Infusion of autologous or heterologous blood for the purpose of increasing known as *blood doping.* Blood doping was used in the Olympic Games as Finnish steeplechaser. During subsequent summer and winter Olympics, cyclists, and skiers acknowledged their use of this practice. The US cyclin using blood transfusions in the 1984 Olympics. Subsequently, the IOC ba

Blood doping is beneficial in endurance athletes. Infusion of 400 mL pack runners increased the total RBC concentration and substantially improved km races.[29] Blood doping also increases the speed performance of cross preparatory technique involves the removal of 1000 mL blood, the immed plasma volume, and the freezing and storage of RBCs. After 5â€“6 weeks return to normocythemia), reinfusion of frozen RBCs resulted in increase from 45% to 49%, 5% increase in oxygen utilization, and increased endu Reinfusion of packed RBCs resulted overnight in an increase in maximal e 23% and increased maximal oxygen uptake by 9%. These improvements increase in hemoglobin concentration.[65]

Altitude acclimatization, which is considered an acceptable practice by WA improvements in performance similar to the banned practice of blood do athletes living at sea level are at a disadvantage in their training compar at high altitudes. One problem with altitude training is that exercise capac intensity of the training is decreased until acclimatization occurs. This offs beneficial effects of altitude training. Many athletes avoid this by â€œlivir lowâ€• or by training in an oxygen rich environment while acclimatizing t increase in hemoglobin due to altitude acclimatization resulted in a 6% in oxygen uptake and 25% increase in endurance capacity upon return to se

Stimulants

Caffeine

Caffeine is a CNS stimulant that causes a feeling of decreased fatigue ar performance[69 , 170] (Chap. 63). These changes may occur through seve mechanisms, including increased calcium permeability in the sarcoplasmic enhanced contractility of muscle, phosphodiesterase inhibition and subse nucleotides, adenosine blockade leading to blood vessel dilation, and inh Caffeine is no longer prohibited by the WADA 2005 Prohibited List World Caffeine and pseudoephedrine are included in a monitoring program that WADA to detect patterns of misuse for substances that are no longer on

Amphetamines

The beneficial effects of amphetamines in sports result from their ability t pain.[55] Initial studies of soldiers showed they could march longer and ign took amphetamines.[225] In one study of college students, resting and max strength, acceleration, and anaerobic capacity increased. However, althou fatigue decreased, lactic acid continued to accumulate and maximal oxyg unchanged.[39] Other studies have shown no significant effects on exercise (Chap. 73).

Sodium Bicarbonate

Sodium bicarbonate loading, known as *soda loading* , has a long history o racing.[16] Sodium bicarbonate may buffer the lactic acidosis caused by ex delaying fatigue and enhancing performance.[86]

During high-intensity exercise, metabolism becomes anaerobic and lactic Intracellular acidosis is said to contribute to muscle fatigue by reducing t muscle contractile apparatus to calcium.[172] Several studies demonstrated performance when sodium bicarbonate was ingested 2â€“3 hours before The study dose was 0.2â€“0.3 g/kg body weight of sodium bicarbonate, $NaHCO_3$ per day. The effects of sodium bicarbonate are greatest when pe

longer than 4 minutes because anaerobic metabolism contributes more to production and energy from aerobic metabolism diminishes.[86 , 88] Adverse bicarbonate loading include diarrhea, abdominal pain, and possible hype

An animal model demonstrated that intracellular acidosis, occurring as a production, reversed muscle fatigue.[3 , 172] Previously, intracellular acidosis contribute to muscle fatigue by reducing the sensitivity of the muscle co calcium, decreasing the force of muscle contraction. However, the mecha excitationâ€“contraction is complex. Because it permeates membranes eas important for maintaining and stabilizing the muscle fiber resting membra pH. Because of this characteristic, a large sodium current is needed to o stabilization and produce an action potential. In intracellular acidosis, m to the chloride ion is reduced, the resting membrane potential is no longe inward sodium influx is needed to produce an action potential. The excita tubule system is therefore increased by acidosis, protecting against musc

Diuretics

The World Anti-Doping Code bans diuretic use.[244] Diuretics are used in sp athlete must achieve a certain weight to compete in discrete weight class weight loss, body builders find that diuretic use gives greater definition to skin draws tightly around the muscles.[1] Diuretics also result in increased thereby diluting the urine and making more difficult the detection of othe xenobiotics.[34 , 56] Diuretic use in a body builder caused hyperkalemia ar 60).

Miscellaneous Xenobiotics

Chromium Picolinate

Chromium acts as a cofactor to enhance the action of insulin.[94] It is foun grains, raisins, apples, and mushrooms.[219] It is sold as chromium picolin acid is thought to enhance chromium absorption.[219] In people who are c chromium supplementation results in increased glycogen synthesis and g Studies have not shown an increase in strength or a change in body com

metabolism when chromium is administered in a controlled fashion.[5, 52] from chromium picolinate doses > 200 Âµg/d.[48] A 24-year-old body build rhabdomyolysis after ingesting 1200 Âµg chromium picolinate, 6-24 times recommended dose of 50â€“200 Âµg, over 48 hours.[147]

Renal failure developed in one patient who took chromium picolinate 600 weight reduction, which is 12â€“45 times the usual intake of dietary chron recommended supplementation dose.[240] Another individual who took 120 chromium picolinate for the previous 4 months for weight loss presented dysfunction, anemia, thrombocytopenia, and hemolysis. Chromium plasma 2â€“3 times normal (Chap. 88). Other causes of the abnormalities were laboratory parameters improved with cessation of chromium ingestion.[37]

Laboratory Detection

Enormous amounts of energy and money are expended to determine the performance-enhancing substances. Nevertheless, the average percentage tests analyzed by the IOC accredited laboratories between the years 1993 1.8%.[230] WADA implemented a worldwide testing program before the 200 Sydney, Australia. In the program, 2846 tests were conducted on athletes 27 different sports. Unannounced out-of-competition testing was performed an Olympic event and began 2 weeks before the games started. The first urine testing for EPO use was introduced in Sydney and represented the f sampling for the detection of previously undetectable performance-enhanc targeted the sports at high risk for EPO use, primarily endurance events. teams of independent observers were involved in monitoring all aspects o process.[164] In the 2004 Olympics in Athens, Greece, approximately 3500 and yielded 30 positive test results. For the first time, drug testing in At unannounced tests during the games and even subsequently when the at home. In previous Summer Olympics, only the top four finishers were te the competition.

Analysis of samples on the international level is performed by a limited r laboratories. The majority of tests are performed on urine, with careful p requirements regarding handling of samples. From the first moment the a

a sample is requested for testing, the athlete must at all times remain wi chaperone who is an official of the anti-doping association. This official d athlete urinating to produce the sample. The athlete must report to the within 60 minutes for a no-advance-notice sample and within 24 hours fo sample collection. The sample is collected in â€œtamper-evidentâ€• con Documentation identifying the athlete is completed but not included with sample is delivered to the laboratory such that the integrity, identity, and sample are assured.[245] Attention must be paid to proper storage of spec bacterial metabolism may increase urinary steroid concentrations.[24 , 60]

Upon the sample's arrival at the testing laboratory, the integrity of the s including the code, seal, visual appearance, density, and pH. Registration completed, and the sample is divided into two aliquots. All testing is done and any positive results are confirmed on the second aliquot. The aliquots referred to as sample A and sample B. Sample preparation is difficult and

Capillary gas chromatography is the most important technique currently Gas chromatography typically is combined with mass spectrometry for de of substances.[160] Analysis of the urine by gas chromatography-mass spe current standard for detection of anabolic androgenic steroids.[34] Such an amount of reference data.[35]

The complexity of the laboratory testing is illustrated in the discovery of undetectable by standard sport doping tests of urine. In the summer of 2 was provided anonymously to the United States anti-doping authority. The the University of California Los Angeles (UCLA) Olympic Analytical Labora furor, now known as the BALCO scandal, resulted in the implication of m athletes in sports doping. BALCO is the acronym for the Bay Area Labora company that provides vitamins and nutritional supplements to athletes.

Through a painstaking process of analyses, an impurity in the substance i identified as a derivative of the AAS norbolethone. â€œA hypothesis for which fit all the dataâ€• resulted in the discovery and synthesis of a new tetrahydrogestrinone (THG).[35] THG has characteristics that differentiate i anabolic steroids. According to the report describing the discovery, synth THG, this new chemical was not a known pharmaceutical or a known vet

Detection of exogenously administered peptide hormones is difficult becau similarity to endogenous substances. Research continues in this area, as report using monoclonal antibodies to detect administration of rhGH.[246] E measured by a monoclonal anti-EPO antibody test, which does not distinq endogenously produced and exogenously administered recombinant EPO. methods of EPO detection are used, such as measurement of hemoglobin

Previously, some sports-governing bodies, such as the International Cyclir International Skiing Federation, selected a hematocrit of 50% in men and action level above which an athlete may be disqualified for presumed EPO normal hematocrit values vary greatly among athletes. Several studies ha hematocrits above the action values of 50% in men and 47% in women a From 3â€“6% of athletes who did not use EPO had hematocrits > 50%.[23 living and training at altitudes between 2000 and 3000 m above sea level hematocrit values > 50%.[234] Other studies confirm the increased hemato training at altitudes from 1000â€“6000 m.[19 , 198 , 199 , 234]

Although many endurance athletes may have increased blood volume, the lowered because of the increased plasma volume, which exceeds the RBC dilutional pseudoanemia is sometimes called *sports anemia* .[205] Additionall measurements are affected by hydration status, upright versus supine po and they demonstrate an approximately 3% diurnal variation.[197] Because among individuals, postural effects, and the ease of manipulation through indirect detection of EPO use by hematocrit measurement is fraught with

The ratio between serum soluble transferrin receptors (sTfr) and ferritin h indirect method for detection of EPO use. Soluble transferrin receptor is r progenitors. EPO stimulates erythropoiesis and causes an increase in

sTfr and a decrease in ferritin.[84] Individuals with other causes of polycyt erythropoiesis also can exhibit increased ratios and be falsely accused of hematocrit with sTfr > 10 Âµg/mL and sTfr-to-serum protein ratio > 153 an indirect measurement of EPO use.[11]

A combination of multiple indirect markers of altered erythropoiesis for d was developed at the 2000 Olympics in Sydney, Australia.[167] Current EPO â€œON-model,â€• and recent, but not current, use of EPO is known as

Five variables predict current rhEPO use: reticulocyte count, serum EPO hematocrit, and percentage of macrocytes. The 3-variable combination of reticulocyte count, and serum EPO concentration was the best mechanism rhEPO use.[167] A major drawback to this method is the instability of these blood so that confirmatory testing of the split blood sample is impossible.

The two isoforms of EPO, recombinant and endogenous, have different c compositions causing differing molecular charges.[169] An immunoblotting advantage of these different net charges, and the proteins can be separa when they are placed in an electric field.[131] Subsequently, by isoelectric obtains an image of EPO patterns in the urine.[130] The technique is difficul WADA considers a positive urine test result by this method definitive, eve testing of indirect markers.[169] Because of darbopoietin's structural similar detection techniques also are effective for darbopoietin.[169]

Masking Agents

Some agents are available for the sole purpose of interfering with urine are added to the urine. Examples include â€œKlear,â€• which is 90% m Seal tea, which produces colored urine.[28] Other commercially available p â€œXxtra Clean,â€• which contains pyridinium chlorochromate, and â€œ contains glutaraldehyde. Such adulterants are easily detected.

Any chemical or physical manipulation done with the purpose of altering t or blood sample is prohibited by WADA.[244] For example, use of intraveno substitution is prohibited. The list of prohibited masking agents includes epitestosterone, probenecid, plasma expanders such as albumin, dextran, starch, and Î±-reductase inhibitors such as finasteride and dutasteride.[24 urinary excretion of the glucuronide conjugates of AAS. A number of urin to contain probenecid at the 1987 Pan American Games, leading to subse probenecid by the IOC.[47 , 236]

Gene Doping

The discovery of the genetic codes for some diseases has made gene the conditions, such as muscular dystrophy, a reality. It is now conceivable t

be used to enhance athletic performance. For example, insertion of a ger produce a desired effect, such as large muscles or increased body produc advantageous substances such as testosterone or growth hormone. In an EPO lead to erythropoiesis and genes for IGF-1 produce increased muscle Myostatin, which belongs to a family of proteins that control growth and tissues in the body, inhibits skeletal muscle growth.[200] Mutations of the result in muscle hypertrophy. A report of an extremely muscular baby bor the myostatin gene illustrates the potential effect of gene alterations on The mother of this infant was a professional athlete, and other members known for their strength.[200]

A gene is introduced into the body by direct injection of DNA or by introc of a virus vector containing the altered DNA.[226] As of 2005, gene doping WADA prohibited list. Gene doping is defined as â€œthe non-therapeutic genetic elements, or of the modulation of gene expression, having the ca athlete performance.â€•[244]

Summary

Although the press spotlights a few world-class athletes, the vast majorit performance-enhancing substances are not in the public view. Some indi consequences. The knowledgeable clinician will identify these health effect and educate susceptible individuals on the risks of using performance-er

Chapter 45
Food Poisoning

Michael G. Tunik

Cases 1 and 2

A 30-year-old woman and her 32-year-old husband, who were on a scuba Puerto Rico, had a local dinner consisting of rice, beans, a large red sna fruit preserves, and wine. That night, approximately 5 hours after dinner, by abdominal discomfort and nausea. These symptoms were followed by Although they were unsure of the order of events, a throbbing headache, numbness of the arms, legs, and mouth ensued. Each patient described f pain with â€œdeep aches in the joints.â€• The woman stated that when warm washcloth to rub on her â€œfreezing skin,â€• the warm washcloth distressing symptom of temperature misinterpretation lasted for 2 days. during the early morning hours, but the nausea and diarrhea continued f crampy, abdominal pain persisted for approximately 4 days. The following spoke to some of the local inhabitants. Many of them described similar s appear after they ate a large fish, such as sea bass, red snapper, groupe

Because so many people had the same symptoms, the couple did not see their return to the mainland 10 days later, they had no clinical or physic

The most common causes of foodborne disease are bacteriaâ€”*Salmonella Clostridium perfringens, Staphylococcus aureus, Campylobacter* spp, *Bacil Escherichia coli, group A Streptococcus, Clostridium botulinum, Vibrio ch* virusesâ€”hepatitis A, E, F, and G, Norwalk virus; parasitesâ€”*Entamoeba lamblia, Trichinella spiralis* ; fishborne toxinsâ€”scombrotoxin, ciguatoxin chemicalsâ€”heavy metals, monosodium glutamate; and plantsâ€”mushro

Foodborne Poisoning with Neurologic Sym

The differential diagnosis of patients with foodborne poisoning presenting symptoms is vast (Tables 45-2 and 45-3). Many of these cases are icht toxins from the muscles, viscera, skin, gonads, and mucous surfaces of t toxicity follows consumption of the fish blood or skeleton. Shellfish poison considered. Most episodes of poisoning are not species specific, although toxicity from Tetraodontiformes (puffer fish), Gymnothoraces (moray eel), and other species) are recognized.

Deep-sea fish, eels, mussels, clams, and crabs are all implicated in diarrl cases of ciguatera poisoning, the major symptoms usually are neurotoxic, gastrointestinal (GI) symptoms are minor. Scombroid poisoning, which is common, is not associated with neurologic manifestations, but facial flush dysphagia are its major signs and symptoms.

Knowing where the fish was caught often is helpful for the diagnosis, bu of foods and rapid worldwide travel can complicate the assessment. Trave Pacific islands, as well as individuals traveling within the United States, h ciguatera poisoning.[88] In geographically disparate regions of Canada,[120] from domoic acid intoxication caused by ingestion of cultivated mussels f Island.

In the differential diagnosis of foodborne poisons presenting with neurolo activities other than eating must always be considered. In particular, spo their activities in high-risk areas (Florida, California, and Hawaii), and oft risk periods (May through August). In the process, they may sustain a bit stingray tail), or laceration (from a deltoid or pectoral fin spine of a lion can cause consequential marine toxicity (Chap. 116).

Ciguatera Poisoning

Ciguatera poisoning is one of the most commonly reported vertebrate fis accounting for almost half of the reported cases in the United States.[36] It water, bottom-dwelling shore reef fish living around the globe between 35 south latitude, including tropical areas such as the Indian Ocean, the Sou Caribbean. Hawaii and Florida report 90% of all cases occurring in the Ur commonly during May through August.[91]

More than 500 fish species are involved, with the barracuda, sea bass, pa grouper, amber jack, kingfish, and sturgeon the most common sources. T the comparably large size of the fish involved.

Large fish (4â€“6 lb or more) become vectors of ciguatera poisoning in a complex feeding patterns inherent in aquatic life. Ciguatoxin can be found protozoa, and the free algae dinoflagellates. These plankton members of

phylum Protozoa are single-celled, motile, flagellated, pigmented organis photosynthesis. Photosynthetic dinoflagellates such as *Gambierdiscus tox* within the dinoflagellates are the origins of ciguatoxin.[45, 71, 96] These d main nutritional source for small herbivorous fish. Because these small fis source for larger carnivorous fish, the ciguatoxin becomes increasingly co flesh, adipose tissue, and viscera of larger and larger fish.[10]

TABLE 45-2. Differential Diagnosis of Possible Foodborne Poisoni Neurologic Symptoms

Ciguatoxin is heat stable, lipid soluble, acid stable, odorless, and tasteles toxin is a large (molecular weight 1100 daltons) complex ester that does is stored in its tissues.[91, 95] The molecule binds to the sodium channel i increases the sodium permeability of the channel.[9, 149] Multiple ciguatoxi the same fish, perhaps explaining the variability of symptoms and differi

can be afflicted after they eat fresh or properly frozen fish prepared by a boiling, baking, frying, stewing, or broiling. The appearance, taste, and s fish usually are unremarkable. The majority of symptomatic episodes beg ingestion, 75% within 12 hours, and all but 4% within 24 hours.[10] Sympto onset of diaphoresis; abdominal pain with cramps, nausea, vomiting; pro and a constellation of dramatic neurologic symptoms.[165] Headaches are c loose, painful teeth may occur. Typically, peripheral dysesthesias and pa predominate. Watery eyes, tingling, and numbness of the tongue, lips, th occur. A strange metallic taste is frequently reported. A reversal of tem is reported, but the pathophysiology remains to be elucidated.[25] Myalgias, lower extremities, arthralgias, ataxia, and weakness are commonly expe and symptoms of dyspareunia and vaginal and pelvic discomfort may occu sexual intercourse with men who are ciguatoxic.[87] Ciguatoxin may be tra milk[18] and can cross the placenta.[118] Vertigo, seizures, and visual disturl vision, manifestations of scotomata, and transient blindness) are describ

Bradycardia and orthostatic hypotension are described.[55] The GI sympto within 24â€“48 hours; however, cardiovascular and neurologic symptoms several days to weeks, depending on the amount of toxin ingested. Delay include protracted itching and hiccoughs. Although deaths are reported, n documented in the United States.[36] Mortality is a result of respiratory pa apparently managed without adequate life support.

Laboratory analysis using an enzyme-linked immunosorbent assay (ELISA) toxin can be performed; alternatively, high-pressure liquid chromatograph The original mouse bioassay was the standard, but the method was slow, destruction of animals, and did not differentiate the variants in ciguatoxi immunobead assay test being developed for field use will allow testing of laboratory processing of the toxin-containing tissues.[9, 69, 117] A useful and management using laboratory testing is excluding other diagnostic p determining the need for, or extent of, specific therapeutic interventions.

Initial treatment for victims of ciguatoxin poisoning includes standard sup toxic ingestion.[165] In most patients, elimination of the toxin is accelerate and diarrhea (70%) have occurred. Administration of activated charcoal m benefit. In patients with significant GI fluid loss through vomiting and/or

fluid and electrolyte repletion is essential. The orthostatic hypotension ma intravenous fluids, atropine, and Î±-adrenergic agonists.

IV mannitol may produce a decrease in neurologic and muscular dysfunc associated with ciguatera. GI symptoms are less responsive to mannitol.[1] randomized

controlled trial, mannitol failed to produce any greater improvement in sy 0.9% sodium chloride solution.[137] Mannitol should be used with caution b hypotension. Vascular reexpansion and cardiovascular stability should be priorities.

Symptoms)

Admission to the hospital for cautious supportive care is essential when t
uncertain or when volume depletion or any consequential manifestations
differential diagnosis includes botulism, organic phosphorus compound po
potentially life-threatening processes (Tables 45-2 and 45-3). The etiolo
must be rapidly identified to provide specific therapy, if available. Diapho
clinical finding and an important factor in the differential diagnosis. Late i
ciguatera poisoning, amitriptyline 25 mg orally twice daily may alleviate
may persist up to 1 year.

Ciguateralike Poisoning

Moray, conger, and anguillid eels carry a ciguatoxinlike neurotoxin in the
and gonads that does not affect the eel itself. The toxin has a complex e
be structurally very similar to ciguatoxin and is heat stable.[113] These sam
ichthyohemotoxin that is resistant to drying but can be destroyed by heat
(65Â°C). Individuals who eat these eels may manifest neurotoxic sympto
that occurring with ciguatoxin, or they may show signs of cholinergic toxi
hypersalivation, nausea, vomiting, and diarrhea. Shortness of breath, mu
cutaneous eruptions may occur. These findings may be present in additio
symptoms.[65] Management is supportive. Mortality is related to the compl
neurotoxicity, such as seizures and respiratory paralysis.

Scombroid Poisoning

Scombroid poisoning originally was described with the Scombroidae fish (
dark-meat marine tuna, albacore, bonito, mackerel, and skipjack). Howev

commonly ingested vectors identified by the Centers for Disease Control are nonscombroid fish, such as mahi mahi and amber jack.[35] All of the i live in temperate or tropical waters. Ingestion of bluefish in New Hampsh cause of scombroid poisoning in 5 people,[46] and mackerel was the likely reported from a prison. The incidence of this disease probably is far grea perceived. This type of poisoning differs from other fishborne causes of ill entirely preventable if the fish is properly stored after it is removed from

Scombroid poisoning results from eating cooked, smoked, canned, or raw fish all have a high concentration of histidine in their dark meat. *Morganel* and *Klebsiella pneumoniae* , commonly found on the surface of the fish, decarboxylase enzyme that acts on a warm (not refrigerated), freshly kil histidine to histamine, saurine, and other heat-stable substances. Althoug suggested as the causative toxin, chromatographic analysis demonstrates found as histamine phosphate and saurine is merely histamine hydrochlo *saurine* originated from saury, a Japanese dried fish delicacy often assoc intoxication. The extent of spoilage usually correlates with histamine co concentrations in healthy fish are < 0.1 mg/100 g fish meat. In fish left the concentration rapidly increases, reaching toxic concentrations of 100 12 hours.

The appearance, taste, and smell of the fish usually are unremarkable.[5] F abnormal â€œhoneycombingâ€•

character or a pungent, peppery taste that may be a clue to its toxicity (C within minutes to hours after eating the fish, the individual experiences a burning sensation of the mouth, dysphagia, headache, and, of particula scombroid poisoning, a peculiar flush characterized by an intense diffuse neck, and upper torso.[78] Rarely, pruritus, urticaria, angioedema, or bron Nausea, vomiting, dizziness, palpitations, abdominal pain, diarrhea, and develop.[58 , 78 , 83 , 105]

The prognosis is good with appropriate supportive care and parenteral ar diphenhydramine. H_2 -Receptor antagonists such as cimetidine or ranitidin alleviating symptoms.[16] The toxic substance should be removed or absorb Inhaled B_2 -adrenergic agonists and epinephrine may be necessary if bro

prominent. Patients usually show significant improvement within a few ho

Elevated serum or urine histamine concentrations confirm the diagnosis. I remains, isolation of causative bacteria from the flesh is suggestive but r capillary electrophoretic assay makes rapid histamine detection possible.[1 concentrations > 50 mg/100 g fish meat is considered hazardous by the U Administration (FDA). Isoniazid may increase the severity of the reaction inhibiting enzymes that break down histamine.[72 , 159]

The patient may be reassured that he or she is not allergic to fish if othe experience a similar reaction to eating the same fish at the same time, or can be preserved and tested for elevated histamine concentrations. If this available, an anaphylactic reaction to the fish must be considered. Table differential diagnosis of flushing, bronchospasm, and headache. Because consume alcohol with fish, alcohol must be considered an independent va

Onset Symptoms/Signs Cause Therapy

TABLE 45-4. Common Foodborne Disease Symptoms: Flushing Headache (Primary Presenting Symptoms)

Shellfish Poisoning

Healthy mollusks living between 30Â° north and 30Â° south latitude inges quantities of dinoflagellates. These dinoflagellates are the major source o during the â€œnon-Râ€• months (May through August) in the northern this time, these dinoflagellates are responsible for the â€œred tidesâ€• t California to Alaska, from New England to St. Lawrence, and across the w Europe.[102] The number of toxic dinoflagellates may be so overwhelming t and humans who walk along the beach may suffer respiratory symptoms

toxin.[104]

Ingestion of shellfish, including oysters, clams, mussels, and scallops, co dinoflagellates or algae may cause neurotoxic, paralytic, and amnestic sy dinoflagellates most frequently implicated are *Ptychodiscus brevis* (forme *breve*), the diatom causing neurotoxic shellfish poisoning; *Protogonyaulax Protogonyaulax tamarensis* , which cause paralytic shellfish poisoning; ar the diatom implicated in amnestic shellfish poisoning. Proliferation of thes a red tide, but shellfish poisoning may occur even in the absence of this

Paralytic shellfish poisoning is caused by saxitoxin. Saxitoxin blocks the sodium channel in a manner identical to tetrodotoxin (see below). The s usually are clams, oysters, mussels, and scallops. A higher number of sh associated with more severe symptoms. Symptoms usually occur within 3 ingestion. Neurologic symptoms predominate and include paresthesias and mouth and extremities, a sensation of floating, headache, ataxia, vertigo paralysis, and cranial nerve dysfunction manifested by dysphagia, dysart transient blindness. GI symptoms are less common and include nausea, pain, and diarrhea. Fatalities may occur as a result of respiratory failure, 12 hours after symptom onset. Muscle weakness may persist for weeks.

