4] In animal models venom induces local vasoconstriction, bradydysrhythmias, atrioventricular nodal block, subendocardial ischemia, seizures, coma, cardiovascular collapse, and death.[3,118] A rabbit model demonstrates initial vasodilation followed by vasoconstriction and cardiac standstill suggesting a direct cardiac effect.[119] Wound specimens reveal necrotic muscle and neutrophilic infiltrates.[6] Other reports show central hemorrhagic necrosis with surrounding lymphoid and eosinophilic infiltrates indicating an immune-mediated cause of delayed wound healing.[65]

Scorpaenidae have 12â€“13 dorsal, 2 pelvic, and 3 anal spines that are covered with an integumentary sheath (see ILLIONFISH in the Image Library). Glands at the base contain 5 to 10 mg of venom each. Ornate pectoral fins are not venomous. Venom can remain stable for 24â€“48 hours after the fish dies.[91] Three main toxins have been isolated from various species of stonefish: stonustoxin (SNTX), verrucotoxin (VTX), and trachynilysin (TLY). SNTX, from *S. horrida*,[66] has 2 subunits, Î± and Î² (71,000 and 79,000 daltons, respectively). It induces formation of hydrophilic pores in cell membranes.[32] Toxicity in animals includes hemolysis, local edema, vascular permeability, platelet aggregation, endothelium-dependent vasodilation, and hypotension. Decreased myocardial contractility occurs in rabbits.[122] VTX, isolated from *S. verrucosa*, has homology to SNTX. It blocks cardiac Ca^{2+} channels.[64] TLY, isolated from *S. trachynis*, is a 159-kDa protein that forms pores in cell membranes. It allows Ca^{2+} entry and causes Ca^{2+}-dependent release of ACh from nerve endings at motor endplates and increased catecholamine release.[79,104,123]

Synanceja trachynis venom causes endothelium-dependent vasodilation and cardiovascular collapse in rats, which appears to be mediated by muscarinic and adrenergic receptors.[33] Hemolysis is demonstrated in animals but does not occur in human erythrocytes.[78] Other venoms of *Scorpaenidae* include hyaluronidase, proteinase, phosphodiesterase, alkaline phosphomonoesterase, arginine esterase, arginine amidinase, 5â€²-nucleotidase, acetylcholinesterase, and biogenic amines. Crude venom from *G. marmoratus*, *P. volitans*, and *S. trachynis* leads to increased intracellular Ca^{2+} and muscle contracture in vivo.[36] Toxins from other spiny fish include dracotoxin (*T. draco*), trachinine (*T. vipera*), and nocitoxin (*N. robusta*).[35] Effects mirror those of *Scorpaenidae* toxins.[126]

Clinical Manifestations

Stepping on the body of a stingray causes a reflexive whip of the tail leading to wounds in the lower extremity. Intense pain out of proportion to the appearance of the wound is characteristic. Symptoms peak 30â€“90 minutes after injury and may persist for 48 hours. Local edema, cyanosis, erythema, and petechiae may follow rapidly and may lead to necrosis and ulceration. Systemic symptoms include weakness, nausea, vomiting, diarrhea, vertigo, headache, syncope, seizures, muscle cramps, fasciculations, hypotension, and dysrhythmias. Chest and abdominal wounds, as well as tetanus, have caused death.[57,110,118]

Stings from stonefish produce immediate severe pain with rapid wound cyanosis and edema that may progress up the injured extremity. Pain reaches a maximum after 30â€“90 minutes and usually resolves over 6â€“12 hours, although pain may persist for days. Wound healing may require months. Systemic symptoms following stonefish envenomation may include headache, vomiting, abdominal pain, delirium, seizures, limb paralysis, hypertension,

respiratory distress, dysrhythmia, congestive heart failure, and hypotension. In one case report, a healthy male received 6 punctures to the foot and developed rapid pulmonary edema requiring intubation.[81] The patient received 3 ampules of stonefish antivenom and recovered in 24 hours.

A Poison Control Center (PCC) case series from 1979â€“1988 identified 23 cases of *P. volitans* envenomation.[139] Reported symptoms included pain, swelling, nausea, numbness, joint pain, anxiety, headache, dizziness, and cellulitis. Another PCC series identified 51 *Scorpaenidae* stings (45 *P. pterois*, 6 *S. guttata*).[77] Intense pain was reported in 98%, extension of pain to the limb in 22%, swelling in 58%, and systemic signs (nausea, diaphoresis, dyspnea, chest pain, abdominal pain, weakness, hypotension, and syncope) in 13%. Thirteen percent of patients in the series developed wound infection; one patient's wound healing was delayed several weeks. Stings from weeverfish are similar to *Scorpaenidae* envenomation. One fatal sting occurred on the coast of Spain.[13] The victim developed syncope and cardiopulmonary arrest within 1 hour of envenomation. Autopsy revealed the puncture wound traversed the greater saphenous vein, suggesting direct IV injection of venom. Catfish stings invoke injuries similar to those of other stinging fish.[42]

Management

Wounds caused by stingrays and spiny fish should be carefully examined for imbedded foreign material. Radiographs may uncover occult spines left behind in the wound. Sting ray wounds can be extensive and require surgical attention for vascular or tendonous disruption. Tetanus prophylaxis should be addressed. As discussed for sea urchin stings, treatment with antibiotics may be appropriate for some injuries. Heating stonefish venom to 122Â°F (50Â°C) for 5 minutes prevents wound necrosis and hypotensive effects in animal models.[144] In a series of 51 stings from *P.*

pterois and *S. guttata*, 80% of patients had complete relief with hot water.[77] Success with using hot water also is reported with weeverfish stings.[117] In a human volunteer study in which subjects received a subcutaneous injection of stingray venom, severe pain developed immediately, and was alleviated with water heated to 122Â°F (50Â°C).[118] Pain increased with application of cold water. If relief is not sufficient, local lidocaine injection can alleviate pain.[57] Oral or parenteral analgesia may be required.

Stonefish antivenom is equine-derived IgG Fab fragment and is raised against the venom of *S. trachynis*. Each ampule contains 2000 units and neutralizes 20 mg venom. Between 1965 and 1981, antivenom was used in at least 267 cases.[40] Anecdotal reports suggest it provides effective relief from pain.[40,145] In a review of 26 documented cases in Australia where antivenom was administered IM, no acute adverse effects were identified.[133] Eight patients required 2 ampules. Two of 15 patients who had followup visits suffered serum sickness. Rash may develop several days postinjection.[145] In vitro and in vivo research with the antivenom demonstrates neutralization of venom from *G. marmoratus*[34] and *P. volitans*;[35] however, the application for human therapy is untested.

The manufacturer recommends IM administration, although IV administration may be considered. Administration is indicated for systemic toxicity or pain not controlled with hot water and other analgesics. Dosing is guided by the number of puncture wounds sustained: 1 vial for 1â€“2 punctures, 2 vials for 3â€“4 punctures, and 3 vials for 5 or more punctures. Epinephrine and diphenhydramine should be readily available for treatment of anaphylactic reactions.

Summary

Fatalities from marine envenomations are rare. However, significant morbidity may result from bites and stings, including

severe pain, retained foreign bodies, infection, respiratory compromise, hypotension, and cardiac dysrhythmias. Interventions should focus on patient comfort and recognition of potential complications. A thorough understanding of the mechanisms of toxicity and expected clinical course following envenomations from marine creatures will provide clinicians with the ability to manage these injuries effectively.

Edward J. Otten

Case 1 A 25-year-old man exploring the mountains of Virginia was bitten toe by an unidentified snake when he was rock climbing in bare feet. He hear a rattle and only caught a glimpse of a copper-colored snake as it c away. Within 10 minutes he noted mild swelling and discomfort around a puncture wound on the top of the fourth toe.

Within 1 hour the man developed moderate throbbing pain in the entire f associated with paresthesias. At 2 hours a hemorrhagic blister developed bite site. The swelling had progressed to the dorsum of the ankle, but he systemic symptoms. A friend drove him to a local hospital. No specific firs was administered. The swelling did not progress past the ankle, and the did not report nausea, vomiting, diaphoresis, dizziness, or systemic weak The vital signs, complete blood cell count, and coagulation profile were r The patient reported only mild pain of the foot.

Because of progression of local symptoms and lack of definitive identifica the snake, the patient was admitted to the hospital. Antivenom was obta but not administered. The patient had moderate pain and stiffness of his Edema reached the lower leg at 24 hours but did not progress further. No systemic symptoms developed, and the laboratory profile remained norm Minor surgical debridement of a small area of skin slough on the toe was required. The patient was discharged after 48 hours to continue extremity elevation, and outpatient physical therapy was arranged. After 10 days of progressive decrease in swelling, the patient had full use of the foot with minor stiffness. Within 3 weeks, the stiffness had disappeared completely

Case 2 A 40-year-old utility worker was bitten on the right hand by a sna while he was working on an electrical box. He had immediate onset of pai the bite site. Coworkers who were familiar with snakes native to the area identified the snake as a western diamondback rattlesnake (*Crotalus atro* intravenous line was established and fluids administered en route to the hospital.

The patient arrived to the emergency department approximately 45 minu after the bite. He complained of worsening pain in his right arm, nausea, dizziness. His presenting vital signs were: blood pressure, 90/45 mm Hg; 118 beats/min; respiratory rate, 24 breaths/min; temperature 97Â°F (36 Two puncture wounds were identified on his right thumb, as were surrou ecchymosis and a small amount of blood oozing from the wounds. Swellin extended from his right hand to just beyond his elbow, and his forearm compartments were soft. No other bleeding was noted, and the remainder physical examination was unremarkable.

A second large-bore intravenous line was placed, and 0.9% sodium chlori solution administered while the patient's blood was sent for analysis. The pharmacy was asked to prepare 6 vials of crotalidae polyvalent immune F (ovine) in 250 mL 0.9% sodium chloride solution. In the meantime, the right arm was splinted in near-complete extension and elevated above the of his heart. While awaiting the reconstituted antivenom, the patient's blo work returned: hemoglobin, 15.1 mg/dL; platelets 90,000/mm^3 ; prothro time, >100 seconds; fibrinogen, 55 Âµg/mL. Following administration of 3

0.9% NaCl, the patient's systolic blood pressure increased to 110 mm Hg his pulse decreased to 95 beats/min. Intravenous fentanyl was given for infusion of 6 vials of crotalidae polyvalent immune Fab (ovine) was initia

After a dose of 6 vials of antivenom was administered, local tissue injury reassessed and repeat laboratory studies obtained. Despite elevation of t arm, the patient developed increased swelling in his hand that progressed shoulder. Repeat blood work demonstrated hemoglobin, 13.2 mg/dL; pla 76,000/mm^3 ; prothrombin time, >100 seconds; fibrinogen, 55 Âµg/mL. dose of 6 vials of antivenom was administered based on worsening labora results and local swelling. At the conclusion of the second dose of antiver the upper extremity swelling, while not resolved, did not appear to be progressing further. Results of hematologic studies performed at the con of the second antivenom dose were improved from the previous results: platelets, 100,000/mm^3 ; prothrombin time, 45 seconds; fibrinogen, 105 Âµg/mL.

The patient was admitted to the intensive care unit, where maintenance infusions of crotalidae polyvalent immune Fab (ovine) were initiated at 2 every 6 hours for a total of 3 additional doses. Hourly measurements of l forearm, and arm circumferences during crotalidae polyvalent immune Fa (ovine) maintenance infusions were unchanged. After all antivenom doses administered, the patient's pain was controlled with oral analgesics. His f laboratory findings were hemoglobin, 13.5 mg/dL; platelets, 175,000/mm prothrombin time, 12 seconds; fibrinogen 240 Âµg/mL. After a 48-hour h stay, he was discharged home with analgesics and strict instructions to a any activity that could result in trauma for 3 weeks. He was informed tha coagulopathy and thrombocytopenia could recur despite the treatment wi antivenom.

At follow-up examination 48 hours after hospital discharge, the patient's swelling had increased slightly, but he stated that he had not kept the ha adequately elevated. He was feeling well but had not returned to work be of the inability to use his dominant hand. Repeat blood work demonstrate platelet count, 100,000/mm^3 ; prothrombin time, 25.2 seconds; fibrinoge

concentration, 75 Âµg/mL. He was reminded that he was at risk for bleed told to return for repeat laboratory studies in 48 hours.

The patient was reevaluated every 2â€“3 days with repeat hematologic s Multiple laboratory studies over the subsequent week demonstrated a sta thrombocytopenia and coagulopathy. Tissue swelling continued to decreas hematologic parameters normalized 2 weeks after the envenomation. The patient had no bleeding episodes or other ill effects.

Epidemiology

Incidence of Venomous Snakebites in the United States

Venomous snakes are found throughout the United States, except Maine, and Hawaii. They are common in the Appalachian states, the south, and t west; they are rare in New England and the northern states. Approximate 6000 to 8000 venomous snakebites occur per year, and many thousands snakebites occur from nonvenomous species. Mortality from snakebites is considered rare in the United States; estimates range from 5â€“15 deaths year.[32 , 51] Exact statistics are lacking, but mortality rates can be signifi higher in other countries. As many as 27,000 rattlesnake bites and 100 occur per year in Mexico,[15] and thousands of deaths per year occur in so developing countries in Asia and Africa.

Because snakes hibernate in the winter, most bites in the United States o between May and October. Snakes may bite at night, but the most comm for envenomation is between 2 and 6 PM.[81] Coral snakes are particularly for their nocturnal habits. The majority of bites occur to the extremities, bites to the face and tongue occur when snakes are purposefully held nea body. The striking range of a snake is approximately half its length.

Children, intoxicated individuals (mostly men), snake handlers, and colle are frequent victims. More than half of the reported bites occur while the individual is purposely handling a known venomous snake. There is a sig market for many illegal and dangerous reptiles, and a surprising number

individuals keep and sell venomous snakes as pets. Many specimens are and highly toxic species from other countries. Some religious groups in th and southeastern states handle poisonous snakes (usually rattlesnakes) a routine ceremonial practice, and envenomation is common.

Identification of a Venomous Snake

There are 120 species of snakes native to North America, including approximately 30 venomous species (Table 117-1). Most of these venom snakes are members of the family Viperidae (subfamily Crotalinae), which include the rattlesnakes (*Crotalus and Sistrurus*) and the copperheads ar water moccasins (*Agkistrodon*) (see ILAGKISTRODONCONTOTRIX1 and ILCROTALUSATROX in the Image Library at http://www.goldfrankstoxicology.com). Snakes of the subfamily Crotalina also called *pit vipers* because of the presence of a pitlike depression of th behind the nostril that contains a heat-sensing organ. The other family of venomous snakes native to the United States is the Elapidae, which inclu coral snakes. The vast majority of venomous snakebites in the United Sta from pit vipers, with approximately 60% of bites from rattlesnakes and th remainder from copperheads and water moccasins.[74] Fewer than 1% of venomous bites are from the docile coral snake.[61 , 69]

Crotalinae (Pit Vipers)
Rattlesnakes

Scientific Name Common Name

TABLE 117-1. Scientific and Common Names of Medically Impor
Venomous Snakes of North America

Pit Vipers

The venomous Crotalinae in the United States have a triangular-shaped h vertically elliptical pupils, and easily identifiable fangs (Figure 117-1). Th fangs are paired, needlelike structures that inject venom and can retract hingelike mechanism into the roof of the mouth. Rattlesnakes have the lo fangs, reaching 3 to 4 cm. In addition to fangs, venomous snakes have ro small teeth. An adult snake usually has 2 fangs, but the fangs may be sin multiple. The undersurface of pit vipers has a single row of plates or scal opposed to the double row found on nonvenomous varieties. Depending o maturity, rattlesnakes may or may not have rattles, which occasionally a heard before a strike. Water moccasins are semiaquatic and have a distin white mouth suggesting their common name (cottonmouths). They repor are quite aggressive and capable of underwater bites. Copperheads are k for their reddish-brown (copper) heads and hourglass markings on their

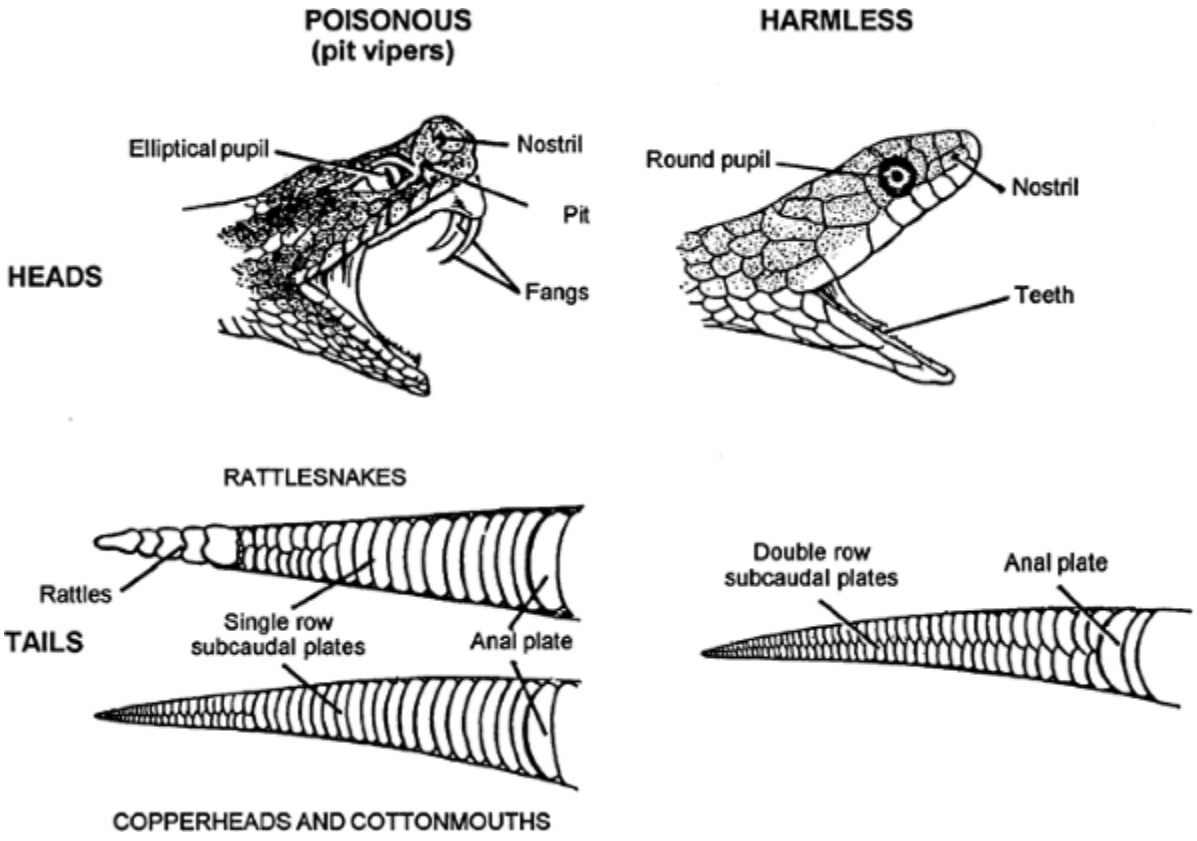

Figure 117-1. Features of pit vipers and harmless snakes. (Modified and reprinted with permission from Parrish HM, Carr CA: Bites by copperheads United States. JAMA 1967;8:201:927.)

Elapidae

The coral snakes (*Micruroides* and *Micrurus* spp) are the brightly colored Elapids, which have easily identifiable red, yellow, and black bands along length of their body. Coral snakes and the similarly colored nonpoisonous scarlet king snake often are confused. In a report of 39 victims of coral s bites, 9 patients were envenomated because they erroneously believed th were dealing with the nonpoisonous scarlet king snake.[48] The coral and k snakes can be distinguished by the spacing of their colored rings and the of the head. Coral snakes have black snouts, whereas king snakes have r snouts. Both species have red, yellow, and black rings, but in different

sequences. The red and yellow rings touch in the coral snake but are sep by black rings in king snakes (â€œRed on yellow kills a fellow, red on bla venom lackâ€•).

The fangs of coral snakes are much smaller (1â€“3 mm) than those of the rattlesnakes, and discrete fang marks may not be obvious after envenom Coral snakes appear to have the curious propensity of hanging onto a vic â€œchewingâ€• for a few seconds, and a history of this activity may hel identify a coral snakebite when the offending reptile cannot be located. Removing a coral snake from the skin has been likened to separating piec hook and loop closure (Velcro).

Exact identification of a snake often is not possible unless the victim brin offending reptile to the hospital. This usually is impossible and poses an additional threat to the victim or prehospital personnel and is discourage Because of the excitement generated by the bite, the victim's identificatio the snake may not be accurate. Identifying a snake by its color or markin difficult for the novice. Knowledge of the indigenous venomous snakes oft helpful to medical personnel. Snake handlers and owners of pet snakes u know the exact species responsible for their bite, but some are reluctant specific information out of fear of prosecution or confiscation of the illega by authorities.

Characteristics of a Venomous Snakebite

The severity and clinical manifestations of envenomation depend on a nur factors, including number of strikes, depth of envenomation, size of the s potency and amount of venom injected, size and underlying health of the and location of the bite (Figure 117-2).[52, 64] Larger snakes generally in more venom, but the potency is species variable. Children and small adul well as those with underlying medical conditions (diabetes, cardiovascula disease) may be more seriously affected by envenomation.[62] Envenomati usually occurs in subcutaneous tissues and less commonly in muscle. Sys absorption occurs via lymphatic and venous drainage of the envenomated Intravenous envenomation may occur and result in the rapid development life-threatening complications.[22] Airway obstruction necessitating trachea

intubation has been reported after a rattlesnake bite to the face and tong
Individuals may be envenomated by rattlesnakes thought to be dead, ever

60 minutes after decapitation, because of persistent reflexes in the venor
apparatus.[75]

Pit vipers produce a characteristic bite when they strike, and distinct fang usually can be identified (see ILDIAMONDBACK1 in the Image Library at http://www.goldfrankstoxicology.com). The small delicate fangs of coral may not produce easily identifiable fang marks. Fang marks may be singl double, and occasionally multiple. Although most snakes have two fangs, exact number of fang marks may vary because of glancing blows and/or strikes. Protection by clothing or shoes can alter these findings. The bites rodents, lizards, and even thorn or cactus injuries can be misdiagnosed a poisonous snakebites.

Pharmacology of Venom

It is difficult to attribute specific pathology or pathophysiology to particu components of snake venom. Crotaline venom is a complex heterogeneou solution and suspension of various proteins, peptides, lipids, carbohydrate enzymes, including ribonuclease and deoxyribonuclease, kinins, leukotrie histamine, phospholipase, serotonin, hyaluronidase, acetylcholinesterase, collagenase, and metallic ions.[44 , 45] It has been referred to as a â€œmo antigens.â€• Numerous unidentified proteolytic enzymes, procoagulants anticoagulants, cardiotoxins, hemotoxins, and neurotoxins abound in cro venom, making it very complex to analyze.

Crotalinae venom can simultaneously damage tissue directly, affect blood vessels and cellular elements of blood, and alter the myoneural junction nerve transmission. Toxic components of snake venom exhibit their patho varying times, and some of the variation in clinical manifestations of envenomation result not only from the specific properties of the venom b differences in absorption rates and ability to permeate membranes and t In addition, the content and potency of venom in any given snake vary w

size, age, diet, climate, time of year, and possible cross-breeding among different species. Venom is present in the circulation and fixed to tissues Circulating venom is more readily neutralized by antivenom, whereas the of tissue-fixed venom are more difficult to counteract. This may partly ex the clinical observation that antivenom corrects systemic dysfunction and coagulopathy but does little to reverse local pathology. Antivenom may h progression of further edema, hemorrhage, and soft-tissue swelling, but these conditions are present, antivenom likely will not rapidly reverse pa at the site of envenomation.

Coral snake venom consists of a number of unidentified neurotoxins with curarelike effects that produce systemic neurotoxicity, as opposed to loca tissue injury.

Pathophysiology and Clinical Manifestation

Crotaline Envenomation

Local Reactions

Crotaline (pit viper) venom usually is injected only into the subcutaneous although deeper, intramuscular (subfascial) envenomation rarely occur. N every bite from a venomous snake results in release of venom into the v so-called â€œdry bitesâ€• occur in up to 20% of strikes.[49] Repeat strikes result in additional envenomation because the snake's entire supply of ve usually was not exhausted with the first attack. Approximately 25â€“75% stored venom is discharged following a rattlesnake bite, and the entire su replenished in 3â€“4 weeks.[69]

Symptoms may range from mild to severe, but the initial benign presenta a pit viper bite may be very misleading[43] (Table 117-2). Generally, withi minutes after significant envenomation from a pit viper, the area around bite becomes swollen and painful. Within minutes to hours, ecchymosis, blistering, and signs of tissue necrosis may be evident both proximal and

to the bite. The patient may describe paresthesias or other neurologic symptoms around the bite. Edema may progress to involve an entire extr within a few hours, and systemic symptoms may develop. The local reacti pit viper envenomation results from altered blood vessel permeability and necrosis of the tissue caused by the venom. Additional tissue damage can from the effects of ischemia, swelling, and rarely secondary infection. In addition to local myonecrosis, generalized severe rhabdomyolysis may occ the absence of impressive muscular swelling. This finding is considered characteristic following envenomation of the canebrake rattlesnake (*Crota horridus atricaudatus*) found in the Gulf Atlantic states.[12] (See ILMASSASAUGA1, ILMASSASAUGA2, and ILRATTLER1 in the Image Librar

Compared with the venom of rattlesnakes, the venom of water moccasins (cottonmouths) produces less severe local and systemic pathology, and envenomation from copperheads tends to be less severe than that of eith rattlesnakes or water moccasins. Although the soft-tissue swelling from a copperhead bite may be significant, envenomation from this snake usually not cause coagulopathy, systemic symptoms, or extensive tissue destruc Copperhead envenomation often results in only minimal edema and pain usually requires only conservative local treatment.[80] (See ILCOPPERHEAD and ILCOPPERHEADTOE in the Image Library). Lethality is so rare that it considered reportable.

TABLE 117-2. Evaluation and Treatment of Crotaline Envenomatio

Envenomation is a dynamic and ever-changing process that can rapidly o

unpredictably progress to serious local or systemic involvement. The full of envenomation may not become evident for a number of hours. On rare occasions symptoms appear to be resolving, only to return minutes to ho later with greater intensity. If local symptomatology initially is ameliorate arrested by antivenom therapy, the swelling may recur when antivenom concentrations drop hours later. As a general rule, however, it may be as that envenomation from a North American pit viper has not occurred (dry if no symptoms develop within 8â€“12 hours from the time of the bite.

Systemic Signs

Most bites from pit vipers that occur on the extremities are limited to loca regional pathology; however, systemic symptoms and life-threatening to may develop. When venom is injected subcutaneously, it travels by lymp and superficial venous channels and spreads slowly to the general circula Generally, subcutaneous envenomation produces systemic symptoms withi number of hours, but this timetable is variable. Occasionally, symptoms rapidly even with subcutaneous envenomation. Intravascular envenomati produces significant systemic symptoms in minutes.[22] Direct intravenous envenomation probably is rare, but this occurrence, in addition to the un case of overt anaphylaxis, may account for the majority of fatalities. Rar respiratory compromise from airway obstruction or bronchospasm is a dir consequence of crotaline envenomation.[28]

Systemic signs of pit viper envenomation vary, and some symptoms resul fear, pain, or anxiety alone. In mild cases, the patient may manifest non weakness, malaise, nausea, and restlessness. More severe envenomation produces confusion, abdominal pain, vomiting, diarrhea, sweating, dyspn tachycardia, hypotension, blurred vision, salivation, and a metallic taste i

mouth. Rarely, patients exhibit disseminated intravascular coagulation (D with spontaneous bleeding, significant hypotension, and multiorgan syste failure.[18 , 29] Although crotaline venom may be directly nephrotoxic, rena failure probably is secondary to hemoglobinuria, myoglobinuria, or cardiovascular collapse.

Local tissue destruction dominates Crotalinae envenomations, but neurot effects also occur with certain species of snakes. The Mojave rattlesnake (*Crotalus scutulatus scutulatus*) produces the neurotoxic Mojave toxin, w can cause lethargy, cranial nerve dysfunction, and respiratory paralysis.[4] acts at presynaptic terminals of the neuromuscular junction by inhibiting acetylcholine release. Mojave toxin is formed by a heterodimer protein composed of an acidic subunit and a basic subunit, both of which are req for a functional neurotoxin. Interestingly, production of Mojave toxin appe be geographically distributed. A western population in California produces functional Mojave toxin A with neurotoxic effects, but little or no tissue destruction. More eastern populations lack the acidic subunit and do not functional Mojave toxin, but do express metalloproteases that lead to tiss necrosis. Mojave rattlesnakes in an intergrade zone (Arizona and New Me between these two populations produce both neurotoxic and tissue destr toxins.[30 , 83] Bites from Mojave rattlesnakes in this zone often look ident bites from other local rattlesnake species, with local tissue effects and hematologic toxicity, but an absence of clinical neurotoxicity. Mojave toxi also been found in the venom of the Southern Pacific rattlesnake (*Crotalu halleri*) found in southern California, with envenomations leading to neu symptoms.[13 , 26] The Timber rattlesnake (*Crotalus horridus horridus*) commonly causes myokymia, particularly of the facial muscles.[7 , 53] Crot a neurotoxic protein found in the venom of the South American rattlesnal (*Crotalus durissus terrificus*), typically produces analgesia at the bite loc and possesses potent opioid activity.[6]

Hematologic

Significant crotaline envenomation may produce complex and dramatic hematologic abnormalities secondary to the effects of the venom on the coagulation pathways, endothelial cells, and platelets[3 , 9 , 68 , 73] (Figure). An initial drop in fibrinogen concentrations (to near zero) and platelet (in the 10,000â€“50,000/mm^3 range), in addition to immeasurably high prothrombin time (PT) and partial thromboplastin time (PTT), frequently after moderate-to-severe crotaline envenomation. Regardless of which sr caused the envenomation, the majority of patients have no clinical bleedi

even with severe coagulopathies and thrombocytopenias. A routine coagu profile and platelet count should be obtained following envenomation by a crotaline and repeated in 4â€“6 hours. Significant coagulopathy and/or thrombocytopenia may be present, but other systemic effects may be spa Coagulopathy is attributed to a complex variety of anticoagulants, procoagulants, fibrinolysin, and hemorrhagins in crotaline venom (Table). Some portions of snake venom may actually have therapeutic uses as anticoagulants or platelet receptor (GPIIb-IIIa) antagonists. Overall, crot venom has a thrombinlike effect, but specific hematologic effects are spe dependent. No single venom contains all of the identified hemostatically components. Thrombocytopenia (<150,000/mm^3) is a common finding f envenomation from most species of rattlesnakes and can occur in the abs elevated PT or PTT.[3] Thrombocytopenia appears to be especially common, often severe, following the bite of the timber rattlesnake (*Crotalus horrid horridus*), which inhabits the Appalachian mountains of the eastern Unite States.[3] The protein crotalocytin, which is found in timber rattlesnake ve causes platelet aggregation and is thought to be at least partially respon for thrombocytopenia. Following the trends in laboratory parameters is an important way to assess the progression or reversal of envenomation.