Treatment is supportive, but with early intervention for respiratory failur and cathartics were used to remove unabsorbed toxin from the GI tract b necessary

or efficacious.[22 , 93 , 109 , 142] Activated charcoal may be given. Antibodi have reversed cardiorespiratory failure in animals,[12] but this therapy has humans. Assays for saxitoxin include a mouse bioassay, ELISA, and HPLC. interlaboratory accuracy,[161] but the differences in saxitoxin derivatives r an analytic test difficult.[8 , 89]

Neurotoxic shellfish poisoning (NSP) is caused by brevetoxin. Brevetoxin, *Krenia brevis* (previously *Gymnodium brevis*), is a lipid-soluble, heat-sta similar to ciguatoxin. It acts by stimulating sodium flux through the sodiu nerve and muscle.[6 , 26] NSP is characterized by gastroenteritis with asso symptoms. GI symptoms include abdominal pain, nausea, vomiting, diarrh burning. Neurologic features include paresthesias, reversal of hot and co

sensation, myalgias, vertigo, and ataxia. Other symptoms may include h tremor, dysphagia, bradycardia, decreased reflexes, and dilated pupils. P occur. The combination of bradycardia and mydriasis is unusual. The incu hours (range 15 minutesâ€“18 hours). GI and neurologic symptoms app Other manifestations of brevetoxin toxicity include respiratory irritation, bronchospasm, which occur when *P. brevis* is aerosolized by wave action Duration of symptoms averages 17 hours (range 1â€“72 hours).[109]

Brevetoxins can be assayed using mouse bioassay, ELISA, and, more rec radioimmunoassay (RIA) and reconstituted sodium channels.[122 , 158] Trea and severe respiratory depression is very uncommon. Therapy includes re from the environment and the administration of bronchodilators. NSP is n

Amnestic shellfish poisoning is caused by domoic acid. The etiologic agent structural analogue of glutamic and kainic acids produced by the diatom *N* documented outbreak occurred in Canada in 1987, when 107 individuals mussels harvested from cultivated river estuaries on Prince Edward Islan Other outbreaks are possible because a similar diatomâ€”*Pseudonitzschia* isolated in shellfish from other areas.[53] Pelican deaths caused by domoic were reported in 1991. Canada instituted monitoring for domoic acid afte death of 400 sea lions in California in 1998 was linked to domoic acid fro *pungens f multiseries* .[138]

Amnestic shellfish poisoning is characterized by GI symptoms of nausea, cramps, and diarrhea, and by neurologic symptoms of memory loss and, seizures, hemiparesis, ophthalmoplegia, purposeless chewing, and grimac include unstable blood pressure and cardiac dysrhythmias. The onset of s ingestion of mussels is 5 hours (range 15 minutesâ€“38 hours). The mort death most frequently occurring in older patients, who suffer more sever symptoms. Ten percent of victims may suffer long-term antegrade memor motor and sensory neuropathy. Postmortem examinations has revealed ne hippocampus and amygdala.[153]

Tetrodon Poisoning

This type of fish poisoning involves only the order Tetraodonti-formes. Alt

fish is not restricted geographically, it is eaten most frequently in Japan, South America, and Australia.[65] Cases in Florida and New Jersey have be Approximately 100 freshwater and saltwater species of this order exist, ir pufferlike fish such as the globe fish, balloon fish, blowfish, and toad fish found in these fish is also isolated from the blue-ringed octopus[49] and th mollusc.[168] It has also caused fatalities from ingestion of horseshoe crab (a local variety of puffer fish) is considered a delicacy, but special licensir prepare this exceedingly toxic fish. In 1989, the FDA legalized the import However, prior to exportation from Japan, the fish must be laboratory tes two Japanese organizations to be tetrodotoxin free. In addition, certain newts (*Taricha* , notophthalmus, triturus, and cynops), particularly *Taricha* Oregon, California, and southern Alaska, can be fatal when ingested. Most salamanders with bright colors and rough skins contain toxins.[20]

Tetrodotoxin is a heat-stable (except in alkaline milieu), water-soluble, aminoperhydroquanizole found mainly in the fish skin, liver, ovary, intest muscle.[65 , 133] The ovary has a high concentration of the toxin and is mo during the spawning season. Tetrodotoxin is detected by mouse bioassay. heated to 212Â°F (100Â°C) in acid, distinguishing it from saxitoxin. Tetro detected using fluorescent spectrometry[8] or detected in the urine of into a combination of immunoaffinity chromatography with fluorometric HPLC. produced by inhibition of sodium channels and blockade of neuromuscula

Symptoms of tetrodon poisoning typically occur within minutes of ingesti diaphoresis, dysesthesias, and paresthesias of the lips, tongue, mouth, fa evolve rapidly. Buccal bullae and salivation may develop. Dysphagia, dys vomiting, and abdominal pain may ensue. Generalized malaise, loss of c fasciculations, and an ascending paralysis (with risk of respiratory paralys hours. Other cranial nerves may be involved. In more severe toxicity, hy In some studies, mortality has approached 50%.[145]

Therapy is supportive. Removal of the toxin and prevention of absorption measures. Supportive respiratory care emphasizing airway protection, inc necessary, is extremely important.

Less Common Poisonings: Echinoderms

The sea urchin usually causes toxicity by contact with its spinous process delicacy also is toxic upon ingestion. When the sea urchin is prepared as containing gonads should be removed because they contain an acetylcho causes profuse salivation, abdominal pain, nausea, vomiting, and diarrhea considered edible by some individuals, although an asteriotoxin with sap produces nausea and vomiting is reported.

Prevention of Marine Foodborne Disease

Careful evaluation of the symptoms and meticulous reporting to local and departments, as well as to the CDC, will allow for more precise analysis o poisoning from contaminated or poisonous food or fish. Many states and developed rigorous health codes with regard to harvesting

certain species of fish in certain areas at certain times. A review of food reported to the CDC over a 5-year period may be representative of the n food poisoning in the United States (Table 45-1). Some examples of acti foreign health agencies in controlling epidemics of fishborne food poisonir

- In 1972, the 3230-km Massachusetts coastline was noted to be unsaf harvesting. A health emergency was declared because of a red tide bl confiscated shellfish and prohibited the marketing, export, and servin
- The health code of Miami, Florida, prohibits the sale of barracuda and fillets from large and potentially toxic fish containing ciguatoxin.
- The Japanese closely regulate preparation and selling of the puffer fi requiring that preparers receive special training and licensing.
- The Canadian government marks the location and time of harvesting mussels are tested for the presence of domoic acid.[53 , 120]

Case 3

A 4-year-old child presented to the emergency department (ED) with a 1 diarrhea, vomiting, and intermittent abdominal pain. The family became

and mucus appeared in the stool after 4 days. At that time, blood tests a obtained at another hospital. Antipyretics were prescribed for fever, and hydration were given. No antibiotics or other therapy was offered, and th other symptoms began to resolve. The parents again became concerned v child appeared pale, was more irritable than usual, had a decreased urine uninterested in eating at a favorite fast-food restaurant. The child was bro evaluation after a brief generalized seizure. The child was otherwise heal medical history, other medication use, or ingestions. The child was atter

Physical examination revealed an afebrile child with blood pressure 125/80 beats/min; and normal respiratory rate. The child appeared pale and irrit the physical examination was significant for a systolic flow murmur on c mild abdominal pain without rebound or guarding, and a liver edge palpab right costal margin. No meningeal signs were evident, and the neurologic nonfocal. Laboratory studies were significant for a white blood count 22, 25%, and platelet count 80,000/mm^3 . A peripheral blood film revealed helmet cells. Serum sodium concentration was 128 mEq/L; potassium 5.9 nitrogen (BUN) 40 mg/dL; creatinine 2.2 mg/dL; and alanine aminotransf Coagulation studies and cerebrospinal fluid analysis were normal.

Foodborne Poisoning Associated with Gas Anemia, Thrombocytopenia, and Azotemia

This constellation of findings is typical for the hemolytic uremic syndrome frequently caused by a bacterial gastroenteritis. The most common organ *coli* O157:H7.[63] Other bacteria producing a Shigalike toxin can cause the xenobiotics also implicated as causes of HUS include estrogen-containing mitomycin C, cyclosporin A, and radiation therapy.[121] Other nontoxicologic clinical picture include autoimmune disease, Kawasaki syndrome, and ba leading to disseminated intravascular coagulopathy and shock.

Laboratory findings typically include microangiopathic hemolytic anemia, acute intrinsic renal failure. Other laboratory findings include hyperkalem hyponatremia, and hypocalcemia. Liver aminotransferase concentrations m pancreatic involvement may produce hyperamylasemia, elevated lipase c

hyperglycemia.

Most children with HUS are younger than 6 years, and many are younger begins with a prodrome of diarrhea 90% of the time. The diarrhea lasts fe frequently becomes bloody. Abdominal pain because of colitis is common. findings include vomiting, altered mental status (irritability or lethargy), fever. At the time of presentation, many children have oliguria or anuria. children present with a generalized seizure at the onset of HUS.[141] Postdi endemic in Argentina.[97] Frequent epidemics occur in North America, and describe the association of enterohemorrhagic *E. coli* (EHEC) or *E. coli* O postdiarrheal HUS.[21, 101, 114, 115, 126, 163] Postdiarrheal HUS occurs the summer months, matching the peak incidence of positive stool culture common source of the organism).[66] Food products from cattle (ground be cheese) and water contaminated with fecal material are common sources Contaminated water used in gardens and unpasteurized apple cider have diarrhea and HUS as a result of EHEC.[14, 40]

EHEC, including *E. coli* O157:H7, produces a toxin similar to the toxin pro *dysenteriae* type I, referred to as Shigalike toxin (SLT) or verotoxin.[52] Th mechanism for SLT damage is intestinal absorption, bloodstream access t endothelium, intracellular adsorption via glycolipid receptors, ribosomal in death.[151] In animal models, organ damage is more severe if endothelial c concentrations of globotriaosylceramide receptors, which have a high bind toxin. Other organs with these receptors include the renal, GI, and centr which may explain the pattern of organ damage in children with HUS. En and other pathologic processes, including platelet and leukocyte activation coagulation cascade, and the production of cytokines, occur.[75, 160] More exists; SLT-1, SLT-2, and variants of SLT-2 structure have been identifie

Detection of *E. coli* O157:H7 through stool culture early in the course of recovery decreases after the first week of illness.[121, 151] *E. coli* O157:H produces SLT; therefore, if stool cultures are negative, enzyme immunoas polymerase chain reaction (PCR) tests can be used to detect SLT in the s no longer be identified by culture.[23]

Treatment of HUS should focus on meticulous supportive care, with fluid the priority. Peritoneal dialysis or hemodialysis should be instituted early

hyperkalemia, acidosis, and fluid overload. Red blood cells are transfused hemoglobin concentrations > 6 g/dL and platelets to maintain hemostasis invasive procedures. Hypertension should be treated with short-acting ca (nifedipine 0.25â€“0.5 mg/kg/dose orally) and

seizures with benzodiazepines. Many therapies have been used for HUS, fibrinolytics, IV immunoglobulin, fresh-frozen plasma, vitamin E, and ant has been obviously beneficial, and some have been deleterious.[156] Plasma used in nondiarrheal HUS and in recurrent HUS after renal transplants. In antibiotics did not change the course or outcome of children with postdia analysis also found no increased risk of antibiotic therapy.[130] Antiâ€“SLT-2 protected mice from SLT-2 toxicity, but IV immunoglobulin with SLT-2 ac outcome in children with HUS. A doubleâ€“blind, placebo controlled study synthetic SLT receptors attached to an oral carrier did not change the m morbidity of HUS syndrome.[157]

The mortality from HUS with good supportive care is approximately 5%; a suffer end-stage renal disease or cerebral ischemic events and chronic r Prolonged anuria (> 1 week) or oliguria (> 2 weeks) or severe extrarenal markers for higher mortality and morbidity.[121]

Strategies to prevent the spread of *E. coli* O157:H7 and subsequent HUS education on thorough cooking of beef to a well-done temperature of 170 pasteurization of milk and apple cider, and thorough cleaning of vegetabl measures include education of clinicians to consider *E. coli* O157:H7 in p diarrhea and routine capability of microbiology laboratories to culture *E.* provide for EIA or PCR determination of SLT. Public health departments s surveillance systems to identify early outbreaks of *E. coli* O157:H7 infect

TABLE 45-5. Common Foodborne Disease: Gastrointestinal (Pr
Symptom)

Foodborne Poisoning Associated with Diarr
Elevated Temperature

The initial differential diagnosis for acute diarrhea involves several etiolc (bacterial, viral, parasitic, and fungal), structural (including surgical), m toxin induced, and food induced. The differential diagnosis is described in

An elevated temperature may be caused by invasive organisms, including *Shigella* spp, *Campylobacter* spp, invasive *E. coli, Vibrio parahaemolyticus* as well as some viruses. Episodes of acute gastroenteritis not associated caused by organisms producing toxins, including *S. aureus, B. cereus, C.* enterotoxigenic *E . coli* , and viruses.[30]

Fecal leukocytes typically are found in patients with shigellosis, salmone enteritis, typhoid fever, invasive *E. coli* colitis, *V. parahaemolyticus* , *Yers* and ulcerative colitis. In all of these conditions, except typhoid fever, the primarily polymorphonuclear; in typhoid fever, they are mononuclear. No noted in cholera, viral diarrhea, noninvasive *E. coli* diarrhea, or nonspeci

The timing of diarrhea onset after exposure or the incubation period can differentiating the cause. Extremely short incubation periods of less than *Staphylococcus* , *B. cereus* (type I), enterotoxigenic *E. coli* ,[30 , 99 , 152] a enterotoxins, as well as roundworm larvae ingestions. Intermediate incub 8â€“24 hours are found with *C. perfringens* , *B. cereus* (type II enteroto *coli* ,[44 , 106] and salmonella. Longer incubation periods are seen in other acute gastroenteritis (Table 45-5).

The three most likely etiologies of diarrhea are infectious, xenobiotics, a three etiologies are not mutually exclusive. The differential diagnosis mus these groups. When the time from exposure to onset of symptoms is brief nonbacterial infectious etiologies (viral, parasitic, fungal, and algal) excep invasion by roundworm larvae can be eliminated. The possibility of a bac enterotoxin production should be considered (Table 45-5).[30 , 51]

Epidemiology

Epidemiologic analysis is of immediate importance, particularly when GI than one person in a group. The questions raised in Table 45-6 must be available, an infectious disease consultant or infection control officer shou assistance. Alternatively, assistance from state and local health departme Often only the CDC or state health department has the resources to inve

presumptive diagnosis in an outbreak. Sophisticated techniques such as matching the organism in the food by phage type with a food handler, ma phage type with other persons, isolating 10 or more organisms per gram [47] or PCR identification of bacterial or plasmid DNA are potentially useful possible using the laboratory and personnel available in most hospitals.[23] metabolic, and functional causes often can be eliminated. As in these dise significant grouping of cases nor a limited clinical history is characteristic such as *Trichinella spiralis* (trichinosis), *Toxoplasma gondii* (toxoplasmosis (giardiasis) must be considered, although acute GI symptoms usually are

Staphylococcus Species

In cases of suspected food poisoning with a short incubation period, the assess the risk for staphylococcal causes. The usual foods associated wit production include milk products and other proteinaceous foods, cream-fi potato and chicken salads, sausages, ham, tongue, and gravy. Pie crust c maintaining the temperature of the cream filling and occasionally permitt even during refrigeration.[4] A routine assessment must be made for the p the hand or nose of any food handlers involved. Unfortunately, â€œcarrie enterotoxigenic staphylococci are difficult to recognize because they usual appear healthy.[70] A fixed association between a particular food and an ill helpful epidemiologically but rarely occurs clinically. Factors such as envi resistance, nature of the agent, and dose make the results surprisingly v

1. Is the occurrence of the disease in a large group significant enough t foodborne disease (two or more cases)?
2. Is the symptomatology in affected individuals well defined and simila
3. Is the onset, time, and duration of illness similar among affected gro (incubation)?
4. What are the possible modes of transmission (ie, contact, food, wate
5. Is there a relationship between the time of exposure of the group and transmission?
6. Do attack rates differ for age, gender, or occupation?
7. Can it be determined which foods were served and to whom?

Can the items which were not eaten by those who did not become ill

8. What is the food-specific attack rate?
9. How was the food procured? How was it stored?
10. Was cooking technique adequate?
11. Was personal hygiene acceptable?
12. Was there animal contamination?

TABLE 45-6. Epidemiologic Analysis of Gastrointestinal Disease

Although patients with staphylococcal food poisoning rarely have a signif elevation, 16% of patients in a review of 2992 documented cases had a s fever.[70] Abdominal pain, nausea followed by vomiting, and diarrhea domi findings. Diarrhea does not occur in the absence of nausea and vomiting. period is 4.4 hours with a mean duration of illness of 20 hours. Two sta food poisoning incidents involving large numbers of people have been rep people attended a public event in Brazil. Within hours of food consumptio suffered nausea, emesis, diarrhea, abdominal pain, and dizziness. Of thes presented to and overwhelmed local emergency departments, 396 (20%) intensive care units), and 16 (young children and elderly) died.[143] In anc individuals became ill with symptoms of diarrhea, vomiting, dizziness, chi after they ate cheese or milk.[144] Staphylococcus enterotoxin was found in by the patients in both reports.

Most enterotoxins are produced by *S. aureus* coagulase-positive species. initiate an inflammatory response in GI mucosal cells and lead to cell de enterotoxins may have a dramatic effect on the emesis center in the brai organ systems. Discrimination of unique *S. aureus* isolates from foodborn made using restriction fragment length polymorphism analysis by pulsed- electrophoresis and PCR techniques. [164]

Salmonella Species

Salmonella enteritidis infections are of great concern in the United States outbreaks define very special problems. In the 1980s, recurrent outbreak grade A eggs or food containing such eggs occurred. In the past, such ou

enteritis were attributed to infection of the egg with salmonella (from the through cracks in the shell. More recently, outbreaks have involved nonc eggs.[107] In these cases, presumably the salmonella has infected the eggs formed. In either case, people who consume raw or undercooked eggs are salmonella enteritis. Raw eggs can be found as ingredients of chocolate sauce, eggnog, egg creams, caesar salads, and

homemade ice cream. Whole, partially cooked eggs may be eaten as sunn eggs.[28] The second group of outbreaks was associated with raw milk,[123] popular in certain communities. Inadequate microwave cooking may caus These outbreaks are of great concern because they frequently involve m salmonella infections.[41] Drinking pasteurized milk may not be protective. salmonellosis resulting in more than 16,000 culture-proven cases was trac dairy. The probable cause of the outbreak was a transfer line connecting milk containment tanks.[129]

Additional concern has developed over the widespread use of antibiotics i poultry, and manure-fertilized vegetables now frequently contain resistant place virtually the entire population at risk.[41 , 129] Household pets known also places families at risk. Chicks, turtles, and iguanas carry salmonella transmit the organism to household contacts, including infants, who are a invasive diseases.[1]

Campylobacter jejuni

Campylobacter jejuni , a curved Gram-negative rod, is a major cause of organism is most commonly isolated in children younger than 5 years and years. Campylobacter enteritis outbreaks are more common in the summe temperate climates. Although most cases of Campylobacter enteritis are are associated with contaminated food and water. The most frequent sou in food are raw or undercooked poultry products[48] and unpasteurized mil common reservoir, and small outbreaks are associated with contamination pecking on milk-container tops.[146] Contaminated water supplies are also Campylobacter enteritis involving large numbers of individuals.[17] *C. jejur* cooking of food, pasteurization of milk, and chlorination of water prevent

The incubation period for Campylobacter enteritis varies from 1â€“7 days Typical symptoms include diarrhea, abdominal cramps, and fever. Other s headache, vomiting, excessive gas, and malaise. The diarrhea may contai frequently leukocytes are present on microscopic examination.[68] Illness u days (range 1â€–8 days). Rarely, symptoms last for several weeks. Seve include lower GI hemorrhage, abdominal pain mimicking appendicitis, a reactive arthritis, and meningitis. The organism may be detected using P techniques.[57] Treatment is supportive, consisting of volume resuscitation quinolone antibiotics in more severe cases.[30]

Group A Streptococcus

Bacterial infections not usually associated with food or food handling occ transmitted by food or food handling. Streptococcal pharyngitis can be tr prepared by an individual with streptococcal pharyngitis.[42]

Clostridium botulinum

In the last 3 decades, a median of 4 cases of foodborne botulism, 3 case and 71 cases of infant botulism have been reported annually to the CDC.[1 and vegetables, as well as commercial fish products, are among the comm botulism. The incubation period usually is 12â€–36 hours; typical symptor GI symptoms, followed by malaise, fatigue, diplopia, dysphagia, and rapic muscle incoordination.[90] In botulism, the toxin is irreversibly bound to t junction, where it impairs the presynaptic release of acetylcholine.[84] The must be made immediately, and aggressive respiratory therapy must be i is to survive. Additional therapeutic measures include administering antito Antidotes in Depth: Botulinum Antitoxin). The differential diagnosis of b myasthenia gravis, atypical Guillain-BarrÃ© syndrome, tick-induced paral chemical ingestions (see Tables 46-1 and 46-2).

Yersinia enterocolitica

Yersinia enterocolitica is a Gram-negative coccobacillus that causes enter children and young adults. Typical clinical features include fever, abdomir

which usually contains mucus and blood.[7, 150, 162] Other associated syn nausea, vomiting, anorexia, and weight loss. The incubation period may be more. Less common features include prolonged enteritis, arthritis, pharyn involvement, and rash. Yersinia is a common pathogen in many animals, pigs. Sources of human infection include milk products, raw pork product pets, and person-to-person transmission[24, 64, 92] Infections may be dia cultures of food, stool, blood, and, less frequently, skin abscesses, phary cultures from other organ tissues (mesenteric lymph nodes, liver). Yersini with PCR.[74] Therapy usually is supportive; however, patients with invasiv bacteremia, bacterial arthritis) should be treated with IV antibiotics. Fluo third-generation cephalosporins are highly bacteriocidal against *Yersinia*

Listeria monocytogenes

Listeriosis transmitted by food usually occurs in pregnant women, their fe immunocompromised individuals (corticosteroid use, malignancy, diabetes, infection).[13, 29, 34, 136] Typical food sources include unpasteurized milk, feta, and undercooked chicken. Individuals at risk should avoid the usual evaluated for listeriosis if typical symptoms of fever, severe headache, m pharyngitis develop. Treatment with IV ampicillin or trimethoprimâ€“sulfa indicated for systemic listerial infections.

Xenobiotic-Induced Diseases

Careful assessment for possible foodborne pesticide poisoning is essential aldicarb contamination has occurred in hydroponically grown vegetables contaminated with pesticides.[62] Eating malathion-contaminated chapatti a resulted in 60 intoxications and 1 death in one outbreak[39] (Chap. 109).

The possibility of unintentional acute heavy-metal ingestion must be cons poisoning most typically occurs when very acidic fruit punch is served in Antimony, zinc, copper, tin, or cadmium in a container may be

dissolved by an acid food or juice medium. Insecticides, rodenticides, ars preparations can be mistaken for a food ingredient. These poisonings usua

of signs and symptoms after exposure.

Mushroom-Induced Disease

Some species produce major GI effects. *Amanita phalloides* , the most p usually causes GI symptoms as well as hepatotoxic effects with a delay t manifestations. The rapid onset of symptoms suggests some of the gast mushrooms (Chap. 113).

Intestinal Parasitic Infections

The popularity of eating raw fish, usually from Japanese restaurants, has reported intestinal parasitic infections. The etiologic agents typically are (*Eustrongyloides anisakis*) and fish tapeworms (*Diphyllobothrium* spp). S anisakiasis, or eustrongylidiasis, that are localized to the stomach typicall after raw fish is eaten, whereas symptoms of lower intestinal involvement days or weeks. Typical gastric or intestinal symptoms include nausea, vo crampy abdominal pain that may mimic a gastric ulcer. Typical lower int include abdominal cramping and, with perforation of the intestinal wall by localized abdominal pain, rebound, and guarding, which may mimic an ac (appendicitis). In some cases, the symptoms include anaphylaxis with or pain. Without an adequate dietary history (of eating raw fish), the diagno impossible to establish. Therapy would be directed toward the most likely (gastric ulcer or appendicitis). Diagnosis usually is established on visual i (on endoscopy, laparotomy, or pathologic examination), which typically are fish that may contain *Eustrongyloides* include minnows (*Fundulus* spp.) a *Anisakis simplex* and *Pseudoterranova decipiens* are Anisakidae that may types of frequently consumed raw fish, including mackerel, cod, herring, yellowfin tuna, and squid. Reliable methods of preventing ingestion of live freezing â€“4Â°F (â€“20Â°C) for 60 hours or cooking at 140Â°F (60Â°C) 98 , 128 , 134 , 166

Diphyllobothriasis (fish tapeworm disease) is caused by eating uncooked f parasite. Hosts include, but are not limited to, herring, salmon, pike, and symptoms are less acute than with intestinal roundworm ingestions and u

weeks after ingestion.[37] Signs and symptoms include nausea, vomiting, flatulence, abdominal distension, diarrhea, and anemia (megaloblastic). Dia history of ingesting raw fish and on identification of the tapeworm proglo Treatment with niclosamide, praziquantel, or paromomycin usually is effe

Another foodborne toxin with GI symptoms is associated with eating rehe Chinese restaurants. *Bacillus cereus* type I is the causative organism, ar and toxin production causes consequential early onset nausea and vomiti toxin causes liver failure.[100] *Bacillus cereus* type II has a delayed onset symptoms, including diarrhea.[54]

Monosodium Glutamate

The so-called â€œChinese restaurant syndromeâ€• is induced by ingestio glutamate (MSG); L-sodium glutamate. Individuals present with burning, headache, flushing, chest pain, GI symptoms usually limited to nausea ar infrequently, life-threatening bronchospasm[3] and angioedema.[148] Intensity symptoms are dose related, with significant variation in individual respons ingested.[135 , 169] MSG causes â€œshudder attacksâ€• or a seizurelike sy children. Absorption is more rapid following fasting, and the typical burni spread over the back, neck, shoulders, abdomen, and occasionally the thi rarely prominent. Symptoms usually can be prevented by prior ingestion symptoms do occur, they usually last approximately 1 hour. The syndrome patrons of Chinese restaurants. It is a reaction to MSG, which is used fre restaurants. MSG is also marketed as an effective flavor enhancer.[11] Man canned soups contain heavy doses of MSG.

MSG (regarded as â€œsafeâ€• by the FDA) can cause other acute and l symptoms. The pathophysiology has not been clarified, although studies receptors.

Spicy Food

Certain religious or cultural customs, such as eating bitter herbs at a Pas wasabi[147] at a sushi bar, are associated with syncope. The precipitant in horseradish. Despite severe oropharyngeal or abdominal pain, no hemat

or fever is noted with horseradish. Gastric mucosal contact with pepperor (capsaicin) may produce a similar syndrome.[61]

Anaphylaxis and Anaphylactoid Presentatic

Some foods and foodborne toxins may cause allergic or anaphylacticlike are also referred to as â€œrestaurant syndromesâ€•[139] (Table 45-4). T syndromes complicates a patient's future approach to safe eating. Isolatir essential so that the risk can be effectively assessed. Manufacturers of p provide an unambiguous listing of ingredients on package labels. Sensitiv parents) must be rigorously attentive.[131 , 170] Those with severe reaction by the immediate availability of epinephrine and antihistamine. Attempts reactions to dairy products by avoiding dairy-containing foods may fail. N contain flavor enhancers of a dairy origin (eg, partially hydrolyzed sodium cause morbidity and death in allergic individuals.[56] Individuals with know frequently fail to carry prescribed spring-injected epinephrine syringes, b allergen is easily identifiable and avoidable.[77] Food additives to consider anaphylaxis include antibiotics, aspartame, butylated hydroxyanisole (BH hydroxytoluene (BHT), nitrates or nitrites, sulfites, and parabens esters.[9] preservatives is limited, and agents such as sulfites are so ubiquitous tha guacamole, cider, vinegar, fresh or dried fruits, wines, or beers do or do sensitizing agents may be difficult.

Illegal Food Additives

Medications are given to animals to increase their health and growth. Cle agonist, has been administered to cattle raised for human consumption. T cause toxicity in humans who eat contaminated animal meat. Tachycardia

nausea, epigastric pain, headache, muscle pain, and diarrhea were preser patients. Other findings included hypertension and leukocytosis.[125] No de reported, but use of antibiotics, $\hat{I}^2_2$ agonists, and other growth enhancers safety concerns and laws against their use, because these practices incre

Vegetables and Plants

Plants, vegetables, and their diverse presentations often are involved in
, 80 , 85 , 86 Edible plants and plant products may be poorly cooked or pre
contaminated. Extensive discussion is given in Chap. 114 .

Food Poisoning and Bioterrorism

The threat of terrorist assaults has received increased attention and is di
and 127 . Food as a vehicle for intentional contamination with the intent
suffering or death has occurred in the United States.[38 , 82 , 155] In the fi
laboratory workers suffered GI symptoms, primarily severe diarrhea, caus
served in the staff break room, which had been purposefully contaminate
type II.[82] Four workers were hospitalized; none had reported long-term
strain is a rare one to cause endemic disease; the identical strain, as ide
gel electrophoresis, was found in 8 of the symptomatic workers, in the pa
break room, and in the laboratory's stock culture of *S. dysenteriae* . This
purposeful poisoning of food eaten by laboratory personnel. The person r
motive remain unknown.

The second case series describes a large community outbreak of food poi
Salmonella typhimurium .[155] The outbreak occurred in the Dalles, Oregon
1984. A total of 751 people suffered salmonella gastroenteritis. The outbr
intentional contamination of restaurant salad bars and coffee creamer by
religious commune using a culture of *S. typhimurium* purchased before th
poisoning. A criminal investigation found a salmonella culture on the relig
grounds that contained *S. typhimurium* identical to the salmonella strain
poisoning victims, as identified by using antibiotic sensitivity, biochemical
restriction endonuclease digestion of plasmid DNA. More than 1 year of i
needed before this purposeful salmonella outbreak was linked to terrorist
the delay in identifying the outbreak as a purposeful food poisoning inclu
motive; (2) no claim of responsibility; (3) no pattern of unusual behavior
(4) no disgruntled restaurant employees identified; (5) epidemic exposur
multiple time points for contamination, suggesting a sustained source of
a single act; (6) no previous event of similar nature as a reference; (7)
seemed more likely (eg, repeated unintentional contamination by restaura

fear that the publicity necessary to aid the investigation might generate activity.

The delay in publication of the event (almost 10 years) also resulted from activity. The activity of the Japanese cult Aum Shinrikyo and its use of b appears to have provided the motivation to release this publication in the purposeful food poisoning patterns can be identified more quickly in the

The third report describes a disgruntled employee who contaminated 200 l supermarket with a nicotine-containing insecticide.[38] Ninety-two people b sought medical care. Symptoms included vomiting, abdominal pain, rectal case of atrial tachycardia.

The capacity for infecting large numbers of people with foodborne agents obtain and disperse is clearly exemplified by two specific outbreaks: the outbreak in Oregon, and the apparently unintentional salmonella outbreak 16,000 culture-proven cases traced to contamination in 1 Illinois dairy w cause of the outbreak was a transfer line connecting raw and pasteurized tanks.[129] These events emphasize the vulnerability of our food supply and ensuring its safety and security because the potential for purposeful cont widespread morbidity is an ever-present problem.

Summary

The diversity of etiologies for food poisoning involves almost all aspects concerns center around the natural toxicity of a product such as a plant c contamination of which can occur in the field, during factory processing, preparation or storage. These events may be intentional or unintentional, our approaches to general nutrition and society. The current debates abo role in food preparation and protection range from bacteria such as *E. co* Creutzfeldt-Jacob disease (bovine encephalopathy) to genetically altered corn. Future discussions of food poisonings and interpretations of the imp problems may dramatically alter our food sources and their preparation.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 46
Botulism

Lewis R. Goldfrank

Neal E. Flomenbaum

A 27-year-old woman was in excellent health until 3 days before admission, when her family gathered for dinner following her mother-in-law's funeral. Shortly thereafter, the patient began experiencing dysphagia and dysarthria and seemed generally anxious. She saw her family physician, who prescribed diazepam. The day prior to her admission, the patient became dyspneic. She began to communicate by writing when talking became impossible. Writing soon became difficult, and the patient complained of having trouble walking and lifting her head. She would not eat and vomited food when she was force-fed. She then began to look straight ahead without moving her eyes.

The next day she was taken to the nearest hospital, where the physicians in attendance noted the peculiarity of the symptoms, the fact that she was taking diazepam, and the temporal relationship to the funeral of her mother-in-law. The family physician was called from the emergency department and told of

the new symptoms that had developed during the previous 2 days. The physician reassured the emergency staff that this was â€œanxietyâ€•; and the woman was discharged.

Shortly after the patient returned home, she became increasingly dyspneic and cyanotic, and then had a cardiopulmonary arrest. Her husband initiated cardiopulmonary resuscitation (CPR) until the paramedics arrived. The paramedics continued CPR and brought her to the hospital.

Physical examination on admission revealed an apneic, intubated, comatose young woman with blood pressure 90/40 mm Hg; pulse 80 beats/min; ventilated respiratory rate 14 breaths/min; rectal temperature 97.0Â°F (36.1Â°C). Her left pupil was 4 mm in diameter, her right pupil was 3 mm, and both pupils were sluggishly responsive to light.

The heart and lungs were unremarkable. The abdomen was soft, and bowel sounds were diminished. The stools were negative for occult blood. There was no response to painful stimuli or cold-water caloric testing. Her upper extremities were flaccid, with absent reflexes. The patient had increased extensor tone in her legs, 2+ patellar reflexes, ankle clonus, and generalized myoclonic jerks.

Cerebrospinal fluid (CSF) examination was normal as was edrophonium (Tensilon) testing. An electromyogram (EMG) demonstrated increased muscle action potentials with rapid repetitive stimulation and posttetanic potentiation.

Botulism was diagnosed, and the patient was given 2 vials of trivalent botulinum antitoxin. However, her condition steadily deteriorated and she died 3 days after admission. Postmortem examination revealed cerebral edema and herniation. Examination of stomach contents revealed undigested mushrooms, from which *Clostridium botulinum* toxin type B was isolated.

Because of the patient's presentation, the mother-in-law's

hospitalization was reviewed: Twelve days before the daughter-in-law's first symptoms, the mother-in-law experienced nausea, vomiting, abdominal cramps, and distension, and she was treated with an antiemetic. Three days later, she complained of a dry throat, dysphagia, and chest pains. Two days after that, she had dyspnea. When an electrocardiogram (ECG) revealed inverted T waves in the precordial leads and occasional premature ventricular contractions, she was hospitalized to â€œrule out myocardial infarction.â€•

The day after the mother-in-law's admission, she was even more dyspneic and stuporous. She was also noted to have dilated, sluggishly reactive pupils. She was intubated and became more alert. However, upon extubation the next day, she developed respiratory distress and required reintubation. A tracheostomy was performed, but she became febrile and died 2 days later.

Following the daughter-in-law's hospitalization and death, the body of the mother-in-law was exhumed. An autopsy revealed bronchopneumonia, an enlarged heart, and mushroom fragments in the small intestines. The mushroom fragments yielded *C. botulinum* toxin type B.

When the diagnosis of botulism was first considered and before the mushrooms were implicated, all family members who had been at the funeral meal were admitted to the hospital for observation. At that time, a third member of the family reported having difficulty swallowing. This woman was the only other family member who had eaten mushrooms at the funeral meal. She was given 1 vial of trivalent botulinum antitoxin, and her symptoms resolved in 3 days. Her stool specimens later revealed *C. botulinum* toxin type B. Twenty days after she was given the antitoxin, the woman developed severe arthralgias and fever suggestive of serum sickness.

At the time of presentation, many of the other family members were understandably anxious. Some complained of dry throat,

headache, or tingling in their extremities, although none had eaten any of the mushrooms, and none had stools positive for *C. botulinum* toxin type B. Most were discharged from the hospital within 24â€“48 hours.[48]

A carefully obtained history revealed that the mother-in-law canned her own peppers, eggplant, artichokes, and mushrooms without using a pressure cooker. When the remaining canned foods were obtained from the mother-in-law's house and examined, only the mushrooms were found to contain *C. botulinum* toxin type B.

Epidemiology

Botulism has been recognized since the end of the 18th century. This classic foodborne poisoning was directly linked to inadequate preservation of varied forms of sausages that more than 200 years ago led to religious, legal, and culinary edicts to protect health. The term *botulism* is derived from the Latin word â€œbotulusâ€• for sausage, demonstrating the epidemiologic link. All clostridial species are ubiquitous, and bacteria and spores are present in soil, seawater, and air.[97] Botulism outbreaks can occur anywhere in the world[112] and have been reported from such diverse areas as Iran, the former Soviet Union, Japan,[71] France, Belgium, Portugal,[53] Scandinavia, and Canada.[68]

Approximately 1.25 cases of foodborne botulism per 10 million people occur annually in the United States.[56] The etiologies of botulism are 72% infant, 24% foodborne, 3% wound, and 1% adult type.[92] When botulism is diagnosed, multiple cases per occurrence do not necessarily follow. In a series of hundreds of outbreaks involving more than 400 persons in total, approximately 70% involved only 1 person, 20% involved 2 persons, and only 10% involved more than 2 persons (mean 2.7 cases per outbreak).[118] When only sporadic patients were affected, they were more severely ill, with 85% requiring intubation, compared

to only 42% requiring intubation in multiperson outbreaks.[118] It is suggested that diagnosis in the index case may lead to appropriate rapid therapeutic intervention for associated cases. It also is possible that these index cases may have been exposed to the greatest amount of toxin and, therefore, had the shortest incubation period. Conversely, a lack of symptoms in others does not necessarily reassure that an individual was not exposed or ultimately will not develop serious sequelae.

Although only 4% of foodborne botulism is associated with food purchased in restaurants, restaurant-related outbreaks usually affect large numbers of individuals and account for > 40% of all reported cases.[56] Over the last 50 years, commercial food processing has accounted for only 7% of reported cases, with vegetables (peppers, beans, mushrooms, tomatoes, and beets, with or without meat) thought to be the causative agents in approximately 70%, meat in 17%, and fish in 13% of cases related to processed food. Home-processed food accounted for 65.1% of outbreaks, whereas 27.9% of outbreaks were of unknown origin.[25]

Concern has been raised regarding minimally processed foods (eg soft cheeses) that lack sufficient quantities of intrinsic barriers to botulinum toxin production, such as salt and acidifying agents.[80] These foods become high-risk sources of botulism when refrigeration standards are violated. The US Food and Drug Administration (FDA) continuously reviews recommendations for appropriate measures to process such foods.[108 , 109] Common home-canning errors responsible for cases include failure to use a pressure cooker and allowing food to putrefy at room temperature.

Outbreaks of botulism are associated with specialty foods consumed by different ethnic groups: chopped garlic in soy oil by Chinese in Vancouver, British Columbia;[68 , 100] fried lotus rhizome solid mustard in Japan;[71] uneviscerated salted fishâ€"called *kapchunka* â€"eaten by Russian immigrants in New York City;[22 , 106] and the same food-called *faseikh* â€"eaten by Egyptians in

Egypt.[114] Other outbreaks have involved fermented salmon eggs, seal and raw whale *muktuk* (skin and pink blubber layer) consumed by Inuits and Native Americans in Alaska,[27, 113] and heat shrink-wrapped meat roll *(Matambre)* consumed in Argentina.[112]

Over the last 50 years, the botulism case fatality rate was 17% toxin type A, 7.4% toxin type B, 15.5% toxin type E, and 18.6% toxin type unknown.[25] As expected, case fatality data have continuously improved, with a fatality rate of 5.8% reported for all types in the most recent analysis.[25] Approximately 67% of patients with toxin type A require intubation, compared to 52% of patients with toxin type B, and 39% with toxin type E botulism.[118] Although the median incubation period for all patients is 1 day, it ranges from 0â€“7 days for toxin type A, 0â€“5 days for toxin type B, and 0â€“2 days for toxin type E.[118] Physicians may need to respond more rapidly to a potential epidemic of toxin type E, but they should be prepared for greater complication rates associated with toxin type A.[118] The improvement in case fatality rates for all botulism toxin types probably represents increasing awareness of the problem associated with earlier diagnosis, appropriate and early use of antitoxin, and better and more easily accessible life support techniques.

Awareness of evolving trends and unusual presentations or locations of botulism and instituting preventive education are important. Although 90% of toxin type E outbreaks have occurred in Alaska because of home-processed fish or meat from marine animals,[30, 56] 1 incident occurred in New Jersey.[23] In the past decade, 3 cases of botulism involved members of the Native American church after they ingested a ceremonial tea that was made from the buttons of dried, alkaline-ground peyote cactus that were prepared in a water-covered refrigerated jar. The resultant alkaline and anaerobic milieu presumably fostered the growth of toxin from naturally occurring spores.[44]

In recent times, concern about the use of botulinum toxin as a biologic weapon has increased. Interest in the adverse consequences of therapeutic botulinum toxin injections also has developed.[8] In ways unimaginable since the first edition of this chapter was published, the medical and public health issues associated with terrorism and botulinum toxin unfortunately only increase the relevance of this chapter in the 21st century (Chap. 127).

Characteristics of *Clostridium Botulinum, Clostridium Butyricum* , and *Clostridium Baratii*

Clostridium botulinum is actually a group of spore-forming, anaerobic, Gram-positive bacilli. Although often classified as a single species, the genus *Clostridium* consists of at least 4 distinct genetic variants that produce 7 homologous neurotoxic proteins that cause botulism: *C. botulinum* , which produces toxin types A, B, and E; *Clostridium baratii* , which produces toxin type F; *Clostridium butyricum* , which also produces toxin type E, and *Clostridium argentinense* , which produces toxin type G.[45 , 92] Rare instances of both adult and infant botulism are attributed to *C. baratii* and *C. butyricum* .[43 , 64 , 72 , 77] This rarity of toxin type F may be exaggerated because of the only recent additional capacity of most laboratories to determine the presence of *C. baratii* and other clostridial species producing toxin type F.[43] Toxin types A through G, with CÎ± and CÎ², have been identified to date. In the United States, toxin type A is found west of the Mississippi,[58] toxin type B is found east of the Mississippi, particularly in the Allegheny range, and toxin type E is found in the Pacific northwest.[24 , 97] Toxin types A and B typically are found in poorly processed meats and vegetables. Toxin type E is commonly found in raw or fermented marine fish and mammals. Toxin type G has

not been associated with naturally occurring disease. Toxin types C and D cause disease in birds and mammals.

Although botulinum toxins have slightly different mechanisms of action, the ultimate pathophysiology and clinical syndromes are identical. All botulinum spores are dormant and highly resistant to damage. They can withstand boiling at 212Â°F (100Â°C) for hours, although they usually are destroyed by 30 minutes of moist heat at 248Â°F (120Â°C).

Factors that promote germination of spores in food are pH > 4.5, sodium chloride content < 3.5%, or a low nitrite concentration. Most viable organisms produce toxin in an anaerobic milieu with temperatures > 80.6Â°F (27Â°C), although some strains produce toxins even when conditions are not optimal. *C. botulinum* organisms can produce toxin type E at temperatures as low as 41Â°F (5Â°C). To prevent spore germination, acidifying agents such as phosphoric or citric acid are added to canned or bottled foods that have a low acid content, such as green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, olives, and certain nonacidic tomatoes. As opposed to the spores, the toxin itself is heat labile and can be destroyed by heating to 176Â°F (80Â°C) for 30 minutes or to 212Â°F (100Â°C) for 10 minutes. At high altitudes, where the boiling point of water may be as low as 202.5Â°F (94.7Â°C), a minimum of 30 minutes of boiling may be required to destroy the toxin. Under high-altitude conditions, pressure cooking at 13â€“14 lb of pressure often is necessary to achieve appropriate temperatures to destroy the toxin.

Food contaminated with *C. botulinum* toxin types A and B often does not look or smell normal and appears putrefied because of the action of proteolytic enzymes.[42] In contrast, because toxin type E organisms are saccharolytic and not proteolytic, food contaminated with toxin type E may look and taste normal.[9]

Pathophysiology

Botulinum toxin is the most poisonous substance known. The LD_{50} for mice is 3 million molecules injected intraperitoneally. The human oral lethal dose is 1 Âµg/kg.[85] The toxin is a protein consisting of a single polypeptide chain, with a molecular weight (MW) of 900,000 daltons, which includes a 750,000 MW nontoxic protein and a 150,000 MW neurotoxic component. To become fully active, the single-chain polypeptide 150,000 MW neurotoxin must undergo proteolytic cleavage to generate a dichain structure with a heavy chain (MW 100,000) that is linked by a disulfide bond to a light chain (MW 50,000). It appears that the single polypeptide chain toxin and the dichain form both are resistant to gastrointestinal degradation.[59] Because the toxin is often demonstrated only in the stool, determining what percentage of the toxin actually is absorbed is difficult.[33 , 34] The botulinum toxin binds to serotype specific receptors on the mucosal surfaces of gastric and small intestinal epithelial cells, where endocytosis followed by transcytosis permits release of the toxin on the serosal cell surface.[51 , 60] The dichain form of the molecule is responsible for all clinical manifestations.[45 , 96] The dichain form binds rapidly and irreversibly to the neuronal cell membrane and is taken up by endocytosis. The heavy chain is responsible for cell-specific membrane binding to acetylcholine-containing neurons.[74] Once inside the cell, the light chain acts as a zinc-dependent endopeptidase to cleave polypeptides that are essential components of the neurotransmitter release apparatus, thereby inhibiting exocytosis.[85] Different botulinum toxin types share the same mechanism of cell entry, but three groups of botulinum toxin types appear to have distinct mechanisms of preventing acetylcholine release, which may be responsible for their variable toxicity.[94] Different light chains specifically cleave different members of the SNARE family. Toxin types B, D, F, and G act on vesicle-associated membrane protein (VAMP)/synaptobrevin

localized on the synaptic vesicle, toxin types A and E cleave synaptosomal associated protein (SNAP)-25, and toxin type C cleaves both presynaptic plasma membrane proteins syntaxin and SNAP-25 (Figure 46-1).[51] Regardless, cholinergic transmission at all acetylcholine-dependent synapses in the peripheral nervous system is impaired. However, the central nervous system and axonal conduction are not affected. The duration of action of the toxin types may vary, depending on the components of the neurotransmitter release apparatus that are disrupted. The persistence of clinical effect may result from the individual cleavage product, the intraneuronal biological half-life of the toxin, or both. Current evidence indicating intraneuronal toxin metabolism or elimination is inadequate.[96]

Signs and Symptoms

Foodborne Botulism, Adult Type (In Vitro)

Although botulism is the most dreaded of all food poisonings, the initial phase of the disease (which occurs the first day following ingestion) often is so subtle that it goes unnoticed. Further compromising the care of exposed individuals is the fact that botulism often is misdiagnosed on the first visit to a physician.[19] , [119] Conversely, when gastrointestinal symptoms are striking and food poisoning is suspected, the differential diagnosis should include other acute poisonings, such as metals, plants, mushrooms, and the common bacterial, viral, and parasitic agents discussed in Chap. 45 .

Because physicians so infrequently encounter the disease (especially compared to other much more common diseases in the differential diagnosis), initiation of appropriate management often is seriously delayed (Table 46-1). This is particularly true of toxin

type E botulism, which typically initially causes much more prominent gastrointestinal signs than neurologic signs.[9] The differences in the appearance of food and initial clinical symptoms associated with the various serotypes may be related to the presence of proteolytic enzymes in toxin types A and B and saccharolytic enzymes in toxin types E and C botulism. The index case of an epidemic or an isolated case often is misdiagnosed at a stage when the risk of morbidity and mortality still could be substantially diminished.