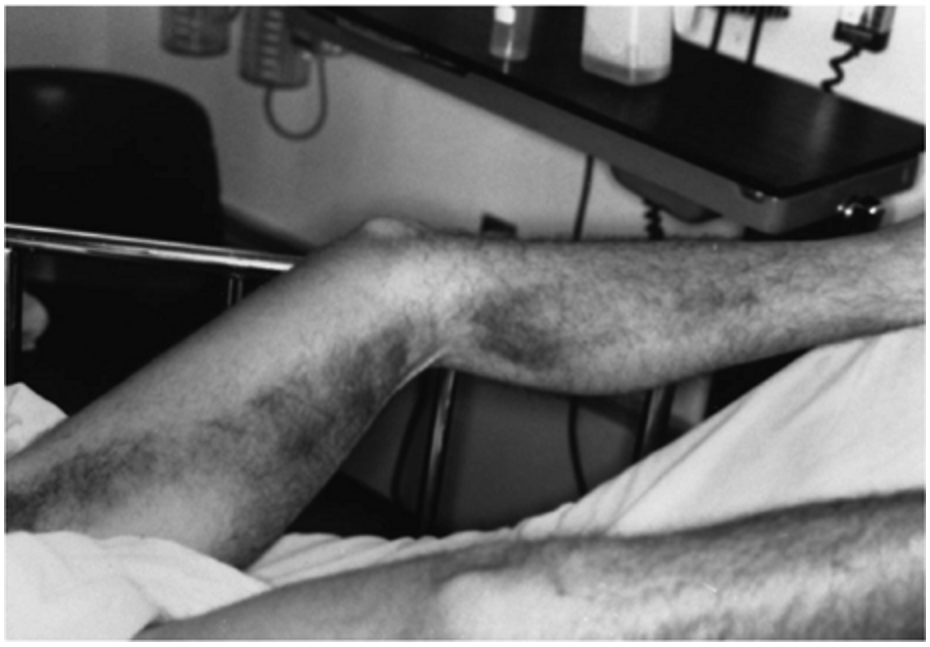

Figure 117-3. Ascending subcutaneous hemorrhagic ecchymosis develop

within 8 hours of a copperhead bite to the foot. The ecchymosis follows t course of lymphatic or venous drainage. Only minor discomfort was noted There was no systemic coagulopathy. The actual cause is unknown, but th is an example of the hemorrhagic diatheses produced by crotaline envenomation. (Reproduced with permission from Roberts JR, Greenberg Ascending hemorrhagic signs after a bite from a copperhead. N Engl J Me 1997;336:1262â€“1263.)

A major difficulty in objectively grading the severity of crotaline envenor and following its progress is that no scoring system readily fits the vagari envenomation. Most patients exhibit only a subset of all of the possible consequences, so all, some, or none of the anticipated signs and symptor develop in any given individual. In addition, some of the characteristics o envenomation (nausea, tachycardia, restlessness, and tachypnea) may be related to fear and not to envenomation. A validated severity score for c assessment of crotaline envenomation has

been developed for research purposes and holds promise as a standardiz tool for clinical evaluation.[21]

TABLE 117-3. General Hemostatic Characteristics of Snake Venom

Anaphylaxis

Rarely, patients bitten by crotalines experience classic anaphylaxis from venom itself. This reaction can complicate evaluation, or mimic a severe systemic reaction to venom. In one report, a man developed pruritus and shortness of breath accompanied by hypotension, generalized urticaria, a wheezing immediately following a rattlesnake bite.[40] The symptoms quick responded to standard treatment for anaphylaxis (epinephrine, antihistar and corticosteroids). The patient was bitten previously and may have bee sensitized at that time. Snake handlers may be sensitized through inhalat skin contact and develop IgE antibodies to venom. Antivenom is not indic for treatment of anaphylaxis, but differentiating anaphylaxis from envene often is clinically difficult. The presence of pruritus and urticaria or whee which is uncommon with envenomation, suggests anaphylaxis.[12]

Elapid Envenomation

The severe local reaction to crotaline envenomation contrasts with the us minor pain and clinically unimpressive local reactions that occur with a co snake bite. However, lack of local symptoms does not signify that serious envenomation has not occurred. Initially judging which patients bitten by snakes will develop symptoms is difficult. In general, less than 40% of p bitten by a coral snake are subsequently determined to have been envenomated; rates for envenomations from the eastern coral snake spe possibly are higher.[48] Coral snake envenomation may be manifested by s systemic reactions with little symptomatology at the actual site of envenomation, even after an asymptomatic period of up to 12 hours. The of the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micr tenere*) are more potent than that of the Sonoran coral snake (*Micruroid*

euryoxanthus). In fact, no cases are reported of serious toxicity followin bite of the Sonoran coral snake, which is found primarily in Arizona and New Mexico.

Systemic Effects

The systemic effects of elapid envenomation (Table 117-4) are characteristically delayed for a number of hours. One report described a who had an asymptomatic period of 13 hours followed by a sudden and precipitous deterioration severe enough to require ventilatory support.[49] neurologic abnormalities noted included slurred speech, paresthesias, pt diplopia, dysphagia, stridor, muscle weakness, fasciculations, and respira paralysis.[49] The major immediate cause of death from coral snake envenomations is respiratory arrest secondary to neuromuscular weakne cardiovascular effects are less common than in crotaline envenomation. can develop total-body paralysis that may last 3â€“5 days and take week resolve completely. With respiratory support, however, the paralysis is completely reversible. Pulmonary aspiration is a common sequela in the subacute phase.

Management

Objectives for Treatment

The specific treatment of a patient with a snakebite is controversial, and literature contains confusing and contradictory recommendations. Folklore home remedies abound. The benign natural history of many bites undoub has accounted for many apparent cures from â€œtherapeuticâ€• interve such as ethanol, electric shocks, carbolic acid, strychnine, cauterization, cryotherapy. Many accepted treatment plans are based on anecdotal or b information, with conclusions drawn from animal studies or uncontrolled reports. There are no universally accepted standards of care for many as

of treatment.[81] Many authors tend to be staunch advocates of their parti regimens and are unwilling to accept a less rigid approach. The initial ob are to determine the presence or absence of envenomation, to provide ba supportive therapy, to treat the local and systemic effects of envenomatio to limit or repair tissue loss and/or functional disability (Table 117-2).

A combination of medical therapy including supportive care, antivenom w warranted, and conservative surgical treatment using debridement of de tissue when indicated, individualized for each patient, likely will provide appropriate results. In general, the more rapidly treatment is instituted, better the final outcome.

Observation of Asymptomatic Patients

All patients who report a history of snakebite from North American crotal should be observed for 8â€“12 hours after the bite, if the skin is broken a offending snake cannot be positively identified as nonpoisonous. The initi presentation of pit viper bites may be misleading. Significant worsening o seemingly benign bite may occur as long as 24 hours after presentation,[4] such cases are unusual. Restlessness, anxiety, abdominal pain, nausea, a tachycardia are nonspecific symptoms, but could signal systemic enveno and they should not be routinely dismissed as resulting from fear or anxi Fang marks may be subtle and easily mistaken for scratches or teeth mar prudent approach is to observe all victims of possible crotaline bites for a 8â€“12 hours after the bite, and admit patients with any evidence of envenomation. If the patient was bitten by an exotic or nonnative snake, period of observation should be extended to 12â€“24 hours.

Eastern coral snake bites can be misleading because of the absence of ea symptomatology. Serious delayed neurologic and respiratory symptoms h been specifically noted, so patients bitten by these snakes should be obs for 24 hours regardless of initial presenting symptoms and treatment.

Initial Treatment

No first aid measures or specific field treatment is proven to positively at the outcome of a crotaline envenomation. Undue importance is placed on immediate prehospital care of patients with snakebites, and some therapi could be detrimental. When the patient is not in extremis and medical at is available within a few hours, the prudent approach is a conservative or excitement or hysteria generated by a possible poisonous snakebite comp some caregivers to intervene quickly, often irrationally, and with unprove harmful procedures. It is common to confuse treatment priorities and cre additional morbidity with hurried or ill-conceived attempts to stop or limi â€œcertain deathâ€• or subsequent amputation. In reality, both death a amputation are rare if proper medical attention is available within a few Most morbidity stems from delayed treatment, either because of inaction patient, often related to alcohol intoxication, or because of inaccessibility medical care. Prehospital care generally should be limited to immobilizatio the patient's affected limb and rapid transport to a medical facility. Physi activity, such as walking, should be avoided because this action may hast systemic absorption of venom. Prehospital personnel should follow standa advanced cardiac life support protocols for the rare unstable snakebite v

Pressure Immobilization

In the past, various methods have been advocated to prevent systemic absorption of venom following snakebites. The traditional tourniquet that occludes venous and arterial flow is contraindicated and may compound t initial insult by increasing edema and aggravating ischemia. (See ILTOURINQUET in the Image Library). Evidence indicates that a broad, fi constrictive wrap (elastic bandage) placed over the bitten area and encir the entire immobilized limb will slow the systemic absorption of venom. In human volunteer study simulating intradermal and subcutaneous enveno using labeled radiotracer, immediately wrapping an entire extremity with rolled elastic bandage to a pressure of 50â€“70 mm Hg significantly dela transit time from periphery to the systemic circulation.[42] This wrapping procedure (the Sutherland wrap) is intended to collapse lymphatics and superficial veins to retard venom uptake. A reasonable guide is to wrap t bandage as tightly as a compression bandage would be applied for a spra

ankle. A constriction band is not a true tourniquet. When a constriction b is applied properly, a finger can be easily placed between the band and t

The pressure immobilization technique has been used for treatment of nonnecrotizing elapid snakebites in Australia where systemic toxicity is th major concern and transit times can be prolonged.[82] The benefit of this technique for the more necrotizing bite of North American pit vipers is les clear. A randomized controlled study using a porcine model with intramu injection of a lethal dose of *C. atrox* (western diamondback) venom follow pressure immobilization versus observation was performed. The results demonstrated prolonged time to death in the pressure immobilization gro also markedly increased compartment pressures. With local tissue necros death, the major morbidity associated with North American pit viper envenomations, the authors concluded that pressure immobilization with compression bandage cannot be suggested as a routine field procedure.[10] not recommend pressure immobilization for management of North Americ viper envenomations.

Venom Removal

Incision and suction, whether by mouth or a commercially available devic cannot be recommended as standard first aid in the field. Incision may le damage of underlying structures such as nerves and tendons, and mouth is unproven and can introduce bacteria into the wound. A commercially a plunger-type suction device (The Extractor, Sawyer Products, Long Beach can generate up to 1 ATA negative pressure when placed over nonincised puncture wounds for extraction of venom.[4] Animal models addressing this intervention give conflicting results. In human models, no benefit of nega pressure venom extraction was found, and additional injury resulting from of the device was possible. Venom extractors currently are unproved the and are not recommended.[1 , 11 , 27] Simple suction cups supplied in first kits are worthless.

It should be stressed that compression dressings and vacuum extraction not be considered if the patient can rapidly reach a hospital. Minor pain c swelling is not an indication for aggressive field treatment. Furthermore,

treatments are never a substitute for rapid transport, in-hospital evaluati antivenom therapy. The bitten area should not be placed in ice, because cryotherapy is not effective in neutralizing venom, and may compound th injury.[56]

Immediate In-Hospital Therapy

The initial in-hospital approach to a victim of a poisonous snakebite follo standard accepted guidelines for stabilization and assessment of any pati with a potentially serious medical problem.[57] A complete medical history, including current tetanus immunization status and known allergies, should obtained. A careful description of the bite and the extent of the local pat should be documented, including measuring the diameter of the extremity noting the extent of edema by marking the skin with a pen to help recogn progression of the envenomation. This evaluation should be repeated as required by the clinical condition. A comprehensive physical examination be performed, with emphasis on vital signs, cardiorespiratory and neurol status, neurovascular status of the extremity, and evaluation for evidence melena, hematuria, and gingival bleeding. A baseline complete blood coun and platelet count), electrolytes, urinalysis, blood urea nitrogen (BUN), g PT, PTT, and fibrinogen concentration should be obtained initially and rep in 4 to 6 hours.

Pain and anxiety should be treated with analgesics and anxiolytics as clin warranted. Tetanus prophylaxis should be addressed. The extremity shoul immobilized in a well-padded splint in near-full extension and elevated to prevent dependent edema. The patient should be reassessed frequently w serial vital signs and repeat physical examinations, specifically noting any progression of swelling. This can be accomplished by taking measurement the circumference of the involved extremity at multiple points proximal to wound.

Victims of proven copperhead bites should be observed for 8 hours and evaluated for signs of systemic involvement, development of coagulation abnormalities, or progression of local pathology. In many instances, the care of a patient with a minimal copperhead envenomation can be accom

in the emergency department, but a conservative approach is advised. H admission for further observation is warranted if follow up cannot be assu if the identification of the snake or progression of symptoms is questiona

Antivenom Therapy

For Crotaline envenomations, antivenom should be considered as first-lin therapy for patients with moderate-to-severe envenomations (Table 117- Each clinical case must be individualized, but in the vast majority of pati who have a significant envenomation, the benefits of antivenom therapy outweigh the risks. Antivenom given in a timely manner can reverse the coagulopathy and halt progression of local symptoms.

The most common currently available antivenom for treatment of North American pit viper envenomation is Crotalidae polyvalent immune Fab Cr Protherics, Savage Laboratories). It is an ovine-derived Fab fragment an developed from commonly encountered North American pit vipers. It has replaced the traditional Antivenin Crotalidae Polyvalent (Wyeth-Ayerst). It has produced far fewer hypersensitivity reactions than reported with administration of the equine-derived whole immunoglobulin product. It is infused intravenously in 4â€“6 vials doses reconstituted in 0.9% sodium solution. The infusions are initiated at a slow rate. If no signs of anaphyl reaction develop (hives, wheezing), the rate is increased to complete the infusion over 1 hour. The patient is reassessed at the end of the infusion evidence of progressive swelling or worsening thrombocytopenia or coagulopathy. If these conditions are present, a repeat dose of 4â€“6 vial infused. This process is repeated until symptoms are controlled. Once co has been gained, maintenance doses are given as 2 vials every 6 hours fo total of 3 maintenance doses. Antivenom therapy is discussed in detail in Antidotes in Depth: Antivenom (Crotaline and Elapid) .

Surgical Therapy

Envenomation may mimic a compartment syndrome by producing distal

paresthesias, tense soft-tissue swelling, pain on passive stretch of muscl within a compartment, and muscular weakness. However, because subfas envenomation is uncommon, much of the impressive edema produced by envenomation does not occur in compartmentalized areas. Using noninva vascular arterial studies and skin temperature determinations in patients rattlesnake envenomation, a report demonstrated that pulsatile arterial b flow to an envenomated extremity actually increased after envenomation, distal to the site of envenomation.[17] A compartment syndrome cannot be reliably diagnosed in envenomated extremities without directly measuring compartment pressures. Although there is little doubt that some crotaline eventually may require some surgical debridement or even skin grafting, initial routine use of tissue excision, fasciotomy, or â€œexploration and debridementâ€• is not recommended.[36 , 76] Excising tissue likely will not significantly halt the envenomation process. Indications for fasciotomy ar and only based on objective data of measured compartment pressures. Following crotaline envenomation, successful treatment of documented e compartment pressure with antivenom and mannitol alone is reported.[33] ILCOMPARTMENT1 and ILCOMPARTMENT2 in the Image Library).

Surgical debridement of necrotic tissue and hemorrhagic blebs and bliste usually is performed between 3 and 6 days after envenomation. Physical should be instituted early to ameliorate joint stiffness and decrease swel

Surgery is not a concern in the treatment of coral snakebites. Similarly, copperhead and water moccasin bites rarely require surgical intervention except for delayed local debridement.

Blood Products

Alterations in platelet count, PT/PTT, fibrin split products, and fibrinogen concentration are commonly encountered with crotaline envenomations. A victims should be evaluated for a coagulopathy, even in the absence of symptoms.[22 , 62] Surprisingly abnormal laboratory results, such as immeasurably low fibrinogen concentrations, PT >100 seconds, and plate count <20,000 are routinely encountered, and such abnormal laboratory alone should not prompt the clinician to treat with blood products in the

of major clinical bleeding. The circulating crotaline venom responsible for initial hematologic changes still is present and likely will inactivate any component transfusions. For this reason, the mainstay of treatment for c envenomation-induced coagulopathy is antivenom, not blood products. Correction of laboratory coagulation abnormalities and bleeding frequentl be achieved with antivenom. Monitoring trends in the coagulation profile i objective way to assess the seriousness of envenomation and the respons antivenom therapy.

Rarely, antivenom alone does not correct a significant coagulopathy, in w case fresh-frozen plasma, cryoprecipitate, packed red blood cells, or plat transfusions are required. The criteria for use of blood products appears t arbitrary in clinical practice, but in general, blood products should be administered along with antivenom only if the patient is actively bleeding

Thrombocytopenia following rattlesnake envenomation may be difficult, o impossible, to totally correct with platelet transfusions or large amounts antivenom. The initial elevation of platelet counts following platelet trans or antivenom administration tends to be transient (lasting only 12â€“24 and thrombocytopenia may persist for days to weeks after normalization other coagulation parameters. The significance of prolonged thrombocyto in the absence of bleeding complications is uncertain. In the absence of bleeding, thrombocytopenia may be a benign self-limiting disorder that is tolerated and closely followed in lieu of repeated platelet transfusions or additional antivenom administration.[67] Persistent thrombocytopenia, as a isolated finding, does not require aggressive threatment.[67] Hypofibrinoge alone generally is not associated with clinically significant bleeding and m require correction. Coral snake venom does not alter coagulation, so no bleeding diathesis is expected.

Treatment of Coral Snake Envenomation

The benign local effects of coral snake envenomation can be misleading a mistakenly equated with a dry bite.[60] Because initially judging which pat are envenomated is impossible, any patient with confirmed coral snake e who have fang marks or other evidence of skin penetration should receiv

antivenom therapy, even in the absence of symptoms. A more conservati approach in the patient with a less likely coral snake envenomation still at least 24 hours of observation. Clinical deterioration may be totally unexpected and progress rapidly. Eastern coral snake envenomation can fatal, but patients usually recover completely with supportive care and antivenom therapy. In one series, 6 of 39 patients required intubation an ventilation, but none died or suffered tissue loss or permanent neurologic sequelae.[49]

Other Considerations

Tetanus prophylaxis should be administered and hyperimmune tetanus a given if primary immunization is inadequate or the history is uncertain.

Prophylactic antibiotics are not indicated, as studies show extremely low (0â€“3%) rates of wound infections.[54] There is no rationale for use of corticosteroids or antihistamines in the routine treatment of patients with snakebites, but they are used to combat the rare cases of anaphylaxis fr exposure to venom or the more common acute and delayed allergic react antivenom. Corticosteroids may be detrimental to local tissue in the early of envenomation.[16] Cardiovascular collapse is a life-threatening conseque severe systemic envenomation and should be treated aggressively with la amounts of antivenom, invasive monitoring, and standard intensive care techniques.[18] Vasopressors may be required, and respiratory compromise should be anticipated in severe cases. Because of sudden and unpredicta respiratory paralysis associated with coral snake envenomation, tracheal intubation should be considered at the first sign of bulbar paralysis. Any given antivenom or who has significant envenomation should be observed intensive care unit.

Multiple treatments with hyperbaric oxygen suggest that enhanced healing myonecrosis may occur in mice injected with *C. atrox* venom. No effect o edema associated with envenomation was observed in one study, and the beneficial effect was dose dependent, with up to 10 treatments (1â€“1.5 at 2â€“2.75 ATA) given.[47] The mechanism of action is not known but is

speculated to be related to enhanced tissue oxygenation. The effects of hyperbaric oxygen therapy for poisonous snakebites in humans is unknow use should be considered experimental at this time.

Recurrence Phenomena of Crotaline Envenomation

Data detailing the natural history of crotaline envenomation following init treatment with traditional Antivenin Crotalidae Polyvalent are sparse. Ho studies assessing the efficacy and safety of ovine Fab antivenom have sh interesting light on the clinical course of victims of crotaline envenomatic treated with this newer antivenom. Definite recurrent local and coagulop effects, in the form of worsening of symptoms after initial clinical improv are described following antivenom.[5 , 72] Recurrence phenomena are attri to the interrelated kinetics and dynamics of venom and antivenom. Simpl stated, Fab antivenom has a clinical half-life shorter than that of venom. tissue injury and coagulation deficits have been halted or corrected, tissu injury and coagulopathies may worsen, unless additional antivenom is administered. This may result in greater tissue injury and a risk of hemo Complicating matters, recurrence of coagulopathy may manifest days afte hospital discharge. The exact clinical significance of this observation and for clinical intervention are uncertain and may be predominately theoreti Currently, the most reasonable way to address possible delayed recurren effects of crotaline envenomation, especially coagulopathy, is careful foll after hospital discharge. This concern has not been extended to coral sna envenomation [see discussion in Antidotes in Depth: Antivenom (Crotalid Elapid)].

Nonvenomous Snakebites

Approximately 50,000 snakebites occur annually in the United States, and (90â€“95%) are from nonvenomous snakes.[32] Most snakes in the United are nonvenomous, and the majority are of the Colubrid family, which are generally considered harmless to humans. However, several authors have

reported toxic secretions from Duverney glands in many common species including the hognose snake, garter snake, parrot snake, banded water s and ringneck snake.[35, 58, 78] Although no deaths have been reported, s victims developed coagulopathies and local edema and hemorrhage that be confused with early crotaline envenomation.[56] No antivenom is availab treatment of bites from these snakes, and serious complications from nonvenomous snakebites are extremely rare.

Although Colubrids do not possess true fangs, some species, such as the common wandering garter snake (*Thamnophis* spp), have elongated and grooved posterior maxillary teeth (a primitive rear fang) that can penetra skin and deliver irritating saliva into the victim via a chewing motion. Son clinicians believe that the presence of teeth marks at the bite excludes th possibility that the bite was made by a venomous snake. Although it is tr fang marks are absent following nonvenomous snakebites, venomous snak have teeth, and abrasions or teeth marks may occur in conjunction with a venomous bite. This fact, along with the possibility that snakes heretofor considered nonvenomous may be dangerous, should make the clinician m cautious in diagnosing a nonvenomous bite based entirely on the presence teeth marks.

When no sign of envenomation is present after an appropriate period of observation following a suspected nonpoisonous snakebite, attention shou focused on the basic principles of wound care. The wound should be clea any foreign material removed, and an appropriate dressing applied. Certa large snakes of the Boidae family (not seen in the United States, except a or in zoologic gardens), including boas, pythons, and anacondas, may pre special problem because the force of contraction of their jaws may be gre enough to cause severe tissue contusion or fractures and retained teeth (117-4). These reptiles also have numerous large, brittle teeth that comm break off and lodge in the wound when the bitten part is forcibly extricate the snake's mouth.

Usually radiographs of the bitten area are required to exclude fracture or foreign body.

Figure 117-4. Significant local morbidity can result from the bite of nonvenomous snakes. This 10-year-old boy was bitten on the hand by a albino python. After the snake was removed, the boy complained of pers pain, redness, and swelling. The radiograph shows retained teeth in the s tissues. Following a short hospitalization for intravenous antibiotics, the recovered without sequelae. (Courtesy of the Toxicology Fellowship of the York City Poison Center.

The morbidity associated with a nonvenomous snakebite results from the case of bony injury and wound infection. Some authors recommend antib for nonvenomous snakebites, but their routine use cannot be supported. report, no infections followed nonpoisonous snakebites in 72 patients bitte variety of nonpoisonous snakes indigenous to New England and imported constrictors and pythons.[79] Although *Clostridium tetani* has not been isol from the mouths of snakes, the ubiquitous nature of this organism requir prophylaxis following the recommended approach for a contaminated wou cogent argument can be made for administering prophylactic antibiotics i nonvenomous snakebites if tooth fragments are retained or soft-tissue c is significant. A first-generation cephalosporin or antistaphylococcal peni given for 7â€“10 days should be adequate. Outpatient therapy is appropr the patient should be instructed on wound care and told to seek medical signs of infection occur. Minor abrasions from nonvenomous snakes requi

local wound care and tetanus prophylaxis. Delayed infection should prompt investigation for a retained foreign body, especially a tooth fragment.[38]

Special Considerations for Management of Pregnant Patients with Snakebites

Scant information on the effects of poisonous snakebites during pregnancy available. Case series show that maternal death is rare, but fetal loss may high as 43%.[24] The mechanism of injury to the fetus from envenomation includes uterine artery hypotension and subsequent hypoxia, hemorrhagic complications such as abruptio placentae, or uterine contractions initiated venom.[63]

Intracranial hemorrhage and death in an infant born at 34 weeks of gesta was reported in a woman envenomated by a copperhead during week 28 pregnancy.[25] At the time of the bite, she was given antivenom and devel anaphylaxis and hypotension, which was treated with large doses of epinephrine. It is suggested that the Î±-adrenergic effects of epinephrine uterine artery, coupled with maternal hypotension, contributed more to th demise than the direct effects of venom. As in each case of snakebite, it prudent to evaluate the need for antivenom carefully during pregnancy ar administer antivenom only when envenomation is significant and the bene antivenom outweigh the possible risks from allergic reactions. Fetal mon should be routine following poisonous snakebite.

Repeated Exposure to Snake Venom

Handlers and collectors are at risk for multiple bites over their careers, a questions have been raised about possible immunity. In a report of 14 pa with two or more bites, evidence that immunity develops as a result of re envenomation was not established.[64] Victims of repeat bites actually may greater risk for anaphylaxis because of a prior sensitization and the development of IgE antibodies to venom.

Exotic Snakebites (See ILNAGANAGA2 in th Image Library)

Approximately 3% of poisonous snakebites in the United States are from nonnative species.[2,8,34] Many such snakes are owned by collectors, ill imported, or stolen from zoos or pet stores. However, private individuals easily purchase a plethora of vipers, cobras, and adders by mail or at rep shows. There is surprisingly little regulation of the sale or ownership of e snakes in the United States. Exotic venomous snakes pose a particularly problem for both diagnosis and management. Many victims are collectors researchers who can identify the offending snake. However, because of fe legal retribution, some owners of exotic snakes can be quite vague about circumstances or origin of their envenomation. If they cannot provide identification, the local zoo, regional poison center, or herpetology society be helpful. Once the snake is identified, the antivenom must be obtained. always a formidable task and often impossible, but local zoos, poison cen collectors may have the antivenom. Some poison centers, some zoos, and American Association of Zoological Parks and Aquariums (301-562-0777) maintain the Antivenom Index, a listing of available antivenoms for exotic snakes, but these resources have limited ability to deliver many antivenc Bites from many nonnative Elapidae snakes, such as mambas, kraits, cob and several Australian species, are associated with high morbidity and m rates. Approximately one-third of bites from the king cobra are fatal.[34] B from these snakes may not display early local or systemic signs (Table 1. therefore, the grading system developed for North American pit vipers is helpful. Although local tissue destruction and edema may develop, classic the neurologic signs, such as ptosis, dysphagia, muscular weakness, pare ophthalmoplegia, and respiratory failure, are noted, often at a delayed or advanced stage. Cobra envenomation usually produces significant local t and these snakes are the only elapids whose venom possesses hemorrha activity. Enzyme-linked immunosorbent assay techniques can be used to specific venom antigens in suspected exotic snakebites. This technique c is not available in the United States but is used in Africa, Asia, and Austr (See ILMALAYSIANCOBRA1 in the Image Library).

Guidelines for the administration of antivenom for exotic snakes are vagu empiric. In addition, there is little standardization of the antivenoms for same snake among the different manufacturers. Exotic snakes generally quite poisonous, so if fang marks are present, envenomation is strongly suspected, the snake is identified, and the specific antivenom is obtained physicians believe it is logical to proceed with antivenom administration empirically. Antivenom is administered according to the package insert. Generally, 4â€“5 vials are administered under the same guidelines given crotaline antivenom. If the antivenom cannot be obtained, then supportiv and close in-hospital observation may be all that is possible. Local incisio suction are best avoided. Compression immobilization of an entire extren with an elastic bandage (the Sutherland wrap) for the bite of some elapid sea snakes, kraits, cobras, and brown snakes) experimentally decreases movement of elapid snake venom from the bite site to the systemic circu and may be useful when antivenom is not available. This intervention, wh does not delay transport to medical care, has been recommended for bite exotic elapids.[82] Crotalinae Polyvalent Antivenom (Wyeth) is ineffective fo bites of elapid snakes, but is active against venom of South American pit such as the bushmaster (*Lachesis muta*) and fer-de-lance (*Bothrops*). W Crotalidae polyvalent immune Fab (Protherics) is effective for South Ame pit viper envenomations is unknown. Coral snake antivenom is active only against the North American eastern coral snake and is not effective

against the western, Mexican, or South American species. It is prudent, b often difficult, to obtain expert assistance with managing any exotic snal

One report documents dramatic reversal of the neurotoxic effects of a monocellate cobra (*Naja kaouthia*) bite following intravenous administrat the anticholinesterase neostigmine methyl sulfate (0.5 mg every 20 minu 4 doses).[31] The major neurotoxin from this snake is believed to resemble curare, causing a postsynaptic blockade of nicotinic neuromuscular recep sites. The neurotoxicity from sea snakes and other elapids has also been experimentally reversed with neostigmine.[71] Edrophonium chloride (10 m administered intravenously with 0.5 mg of atropine) has also been sugge

Other Poisonous Reptiles in the United Sta

In North America there are 2 indigenous species of venomous lizards that belong to the order Squamata, the same order as venomous snakes: the monster (*Heloderma suspectum*) and the beaded lizard (*Heloderma horr* These lizards are found primarily in the desert areas of Arizona, southwe Utah, southern Nevada, New Mexico, California, and Mexico. They are lar slow-moving, nocturnal thick-bodied lizards that are prized by collectors hobbyists. Adults are 30â€“40 cm long. In general, they are shy creature bites are relatively rare, usually unintentional or secondary to handling. monsters are known for their forceful bite. They have a propensity to han tenaciously during a bite and may be difficult to disengage. Some rather innovative anecdotal techniques have been developed to remove a Gila m from an extremity, including the use of chisels, screwdrivers, and crowba pouring gasoline or ammonia into the lizard's mouth, or holding a flame t animals jaw. Teeth may break off in the wound.