Early gastrointestinal signs and symptoms of botulism include nausea, vomiting, abdominal distension, and pain. A time lag (from 12 hours to several days, but typically not more than 24 hours) may or may not be observed before one or more of the following signs and symptoms appear: constipation, dry or sore mouth and throat, dysphonia (typically manifested by a nasal quality to the voice), dysarthria, dysphagia (at times predominant and severe); blurred vision with impaired accommodation, diplopia, descending, bilaterally symmetric motor paralysis beginning with abducens (VI) or oculomotor (III) nerve palsy (frequently resulting in strabismus); mydriasis (often fixed); respiratory insufficiency; and urinary retention. Although many of these initial signs and symptoms are anticholinergic in nature, mental status and the remainder of the neurologic examination remain normal.

The Centers for Disease Control and Prevention (CDC) case definition for foodborne botulism is established in a patient with a

neurologic disorder manifested by diplopia, blurred vision, bulbar weakness, and symmetric paralysis in whom

- Botulinum toxin is detected in serum, stool, or implicated food samples or
- *C. botulinum* is isolated from stool, or

- A clinically compatible case is epidemiologically linked to a laboratory-confirmed case of botulism[24]

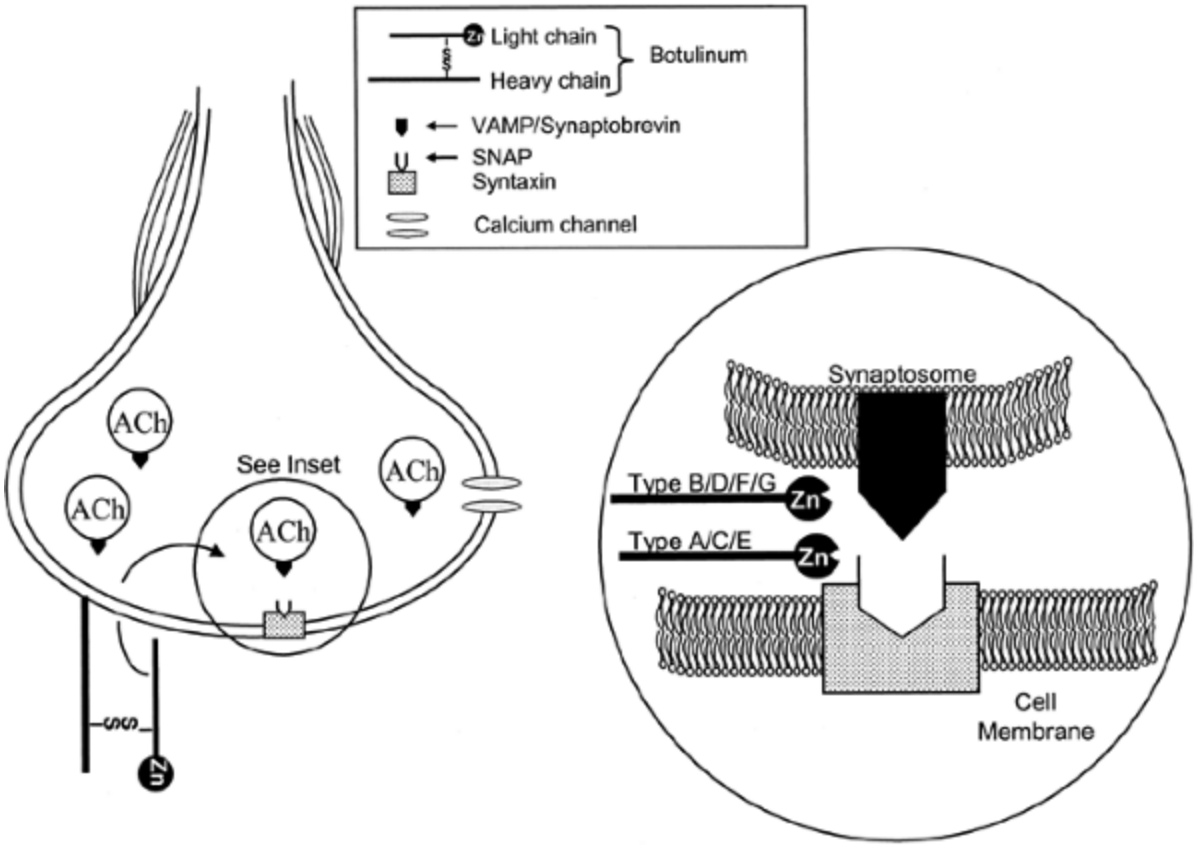

Figure 46-1. Botulinum toxin consists of two peptides linked by disulfide bonds. The heavy chain is responsible for specific binding to acetylcholine (ACh)-containing neurons. Following binding to the cell surface, the entire complex undergoes endocytosis and subsequent translocation of the light chain into the nerve cell cytoplasm. The light chain contains a zinc-requiring endopeptidase that cleaves proteins required by the docking/fusion complex critical to neuroexocytosis. Botulinum toxin type B targets both vesicle-associated membrane protein (VAMP)/synaptobrevin, a docking protein located on the acetylcholine-containing synaptic vesicles (synaptosome). Botulinum toxins types A and E proteolyse synaptosomal associated protein (SNAP), a component of the presynaptic cell-membrane docking complex (associated with

syntaxin). After these important components of the docking complex are destroyed, neurotransmitter release cannot proceed, resulting in clinical findings consistent with acetylcholine deficiency.

When lateral rectus palsy, ptosis, and sluggish pupillary reactivity occur, respiratory insufficiency usually follows. As weakness progresses, deep-tendon reflexes may diminish. The pulse frequently is normal or slow, and temperature in adults typically remains normal. The absence of a tachycardia is surprising in the presence of other typical anticholinergic findings. The normal mental status and temperature in the presence of ophthalmoplegia and generalized muscle weakness (nicotinic findings) that occur with botulism, but not with antimuscarinic poisoning, should lead the clinician to rapidly suspect or diagnose botulism and institute appropriate management for the patients affected by this life-threatening toxin.[107] When suspicion of disease is high and the vital capacity is < 30% of predicted, intubation should be strongly considered.[104] The most difficult and frequently encountered problem in correctly diagnosing botulism is differentiating between botulism and the Miller Fisher variant of the Guillain-BarrÃ© syndrome (Table 46-2).

Infant Botulism (In Vivo Infant Intestinal Colonization)

First described in California[6 , 46 , 50] in 1976, several thousand cases of infant botulism have now been confirmed across the world. Interestingly, 95% of these cases are reported in the United States.[31 , 72] Although infant botulism is reported from approximately half of the states in the United States and all inhabited continents except Africa,[31] 50% of reported cases originate from California, Utah, Pennsylvania, and New Mexico.[117] In California, aggressive surveillance and educational efforts with

infant botulism have been practiced since 1976, which may explain in part the disproportionate distribution of cases.[5]

Aminoglycoside poisoning
Postanesthetic paralysis, intraoperative exposure
Anticholinergic poisoning
Mydriasis, vasodilation, fever, tachycardia, ileus, dry mucosa, altered mental status
Buckthorn (*Karwinskia humboldtiana*)
Rapidly progressive ascending paralytic neuropathy with quadriplegia
Carbon monoxide poisoning
Headache, nausea, altered sensorium, tachypnea, elevated carboxyhemoglobin concentration
Diphtheria (polyneuritis)
Exudative pharyngitis, cranial polyneuropathy (late), cardiac manifestations, hypotension
Eaton-Lambert syndrome
Neoplasm, ophthalmoplegia (rare), no respiratory paralysis, increased strength following sustained contractions, posttetanic facilitation on electromyography, calcium channel-blocking antibodies
Elapidae (coral snake) envenomation
Euphoria, light-headedness, fasciculations, tremor, weakness, salivation, nausea, vomiting followed by bulbar palsy, paralysis including slurred speech, diplopia, ptosis, dysphagia, dyspnea, respiratory compromise
Encephalitis
Fever, mental status abnormalities, seizures, elevated CSF protein, pleocytosis
Food poisoning (other bacterial)
Rapid onset of disease, absence of cranial nerve findings
Guillain-BarrÃ© syndrome (Miller Fisher variant)

Acute inflammatory demyelinating polyneuropathy, areflexia, paresthesias, ataxia, elevated CSF protein without cells, denervation, prolonged nerve conduction velocity on electromyography

Hypermagnesemia

Respiratory compromise, diffuse flushing, weakness, thirst

Inflammatory myelopathies (acute myelitis, transverse myelitis, necrotic myelopathy)

Complete (transverse) or incomplete spinal syndrome: posterior column myelopathy with ascending paresthesias or ascending spinothalamic findings or Brown-Sequard syndrome; typically follows viral illness, back pain, progressive paraparesis, asymmetric ascending paresthesias in legs; CSF: 5â€“50 lymphocytes/mm^3 , elevated creatine kinase concentrations

Multiple sclerosis

Weakness, visual blurring (optic neuritis), sensory disturbances, diplopia, ataxia; lesions separated in space and time; mononuclear cell pleocytosis in CSF; evoked response testing: slow or abnormal conduction in visual, auditory, somatosensory, or motor pathways; abnormal MRI with a paramagnetic dye (gadolinium)

Myasthenia gravis

Aggravation of fatigue with exercise, recurrent paralysis, positive edrophonium test, acetylcholine receptor antibodies

Organic phosphorus compound poisoning

Salivation, lacrimation, urination, defecation, fasciculations, bronchorrhea, delayed neuropathy

Paralytic shellfish poisoning

Incubation < 1 h, dysesthesias, paresthesias, impaired mentation, respiratory paralysis

Poliomyelitis

Fever, GI symptoms, asymmetric neurologic findings

CSF pleocytosis, elevated CSF protein

Polymyositis

Insidious onset, proximal limb weakness, dysphagia, muscle

tenderness, cramping, â†‘ESR, electromyography: fibrillation and sharp waves
Stroke syndrome (midbrain)
Asymmetric focal paralysis, abnormal brain neuroimaging (CT, MRI)
Tetanus
Cranial nerve defects (rare), spasticity, rigidity
Thallium poisoning
Constipation, cranial neuropathy, ascending sensory neuropathy, Mees lines, alopecia
Tick (*Dermacentor* spp): related paralysis
Ataxia, progressive large muscle weakness, ascending paralysis, absence of paresthesias, normal CSF analysis, presence of an embedded tick and resolution upon removal

Botulism	Guillain-BarrÃ© Syndrome	Miller Fisher Variant of Guillain-BarrÃ©

TABLE 46-2. Differentiating Botulism from Guillain-BarrÃ© Syndrome

Infant botulism is the most common form of botulism in the United States, and 99% of these cases are from botulinum neurotoxin type A or B.[72] Affected children are always younger than 1 year (usually 1â€“3 months) and characteristically have normal gestations and births. The first signs of infant botulism are constipation; difficulty with feeding, sucking, and swallowing;

feeble crying; and a â€œfloppyâ€• baby with diffuse, decreased muscle tone. The decreased muscle tone is particularly apparent in the limbs and neck. Ophthalmoplegia, loss of facial grimacing, dysphagia, diminished gag reflex, poor anal sphincter tone, and respiratory failure are present, but fever and enteric symptoms do not occur. The differential diagnosis of infant botulism initially includes dehydration, failure to thrive, hypotonia, sepsis, and a viral syndrome. Conversely, many of the signs and symptoms of infant botulism and many of the syndromes cited in Table 46-1 are relevant to the evaluation of sick children, or children with the rarer neurologic, myopathic, and congenital syndromes that occur in the first year of life.[50] Because the

toxin in infant botulism is absorbed gradually as it is produced, the onset of clinical manifestations of botulism may be less abrupt than in severe cases of foodborne botulism caused by large amounts of preformed toxin absorbed over a brief period of time. A single case of foodborne botulism associated with home-canned baby food was reported in a 6-month-old infant.[4]

Only certain children are susceptible to infant botulism. As opposed to the better-understood foodborne botulism variants, infant botulism may result from ingestion of *C. botulinum* organisms in food or following the inspiration or ingestion of organism-laden aerosolized dust. Some infants may be immunologically unprepared for spore control, a deficiency that allows subsequent germination and toxin development within their gastrointestinal tracts and subsequent gut absorption. Also, an infant's gastrointestinal tract lacks bile acids and gastric acid, which when present may inhibit clostridial growth in older children and adults. Approximately 70% of infant botulism cases occur in breast-fed infants, even though only 45â€“50% of all infants are breast-fed. Bacterial growth associated with breast-feeding may favor *Bifidobacterium* development, whereas formula-fed infants are rapidly colonized by *Coliforme* spp, *Enterococcus* spp, and

Bacteroides spp. All three of the species colonizing formula-fed infants may inhibit *C. botulinum;* conversely, the absence of these typical organisms in breast-fed infants may facilitate *C. botulinum* multiplication.[46]

Epidemiologic studies indicate that ingestion of honey was associated with 34.7% of hospitalized cases of infant botulism worldwide. Moreover, of all nutritional items tested as possible epidemiologic sources, only honey was found to contain *C. botulinum* spores.[6] When *C. botulinum* spores were isolated from honey implicated in cases of infant botulism, the same toxin type was isolated from the infant and, as noted previously, no preformed toxin was isolated. The epidemiologic link to honey is debated, because similar clostridial organisms are found in household dust, yard dirt, and the honey ingested.

Previous studies suggested a correlation between the presence of both *C. botulinum* organisms and toxin and sudden infant death syndrome (SIDS).[98] However, in a prospective study of 248 infants with SIDS, *C. botulinum* was not found on stool culture of any of the children.[20] Cases of infant botulism must be managed in the hospital, preferably in a pediatric intensive care unit for at least the first week, when the risk of respiratory arrest is greatest. In 1 study, approximately 80% of children with botulism required intubation for reduced vital capacity, and 25% of these children had frank respiratory compromise.[87] In a group of 57 affected infants 18 days to 7 months of age managed during the decade ending in the mid-1980s, 77% were intubated and 68% required mechanical ventilation. In the subsequent decade ending in the late 1990s, investigators from the same institution found that 61.7% of 60 infants required endotracheal intubation for a mean of 21 days.[2] Better understanding of disease progression with close observation permitted a decrease in intubations and complications. In this study, the investigators also demonstrated that airway complications such as stridor, granuloma formation, and subglottic stenosis were common, yet tracheotomy was

infrequently performed. Loss of airway protection was the best indicator of patients who required aggressive management.[88] The survival rate in infant botulism is approximately 98%.[88]

Several children with infant botulism sustained unexpected respiratory arrests,[7] often associated with procedures such as lumbar punctures or radiographic examinations. However, it appears that the cardiopulmonary status was often unintentionally compromised during these procedures.[54]

Wound Botulism (In Vivo)

Wound contamination previously was considered an uncommon cause of botulism. The first case of wound botulism was not reported until 1943, and the total number of wound-related cases identified by the CDC to date is approximately 100. The â€œclassicâ€• presentation of wound botulism is that of a patient injured in an automobile crash who sustains a deep muscle laceration, crush injury, or compound fracture treated with open reduction. The wound typically is quite dirty and usually associated with inadequate dÃ©bridement, subsequent purulent drainage, and local tenderness, although the wound may appear unremarkable in other cases. Four to 18 days later, cranial nerve palsies and the other neurologic findings typical of botulism may appear.[65] Other signs of food-related botulism, such as the gastrointestinal manifestations, usually are absent. Most of the recent cases of wound botulism are associated with subcutaneous injection of heroin.

In wound botulism, fever may be prominent and associated with the abscess, sinusitis, or other tissue infection presumed to harbor the clostridial organisms. Although in some cases the patients may require management for wound-related problems, in other cases, the wounds appear clean and uninfected. No particular vehicle, vector, or pathophysiologic etiology for wound botulism has been identified. Recognition of wound botulism as a potential

complication of wound infections is essential for appropriate early and aggressive therapy.

In a small series of parenteral drug-using patients with botulism in New York City, the most prominent symptoms were dysphagia, dysarthria, and dry mouth. In these patients and 3 other clinically comparable patients with botulism, the CDC investigators were not able to find any organism or toxin in serum, stool, or skin lesions.[57]

Cocaine[76, 101] and heroin,[19] particularly subcutaneously injected â€œblack tar heroin,â€• are associated with an increasing number of wound botulism cases.[73, 83, 115] The markedly increased frequency associated with black tar heroin use appears to be related, at least in part, to physical characteristics such as its viscosity, its potential to facilitate anaerobic growth and spore germination, and its ability to devitalize tissue or inhibit wound resolution.[11]

Adult Infectious Botulism (In Vivo Adult Intestinal Colonization)

This fourth class of botulism includes any patient older than 1 year in whom a particular food source cannot be implicated. Until the recent recognition of â€œtherapeutic botulism,â€• adult infectious botulism was the rarest form of botulism, with only 15 cases reported by 1997.[41, 64] Some cases of in vivo adult intestinal colonization may represent a variant form of infant botulism.[67]

There is a well-documented case of an adult female with botulism resulting from the ingestion of a food source contaminated with *C. botulinum* type A organisms and no preformed toxin.[29] In this case, the combination of a long incubation period with toxin present in the serum and stool for 3 weeks after exposure and the absence of disease in the patient's spouse who shared the food suggested in vivo intraluminal elaboration of toxin. This patient

was a very unusual host in that she had a history of peptic ulcer disease treated with truncal vagotomy, antrectomy, and a Billroth I anastomosis. She had received perioperative antibiotics 5 weeks prior to the development of botulism. All of these factors may have compromised the gastric and bile acid barrier, gut flora, and motility, thus allowing spore germination, altered bacterial growth, and

toxin development. Other cases of adult infectious botulism occurred in patients after ileal bypass surgery and Crohn disease,[12] jejunoileal bypass for obesity,[38, 63] gastroduodenostomy,[63] vagotomy and pyloroplasty,[63] and necrotic volvulus.[56] The general risk factors favoring organism persistence and *C. botulinum* colonization include recent antibiotic therapy, achlorhydria (surgically or pharmacologically induced), and previous intestinal surgery.

In a single case report, production of endogenous antibody to botulinum toxin was demonstrated.[41] A 67-year-old man with long-standing Crohn disease who had undergone terminal ileum and right colonic resection presented with abdominal pain. Prior to admission, the patient had experienced several episodes of diplopia. After admission, systemic paralysis developed. The patient had a prolonged recovery after receiving two courses of equine trivalent botulinum antitoxin and 81 days of antibiotic treatment. A mouse assay performed to determine the persistence of any previously administered antitoxin prior to administering additional antitoxin identified a particularly high level of antitoxin specific to toxin type A but not toxin type B. An enzyme-linked immunosorbent assay (ELISA) test performed to distinguish equine from human antitoxin antibodies demonstrated an endogenous human antitoxin response to the toxin. This response points out a distinct characteristic of adult infectious botulism, as other investigators have shown that antitoxin immunity does not develop in patients with foodborne botulism.[85]

Therapeutic and Inadvertent Botulism (In Vitro)

The fifth and most recently recognized form of botulism is purely iatrogenic. Currently doses ranging between 10 and 100 ng botulinum toxin type A (BotoxÂ® or DysportÂ® [available in Europe]) or botulinum toxin type B (MyoblocÂ®) are used therapeutically.[21] The initial therapeutic use of botulinum toxin involved injections into extraocular muscles under electromyographic control as a treatment for blepharospasm or as a supplement to corrective strabismus surgery.[49] Its use is supported by animal investigation[105] and suggested by clinical experience[49] indicating that the neurotoxinâ€"at the smallest effective clinical dosesâ€"would not diffuse from the injection site, avoiding the risk of excessive local or systemic complications. Currently used without intensive monitoring, these agents are used to cause the temporary weakness necessary to treat facial nerve disorders and to eliminate frown lines, achalasia, dysphagia, dystonia, torticollis, axillary hyperhidrosis, migraine headaches, obesity, spasticity, voice and speech disorders (spasmodic dysphonia), and chronic anal fissures.[18,61]

The relative potencies of commercially available botulinum toxins are quite variable[69,81,90] (Table 46-3). The doses of botulinum toxin selected are measured in functional units corresponding to the median lethal doses (LD_{50}) used for female Swiss Webster mice weighing 18â€"20 g. The units of each marketed agent are distinctly different and may confuse the clinician, leading to inadvertent botulinum toxin poisoning.[21] The potential for clinician confusion may be substantial when switching from type A to type B botulinum toxin. For example, 1 U BotoxÂ® equals 50 U MyoblocÂ®, which represents 100 U botulinum toxin A per vial and 5000 U botulinum toxin B per vial, respectively.[17] The approximate estimate of quantities of type A botulinum toxin

causing disease by different routes of administration are given in Table 46-3 .

Doses range widely depending on the size of the muscle to be treated, the degree of weakness required, and the commercial preparation of the toxin.[42] These injections irreversibly block the local neuromuscular junction. The affected muscles then weaken by atrophy over a 3-week period but recover within 2â€“4 months as nerve transmission is restored through sprouting of new nerve endings and functional connections at motor endplates.[1,85] Repetitive doses of botulinum toxin may be indicated to prolong duration of action for several months.[42,49,55]

Intravenous
0.09â€“0.15 Âµg (90â€“150 ng) = 0.001 Âµg/kg
Inhalation
0.70â€“0.90 Âµg (700â€“900 ng) = 0.01 Âµg/kg
Intramuscular
7.0 Âµg (7000 ng) = 0.1 Âµg/kg
Intraperitoneal
7.5 Âµg (7500 ng) [approximate, equals] 0.1 Âµg/kg
Oral
70 Âµg (70,000 ng) = 1 Âµg/kg
1 U BotoxÂ® = lethal intraperitoneal dose in mice
1 U BotoxÂ® = 2.5 ng botulinum toxin type A
100 U BotoxÂ®/vial powder for reconstitution for intramuscular use[68,79]
1 U BotoxÂ® [approximate, equals] 3â€“5 U Dysportâ‰ˆ[107]

Route of Exposure	Dose

TABLE 46-3. Botulinum Toxin Type A (Crystalline)[36,83,88] Very Approximate Human LD_{50}

Although one early marketing assumption was that the neurotoxin

did not diffuse from the injection site,[79] botulinum toxin does diffuse into local tissues and adverse effects typically occur locally.[79] Systemic manifestations are of concern when an inadvertent, excessive, or misdirected dose of toxin is administered. In addition, a number of studies demonstrate that even appropriately injected doses result in neuromuscular junction abnormalities throughout the body, infrequently producing autonomic dysfunction without muscle weakness.[39 , 52 , 70] Several cases of iatrogenic botulism characterized by asthenia, diplopia, and severe generalized muscle weakness with widespread EMG abnormalities have resulted from therapeutic doses of botulinum toxin injected intramuscularly.[10 , 13 , 110]

In a large series of 107 patients treated successfully for spasmodic torticollis, 44% of all treatments resulted in dysphagia. Of this subgroup, several patients developed stridor and/or aspiration and required hospitalization.[3]

Following repeated injections of therapeutic doses of botulinum toxin, patients typically develop neutralizing antibodies that subsequently may limit the toxin's efficacy and lead to increased use of a different toxin type.[16] In Japan and the United Kingdom, a preparation of botulinum toxin type F is also used when antibodies to type A develop.[93] Some studies[14] suggest that animals receiving type F botulinum toxin have a more transient and reversible weakness than that associated with types A and B. Interestingly, however, recurrent episodes of foodborne botulism occurring in one individual suggest that repeated exposure to clinically significant quantities of toxin do not result in long-term immunity.[85]

Diagnosis

Routine laboratory studies, including CSF analysis, are normal in patients with botulism. Specific tests that are uncommonly used but are particularly helpful in diagnosing botulism include the

following.

Tensilon Test

Edrophonium (Tensilon) is a rapidly acting anticholinesterase used to diagnose myasthenia gravis and occasionally used to differentiate myasthenia gravis from botulism. This drug prevents metabolism of

the available acetylcholine, permitting continued reaction with the reduced number of postsynaptic acetylcholine receptors in myasthenia gravis. An IV injection of 10 mg is prepared and then 1â€“2 mg is administered slowly to avoid the nausea and vomiting commonly associated with larger doses. The remainder of the edrophonium is given over the next 5 minutes. The strength of patients who have myasthenia gravis but not botulism dramatically improves within 30â€“60 seconds, and the improvement lasts 3â€“5 minutes. In rare cases, early in the course of botulism, limited improvement in strength occurs that is far less dramatic than that seen in patients with myasthenia gravis.[75] Anticholinesterase drugs, such as edrophonium, have no effect on the toxin's action but may affect patients clinically if some cells can still release acetylcholine. Because acetylcholine release is impaired in botulism, prevention of its metabolism is of limited importance.

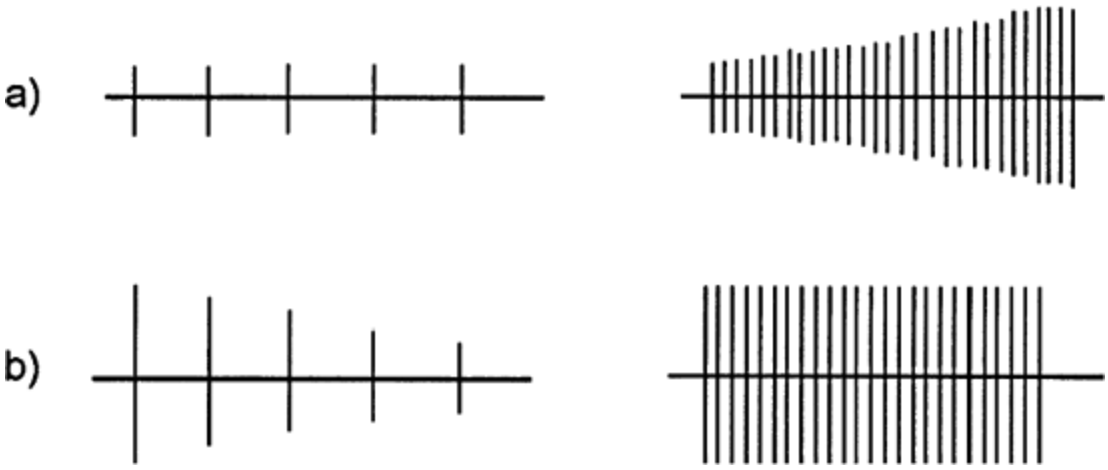

Figure 46-2. Electromyographic findings. Schematic representations of repetitive nerve stimulation at low (5/sec) and high (50/sec) frequencies. In botulism (a), repetitive stimulation produces a small-muscle action potential that facilitates (increases in amplitude) at higher frequencies. This effect results from increased acetylcholine release with high-frequency stimulation because of increased intracellular calcium concentration. In contrast, myasthenia gravis (b) is associated with a normal muscle action potential amplitude and a decremental response at low-frequency stimulation with a normal response at high-frequency stimulation. Myasthenia gravis, a disorder of the muscle endplate, produces this decremental response at low frequencies because the natural reduction in acetylcholine response with subsequent stimulation falls below threshold.[75, 111]

Electromyography

The EMG pattern in all forms of botulism is characterized by brief, small, abundant motor-unit action potentials (BSAPs; or low-amplitude, short-duration potentials) (Figure 46-2). Motor nerve conduction velocity remains normal because axon conduction is not affected. Normal sensory nerve amplitudes and latencies are found. Primary muscle diseases also produce normal conduction velocity and a BSAP pattern, but in botulism, serum concentrations

of muscle enzymes and muscle biopsy are normal. Another typical EMG finding of botulism is an increment in small compound muscle action potential (CMAP) amplitude directly related to acetylcholine release following repetitive stimulation at 20â€“50 Hz. Posttetanic facilitation may be noted in cases of botulism and in other entities such as Eaton-Lambert paraneoplastic syndrome, aminoglycoside-associated paralysis, and hypermagnesemia. Although not pathognomonic, EMG findings interpreted in light of the total clinical presentation can help establish the diagnosis of botulism.[75, 111]

Classification	Foodborne	Infant	Wound	Adult Infectious

TABLE 46-4. Epidemiologic and Laboratory Assessment of Botulism

Laboratory Testing

Samples of serum, stool, vomitus, gastric contents, and suspected foods should be subjected to anaerobic culture (*C. botulinum*) and toxin mouse bioassay (botulinum toxins) (Table 46-4). A medication list for the patient should accompany each sample to exclude any other potential xenobiotics that might be toxic to the mice. The serum samples must be collected prior to initiation of antitoxin therapy. If wound botulism is suspected, serum, stool, exudate, dÃ©brided tissue, and swab samples should be collected. For infant botulism, feces and serum samples also should be obtained. Infants who are constipated may require an enema with nonbacteriostatic, sterile water to facilitate collection. All enema fluid and stool should be sent for analysis. The specimens should be refrigerated (not frozen) and examined and tested as soon as

possible after collection. The earlier the specimens are collected after the onset of illness, the more likely the toxin assay will be positive.[113] Later in the course of illness, stool culture more likely will be positive.

Although polymerase chain reaction studies can determine the presence of *C. botulinum* in food, this test is not yet available to determine the presence of *C. botulinum* in human specimens.[34, 103] Stool, serum, or suspected food samples can be used for a mouse neutralization bioassay. Although botulinum poisoning normally is lethal within 6â€“24 hours, in mice, illness or death may not occur for up to 4 days. The mouse bioassay is the most sensitive diagnostic technique, detecting as little as 0.03 ng of botulinum toxin.[84] The materials are injected into the mouse peritoneum, and

subsequent paralysis and death of the mouse are considered to be a positive test. Control animals receive portions of the specimen materials that have been boiled to destroy the toxin or previously incubated with antitoxin to achieve neutralization. Stool specimens are incubated anaerobically and then subcultured on an egg yolk agar to search for lipase-producing Gram-positive anaerobic rods.[56]

Approximately 60â€“70% of botulism cases reported since 1950 had an identifiable toxin type. Because isolation of *C. baratii* and *C. butyricum* from food and stool requires techniques that deviate from the usual laboratory protocols, it is conceivable that some of the 30â€“40% of unconfirmed and suspect botulism cases result from the more recently appreciated and more rarely sought after species.[43]

Treatment

Supportive Care

Respiratory compromise is the usual cause of death from botulism. To prevent or treat this complication, hospital admission of the patient and of all individuals with suspected exposure to a possible source is mandatory. Careful continuous monitoring of respiratory status using parameters such as vital capacity, peak expiratory flow rate, negative inspiratory force (NIF), pulse oximetry, and the presence or absence of a gag reflex is essential to determine the need for intubation or tracheostomy, as the patient begins to manifest signs of bulbar paralysis.[87] The most reliable, readily obtainable test is the NIF, which can be used in most institutions to determine the need for intubation. A reverse Trendelenburg positioning at 20â€“25Â° with cervical support has been suggested to be beneficial by enhancing diaphragmatic function, but the clinical application to seriously ill patients has not been validated.[8] This approach may reduce the risk of aspiration while decreasing the pressure of abdominal viscera on the diaphragm, with resultant improvement in ventilatory effort.

Gastric Decontamination

An attempt should be made to remove the spores and toxin from the gut. Although most patients present after a substantial time delay, the etiologic agent may still be present hours or even days later. Activated charcoal should be a routine part of supportive care, because it adsorbs *C. botulinum* type A toxin in vitro and probably also the other botulinum toxin types.[40] Gastric lavage or emesis should be initiated only for an asymptomatic person who has very recently ingested a known contaminated food. If a cathartic is chosen, sorbitol is the preferable agent because other agents such as magnesium salts may exacerbate neuromuscular blockade. Theoretically, whole-bowel irrigation may have a role in decontamination, particularly if there is concern about initiating emesis, but interventions other than activated charcoal have not been evaluated under these circumstances.

Wound Care

Thorough wound dÃ©bridement is the most critical aspect in the management of wound botulism and should be performed promptly.[47, 56] Antibiotic therapy alone is inadequate, as evidenced by several case reports of disease despite antibiotic therapy. Aminoglycoside antibiotics[84] and clindamycin[89] should not be used because they may exacerbate neuromuscular blockade.

Botulinum Antitoxin

Botulinum antitoxins types AB (bivalent) and ABE (trivalent) are available. The type-specific antitoxins are ineffective against any other antigen. In humans, the efficacy of the type-specific antitoxin to type B strain toxin is unknown, whereas the type-specific antitoxins to A and E probably are beneficial.[104]

A 45-year-old woman with presumed botulism was administered bivalent (AB) botulinum antitoxin, but her condition deteriorated. Four days later, the culture demonstrated type F botulinum toxin, and the CDC released heptavalent experimental botulinum antitoxin.[77] Minimal improvement in strength may have resulted. Some debate in the literature exists as to whether type E antitoxin has partial neutralizing potential against type F antitoxin. Currently no human experiences validate this hypothesis, which might lead to use of trivalent (ABE) antitoxin if type F botulinum antitoxin were unavailable.[43, 64]

Antitoxin can prevent paralysis but does not affect already paralyzed muscles.[37] This finding is supported by the sustained duration of weeks to months of toxin type A and B in tissue after therapeutic injection in humans and animals. For greatest effectiveness, trivalent antitoxin must be used immediately upon consideration of the disease in both symptomatic and asymptomatic individuals recently exposed to a presumptive food source.[92] Botulinum antitoxin types AB should be used for

presumptive wound botulism.

In a review of 132 cases of type A foodborne botulism, a lower fatality rate and a shorter course of illness were demonstrated for patients who received trivalent antitoxin, even after controlling for age and incubation period.[104] The earlier a patient received antitoxin, the shorter was the clinical course. In addition, no respiratory arrests occurred more than 5 hours after antitoxin was administered. In view of the high mortality rate associated with foodborne botulism and the limited statistical data, the antitoxin should be given IV to all exposed patients. Two studies on the use of antitoxin in the presence of wound botulism demonstrate that the longer the delay to antitoxin administration, the more prolonged the requirement for ventilatory support and the poorer the outcome.[28]

Although specific foods tend to correlate relatively well with botulinum type, trivalent antitoxin (7500 U type A, 5500 U type B, and 8500 U type E) should be used. An entire 10-mL vial of trivalent antitoxin should be given IV as a 1:10 vol/vol dilution in 0.9% sodium chloride over several minutes. If epidemiologic investigation identifies the organism, subsequent type-specific antitoxin therapy can be instituted if the product is available. Because antitoxin is an equine globulin preparation, hypersensitivity testing for horse serum has sometimes been recommended. However, this testing is of no value because the predictive value is limited and antitoxin therapy is essential. Epinephrine should always be readily available to treat anaphylaxis. The overall rate of adverse reactions, including hypersensitivity and serum sickness,[15] is 9â€“17%, with an incidence of anaphylaxis as high as 1.9%[9 , 66] (Antidotes in Depth: Botulinum Antitoxin).

Guanidine, 4-Aminopyridine, and 3,4-Diaminopyridine

Guanidine is no longer recommended for treatment of botulism, because its merits were not substantiated[35] (see previous editions of

this text for a more extensive discussion). Several studies[82] and case reports[32] have proposed that 4-aminopyridine and 3,4-diaminopyridine are effective in improving neuromuscular transmission by enhancing acetylcholine release from the motor nerve terminal.[82] In a rat botulinum toxin type A model, 3,4-diaminopyridine restored neuromuscular function and enhanced animal survival.[95] The therapeutic efforts for those with Eaton-Lambert syndrome and the successful animal results all suggest that further investigative efforts are necessary. It is suggested that 4-aminopyridine's potential for inducing seizures at therapeutic doses limits its clinical usefulness. The fact that 3,4-diaminopyridine does not substantially cross the bloodâ€“brain barrier, resulting in limited CNS manifestations, makes this agent appropriate for further investigation.

Penicillin

Penicillin G is one of many drugs with excellent in vitro efficacy against *C. botulinum* and is useful for wound management.[102] However, penicillin has no role in the management of botulism caused by preformed toxin, nor has it been shown to prevent gut spores from germinating. For these reasons, penicillin is not considered useful in infant and adult infectious botulism, and it is not by itself considered adequate for wound botulism.

Treatment and Prevention of Infant Botulism

Whether botulinum antitoxin or antibiotics have a role in infant botulism is unclear. Cases of children surviving without either

antitoxin or parenteral antibiotics are documented. Currently, antitoxin is not recommended because circulating toxin is believed to be present at very low concentrations, and antitoxin has no effect on toxin-producing organisms in the gut.[50, 53, 86] Therefore, antitoxin is not expected to halt syndrome progression. Moreover, in fully recovered children, both toxin and spores can be found in the stools for months despite use of oral or parenteral antibiotics and/or antitoxin administration. Human-derived botulism immune globulin (BIG) is an investigational new drug available for IV treatment only as part of an FDA-approved â€œopen label administrationâ€• study by the California Department of Health Services[5, 26, 36, 66] (Antidotes in Depth: Botulinum Antitoxin).

Measures used to prevent infant botulism include limiting exposure to spores by thoroughly washing foods and objects that might be placed in a child's mouth. In addition, honey should not be given to infants younger than 6 months.

Prognosis

The prolonged and variable period of recovery that occurs after exposure to botulinum toxin is directly related to the extent of neuromuscular blockade and neurogenic atrophy and the regeneration rates of nerve endings and presynaptic membrane.[62] If the patient has excellent respiratory support during the acute phase and receives adequate parenteral nutrition, residual neurologic disability may not occur. Although the initial course may be protracted, near total functional recovery can follow within several months to 1 year. Common long-term sequelae include dysgeusia (Chap. 21), dry mouth, constipation, dyspepsia, arthralgia, exertional dyspnea, tachycardia, and easy fatigability.

The long-term status of 13 patients who survived a toxin type B botulinum outbreak was characterized 2 years later by persistent dyspnea and fatigue, although surprisingly, pulmonary function

tests had returned to normal in all patients.[115] Inspiratory muscle weakness persisted in 4 of 13 patients. Maximal oxygen consumption and maximal workload during exercise were diminished in all patients, and all had more rapid shallow breathing and a higher dyspnea score than controls. The reasons for premature exercise termination may be multifactorial. Although persistent respiratory muscle weakness may be an explanation, most dyspnea and fatigue appeared to be related to reduced cardiovascular fitness, leg fatigue, and diminished nutrition.[116] Nevertheless, because long-term prognosis can be so good, early recognition of the disease and supportive care are essential.

Pregnancy

At least 3 cases of botulism occurring during pregnancy have been reported. One case occurred during the second trimester,[78] and 2 cases occurred during the third trimester.[99] Although botulinum toxin or *C. botulinum* was isolated in the mother in 2 of the botulinum cases prior to administration of antitoxin therapy, no detectable toxin was isolated from the neonates in either of the third-trimester cases. The large MW of the neurotoxin (150,000 daltons) makes passive diffusion through the placenta unlikely,[45] and, although theoretically possible, no active transport system has been identified.[99] None of the three neonates had neurologic evidence of botulism. Appropriate care of the mother and preparation for maternal complications of delivery appear to assure the best potential outcome for a normal infant.

Epidemiologic and Therapeutic Assistance

Whenever botulism is suspected or proven, the local health department should be contacted. The health department should report to the CDC Emergency Operations Center at 770-488-7100.

The center, which is available 24 hours per day, 7 days per week, pages the Foodborne and Diarrheal Diseases Branch Medical officer. The CDC can provide or facilitate diagnostic, consultative, and laboratory testing services, access to bivalent or trivalent botulinum antitoxin, and assistance in epidemiologic investigations. All foods that possibly are responsible for the illness should be preserved for epidemiologic investigation. The merits of this surveillance and antitoxin release system were demonstrated in Argentina,[112] where the CDC assisted in establishing comparable principles that are nation specific, including local stocking of antitoxin and establishing mechanisms for distribution, emergency identification, response, and laboratory confirmation for suspect cases. Expansion of this system to other nations will enhance worldwide botulism surveillance for foodborne botulism and for potential terrorist dissemination of botulinum toxin.[91]

Summary

Botulism remains one of the rarest poisonings while its etiologies have become increasingly diverse. The incidences of wound botulism and the adult infectious form of botulism have increased dramatically. Previously unrecognized complications of therapeutic botulinum toxin now permit a better understanding of the effects of the toxin and an appreciation of its risks. The international experience with botulism epidemics has allowed the CDC to enhance epidemiologic surveillance and to prepare for the possible use of botulinum toxin as a biologic weapon. Further treatment strategies are being developed to include an $F(ab€²)_2$ despeciated heptavalent immune globulin, a human BIG, a recombinant vaccine, and other creative advances (Antidotes in Depth: Botulinum Antitoxin).

Antidotes in Depth

Botulinum Antitoxin

Lewis R. Goldfrank

Equine Immunoglobulins

The production of antitoxin is complex, requiring almost 2 years to immunize healthy horses against botulinum toxin. The resultant immunoglobulin product, which is then defibrinated, digested, dialyzed, and purified as a 20% protein antitoxin,[5] can be lyophilized and preserved.[24] Bivalent (serotypes A and B) and trivalent (serotypes A, B, and E) botulinum antitoxin are the equine immunoglobulin preparations available in the United States. The bivalent (AB) preparation is used for patients with presumed wound botulism. The trivalent product is reserved for patients with foodborne botulism.

Botulinum antitoxin is distributed from the 9 regional centers of the Centers for Disease Control and Prevention (CDC) on a named patient basis, after a probable diagnosis of botulism is established. Each 10-mL vial of the currently available trivalent botulinum antitoxin contains 7500 IU (2381 US units) of type A botulinum antitoxin, 5500 IU (1839 US units) of type B antitoxin, and 8500

IU (8500 US units) of type E antitoxin.[9] The proportion and quantity of types A, B, and E antitoxin are assumed to be adequate to neutralize the quantities of circulating toxins in a typical case of botulism.[5,9]

Evidence substantiating the efficacy of types A and E antitoxin is available,[14,28] but the efficacy of type B antitoxin has not been established in clinical trials.

Currently only limited data are available on the relationship of dose and route of administration, the amount of circulating antitoxin found in treated patients, the toxin-neutralizing capacity of this material, and the half-life of the antitoxin. Peak serum concentrations of antitoxin are 10â€“1000 times higher than the concentrations of antitoxin calculated to be necessary to achieve toxin neutralization.[10] Ninety percent of the activity of the equine antitoxin administered was detected when all the circulating toxin was neutralized.[16] The half-life for antitoxin persistence in a single patient was calculated at 6.5, 7.6, and 5.3 days for antitoxin types A, B, and E, respectively.[10] The prolonged half-life of the antitoxin, and the exceedingly small quantities of toxin measured, explain the limited decrease in antitoxin titers following toxinâ€“antitoxin binding.

In the presence of disease, 1 vial of the antitoxin is administered slowly IV, over several minutes, as a 1:10 vol/vol dilution in 0.9% sodium chloride solution. Subsequent doses can be given IV every 2â€“4 hours, depending on the progression of clinical findings.[5,9]

Like many other heterologous proteins, administration of this horse serum-derived preparation results in substantial adverse effects.[15] Each patient treated during the initial decade during which antitoxin was available (1967â€“1977) was studied to determine both hypersensitivity reaction rates and the efficacy of the antitoxin in treating botulism. The overall rate of adverse reactions, including hypersensitivity and serum sickness, was 9â€“17%, with an incidence of anaphylaxis as high as 1.9%.[2,18]

However, the doses of antitoxin used in that era were substantially larger than those currently used. Because of the lethality of botulinum toxin, the risk of adverse drug reaction for the antitoxin is considered acceptable for anyone with presumed illness and for anyone potentially exposed to the toxin. Pregnancy is not a contraindication to antitoxin administration, and antitoxin has been used successfully in these circumstances.[23,28]

Anaphylaxis should be anticipated, and the clinician should be prepared to treat this complication immediately with epinephrine. The smaller quantities of botulinum antitoxin used for botulism present a far smaller risk for serum sickness[2] than do the larger amounts of antivenom used to treat snake envenomation. The risk of serum sickness from the refined serum proteins in botulinum antitoxin is approximately 4â€“10%.[3,9]

Patients who received antitoxin within the first 24 hours after exposure had a shorter clinical course of botulism without regression of symptoms, but a comparable mortality rate to those who received antitoxin later.[29] Reduced mortality can only be demonstrated in animal models.[20] Morbidity and mortality studies are difficult to perform for a disorder that is so rare and often recognized at a delayed stage, when the toxin already is tightly bound to the neuromuscular junction. Also, most of the reported case series involve patients who received varying degrees of supportive care, further making evaluation or comparison unreliable.

Investigations: Despeciated Immune Globulins

$F(ab'â€²)_2$ â€œdespeciatedâ€• heptavalent (against toxin types A, B, C_1, D, E, F, and G) botulism immune globulin (dBIG) is currently under investigation and available from the CDC.[22] This equine immune globulin[7] is extensively purified to eliminate

fibrinogen, plasminogen, and other proteins. Pepsin is used to remove the Fc fragment of the immunoglobulin in order to reduce the potential for allergic manifestations, should reexposure to equine protein occur.[12] The single-dose vials available contain > 4000 IU of serotypes A, B, C, E, and F and > 500 IU for serotypes D and G.[22] When given prior to exposure, this $F(ab€^2)_2$ immunoglobulin protected mice from inhaled toxin at doses 10 times that of the LD_{50} and was still fully protective when given after exposure but prior to the onset of clinical signs.[13]

Although 10 of 45 patients given dBIG in the Egyptian type E botulism outbreak manifested adverse reactions, 9 were considered mild and 1 episode was classified as serum sickness.[12] In this botulism epidemic, the incidence of adverse effects of dBIG was comparable to those of numerous other internationally available botulinal antitoxins. Although followup of individuals was limited, the agent appeared to be as safe as other commercially available antitoxins. Further investigations with regard to safety and efficacy are necessary.

Human Immunoglobulins

Human-derived preparations of type E antitoxin were developed as 5000 IU per 2-mL vials for intramuscular use. This human-derived

type E botulinum antitoxin was dosed between 1000 and 5000 IU based on the estimated quantity of toxin ingested for 100 Egyptians who presumably had ingested botulinum toxin-contaminated, uneviscerated, salted, mullet fish.[8,32] The safety of the human-derived preparation allowed for repetitive dosing in any individual, if clinical findings developed.[7] This regimen was based on the premise that effective treatment could be achieved by delivering small antitoxin doses prior to tissue binding of circulating toxin.

Human-derived botulism immune globulin (BIG) was developed for

use in the treatment of infant botulism. This pentavalent (types A, B, C, D, and E) immune globulin is harvested by plasmapheresis from human donors who received multiple immunizations with pentavalent botulinum toxoid.[21,30] A longer biologic half-life, with a prolonged effective level, should be possible with BIG.[14] Both of these effects are substantial clinical advantages, particularly for the infant form of botulism, where toxin is slowly and continuously produced in the intestine and absorbed. Use of a human immune globulin obviously avoids the risk of hypersensitivity that is associated with foreign equine proteins. Results of the orphan-drug infant botulism prevention clinical trial of the human BIG suggest many advantages over the current equine antitoxin therapy.[1,6] BIG became available for clinical trials in California in 1991.[6]

Human BIG was used successfully in a 3-year-old child who developed altered gut microbial flora and botulism following bone marrow transplantation.[25] This case is a relatively rare example of infant type (in vivo intestinal colonization) botulism, in a 3-year-old child.

Other Investigatory Modalities

A pentavalent toxoid vaccine (types A, B, C, D, and E) was developed at the US Army Medical Research Institute of Infectious Diseases (USAMRID) at Fort Detrick, Maryland, and has been studied for more than 40 years.[4,16] Its use remains investigational and is suggested only for laboratory personnel who work with *Clostridium botulinum* or for those who might be first responders in the case of terrorism.[26] An additional monovalent toxoid type F vaccine was manufactured for the US Army and has been tested by USAMRID.[11,17]

Recombinant vaccines,[4,27] recombinant monoclonal antibodies, recombinant oligoclonal antibodies,[19] and drugs that act as metalloproteinase inhibitors (thereby preventing toxin uptake) are

all currently under investigation by the Department of Defense.[7]

Summary

Consultation with a regional poison center and local health department and ultimately between the health department and the CDC at 770-488-7100, 24 hours per day, 7 days per week (or other comparable agencies in other parts of the world) provide improved access to rapid diagnostic tests for botulism and effective therapeutic modalities. Earlier disease recognition and the currently organized public health approach appear to be responsible for decreasing morbidity and increasing survival after typical foodborne botulism.[24,31] Results of current research on infant botulism will demonstrate whether sufficient circulating toxin is present in that variant to be amenable to antitoxin treatment. Antitoxin may be useful if, as suggested, a low level of absorbed toxin is present in these disorders.[16] After these issues are clarified, providing adequate treatment for the infant form of botulism, which has become the most prevalent form of botulism, may be possible.

Therapeutic serum concentrations

Drug	*mg* /L	Âµmol/L

A 45-year-old man with a history of alcoholism, posttraumatic stress disc was brought to the emergency department (ED) after ingesting unknown gabapentin. He was suffering from depression, and he had ingested all of hours prior to presentation.

Upon arrival to the ED, the patient was unresponsive. His vital signs were pulse 110 beats/min; respiratory rate 12 breaths/min; temperature 98.6Â all extremities to deep pain. His head was atraumatic with 3-mm pupils t Gag reflex was absent. Examination of his lungs, heart, and abdomen wer track marks, cyanosis, or edema. Deep-tendon reflexes were symmetrical extension was present.

The patient was endotracheally intubated and connected to a ventilator. A concentration was 70 mg/dL, and 50 mL of 50% dextrose was administer mental status. The electrocardiogram (ECG) revealed sinus tachycardia wi nasogastric tube was inserted, and 75 g activated charcoal was instilled.

Serum ethanol and acetaminophen concentrations were negative. Initial s was 236 mg/L, serum ammonia concentration 45 Âµmol/L (normal 9â€“3 concentration 19 mg/L.