Gila monster venom is complex, containing components similar to those o snake venoms, including numerous enzymes, hyaluronidase, phospholipas kallikrein, and serotonin.[37 , 70 , 77] Helothermine is the suspected toxin. venom delivery systems are not as efficient as those of poisonous snakes consist of venom glands and grooved teeth rather than fangs. Dry bites o occur because of the ineffective mechanism of delivery. Following skin pu and venom release, the victim experiences local tenderness and soft tissu swelling, pain, and edema. Anaphylactoid reactions, hypotension, angioed lip, tongue, and throat, respiratory depression, coagulopathy, and myoca infarction are reported occasionally.[65 , 66] Significant tissue destruction i unusual, but maceration may occur, and a cyanosis or blue discoloration noted about the wound. No antivenom against lizard venom is available. Treatment consists of avoiding overaggressive local treatment and provid supportive care and wound care. Serious morbidity from lizard bites is un The characteristics of the beaded lizard are similar, but their bites are les commonly confronted clinically.

Other Venomous or Poisonous Animals

It was generally believed that there are poisonous or venomous members classes of animals except birds. However, discoveries in New Guinea have birds to the list.[23, 41] Three avian Pitohui species have been found to co homobatrachotoxin, a poison very similar to that in poison dart frogs of S America. Like the frogs, the Pitohui birds are conspicuous and brightly co Little information on the toxicity of these birds is available.

Several species of mammals contain venomous members. For example, th Australian duckbilled platypus (*Ornithorhynchus anatinus*) has a hollow s that can inject venom. The Cuban insectivore (*Solendon paradoxes*) and American short-tailed shrew both secrete venom from the maxillary gland bite with the lower incisors. Envenomations from mammals are rare, and known about the specific clinical toxicity from these creatures.

Several species of amphibians, frogs, toads (*Anura*), newts, and salaman (*Urodela*) can secrete toxins through their skins, which may be a defens repellant or alarm mechanism.[6, 14, 19, 20, 39] These creatures are not venomous because they have no specific mechanism for delivering the xenobiotic. Most cases of toxicity involve children or pets ingesting the a The best-known examples are the Colombian poison dart frogs (*Phyllobat Atelopus*), which secrete the toxins zetekitoxin, tetrodotoxin, and batrachotoxin.[59] Batrachotoxin irreversibly activates (depolarizes) the so channel and is 250 times more toxic than curare in mice. Newts of the ge *Taricha* contain the irreversible sodium channel-blocking agent tetrodotox their skin and internal organs. Their toxicity is expected to be similar to occurring with puffer fish (fugu) poisoning (Chap. 45). Ingestion of a ne potential adverse consequences. Treatment is supportive. The East Coast species is less toxic than the West Coast variety, the Oregon rough-skinn newt (*Taricha granulosa*). Salamanders of the genus *Salamandra* contain very potent CNS toxin salamanderin. Large exposures theoretically could produce neurotoxicity.

Toad species of the genus *Bufo* have been abused by a curious technique licking their skin, which contains a number of toxic substances, including biogenic amines (serotonin), steroids, and polypeptides. A lysergic acid diethylamide (LSD)-like high is reported, but there is considerable folklore

confusion on the exact effects.[55] Toxicity is reported following toad lickin mouthing, toad ingestion, and toad soup consumption. Salivation, seizure cardiac dysrhythmias have been reported with ingestion of toxin from *Bu alvarius* , the Colorado River toad. The cane toad (*Bufo marinus*) is less Bufotalin, a cardioactive steroid toxin (bufadienolide) derived from this t has a chemical structure very similar to that of digoxin[50] (further details Chap. 62).

Summary

The physician faces numerous critical decisions when treating a patient w possibly has been bitten by a poisonous snake. The most basic questions address are whether or not the patient actually was bitten by a snake and whether envenomation has occurred. Careful history and examination, al with judicious use of laboratory data and observation, should answer thes questions. For patients with significant envenomations, supportive care a early use of antivenom are the mainstays of treatment.

Antivenom (Crotaline and Elapid)

Anthony F. Pizon

Bradley D. Riley

Anne-Michelle Ruha

James R. Roberts

Edward J. Otten

For decades, Wyeth Laboratories (Marietta, PA) has manufactured a crotaline antivenom for treatment of snakebites in the United States. It is a whole immunoglobulin product derived from horse serum. Wyeth temporarily stopped production of this antivenom but has resumed manufacturing the product; however, supplies are available on a limited basis. In October 2000, the US Food and Drug Administration approved the use of another crotaline antivenom. It is a refined crotaline antivenom (crotalidae polyvalent immune Fab (ovine), Protherics, Savage Laboratories), derived from sheep serum and formulated more specifically for the crotalines found in the United States. Crotalidae polyvalent immune Fab (ovine) is an

effective and less allergenic alternative to the horse serum products.[7,11,19] Thus, crotalidae polyvalent immune Fab (ovine) has become the most practical antivenom option currently available, and the most widely used snake antivenom in the United States. A comparison of available crotaline antivenoms is given in Table A33-1.

Wyeth also produces a coral snake antivenom effective against the eastern and Texas coral snakes. Numerous other antivenoms exist for bites from exotic or foreign snakes, but they are of limited availability, are difficult to obtain, and are rarely used. Poison control centers or local zoos may have information regarding access to these antivenoms.

Crotaline antivenom is given to ameliorate the effects of local and systemic envenomation by pit vipers, and it is considered lifesaving by some clinicians.[10] Animal studies document decreased mortality when antivenom is given immediately after envenomation.[8] A delay in treatment of even a few hours lessens the beneficial effects of antivenom in animal models.[12] Case reports, anecdotal evidence, and now prospective studies support the concept that antivenom will halt the progression of local tissue swelling and at least temporarily reverse systemic effects, including most coagulation and platelet defects.[4,9,10,15]

When indicated, antivenom should be given as soon as possible to neutralize circulating venom. However, it is impossible to define the exact benefit at any specific time, and the value of late administration is impossible to quantify. Delay of antivenom administration for a few hours likely will not significantly change morbidity or mortality in the majority of cases. However, crotaline antivenom should not be given â€œprophylacticallyâ€• to patients with minimal symptoms, or those with no evidence of envenomation. Envenomation following a rattlesnake bite often progresses such that antivenom is required, whereas envenomation following a copperhead bite is less likely to require antivenom administration. The severity of envenomation by water moccasins is somewhere between that of the

relatively benign copperhead and the more tissue-destructive rattlesnake. In contrast, coral snake antivenom should be administered in cases where a coral snake bite is assumed or proven, even in the absence of symptoms.

Indications for crotaline antivenom treatment must be individualized for each patient's condition. Because antivenoms can cause life-threatening allergic reactions and delayed serum sickness, the risks and benefits must be weighed prior to treatment initiation. The major indications for crotaline antivenom therapy are (1) rapid progression of swelling, (2) significant coagulopathy or thrombocytopenia, (3) neuromuscular toxicity, or (4) hemodynamic compromise. Patients with previous life-threatening reactions to specific antivenoms still can receive those antivenoms in the absence of an effective alternative antivenom, but only if the envenomation is suspected to result in severe morbidity or mortality. Precautions must be taken to prevent and treat anaphylaxis prior to initiating antivenom therapy. Patients who are sensitized or have a known allergy to horse-derived antivenoms should receive the newer ovine-derived antivenom for crotaline envenomation.

Patients with only mild local tissue swelling following crotaline envenomation should not be given antivenom. There is no justification for infusions of 1 or 2 vials in minor cases. Standard doses for each antivenom are described. No dosing adjustment is required for children or small adults because the amount of venom requiring neutralization is not dependent upon the patient's weight. The initial dose of antivenom should be given as soon as possible but administered cautiously to limit anaphylactoid reactions from rapid infusion. Anecdotally, antivenom may reverse some of the venom-induced coagulopathy even if the antivenom is given more than 24 hours after the bite. Once symptoms begin to progress rapidly, they usually continue and antivenom is warranted. Early treatment likely will be more effective than late administration. All patients who receive antivenom should be hospitalized for at least 24 hours.

Both the equine- and ovine-derived antivenoms can cause anaphylactic and anaphylactoid reactions, as well as serum sickness.[1] Even though the refined crotaline antivenom is a purified immune Fab product, allergic reactions are reported. The true incidence of these allergic reactions is unknown, but premarketing and postmarketing data report rates much lower than for the equine-derived whole immunoglobulin products.[9,19] Because of the potential for life-threatening reactions, antivenom should be administered only in areas where resuscitation efforts can occur. Epinephrine infusion, H_1 and H_2 antihistamine receptor blockers, and corticosteroids should be available at the patient's bedside before therapy is initiated.

Discharged patients should have telephone followup for 3 weeks after antivenom treatment to permit evaluation for signs of serum sickness. Although the incidence of serum sickness is much lower for the Fab product than for the equine-derived antivenoms, serum sickness from all snake antivenoms is reported.

In addition to evaluation for serum sickness after Fab treatment, repeat outpatient laboratory studies are necessary, following hospital discharge. Crotalidae polyvalent immune Fab (ovine) use has led to the creation of a new term in antivenom treatment called *recurrence.* After crotalidae polyvalent immune Fab (ovine) stops the progression of tissue swelling and reverses coagulopathy and thrombocytopenia, a significant number of patients demonstrate recurrence of either local tissue edema and/or hematologic abnormalities. Several theories have been suggested, but the likely explanation for this phenomenon is an apparent mismatch between effective duration of

Fab antivenom and venom-induced local and systemic pathology.[19] Patients who initially have significant coagulopathy or thrombocytopenia appear to be at greater risk for recurrence of these venom effects, although the significance of these findings, or the need for treatment, is unknown. The appropriate management of recurrence is still debated.

TABLE A33-1. Comparison of Available Crotaline Antivenom

	Crotaline Polyvalent Immune Fab Antivenom (Savage Laboratories)	Antivenom Crotalidae Polyvalent (Wyeth Laboratories)
Animal source	Sheep	Horse
Venom component	*Crotalus atrox*	*Crotalus atrox*
	Crotalus adamanteus	*Crotalus adamanteus*
	Crotalus scutulatus	*Crotalus durissus terrificus*
	Agkistrodon piscivorus	*Bothrops atrox*
Immunoglobulin	IgG Fab	IgG (whole)
Hypersensitivity reactions		
Acute	14.3%	23â€“56%
Delayed	16%	75â€“86%

Recurrence[a]	Common	Rare
Dose	4â€“6 vials repeated as needed for control,[b] then 2 vials every 6 hours for 3 doses	10 vials repeated as needed for control[b]

[a]Recurrence of local tissue swelling or hematologic abnormality anytime after completion of treatment.
[b]Control = arrest of local tissue manifestations and clear improvement in coagulopathy and thrombocytopenia.

Crotaline Polyvalent Immune Fab Antivenom (Ovine Origin)

Polyvalent ovine-derived antivenom is obtained by inoculating sheep with the venom of the eastern diamondback rattlesnake (*Crotalus adamanteus*), western diamondback rattlesnake (*Crotalus atrox*), cottonmouth (*Agkistrodon piscivorus*), and Mojave rattlesnake (*Crotalus scutulatus*). This process results in an antivenom that is more specific to snakes found in the United States than the traditional Wyeth product. One report anecdotally suggests that the Fab antivenom has superior activity against the neurotoxicity of the Mojave rattlesnake.[7] The manufacturing process includes papain digestion of isolated IgG antibodies to eliminate the Fc portion of the immunoglobulin and to isolate specific antibody fragments (Fab and $F(ab)_2$), as well as affinity purification and lyophilization. The Fab fragments have a smaller molecular weight, are less immunogenic, and may have increased tissue penetration compared to whole IgG. In preliminary studies, the number of severe acute and chronic

hypersensitivity reactions associated with the Fab use was significantly reduced compared with horse serum products, but clinical experience is limited.[9] Few clinical trials have evaluated the safety of antivenom, but a study reported a 14.3% incidence of acute and 16% incidence of delayed hypersensitivity reactions.[10] Despite the uncertainty, antivenom has been safely administered to children as young as 14 months.[17] Urticaria, rash, bronchospasm, pruritus, angioedema, delayed serum sickness, and anaphylaxis all are associated with use of this product.[9,19] The same cautions that have been used with whole immunoglobulin antivenoms should be practiced with the Fab product.

The pharmacokinetics and pharmacodynamics of Fab antivenom differ from those of other antivenoms, and there is an apparent mismatch between effective duration of Fab antivenom and venom-induced local and systemic pathology.[19] The duration of action of the Fab antivenom appears to be less than that of traditional equine-derived polyvalent antivenom. The elimination half-life of 12â€“23 hours is less than that of the venom itself, so periodic or repeat dosing of Fab antivenom is required to prevent or treat recurrent symptoms.[4]

Prospective data on patients who have been treated with Fab antivenom have generated important information on the clinical utility of antivenom. The use of a clinical severity-of-illness scale has demonstrated that antivenom will correct coagulopathies and thrombocytopenia associated with envenomation from snakes native to the United States.[10] In an animal lethality model, the new ovine-derived antivenom was 5 times more potent than traditional equine-derived antivenom against 14 different crotaline snake venoms.[8] However, the progression of local tissue injury was ameliorated but not significantly reversed, suggesting that once ecchymosis, edema, and local cell injury secondary to crotaline venom develop, they are essentially irreversible. Initial experience with the Fab antivenom has been promising, and the antivenom appears to be effective in halting progression of many aspects of crotaline envenomation while minimizing allergic reactions.

Technique of Administration

A thorough history regarding asthma, atopy, concurrent use of Î²-adrenergic antagonists, allergy to papaya or papain, and previous use of antivenoms should be obtained. According to the manufacturer, the only absolute contraindication to the Fab antivenom use is allergy to papaya or papain, which is a contaminant left after the Fab portion of the immunoglobulin is cleaved from the Fc portion. A history of asthma, atopy, or use of Î²-adrenergic antagonists should be carefully considered when weighing the risks and benefits of antivenom for a particular patient. These conditions should not exclude the use of antivenom if the patient is suffering from moderate-to-severe envenomation. In cases of mild envenomation, the risk of allergic reaction to antivenom or inability to effectively treat an allergic reaction in a patient receiving Î²-adrenergic antagonists might outweigh any benefit in this patient population. Because the Fab antivenom is ovine derived, reactions from previous use of equine-derived antivenoms should not preclude use of this product.

Our practice has been to prepare for administration of the Fab antivenom in the same manner as for administration of the whole immunoglobulin antivenoms. Prior to drug infusion, an intravenous epinephrine infusion (250 mL D_5W mixed with 1 mg epinephrine), 1â€“2 mg/kg methylprednisolone, 0.5â€“1 mg/kg diphenhydramine, and an H_2 antihistamine receptor blocker are placed at the patient's bedside. Antivenom is always administered in a monitored unit where resuscitation can be performed and airway supplies can be quickly accessed.

Each vial of the Fab antivenom must be reconstituted in 10 mL sterile 0.9% sodium chloride solution prior to use. A continuous gentle swirl or rolling method is used to expedite the reconstitution. To prevent foaming, shaking and other vigorous methods should not be used. Four to 6 vials of the reconstituted antivenom are mixed in 250 mL

0.9% sodium chloride solution and administered over 1 hour. The exact concentration of antivenom is not critical. For children, the total volume of fluid in which the antivenom is diluted can be decreased when necessary. The antivenom is infused at an initial rate of 10 mL/h while the patient is observed for evidence

of hypersensitivity reactions. The rate is doubled every few minutes as tolerated by the patient. If no adverse reactions are witnessed, the remaining dose can be given over 1 hour. If the patient tolerates the initial dose without adverse effects, subsequent doses can be given over 1 hour without slowly increasing the rate.

When antivenom is administered too rapidly, mast cells release histamine and produce nonimmunogenically mediated anaphylactoid reactions. In general, patients appear to tolerate 4â€“6 vials per hour without developing anaphylactoid reactions. If the patient requires rapid administration of antivenom because of the severity of the envenomation, H_1 and H_2 antihistamine receptor blockers may be needed in addition to an epinephrine infusion. Clinically differentiating between anaphylactoid and anaphylactic reactions may be difficult, especially when antivenom is administered rapidly.

For acute anaphylactic reactions (which often occur shortly following initiation of even low doses of antivenom), the antivenom should be stopped, and intravenous steroids, H_1 and H_2 antihistamine receptor blockers, and epinephrine given. Epinephrine 2â€“4 Âµg/min (0.03â€“0.06 Âµg/kg/min for children) can be initiated and then titrated to effect. After the symptoms of hypersensitivity resolve, the antivenom should be restarted only in patients at high risk for significant morbidity or mortality from snake envenomation. In such cases, the antivenom infusion is restarted at 1â€“2 mL/h, while the epinephrine infusion is continued. The antivenom infusion rate can be slowly increased as the patient tolerates. If anaphylaxis recurs, the antivenom should be stopped and the epinephrine infusion increased until symptoms resolve. Antivenom then can be restarted while epinephrine is continued at the higher rate. With constant monitoring

of patients at the bedside and titrating epinephrine and antivenom infusions, patients with life-threatening envenomation should tolerate the full antivenom dose. Patients have safely received subsequent doses of crotalidae polyvalent immune Fab (ovine) after an acute life-threatening reaction.[6]

After two preclinical trials studied crotalidae polyvalent immune Fab (ovine), the therapeutic regimen was empirically determined to include repeat doses of 4â€“6 vials until â€œcontrolâ€• is obtained, followed by regularly scheduled maintenance infusions. The manufacturer defines *control* as arrest of local tissue manifestations and return of coagulation parameters, platelet counts, and systemic signs to normal. However, select patients develop coagulopathy and thrombocytopenia that is resistant to antivenom treatment.[19] Some authors advocate control to mean clear improvement in hematologic parameters rather than complete normalization.[19] This definition may be more realistic for the subset of patients with difficult-to-treat coagulopathy and thrombocytopenia. After each dose of 4â€“6 vials, prothrombin time, fibrinogen, and platelet counts are determined, and the patient's local injury is reexamined. Multiple doses may be required to achieve control. The optimal dose has not yet been determined. After achieving control, a maintenance dose of 2 vials every 6 hours is given, for a total of 3 doses. Again, the 2 vials are added to 250 mL 0.9% sodium chloride solution and administered over 1 hour. Because the duration of action of antivenom is not as prolonged as that of the venom, the maintenance doses are an attempt to prevent recurrence of local manifestations, thrombocytopenia, and coagulopathy. An algorithm for crotalidae polyvalent immune Fab (ovine) antivenom administration for treatment of significant crotaline envenomation is shown in Figure A33-1.

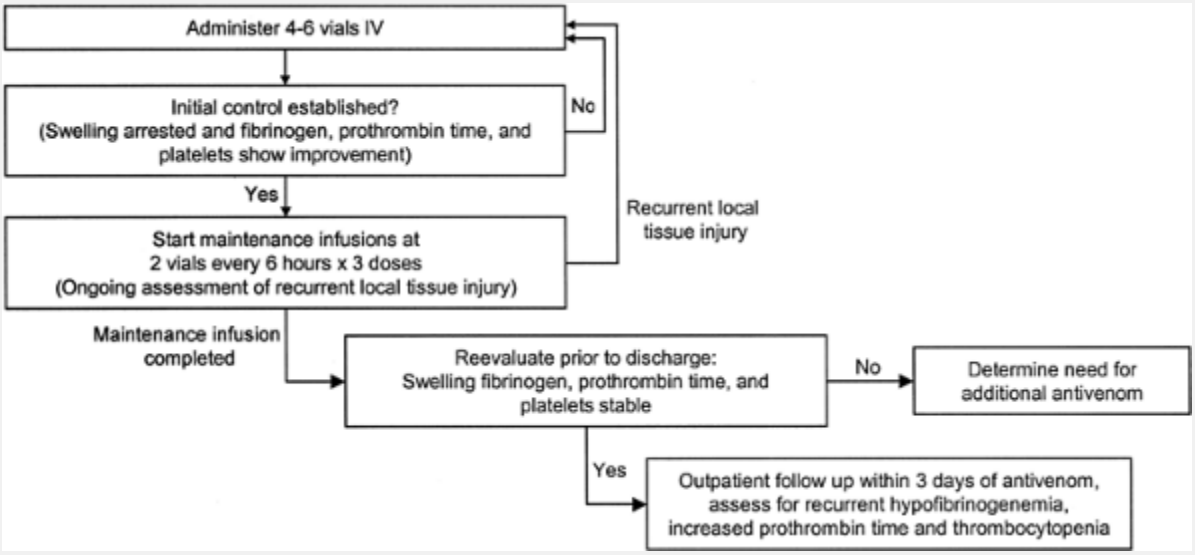

Figure A33-1. Algorithm for crotaline polyvalent immune Fab antivenom administration for treatment of significant crotaline envenomation.

At the time of discharge, the patient should be informed of the possibility of recurrence and told to refrain from activities associated with high risk for trauma and to avoid any surgical procedures for 3 weeks. The patient should receive instructions to watch for signs of bleeding, which may be associated with coagulopathy or thrombocytopenia. Followup prothrombin time, fibrinogen level, and platelet count should be obtained within 3â€“5 days of antivenom completion in all patients. In most patients who develop recurrence, the decrease in platelets or increase in prothrombin time usually is evident within 3 days of last antivenom therapy. Recurrence occurs in approximately 25â€“50% of patients with rattlesnake envenomation who receive crotalidae polyvalent immune Fab (ovine).[3,19] Early administration of antivenom may have masked the findings in patients who initially did not demonstrate

coagulopathy or thrombocytopenia, and these patients still may develop these effects within days of completing antivenom treatment. Treatment recommendations for recurrence of venom effects vary. Clinical experience demonstrates that recurrence may be resistant to additional antivenom,[19] so the benefits of re-treatment in the absence of active bleeding are unclear. No specific dosing regimen for re-treatment is known at this time. In our practice, where we frequently encounter recurrence, our approach is to re-treat patients who develop (1) isolated thrombocytopenia with platelet count <10,000â€“20,000/mm^3, (2) platelet count <30,000/mm^3 and prothrombin time >20 seconds or fibrinogen <150 mg/dL, or (3) active bleeding. A more conservative approach can be used for patients with additional risk factors for bleeding, such as high risk for trauma or use of warfarin (Coumadin). Other patients with less severe recurrence, or isolated coagulopathy without thrombocytopenia, usually can be managed at home with close followup and repeat laboratory tests every few days. Increased local tissue swelling at the time of followup usually is not an indication for redosing antivenom and most often is the result of dependent edema from inadequate extremity elevation. In the absence of any recurrence phenomenon, patients should have regular telephone followup for 3 weeks to check for signs of serum sickness.

Mild cases of serum sickness consist of urticaria, pruritus, and mild systemic symptoms, such as malaise. Occasionally arthralgias, lymphadenopathy, and fever develop. Immune-complex glomerulonephritis, neuritis, vasculitis, and myocarditis occur rarely. The syndrome of serum sickness after antivenom use has not been well characterized or studied, but usually it is neither serious nor associated with chronic sequelae.[13] Most patients respond favorably to antihistamines and systemic corticosteroids. Immediately after onset of symptoms, 2 mg/kg prednisone divided into twice daily dosing are given for 1 week. Oral antihistamines can be used for symptomatic treatment as well. After 1 week of corticosteroid therapy, the dose is slowly tapered over the following week. If

symptoms recur during the taper, the dose is increased for 3 days before the taper is reinstated. The vast majority of patients can be managed as outpatients.

As experience with the Fab antivenom expands, alternate dosing regimens may reduce the number of patients who develop recurrence. In the meantime, all patients should be considered at risk for delayed coagulopathy or thrombocytopenia. Furthermore, acute and delayed allergic reactions are less common than those reported with use of whole immunoglobulin antivenoms, but do occur. The same precautions used when administering other antivenoms should be used with the Fab antivenom.

Crotaline Polyvalent Antivenom (Equine Origin)

Crotaline polyvalent antivenom (Antivenin Crotalidae Polyvalent, Wyeth-Ayerst) is active against the venom of rattlesnakes (*Crotalus*, *Sistrurus*), water moccasins, copperheads (*Agkistrodon*), some South American pit vipers, and some Asian snakes. It is not effective for bites of exotic snakes, such as cobras and other Elapidae. This antivenom is a refined and concentrated preparation of equine serum immunoglobulins (IgG) formulated into a freeze-dried powder that is reconstituted before use. It is a suspension of various venom-neutralizing antibodies prepared from the serum of horses that are gradually hyperimmunized against the venom of a specific cadre of pit vipers found in the western hemisphere: eastern diamondback rattlesnake (*C. adamanteus*), western diamondback rattlesnake (*C. atrox*), tropical rattlesnake (*C. durrisus terrificus*), and fer-de-lance (*Bothrops atrox*). These crotalines share many of the common antigens found in pit viper venom throughout the world, so the polyvalent antivenom is presumed effective against a number of species, including all pit vipers found in the United States. Even though the polyvalent antivenom is not derived from copperheads or other crotalines, such as the Mojave rattlesnake, Pacific rattlesnake,

and timber rattlesnake, it is commonly administered following severe envenomation from these species.[2] The antivenom may be less effective against these snakes, and the neurotoxicity from the Mojave rattlesnake has been suggested to be resistant to crotaline polyvalent antivenom.[5]

Because this antivenom is a whole immunoglobulin product, its use entails a significant incidence of immediate and delayed hypersensitivity reactions,[13] including minor cutaneous hypersensitivity (urticaria), anaphylaxis, anaphylactoid reactions, and serum sickness. As the dose or rapidity of administration of antivenom is increased, the incidence of immediate and delayed hypersensitivity reactions also increases. Because the ammonium sulfate precipitation process currently used to prepare this antivenom is inefficient, the serum contains unwanted contaminants in the form of extraneous heterologous proteins such as albumin, Î±- and Î²-globulins, and IgM, in addition to the venom-specific IgG. These contaminants are largely responsible for the allergic properties of the antivenom.

Anaphylactic reactions result from the presence of circulating IgE antibodies to horse protein in the recipient's blood leading to degranulation and histamine release from mast cells or basophils. Serum sickness is caused by delayed production of antibodies by the recipient following infusion of a relatively large dose of foreign protein (antigen excess reaction). Serum sickness develops a few days to weeks after administration of horse serum-derived antivenom in the majority of patients who receive this therapy. Fortunately, serum sickness generally is mild, easily treated, and not associated with significant chronic sequelae, although rarely immune-complex vasculitis, myocarditis, neuritis, and glomerulonephritis are noted. Few data on the exact incidence of allergic reactions are available, but some form of acute hypersensitivity reportedly occurs in nearly 25% and delayed serum sickness in 50% of patients receiving antivenom.[14] Moreover, more than 80% of patients develop serum sickness if more than 8 vials of antivenom are administered.[14] The

majority of patients given antivenom experience urticaria as the only acute adverse reaction.

Technique of Administration

Before antivenom is administered, the patient should be asked about a history of asthma, atopy, current use of Î²-adrenergic antagonists, and previous horse serum-derived antivenom exposure. If any of these conditions are present, efforts should be made to obtain crotaline polyvalent immune Fab antivenom. Use of skin testing for sensitivity to horse serum is controversial, and we do not recommend its use before antivenom administration. Skin testing is an unreliable predictor of either immediate or delayed hypersensitivity reactions. Both false-positive (~50%) and false-negative (~20%) skin tests are encountered. A 1-mL vial of horse serum is included in the Wyeth Crotalidae antivenom kit with instructions for skin testing use. In life-threatening situations, and if the Fab antivenom is not available, administration of antivenom to patients with a positive skin test or known allergy to horse serum is warranted.[16,18] Antivenom administration can be continued in selected

cases of serious envenomation even in the presence of an allergic reaction. In such cases, where the skin test is positive or a reaction develops during administration of antivenom, prophylactic or concomitant use of corticosteroids, epinephrine, and antihistamines has alleviated most of the allergic symptoms. Treatment should entail use of both H_1 and H_2 antihistamine receptor blockers. In a study, the cutaneous and systemic signs and symptoms of immediate hypersensitivity were all effectively treated with antihistamines and epinephrine, with no adverse sequelae.[14] Slowing the rate of infusion of antivenom or increasing the dilution frequently lessens the severity of the allergic reaction (Chap. 117). There is no practical way to desensitize patients to horse serum. However, the Fab antivenom is a safe alternative available for horse-serum allergic patients.

The same procedure used in reconstitution of the Fab antivenom can be used for the equine product. A diluent is included in the Wyeth antivenom kit, but the diluent offers no benefit to sterile 0.9% sodium chloride solution and actually may prolong reconstitution because the diluent volume is inadequate to completely fill each antivenom vial. The same technique is described for administration of both products. It is essential that intravenous corticosteroids, H_1 and H_2 antihistamine receptor blockers, and intravenous epinephrine infusion (1 mg epinephrine mixed in 250 mL D_5W) be available at the patient's bedside. Antivenom treatment should never be initiated without close access to resuscitation equipment. Dosing differs for these two products. Ten to 20 vials are given as an initial dose, and no maintenance doses are used. After the initial dose, prothrombin time, fibrinogen level, and platelet counts are drawn, and the patient's local injury is reexamined. Repeat antivenom doses of 10 vials are given as needed to control coagulopathy, thrombocytopenia, and worsening tissue injury. On average, 30 vials are often required for adequate treatment of rattlesnake envenomation.

Followup care for patients receiving equine antivenom usually does not require repeat hematologic studies, unless patients develop signs of bleeding, because recurrence is rarely reported. Although recurrence of coagulopathy and thrombocytopenia is less frequent than with the Fab antivenom patients can have delayed bleeding, if they are not closely monitored. Long-term followup is important following administration of the equine antivenom. There is an approximately 80% chance of developing serum sickness within 3â€“20 days of antivenom administration, especially if more than 8 vials are administered.[14] The frequency of serum sickness is directly related to the number of vials of antivenom administered. The full description of serum sickness treatment is discussed in the Technique of Administration for the Fab antivenom.

Elapid Antivenom (Equine Origin)

Antivenom of equine origin is available in limited supplies from Wyeth for treatment of envenomation by the eastern coral snake (*Micrurus fulvius fulvius*) and Texas coral snake (*Micrurus fulvius tenere*). Toxicity requiring treatment with antivenom has not been reported following bites from the less virulent Arizona (Sonoran, *Micruroides euryoxanthus*) coral snake. The coral snake antivenom does not treat envenomation from coral snakes found in Mexico, Central America, or South America. In contrast to the recommendation to withhold crotaline polyvalent antivenom unless signs of significant envenomation are evident, prophylactic use of coral snake antivenom is recommended in any asymptomatic cases where a coral snake bit is assumed or proven.[15] Limited supplies of this antivenom may make adherence to this recommendation difficult. For a number of hours following the bite of a coral snake, little objective evidence suggests envenomation, but systemic symptoms can develop insidiously. Therefore, at least 3â€“5 vials of coral snake antivenom are given initially and repeated on the basis of the clinical condition. The caveats for administration of crotaline antivenom (skin testing, rate of infusion, treatment of reactions) apply to coral snake antivenom, except less antivenom usually is required for coral snakes. Up to 10 vials can be administered, but dosing recommendations are vague.