The patient was admitted to the intensive care unit (ICU). Four hours lat concentration was 810 mg/L and serum ammonia 82 Âµmol/L. Multiple do administered. Hemoperfusion was considered but was not instituted. The was 933 mg/L and serum ammonia 141 Âµmol/L. An intravenous (IV) load started, followed by a maintenance dose of 1 g every 4 hours IV for 24 l unchanged. Approximately 18 hours postingestion, the valproic acid conce The 28-hour valproic acid concentration was 481 mg/L, serum ammonia 3 concentration

2.7 mg/L. The patient's mental status improved, but he developed a fever He remained intubated and mechanically ventilated. Two days later, his p 30,000/mm^3 from the admission value of 156,000/mm^3 . There were no expanding hematoma developed at an arterial puncture site. He responde His liver enzymes remained normal throughout his hospital stay. The pat his complete blood cell count normalized 3 days later. He was discharged with psychiatric support.

History and Epidemiology

The prevalence of seizures in the United States is 3%. Historically, seizure methods, including barbiturates, bromides, ketogenic diets, fluid restriction or irritable cortical foci. The first truly effective therapy was introduced in bromides was noted to sedate patients and significantly reduce their seiz to treat seizures in 1912. Consequently, sedation was erroneously believed seizure therapy.

The search for nonsedating anticonvulsive agents led to the introduction o the anticonvulsants introduced subsequently, such as primidone, had chem phenobarbital. After 1965, benzodiazepines, carbamazepine, and valproic gained wide use as anticonvulsants. These anticonvulsants were the only when the US Food and Drug Administration approved numerous new anti gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiram zonisamide.

Anticonvulsants are also currently used for treatment of mood disorders, trigeminal neuralgia, bruxism, migraine headaches, drug withdrawal synd

In a review of more than 5000 patient suicides, anticonvulsants were imp suggesting a fairly high rate of suicidal ideation among people with acces last decade, as reported in the American Association of Poison Control Ce Surveillance System (TESS) data, a shift occurred from predominantly ca exposures to VPA and newer anticonvulsants. VPA is involved in 44% of anticonvulsants (Chap. 130).[160]

This chapter reviews the toxicity and management of overdoses with ant

benzodiazepines and barbiturates are discussed in Chap. 72 .

Pharmacology

A *seizure* is defined as the clinical manifestation of excessive neuronal ac system (CNS). It is accompanied by various degrees of motor, sensory, result from 1 of 4 cellular mechanisms: sustained repeated firing of the conductance, increased excitatory neurotransmission (eg, glutamic acid), c inhibitory neurotransmitters (eg, Î³-aminobutyric acid [GABA]).

Correspondingly, the mechanisms of action of anticonvulsants fall into 1 c channel inhibition, calcium channel inhibition, inhibition of excitatory amir Frequently, more than 1 mechanism accounts for a drug's anticonvulsive

During seizures, a high-frequency pattern of neuronal firing is detected. T normal physiologic neuronal activity. Voltage-gated sodium channels are neuronal firing that occurs in epilepsy. Under the influence of anticonvuls channels remain partially open, but their functionality is hindered by pers gate. The sodium channels cannot recover from inactivation and are preve frequencies. Phenytoin, carbamazepine, VPA, lamotrigine, topiramate, ox felbamate all attach themselves to the batrachotoxin binding site (or adja and prolong the channel's recovery from inactivation[91 , 99 , 159 , 162] At channel blockade is selective. At toxic concentrations, selectivity is lost a spontaneous sodium channels are inhibited. For several of these medicati occurs.

Voltage-gated calcium channels are multisubunit complexes that are broa high-voltage groups. The low-voltage group encompasses the T-type calc and ethosuximide inhibit flow of calcium through these channels, thus red the *pacemaker current* .[50 , 115 , 125] The high-voltage group consists of th Calcium entry into presynaptic nerve terminals is regulated by these cha inhibits the N-type calcium channels.[90 , 125]

The *N* -methyl-D-aspartate (NMDA) receptor is the glutamate receptor of respect to development of seizures. When stimulated by glutamate, the N gated ion channel that permits entry of Na^+ and Ca^{2+} into the neuronal c glutamateâ€“NMDA interaction is protective against seizures.[99] Felbamate

glutamate antagonists at the NMDA receptors.[59] More specifically, felbama insensitive glycine recognition site on the NMDA receptor[98] (Chap. 14). phenytoin inhibit glutamate release by binding to presynaptic Na^+ channe as opposed to the NMDA glutamate receptor subtype, and blocks Na^+ ent

GABA acts through fast chloride-permeable ionotropic $GABA_A$ receptors a coupled $GABA_B$ receptors.[3] Pharmacologic enhancement of GABA receptor effective approach to epilepsy. Anticonvulsants may interact with the GAB kinetics of GABA itself. Vigabatrin irreversibly inhibits GABA transaminase responsible for GABA metabolism.[52] VPA may have similar effects.[99] Tiaga transporter GAT-1 and thereby prevents reuptake of GABA into presynap [120] Despite its design as a GABA agonist, gabapentin does not mimic GAB poorly understood. Gabapentin may increase GABA release from vesicles [56] or inhibit the L-type high-voltage calcium channel.[62] Figure 47-1 sum

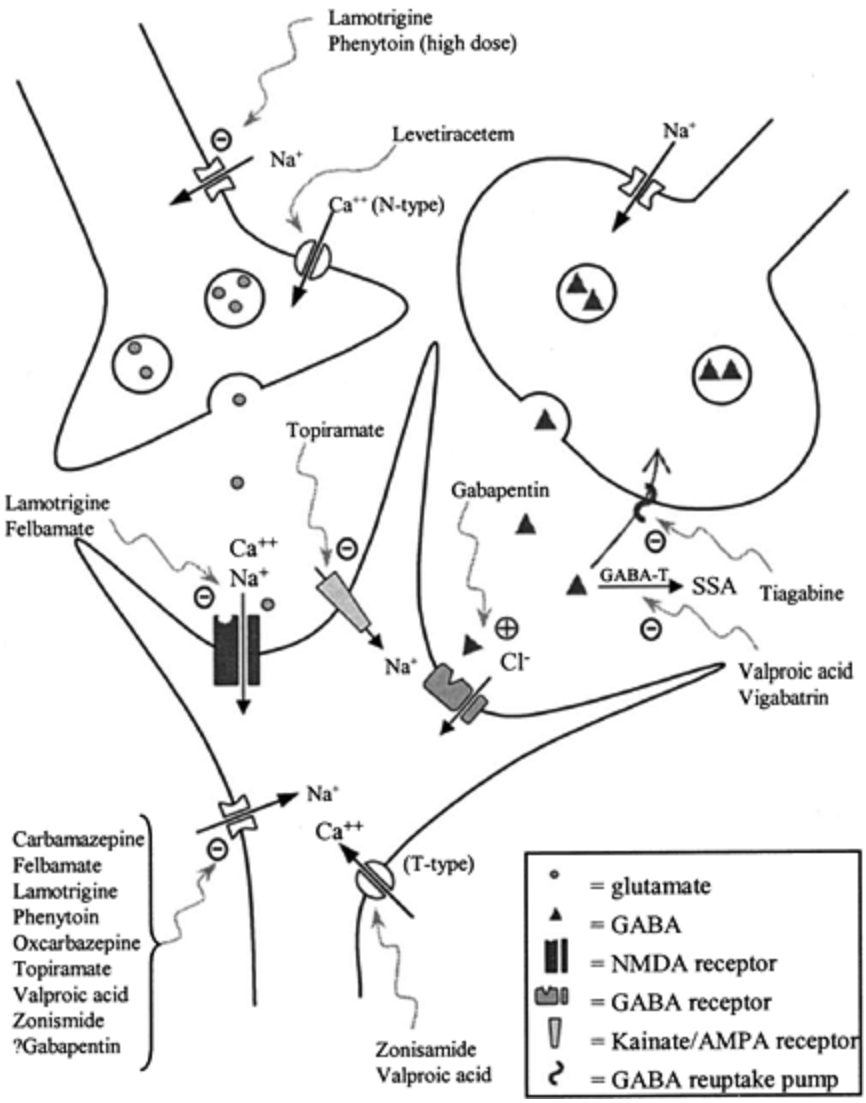

Figure 47-1. Mechanism of action of anticonvulsants. SSA = succinic aci transaminase.

Phenytoin/Fosphenytoin

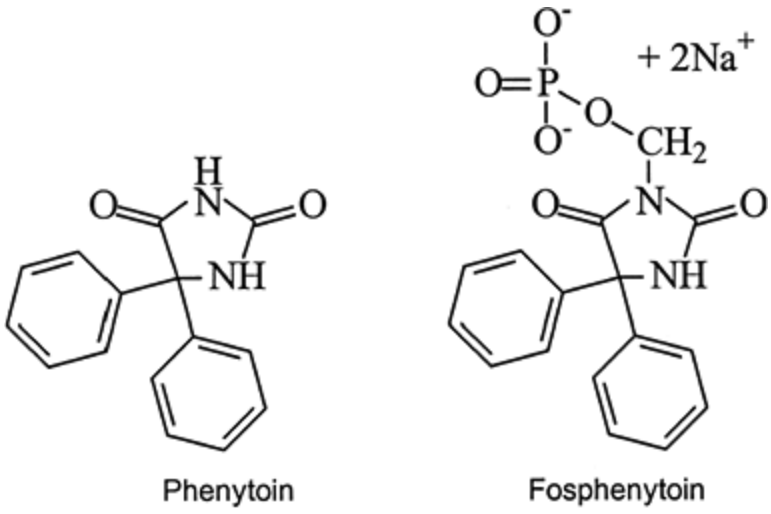

Figure. No Caption Available.

Phenytoin, introduced in 1938, is still a first-line anticonvulsant for treatr except absence seizures.[95] It has no role in the treatment of toxin-relate withdrawal syndrome.[22] It is nonsedating in therapeutic doses and theref GABAergic anticonvulsants for long-term management of epilepsy.

Fosphenytoin, a water-soluble phenytoin derivative introduced in 1997, wa apparent shortcomings of parenteral phenytoin, such as its poor water so intramuscular injection. Its clinical utility derives from the rapid achiever concentrations, its potential for intramuscular administration, and its lower cardiotoxicity.[13 , 99]

Pharmacokinetics and Toxicokinetics

Phenytoin is a weak acid (pK_a 8.3) that is highly protein bound and is ra Single-dose oral therapeutic loading using 18 mg/kg phenytoin capsules is incomplete in 36% of patients at 8 hours.[112] In very large oral overdose be delayed even more, up to several days.[21 , 30] Some authors suggest p absorption in the colon because of its lipophilic properties.[148] Phenytoin d the gastrointestinal tract.[21]

Phenytoin is extensively bound to serum proteins, mainly albumin. Only t biologic membranes and exert pharmacologic action. A significant fraction

neonates, uremic patients, and other patients with hypoalbuminemia.[55] L
phenytoin is excreted unchanged in the urine. The remainder is metabolize
phenytoin metabolite, a parahydroxylphenyl derivative, is inactive but is b
hypersensitivity reaction associated with phenytoin administration.[78] The
saturable enzyme kinetics explains the relationship between phenytoin do
steady state. At phenytoin concentrations below 10 mg/L, elimination usu
half-life ranges between 6 and 24 hours. At higher concentrations, zero-c
dependent elimination) occurs as a result of saturation of the hydroxylati
elimination half-life increases to 20â€“60 hours.[99 , 24] Therefore, the app
phenytoin is progressively prolonged as plasma concentration increases[99]

Fosphenytoin (1.5 mg fosphenytoin = 1 mg phenytoin) is a water-soluble
phenytoin. It is available in a water-based parenteral formulation that cor
a pH of 8â€“9. Fosphenytoin is converted entirely to phenytoin by circula
minutes of IV injection. Peak phenytoin concentrations are reached 30 m
injection. The loading dose, expressed in phenytoin equivalents (PE), is th
47-1).

Clinical Manifestations

Acute phenytoin toxicity produces predominantly neurologic dysfunction th
and vestibular systems. Phenytoin concentrations greater than 15 mg/L u
nystagmus, concentrations greater than 30 mg/L are associated with ata
50 mg/L are associated with lethargy, slurred speech, and pyramidal an
[101] CNS concentrations correlate best with free serum phenytoin concent
seizures on extremely rare occasions, usually in the setting of acute over
seizures.[149] Young children and the elderly may present with atypical ma
example, phenytoin-induced chorea and opisthotonic posturing are reporte
children.[101]

Cardiotoxicity resulting from oral overdoses of phenytoin has not been re
phenytoin impairs myocardial contractility, decreases peripheral vascular

myocardial conduction. In a large case series, IV phenytoin was associated
hemodynamic complications.[40] Deaths following IV administration of phen
[164] These complications correlate with rate of administration and total dos

ascribed to the diluents used in the IV preparation of phenytoin, that is, ethanol (10%).[103] Propylene glycol in particular depresses myocardial tis vascular resistance (Chap. 53). However, fosphenytoin, which does not c diluent, also impairs cardiac conduction and contractility. Two reports of 5â€“10 times in excess of the required dose, administered to young infa in bradycardia, hypotension, and asystole.[83 , 127] Still, the water solubilit therapeutic IV administration, and fosphenytoin can be infused at a maxim is 3 times that of phenytoin.[13]

	Time to Peak Plasma Concentrationa(h)	Therapeutic Serum Concentrations (mg/L)	Vd (L/kg)	Plasma protein binding (%)	Urina elimina unchan (%)

TABLE 47-1. Pharmacokinetics of Anticonvulsants[a]

Intravenous phenytoin is commonly associated with local irritation. Extrava necrosis, possibly necessitating surgical intervention.[26 , 40 , 75] These cor from the propylene glycol diluent and pH. The risk of fosphenytoin-induce its water solubility.

Chronically elevated phenytoin concentrations may result in gingival hyp behavioral changes, and encephalopathy. Hyperactivity, confusion, lethar the behavioral changes. Chronic use of phenytoin is associated rarely wi produce hepatotoxicity, which may or may not be part of the anticonvul (AHS, discussed below under Anticonvulsant Hypersensitivity Syndrome).

Diagnostic Testing

Serum phenytoin concentrations should be performed in all cases of pher unpredictable absorption, phenytoin concentrations should be repeated a concentrations are 10â€“20 mg/L. Because of the switch to zero-order e concentrations may take days or weeks before they return to the therape

Patients with impaired or decreased protein-binding capacity can develop concentrations within the therapeutic range. Patients at greatest risk incl hypoalbuminemic, hyperbilirubinemic, and uremic patients, and patients with VPA, salicylates, and sulfonamides because these agents displace ph sites. In such patients, determination of the free phenytoin fraction is he reliably with the CSF concentrations than does the total phenytoin conce fraction can be measured directly by a number of analytical methods, in followed by gas chromatography or enzyme-multiplied immunoassay tech free phenytoin concentrations are 1.0â€“ 2.1 mg/L.

Equation 47-1 approximates the total phenytoin concentration that would measured serum phenytoin concentration and measured albumin concen

$$[\text{Phenytoin}] = \frac{[\text{Measured phenytoin}]}{(0.25 \times [\text{Measured albumin}]) + 0.1.}$$

(Eq. 4

Management

The treatment of patients with acute or chronic phenytoin overdoses ren related deaths are rare, even after massive overdoses. Because the use (MDAC) reduces the elimination half-life of intravenously administered phe it is recommended in patients in whom serial serum concentrations are i elevated.[96] Aggressive lowering of the serum phenytoin concentration may patient, and MDAC should be used cautiously in these patients. Given the hemodialysis and hemoperfusion are of little benefit in the management toxicity.[71 , 81]

Severe ataxia mandates careful evaluation of patients because of concern determinations are necessary because of the unpredictable absorption an Patients admitted to the hospital after oral phenytoin

overdoses do not require routine cardiac monitoring because they do not cardiovascular complications.[42 , 163]

Phenytoin-induced agranulocytosis can be treated successfully with admi stimulating factor.[152]

Hypotension, cardiac dysrhythmias, and dyskinesias during IV administrati transient and usually resolve spontaneously in 30â€“60 minutes unless c phenytoin infusion for a few minutes and administering a bolus of 250â€“ solution generally is sufficient for treatment of hypotension in an adult. R initial rate is recommended.[140] Prolonged periods of cardiopulmonary resu cases of fosphenytoin- or parenteral phenytoin-induced dysrhythmias, in other tissues thereby permitting time for the cardiotoxicity to resolve.[83 ,

The management of extravasation is discussed in Chap. 6 .

Carbamazepine/Oxcarbazepine

Oxcarbazepine is rapidly converted to the pharmacologically active 10 metabolite before conjugation and renal elimination. It is a less potent in

Clinical Manifestations

Acute carbamazepine toxicity is manifest by neurologic signs and sympto cardiovascular effects. The initial neurologic disturbances include nystagm patients with a large overdose, fluctuations in level of consciousness is c [63, 135, 137, 161] Carbamazepine toxicity may cause seizures both in nor with underlying epilepsy. The mechanism underlying carbamazepine-induc understood.[63, 115] In some cases, an increase in seizure frequency, una symptoms, is the only presenting symptom of carbamazepine toxicity. St acute carbamazepine toxicity.[139, 143, 154] In 1 case series, 55% of adu concentrations > 40 mg/L developed seizures.[63] Children may experience concentrations.[142]

Cardiovascular effects include sinus tachycardia, which occurs in 35% of o anticholinergic mechanism, hypotension with myocardial depression, and abnormalities.[49 , 63 , 84] High concentrations of carbamazepine may cause of the action potential in cardiac tissue.[147] In a large case series of carb incidence of QRS complex prolongation (> 100 msec), 50% incidence of (msec), and no cases of terminal 40-msec axis deviation of the QRS comp These abnormalities can be delayed for as long as 20 hours and may occ [70 , 151]

The toxicity of carbamazepine in children differs slightly from that in adu incidence of dystonic reactions, choreoathetosis, and seizures and have a electrocardiographic abnormalities.[12 , 142 , 150]

Chronic carbamazepine overdose can result in headaches, diplopia, or at are common.[130] Vasopressin secretion can be stimulated at high carbam hyponatremia (syndrome of inappropriate antidiuretic hormone)[47] (Chap.

Diagnostic Testing

A serum carbamazepine concentration should be obtained in all cases of exposure. Because of erratic absorption, the concentrations should be rep closely monitored until a downward trend is observed. Therapeutic conce Patients receiving multiple anticonvulsants may not tolerate high concent should be maintained at 4â€“8 mg/L. Concentrations > 40 mg/L tend to respiratory depression, and cardiotoxicity.[63] Carbamazepine may cross-rea tricyclic antidepressants (Chap. 7).[46]

Increases Concentrations of	Decreases Concentrations of	Toxicity Enhanced by

TABLE 47-3. Anticonvulsant Drug interactions

The contribution of active metabolites to the toxicity of carbamazepine m receiving multiple anticonvulsants, especially combination therapy with VP clinical toxicity with carbamazepine concentrations within the therapeutic concentrations of the circulating carbamazepine-10,11-epoxide metabolite attributed to the additive inhibitory effects of VPA and lamotrigine on the Carbamazepine-10,11-epoxide concentrations in the 1â€“10 mg/L range carbamazepine/carbamazepine-epoxide ratio usually is > 1.7 and is appro monotherapy.[117]

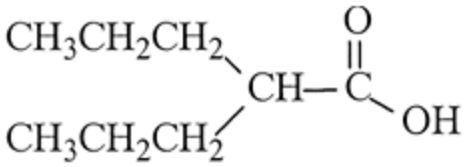
Oxcarbazepine is detected on the carbamazepine assay and concentrations

Management

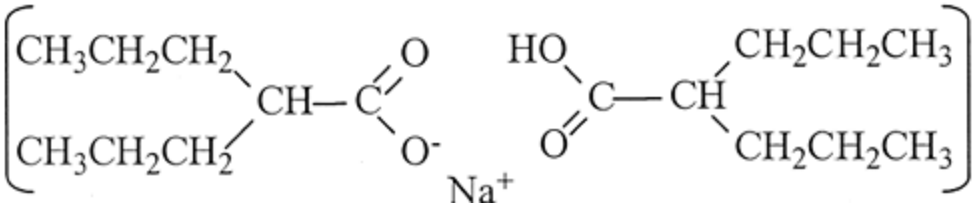
MDAC has a therapeutic role in the management of patients with carbama particularly helpful by reducing enterohepatic circulation.[109,154] Concreti suspected when serum concentrations rise or symptom occurrence is dela occurrence of QRS or QTc abnormalities is recommended. Although not f bicarbonate should be administered if the QRS duration exceeds 100 ms seizures usually respond to benzodiazepines.

Because carbamazepine is poorly water soluble, hemodialysis is relatively be associated with a 20% reduction in serum carbamazepine concentratio improvement.[49] Success with use of high-efficiency hemodialysis and ver reported.[7,136] It must be emphasized that MDAC remains as effective a less invasive, and is associated with comparable outcomes.[154]

Valproic Acid



Valproic acid



Divalproex Sodium

Valproic acid (di-*n* -propylacetic acid [VPA]), a simple branched-chain car of a broad spectrum of seizure disorders, ranging from simple and compl partial and myoclonic seizures. It is widely used as a mood stabilizer in t psychiatric illnesses, especially bipolar affective disorders for which it is a prophylaxis. VPA inhibits voltage-gated sodium channels and inhibits GAE

Pharmacokinetics, Toxicokinetics, and Pa

VPA is available in soft gelatin capsules, in syrup form, as enteric-coated in sprinkle capsules that can be added to food. An IV form is available. I tolerated.

VPA is almost 100% absorbed from the gastrointestinal tract. Peak concer hours, except for enteric-coated and probably extended release preparatio for up to 24 hours.[14 , 58] VPA is 90% protein bound at therapeutic conce decreases as the VPA concentration increases (Table 47-1).

VPA metabolism is complex. It is extensively metabolized (95%) by hepa using uridine diphosphate glucuronosyltransferase enzymes and Î²-oxidatio glucuronic acid and then oxidized in 1 of 2 ways: mitochondrial Î²-oxida

Nine different metabolites are isolated. The 3 Î²-oxidation metabolites are metabolites are quantitatively less important.[38] Mitochondrial Î²-oxidation VPA involves activation and linkage to coenzyme A (CoA) followed by tra in the mitochondrial matrix[87] (Figure 47-2 and Table 47-4).

VPA decreases carnitine stores through a number of different mechanisms excretion via formation of valproylcarnitine, which is renally excreted. S ATP-dependent carnitine transporter located on the plasma membrane. Th mitochondrial CoA. Mitochondrial CoA trapping (or depletion) decreases AT negatively affects the carnitine transporter.[121] Because of the reductions fatty acids arriving to the liver for metabolism

via Î²-oxidation cannot be transported effectively into the mitochondria ar cytoplasm. This process accounts for the development of fatty liver assoc

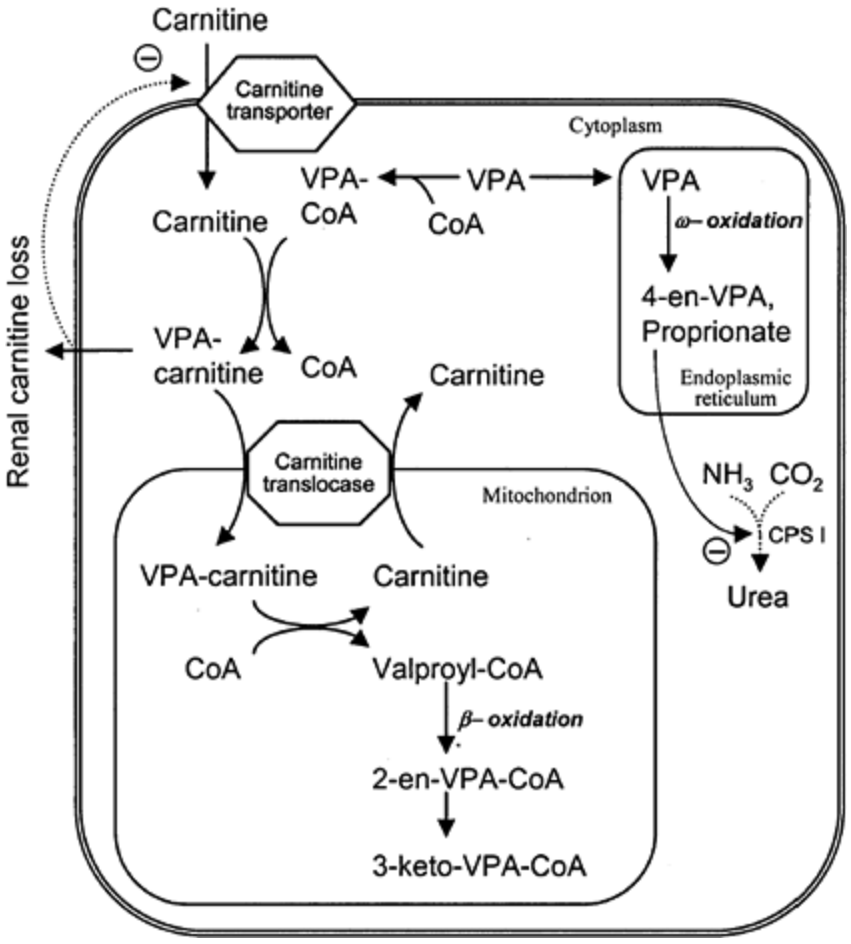


Figure 47-2. Valproic acid metabolism by the hepatocyte. Valproic acid, to coenzyme A (CoA) by acyltransferase I and subsequently transferred = carnitine) is shuttled into the mitochondrion where, after transfer back undergoes Î²-oxidation yielding several metabolites. These metabolites se the Î²-oxidation of other fatty acids. This process may lead to a Reyelike Alternatively, valproylcarnitine may diffuse from the cell and be renally el uptake of carnitine. In either case, the cellular depletion of carnitine shi microsomal Ï‰-oxidation. This pathway forms 4-en-valproate, a putative severe hepatotoxicity associated with valproic acid. Ï‰-Oxidation product carbamoylphosphate synthase I (CPS I), the initial step in the urea cycle

Predictable Idiosyncratic

TABLE 47-4. Adverse Events Associated with Anticonvulsants

Mitochondrial CoA is essential to the formation of *N*-acetylglutamate, an
synthetase I (CPS I). CPS I is the primary enzyme responsible for incorpo
cycle. In the absence of adequate mitochondrial CoA stores, CPS I activity
accumulates. Evidence indicates that CPS I is directly inhibited by VPA. I
effect of carnitine depletion and/or CPS I inhibition is suppression of hep
accumulation of ammonia.

Clinical Manifestations

Overdoses of VPA result in symptoms varying from lethargy to coma asso
Nystagmus, ataxia, and tremor typically do not occur. The neurotoxicity o

of acute overdose in patients chronically taking VPA.[67]

Metabolic complications following acute VPA overdoses include hypernatr acidosis, hypocarnitinemia, and hyperammonemia.[3 , 4 , 74] Metabolic acid overdoses and is a poor prognostic sign.[43 , 105] It results from accumulat carboxylic, and proprionic acids.[3 , 27 , 58 , 104 , 105 , 127]

Bone marrow suppression occurs 3â€“5 days following acute massive over by pancytopenia.[3 , 27 , 127] These hematopoietic disturbances usually reso days.

Pancreatitis, hepatotoxicity, and renal insufficiency are rare manifestations Chronic VPA therapy may lead to hepatotoxicity secondary to the aforem fatty acid metabolism rather than, as with other anticonvulsants, a hype findings may vary from asymptomatic elevation of aminotransferase conc Microvesicular steatosis, in which the hepatocyte cytoplasm contains large appearance on liver biopsy.[15 , 36]

Valproate-induced hyperammonemic encephalopathy (VHE) is characterized confusion or lethargy, focal or bilateral neurologic signs, and increased se accompanied by elevated VPA concentrations. The etiology is uncertain, b concentrations coupled with elevated concentrations of some of the more be responsible.[156]

Diagnostic Testing

Serum VPA concentrations should be obtained in all cases of VPA exposur obtained every 4â€“6 hours and closely monitored until a downward tren concentrations are 50â€“100 mg/L, although some clinicians use higher

All 9 VPA metabolites can be measured in the urine. The 4-en-VPA conce indicating excessive Ï‰-oxidation. The Î²-oxidation metabolite 2-en-VPA r inhibition of Î²-oxidation and/or carnitine depletion. Concentrations of th 1â€“3 days following acute ingestion, signaling the return to normal Î²-o

Electrolytes, blood gases, and serum lactate and serum ammonia concent patients. Hyperammonemia (> 80 Âµg/dL or > 35 Âµmol/L) occurs in 16 chronic VPA therapy.[29 , 111 , 156]

An inverse correlation exists between serum carnitine concentrations and patients receiving chronic VPA therapy.[111] Free serum carnitine concentra acylcarnitine/free carnitine ratio > 0.4 are indicative of carnitine deficien measurement of drug-induced hypocarnitinemia.

Management

Supportive management is sufficient to ensure complete recovery in most Discontinuation of all medications that likely affect VPA metabolism is als

MDAC reduces the half-life of VPA from a mean of 12 hours to 4.8 hours whom serum concentrations are continuously rising.[43] Although VPA is ex theoretically not amenable to MDAC, the percentage of bound VPA decrea 29%) as the concentration increases.[43]

In vitro studies suggest that naloxone has GABA antagonistic properties, endogenous opioid system, and may inhibit the effects of VPA on GABA r describe rapid resolution of CNS symptoms in VPA-overdosed patients fo naloxone.[2 , 142] These patients had minimally elevated VPA concentrations however, showed no effect in patients with much higher VPA concentratio experience does not support the routine use of naloxone for reversing VP not recommended.

Carnitine should be administered if evidence indicates the presence of hy hepatotoxicity.[32] The loading dose is 100 mg/kg IV over 30 minutes (max IV over 10â€“30 minutes every 4 hours until clinical improvement occurs

Hemodialysis and hemoperfusion increase VPA clearance but should be res rapid deterioration, evidence of hepatic dysfunction, apparent continued a VPA concentrations > 1000 mg/L.[58 , 104]

Gabapentin

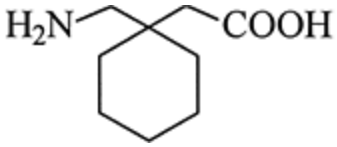

Figure. No Caption Available.

Gabapentin is a cyclohexane derivative of GABA approved as adjunctive t partial seizures with and without secondarily generalized seizures in adult postherpetic neuralgia. It is currently used as a treatment for posttraum disorders, mood disorders, bruxism, migraine prophylaxis, neuropathic pair neurologic disturbances.

Pharmacokinetics and Toxicokinetics

The bioavailability of gabapentin is approximately 60% in the therapeutic and easily crosses the bloodâ€“brain barrier. Dosage adjustments are nec renal function (creatinine clearance < 60 mL/min). It is not metabolized b function oxidase system[99] (Table 47-1).

Clinical Manifestations

Sedation, ataxia, movement disorders,[17 , 122] slurred speech, and gastro following acute gabapentin overdose.[45 , 76] In a case series of 20 patien lethargy, ataxia, and gastrointestinal symptoms developed in less than 5 hours.[76]

In 1 case report of chronic overdose in a patient with renal failure, trem were noted. The serum concentration was 85 mg/dL. Symptoms were sel dose adjustment.[155]

Catatonia following abrupt withdrawal of gabapentin is described.[129]

Diagnostic Testing

The preferred method for gabapentin analysis is high-pressure liquid chr concentration for seizure control is generally 2â€“15 mg/L, although the evolving. Because gabapentin is not appreciably protein bound, this rang

gabapentin.

Management

The treatment of patients with gabapentin overdose is largely supportive. to limit absorption. No specific antidote exists, but in 1 case report, an e dose of flumazenil, a benzodiazepine receptor antagonist devoid of GABA case report, flumazenil is not recommended for the management of gaba persistent neurologic symptoms must be admitted to the hospital. Hemod generally required, except in severely symptomatic patients with significa supportive care is sufficient in most instances.

Lamotrigine

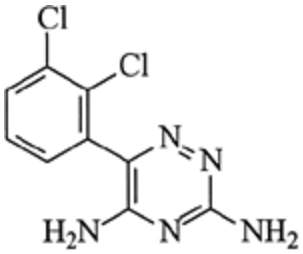

Figure. No Caption Available.

Lamotrigine is approved as an adjunctive medication for treatment of par patients. It also is approved for maintenance treatment of bipolar mood

Pharmacokinetics and Toxicokinetics

The bioavailability of lamotrigine is 98%. It is metabolized predominantly 2-*N* -glucuronide. The elimination half-life is approximately 25 hours but c phenytoin and carbamazepine, which can induce glucuronidation, and can because of competition with lamotrigine for the same step in the glucur reduced clearance of lamotrigine occurs in patients with Gilbert syndrome glucuronidation). Lamotrigine does not affect the cytochrome P450 system except when it is administered concomitantly with carbamazepine, when i of the carbamazepine epoxide metabolite.[53]

Clinical Manifestations

Neurologic manifestations such as lethargy, ataxia, nystagmus, and gast described following lamotrigine overdose. Coma, seizures, and cardiac co occur.[11,16,88,110] The 2-*N*-methyl metabolite of lamotrigine causes C

Chronic overdoses of lamotrigine result in multiorgan involvement, includ elevated hepatic aminotransferase and serum creatinine phosphokinase c findings represent AHS etiologically is unclear. All abnormalities resolved

Diagnostic Testing

Lamotrigine concentrations can be measured by high-performance liquid greater than 18 mg/L are potentially toxic.

Management

Activated charcoal should be administered. Supportive care and ECG mor Lamotrigine-induced seizures should be treated with benzodiazepines.[18] M hemodialysis and hemoperfusion are available.

Topiramate

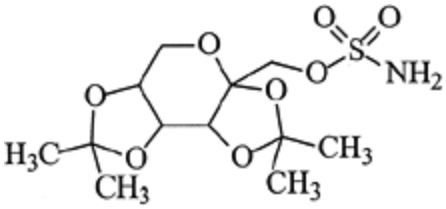

Figure. No Caption Available.

Topiramate is a sulfamate-substituted monosaccharide approved as adjunc partial-onset seizures. It also is approved for migraine prophylaxis, infant seizure disorders in infants and children. Although the precise mechanism blocks sodium channels, enhances the action of GABA, and diminishes the

receptor stimulation.[118] Topiramate's sulfamate moiety weakly inhibits ca the CA-II and CA-IV isoforms present in the kidney and CNS.[35 , 138]

Pharmacokinetics and Toxicokinetics

Topiramate is readily bioavailable. Only 20% of the dose is hepatically r hydrolysis, and glucuronidation; the remaining 80% of the drug is elimina plasma elimination half-life is long[68] (Table 47-1).

Clinical Manifestations

Lethargy, ataxia, nystagmus, myoclonus, coma, seizures, and status epil topiramate overdose.[25 , 44 , 141] Echolalia and repetitive mouthing are r metabolic acidosis resulting from inhibition of renal cortical CA may be pr serum chloride, as well as hypokalemia (2.0â€“3.2 mEq/L). Metabolic acid ingestion and can persist for days.[25 , 44 , 94 , 116 , 153]

Diagnostic Testing

Topiramate concentrations are performed by liquid or gas chromatograph between 4 and 30 mg/L. A death with a postmortem concentration of 170 chemistry and/or arterial blood gas analysis should evaluate for hyperch metabolic acidosis.

Management

Activated charcoal and supportive care are recommended. Severe hyperc be treated with sodium bicarbonate 1â€“2 mEq/kg intravenously. Howeve sodium bicarbonate may impair the anticonvulsive effect of topiramate.[25] topiramate can be significantly affected by hemodialysis, resulting in 4- t rates.[48] Hemodialysis is generally recommended in patients who overdose associated neurologic impairment, electrolyte abnormalities that have not therapy, or renal insufficiency.

Tiagabine

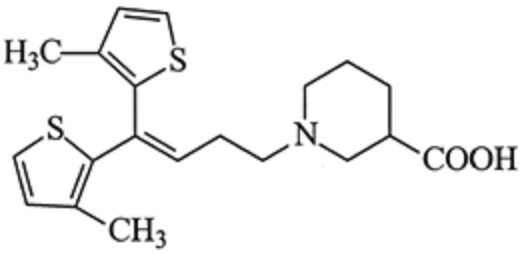

Figure. No Caption Available.

Tiagabine inhibits the presynaptic reuptake of GABA and is approved as a and secondarily generalized seizures. It is also being prescribed for a va

Pharmacokinetics and Toxicokinetics

Tiagabine is quickly and completely absorbed within 2â€“3 hours of inges easily crosses the bloodâ€“brain barrier.[69] It is metabolized by the CYP3 The elimination half-life is reduced by 50% in patients taking enzyme-in has no effect on the CYP450 system.[82 , 89]

Clinical Manifestations

Lethargy, facial myoclonus (grimacing), nystagmus, and posturing are des on tiagabine. Seizures and status epilepticus are reported at very high s previously healthy toddler developed 3 seizures after an unintentional ov tiagabine concentrations were 530 ng/mL.[72] A patient presented in status be noncompliant with therapy until a tiagabine concentration of 1870 ng/r overdose determined.[113] Stimulation of the presynatpic $GABA_B$ receptors the underlying mechanism for tiagabine-induced seizures.[124]

Symptoms generally persist for 12â€“24 hours, and permanent neurologic [, 72 , 113]

Diagnostic Testing

Tiagabine concentrations are performed by high-performance liquid chr Therapeutic tiagabine concentrations are 5â€“70 ng/mL.

Management

Activated charcoal and supportive care are recommended. Seizures respor benzodiazepines. Refractory status epilepticus should be treated with barbi hemodialysis and hemoperfusion are available.[20 , 72 , 113]

Levetiracetam

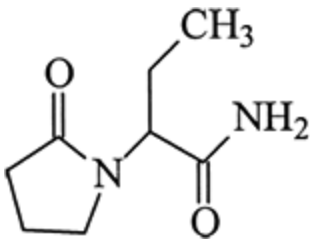

Figure. No Caption Available.

Levetiracetam is approved as an â€œadd-onâ€• medication for the mana mechanism of action remains incompletely understood, although it inhibit Research has illustrated both a neuroprotective and an antiinflammatory

Pharmacokinetics and Toxicokinetics

The bioavailability of levetiracetam approaches 100%. The major metabo hydrolysis. There are no active metabolites. Dosage adjustments are nec renal function (creatinine clearance < 60 mL/min).[119]

Clinical Manifestations

In 1 reported case of levetiracetam overdose, lethargy, coma, and respir Nystagmus was absent. Symptoms persisted for 24 hours.[9]

Diagnostic Testing

Levetiracetam concentrations can be assessed using gas chromatography 3â€“70 Âµg/mL.[119]

Management

Activated charcoal should be administered. Supportive care is recommende hemodialysis and hemoperfusion are available.

Other Anticonvulsants

Vigabatrin

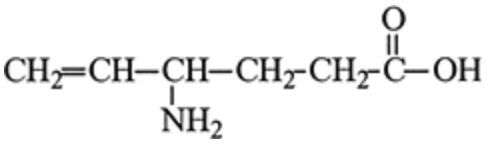

Figure. No Caption Available.

Vigabatrin, or vinyl GABA, is a stereospecific irreversible inhibitor of GA vigabatrin has a short elimination half-life, its duration of action is 24 hc necessary in patients with impaired renal function.[52] Agitation, coma, and after acute ingestion.[31 , 85]

Chronic toxicity may result in psychosis, dizziness and tremor, which usua as depression and psychosis.[85] Treatment of vigabatrin toxicity is largely best treated with IV benzodiazepines. Some cases of mild vigabatrin-indu withdrawal of the medication.[85]

Felbamate

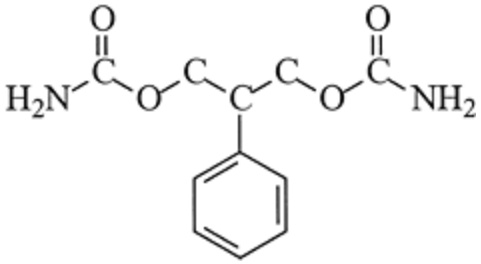

Figure. No Caption Available.

Felbamate is a phenyl dicarbamate derivative structurally similar to mepr adverse effects, including hepatic failure and aplastic anemia, it is a thera of seizures. It is absorbed quickly, and 50% of an ingested dose is excre Mild lethargy and gastrointestinal symptoms are reported following acute reversible renal failure following an acute overdose are reported.[123] Treat largely supportive.

Zonisamide

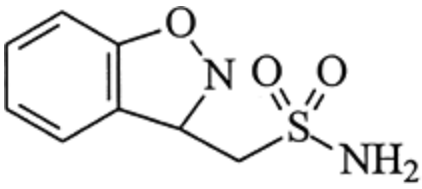

Figure. No Caption Available.

Zonisamide is structurally similar to other current anticonvulsants. It inh T-type calcium channels, and possibly CA. Somnolence is a commonly re experience with zonisamide is limited. In one case report, status epileptic attributed to zonisamide overdose despite a minimally elevated concentra 10â€“40 mg/L).[145]

Anticonvulsant Hypersensitivity Syndrome

Ill defined since it was first described in 1950, AHS is a disorder that occ 1000â€“10,000 exposures to anticonvulsants. AHS is traditionally associat anticonvulsants such as phenytoin, carbamazepine, phenobarbital, and pr the inclusion of the nonaromatic lamotrigine as a causative agent. The in regardless of gender and ethnic origin. Data suggest

a genetic defect in drug metabolism. First-degree relatives of patients with developing this syndrome.[78 , 157]

AHS occurs most frequently within the first 2 months of therapy and is nc concentration. The pathophysiology of AHS is related to accumulation res

detoxification by the enzyme epoxide hydrolase of arene oxide metabolite These reactive arene oxides bind to macromolecules and cause cellular ap form neoantigens that may trigger an immunologic response. Interestingly to cause other serious dermatologic reactions, such as Stevens-Johnson s necrolysis. The pathophysiology of lamotrigine-induced hypersensitivity sy unknown; only a small proportion undergoes CYP450 metabolism.[132 , 134

AHS is defined by a triad of fever, rash, and internal organ involvement. malaise, and pharyngitis (including tonsillitis). A skin eruption characteriz into a pruritic and confluent papular rash primarily involving the face, tru tender lymphadenopathy usually follows. Severely affected cases develop rash usually spares the mucous membranes. Multiorgan involvement usual syndrome. The liver is the most frequently affected organ, although invol cardiac muscle (myocarditis), lungs (pneumonitis), renal system (nephriti thyroiditis followed by hypothyroidism) are rare but possible. Liver distur aminotransferase concentrations to fulminant hepatic failure.[78 , 157

Leukocytosis is present and consists of a large number of atypical lymph biopsies reveal perivascular lymphocytic infiltration, spongiotic or lichenoi of edema.[157] Lymph node histology reveals benign hyperplasia, atypical l laboratory abnormalities include a positive rheumatoid factor, antinuclea DNA smooth muscle antibodies, cold agglutinin, and hypogammaglobinem novel, easy, fast, objective lymphocyte toxicity assay is being studied.[108

Prompt discontinuation of the offending agent is essential to prevent syr be admitted to the hospital and receive methylprednisolone 0.5â€“1 mg/k Other promising therapies include use of IV immunoglobulin.[97 , 133 , 157

In 1 case study, 90% of patients with AHS showed in vitro cross-reactivit anticonvulsant.[40] Based on this evidence, avoidance of phenytoin, carba primidone, lamotrigine, and potentially oxcarbazepine is recommended. topiramate, tiagabine, and levetiracetam are safer alternatives.[140]

Summary

All anticonvulsant drugs produce CNS symptoms when taken in overdose. findings is difficult. Lethargy, sedation, ataxia, and nystagmus occur follo

anticonvulsants. Coma occurs following substantial overdose of all anticc Seizures, including status epilepticus, may occur with carbamazepine, ph overdoses.

Hemodynamic instability and abnormal electrocardiograms are rare findi and possibly topiramate can cause QRS prolongation. Electrolyte abnorm with VPA and topiramate. Topiramate is uniquely associated with hyperc

Except for VPA overdoses, no specific antidotes exist for overdoses of a alone usually yields beneficial outcomes. Administration of activated char because of its safety and efficacy. Anticonvulsant-induced seizures are tr barbiturates. Patients with VPA overdoses in most cases should receive removal is rarely necessary and should be reserved for patients with sev topiramate overdoses and associated electrolyte abnormalities, hemodyna deterioration. Overdoses and toxicity associated with the newer anticonv so few data are available. However, most reported patients do not appea consequences.

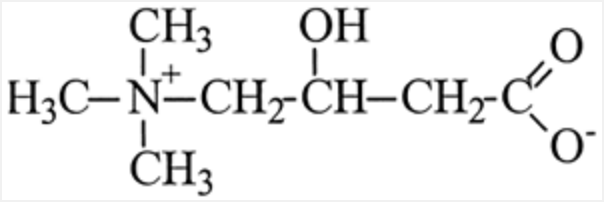
Antidotes in Depth

L-Carnitine

Mary Ann Howland



L-Carnitine

L-Carnitine (levocarnitine) [R-3-carboxy-2-hydroxy-*N,N,N*-trimethyl-1-propanaminium, inner salt or 3-hydroxy-4-(*N,N,N*-trimethylaminobutyrate] is an amino acid that is vital to

mitochondrial utilization of fatty acids. It is an orphan drug approved by the FDA for treatment of L-carnitine deficiency secondary to valproic acid toxicity, resulting from inborn errors of metabolism, associated with hemodialysis, and for zidovudine (AZT)-induced mitochondrial myopathy and pediatric cardiomyopathy.

L-Carnitine decreases valproic acid-induced hyperammonemia and limits valproic acid-induced hepatic toxicity. L-Carnitine should be administered IV to symptomatic patients to circumvent the low bioavailability from oral administration.

History

L-Carnitine is found in mammals, in many bacteria, and in very small amounts in most plants.[27] Carnitine was first discovered in 1905 in extracts of muscle, and its name is derived from *carnis*, the Latin word for flesh.[15] Over the next 25 years, its chemical formula and structure were identified, and in 1997 its enantiomeric properties were confirmed.[27] Carnitine was formerly known as vitamin BT.

Chemistry

Carnitine can exist as either the D or L form. Only the L isomer is found endogenously, is active, and should be used therapeutically. L-Carnitine ($C_7H_{15}NO_3$) has a molecular weight of 161 daltons. It is a water-soluble amino acid derivative that belongs to the same chemical family as choline. At physiologic pH, L-carnitine contains both a positively charged quaternary nitrogen ion and a negatively charged carboxylic acid group.[11]

Fatty acids provide 9 kcal/g and are an important source of energy for the body, especially for the liver, heart, and skeletal muscle. The utilization of fatty acids as an energy source requires L-carnitineâ€“mediated passage through both the outer and inner

mitochondrial membranes to reach the mitochondrial matrix where Î²-oxidation occurs (Figure 47-2). Enzymes in the outer and inner mitochondrial membranes (carnitine palmitoyltransferase and carnitine acylcarnitine translocase) catalyze the synthesis, translocation, and regeneration of L-carnitine.[23] Binding of L-carnitine to fatty acid occurs through esterification at the hydroxyl group on the chiral carbon.[11] The L-carnitine regenerated in the mitochondrial matrix is able to translocate in the opposite direction, from the matrix and through the inner membrane back to the space between the outer and inner membrane. The fatty acyl-coenzyme A (CoA) undergoes Î²-oxidation in the mitochondrial matrix, generating acetyl-CoA that then enters the citric acid cycle.

L-Carnitine Homeostasis

Approximately 54â€“87% of endogenous L-carnitine is derived from the diet; the remainder is synthesized.[27] Meat and dairy products are the primary dietary sources. Although most plants supply very little L-carnitine, avocado and fermented soy products are exceptionally rich in this amino acid. The remainder of the carnitine needed by the body is synthesized from trimethyllysine. This amino acid, found largely in skeletal muscle, is converted to trimethylammoniobutanoate (Î³-butyrobetaine) and then carried to the liver and kidney for hydroxylation to L-carnitine.[15] Synthesis of L-carnitine in the liver and kidney occurs at a rate of approximately 2 Âµmol/kg/d and is regulated by the amount of diet-derived trimethyllysine.[15,27] L-Carnitine is filtered by the kidneys, and tubular reabsorption keeps L-carnitine serum concentrations in the normal range.

Pharmacokinetics of Exogenous L-Carnitine

Our current understanding of L-carnitine pharmacokinetics is largely derived from three major studies.[7,14,31] L-Carnitine is not bound to plasma proteins. Vc (volume of distribution of the central compartment) is 0.15 L/kg, approximating extracellular fluid volume. Vd (volume of distribution) is 0.7 L/kg. Both vary depending on the compartment model analyzed. The $t_{1/2}$ Î± is 0.6â€“0.7 hours. The terminal elimination half-life averages 10â€“23 hours but may be 25â€–50% shorter. Baseline plasma values for L-carnitine are 40 Âµmol/L but increase to 1600 Âµmol/L following administration of 40 mg/kg of the amino acid intravenously (IV) over 10 minutes. Whereas 2 g of the amino acid administered IV produced a peak plasma concentration of 1000 Âµmol/L, oral administration of 2 g produced peaks of only 15â€“70 Âµmol/L. The time to peak concentrations following oral administration occurs at 2.5â€–7 hours, indicating slow uptake by intestinal mucosal cells. Oral absorption is already saturated following a 2-g dose, and no further absorption occurs after administration of 6 g. Following a radiolabeled dose, most L-carnitine is metabolized to trimethylamine *N*-oxide and butyrobetaine, with only approximately 4â€–8% remaining unchanged. The metabolites trimethylamine and trimethylamine *N*-oxide may accumulate after chronic high-dose oral therapy in patients with severely compromised renal function.[7] Fecal excretion of L-carnitine is < 1% of the total dose.