Conclusion

In the past, equine crotaline polyvalent antivenom was the only antivenom available for treatment of crotaline envenomation. It is an effective therapy, but carries a significant risk of life-threatening immediate and delayed hypersensitivity reactions. Some hospital pharmacies still maintain supplies of the antivenom, and Wyeth will provide it on an â€œas neededâ€• basis. In recent years, ovine crotaline polyvalent immune Fab antivenom (CroFab) has become the more commonly available treatment for crotaline envenomation. Although treatment with the Fab antivenom requires maintenance doses and often leads to recurrence of envenomation effects, it is

clearly a safer alternative to the equine product. One aspect of crotaline therapy that has not yet been fully evaluated is a cost-to-benefit analysis comparing the two antivenoms. As experience with the Fab antivenom grows, the cost of drug administration, followup care with repeated laboratory examinations, and possible rehospitalization for recurrence may become more evident. Regardless, most physicians are restricted to the Fab antivenom use merely because supplies are more easily secured, thus making any cost-to-benefit analysis less meaningful.

Chapter 118

Industrial Poisoning: Information and Control

Peter H. Wald

Three workers engaged in the production of mercuric acetate were admitted to hospital within 22 calendar days of each other, 30, 48, and 5 days, respectively, after their last working day. The workers served the same reactor in which elemental mercury was oxidized by peroxide to mercuric oxide, and mercuric acetate was formed by the reaction of mercuric oxide with acetic acid. They all presented with neurologic findings including ataxia, dysarthria, tremor, deteriorating vision, and cerebellar signs. The first two had rapidly progressive downhill courses to coma that ended in death. The diagnosis of mercury vapor intoxication of the first two patients was established 21 and 16 days after their admission, when the third patient was admitted and hospitals were informed about their exposure. Blood mercury levels in all three patients were approximately 2000 Âµg/L with low urine mercury levels. All patients were chelated with penicillamine without any noticeable

effect.

Organic mercury probably was formed as an unintended byproduct of this reaction. In this reaction, methyl mercury acetate, which is 5.4 times more volatile than mercury vapor, could have been formed. The incorrect diagnosis of mercury vapor exposure in these cases was established despite the facts that (1) the observed signs of a rapid irreversible clinical course, ataxia, dysarthria, and constriction of visual fields are rarely present in mercury vapor poisoning and are characteristic of organic mercury poisoning; (2) the degree of deterioration after removal from exposure further implicated organic mercury, not mercury vapor; (3) blood mercury concentrations were in the range associated with severe poisoning in the Iraq methyl mercury epidemic; (4) patients had little response to treatment with penicillamine, the opposite of what is expected with mercury vapor; and (5) the blood-to-urinary mercury concentration ratios were high, whereas this ratio usually is <0.5 in mercury vapor toxicity or in workers exposed to mercury vapor.

The other important facet of these cases is the public health implications of this sentinel health event. Three employees in this workplace were affected by this exposure. Were there any others?

These cases illustrate three important problems associated with the diagnosis and treatment of occupational or environmentally caused diseases: (1) the ability to establish the diagnosis correctly, (2) the ability to treat the condition correctly, and (3) the ability to act correctly on any public health issues related to the exposure. The following discussion instructs the clinician on how to assemble adequate information to achieve the appropriate diagnosis and treatment.

Taking an Occupational History

Because time spent at work is a large percentage of many people's

day, the occupational health history should be a routine part of any medical history. This is especially true of patients who present to a physician with potential chemical exposures at work or unusual symptoms. The history should include several brief survey questions. Positive responses then lead to a more detailed occupational and environmental history, which is composed of three elements: present work, past work, and nonoccupational exposures.

The Brief Occupational Survey

The following three questions should be incorporated into the occupational survey:

- Exactly what kind of work do you do?
- Are you exposed to any physical (radiation, noise, extremes of temperature or pressure), chemical (liquids, fumes, vapors, dusts, or mists), or biologic hazards at work (Table 118-1)?
- Are your symptoms related in any way to starting or being away from work? For example, do the symptoms start when you arrive at work at the beginning of the day or week or when you work at a specific location, or during a specific process at work?

TABLE 118-1. Hazard Classes, Hazard Types, and Several Common Examples Found in the Workplace

Hazard Class	Hazard Type	Examples
Physical hazards	Manâ€“machine interfaces	Repetitive motion Lifting

		Vibration Mechanical trauma, electric shock
	Physical environment	Temperature Pressure Long/rotating shifts
	Energy	Ionizing radiation: x-ray, ultraviolet Nonionizing radiation: infrared, microwave, magnetic fields Lasers Noise
Chemical hazards	Solvents	Aliphatics, aromatics, alcohols, ketones, ethers, aldehydes, acetates, peroxides, halogenated compounds
	Metals	Lead, mercury, cadmium
	Gases	Combustion products, irritants, simple and chemical asphyxiants
	Dusts	Organic (wood) and inorganic (asbestos/silica)

	Pesticides	Organic chlorine, organic phosphorus, carbamate
	Epoxy resins and polymer systems	Toluene diisocyanate, systems phthalates
Biologic hazards	Bacteria	*Bacillus anthracis, Legionella pneumophila, Borrelia burgdorferi*
	Viruses	Hepatitis, human immunodeficiency virus, hantavirus
	Mycobacteria	*Mycobacterium tuberculosis*
	Rickettsia and *Chlamydia*	*Chlamydia psittaci, Coxiella brunetti*
	Fungi	*Histoplasma capsulatum, Coccidioides immitis*
	Parasites	*Echinococcus* spp, *Plasmodium* spp
	Envenomations	Arthropod, marine, snake
	Allergens	Enzymes, animals, dusts, insects, latex, plant pollen dusts

Present Work

Collected data on a person's present job reveals what his or her present exposures may be, which can help formulate the differential diagnosis for the employee's complaints. These data can be systematically collected by focusing on four areas: specifics of the job, hazardous exposures, health effects, and control measures (Table 118-2).

Specifics of the Job

It is not sufficient simply to inquire what the patient does for a living. Like healthcare professionals, workers in other industries have their own jargon. When asked for a job title, a patient may respond with a title that has meaning only in his or her trade. Even if the job title is recognizable, it may not provide any useful information and, in fact, may be misleading. A secretary working in a small plastics manufacturing plant may have occupational exposures quite different from the secretary who works for a law firm.

The important specific information requested should include name of employer, type of industry, duration and location of employment, hours and shift changes, process description including unusual occasional activities, and adjacent processes. The employer may be able to provide information about materials used at the plant. However, clinicians should always obtain the patient's permission before calling the employer. A patient may be fired or otherwise discriminated against (despite legal protections) for suggesting that health problems are work related.

It is important to learn actually what happens in the patient's immediate work environment because nearby work processes may

contribute other exposures. If possible, the patient should be asked for a diagram of the work area. The patient also should be questioned

about job process changes. A previously safe job may have been changed to a potentially dangerous job without a change in the patient's job title.

TABLE 118-2. Components of an Occupational Health History

Current work history
  Specifics of the job
    Employer's name
    Type of industry
    Duration of employment
    Employment location, hours, and shift changes
    Description of work process
    Unusual activities of the job that are occasional (maintenance)
    Adjacent work processes
  Hazardous exposures (Table 118-1)
  Possible health effects
    Suspicious health problems
    Temporality of symptoms
    Specific distribution of symptoms (rash, paresthesias)
    Affected coworkers
    Presence or absence of known risk factors (smoking, alcohol)
  Workplace sampling and monitoring
    Individual and/or area air monitoring
    Surface sampling
    Biologic monitoring

- Medical surveillance records
- Exposure controls
  - Administrative controls
  - Process engineering controls
    - Enclosure
    - Shielding
    - Ventilation
    - Electrical and mechanically controlled interlocks
  - Personal protective equipment
    - Respirators
    - Protective clothing
    - Earplugs, glasses, gloves, face shields, head and foot protection
- Past work history
  - Review current work history for all past employment
- Nonoccupational exposures
  - Secondary employment
  - Hobbies
  - Outdoor activities
  - Residential exposures
  - Community contamination
  - Habits

The patient should describe exactly what he or she does on any given day and for how long. Unusual and nonroutine tasks, such as those performed during overtime, maintenance, or in an emergency, should be described. The primary job may not involve chemicals, but the patient may nevertheless perform tasks that entail unprotected exposure to a toxic chemical.

Hazardous Exposures

The names and/or types of all chemicals or substances to which the patient may be exposed are important in determining potential

adverse effects and any relationship to the patient's complaints. It is important to elicit any recent changes in suppliers of these products, as even a slight change in the formulation of a chemical may cause adverse effects in an individual who previously had no problems working with that compound. This information may be obtained from the material safety data sheet (MSDS), an important but not universally reliable source of information about the chemical. In addition to adverse health effects, the MSDS contains information on chemical reactivity, safety precautions, and other data. As an initial step, the MSDS should be requested and reviewed; however, information provided on health effects should be confirmed using other resources. Four major concerns result from relying solely on the MSDS: (1) some MSDS forms are excellent, but others are incomplete and inadequate; (2) components of a product that are regarded as â€œtrade secretsâ€• do not have to be revealed; (3) components that have important health effects (eg, solvent or solid carriers of the â€œactive ingredientsâ€•) often may be grouped together under â€œinert ingredientsâ€• without being specifically named; and (4) process intermediates or unintended byproducts of a manufacturing process may not be identified. However, if a chemical is believed to be related to a health effect, manufacturers are required to release to a physician all information, including trade secrets and inert components.

Exposures to physical and biologic xenobiotics can be elicited during the review of job processes. Most patients know what they are, or have been, exposed to, even if they do not know the exact name of the xenobiotics or its medical effects.

Health Effects

Significant occupational exposures usually cause medical effects, although some do so only after a substantial latency period. Key areas of interest include suspicious health problems, temporality

of symptoms, and affected coworkers. These data, combined with workplace monitoring and sampling data, can help in determining whether the patient is suffering a work-related illness (Table 118-3). Patients may suspect that their illness or complaint is work related, especially when symptoms occur at the workplace and improve or disappear over the weekend or during a vacation. Specific distribution of findings, such as a rash in a bilateral glove pattern, is supportive of an occupational etiology. Coworkers with similar complaints (not necessarily of the same severity) should raise suspicion that a workplace exposure is responsible for a particular symptom complex. Finally, diseases such as lung cancer or hepatitis, which occur in the absence of known risk factors such as smoking and alcohol, are important.

TABLE 118-3. Evidence Supporting Work-Relatedness of Occupational Disease

Known or documented exposure to a causative agent
Symptoms consistent with suspected workplace exposure
Suggested or diagnostic physical signs
Similar problems in coworkers or workers in related occupations
Temporal relationship of complaints related to work
Confirmatory environmental or biologic monitoring data
Scientific biologic plausibility
Absence of a nonoccupational etiology
Resistance to maximum medical treatment because employee continues to be exposed at work

Workplace Sampling, Monitoring, and

Control

Control of workplace hazards begins with an industrial hygiene monitoring program. Employers are required to give results of both area and individual sampling to employees. A medical surveillance program that includes periodic spirometry and respiratory questionnaires usually indicates that the patient works with a potential respiratory toxin. A medical surveillance program that includes biologic monitoring for a specific substance also may provide an immediate clue to what may be causing the patient's complaints. Finally, if the patient knows exactly what he or she is working with, the physician usually can quickly determine whether any of the substances are compatible with the patient's complaints. Many companies do not perform routine industrial hygiene monitoring or medical surveillance. Individuals who became sick or ill at work often are sent to local emergency departments. In such situations, emergency physicians must be prepared to develop the type of time-consuming, detailed occupational history outlined here or be able to consult or refer immediately to appropriate individuals or clinics.

Portions of Table 118-2 and the following section on Evaluation and Control of Workplace Hazards detail the types of controls usually used in workplaces. It is important to determine whether the workplace uses any control measures, engineering controls, work practice protocols, administrative controls, and personal protective equipment. The existence of control measures usually indicates that the employer recognizes and has attempted to deal with a hazardous exposure.

Past Work

It is important not to limit the occupational history to the patient's current workplace and job. Many occupational diseases have long latency periods between exposure to a toxic agent(s) and initial development of clinical symptoms. In addition, patients may have

been exposed to xenobiotics at work that make them more sensitive to other environmental agents. For example, someone who developed asthma secondary to a previous workplace exposure may suffer asthma attacks upon exposure to simple irritants in the current workplace. When taking an in-depth occupational history, explore issues relevant to the current work history for each previous job.

Nonoccupational Exposures

Workers may be exposed to toxic xenobiotics in the course of pursuing secondary employment, hobbies, or outdoor activities in contaminated or industrial areas. Residential exposures, such as those from gas and wood stoves, chemically treated furniture and fabrics, and pest control, may be relevant. It is important to ask patients about these potential exposures before focusing entirely on exposures in their primary place of employment. This obviously includes relevant issues from the social history, such as tobacco, alcohol, and licit and illicit drug use.

Evaluation and Control of Workplace Hazards

Initial Workplace Evaluation

The Occupational Safety and Health Act places legal responsibility for providing a safe and healthy workplace on the employer. The rationale for this placement of responsibility is that the employer is in the best position to make any modifications necessary to prevent additional work-related illness and injury. The physician may wish to initiate a dialogue with a patient's employer to promote preventive action but should do so only with the patient's informed consent. The initial treating physician may also refer to

an occupational medicine specialist, who is specifically trained to manage work-related exposures and diseases and initiate prevention programs.

Because the initial contact may influence subsequent events, it is important to identify an individual with an appropriate administrative role, such as someone in the company medical department, the patient's supervisor, the plant's safety officer, or the shop manager. If management is willing to examine the hazardous conditions, a plant walk-through inspection can provide unique insight and information usually unavailable in an office setting. A walk-through by an occupational medicine specialist makes it easier to understand the work environment, identify safety and health hazards, assess control measures, and recognize opportunities for prevention. It also facilitates a good working relationship with key personnel in management and labor. The physician who cares for a number of patients who work in the plant or who provides health services to the workers through the company or labor union may wish to be involved in the walk-through. Assistance with plant inspections can be obtained from occupational health specialists, such as occupational physicians or industrial hygienists.

Industrial Hygiene Sampling and Monitoring

Equipment is available to measure airborne concentrations of toxic xenobiotics, noise levels, radiation levels, temperature, and humidity. Employees can be fitted with pumps and other devices to measure individual exposure levels at the breathing zone, where, depending on what controls are used, concentrations may vary from those in the general work area. These results then can be compared with Occupational Safety and Health Act (OSHA) and other available standards to help determine the extent of the hazard and to formulate a control plan. OSHA requires that

employers monitor the levels of only a few specific hazards, including asbestos, formaldehyde, lead, vinyl chloride, noise, and ethylene oxide. Ongoing sampling of the remaining estimated 60,000 chemicals used in the workplace is not required. Where industrial hygiene sampling is performed, OSHA's medical access standard gives any exposed worker or his or her representative the right to review and copy all sampling data.

Control of Workplace Hazards

Workplace hazard control traditionally has relied on a hierarchy of methods to protect workers from exposure. The preferred solution is complete elimination of the hazard by *substitution*. Where substitution is not possible, the next preferred method consists of controls that shield workers or reduce their exposure. The least favored method us personal protective equipment, which requires a positive action from the worker.

Engineering Controls

Health and safety professionals prefer, and OSHA regulations require where feasible, the use of engineering controls to reduce worker exposure to hazardous xenobiotics because such controls intercept hazards at their source or in the workplace atmosphere before they reach the worker. Engineering controls include redesign or modification of process or equipment to reduce hazardous emissions, isolation of a process through enclosure, automation of an operation, and installation of exhaust systems that remove hazardous dusts, fumes, and vapors. Local exhaust systems, such as hoods, are preferable to general dilution ventilation because the former removes contaminants closer to their source and at relatively high rates.

Engineering controls have several advantages over control measures focused on the worker. Properly installed and maintained

engineering controls are reliable and consistent, and their effectiveness does not depend on human supervision or interaction. They can limit exposure through several routes, such as inhalation and skin absorption, simultaneously. In addition, engineering controls do not place a burden on the worker or interfere with worker comfort or safety.

Work Practices

Work practices are procedures that the worker can follow to limit exposure to hazardous agents. Examples are the use of high-powered vacuum cleaners instead of compressed air cleaning and pouring techniques that direct hazardous material away from the worker. Although not as effective as engineering controls, work practice can be a useful component of an overall hazard control program.

Administrative Controls

Administrative controls reduce the duration of exposure for any individual worker or reduce the total number of workers exposed to a hazard. Examples are rotating workers into and out of hazardous areas so that no single worker is exposed full time and scheduling procedures likely to generate high levels of exposure, such as cleaning or maintenance activities, during nights or weekends. Administrative controls sometimes have the side effect of exposing more workers to a hazard, albeit at lower doses that are hoped do not cause health effects.

Personal Protective Equipment

Personal protective equipment, such as respirators, earplugs, gloves, and hard hats, is the least effective but most commonly used control method. Employers may often favor personal protective equipment over the institution of more costly

engineering and administrative controls.

Respirators and other forms of personal protective equipment often are hot, uncomfortable, and awkward to wear and may make it difficult for workers to breathe, speak, or hear, depending on the equipment involved. Consequently, workers often remove or refuse to wear the protection. Respirators place extra stress on the heart and the lungs. Both respirators and earplugs limit conversation and therefore present a safety hazard in themselves.

Because personal protective equipment does not stop a hazard from entering the environment, the worker is entirely vulnerable to exposure if the equipment fails. In addition, generally only one route of exposure is protected. For example, the commonly used half-mask respirator still leaves the skin and eyes exposed.

Choosing the right piece of personal protective equipment can be difficult and may depend on the nature and extent of the hazard. For example, each type of respirator is rated for the amount of protection it provides; as expected, the cost of a respirator increases with its protection factor. Use of the wrong type of respirator can leave the worker insufficiently protected.

Half-mask respirator cartridges are available in various colors, coded to the contaminant filtered out of the breathing environment. If the wrong cartridge is used, the worker is essentially unprotected from the hazardous contaminant. To be effective, a respirator must be meticulously fit to the individual worker. Failure to achieve a proper seal negates the respirator's usefulness. High cheekbones, dentures, scars, perspiration, talking, head movements, and facial hair can prevent a proper seal. These factors often are ignored or overlooked by an employer who adopts a â€œone-size-fits-allâ€• policy.

Even if each employee is provided the proper respirator, the respiratory protection program may not be effective. OSHA

requires that employers institute a program of proper fit testing, cleaning, maintenance, and storage of respirators, which can be at least as costly as the institution of engineering controls.

In some instances, use of personal protective equipment may be unavoidable. An employer may need to control a hazardous exposure through a combination of measures, such as engineering controls and personal protective equipment. Ideally, the employer is using personal protective equipment as a control of last resort and in strict compliance with OSHA standards.

Worker Education and Training

Regardless of the control measures used, workers and supervisors must be educated in the recognition and control of workplace hazards and the prevention of work-related illness and injury. The OSHA Hazard Communication Standard requires that employers train workers in ways to detect the presence or release of hazardous chemicals, their physical and health hazards, methods of protection against the hazards, and proper emergency procedures, as well as how to read the labeling system and how to read and use an MSDS.

With the passage of federal, state, and local right-to-know laws, many consulting companies now offer hazard communication training. These programs are of uneven quality. Those that tend to focus on acute hazards, ignore chronic effects, and emphasize personal protective equipment over other control measures may not be effective in training workers to recognize and control chemical hazards.

Medical Monitoring

Together with worker education and industrial hygiene, a medical program can form the foundation of an effective occupational disease prevention regimen. However, medical monitoring is

fraught with technical and ethical pitfalls. Medical monitoring encompasses both medical screening and medical surveillance.

Medical screening refers to the cross-sectional testing of a population of workers for evidence of excessive exposure or early stages of disease that may or may not be related to work and that may or may not influence the ability to tolerate or perform work.

Preemployment and preplacement physical examinations are another type of medical screening, often favored by employers. The new Americans with Disabilities Act (ADA) regulates the timing, scope, content, and use of these examinations and the information gathered. Comprehensive resources for information on the ADA are available at http://www.adata.org. The ADA prohibits â€œpreemploymentâ€• medical examinations and inquiries. After a job offer has been made, â€œpreplacementâ€• examinations and inquiries can be conducted to determine whether an applicant can perform a job safely and effectively. The physician evaluates past medical history, current symptoms, and physical laboratory findings to determine whether an individual currently has the physical or mental abilities necessary to perform the essential functions of the job and whether the individual can do so without posing a â€œdirect threatâ€• to the health or safety of self or others. This threat must be more than theoretical and cannot be based on some future time; the threat must be concrete and relatively immediate.

Few tests and few conditions are good predictors of either ability to perform a task or increased susceptibility to a particular exposure. Many workers and their advocates view preplacement examinations as a way for employers to choose the â€œfittestâ€• worker and to avoid their legally mandated obligation to provide a safe and healthy workplace for all workers. This is not true for most employers. Physicians asked by an employer to perform preplacement examinations should be sure that each component of the examination relates to the actual job the individual is being

hired to perform and the actual risks he or she will encounter on the job. Both the law and sound occupational medical practice dictate that the employer's attention and efforts be directed toward redesign of the job and its hazards so that it is safe and healthy for all workers to perform.

Medical surveillance refers to the ongoing evaluation, by means of periodic examinations, of high-risk individuals or potentially exposed workers to detect early pathophysiologic changes indicative of significant exposure. OSHA requires little in the way of medical surveillance, although several OSHA standards require employers to institute medical surveillance programs, for example, for workers exposed to asbestos, arsenic, vinyl chloride, lead, and ethylene oxide. Depending on the potential exposure, medical surveillance can include a history and physical examination, chest radiograph, pulmonary function tests, blood and urine tests, and other laboratory evaluations.

A medical surveillance program also can include biologic monitoring, the purpose of which is not to identify the occurrence of disease but to measure the uptake or presence of a particular substance or its metabolites in body fluids or organs. Ideally, this occurs before any pathophysiologic damage occurs. Consequently, biologic monitoring is potentially a primary preventive measure. For example, several volatile organic compounds, such as benzene and toluene, if inhaled or absorbed through the skin, produce metabolites that can be measured in urine.

Biologic monitoring can have some advantages over air monitoring because biologic monitoring measures the *actual* absorption of a substance by the body as opposed to ambient levels in the workplace. The amount of a chemical absorbed may not be closely correlated to ambient levels for several reasons, including differences in individual work habits, use and effectiveness of personal protective equipment, dermal absorption of chemicals unrelated to their concentration in the air, and nonoccupational

exposures.

Biologic monitoring, however, has several significant limitations. For most xenobiotics, there are no standards of â€œnormalâ€• or â€œsafeâ€• levels against which results can be compared. Obtaining specimens may be difficult, expensive, and invasive (eg, fat biopsies to detect dioxin). The timing of specimen collection is critical because different xenobiotics have different biologic half-lives. The

storage and handling of specimens and interpretation of results are vulnerable to error. Nevertheless, if carefully designed and implemented, biologic monitoring can be a useful complement to a comprehensive industrial hygiene program.

With the exception of biologic monitoring, medical monitoring programs identify disease processes already underway and therefore are, at best, a form of secondary prevention. Employers use results to remove workers rather than remediating the hazard abuse medical and biologic monitoring programs. To be an effective preventive measure, these programs must be coordinated with environmental monitoring programs that identify the nature, source, and extent of workplace hazards; implementation of engineering controls and other measures that control hazards as close as possible to the source; and worker education programs that, at a minimum, inform workers of exposures, their effects, and proper control measures.

Both medical monitoring programs and preplacement examinations raise issues of doctorâ€“patient confidentiality. Employee medical records should be available only to the corporate medical or first-aid department and not to the personnel office and general management. Unless required by statute, employers should never be told the results of history, physical, or diagnostic examinations unless the patient gives his or her written consent. The examining physician need only inform the employer that an individual is or is

not capable of performing a particular job with or without specified restrictions. The physician should not disclose diagnostic information about medical conditions.

Information Resources

Healthcare professionals require information on industrial toxins in a number of situations, ranging from caring for an acutely ill patient in an emergency department, when information must be obtained quickly, to caring for a patient with chronic symptoms that may reflect an occupational disease. The American College of Occupational and Environmental Medicine publishes a suggested reading list (http://www.acoem.org) that provides reference sources for information on toxicology, acute and chronic health effects, diagnosis, and treatment; assists in screening and surveillance; and provides information on groups at risk, product uses, and sources of further information. However, use of these resources depends on the proper identification of the substance in question. If the substance, its generic name, and ingredients are not known, the research process becomes more difficult.

The practitioner should take a logical approach to seeking information about industrial xenobiotics. First, the xenobiotics must be identified by its generic name. This can be done by reviewing the MSDS or by contacting poison control centers (PCCs), the employer, manufacturer, unions, or government agencies. MSDSs also are available by searching online. MSDS Online (http://www.msdsonline.com) is a good starting point, but typing â€œMSDSâ€• into any online search engine yields a number of sites offering data sheets.

Poison Control Centers

Regional PCCs can provide assistance even when the exact chemical name is unknown because information on xenobiotics and

their management may be cross-referenced by trade name and manufacturer. Moreover, PCC personnel usually can suggest additional resources. Most PCCs have computerized listings of poisons that are updated regularly. The best-known system is POISINDEX (Micromedex, Englewood, CO). Subscribers to this system receive quarterly updates of an alphabetically organized listing of approximately 500,000 industrial and nonindustrial xenobiotics. The system includes trade names, the components, and the concentrations, when available, of each compound listed. These elements are then cross-referenced to management protocols. The name of the manufacturer is also listed.

Employers and Manufacturers

Many state and federal laws require manufacturers to generate, retain, and disclose information that may help physicians care for persons with work-related health problems. Scientific information, exposure data, information on health effects, and collected medical data are included in the types of information that must be retained.

The Chemical Transportation Emergency Center (CHEMTREC; 1-800-262-8200; http://www.chemtrec.org), sponsored by the Chemical Manufacturers Association, has as its primary responsibility providing information to healthcare practitioners responding to hazardous spills. However, it also will provide information on commercial products found in a patient's workplace. Employers are required to furnish this information to employees in the form of MSDSs.

Worker's Compensation Insurance Carriers

Smaller companies often lack internal health and safety staffs. Worker's compensation or company risk insurance carriers may

have valuable information about exposures and controls in the workplace. As a service to their clients, carriers often will do walk-throughs and hazards evaluations for clients that lack these resources and suggest appropriate engineering controls. Healthcare professionals can contact the carrier directly to see what additional information is available.

Regulatory Agencies

OSHA requires chemical manufacturers to create a MSDS for each chemical they produce, and employers who use chemicals must retain the MSDSs in the workplace. Required information includes chemical and common names; physical, safety, and health hazard data; exposure limits; precautions for safe handling and use; generally applicable control measures; and emergency and first-aid procedures. The OSHA Hazardous Communication Standard requires individual employers to provide employees with information on the xenobiotics used in their workplaces. With the patient's permission, a call to the plant manager, foreperson, or safety officer may be all that is necessary to determine the name of the substance in question. Employers may be able to provide information on exposure levels in the patient's work environment. In addition, company medical departments (where they exist) may have results of medical testing done on the patient.

There is an important point to reiterate about MSDSs: healthcare providers should not rely on these sheets as the sole source of information. The MSDSs are created by the chemical manufacturers as they generate scientific and health data during the course of seeking approval from the Environmental Protection Agency (EPA) to manufacture xenobiotics and will not be a complete product evaluation. In addition, Section 8(c) of the Toxic Substances Control Act (TSCA) requires chemical manufacturers to report records of significant adverse reactions to human health or the

environment. When contacting chemical manufacturers, physicians should ask to speak with a toxicologist, chemist, or someone in the products information department.

Unions

Labor unions, where they exist, can be excellent sources of information on xenobiotic exposures. At the local level, union officers, health and safety committee members, and shop stewards may be able to provide MSDSs, exposure data, medical and epidemiologic information, and reports of incidents or cases of interest in a particular plant. The health and safety department of the American Federation of Labor and Congress of Industrial Organizations (AFL-CIO), (http://www.aflcio.org) in Washington, DC, can provide information on occupational health and safety activities and advice on which member unions may be of specific help. At the international level, unions often have well-trained health and safety professionals who may provide or suggest sources of helpful information. In addition, some cities have a coalition of occupational safety and health groups that may provide information about other known exposed or affected workers.

Government Agencies

A myriad of agencies have some regulatory authority over manufacturing and services industries. These agencies and their important regulatory authority are listed in Table 118-4.

OSHA of the US Department of Labor (http://www.osha.gov) is responsible for setting and enforcing workplace health and safety standards. It is empowered to investigate occupational health and safety complaints and can inspect work sites and levy fines for violations of its standards. In approximately half of the 50 states,

the OSHA program is implemented by a state agency. Individual workers, their representatives (unions), or their physicians can file a complaint with the state or federal OSHA program and request an inspection. OSHA regulations protect workers from discrimination and punishment by their employer, who may be angered by their filing a complaint.

Some state OSHA agencies have separate enforcement and consultation arms. Thus, companies can request assistance from the occupational health specialists in the consultation branch without fear of reprisal from the enforcement branch. Healthcare workers should be familiar with the functions of their state agency and workers' rights under the law.

The National Institute for Occupational Safety and Health (NIOSH) of the US Department of Health and Human Services is part of the Centers for Disease Control (http://www.cdc.gov/niosh). It is not a regulatory agency. NIOSH is responsible for researching the causes of occupational disease and injury and methods for their prevention and control; evaluating workplace conditions; recommending exposure limits to OSHA for standard setting; and training occupational health and safety professionals. It is empowered to conduct on-site evaluations of health hazards in response to requests from employee representatives or employers. After conducting these evaluations, NIOSH investigators immediately contact OSHA, the employees, and the employer if they find that the workers are in imminent danger.

As part of the process of recommending exposure standards to OSHA, NIOSH develops comprehensive documents that critically evaluate all available scientific data on particular chemicals. These â€œcriteria documentsâ€• review the chemical's properties, production methods, uses, and workers at risk as well as studies of exposure effects in humans and animals. Methods of screening, surveillance, and control are presented. The agency periodically issues technical reports and special occupational hazard reviews of

specific occupations. In conjunction with OSHA, NIOSH develops and disseminates health hazard alerts to inform employers, employees, and healthcare professionals of serious health effects of particular chemicals.

The EPA (http://www.epa.gov) is charged with protecting the nation's land, air, and water. The agency administers a number of laws designed to preserve the public health and environment, one of which is the TSCA. This act authorizes the EPA to collect information on chemical risks from manufacturers and processors and to review information on new chemicals and new uses of chemicals before they are manufactured. Unless designated a trade secret, this information is subject to disclosure and therefore is available. The TSCA assistance office may be most useful when resource materials and government documents contain no information about the chemicals or processes in question.

The National Toxicology Program (NTP; http://www.ntp-server.niehs.nih.gov) is a federal program established in 1978 to develop scientific information on exposure to xenobiotics.

The Agency for Toxic Substances and Disease Registry (ATSDR; http://www.atsdr.cdc.gov) is part of the Public Health Service created by Congress to implement the health-related sections of laws that protect the public from hazardous wastes and environmental spills of hazardous substances. In 1986, the Superfund Amendments and Reauthorization Act (SARA) made amendments to the initial enabling legislation of 1980 and broadened ATSDR's responsibilities in the areas of health assessment, toxicologic databases, information dissemination, and medical education. One of its offices, the Office of Health Assessment, provides emergency response for toxic and environmental disasters, consults in public health emergencies, assesses hazardous waste sites, provides technical assistance to agencies and organizations, and estimates health risks to humans from exposure to hazardous substances. The program areas in

which ATSDR operates include health assessments, toxicologic profiles, emergency response, and exposure and disease registries.

Online Databases

Printed material often is adequate for determining the adverse health effects of chemical exposures, but some resources may be unavailable to physicians, and textbook publications usually lag 2 years or more behind new information. As a result, up-to-date findings and reports may be missed if the practitioner relies solely on printed material. The National Library of Medicine (http://www.nlm.nih.gov) now sponsors Internet searching of both Medline and a number of databases in the Toxicology Data Network (TOXNET) that are very useful for finding information about industrial chemicals. Additional databases are available for searching on the OSHA, NIOSH, EPA, and ATSDR web sites.

Obligations of the Healthcare Provider to the Individual Patient, Coworkers, Employer, Government, and Community

Occupational diseases and injuries are, in principle, preventable. Physicians who diagnose a work-related disease or injury have an

opportunity, and an ethical obligation, to participate in the identification and control of workplace hazards and the prevention of further occupational illness and injury. Physicians can choose from a range of possible followup measures, the goals of which are to prevent recurrence or worsening of the disease or injury in the patient and to prevent the development of disease or injury in other potentially exposed workers. Some of these activities may necessitate contact with occupational medicine physicians,

toxicologists, industrial hygienists, lawyers, journalists, government officials, management personnel, and union officials.

TABLE 118-4. Government Agencies and Their Important Regulatory Authority of the Workplaceâ€”A Timeline

Regulation	Agency	Authority
Occupational Safety and Health Act (OSHA, 1970)	Department of Labor	Congress passed the Occupational and Safety Health Act and created the Occupational Safety and Health Administration to ensure worker and workplace safety. Their goal was to make sure employers provide their workers a place of employment free from recognized hazards to safety and health, such as exposure to toxic chemicals, excessive noise levels, mechanical dangers, heat or cold stress, or unsanitary conditions. In order to establish standards for workplace health and

			safety, the Act also created the National Institute for Occupational Safety and Health (NIOSH) as the research institution for the Occupational Safety and Health Administration. Part 1910.1200 of the Act established the Hazardous Communication Standard (HazCom). The purpose of this section is to ensure that the hazards of all chemicals produced or imported are evaluated and that information concerning their hazards is transmitted to employers and employees. This transmittal of information is to be accomplished by means of comprehensive hazard communication programs, which are to include container	

		labeling and other forms of warning, material safety data sheets, and employee training.
Resource Conservation and Recovery Act (RCRA, 1976)	Environmental Protection Agency (EPA)	RCRA (pronounced â€œrick-rahâ€•) gave the EPA the authority to control hazardous waste from â€œcradle to grave.â€• This includes the generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of nonhazardous wastes. The 1986 amendments to RCRA enabled the EPA to address environmental problems that could result from underground tanks storing petroleum and other hazardous substances. RCRA focuses only on active and future facilities

		and does not address abandoned or historic sites (see CERCLA). HSWA (pronounced â€œhiss-waâ€•), the Federal Hazardous and Solid Waste Amendments, are the 1984 amendments to RCRA that required phasing out land disposal of hazardous waste. Some of the other mandates of this strict law include increased enforcement authority for the EPA, more stringent hazardous waste management standards, and a comprehensive underground storage tank program.
Toxic Substances Control Act (TSCA, 1976)	EPA	TSCA was enacted by Congress to give the EPA the ability to track the 75,000 industrial chemicals currently produced or imported into the United States. The EPA repeatedly

		screens these chemicals and can require reporting or testing of those that may pose an environmental or human-health hazard. EPA can ban the manufacture and import of those chemicals that pose an unreasonable risk. Reporting requirements include (1) premanufacturing notification for new chemicals, (2) allegation of significant adverse reactions, (3) reporting of health and safety studies, and (4) notification of suspicion of substantial risk to health.
Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, 1980)	EPA	The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), commonly known as the Superfund, was

			enacted by Congress on December 11, 1980. This law created a tax on the chemical and petroleum industries and provided broad federal authority to respond directly to releases or threatened releases of hazardous substances that may endanger public health or the environment. Over 5 years, $1.6 billion was collected, and the tax went to a trust fund for cleaning up abandoned or uncontrolled hazardous waste sites. CERCLA: (1) established prohibitions and requirements concerning closed and abandoned hazardous waste sites, (2) provided for liability of persons responsible for releases of hazardous waste at these sites, and (3) established a trust	

			fund to provide for cleanup when no responsible party could be identified. The law authorizes two kinds of response actions: (1) short-term removals, where actions may be taken to address releases or threatened releases requiring prompt response, and (2) long-term remedial response actions that permanently and significantly reduce the dangers associated with releases or threats of releases of hazardous substances that are serious but not immediately life threatening. These actions can be conducted only at sites listed on the EPA's National Priorities List (NPL).
	Superfund Amendments and	EPA	SARA reflected the EPA's experience in administering the

	Reauthorization Act (SARA, 1986)		complex Superfund program during its first 6 years and made several important changes and additions to the program. SARA: (1) stressed the importance of permanent remedies and innovative treatment technologies in cleaning up hazardous waste sites, (2) required Superfund actions to consider the standards and requirements found in other state and federal environmental laws and regulations, (3) provided new enforcement authorities and settlement tools, (4) increased state involvement in every phase of Superfund, (5) increased the focus on human health problems posed by hazardous waste sites, (6) encouraged greater citizen	

participation in making decisions on how sites should be cleaned up, and (7) increased the size of the trust fund to $8.5 billion. SARA also required the EPA to revise the Hazard Ranking System (HRS) to ensure that it accurately assessed the relative degree of risk to human health and the environment posed by uncontrolled hazardous waste sites that may be placed on the National Priorities List (NPL). Emergency Planning and Community Right-to-Know Act (EPCRA), also known as Title III of *SARA*, was enacted by Congress as the national legislation on community safety. This law was designated to help local communities protect public health, safety, and the environment from

		chemical hazards. The law requires manufacturers to report the amount of toxic substances released each year (Toxic Release Inventory, TRI). To implement EPCRA, Congress required each state to appoint a State Emergency Response Commission (SERC). The SERCs were required to divide their states into Emergency Planning Districts and to name a Local Emergency Planning Committee (LEPC) for each district.
Americans with Disabilities Act (ADA, 1990)	Department of Labor	ADA was enacted by Congress to establish clear and comprehensive prohibition of discrimination on the basis of disability. The act specifically covers discrimination in the areas of (1) employment, (2)

		public services, (3) public accommodations and services operated by private entities, and (4) telecommunications.

Obligations to the Patient

Inform the Patient That the Illness May Be Work Related

When the workplace is determined to be a factor in the etiology or aggravation of the patient's illness, this fact and its implications should be discussed with the patient. It should never be assumed that the patient is fully aware of the health risks associated with any workplace exposure. He or she should be provided information regarding the nature of workplace hazards, their health risks, and preventive measures, and recommendations regarding continued exposure.

Suggest How the Patient Can Reduce the Exposure

In some cases the patient can take steps to reduce exposure. Adjustments in work habits that may be helpful include using a respirator or other personal protective equipment provided by the employer, using workplace shower and dressing rooms to avoid carrying toxic chemicals from the workplace to the home, and avoiding ingestion of workplace toxins by careful hand washing before eating or smoking and by taking lunch, coffee, and smoking breaks away from the work station. Obviously, these

recommendations assume that the employer provides the appropriate equipment and facilities, which is not always the case. The most effective hazard control measures require significant commitment by, and cooperation from, the employer.

Suggest that the Patient Remove Himself or Herself from the Exposure

The employer may be willing to transfer the patient to a location away from the offending hazard. This may result in a reduction in pay, seniority, or other benefits, which may be compensable under Workers' Compensation. The employment provisions of the ADA require employers to make â€œreasonable accommodationsâ€• for both work- and nonâ€“work-related disabilities. Nevertheless, the employer may not be able to accommodate the patient. The patient should be counseled carefully, and other options should be explored.

Advise the Patient to Notify the Employer

Patients who are suffering from a work-related illness may be entitled to Workers' Compensation benefits, Social Security disability, or other government-sponsored benefit programs. In addition, they may have a valid claim against the manufacturer of a chemical, a defective product, or another third party. The degree of disability necessary to bring a successful claim varies.

Once a patient is informed that he or she has a work-related illness, strict time limits are set in motion, and failure to meet them can preclude the patient from successfully filing a claim or receiving needed benefits. The patient should be advised to provide written notice immediately to his or her employer of a work-related illness (supported by a physician's letter) and to seek advice about statutes of limitations and other requirements. This information is generally available from the State Workers'

Compensation Board and usually is required to be provided to the employee by the employer. If a union is available at the workplace, it may be able to advise and assist the patient.

Obligations to Coworkers

A patient with a work-related illness should be advised to inform coworkers about his or her condition. If the patient belongs to a union, he or she should inform the union representative. If there is no union, the patient may contact OSHA or discuss the situation with the employer.

If the patient is a union member and agrees, the physician can contact the union, which may assist in hazard investigation, identify and warn other workers potentially affected by the hazard, and pressure the employer to take corrective action if it is unwilling to do so. The union can help the patient to obtain any available benefits. The patient may be able to identify appropriate contacts, such as shop stewards, members of the union's health and safety or workers' compensation committees, an occupational health specialist employed by the union at the local or national level, or an official of the union local.

Committees on Occupational Safety and Health (COSH), coalitions of labor, health, and legal professionals and community and environmental activists working to prevent job-related illness and injury, may be able to help with diagnosis and followup of occupational diseases. These groups provide education and technical assistance nationwide on a range of topics, including the health effects of specific hazards, control measures, how to use government agencies, and the legal rights of disabled workers.

Obligation to Notify the Employer

When treating an occupational injury or illness, healthcare providers often are required to report to government agencies,

health departments, or insurance carriers. As part of that reporting process, the employer should also be notified. When there is imminent danger to coworkers or the public health, the employer should be contacted to correct the exposure situation.

Obligations to Notify the Government

States may have laws that require direct physician reporting of occupational disease. If management is uncooperative despite notification of a hazardous situation, OSHA should be contacted, with the patient's consent. In addition to the federal agencies specifically empowered to protect worker health and safety, physicians may contact the state or local health department, which may initiate action or refer the problem to one of the federal agencies. Many states also require physicians to report any occupational injury or illness to the Workers' Compensation carrier.

Obligation to Inform Colleagues and the Public

On occasion, an individual primary care physician or specialist is the first to suspect a link between a workplace exposure and a serious health problem. This is likely to recur in the future, especially if the physician practices in a small town or industrial area or provides healthcare to worker groups through a company or union. Armed with an increased index of suspicion and the occupational history, the physician may be able to alert workers and companies and prevent the occurrence of a major health problem. Even if the

physician chooses not to be involved in subsequent investigation or research, it is important that information about suspected problems and hazards be made available to workers and employers

in similar industrial settings, government agencies, healthcare professionals, and, perhaps, the public at large. Case reports discussed in the medical literature, at medical meetings, or through the media can be helpful in this regard.

Summary

Industrial, workplace, and environmental exposures represent a different kind of challenge to primary care and emergency physicians. Patients often present as a diagnostic dilemma or with common symptoms that do not respond to the usual medical treatment. The challenge for the nonoccupational health professional is to correctly establish and treat the condition. This chapter offers a basic approach to all patients that will aid in the diagnosis and treatment of occupational and environmental diseases. This approach uses additional questions applied to the medical history and access to printed and electronic information resources. Exposures to these materials have public health implications. Physicians who make the diagnosis of an occupationally or environmentally related disease have an obligation to prevent further injury. They should work with employee groups, employers, and government agencies to identify the toxic agent and prevent the development of disease in other potentially exposed individuals.

Chapter 119

Simple Asphyxiants and Pulmonary Irritants

Lewis S. Nelson

On a daily basis our bodies are exposed to a variety of potentially damag influences. Although most organs remain relatively protected from influer skin and respiratory tract, by their nature, maintain constant contact with external environment. At rest, the respiratory tract encounters nearly 300 during a typical 8-hour workday, and even mild exertion can triple the vo inhaled. Several critical mechanisms exist within the respiratory system t or minimize toxicity from without and allow humans to breathe safely in v potentially is a toxic environment. Although these efficient mechanisms p substantial protection under normal circumstances, occasionally they can overburdened. Additionally, the lungs are a common portal of entry for s toxic xenobiotics that have no pulmonary effects; the best examples are l 91), carbon monoxide (Chap. 120), and cyanide (Chap. 121).

The respiratory tract performs several important physiologic functions (Cl Its most important role involves the transfer of oxygen to hemoglobin acr pulmonary endothelium. This transfer facilitates oxygen distribution throu

body to permit effective cellular respiration. Diverse xenobiotics may act points in this distribution pathway to limit or impair tissue oxygenation. F example, opioids or paralytic agents may induce hypoventilation, whereas monoxide or methemoglobin inducers may prevent binding of oxygen to Certain xenobiotics prevent adequate oxygenation of hemoglobin at the le pulmonary gas exchange. Two mechanistically distinct groups of xenobiot capable of interfering with gas exchange: simple asphyxiants and pulmor irritants. Impairment of transpulmonary oxygen diffusion, regardless of t reduces the oxygen content of the blood and can result in tissue hypoxia.

Simple Asphyxiants

Case 1 A 50-year-old medical researcher was discovered dead in a small refrigerated room that contained 10-cubic-inch blocks of dry ice. Fifteen arrived blocks of dry ice were placed in the refrigerated room (39.2Â°F [4 approximately 9 AM on the day of the scientist's death. The researcher w at approximately noon, suggesting that at least 3 hours had elapsed betw initial dry ice storage and his first exposure. Scene analysis suggested tha time of his death, the decedent was crouching several inches from the gr store samples in a container. There were no signs of struggle, and the de no history of psychiatric disorders, recent personal crises, or medical illn

Postmortem examination and toxicologic evaluation of the decedent were unrevealing. Blood PCO_2 was not performed because of its well-described postmortem rise. In order to confirm the cause of death, the conditions a of the event were reproduced using the same cold room. Air was sampled several heights; the O_2 concentration fell and the CO_2 concentration rose minutes and peaked by 3 hours. Three hours after dry ice storage, FiO_2 v and CO_2 concentration was 27.6%, both at a height of 9 inches. Concent 20â€“30% (200,000â€“300,000 ppm) CO_2 are associated with rapid deve unconsciousness and death. In addition, the room temperature had fallen (â€“15Â°C). Thus, it appears that even at the cold temperatures of the c sublimation of dry ice progresses rapidly.

Pathophysiology

Simple asphyxiants displace oxygen from ambient air, thereby reducing t of oxygen in air, or FiO_2 , to <21%, resulting in a fall of the partial press oxygen. The partial pressure is a measure of the oxygen contribution to t inspired air and is based on both FiO_2 and barometric pressure. For exam because the ambient pressure at sea level (less water vapor, 47 mm Hg) Hg and the percentage of oxygen is 21%, the partial pressure of oxygen is 150 mm Hg. Under these typical conditions, FiO_2 is a suitable surrogate partial pressure of oxygen. However, this relationship is not applicable at barometric pressures. For example, at the summit of a mountain, the red barometric pressure results in a fall in the partial pressure of oxygen des normal FiO_2 . This reduced partial pressure may be insufficient to allow a oxygen saturation, and supplemental oxygen becomes necessary. As bar pressure falls, exposure to simple asphyxiant gases may further reduce t partial pressure to life-threatening levels. Conversely, underwater divers their FiO_2 to <21% by adding simple asphyxiant gases, such as helium, t breathing mixture in order to avoid oxygen toxicity, yet they still maintai oxygenation. This

is because the elevated barometric pressure raises the partial pressure of normal levels despite the addition of an asphyxiant gas. However, syster poisonous gases that enter the breathing mixture would have a magnified given their increased partial pressure at depth.

In general, simple asphyxiants have no pharmacologic activity. For this r exceedingly high ambient concentrations of these gases are necessary to asphyxia. Asphyxiation occurs in confined spaces or with extremely conc forms of the simple asphyxiants. Recommendations for use of simple asp a relatively undetectable method for committing suicide can be found on Internet.[57 , 65] The widespread use of liquefied gas, which expands seve fold on depressurization or warming, accounts for a substantial number o injuries.[106 , 159]

Clinical Manifestations

A patient exposed to any simple asphyxiant gas will develop characteristi

of hypoxia (Table 119-1), which are directly related to the partial pressu gas in the air or, more correctly, to the reduction in ambient oxygen part pressure.[106] Cardiovascular and central nervous system complications of asphyxiants predominate, because these organ systems have the greates requirements. As hypoxemia becomes severe, multisystem organ failure a may occur.[42]

During simple asphyxiation, carbon dioxide exchange is not impaired, and hypercapnia does not occur. Because dyspnea develops more rapidly from hypercapnia than hypoxemia, the breathlessness associated with physical chemical asphyxiation does not develop until severe hypoxemia intervene these circumstances, victims may succumb to hypoxemia without develop expected warning symptoms. In the case of carbon dioxide inhalation, hy may occur very rapidly, which itself can produce acute cognitive impairm

Specific Agents

Noble Gases: Helium, Neon, Argon, Xenon

Noble gases, which are stored almost exclusively in the compressed form numerous industrial and medical roles. Argon is predominantly used as a gas during welding operations. Neon is used in lighting manufacture. Xenc radioactive gaseous form, has diagnostic medical applications in ventilationâ€“perfusion scans. Helium has the lowest molecular weight and smallest member of the noble gas family of elements. Because of its lowe solubility, helium is used by divers to replace nitrogen to prevent nitroge at depth (see Nitrogen). Even at diving gas mixtures of 50% helium, div no adverse effects as long as a normal partial pressure of oxygen is mair the mixture. The fact that helium has a lower density than nitrogen result lower viscosity, or a marked decrease in flow resistance. This property of the basis for its use in patients with increased airway resistance, such as It also facilitates breathing by divers at depth, where the quantity (molar not volume) of air inspired per breath is several-fold greater than that at Similarly, helium's low viscosity has led to its use as an inflation gas for balloons, for which rapid inflation and deflation are critical. All noble gase

compressed, form cryogenic liquids, which expand rapidly to their gas pha decompression. Liberation of these gases in closed spaces may result in or freezing injuries. Xenon has unique anesthetic properties because of its solubility. The other noble gases have no direct toxicity.

21
None
16â€“12
Tachypnea, hyperpnea, (resultant hypocapnia), tachycardia, reduced atte alertness, euphoria, headache, mild incoordination
14â€“10
Altered judgment, incoordination, muscular fatigue, cyanosis
10â€“6
Nausea, vomiting, lethargy, air hunger, severe incoordination, coma
< 6
Gasping respiration, seizure, coma, death
[a] At sea-level barometric pressure appropriate adjustments must be made altitude and depth exposures.

FiO_2 [a] Symptoms/signs

TABLE 119-1. Clinical Findings Associated with Reduction of I Oxygen

Short-Chain Aliphatic Hydrocarbon Gases: Me Ethane, Propane, Butane

Methane (CH_4) has no direct toxicity. Animals can breathe a mixture of 8 methane and 20% oxygen without manifesting hypoxic symptoms because , and thus their oxyhemoglobin saturation, essentially is normal. Methane known as natural gas and â€œswamp gas,â€• may be present in high an concentrations in bogs of decaying organic matter. In addition, compress gas now is used as an alternative fuel for automotive use. Methane expos occupational hazard for miners, who historically carried canaries into the

as an â€œearly warningâ€• sign for the presence of toxic gases or oxyge deficiency. Theoretically, the higher metabolic and respiratory rates of sr (and children) make them more rapidly susceptible to gas exposures.

Methane is odorless and undetectable without sophisticated equipment.[28] reason, natural gas is intentionally adulterated with a small concentration mercaptan, a stenching agent, which is responsible for the well-recognize odor of natural gas. Cooking with natural gas may lead to increased resp symptoms and pulmonary dysfunction.[79] However, methane itself is unlike the etiology because its combustion is generally complete, and ambient le negligible. It is likely that exposure to nitrogen dioxide (NO_2), one of th of combustion of methane in air (70% nitrogen), is the explanation for th symptoms.

Ethane ($C_2 H_6$) is an odorless gas with characteristics similar to methane occasionally is implicated as a simple asphyxiant. It is also a component gas and is used as a refrigerant. Propane ($C_3 H_8$) is widely used in comp liquefied form both as an industrial and domestic fuel and as an industria Butane ($C_4 H_{10}$) is a prevalent fuel and solvent. Deliberate butane inhala cigarette lighters or air fresheners for recreational purposes predominantl adolescents is associated with cardiovascular dysfunction and cerebral da (Chap. 79).[50 , 155]

Carbon Dioxide (CO_2)

Introduction

Although not a simple asphyxiant gas by definition because it produces p effects, carbon dioxide closely resembles simple asphyxiants from a toxi viewpoint. Carbon dioxide gas has many practical industrial uses, such as of carbonation in soft drinks and use as a shielding gas during welding. C dioxide is widely used to extinguish fires because of its ability to safely d oxygen from the local environment.[64] Dry ice, the frozen form of carbon an

extremely cold substance (â€“141.3Â°F [â€“78.5Â°C]) that undergoes co

from solid to gas without liquefaction, a process known as *sublimation.* F poisoning may occur when dry ice is allowed to sublimate in a closed spa as the cabin of a car or, as in the case above, in a cold storage room at (4Â°C).[64] The large-scale emission of carbon dioxide from Lake Nyos, a volcanic crater lake in Cameroon, West Africa, resulted in nearly 2000 hu many more livestock deaths (Chap. 2).[9] In this disaster, simple asphyxia likely because medical evaluation of both survivors and fatalities demons neither signs of cutaneous or pulmonary irritation nor toxicologic abnorn Furthermore, inadvertent connection of respirable gas hoses to carbon di other nonrespirable sources has occurred in both industrial[76 , 160] and m settings, with resultant worker and patient fatalities. This occurrence is because of the mandated use of engineering controls to prevent the inco connection of hose and source terminals.

Pharmacology/Pathophysiology

Carbon dioxide, an end product of normal human metabolism, dissolves ir plasma and is in equilibrium with carbonic acid (H_2CO_3). Dissolved carb measured as PCO_2 , is primarily responsible for our respiratory drive, and tightly controlled by the central nervous system through regulation of br this reason, exogenous carbon dioxide, combined with oxygen, was at one medically as a respiratory stimulant in neonates. Under normal conditions air contains approximately 0.03% CO_2 . When ambient concentrations ris level, uptake of carbon dioxide occurs, which stimulates respiration furth increasing the uptake of ambient carbon dioxide. Accordingly, closed ane systems use scrubbers containing sodium hydroxide to chemically elimina carbon dioxide. Failure of the scrubber system results in increasing depth anesthesia from hypercapnia-induced hyperventilation.

Clinical Manifestations

Carbon dioxide produces both acute and subacute poisoning syndromes. T occurs during hypoventilation, when a patient fails to eliminate endogeno dioxide, develops hypercapnia, and typically presents with gradual somno occurrence may be linked to respiratory failure, as in the case of emphys

opioid poisoning, or it may be iatrogenic, as occurs during permissive hypercapnia.[116] Alternatively, intense carbon dioxide exposure may produ and lethal poisoning. However, unlike other simple asphyxiants, experime of acute carbon dioxide poisoning in which FiO_2 is maintained at normal l demonstrate that central nervous and respiratory systems manifestations within seconds.[78] This finding suggests that CO_2 is not solely a simple as but also possesses a potential for systemic effects.

Nitrogen (N_2) Gas

Introduction

Although nitrogen, like carbon dioxide, may produce clinical effects indep hypoxemia, most poisonings are characterized by the manifestations of s asphyxiants. Nitrogen gas is used as a carrier gas for chromatography, as fertilizer, as a cryogenic gas for surgery, and extensively in manufacturir Poisoning by nitrogen gas is uncommon but may occur following rapid ev the liquid.[83]

Clinical Manifestations

Inadvertent connection of air-line respirator hoses to nitrogen and other sources results in acute asphyxiation, with unconsciousness occurring in approximately 12 seconds[76, 106, 159] and death shortly thereafter. More inhalational poisoning by nitrogen is characterized by impairment of inte function and judgment, giddiness, and euphoria, which is qualitatively sim ethanol intoxication.[109] More severely poisoned patients may manifest le coma.[56] Systemic absorption is not rapid, however, and prolonged, high- exposure is required for poisoning. Nitrogen poisoning, also known as *nit narcosis*, occurs in underwater divers while they are breathing air, which 70% nitrogen. It has been called *rapture of the deep* (*l'ivresse des grand profondeurs*) and has led to many deaths in the subaquatic environment. underlying mechanism of nitrogen narcosis is unknown,[41] but the simple and relatively high lipophilicity of nitrogen suggest a mechanism similar to the anesthetic gases.[56] To avoid nitrogen narcosis, less lipid-soluble inert

as hydrogen or helium are generally substituted for nitrogen. Substitution oxygen, although intuitively logical, is inappropriate because of the risk o toxicity (see Oxygen).

Dermal exposure to liquid nitrogen produces frostbite because of liquid r extremely cold temperature.[137] Ingestion of liquid nitrogen similarly prod freezing injury of the gastrointestinal tract.[87] Rarely, bubbles introduced skin embolize through the vascular system and impair organ blood flow.[49

Treatment

Treatment of all individuals poisoned by simple asphyxiants begins with removal of the persons from exposure and ventilatory assistance. Provisio supplemental oxygen is preferable, but room air usually suffices. Hyperba therapy is unnecessary. Restoration of oxygenation through spontaneous mechanical ventilation occurs after only several breaths. Support of vital the mainstay of therapy but generally is unnecessary following a brief ex

Pulmonary Irritants

Case 2 In an attempt to clean a grimy bathtub in a newly purchased hous year-old woman mixed several over-the-counter cleaning products includi and toilet bowl cleaner. Seconds after the mixture was created, an acrid o green-tinted gas filled the room. The woman was able to escape the fum but quickly began feeling pain in her eyes and throat. She remained at ho minutes but her symptoms progressed. She arrived in the emergency de with significant dyspnea, cough, and diffuse chest discomfort.

Her vital signs were: blood pressure, 120/85 mm Hg; pulse, 120 beats/m respiratory rate, 32 breaths/min; oral temperature 99Â°F (37.2Â°C). Puls revealed 83% saturation on room air, and 2 L nasal oxygen was administ Pertinent findings on physical examination included teary, red eyes with vision. Her oropharyngeal mucosa was unremarkable, although she was She had no stridor, hoarseness, or dysphagia. Lung examination demons bilateral crackles, and her heart sounds were normal. Arterial blood gas measurement yielded: pH, 7.50; PCO_2 , 25 mm Hg; PO_2 , 50 mm Hg, on

oxygen by nasal cannula. She was attached to a nonrebreather oxygen fa and her oxygen saturation climbed to 94%. Electrocardiogram showed sir tachycardia.

Portable chest radiograph showed significant bilateral alveolar filling with sized heart.

She received one dose of nebulized dilute sodium bicarbonate and several albuterol and was admitted to the intensive care unit (ICU) for observatic next 24 hours, her symptoms and abnormal pulmonary findings resolved, was discharged. At 2-week followup she was asymptomatic with a normal examination.

Introduction

The irritant gases are a heterogeneous group of chemicals that produce t via a final common pathway: destruction of the integrity of the mucosal b the respiratory tract (Table 119-2).

Pathophysiology

Pathologically, irritant chemicals damage both the more prevalent type I pneumocytes and the surfactant-producing type II pneumocytes.[89] Neutro recruited in response to macrophage-derived inflammatory cytokines such necrosis factor-Î±, releases toxic mediators that disrupt the integrity of endothelial cells.[99 , 134] This host defense response results in accumulatio cellular debris and plasma exudate in the alveolar sacs, producing the c clinical findings of acute lung injury (ALI). The specific mechanisms by wh irritant gases damage the pulmonary endothelial and epithelial cells vary. irritant gases require dissolution in lung water to liberate the ultimate to which often is an acid, as occurs when hydrogen chloride gas produces h acid. The exact mechanism by which acids damage cells and induces an response remains uncertain. Oxidation of intracellular proteins may result cytoskeletal shortening, creating spaces between endothelial cells and all movement into the alveolar spaces.[165] Other gases, such as oxygen, indu

pulmonary damage solely through free radicalâ€“mediated oxidative stress cellular membranes. NO_2 and chlorine are characteristic of a group of gas produce both acid and free radical oxidants. Furthermore, other respirabl xenobiotics, such as metals, injure the respiratory tract through oxidant other mechanisms. Because the precise toxicologic and pathophysiologic widely depending on the physicochemical properties of the chemical, thes mechanisms are covered more completely in the discussions of the specif

TABLE 119-2. Characteristics of Common Respiratory Irritants

By virtue of its use as a war agent, phosgene has received more investig
the other irritant gases. In fact, much of our

current understanding of irritant gas poisoning derives from the study of
toxicity. Although the specific mechanisms of toxicity of the other irritant
poorly defined, they likely cause injury through a similar process. The ac
upon dissolution in the mucosal water react with functional groups on ep
endothelial cell membranes and, via cellular messengers, result in a com
systemic inflammatory response. Phosgene stimulates the synthesis of li
derived leukotrienes. Leukotrienes are important chemotactic factors for
which accumulate, liberate oxidants, and produce ALI.[77] ALI can be preve
rabbits by tomelukast, a leukotriene receptor antagonist,[70] and by
methylprednisolone, which blocks leukotriene synthesis, although both x
offer postexposure benefit.[70] Ibuprofen, an inhibitor of the arachidonic a
and xenobiotics capable of reducing neutrophil influx, such as colchicine

cyclophosphamide, reduce lung injury and mortality in mice when they ar administered shortly following phosgene exposure.[63, 145] Intratracheal cyclic adenosine monophosphate (DBcAMP), a cAMP analog, and other cAl amplifiers, such as terbutaline or aminophylline, inhibit the release of le and reduce toxicity.[82, 146] Intratracheal *N*-acetylcysteine (NAC), adminis minutes postexposure to phosgene-poisoned rabbits, decreases the forma leukotrienes by an undefined means and limits the development of ALI.[14] Presumably administration via nebulization would prove similarly effectiv Intravenous administration of NAC to patients with mild-to-moderate ALI, whom had phosgene-induced pulmonary damage, improved systemic oxy and reduced the need for ventilatory support.[161] However, progression to failure was not altered. Because damage to the lung had already occurred observed benefit of NAC may be related to improved hemodynamic functi than an antioxidant effect (Antidotes in Depth: *N*-Acetylcysteine).[73]

Free radicals are highly reactive molecular derivatives, typically from oxy nitrogen, that bind to and destroy tissue near their site of generation. Th initiation of a lipid peroxidative cascade, free radicals destroy lipid memb inhibit energy production through the electron transport chain (Chap. 12 of lipid peroxidation and cellular damage initiate neutrophilic influx, presu an immunologic attempt to combat a pathogen. Ironically, free radicals g the invading inflammatory cells contribute to pulmonary damage. Fortuna lung has antioxidant systems, both enzymatic (eg, superoxide dismutase, glutathione peroxidase, catalase) and nonenzymatic (eg, glutathione, as which detoxify virtually all free radicals present in the lung.[131] However, burden imposed by oxidant gases can preempt these detoxifying systems produce cellular damage. For example, nebulization of manganese superc dismutase into the airway 1 hour after smoke inhalation, a form of oxidar injury, did not improve lung edema or pulmonary gas exchange.[97]

Clinical Manifestations

Regardless of the mechanism by which the mucosa is damaged, the clinic presentations of patients exposed to irritant gases are similar. Those exp gases that result in irritation within seconds generally develop mucosal i

to the upper respiratory tract. The rapid onset of symptoms usually is a signal to the patient to escape the exposure. Patients may present with c and pharyngeal pain in addition to drooling, mucosal edema, cough, or s Conjunctival irritation or chemosis, as well as dermatologic irritation, is c because concomitant ocular and cutaneous exposure to the gases usually unavoidable. Gases that are less rapidly irritating may not provide an ad signal of their presence and may not prompt expeditious escape. In this prolonged breathing allows entry of the toxic gas further into the bronch system, where delayed toxic effects may subsequently be noted. Trache bronchiolitis, bronchospasm, and ALI are typical inflammatory responses anatomic region and represent the spectrum of acute lower respiratory tr

Experimental models assessing the water solubility of a gas to predict the its associated lesions have largely agreed with the clinical data.[84] Howev exceptions to this relationship of a gas and its expected toxicity are comr example, in situations where escape from ongoing exposure is prevented may develop lower respiratory tract injury after prolonged exposure to a irritating gases. Alternatively, rapid onset of upper respiratory irritation m noted in patients following exposure to concentrated gases that are gene associated with delayed symptomatology. Exposure to exceedingly high concentrations of any gas may produce hypoxemia analogous to that resu exposure to a simple asphyxiant gas.

The most characteristic and worrisome clinical manifestation of irritant ga is ALI, a syndrome formerly described as noncardiogenic pulmonary eden consists of the clinical, radiographic, and physiologic abnormalities caused pulmonary inflammation and alveolar filling that must be both acute in on attributable solely to pulmonary capillary hypertension as occurs in patier congestive heart failure.[12] The most severe manifestation of ALI is the ac respiratory distress syndrome (ARDS). The criteria for diagnosis of ARDS the ratio of the partial pressure of dissolved oxygen (PaO_2) to the inspir fraction (FiO_2),[12] that is, patients with an appropriate history and clinica presentation for ALI with $PaO_2/FiO_2 < 200$ meet the definition of ARDS. positive end-expiratory pressure (PEEP) is not part of the oxygenation cr (Chap. 22). Both ALI and ARDS are nonspecific syndromes resulting from physiologic insults such as sepsis or trauma. Patients with ALI may prese

dyspnea, chest tightness, chest pain, cough, frothy sputum, wheezing or arterial hypoxemia. Typical radiographic abnormalities include bilateral p infiltrates with an alveolar filling pattern and a normal cardiac silhouette differentiate this syndrome from congestive heart failure.

Specific Agents

Acid- or Base-Forming Gases

Highly Water-Soluble Agents

Ammonia (NH_3)

Ammonia is a common industrial and household chemical used in the syn plastics and explosives, and as a fertilizer, a refrigerant, and a cleaning a odor is characteristic and may be an effective warning signal of exposure stimulus to avoid further exposure. Dissolution of NH_3 in water to form th ammonium hydroxide (NH_4 OH) rapidly produces severe upper airway irr Patients with exposures to highly concentrated NH_3 or exposures for prol periods may develop tracheobronchial or pulmonary inflammation. Exper inhalation of nebulized high-dose ammonia causes ALI that is manifested b oxygen saturation and a rise in airway pressure within 2 minutes of the s exposure.[151] Corroborating the

development of ALI, ultrastructural study of the lungs from two individua acutely of ammonia inhalation revealed marked swelling and edema of typ pneumocytes.[27] Chronic inhalation of low concentrations of NH_3 or repeti exposure to high concentrations of ammonia may cause pulmonary fibros

ammonia form monochloramine and dichloramine. B. Chloramine dissolves to liberate hypochlorous acid, hydrochloric acid, ammonia, and nascent o an oxidant.

Chloramines

This series of chlorinated nitrogenous compounds (Figure 119-1) include monochloramine (NH_2 Cl), dichloramine ($NHCl_2$), and trichloramine (NCl_3 chloramines are most commonly generated by the admixture of ammonia sodium hypochlorite (NaOCl) bleach, often in an effort to potentiate their cleaning powers.[58 , 122] Interestingly, the addition of bleach to septic sys result in liberation of the chloramines following the reaction of bleach wit nitrogenous compounds.[107] On dissolution of the chloramines in the epit fluid, hypochlorous acid, ammonia, and oxygen radicals are generated, all act as irritants. Although less water soluble than ammonia, the chloramir promptly result in symptoms. Because these initial symptoms are often n however, they may not prompt immediate escape, resulting in prolonged recurrent exposure.[135] Exposure to trichloramine occurs at indoor swimm and is responsible for inducing permeability changes in the pulmonary e the consequences of which are not yet understood.[30]

Hydrogen Chloride (HCl)

The largest and most important use of hydrogen chloride gas is in the pr hydrochloric acid. Dissolution of hydrogen chloride gas in lung water afte similarly produces hydrochloric acid.[26 , 129] Pyrolysis of polyvinyl chloride commonly used in pipe fabrication, generates HCl and is an occupational firefighters.[119] By adsorbing to respirable carbonaceous particles generate fire, HCl may be deposited at the alveolar level and produce pulmonary

Hydrogen Fluoride (HF)

Hydrogen fluoride and its aqueous form, hydrofluoric acid, are used in th glassware, building renovation, and semiconductor industries. Hydrogen f dissolves in epithelial lining fluid to form the weak acid hydrofluoric acid.

HF molecule is the predominant form in solution, and few free hydronium liberated. Low-dose inhalational exposures may result in irritant sympton large exposures may cause bronchial and pulmonary parenchymal destru Death following inhalation may result from ALI but usually is related to s fluoride poisoning independent of the route of exposure because of the r calcium binding and subsequent hypocalcemia and hyperkalemia.[18 , 47]

Patients with inhalational exposure to hydrogen fluoride should undergo electrocardiographic evaluations and correction of serum electrolytes. A of nebulized 2.5% calcium gluconate should be considered in order to lim fluoride absorption (made as 1.5 mL 10% calcium gluconate plus 4.5 mL sodium chloride solution or sterile water).[86 , 91] By binding fluoride ion l nebulized calcium may prevent fluoride-induced cellular and systemic tox Systemic calcium salts should be administered as needed to correct hypo (Chap. 101 and Antidotes in Depth: Calcium).

Sulfur Dioxide/Sulfuric Acid (SO_2 /H_2 SO_4)

Sulfur dioxide has multiple industrial applications and is a byproduct found smelting and oil refinery industries. It may also be generated by the inad mixing of chemicals, such as an acid with sodium bisulfite ($NaHSO_3$). Su is highly water soluble and has a characteristic pungent odor that provide of its presence at concentrations well below those that are irritating. In t of catalytic metals (Fe, Mn), environmental sulfur dioxide is readily conve sulfurous acid (H_2 SO_3) within water droplets. Sulfurous acid is a major environmental concern and the cause of â€œacid rain.â€• Atmospheric s dioxide and H_2 SO_4 have severe health consequences. During the London incident in 1952, 4000 deaths occurred primarily from respiratory causes to atmospheric sulfur dioxide results in a roughly dose-related bronchosp is most pronounced and difficult to treat in asthmatic patients. Inhalation sulfurous acid or dissolution of sulfur dioxide in epithelial lining fluid pro typical pathologic and clinical findings associated with ALI.[136] In addition effect of acid generation upon dissolution, sulfur dioxide can cause oxida to the lungs.[105] Large acute exposure to either xenobiotic produces the acute irritant response of both the upper and lower respiratory tracts,[33] a

pulmonary dysfunction (see Asthma and Reactive Airways Dysfunction Sy may persist for several years.[126]

Intermediate Water-Soluble Agents

Chlorine (Cl_2)

Chlorine gas is a valuable oxidizing agent with various industrial uses, an occupational exposure is common. Chlorine gas was used as a chemical w agent by both the French and the Germans in World War I (Chap. 126). chlorine gas is not generally available for use in the home, domestic expo chlorine gas is common. The admixture of an acid to bleach liberates chlo (Figure 119-2).[66, 113] Because the anionic component of the acid is not the reaction, combining hypochlorite with virtually any acid, such as pho hydrochloric, or sulfuric acid, may result in the release of chlorine gas. As inappropriate mixing of cleaning agents is the cause of most nonoccupati exposures.[113] Rarely patients have intentionally generated chlorine gas in manner for purportedly â€œpleasurableâ€• purposes.[132] Concentrated ch may be generated when aging swimming pool chlorination tablets, such a

calcium hypochlorite [$Ca(OCl)_2$] or trichloro-*s*-triazinetrione (TST), dec [180] Inadvertent mixture of $Ca(OCl)_2$ and TST results in excessive chlorine generation and may be explosive.[96] Acute chlorine toxicity may occur wh compressed chlorine gas is used for direct chlorination of public swimmin or drinking water systems. Occasional mass poisoning may occur during industrial, or transportation incidents.[32, 168]

Figure 119-2. Chlorine chemistry. A. Formation of chlorine gas from the acidification of hypochlorous acid. B. Dissolution of chlorine in mucosal w

generate both hydrochloric and hypochlorous acids (HCl and HOCl) and o

The odor threshold for chlorine is low, but distinguishing toxic from perm levels may be difficult until toxicity is manifest. The intermediate solubili characteristics of Cl_2 result in only mild initial symptoms following moder exposure and permit a substantial time delay, typically several hours, be symptoms develop. Chlorine dissolution in lung water generates HCl and hypochlorous (HClO) acids. Hypochlorous acid rapidly decomposes into HC nascent oxygen (O^-). The unpaired nascent oxygen atom produces addit pulmonary damage by initiating a free radical oxidative cascade. Although majority of life-threatening chlorine poisonings follow acute, large expos patients with chronic, low-concentration exposure or recurrent, moderate concentration poisonings may manifest increased bronchial responsivenes

Hydrogen Sulfide (H_2 S)

Hydrogen sulfide exposures occur most frequently in the waste managem petroleum, and natural gas industries,[74] although poisoning occurs in asp synthetic rubber, and nylon industry workers and rarely in hospital worke acid to clean drains clogged with plaster of Paris sludge.[124] Hydrogen sulf present in natural sources such as volcanic emission, in caves, and in su It is a decay product of organic material found in sewers or manure pits. sulfide, hydrogen fluoride, and phosphine are differentiated from the oth gases by their ability to produce significant systemic toxicity. Hydrogen s inhibits mitochondrial respiration in a fashion similar to that of cyanide (C).[51 , 133]

H_2 S has the distinctive odor of â€œrotten eggs,â€• which, although help diagnosis, is not specific for the agent. Despite a sensitive odor threshold parts per billion,[133] rapid olfactory fatigue ensues, providing a mispercep the exposure and its attendant risk have diminished. At low and moderate to 500 ppm), upper respiratory tract mucosal irritation occurs and is the toxicity.[163] The rapidity of death in patients exposed to high H_2 S levels likely that either simple asphyxiation or cytochrome oxidase inhibition is most cases.

Poorly Water-Soluble Agents

Phosgene (Carbonyl Chloride [$COCl_2$])

During World War I, phosgene was an important weapon of mass destruc produced countless deaths (Chap. 126). Currently, phosgene is used in t synthesis of various organic compounds, such as isocyanates, and it occ produces poisoning. It is a byproduct of heating or combustion of various organic compounds.[153]

Exposure to phosgene initially may produce limited manifestations but car acute mucosal irritation following intense exposure. In fact, the pleasant fresh hay, rather than prompting escape, ironically may promote deep ar breathing of the toxic gas. The most consequential clinical effect related exposure is delayed-onset ALI.[19] Because of the accumulation of a signif alveolar burden of phosgene, symptoms generally are severe once they o delay in onset may be nearly one day, so prolonged observation of patien to be phosgene poisoned is warranted. The mechanism of phosgene toxici dependent on the dissolution of the gas into the fluid of the epithelial lini resultant liberation of hydrochloric acid and reactive oxygen species.[143]

Oxidant Gases

Rather than acidic or alkaline metabolites, free radicals mediate the puln toxicity of certain irritant gases. Many of the chemicals discussed particip acidâ€“base and oxidant types of injury. However, the clinical distinction acid- or alkali-forming agents and oxidant gases is difficult but ultimately therapeutically relevant.

Oxygen (O_2)

Oxygen toxicity is uncommon in the workplace but, ironically, is common hospitalized patients. Although O_2 may produce central nervous system a toxicity, pulmonary damage is more common.[152] Several clinical studies that humans can tolerate 100% O_2 at sea level for up to 48 hours witho

acute pulmonary damage.[29 , 44] Under hyperbaric conditions (2.0 atmosp absolute), such as during compressed-air diving or while inside a pressur hyperbaric chamber, oxygen toxicity may develop within 3â€“6 hours.[36] A in approximately 5% of patients administered hyperbaric oxygen for ther purposes.[152] Delayed pulmonary fibrosis, presumably from healing of su injury, may develop in patients breathing lower concentrations of O_2 at s shorter periods.

Although it appears paradoxical that O_2 , an essential molecule, may be at elevated concentrations, it is not. In mitochondria, O_2 plays a critical r ultimate acceptor for electrons completing the electron transport chain. It same potent oxidizing activity that allows O_2 to remove electrons from ot compounds generating the reactive oxygen intermediates.[139]

Generation of reactive oxygen species, including superoxide (O_2^-), hydr (OHÂ·), hydrogen peroxide (HOOH), and singlet oxygen (OÂ·), and nitric produces cellular necrosis, increases pulmonary capillary permeability, an apoptosis.[120 , 139] NO, produced by inducible NO synthase in the setting stress, is directly cytotoxic or can combine with superoxide anions to form reactive oxidant peroxynitrite.[75] Experimental prevention of these effects administration of either parenteral NAC,[140 , 175] a chemical antioxidant, c superoxide dismutase, an enzymatic antioxidant,[29 , 169] suggests that th mechanism of toxicity relates to the oxidant, or electrophilic, effects of t reactive oxygen species (Chap. 12). Although several other agents have promise in preventing oxygen-mediated toxicity, none has yet proved to therapeutic for patients who already manifest pulmonary toxicity. Curren for preventing pulmonary oxygen toxicity emphasize reduction of the ins oxygen concentration by use of PEEP ventilation, although this approach prove beneficial in at least one clinical trial. The potential role of liquid v the lung with perfluorocarbons to prevent or treat pulmonary oxygen toxi under investigation.[7]

Oxides of Nitrogen (NO_x)

Oxides of nitrogen are a series of variably oxidized nitrogenous compoun most important substances included in this series are the stable free radi

and NO, as well as nitrogen tetroxide (dinitrogen tetroxide [N_2O_4]), nitr trioxide (N_2O_3), and nitrous oxide (N_2O). The oxides of nitrogen are of value in industrial operations, although they may be generated during we brazing. NO_2, in addition to

hydrogen cyanide, is produced in the pyrolysis of nitrocellulose, which is substantial component of radiographic film. For example, a fire in the rad department of the Cleveland Clinic in 1929 resulted in 125 casualties, wi all deaths resulting from cyanide or NO_2 gas poisoning.[67] NO_2 toxicity car when propane-driven ice-cleaning machines are used in indoor ice skating poor ventilation, thereby allowing accumulation of the generated NO_2.[92] exposure to high NO_2 levels may occur during closed-space fires, as in s NO_2 also causes silo-filler's disease, in which the toxic gas generated dur decomposition of silage accumulates within the silo shortly after grain st eliminating rodents that feast on the grains.[48, 182] In the absence of ve high concentrations of NO_2 may accumulate in the silo such that an indiv entering the silo is rapidly asphyxiated from the depletion of oxygen.[68] A substantial quantities of NO_2 remaining after incomplete ventilation may delayed-onset pulmonary toxicity characteristic of silo filler's disease. Ch exposure to NO_2, generated during cooking,[79] or outdoor exposure to p smog, of which the oxides of nitrogen are a component, may predispose t development or exacerbation of chronic lung diseases.

The various oxides of nitrogen may directly oxidize respiratory tract cellu membranes but more typically generate reactive nitrogen intermediates, such as peroxynitrite ($ONOO^-$), which subsequently damage the pulmona cells.[123] In addition to generating oxidant cascades, dissolution in respira water generates nitric acid (HNO_3) and NO, which produce injury consist other inhaled acids. In fact, inhalation of HNO_3 produces the same clinica pathologic syndrome.[71] Antioxidants afford significant protection to huma endothelial cells exposed to NO_2, indicating an important role of free rad toxicology of these agents.[170]

NO, an endogenous compound important as a neurotransmitter and vaso used clinically as exogenous inhalational therapy for pulmonary hypertens ALI.[166] In patients with ALI not resulting from sepsis (although not speci

inhalational injury), low-level inhaled NO (5 ppm) did not improve clinica outcome.[166] However, one patient with NO_2 pulmonary toxicity improved following NO therapy, so further consideration is warranted.[90] Furthermore in premature infants with respiratory distress syndrome is well accepted.[less soluble in the fluid lining the epithelial surfaces than are the other o nitrogen and produces irritant effects following large exposures.[72 , 178] It pulmonary oxidative toxicity, the manifestations of which are typical of th gases, is substantially enhanced by conversion to reactive nitrogen inter such as $ONOO^-$.[11] This radical selectively interacts with tyrosine to prod nitrotyrosine, which may subsequently serve as a marker for oxidant dan may be absorbed from the lung and is rapidly bound by hemoglobin to fo nitrosylhemoglobin and methemoglobin.

Ozone (O_3)

Ozone is abundant in the stratospheric region found between 5 and 31 m the planet. Ozone is formed by the action of ultraviolet light on oxygen m thus reducing the amount of solar ultraviolet irradiation reaching Earth. T concentration in passenger aircrafts may at times be above regulatory lir although a specific relationship with the development of clinical effects in crew members is elusive.[114] Ozone is another important component of photochemical smog and, as such, contributes to chronic lung disease.[24] produced in significant quantities by welding and high-voltage electrical and in more moderate doses by photocopying machines and laser printers of its high electronegativity (only fluorine is higher), ozone is one of the oxidizing agents available. For this reason it is used as a bleaching agent particularly as an alternative to chlorine in water purification and sewage

The pulmonary toxicity associated with ozone primarily results from its h reactivity toward unsaturated fatty acids and amino acids with sulfhydryl groups.[13 , 81] Ozonation and free radical damage to the lipid component o membrane initiates an inflammatory cascade, with resultant influx of infl cells.[14 , 134] Reactive nitrogen species also are implicated, as NO synthas mice are relatively protected from ozone-induced inflammation and tissue Increased permeability of the pulmonary epithelium results in alveolar fill

the transudation of proteins and fluids characteristic of ALI. Antioxidant a vitamin E) that react preferentially with free radicals before membrane d occurs prevent or limit the pulmonary toxicity of ozone.

Miscellaneous Irritant Gases

Methylisocyanate

Methylisocyanate (MIC, Figure 119-3) is one of a series of compounds sh similar isocyanate (N=C=O) moiety. Toluene diisocyanate (TDI) and diphenylmethane diisocyanate (MDI) are important chemicals in the polyr industry. In 1984, an inadvertent release of MIC in Bhopal, India, resulte immediate and persistent respiratory symptoms in approximately 200,000 inhabitants, with approximately 2500 deaths.[10 , 45] ALI was evident both and radiographically.[108] MIC is a significantly more potent respiratory irr the other regularly used isocyanate derivatives such as TDI).[4] Cyanide p does not occur, and empiric antidotal therapy is not indicated.

Riot Control Agents: Capsaicin (OC), Chlorobenzylidenemalononitrile (CS), and Chloroacetophenone (CN)

Historically, riot control agents (Figure 126-5), or Mace, consisted prima chloroacetophenone (CN) or chlorobenzylidenemalononitrile (CS).[16] Both solids that are dispersed as aerosols. The dispersion is generally accomp through mixture with a pyrotechnic agent such as a grenade or with a vo organic solvent in a personal protection canister. Because the delivery sy these agents are of limited sophistication and are subject to prevailing environmental conditions, dosing is unpredictable, and unintended self-po common.[16] After low-level exposure, ocular discomfort and lacrimation al expected, accounting for the common appellation *tear gas.* The effects a and complete recovery within 30 minutes is typical, although long-lasting

pulmonary effects may occur (see Asthma and Reactive Airways Dysfunct

Syndrome).[138] Closed-space or close-range exposure, as well as physica during exposure, may produce significant ocular toxicity, dermal burns, laryngospasm, ALI,[167] or death.[16] Because of their high potential for sev CN and CS were replaced for civilian use by oleoresin capsicum (OC), alsc *pepper spray* or *pepper mace.* Although capsaicin, its active component, considerably less toxic, it is occasionally responsible for pneumonitis[15] ar

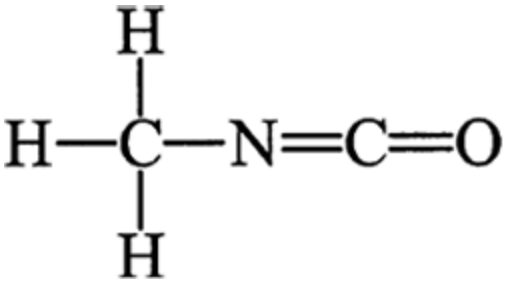

Figure 119-3. Methylisocyanate.

Capsaicin interacts with the vanilloid receptor-1 (VR1), which was recentl the transient receptor potential vanilloid-1 (TRPV1).[162] Stimulation of thi invokes the release of substance P, a neuropeptide involved with transmi pain impulses. Substance P also induces neurogenic inflammation, which, results in ALI and bronchoconstriction (see Asthma and Reactive Airways Syndrome).[162] The severe pulmonary toxicity of CS and CN likely is relat ability to alkylate tissues in a manner similar to mustard agents.[37]

Current therapy for inhalation of capsaicin, or of any tear gas, is primaril supportive. Extracorporeal membrane oxygenation has been used in child maintain oxygenation in the presence of severe pulmonary toxicity resulti capsaicin exposure.[15] Although no antidotes currently are available, the developing insight into the receptor mechanism of capsaicin suggests that active agent may hold future promise.

Metal Pneumonitis

Acute inhalational exposures to certain metal compounds produce clinical identical to the chemical irritants.[125] For example, zinc chloride ($ZnCl_2$) formerly used as artificial smoke because of the dense white character of

and an aqueous solution is still used as a soldering flux. Cadmium oxide
generated during the burning of cadmium metal in an oxygen-containing
environment, as occurs during smelting or welding. The refining of nickel
carbon monoxide (Mond process) produces nickel carbonyl [$Ni(CO)_4$], a
pulmonary oxidant.[148] Inhalation of volatilized elemental mercury,[112] whi
during the vacuuming of mercury spills or home extracting of precious m
be toxic. Although at sufficient concentration many of these metal exposu
produce warning symptoms, severe toxicity may occur even in the absenc
warning symptoms. The mechanism of toxicity may relate to overwhelmir
stress or inactivation of natural antioxidant systems.[181] Patients with m
pneumonitis present with chest tightness, cough, fever, and signs consist
ALI. Metal pneumonitis is distinguishable from other causes of ALI only by
retrospectively, by elevated serum or urine metal concentrations.[5] In pa
metal pneumonitis should be differentiated from the more common and
less consequential metal fume fever. In addition to standard supportive
patients with acute metal-induced pneumonitis should be hospitalized and
corticosteroids. Chelation therapy has no documented benefit for treatmer
but should be used based on conventional indications.

Management

Standard and Supportive Measures

Management of patients with acute respiratory tract injury begins with n
support of airway patency, by limiting bronchial and pulmonary secretions
maintaining oxygenation. Although various theoretical and experimental
modalities have been proposed, supportive care remains the mainstay of
Supplemental oxygen, bronchodilators, and airway suctioning should be u
clinically indicated. Nitrovasodilators, diuretics, and morphine have little r
management of ARDS, although low-dose morphine may prove beneficial
anxiolytic agent.[127] Corticosteroid therapy, designed to reduce the inflar
host defense response, frequently improves surrogate markers of pulmor
damage,[101, 102] such as oxygenation status, but generally offers little o
enhancement in patients with ARDS.[2] Importantly, most studies of ARDS

predominantly septic or traumatized patients, with few patients suffering inhalational poisoning. Because the inflammatory response initiated by b endotoxin differs from that caused by irritant gases, the applicability of t to the treatment of poisoned individuals is limited. There is an interesting simultaneous, presumably equivalent chlorine exposure in two sisters, wi outcome in the sister who received steroid treatment.[34] Most available r evaluates parenterally administered corticosteroids, although animal mod demonstrate a beneficial effect of nebulized beclomethasone[69] and nebul budesonide[176] following acute chlorine poisoning. However, a human pre model of inhaled budesonide fails to document a substantive alteration of of ozone inhalation.[115] Ketoconazole, an antifungal with antiinflammatory and nonsteroidal antiinflammatory agents, such as ibuprofen,[144] variably experimental lung function or mortality in patients with ALI of various n etiologies and have little current role in the therapeutic armamentarium. Furthermore, most of the aforementioned studies assess acute outcome a long-term effects in survivors. Because corticosteroids experimentally red late fibroproliferative phase during lung recovery, they ultimately may pr beneficial. Overall, there is little reason to suspect any specific benefit of corticosteroids and other antiinflammatory drugs in most poisoned patien However, because most studies demonstrate some benefit and little iden corticosteroid use appropriately remains routine and based largely on loc

The clinical similarities among patients with irritant gas exposure and oth etiologies of ALI suggest that similar management principles should be a Prone ventilation,[60] PEEP,[54] and inverse-ratio ventilation are successful i the oxygenation of patients with ALI of various etiologies but not necessa successful in improving outcome. Lower-tidal-volume mechanical ventilatio mL/kg and plateau pressures 30 cm H_2O attenuated the inflammatory re and resulted in lower mortality and less need for mechanical ventilation t traditional volume ventilation with 12 mL/kg.[1,110] Although not specifica evaluated in any of these studies, there are sound theoretical reasons to all of these modalities should improve oxygenation in poisoned patients a Although it is always important to reduce the inspired concentration of ox <50% as rapidly as possible, patients poisoned by irritant gases may be susceptible to oxygen toxicity as a result of depletion of endogenous ant

barriers.[150]

Neutralization Therapy

A therapy unique to several of the acid- or base-forming irritant gases is neutralization. Although contraindicated in acid or alkali injury of the ga tract, the large surface area of the lung and the relatively small amount xenobiotic present allow dissipation of the heat and gas generated

during neutralization. Case studies suggest that nebulized 2% sodium bi may be beneficial in patients poisoned by acid-forming irritant gases.[173] majority of these cases involve chlorine gas exposure, and most patients other symptomatic therapies as well.[20] Although there appears to be no benefit for patients exposed to chloramine, nebulized bicarbonate therapy be safe.[122] An adequately controlled, prospective evaluation of the safety of bicarbonate therapy in poisoned patients has not yet been attempted. bicarbonate solution used should be sufficiently diluted to prevent irritati Typically, 1 mL of 7.5% or 8.4% sodium bicarbonate solution is added to sterile water (resulting in an approximately 2% solution for nebulization)

Whether nebulized sodium bicarbonate therapy alters the natural course induced pulmonary damage remains uncertain. The fact that many irritan concomitant oxidant injury suggests that it may not. Nebulized 4% sodiu bicarbonate administered to chlorine-poisoned sheep improved oxygenatic failed to decrease mortality rates.[35] Therefore, patients receiving nebuliz bicarbonate therapy require observation beyond the time of symptom re Because administration of neutralizing acids for alkaline irritants, such as has not been attempted, their use cannot be recommended at this time.

Antioxidants

Antioxidant agents include reducing agents such as ascorbic acid, NAC,[85] scavengers such as vitamin E, and enzymes such as superoxide dismutas in humans have noted both increased[141] and decreased[21] endogenous a levels in bronchoalveolar lavage fluid in patients with ALI. Although the c treating pulmonary oxidant stress with antioxidants or free radical scaver

intriguing, most currently available evidence suggests that these xenobio negligible benefit.[111, 118] The rapid onset of the self-perpetuating destr effects initiated by redox reactions may hinder any postexposure therapy. interpretation is supported by pretreatment models in which antioxidants effective at preventing or at least limiting the pathologic effects. Use of t other newer therapies targeted against inflammatory mediators or the ox cascade are in the earliest investigative stages.

Advanced Pharmacologic Therapy

Perfluorocarbon Partial Liquid Ventilation

Partial liquid ventilation involves the intrapulmonary administration of perfluorocarbons, which are inert liquids with low surface tension and ex oxygen-carrying capacity. Studies in patients with nonchemically-induced suggest that exfoliated tissue, and presumably persistent xenobiotic, may effectively lavaged from the bronchopulmonary tree by this method.[40] Perfluorocarbons improve oxygenation and may have an antiinflammatory demonstrated by reduced oxidant lung injury following liquid ventilation i animals.[39] Although this may prove to be a highly useful therapy in the f limited availability, high cost, and lack of demonstrated efficacy make it only for an academic or research setting.[40]

Exogenous Surfactant

Several other recent developments may prove useful in the general mana patients with ARDS. Surfactant replacement therapy initially received atte treatment for patients with ARDS because of its beneficial effects in infan respiratory distress syndrome. Although several experimental and clinical suggested the safety and efficacy of surfactant therapy in patients with A randomized, controlled clinical trials fail to show a benefit on survival.[156] who received surfactant had a greater improvement in gas exchange durin hour treatment period than patients who received standard therapy alone suggesting the potential benefit of a longer treatment course.[156] Because studies involved patients with sepsis-related ARDS, the inability to show

effect may not adequately reflect the potential of surfactant in irritant g ARDS.[128] Many oxidant gases inactivate endogenous surfactant, although specific effects on exogenous surfactant are not well understood.[128]

Other Inhalational Pulmonary Xenobiotics

A particulate, or dust, is a solid dispersed in a gas. Dust is a substantial occupational particulate exposure and is an important cause of acute pul toxic syndromes. A respirable particulate must have an appropriately sma (generally <10 Âµm) and aerodynamic properties to enter the terminal r tree. Nonrespirable particulates, also called *nuisance dusts* , are trapped upper airways and are not generally thought to cause pulmonary damage. distinction from the irritant gases, there is no unifying toxic mechanism a respirable particulates. Many of the particulate diseases, such as asbesto and its sequelae, are chronic in nature; only the acute or subacute syndr discussed here.

Inorganic Dust Exposure

Silicosis is a range of pulmonary diseases associated with inhalation of c silica (SiO_2), or quartz. It typically occurs in workers involved in occupa rock or granite is pulverized, including mining, quarry work, or sandblast Although typically a chronic disease, intense subacute exposure may proc silicosis in a few weeks and death within 2 years. The mechanism of toxi probably relates to the relentless inflammatory response generated by th pulmonary macrophages.[117] These cells engulf the indigestible particles a destroyed, releasing their lytic enzymes and oxidative products locally wi pulmonary parenchyma. Patients present with dyspnea, cor pulmonale, r lung findings, and classic radiographic findings. Treatment is limited and steroids and supportive care.

Silica combined with other minerals are referred to as *silicates* , the mos of which include asbestos and talc. Talc, or magnesium silicate [(Mg_3 Si_4], is widely used in industry, but its use in the home has been curtailed o two decades because of cases of severe pulmonary injury.[95] Much of the

talc is related to free silica or asbestos contamination. Improvement follc massive exposure may be accompanied by progressive pulmonary fibrosis

Organic Dusts

Inhalation of dusts from cotton or similar natural fibers, usually during th refinement of cotton fibers (byssinosis), produces chest tightness, dyspne fever that typically begin within 3â€“4 hours of exposure. Symptoms ofte during the work week but

return after a weekend hiatus. Byssinosis probably is caused by an endot present on the cotton and is not immunologic in nature.[177] A similar synd â€œgrain fever,â€• which is caused by a respirable compound associated dust, as occurs during harvesting, milling, or transporting.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as *extrinsic allergic alveolitis* , common pathway for many different organic dust exposures.[158] The nam to the individual syndrome typically identifies the associated occupation c substrate. For example, *bagassosis* is the term associated with sugar can (bagasse), and *farmer's lung* is the term associated with moldy hay, alth conditions are caused by thermophilic *Actinomycetes.* When associated w mushroom spores *(Lycoperdon* spp), the syndrome is called *lycoperdonos* 113); when caused by bird droppings, it is called *bird fancier's lung.* The allergen is capable of depositing in the pulmonary parenchyma and elicitir mediated (type IV) immunologic response. Clinical findings include fever, dyspnea beginning 4â€“8 hours after exposure. The chest radiograph usu normal but may reveal diffuse or discrete infiltrates. Progressive disease associated with a honeycombing pattern on the radiograph and a restricti disease pattern on formal pulmonary function testing. Treatment includes corticosteroids and avoidance of the antigen.

Metal Fume Fever/Polymer Fume Fever

Metal fume fever is a recurrent influenzalike syndrome that develops sev after exposure to metal oxide fumes generated during welding, galvanizin smelting. Although most symptoms of metal fume fever are similar to tho with irritant gas exposures (dyspnea, cough, chest pain), the presence of typically 100.4Â°Fâ€“102.2Â°F (38Â°Câ€“39Â°C), distinguishes the synd addition, patients may experience headache, metallic taste, myalgias, and Direct pulmonary toxicity probably does not occur, and patients with meta fever generally have normal chest radiographs. Interestingly, acute toler develops, so repeat daily exposures produce progressively milder sympto However, the tolerance disappears rapidly, and after a short work hiatus s weekend, the original intensity resumes, thus accounting for the designa *morning fever.* Many metal oxides are capable of eliciting this syndrome, noted most frequently in patients who have welded galvanized steel, whi zinc. Metal fume fever also occurs commonly after the high-temperature copper-containing compounds, thus accounting for the historical appellat *foundry workers ague.* There is a strong association between welding-rela fume fever and welding-related respiratory symptoms suggestive of occu asthma.[52] Serum and urine metal concentrations typically are not elevate acute event, although they may be chronically elevated from daily occup exposure. The etiology of metal fume fever is debated, but the syndrome features suggestive of both an immunologic and a toxic etiology.[17] Antige with immunologic response appears to be responsible for the induction of On subsequent exposure, proinflammatory cytokines, such as tumor necr Î±, and various interleukins can be detected in bronchoalveolar lavage fl However, because symptoms can occur with the patient's first exposure to direct toxic effect on the respiratory mucosa presumably exists.[100] Exposu certain metal fumes, such as cadmium oxide or other zinc compounds, m direct toxic effects on the pulmonary parenchyma.[100]

The management of patients with metal fume fever is supportive and incl analgesics and antipyretics. There is no specific antidote, and chelation t should not be instituted unless otherwise indicated. Patients with ALI pro suffering from metal toxicity (eg, cadmium pneumonitis). The natural cou metal fume fever involves spontaneous resolution within 48 hours. Persis symptoms are rare and should prompt investigation for metal toxicity.

A remarkably similar syndrome occurs subsequent to inhaling pyrolysis p fluorinated polymers (eg, Teflon), which is aptly termed *polymer fume fe* Patients develop self-limited viral illness-type symptoms several hours af exposure to the fumes. As with metal fumes, very large exposures to pol may result in direct pulmonary toxicity. Supportive care is the therapy of

Asthma and Reactive Airways Dysfunction Syndrome

Asthma, or *reversible airways disease* , is a clinical syndrome that include intermittent episodes of dyspnea, cough, chest pain or tightness, wheezes auscultation, and measurable variations in expiratory airflow. Episodes ty triggered by a xenobiotic or physical stimulus and resolve over several h appropriate therapy. The underlying process is immunologic in most cases allergen-triggered release of inflammatory mediators causing bronchiolar muscle contraction and subsequent inflammation. Because asthma affects of the world's population and the triggers often are nonspecific, it is not that work-aggravated asthma is extremely common. The patients are pr sensitized, and the initial irritant exposure causes bronchospasm or simil symptoms. Thus, work-aggravated asthma is discovered early in the wor employment, and a more appropriate workplace or occupation can be pu

Occupational asthma, or asthma occasioned by a workplace exposure to xenobiotic, accounts for perhaps 10% of all newly diagnosed asthma in a Casual exposure to one of the 250 or more known sensitizers (Table 119- is associated

with a latency period of weeks or months of exposure before symptom or symptoms begin, however, they recur consistently following reexposure to inciting trigger agent. Occupational asthma with latency may be IgE depe which case it is identical to allergic asthma, or is IgE independent.[172] The dependent form is most commonly associated with high-molecular-weight (>5000 daltons) or with certain haptenic low-molecular-weight agents (eg anhydride). The low-molecular-weight agents (eg, nickel, isocyanates) m cause IgE-independent disease, which manifests as the delayed reaction

cell-mediated, or type IV, hypersensitivity. Because contact with a trigger difficult to avoid in either case, reassignment or an outright occupational may be required. Treatment for exacerbations is comparable to standard therapy and includes bronchodilators and corticosteroids.

Xenobiotics by Molecular Weight	Example of Sensitizer	Primary Occupat

TABLE 119-3. Common Xenobiotic Sensitizers Producing Occup
Asthma

Acute exposure to irritant gas may result in the development of a persist asthmalike syndrome also termed *reactive airways dysfunction syndrome irritant-induced asthma* , or *occupational asthma without latency.* Virtuall irritative xenobiotic is reported to cause this syndrome, and those not ye probably are simply unrecognized. Although asthma typically is associated massive inhalational exposure, as following the World Trade Center collap occasional patients are susceptible to low-level exposure.[25] RADS often is to occupational asthma because both disorders are chemically induced an frequently occur following chemical exposure in the workplace.[38] However comparison with those who develop occupational asthma, patients who de have a lower incidence of atopy and are exposed to agents not typically to be immunologically sensitizing.[25] In addition, the airflow improvement adrenergic agonist therapy is significantly better in patients with occupat asthma.[61] Bronchial biopsy performed in patients with RADS generally rev chronic inflammatory response.[61] RADS may have a neurogenic etiology[1(opposed to an immunologic origin, as in patients with occupational asthm may differentiate these clinically similar diseases on a mechanistic basis. inflammation results from increased vascular permeability, presumably se release of substance P from unmyelinated sensory neurons (C fibers).[46] N inflammation is inhibited by substance P depletors such as capsaicin and by substances that inhibit neutral endopeptidase, the enzyme responsible degradation of substance P.[103] The role of corticosteroids is undefined, b models suggest an antiinflammatory benefit.[43] Recovery may take months delay related to either ongoing low-level exposures to endopeptidase inhi persistent irritation of impaired tissue by environmental irritants such as

Summary

The overall quality of the air we breathe continues to deteriorate, and flu environmental pollutants periodically cause epidemic disease. Although th of xenobiotics capable of causing pulmonary toxicity is large, the patholo are rather limited. Gases that have little or no irritant potential or syster cause simple asphyxiation, in which the ambient atmosphere has a dimin oxygen concentration. Parenchymal irritation and ALI occur after exposure forming or free radicalâ€“generating gases and can progress to severe to

manifesting as ARDS. RADS is described in patients following exposure to all of the irritant gases. Treatment of all such exposures centers on symp supportive care.

A 38-year-old woman presented to the hospital complaining of vomiting, watery diarrhea, light-headedness, and headache one morning in August. husband had similar symptoms. The couple arrived 2 days earlier at a res town after a 3-hour flight on which they ate turkey sandwiches of questi quality. The woman denied taking any medications and stated that she ha contacts or recent travel outside the United States.

On physical examination, both patients appeared ill and dehydrated. The woman's vital signs were: blood pressure, 125/63 mm Hg; pulse, 100 be respiratory rate, 16 breaths/min; temperature, 100.5Â°F (38.1Â°C). Her examination was essentially normal, except for dry mucous membranes a epigastric tenderness. The only remarkable standard laboratory test was blood cell count of 12,300/mm^3 . Bicarbonate was normal at 22.4 mEq/L. receiving 1 L of 0.9% sodium chloride solution, ketorolac, and droperidol, patient was discharged several hours later feeling much better with norm signs. Her husband was treated similarly.

The next morning, the couple did not show up for the medical conference were attending. A friend convinced security to break into the room when was no answer at the door. The couple was found unconscious. The husba no pulse and could not be resuscitated. The wife, who was responsive to pain only, was transported with 100% face mask oxygen. Naloxone and were given IV en route, without any change in her symptoms. On arrival emergency department (ED), the patient's vital signs were: blood pressu 108/65 mm Hg; pulse, 112 beats/min; respiratory rate, 14 breaths/min; temperature, 101.9Â°F (38.8Â°C). Laboratory tests were unremarkable e for a glucose concentration of 306 mg/dL and a creatinine concentration mg/dL. Arterial blood gas showed: pH, 7.5; PCO_2 , 22.8 mm Hg; PO_2 , 17 Hg. Because of the strong odor of gas, a carboxyhemoglobin (COHb) leve sent for analysis and returned a value of 29.9%. The patient was immed transferred by helicopter to a tertiary medical center, where she was trea with hyperbaric oxygen (HBO). However, her course was complicated by

aspiration pneumonia, and she subsequently had persistent problems witl concentration, memory, and â€œnot being able to find my words.â€• Th source of the carbon monoxide poisoning subsequently was determined to faulty hot-water heater.

History and Epidemiology

Carbon monoxide (CO) is the leading cause of poisoning morbidity and m in the United States. Based on US national death certificate data, 2379 n fireâ€“related CO deaths occurred in 1998.[158] Of note, only 491 of the d were unintentional; more than half were related to motor vehicle sources figure remained essentially unchanged in 2002 despite increased CO dete use.[38] From 2001â€“2003, 15,200 patients were treated annually in eme departments for nonfatal, unintentional, non-fireâ€“related CO exposure. than half of the cases (64%) occurred in homes with faulty furnaces, usu the fall or winter months. CO poisoning is also a contributor to the appro 5613 smoke inhalation deaths each year.[47]

The more significant problem with CO poisoning may be the morbidity ra than mortality. The most serious complication is persistent or delayed co sequelae, which occur in up to 50% of patients with symptomatic acute poisonings.[88 , 193 , 259]

Because no method for predicting bad outcomes is completely reliable, C poisoning should be treated aggressively with HBO therapy.

Anesthetic lime absorbents[122]
Automobiles
Banked blood

Underground mine explosions[147]
Wood pellet storage

TABLE 120-1. Sources of Carbon Monoxide Implicated in Poisonin

Potential sources of CO abound in our society and often result in uninten poisoning (Table 120-1). Although CO is found naturally in the body as a byproduct of hemoglobin degradation,[48] it is readily available for inhalati the incomplete combustion of any carbonaceous fuel. Alternatively, absorptionâ€"dermal, ingestion, or inhalationâ€"of methylene chloride car in CO toxicity from hepatic metabolism (Chap. 102).[169] Despite use of c converters and other emission controls, more than half of unintentional C deaths are caused by motor vehicle exhaust.[47 , 158] Occupants of motor are not the only victims of exhaust gases. CO poisoning also is reported i children riding in the back of pickup trucks.[98] Workers can become symp from indoor use of propane-powered equipment, such as ice skating rink resurfacers[118] and forklifts.[67 , 72] For optimal performance, propane-pow forklifts typically are adjusted to produce no less than 10,000 ppm CO in and in fact average more than 30,000 ppm.[70] In an enclosed warehouse poor ventilation, CO levels could exceed toxic levels within one hour at th of production. Even occupants of boats are not immune to this insidious , 36 , 212

In the past 10 years, nonvehicular sources of CO have increasingly accou most unintentional poisonings, with fewer than 400 deaths each year in t United States.[38 , 47 , 158] Predominantly, these deaths have involved the of charcoal, wood, or natural gas for heating and cooking.[54 , 73 , 76 , 96] Propane-burning furnaces used for heating are often the culprits, especia when the flue is blocked.[18 , 38 , 90 , 101 , 102] Gas kitchen stoves are ano important source of CO in indigent populations with marginal heating

systems.[102 , 218] In fact, use of gas stoves for supplemental heat is pred CO poisoning in patients who present to the ED with headache and dizzin During ice storms, hurricanes and earthquakes, use of gasoline-powered generators and charcoal-burning grills, the latter particularly in immigran populations, has resulted in epidemic CO poisoning outbreaks.[37 , 109 , 26

Fires are another important source of CO exposure. CO is estimated to be cause or a major contributor to more than 1500 fire deaths annually.[47] C considered the most common hazard to smoke inhalation victims.[18 , 210]

Chemistry

CO has a molecular mass of 28.01 daltons and a density of 0.968 relative CO is found naturally in the body as a byproduct of heme degradation.[48] oxygenase, found in the liver and spleen, is the major endogenous source A second form of the enzyme in the brain that also produces CO behaves nitric oxide (NO), binding to guanylate cyclase and thereby increasing cy guanosine monophosphate (cGMP) concentrations.[148] Although low endo levels are physiologic, excessive concentrations of CO from exogenous s may be problematic because CO persists much longer than NO.[87] CO appe be a neuronal messenger by virtue of the fact that as a gas it can diffuse signal adjacent cells.[11]

CO is readily absorbed after inhalation. The Coburn-Forster-Kane (CFK) r allows the prediction of COHb levels based on exposure history.[50] This m been simplified to allow estimation of the equilibrium based on the ambie concentration of CO in ppm: COHb (%) = 100/[1 + (643/ppm CO)].[245] Th model assumes that the individual weighs 70 kg and is not anemic. With exponential uptake, more than 4 hours may be necessary to attain equili Therefore, within minutes of high CO exposures, the arterial COHb level r actually overshoot predicted estimates prior to equilibration.[16 , 27] Endog production of CO results in a COHb of 2%.

Once absorbed, CO is carried in the blood, primarily bound to hemoglobin Haldane ratio states that CO has an approximately 200â€“250 times grea affinity for hemoglobin than does oxygen.[33] Therefore, CO is primarily co

to the blood compartment, but eventually up to 15% of total CO body sto taken up by tissue, primarily bound to myoglobin.[49] The dissolved CO concentration in the serum may better reflect the ultimate potential for poisoning because dissolved CO is available for diffusion into all tissue compartments, including the brain.[139]

Elimination of CO from the blood, like absorption, can be modeled mathematically using the CFK model. The equation predicts a half-life of minutes.[50] In actual volunteer studies, means of 249 and 320 minutes ar reported.[181 , 189] With 100% oxygen, these half-lives can be reduced significantly to means of 47, 78, and 80 minutes in studies of volunteers attain COHb levels of 10â€“12%.[181 , 189 , 224] Two series of patients pois with CO showed actual mean half-lives of 74 and 131 minutes when patie were treated with 100% oxygen.[24 , 261]

Methylene chloride, a paint-stripper is another source of CO. It is readily absorbed through the skin, by ingestion, or by inhalation. It is metabolize the liver to CO.[221] After a delay of 8 hours or longer, peak levels of COHl range from 10â€“50%.[69 , 133 , 138 , 197] Because of ongoing CO productio apparent COHb half-life is prolonged to 13 hours in these patients.[195] CO levels after methylene chloride exposure appear to be proportional to the concentration and duration of exposure.[210]

Pathophysiology

The most obvious effect of CO is its binding to hemoglobin, which renders hemoglobin incapable of delivering oxygen to the cells.[64] Therefore, desp adequate partial pressures of oxygen in blood (PO_2), arterial oxygen cor decreases. Further insult occurs because CO causes a leftward shift of the oxyhemoglobin dissociation curve, thus decreasing the offloading of oxyge hemoglobin

to tissue.[200] This may result in part from a decrease in erythrocyte 2,3-diphosphoglycerate concentration.[9 , 243] The net effect of all these proce the decreased ability of oxygen to be carried by the bloodstream and rele cells.

CO toxicity cannot be attributed solely to COHb-mediated hypoxia.[196] Nei clinical effects nor the phenomenon of delayed neurologic deficits can be completely predicted by the extent of binding between hemoglobin and C [174 , 216 , 237] Furthermore, such a model fails to explain why even negli levels of COHb (4â€“5%) can result in cognitive impairment.[248] An early showed that dogs breathing 13% CO died within one hour and had COHb of 54â€“90%. However, exchange transfusion of the same blood into hea dogs caused no untoward effects.[86] Comparable levels of anemia also lac adverse effects. The appropriate conclusion was that inherent to CO toxic the delivery of CO to target organs such as the brain and heart, and that although easily measured, rarely makes a significant contribution to clini toxicity.[85 , 86]

The delivery of CO intracellularly and its subsequent binding to heme pro other than hemoglobin also may account for CO toxicity. Ten to fifteen p of the total body store of CO is extravascular, primarily binding to myogl [49] Some of this CO may interfere with cellular respiration by binding to mitochondrial cytochrome oxidase, as occurs in vitro.[10 , 40] Initial studies that this binding is especially exaggerated under conditions of hypoxia an hypotension.[25]

Inactivation of cytochrome oxidase may be only an initial part of the casc events resulting in ischemicâ€“reperfusion injury to the brain after CO p During recovery from the initial poisoning, white blood cells are attracted adhere to the damaged brain microvasculature.[240] This attraction may be attributable to endothelial changes from initial cytochrome oxidase dysfu mediated primarily through the free radical NO.[113 , 230 , 236] CO displaces from platelets that in turn form peroxynitrites, which are even stronger inactivators of cytochrome oxidase.[240] Multiple animal studies demonstrat NO ultimately is responsible for much of the endothelial damage from CO that NO synthase inhibitors can prevent toxicity.[232 , 239 , 242] In rats, CO poisoning causes an immune cascade in the brain whereby activated lym are attracted to CO-modified myelin basic protein.[233] After leukocytes att the damaged endothelium, they release proteases that convert xanthine dehydrogenase to xanthine oxidase, an enzyme that promotes formation

oxygen free radicals.[228] The end result of this process is delayed lipid peroxidation of the brain, which can be correlated with decrements in lea rodents.[227]

All this perivascular oxidative stress in the brain leads to activation of ex amino acids that ultimately may be responsible for subsequent neuronal loss.[236] In fact, glutamate increases in rat brains after CO poisoning.[270] Glutamate is an excitatory amino acid that can bind at *N* -methyl-D-aspa (NMDA) receptors and cause intracellular calcium release, resulting in de neuronal cell death (see Chap. 14).[20] Blockade of NMDA receptors can p the neuronal death and learning deficits that accompany serious CO poisc mice.[114] Newer data suggest that ultimately CO neuronal cell death may b form of apoptosis.[249] Increases in glutamate concentration in rat brain in first hour after severe CO poisoning are followed by a later rise in hydrox radicals.[190] Ultimately, at 1â€“ 3 weeks the animals show histologic evide both neuronal necrosis and apoptosis in the frontal cortex, globus pallidus cerebellum that are accompanied by deficits in learning and memory.

The role of apoptosis as the final cause of toxic damage in CO poisoning been confirmed in various models. In bovine pulmonary artery cells, CO exposure is accompanied by activation of caspase-1, a protease implicate delayed cell death.[235] The same study provided confirmatory evidence tha caspase-1 and NO synthase inhibitors blocked apoptosis. The end result o these cellular processes is brain injury, particularly in the basal ganglia a hippocampus, resulting in impaired learning.[231] Thus, animal models cor well with the final occurrence in victims of serious CO poisoning, namely, persistent or delayed deficits in learning and memory associated with str changes in the brain.

Myoglobin is another heme protein that binds CO. It has an affinity approximately 60 times greater than that of oxygen.[51] A dog model demonstrates that this binding is enhanced under hypoxic conditions.[51] T binding may partially explain the myocardial impairment that occurs both animal studies[56] and with low-level exposures in patients with ischemic h disease.[7] Isolated rat heart studies demonstrate that the effect on the he occurs regardless of COHb formation.[41] The combination of COHb formati

which decreases oxygen-carrying capacity, and the production of reduced myoglobin in the heart, which decreases oxygen extraction, may explain preterminal dysrhythmias that occur in animals.[82] Volunteers, especially with preexisting heart disease, develop an increase in life-threatening dysrhythmias and ischemic changes during stress testing even with low-l exposures (resulting in COHb levels up to 6%).[3 , 208]

Several studies suggest that CO effects on the cardiovascular system are necessary for ischemicâ€“reperfusion injury of the brain. Hypotension is a essential component and results from a combination of myocardial depre and vasodilation. CO activates guanylate cyclase, which in turn relaxes v smooth muscle.[252 , 255] CO can act on platelets to displace NO, which is a potent vasodilator.[128 , 234] These factors contribute to the hypotension tl occurs in animal experiments involving high doses of CO toxicity.[84 , 92] S episode of hypotension may be represented clinically by the syncope or lo consciousness that accompanies serious CO poisoning and portends a wo clinical outcome.[45 , 75 , 154] In the rhesus monkey, cerebral white matter correlate better with decreases in blood pressure than with COHb level.[84] Lipid peroxidation of the brain in rats develops one hour after CO exposu produced syncope and hypotension.[227] This delay is comparable to the ti necessary to produce mitochondrial destruction from oxidative stress in r exposed to CO.[269] In a feline model, central nervous system damage from can be reproduced only when hypoxia is accompanied by an interval of is confirming the ischemicâ€“reperfusion model.[176]

Clinical Manifestations

Effects of Acute Exposure

The earliest symptoms associated with CO poisoning often are nonspecific readily confused with other illnesses, typically a viral syndrome (Table 12 Headache is the initial symptom reported by volunteers within 4 hours of exposure to 200 ppm COHb levels (15â€“20%). Shorter exposures at 500 also produce nausea.[222 , 223] The incidence of CO poisoning in symptoma patients presenting to EDs in the winter with influenzalike symptoms rang

from 3â€“24% in some series.[42,63,100,102] Because the typical prese complaints include headache, dizziness, and nausea and the most freque exposures occur during winter, it is

not surprising that influenza is the most common misdiagnosis.[63,90] Hea the most common symptom, usually is described as dull, frontal, and continuous.[95] CO poisoning also is frequently misdiagnosed as food poisc gastroenteritis,[76,107] and even colic in infants.[191] Like adults, children t develop nonspecific symptoms (eg, nausea, headache, and vomiting), ma the diagnosis equally difficult.[57]

TABLE 120-2. Clinical Manifestations of Carbon Monoxide Poisoni

Continued exposure to CO can lead to symptoms attributable to oxygen deficiency in the heart. Low-level exposures (COHb 2â€“4%) in volunteers stable angina result in decreased exercise tolerance and signs and sympt myocardial ischemia.[2,6,8] At higher levels (COHb 6%), a greater frequ premature ventricular contractions is observed during exercise.[208] Myoca infarction, life-threatening dysrhythmias, and cardiac arrest are commonl

described in victims of CO poisoning.[5 , 145 , 204] In fact, acute mortality f usually results from ventricular dysrhythmias, probably predominantly cau the accompanying hypoxia.[3 , 5 , 56 , 204]

The central nervous system is the organ most sensitive to CO poisoning. otherwise healthy patients may manifest headache, dizziness, and ataxia COHb levels as low as 15â€“20%. With longer exposures, syncope, seizur coma can result.[31 , 104] Patients may present with symptoms of an acute stroke.[13 , 121] The EEG can show diffuse frontal slow-wave activity.[75 , 17 Within one day of exposures that result in coma, the computerized tomo (CT) scan can show decreased density in the central white matter and glo pallidus (Figure 120-1).[211 , 246] Autopsies show involvement of other ar including the cerebral cortex, hippocampus, cerebellum, and substantia r

Metabolic changes may reflect the toxic effects of CO better than any pa COHb level. Mild CO cases may be accompanied by respiratory alkalosis t compensate for the reduction in oxygen-carrying capacity and delivery.[14] Longer exposures with decreased levels of consciousness result in metab acidosis from the lactate production that accompanies tissue hypoxia.[216] a series of 48 CO-poisoned cases showed retrospectively that hydrogen io concentration, rather than COHb level, was a better predictor of poor rec during initial hospitalization.[251]

Although the brain and heart are the most sensitive, other organs can m the effects of CO poisoning. One fifth to one third of severe CO cases (ie, that required endotracheal intubation) develop cardiogenic pulmonary ed [217] This finding does not appear to be a direct effect of CO on lung tissue Studies of sheep with prolonged exposure to CO resulting in COHb levels showed no anatomic or physiologic change in lung function.[209] Although myonecrosis and even compartment syndromes occur, patients rarely de renal failure.[17 , 207] Retinal hemorrhages can develop with exposures >1 hours.[60 , 121] Cherry-red skin coloration occurs only after excessive expo (2â€“3% of cases referred to one hyperbaric center) and may represent a combination of CO-induced vasodilation with concomitant tissue ischemia [198] Another classic but uncommon phenomenon is the development of cu bullae following severe exposures.[166] These bullae are thought to be caus

combination of pressure necrosis and possibly direct CO effects in the epidermis.[110 , 136]

Delayed Cognitive Effects

The persistent or delayed effects of CO poisoning are varied and include dementia, amnestic syndromes, psychosis, parkinsonism, paralysis, chore cortical blindness, apraxia and agnosias, peripheral neuropathy, and incontinence.[81 , 137] Neurologic deterioration can be preceded by a lucid of 2â€“40 days after the initial CO poisoning.[45] In patients admitted to a intensive care unit for severe CO toxicity and treated with 100% oxygen, survivors had permanent neurologic impairment.[128] In a Korean series of CO-poisoned patients, only 3% continued to show memory failure or parkinsonian features one year after exposure.[45] In contrast, another ser 63 seriously poisoned patients showed memory impairment in 43% and deterioration of personality in 33% at 3-year follow-up.[216] Children also behavioral and educational difficulties after severe poisoning.[132] However, patients (age >30 years) appear to be much more susceptible to develop delayed sequelae.[45] Most cases of delayed neurologic sequelae are assoc with loss of consciousness in the acute phase of toxicity.[45 , 75 , 215]

Delayed or persistent neurologic sequelae probably involve lesions of the cerebral white matter and basal ganglia.[81] Weeks after exposure, autopsi necrosis of the white matter, globus pallidus, cerebellum, and hippocamp CT and magnetic resonance imaging (MRI) scans confirm the damage to t white matter and hippocampus.[74 , 108 , 177 , 211 , 246] Animal studies sho marked COHb alone cannot cause similar white-matter lesions; an episode hypotension also must have occurred.[84 , 176] The fact that the areas

permanently damaged in serious CO poisoning cases are the areas with t poorest vascular supply in the brain is consistent with these animal findi

Effects of Chronic Exposure

Patients often complain of persistent headaches and cognitive problems a long-term exposure to low levels of CO. Unfortunately, no controlled stuc have demonstrated that in the absence of a severe acute poisoning episo type of exposure results in any long-term sequelae. However, with docur continued exposure to low levels of CO, highway toll workers have troubl performing parallel processing tasks.[117] Warehouse workers chronically to CO from propane combustion have intermittent problems with headach nausea, and light-headedness.[67] Fortunately, symptoms resolve in most unless there has been an episode of severe poisoning with acute deterior One series of chronic CO poisoning demonstrates a high incidence of hea and memory complaints, along with motor slowing and memory problems

neuropsychological tests.[163] Although many of the objective deficits impr with elimination of the exposure and HBO treatment, many patients conti have posttraumatic neurosis and conversion disorders. One case report n permanent verbal memory, visual recall, and learning problems after a 3 exposure to 180 ppm CO from a faulty furnace.[202] Although it is unclear chronic exposure to low levels of CO can cause permanent damage, heal providers still should be vigilant for symptomatic individuals in order to p continued or catastrophic outcomes.

Diagnostic Testing

The most useful diagnostic test for suspected CO poisoning is the COHb l Normal COHb levels range from 0â€“5%. Levels at the high end of this ra occur in neonates and patients with hemolytic anemia,[265] as CO is a natu byproduct of the breakdown of protoporphyrin to bilirubin.[48] COHb levels average 6% in 1-pack-per-day smokers but can be as high as 10%.[220] Al high COHb levels confirm exposure to CO, particular levels are not neces predictive of symptoms or outcome. In fact, COHb can return to normal o zero if the patient was treated with oxygen prior to the blood test.[162 , 17

The usual method for measuring COHb is with a co-oximeter, which spectrophotometrically reads the percentage of total hemoglobin saturate CO.[14 , 52] Traditionally, arterial blood is used for this determination; hov venous blood concentrations are just as accurate.[248] Of note, refrigerate heparinized samples yield accurate COHb levels for months, making retrospective evaluations possible.[62 , 130] Bedside tests with ammonia or hydroxide cannot reliably differentiate various levels of COHb versus con Breath-sampling methods may be used for screening patients; however, a common cointoxicant, can falsely elevate breath levels unless an activa charcoal filter is used.[131 , 189 , 250] Because of the similarities in extincti coefficients, COHb is misinterpreted as oxyhemoglobin on pulse oximetry 22).[12] Thus the pulse oximeter reading overestimates oxyhemoglobin by approximate amount of COHb present.[23 , 29 , 94]

Some clinicians have started to measure CO, rather than COHb, directly i samples.[139] This technique involves assaying CO directly with infrared

spectrophotometry after it is extracted from the blood sample with a manometer.[159] Based on calculations rather than true experimental data, assumption is made that for a patient with a normal hemoglobin, a CO concentration of 1 mmol/L corresponds to 11% COHb.[180] A simpler metho measuring plasma CO content is to add a known solution of hemoglobin t by sodium dithionite to form COHb.[43] The resulting COHb is measured spectrophotometrically, with the assumption that 1 mole of hemoglobin bi moles of CO. Interestingly, in one study, plasma CO ranged from 0.14â€“ mg/L but was the same in smokers and nonsmokers (average COHb 4.6% 1%, respectively).[43] Further research is required to determine the clinica importance of plasma CO content.

Additional laboratory tests may be useful in severe poisoning cases. Arter venous blood gas analysis will confirm the presence of metabolic acidosis presumably is a reflection of high lactate and may serve as a more reliab of severity than COHB.[216] Unfortunately, arterial pH does not correlate w either initial neurologic examination or the COHb level, making it a poor for deciding the need for HBO treatment.[162]

Cardiac monitoring and a 12-lead ECG are essential for documenting ischo dysrhythmias in symptomatic patients with preexisting coronary artery d or severe exposure. Mild elevations of creatine phosphokinase are commo (range 20â€“1315 IU/L in a series of 65 cases) and usually result from rhabdomyolysis rather than cardiac sources.[207] However, CO can cause myocardial infarction, even in the presence of normal coronary arteries.[1 Therefore, it is not surprising to observe nonspecific rises in troponin concentrations, which may reflect diffuse cardiac myonecrosis rather than coronary artery disease.[39]

The problem with using COHb levels as the basis for treatment is the wid variation in clinical manifestations with identical COHb levels.[161 , 168] Furthermore, particular COHb levels are not predictive of symptoms or fi outcome.[149 , 162 , 174 , 216] In a large prospective study of CO poisoning, levels did not correlate with loss of consciousness and were not predictive delayed neurologic sequelae.[193] Part of the problem is that admission CO levels are inaccurate predictors of peak levels.[162] Use of nomograms to

extrapolate to earlier levels has not been validated. The credibility of nomograms is suspect because of the great variability in COHb half-lives differences in treatment with oxygen.

Because of the inherent unreliability of COHb levels in predicting outcome researchers are investigating other surrogate markers. Rats have early i in glutathione release from erythrocytes, a potential marker for CO oxida stress that ultimately could lead to brain injury.[238] Another promising ma serum S100B, a structural protein in astroglia that is released from the b after hypoxic stress.[22] A series of 38 consecutive patients poisoned with showed that those who presented with normal neurologic findings and no consciousness had normal S100B levels. Patients who presented with loss consciousness and neurologic deficits all had elevated levels.[28] However, studies have failed to find a difference between CO-poisoned patients and controls with respect to such markers (ie, S100B protein and neuron-spe enolase).[194]

Neuropsychological Testing

The extent of neurologic insult from CO can be assessed with a variety of The most basic is documentation of a normal neurologic examination with miniâ€“mental status examination. A more sensitive indicator of the acut effects of CO on cortical function is a detailed neuropsychological test ba developed

specifically for CO patients.[165] The advantages of such testing, which usu takes approximately 30 minutes, are that the test (1) can reliably disting 79% of the time between CO-poisoned patients and controls, and (2) sho improvement with appropriate HBO treatment.[152] Unfortunately, such tes has a sensitivity of only 77% and specificity of 80% for CO poisoning.[199] addition, practice effects may be observed if repeated testing is performe Another study suggested that the degree of impairment displayed by CO on a test of short-term rote and context aided verbal memory correlated with the number of HBO treatments needed.[150] The biggest problem with neuropsychiatric testing is the uncertainty as to whether deficits in the te

during the acute CO poisoning phase are at all predictive of the developm neurologic sequelae and therefore the need for HBO treatment.

Neuroimaging

Acute changes on CT scan of the brain occur within 12 hours of CO expos resulted in loss of consciousness.[119 , 155 , 170] Symmetric low-density are the region of the globus pallidus, putamen, and caudate nuclei are frequ noted.[111 , 123 , 170] Although a normal initial CT scan usually predicts a favorable outcome, changes in the globus pallidus and subcortical white early on the first day after poisoning are associated with poor outcomes (120-1).[155 , 192] The corollary to this finding is that, in a series of 18 pa negative CT within 1 week of admission was associated with favorable outcome.[246] The use of contrast may enhance early isodense changes no on initial CT scan.[268] MRI appears to be superior for detecting basal gan lesions after CO poisoning.[108 , 120] One study found a much higher incide periventricular white matter changes on MRIs performed on the first day exposure. However, such changes had no correlation with COHb level or cognitive sequelae.[182] Diffusion-weighted MRI may have more promise in detecting changes in subcortical white matter within hours of serious CO poisoning.[225] Regardless, neuroimaging usually does not influence patien management and its use reserved for patients who show poor response o an equivocal diagnosis.

The most promising area of neuroimaging after CO poisoning is in assess regional cerebral perfusion. Single-photon emission computed tomograph (SPECT) gauges regional blood flow noninvasively using an iodine or tech tracer.[61] In a series of 13 patients with delayed neurologic sequelae, all showed patchy hypoperfusion throughout the cerebral cortex within 11 da poisoning.[46] These changes in perfusion can occur as early as one day af poisoning and primarily involve watershed regions such as the temporoparietooccipital area.[61] Xenon-enhanced CT, which may be more available, appears to parallel perfusion changes noted on SPECT scanning Perfusion defects on SPECT scanning appear to be associated with neuropsychological impairment months after serious CO poisoning.[44 , 74

Unfortunately, because of the scant availability of the procedure and the comprehensive studies, SPECT scanning is not the definitive tool for dete prognosis or need for HBO at this time.

Positron emission tomography (PET) also can be used for assessing regio blood flow and oxygen metabolism in the brain after CO exposure. In a s severely CO-poisoned patients, PET examination after HBO treatment sho increased oxygen extraction and decreased blood flow in the frontal and temporal cortices.[58] Of note, patients with permanent deficits persisted i showing these abnormalities on PET scanning. One delayed PET study demonstrated that increases in dopamine D_2 receptor binding in the caud putamen after CO poisoning were improved with bromocriptine, at which neuropsychiatric symptoms resolved.[267] Although PET scanning cannot be to predict outcome, abnormalities that persist on the scan may be indicat patients with permanent neurologic sequelae.

To complement perfusion studies, EEG mapping has been performed on C poisoned patients. Although initial studies demonstrate that many patient regional EEG abnormalities after poisoning, whether these abnormalities predictive of persistent or delayed neurologic problems is unknown.[61 , 65] mapping may be discrepant relative to SPECT scanning, as EEG preferen demonstrates subcortical lesions.[61]

Management

The mainstay of treatment is initial attention to the airway. One hundred oxygen should be provided as soon as possible by either non-rebreather mask or endotracheal tube. It is important to remember that a non-rebre mask delivers only 70â€“90% oxygen; a positive pressure mask or an endotracheal tube is necessary to achieve higher oxygen concentrations.[3] immediate effect of oxygen is enhancement of the dissociation of COHb.[2] volunteers, the COHb half-life is reduced from a mean of 5 hours (range hours) when breathing room air (21% oxygen) to approximately one hou 36â€“137 minutes) when breathing 100% oxygen at normal atmospheric pressure.[181 , 189] Actual poisonings show a range in half-lives of 36â€“13 minutes (mean 85 minutes) when breathing 100% oxygen; the longer

elimination half-lives appear to be most often associated with long, low-l exposures.[116 , 164 , 260] With oxygenation and intensive care treatment, mortality rates for serious exposures range from 1.0â€“30%.[13 , 75] The of treatment is unclear, with a valid endpoint being resolution of symptor usually accompanied by COHb <5%.[112]

Cardiac monitoring and intravenous access are necessary in any patient v systemic toxicity from CO poisoning. Hypotension initially can be treated intravenous fluids. Inotropic agents may also be necessary to treat myoc depression.[143] Evaluation for cardiac ischemia, including ECG and cardiac enzyme concentrations, should be considered in symptomatic patients at Standard advanced cardiac life support protocols for treatment of life- threatening dysrhythmias can be followed. A rapid bedside blood glucose should be performed in patients with depressed mental status. Animal stu CO poisoning suggest that hypoglycemia can be deleterious.[185 , 186 , 188] Correction of any acidemia with bicarbonate is controversial and could res further cellular injury secondary to a left shift of the oxyhemoglobin diss curve.

Hyperbaric Oxygen

HBO therapy appears to be the treatment of choice for patients with sign CO exposures.[71 , 174] At 2.5 atmospheres absolute (ATA), the half-life of is reduced to 20 minutes.[181 , 189 , 203] Actual CO-poisoned victims treated HBO have half-lives ranging from 4â€“86 minutes.[164] HBO also increases amount of dissolved oxygen by approximately 10 times, which alone is s to supply metabolic needs.[20] However, this situation is rarely an importa clinical issue because most patients have already been stabilized, have appreciably decreased COHb with

ambient oxygen alone, and have the time required for transport to an HB facility.

TABLE 120-3. Summary of Randomized Clinical Trials of Hyperb
Oxygen in Carbon Monoxide

HBO is more than just a modality for clearing COHb more quickly than ar
oxygen. More importantly, in rats following loss of consciousness from CO
exposure, hyperbaric, but not normobaric, oxygen therapy prevents brain
peroxidation.[226] HBO appears to prevent ischemicâ€“reperfusion injury by
variety of mechanisms. First, in animal models, HBO accelerates regenera
inactivated cytochrome oxidase, which may be the initiating site for CO r
damage.[26] Second, HBO prevents subsequent leukocyte adherence to bra
microvascular endothelium, a process essential for amplification of centra
nervous system damage from CO.[41 , 229] This may explain why HBO, but
100% oxygen at atmospheric pressure, prevented delayed deficits in a le

and memory maze model.[247]

Clinical studies of the effectiveness of HBO in preventing neurologic dama from CO are not as convincing as basic science studies would suggest. In uncontrolled human clinical series, the incidence of persistent neuropsyc symptoms, including memory impairment, ranged from 12â€“43% in pati treated with 100% oxygen and was as low as 0â€“4% in patients treated HBO.[89 , 149 , 167 , 174 , 214]

Several controlled clinical trials have evaluated the efficacy of HBO in CO poisoning (Table 120-3). The first randomized study of CO poisoning had than 300 patients and failed to show a benefit from HBO in patients who initial loss of consciousness.[193] Unfortunately, seriously ill patients were randomized to surface pressure oxygen; they received either one or three treatments. Flaws in that study included significant delays to treatment a of suboptimal pressure of 2.0 ATA. A smaller (n = 60), more recent cont study avoided some of these flaws and showed that HBO was able to dec delayed neurologic sequelae from 23% to 0% in CO-poisoned patients wi loss of consciousness.[241] However, all patients with syncope, a marker of serious poisoning, were excluded. A very small study (n = 26) of patients presenting with GCS >12 after CO poisoning included almost half with los consciousness.[65] Randomization to HBO versus 100% normobaric oxygen resulted in decreased EEG abnormalities and less reduction in blood flow reactivity to acetazolamide at 3 weeks. Unfortunately, all of these studies to definitively study all CO-poisoned patients, including those with syncop coma.

The first randomized trial to really address the issue of HBO efficacy in s CO-poisoned patients was completed with 191 patients.[205] All CO-poisone patients referred for HBO treatment were randomized to a minimum of 3 treatments of HBO (2.8 ATA for 60 minutes) or 100% oxygen at 1.0 ATA. Although the HBO group had a higher incidence of persistent neurologic at 1 month, there was no significant difference between the 2 groups; mo two thirds of each group had persistent problems. This study is the larges controlled, randomized study to date but has several flaws.[157] Fewer than the patients had follow-up at 1 month. Disproportionate numbers of suici

cases (approximately two thirds) and drug toxicity (44%), with accompa neuropsychological defects, could have confounded any beneficial effect HBO. Finally, HBO treatment was delayed for more than 6 hours, making treatment much less likely to be effective.[89 , 193]

The most recent randomized, doubleâ€“blind, controlled study showed a beneficial effect of HBO in CO-poisoned patients.[259] Most of these patient ill, with a mean initial COHb level of 25% and a 50% incidence for loss of consciousness. Patients were all treated within a 24-hour window after e but the success of the study might stem from the <2-hour mean time to treatment. Patients were treated 3 times at intervals of 6â€“12 hours, ea 2.0 ATA, except for the first hour of the first treatment, which was at 3.0 Control patients received sham treatments in the HBO chamber with 100 oxygen at 1.0 ATA. At 6 weeks, the HBO group had a 24% incidence of c sequelae versus 46% in the control group. Based on these data, the numb patients needed to treat in order to prevent one case of cognitive impairm only five. Critics of this study point out that the neuropsychiatric tests we significantly different between the groups except for digit spam and trail in addition, there was no difference in activities of daily living. However, authors' defense, patients had increased self-reported memory problems a weeks (28% vs. 51%), and the beneficial effect on cognitive sequelae las into 12 months.

Based on these studies, it is not surprising that the Underwater and Hyp Medical Society recommends HBO treatment for any CO patient with signs serious intoxication.[71] Given the low risk associated with this procedure,[2] almost 1500 patients in the United States are treated with HBO for CO p each year.[97] Therefore, HBO has become the standard of care for serious poisoning despite the lack of evidence-based guidelines for patient select

Indications for Hyperbaric Oxygen Therapy

Specific indications for HBO after acute CO poisoning are listed in Table 1 but these indications have not been prospectively evaluated. The patients likely to benefit are those most at risk for persistent or delayed neurolog sequelae, such as those presenting

in coma.[125, 214, 266, 271] Another potential marker for delayed neurolog sequelae is a history of syncope.[45, 75, 154, 215] This may represent the episode of hypotension that is necessary for causing neuronal damage fro induced ischemicâ€“reperfusion injury in animal models.[84, 177] However, syncope is neither an extremely sensitive nor specific marker for cognitiv sequelae.[259] Patients with long exposures, or â€œsoakingâ€• periods, al at greater risk for neurologic sequelae.[21, 258] The presence of significant metabolic acidosis may be a surrogate marker.[135, 216, 251] Some autho advocate ongoing myocardial ischemia as an indication for HBO; however, experience, these patients usually already meet neurologic criteria for tr (eg, loss of consciousness, ongoing mental status changes). More import isolated cardiac ischemia deserves immediate proven myocardial salvagin therapy rather than delayed treatment with an unproven therapy such as

Syncope
Coma
Seizure
Altered mental status or confusion
Carboxyhemoglobin >25%
Abnormal cerebellar examination
Fetal distress in pregnancy

TABLE 120-4. Suggested Indications for Hyperbaric Oxygen

Some authors advocate HBO treatment for all patients with COHb levels â‰¥40%.[112, 160] Many HBO centers arbitrarily use a more conservative of 25% as an indication for HBO treatment. More important than actual le patient history and examination. Further analysis of data from the most controlled trial[259] demonstrates that in patients not treated with HBO, no factorsâ€”COHb level, loss of consciousness, or base excessâ€”reliably p who progressed to cognitive sequelae (L. Weaver, Personal Communicatio March 2005). Therefore, at this time it would be prudent to refer for HBO treatment those patients with the most serious neurologic symptoms, re

of COHb level. Symptoms include coma, seizures, focal neurologic deficits altered mental status, and, although controversial, loss of consciousness. group of patients who probably could be excluded from HBO therapy are who experienced a cardiac arrest from CO; these cases have been univer fatal.[99]

Whether mild neurologic symptoms (eg, confusion, headache, dizziness, blurring) or abnormal mental status testing on initial presentation after C poisoning is prognostic for cognitive sequelae is unclear. These symptoms represent CO poisoning, which, at COHb levels approaching 10% in volur can cause temporary impairment of learning and memory.[4] In a prospect clinical trial of CO poisoning, the incidence of cerebellar dysfunction porte higher incidence of cognitive sequelae (odds ratio 5.7 [95% confidence i 1.7â€“19.3]).[259] Therefore, difficulty with finger-to-nose, heel-to-shin, r alternating hand movements, or even ataxia, should all be considered in for HBO. Patients with other mild neurologic findings (eg, headache) warr least several hours of oxygen by non-rebreather face mask until sympton resolve. If symptoms do not resolve, HBO can be considered; however, a delay in HBO may decrease its efficacy.[89]

Some authors recommend selective use of HBO because of cost and diffic transport if the primary facility lacks a chamber.[178] However, complication can make such transfers and treatment unsafe are rare.[213] Although HBO be recommended for every patient with CO poisoning, it is a relatively sa treatment that should be considered in all serious exposures. Fortunately without HBO, anywhere from one third to three fourths of cases with per cognitive sequelae resolve over the subsequent year.[45 , 259]

Delayed Administration of Hyperbaric Oxyg

The optimal timing and number of HBO treatments for CO poisoning are Patients treated more than 6 hours after exposure tend to have worse ou in terms of delayed sequelae (30% vs. 19%) and mortality (30% vs. 14% This may explain the failure of one of the first randomized trials on HBO i which had a mean time to treatment of more than 6 hours after poisoning Meanwhile, HBO treatments delivered within 6 hours after poisoning in p

with loss of consciousness after CO seem to almost completely prevent neurologic sequelae.[168, 271] However, patients may benefit if treated ev later. In the most recent randomized clinical trial showing beneficial effec HBO, although all patients were treated within 24 hours of exposure, only of patients were treated after more than 6 hours. Therefore, it is not unreasonable to consider HBO, contingent on transport limitations, within hours of presentation for symptomatic acute poisoning.

One case series suggests beneficial effects for HBO used up to 21 days postexposure, once patients have developed neuropsychological sequelae The problem with studies showing HBO benefits days after an acute poisc after chronic poisoning, is that these cases are all anecdotal and lack cor In fact, almost all cases of delayed neurologic sequelae resolve within 2 in mild poisoning,[241] and one third resolve within 1 year of serious CO p that survives to HBO treatment.[259] The benefits in delayed or chronic cas simply represent the salutary effects of HBO. A preliminary study shows HBO improves memory scores temporarily by >50% in normal (nonpoisor volunteers.[115]

Repeat Treatment with Hyperbaric Oxygen

A randomized clinical trial demonstrated that three HBO treatments within first 24 hours improves cognitive outcome.[259] Unfortunately, no group wa treated with only one or two HBO sessions. Regardless, some authors ad multiple treatments for patients who have persistent symptoms, particula coma, and do not clear after their first HBO session.[59] In a nonrandomize retrospective study, CO-poisoned patients who received a second HBO tr had a reduction in delayed neurologic sequelae from 55% to 18% compar controls who had only one treatment.[88] Prospective studies comparing si versus multiple courses of HBO therapy failed to confirm any benefit from repeated HBO treatment; therefore, multiple treatments cannot be recon at this time.[193] The most recent clinical guidelines from the Underwater a Hyperbaric Society state that the optimal number of HBO treatments for poisoning is unknown at this time, and that multiple treatments should be reserved for patients who do not fully recover after one treatment.[71]

Treatment of Pregnant Patients

The management of CO exposure in pregnant patients is difficult because potential adverse effects of both the xenobiotic and its treatment. A liter review of all CO exposures during pregnancy revealed a high incidence of central nervous system damage and stillbirth after severe maternal poisonings.[254] A series of three severely symptomatic patients who did n receive HBO

had adverse fetal outcomes: two stillbirths and one case of cerebral palsy Cases of limb malformations, cranial deformities, and a variety of mental disabilities in children poisoned in utero are reported.[32 , 140] Although neurologic sequelae have been noted after severe acute exposures, a retrospective case control study showed no association between CO expos the last trimester and low birth weight.[1]

Traditionally, it was thought that fetal hemoglobin had a high affinity for Studies of pregnant ewe show a delayed but substantive rise in COHb lev the fetus exceeding the level and duration of that in the mother.[142] Thus, appears that the fetus is a sink for CO and could be poisoned at levels lo than the mother. However, such data may not apply to humans because i work shows that, as opposed to sheep, human fetal hemoglobin actually l affinity for CO than maternal hemoglobin, at a ratio of 0.8.[68] The more important issue with maternal CO exposure is the precipitous drop in feta arterial oxygen content that occurs within minutes at levels of 3000 ppm. Therefore, the ensuing hypoxia of the fetus, rather than the increase in f COHb, is of concern.

Maternal COHb levels do not accurately reflect fetal hemoglobin or tissue levels.[53] In primate studies, a single CO exposure insufficient to cause cl disease in the mother led to intrauterine hypoxia, fetal brain injury, and increased rate of fetal death.[83 , 84] A few cases of fetal demise, with ext low maternal COHb levels (ie, less <10%), are reported in humans.[32] Par problem is that some mothers in the series were treated with oxygen prio determination of their COHb level. In one case of fetal loss, the fetus had

higher levels than the peak COHb of 24% measured in the mother.[55] Ano issue with some of these data is that the mothers often had been chronic â€œsoakedâ€• with CO, making levels difficult to interpret. Rodent studi that chronic low-level CO exposure in pregnant mothers can result in per cognitive deficits in the subsequent progeny.[144]

Because maternal COHb does not necessarily predict fetal demise, clinicia must direct their attention to maternal symptoms of CO toxicity. Multiple series demonstrate that pregnant women who present with normal menta and no loss of consciousness have excellent outcomes in terms of normal deliveries.[32 , 127 , 175] Their infants have no subsequent delay in attainin developmental milestones.[127] Therefore, it appears that mothers who ap well after acute CO poisoning will have good pregnancy outcomes.

The bigger dilemma facing the clinician is the approach to treatment of s symptomatic CO-poisoned pregnant patients. All mothers should receive oxygen by face mask, at least until symptoms resolve. Some authors rec longer oxygen therapy. The problem is that CO absorption and eliminatior slower in the fetal circulation than in the maternal circulation.[83 , 141] A mathematical model predicts that elimination of CO from the fetus takes times longer than maternal CO elimination.[105] However, based on the fac some of these data are based on sheep fetal hemoglobin kinetics, the op time for treatment of the mother cannot be recommended at this time.

For more ill pregnant patients with loss of consciousness or high COHb le HBO might be considered. Unfortunately, pregnant patients were excluded all prospective trials documenting HBO efficacy. In addition, treatment of pregnant patients with HBO is not without theoretical risk. Animal studies conflicting results on the effects of HBO on fetal development.[254] Some s showed that HBO causes developmental abnormalities in the central nerv cardiovascular, and pulmonary systems of the rodent fetus.[153] This is in contrast to the extensive Russian experience, in which hundreds of pregr women treated with HBO apparently had no significant perinatal complica and showed improvement in fetal/maternal status of their underlying cor (eg, toxemia, anemia, diabetes).[156] Cases of HBO use for mild CO poison the United States have resulted in normal infants at birth.[66 , 106 , 127 , 2

However, less than optimal outcomes have occurred in sicker cases where mother had loss of consciousness or presented in coma.[66] Thus, it appear HBO should be safe and have the same efficacy for pregnant patients as i nonpregnant patients. However, its effect in preventing adverse fetal out is unclear.

There currently is no scientific validation for an absolute level at which to provide HBO therapy for CO exposure in pregnant patients. Arbitrarily, CO levels >20% have been touted as an indication in pregnant patients rega of symptoms.[254] Pregnant patients should not be treated any differently i meet the criteria for HBO therapy (Table 120-4). Additional criteria inclu signs of fetal distress, such as abnormal fetal heart rate.

Treatment of Children

Children have been suggested to be more sensitive to the effects of CO b of their increased metabolic rate.[57] Epidemiologic studies suggest that ch can become symptomatic at COHb levels <10%, which is lower than com expected in adults.[126] The other problem is that children may have unusu presentations. Most children manifest nausea, headache, or lethargy.[57] H an isolated seizure or vomiting may be the only manifestation of CO toxic an infant or child.[104]

When drawing COHb levels in infants, clinicians must be aware of two confounding factors. First, many cooximeters can give falsely elevated CO levels, in proportion to the amount of fetal hemoglobin present.[256] Second produced during breakdown of protoporphyrin to bilirubin. Therefore, infa normally have higher levels of COHb that are even higher in the presence kernicterus.[219 , 257] Thus, before an elevated COHb level is assumed to b poisoning in an infant, the contribution of jaundice and fetal hemoglobin considered in the final analysis.

Although children may be more susceptible to acute toxicity with CO, the term outcomes appear to be more favorable than the outcome in adults. I series of 2360 serious CO cases, all incidences of delayed neurologic seq were in adults older than 30 years.[45] Two series of CO poisoning in childr

demonstrated an approximately 10% incidence of delayed neurologic seq after severe CO poisoning.[124, 151] This low incidence in patients treated with 100% oxygen at 1.0 ATA has been used as an argument against HBO therapy.[151] However, there still is a real risk of sequelae, which are succ prevented by HBO use.[201] If surface-pressure oxygen is used to treat a c is comforting to know that the COHb half-life is approximately 44 minutes is comparable to that in adults.[126]

Novel Neuroprotective Treatments

A variety of neuroprotective agents have been tested in animal models. T targeted primarily at preventing the delayed neurologic sequelae associat serious CO poisoning. One of the simplest treatments tested is insulin. Hyperglycemia has been shown to exacerbate neuronal injury from stroke during arrest situations. In CO poisoning of rodents, hyperglycemia is as with worse neurologic outcome.[188] However, insulin, independent

of its glucose-lowering effect, may be the protective agent after ischemia rodent studies, insulin treatment improved neurologic outcome after CO poisoning, as measured by locomotor activity.[263] In light of these findings reasonable to aggressively treat documented hyperglycemia with insulin i of serious CO poisoning.

Many neuroprotective xenobiotics involve blockage of excitatory amino ac are implicated in neuronal cell death after CO poisoning. Pretreatment of with dizocilpine (MK-801), which blocks the action of glutamate at NMDA receptors, ameliorates learning, memory, and hippocampal deficits result from CO poisoning.[114] Ketamine, another glutamate antagonist, decrease mortality of rats poisoned with CO after carotid ligation.[187] Posttreatment mice with various glutamate antagonists prevents learning and memory in a model of CO poisoning.[78, 244] Blockage earlier in the immunologic c using a neuronal NO synthetase inhibitor also prevented NMDA receptor activation, thus protecting mice from learning deficits after CO poisoning.[236] One exciting approach is the use of antioxidants, such as dimethyl su and disulfiram, which prevent learning and memory deficits when given a

poisoning in mice.[79, 80] Use of such related xenobiotics appears promisin awaits further animal testing because of potential adverse effects.

Other modalities for preventing neuronal damage from CO have been tes without much success. Hypothermia, rather than being beneficial, actuall increases mortality in animals.[183] Allopurinol given to prevent formation radicals through xanthine oxidase has been tested. This drug, when given pretreatment, prevents lipid peroxidation mediated by xanthine oxidase in poisoning.[228] This strategy has not been promising because of the need f pretreatment.

Prevention

Early diagnosis prevents much of the morbidity and mortality associated poisoning, especially in unintentional exposures. The increased quality of CO-detecting devices will allow personal intervention to prevent CO expo If a patient complains that his or her CO alarm sounded, realize that the threshold limit of the alarm is set to approximate a COHb level of 10% at Therefore, manufacturers must set their alarms to activate within 189 mi 70 ppm CO, 50 minutes at 150 ppm, and 15 min at 400 ppm (Underwrite Laboratories, UL2034). Alarms are not to activate for prolonged exposure ppm in order to prevent epidemic alarms during winter inversions in large cities.[19] Government ordinances for obligatory CO alarms potentially coul prevent many poisonings, particularly during winter storms.[37]

Routine laboratory screening of ED patients during the winter is not effic in diagnosing unsuspected CO poisoning. The yield is <1% when patients whom the diagnosis of CO exposure was already excluded by history are tested.[103, 250] Instead, selecting patients with CO-related complaints, su headache, dizziness, or nausea, increases the yield to 5â€“11%.[91, 250] D winter, risk factors such as gas heating or symptomatic cohabitants in pa with influenzalike symptoms (eg, headache, dizziness, nausea) will be the useful method for deciding when to obtain COHb levels in potential cases [101 and 102]

The issue of symptomatic cohabitants is especially important from a prev

standpoint. Alerting other cohabitants to this danger and effecting evacu may prevent needless deaths.[262] Most communities have multiple resourc on-site evaluation. Usually the local fire department or utility company ca either check home appliances or measure ambient CO levels with portable monitoring equipment. Current workplace standard for ambient CO expos 35 ppm averaged over 8 hours, with a ceiling limit of 200 ppm (measured 15-minute period).[172] Just a 4-hour exposure to 100 ppm CO can result i >10% with symptoms.[189] Until rescue personnel arrive, appliances fueled natural gas should be turned off and the area evacuated, leaving all wind doors open.

Summary

Unintentional exposures to CO can easily be misdiagnosed. Patients with suspected influenza should be screened for potential home sources of CO symptomatic cohabitants alerted. CO should be suspected in any patient coma, acidosis, or signs of cardiac ischemia, especially if attempted suicid suspected. Fire victims, in addition to suffering airway problems and pote cyanide toxicity, may die of CO toxicity.[15] In all these cases, the mainsta treatment is good supportive care with early oxygenation to increase CO elimination. Because of the overwhelming clinical successes with HBO and limited risks, early use of this treatment modality in severe exposures is encouraged. Discussion with a regional poison control center or hyperbar facility will help identify those patients most likely to benefit from such treatment.