Carnitor (levocarnitine) tablets are bioequivalent to the Carnitor oral solution, with an absolute bioavailability of approximately

15%. After 4 days of dosing at 1980 mg (6 Ã— 330-mg tablets) twice per day or 2 g twice per day of the oral solution, the maximum plasma concentration was 80 Âµmol/L.

Valproic Acid and Hyperammonemia

Valproic acid can cause hyperammonemia (defined as plasma

ammonia concentration > 80 Âµg/dL or > 35 Âµmol/L) with or without symptoms and with or without hepatic dysfunction. Hyperammonemia and hepatic toxicity may occur either with therapeutic dosing or following an acute overdose. Approximately 35% of patients receiving valproic acid demonstrate hyperammonemia, often with corresponding reduced plasma L-carnitine concentrations.[6] In the absence of hepatic dysfunction, the postulated mechanisms for hyperammonemia are unclear but may result from interference with hepatic synthesis of urea or a small increase in ammonia production by the kidney.[18,33] Valproic acid induces both carnitine and acetyl-CoA deficiencies by combining with L-carnitine as valproylcarnitine and with acetyl CoA as valproyl-CoA. Ultimately, Î²-oxidation of all fatty acids is reduced, resulting in decreased energy production. Valproic acid stimulates glutaminase favoring glutamate uptake and ammonia release from the kidney. Reduced glutamate concentrations lead to impaired production of *N*-acetylglutamate (NAGA), a cofactor for carbamoyl phosphate synthetase I (CPS I), that is used in the liver to synthesize urea from ammonia.

In humans taking valproic acid, L-carnitine supplementation reduces ammonia concentrations.[1,,2,,4,,6,,13,,22,,24,,25] The exact time frame for normalization of ammonia concentrations is unknown, but a preliminary report suggests hastening of ammonia elimination with L-carnitine (3â€“15 h) compared to published controls (11â€“90 h).[30]

Valproic Acid and Hepatotoxicity

Valproic acid therapy is commonly associated with a transient dose-related asymptomatic rise in liver enzyme concentrations and a rare symptomatic, life-threatening, idiosyncratic Reyelike hepatotoxic syndrome.[3] Liver histology of the latter demonstrates microvesicular steatosis, similar to that described in hypoglycin-induced Jamaican vomiting sickness and Reye syndrome. This

occurrence presumably results from L-carnitine and acetyl-CoA deficiency, which inhibits mitochondrial Î²-oxidation of valproic acid and other fatty acids, causing them to accumulate in the hepatocyte.

Evidence for the benefit of L-carnitine treatment in improving survival from valproic acid-induced hepatotoxicity comes from the retrospective analysis of patients identified by the International Registry for Adverse Reactions to valproic acid.[5] When 50 patients with acute, symptomatic hepatic dysfunction who were not treated with L-carnitine were compared with 42 similar patients treated with L-carnitine, only 10% of the untreated patients but 48% of the L-carnitineâ€“treated patients survived.[5] Early diagnosis of patients, prompt discontinuance of valproic acid, and administration of IV rather than oral L-carnitine resulted in the greatest survival.[5] Most patients received 50â€“100 mg/kg/d L-carnitine, regardless of the route of administration.[5] Additionally, case reports and animal studies[29] offer both support[28,32] and lack of support for the beneficial effects of L-carnitine in the presence of valproic acid-induced hepatotoxicity.[17,21]

L-Carnitine Concentrations

In the plasma, 80% of L-carnitine is free, and the rest is acylated.[10] Normal plasma concentrations of free L-carnitine in omnivorous adults and children older than 1 year are 22â€“66 Âµmol/L and of total L-carnitine concentrations are 28â€“84 Âµmol/L. Vegetarians have L-carnitine concentrations 12% to 30% lower than omnivores.[26]

Numerous studies in patients taking valproic acid demonstrate decreases in both free and total plasma L-carnitine concentrations.[25]

Case studies demonstrate reduced plasma free L-carnitine concentrations and abnormal valproic acid metabolite profiles that

normalize with L-carnitine supplementation.[16,19,20] All of these data support the use of L-carnitine and provide a potential mechanism for its beneficial effects in valproic acid-induced hepatotoxicity.

Adverse Effects and Contraindications to L-Carnitine

L-Carnitine administration is well tolerated. Transient nausea and vomiting are the most common side effects reported, with diarrhea and a fishy body odor noted at higher doses.[7] Following chronic high doses of L-carnitine in patients with severely compromised renal function, the potentially toxic L-carnitine metabolites trimethylamine and methylamine *N*-oxide accumulate. The importance of this accumulation is unknown. Trimethylamine and its metabolite dimethylamine may contribute to cognitive abnormalities and the fishy odor.[9] In a pharmacokinetic study following intravenous administration of 6 g over 10 minutes, 2 of 6 subjects complained of transient visual blurring; 1 subject also complained of headache and light-headedness. The manufacturer of L-carnitine has received case reports of convulsive episodes following L-carnitine use by patients with or without a preexisting seizure disorder. This concern is currently included in the package insert. No reports of seizures related to L-carnitine can be found in the human literature. The only data suggesting carnitine-related seizures are found in a rat model.[12]

There are no known contraindications to the use of L-carnitine. However, only the L isomer and not the racemic mixture should be used because the DL mixture may interfere with mitochondrial utilization of L-carnitine. L-carnitine is considered pregnancy category B.

Overdose of L-carnitine

No cases of toxicity from overdose are reported, although large oral doses may cause diarrhea.[7] The LD_{50} in rats is 5.4 g/kg IV and 19.2 g/kg oral.[7]

Dosage and Administration

The optimal dosing of L-carnitine for valproic acid-induced hyperammonemia or hepatotoxicity is not established.

Recommendations for intravenous L-carnitine administration to patients with acute metabolic disorders resulting from L-carnitine deficiency range from 50â€“500 mg/kg/d.[7,8] A loading dose equal to the daily dose may be given initially, followed by the daily dose divided into every 4 hourly doses. The 500 mg/kg/d dose was intended for children[8] and did not list a maximum dose, although we

suggest a maximal daily dose of 6 g in addition to the loading dose. The oral dosing of L-carnitine usually is 50â€“100 mg/kg/d up to 3 g/d and should be reserved for patients who are not acutely ill.

For patients with end-stage renal disease undergoing hemodialysis, the package insert recommends an intravenous starting dose of 10â€“20 mg/kg dry body weight as a slow intravenous bolus over 2â€“3 minutes after completion of dialysis, followed by a dose adjustment according to L-carnitine trough (predialysis) plasma concentrations (normal 40â€“50 Âµmol/L).

For patients with an acute overdose of valproic acid and without hepatic enzyme abnormalities or symptomatic hyperammonemia, L-carnitine administration can be considered prophylactic, and enteral doses of 100 mg/kg/d divided every 6 hours up to 3 g/d is appropriate. For patients with valproic acid-induced symptomatic hepatotoxicity or symptomatic hyperammonemia, intravenous L-carnitine should be administered. We suggest a dose of 100 mg/kg

IV up to 6 g administered over 30 minutes as a loading dose, followed by 15 mg/kg every 4 hours administered over 10â€“30 minutes.

Availability

L-Carnitine is available as a sterile injection for intravenous use (Carnitor) in 1 g/5 mL single-dose vials. L-Carnitine is supplied without a preservative. Once the vial is opened, the unused portion should be discarded. Carnitor injection is compatible and stable when mixed with normal saline or lactated Ringer solution in concentrations as high as 8 mg/mL for as long as 24 hours.[7] L-Carnitine as Carnitor is also available as a 330-mg tablet and as an oral solution (with artificial cherry flavoring and methylparaben and propylparaben as preservatives) at a concentration of 100 mg/mL. The oral solution can be consumed without dilution, or it can be dissolved in other drinks to mask the taste. Slow consumption reduces gastrointestinal side effects.[7]

Glucose

An 80-year-old woman with a history of diabetes mellitus was found by family members to be unresponsive at home. Emergency medical services was called and recorded a rapid reagent glucose concentration of 39 mg/ She was given 50 mL of 50% dextrose intravenously, which resulted in ra improvement of mental status. She had a history of hypertension. Curren medications included metformin and atenolol. She denied using any other medications or ethanol, but she smoked cigarettes. Upon further questior in the emergency department (ED), she stated that she had not eaten mu

over the past several days and had â€œcoldâ€• symptoms of nonproduc cough. She denied having fever, shortness of breath, chest pain, nausea, vomiting, or diarrhea. Review of organ systems was negative.

Physical examination revealed: blood pressure, 120/67 mm Hg; pulse, 74 beats/min; respiratory rate, 26 breaths/min; temperature, 98.2Â°F (36.8Â°C). Initial pulse oximetry was 87% on room air. The patient was alert and oriented, with no focal neurologic deficits. The pupils were equa and reactive to light. Cardiopulmonary examination revealed bilateral rhonchi, expiratory wheezes, and a regular rate and rhythm without murmurs, rubs, or gallops. The abdomen was nontender to palpation.

The patient was admitted to the medicine service for monitoring and observation for recurrent hypoglycemia and for treatment of chronic obstructive pulmonary disease exacerbation. Further questioning of family members revealed that the patient was also taking glyburide. Intravenous access was maintained, her antidiabetic medications were withheld, and s was placed on a sliding-scale insulin regimen. During her hospitalization, had several episodes of altered mental status. Two episodes coincided wi rapid reagent glucose readings in the low 40 mg/dL range. Both episodes were treated with 50% dextrose intravenously. The patient was discharge to the care of her private physician 3 days later with an intact neurologic examination. Her respiratory status was improved, but she was instructed use home oxygen continuously at night and as needed during the day. At discharge, glyburide was restarted, but metformin was withheld.

Although various pharmacologic agents and medical conditions may cause hypoglycemia, this chapter focuses on the medications used for treatment diabetes mellitus. These medications include insulin and oral agents: the sulfonylureas, biguanides, Î±-glucosidase inhibitors, thiazolidinediones, a meglitinides. Some of the medications in these chemically heterogeneous groups of xenobiotics can cause unique toxic effects in addition to hypoglycemia.

Most patients with diabetes mellitus are classified as having either insulin dependent diabetes mellitus (IDDM), also known as type I diabetes, or nonâ€“insulin-dependent diabetes mellitus (NIDDM), also known as type

diabetes. This classification scheme for diabetes mellitus is not perfect. F example, some patients with type II diabetes may require insulin in addit to oral agents. Early in the course of type I diabetes, patients may enter remission period during which insulin is not required.

In diabetes mellitus, the body fails to maintain normal blood glucose concentrations. In general, neurohormonal control of glucose production healthy individuals maintains a fasting serum glucose concentration in the range from 60â€“100 mg/dL. The two glycemic complications of diabetes mellitus and its therapy are hyperglycemia and hypoglycemia.

History and Epidemiology

Insulin first became available for use in 1922 after Banting and colleague successfully treated diabetic patients with pancreatic extracts.[10] In an attempt to more closely simulate physiologic conditions, newer â€œdesignerâ€• insulins with unique kinetic properties

have been developed, including an ultrashort-acting preparation known a *lispro* .[62 , 125] Several oral delivery systems for insulin have been studied Development of a system for use in humans has not been successful beca of degradation of the oral form of insulin by digestive enzymes. Using zo occludens toxin, modulation of intestinal tight junctions in animal models has resulted in significant increases in enteral absorption of insulin.[38] An inhaled form of insulin has also been studied and appears promising.[24]

The hypoglycemic activity of a sulfonamide derivative used for typhoid fe was noted during World War II.[68] This discovery was verified later in animals. The sulfonylureas in use today are chemical modifications of tha original sulfonamide compound. In the mid-1960s, the first-generation sulfonylureas were widely used. Newer second-generation agents differ primarily in their potency.

Although insulin is widely used for treating diabetes mellitus, sulfonylurea exposures are much more commonly reported to poison centers than are insulin exposures, based on 15 years of data from 1989â€“2003 (Chap. 1

). These data likely reflect a significant percentage of intentional overdos cases. In a review of 1418 medication-related cases of hypoglycemia, sulfonylureas (especially the long-acting agents chlorpropamide and glyburide) alone or with a second agent accounted for the largest percentage of cases (63%).[115] Only 18 of the sulfonylurea cases in this series involved overdose with suicidal intent. Ethanol, propranolol, and salicylate, either alone or with another hypoglycemic drug, accounted for another 19% of cases of hypoglycemia. Quinine, quinidine, pentamidine, ritodrine, and disopyramide were the most common of the less frequently associated agents. Hypoglycemia is reported in as many as 20% of patien using sulfonylureas.[55] Besides sulfonylurea use, advanced age and fasting are identified major risk factors for hypoglycemia. Despite the lack of evidence reported in the literature, we speculate that insulin-induced hypoglycemia occurs frequently in settings other than volitional overdose

The biguanides metformin and phenformin were developed as derivatives *Galega officinalis* , the French lilac, recognized in medieval Europe as a treatment for diabetes mellitus.[7] Phenformin was used in the United Stat until 1977, when it was removed from the market because of its associat with life-threatening lactic acidosis (64 cases/100,000 patient-years). However, phenformin still is available outside the United States.[76] Travel and immigrants to the United States who continue to receive medication from their native countries may present with phenformin-induced lactic acidosis. Metformin became available in the United States in 1995. Its use also associated with lactic acidosis but to a much lesser degree than with phenformin (only 3 cases/100,000 patient-years).[28] Metformin-associated lactic acidosis is discussed in detail in Metformin-associated Lactic Acidos below.

Several newer agents for treatment of diabetes mellitus have been introduced. They include the Î±-glucosidase inhibitors acarbose and migl the thiazolidinedione derivatives troglitazone, rosiglitazone, and pioglitazone; and the meglitinides repaglinide and nateglinide. Developm of the Î±-glucosidase inhibitors began in the 1960s when an Î±-amylase inhibitor was isolated from wheat flour.[110] Acarbose was discovered more than 10 years later and approved for use in the United States in 1995.

Troglitazone and repaglinide were approved for use in the United States i 1997. The FDA subsequently directed the manufacturer of troglitazone to withdraw the product from the US market in 2000 because of associated liver toxicity.

TABLE 48-1. Causes of Hypoglycemia

Various xenobiotics other than the antidiabetic medications can cause hypoglycemia. Ethanol is a common cause of hypoglycemia and is discuss in depth in Chap. 75 . Other xenobiotics, including Î²-adrenergic antagon and salicylates, and a variety of medical conditions, such as sepsis and

insulin-secreting tumors, may cause hypoglycemia (Table 48-1). Certain plant xenobiotics may be implicated as well. Although not a particular problem in the United States, ingestion of the unripe fruit of the Ackee tr *Blighia sapida* , in countries where food is in short supply may result in significant hypoglycemia resulting from the compound hypoglycin contain in the unripe fruit.

Pharmacology

Insulin is synthesized as a prohormone in the Î²-islet cells of the pancrea Upon release, the prohormone is cleaved, resulting in release of both a C peptide and insulin itself, a double-chain molecule containing 51 amino a residues. Glucose concentration plays a major role in the regulation of insulin release.[102] Glucose is phosphorylated after transport into the Î²-i cell of the pancreas. Further metabolism of glucose-6-phosphate results i the formation of ATP. ATP inhibition of the K^+ channel results in cell depolarization, inward calcium flux, and insulin release. After release, ins binds to specific receptors on cell surfaces in insulin-sensitive

tissues, particularly the hepatocyte, myocyte, and fat cells. The action of insulin on these cells involves various phosphorylation and dephosphorylation reactions.

Figure 48-1 depicts the chemical structures of oral agents representing th major classes of antidiabetic and hypoglycemic agents. The sulfonylureas stimulate the Î² cells of the pancreas to release insulin; therefore, they a ineffective in type I diabetes mellitus resulting from islet cell destruction (Figure 48-2). This stimulatory effect diminishes with chronic therapy. A the sulfonylureas bind to high-affinity receptors on the pancreatic Î²-cell membrane, resulting in closure of K_{ATP} channels.[37 , 43 , 44] Inhibition of potassium ion efflux mimics the effect of naturally elevated intracellular A and results in insulin release. High-affinity sulfonylurea receptors also present within pancreatic Î² cells are postulated to be either located on granular membranes or part of a regulatory exocytosis kinase. Binding to these receptors promotes exocytosis by direct interaction with secretory

machinery not involving closure of the plasma membrane K_{ATP} channels.[3] [43, 44] Repaglinide is a new oral agent that is structurally different from t sulfonylureas. However, it also binds to ATP-sensitive potassium channels pancreatic Î² cells, resulting in increased insulin secretion.[83]

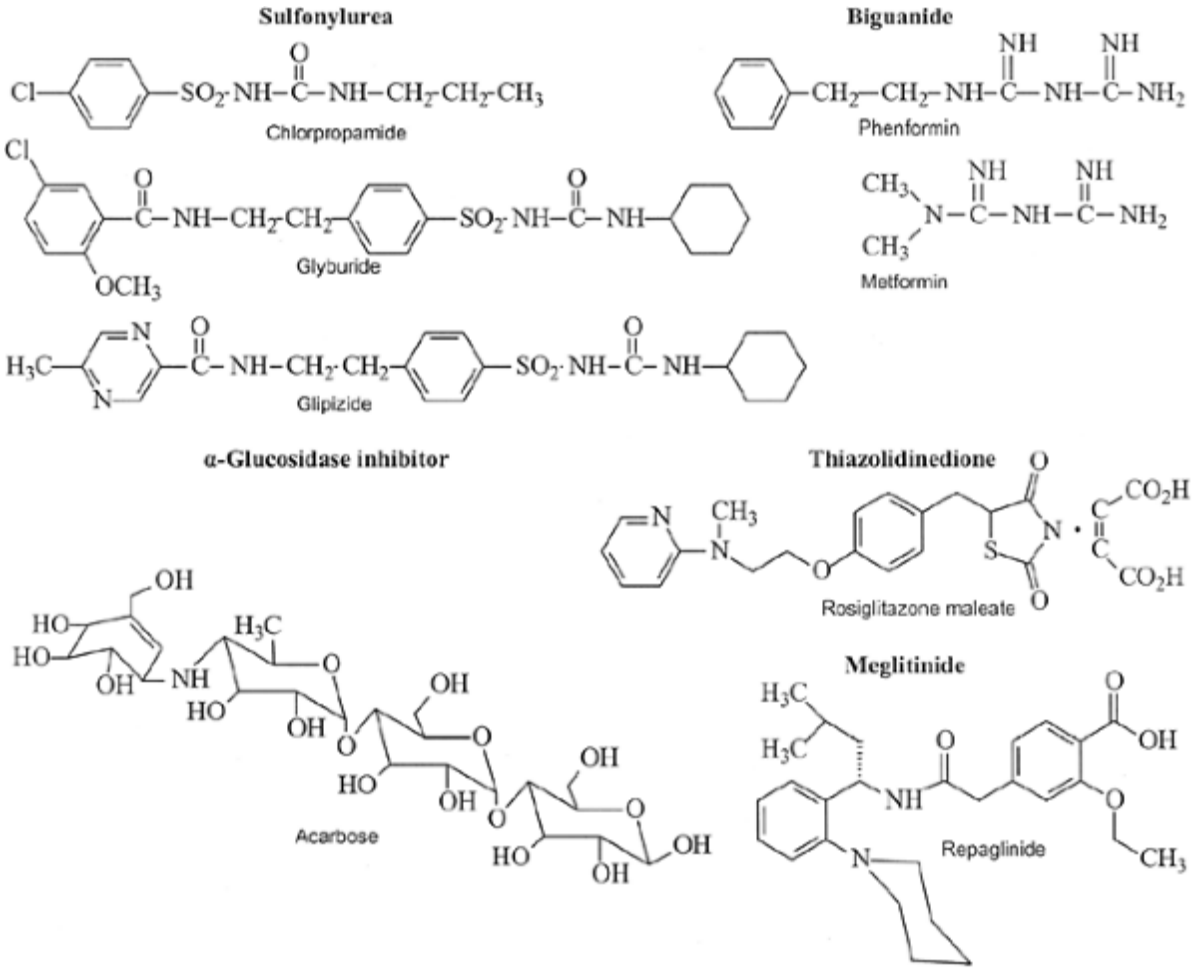

Figure 48-1. Chemical structures of representative oral antidiabetics and hypoglycemics.

The linkage of two guanidine molecules forms the biguanides. Metformin an oral compound approved for treatment of type II diabetes mellitus. Its glucose-stabilizing effect is caused by several mechanisms, the most important of which appears to involve inhibition of gluconeogenesis and subsequent decreased hepatic glucose output. Enhanced peripheral gluco uptake also plays a significant role in maintaining euglycemia. Metformin

ability to lower blood glucose concentrations also occurs as a result of decreased fatty acid oxidation and increased intestinal use of glucose.[8] In skeletal muscle and adipose cells, metformin causes enhanced activity and translocation of glucose transporters. Although the details are unclea the mechanism by which this process occurs involves an interaction betw metformin and tyrosine kinase on the intracellular portion of the insulin receptor. Figure 48-3 depicts the mechanism of action of metformin.

Insulin resistance in patients with type II diabetes mellitus may occur because of secretion of biologically defective insulin molecules, circulatin insulin antagonists, or target tissue defects in insulin action.[92] The thiazolidinedione derivatives decrease insulin resistance by potentiating insulin sensitivity in the liver, adipose tissue, and skeletal muscle. Uptake glucose into adipose tissue and skeletal muscle is enhanced, while hepati glucose production is reduced.[18, 54]

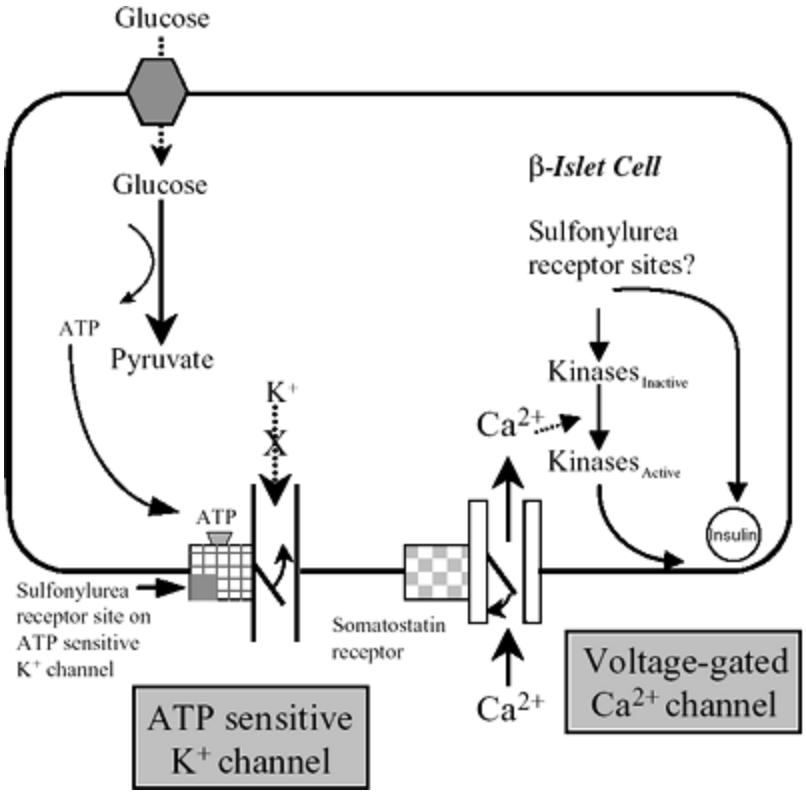

Figure 48-2. Under normal conditions, cells release insulin in response t elevation of intracellular ATP concentrations. Sulfonylureas potentiate the

effects of ATP at its â€œsensorâ€• on the ligand-gated K^+ channels and prevent efflux of K^+ . The subsequent rise in intracellular potential opens voltage-gated Ca^{2+} channels, which initiates a series of phosphorylation reactions culminating in fusion of the insulin-containing granule with the membrane and release of insulin. Release of insulin is also caused by binding of sulfonylureas to postulated receptor sites on regulatory exocytosis kinase and insulin granular membranes.

Acarbose and miglitol are oligosaccharides that inhibit Î±-glucosidase enzymes such as glucoamylase, sucrase, and maltase in the brush border the small intestine. As a result, postprandial elevations in blood glucose concentrations after carbohydrate ingestion are blunted.[134] Delayed gast emptying may be another mechanism for the antihyperglycemic effect of these oligosaccharides.[105]

Pharmacokinetics and Toxicokinetics

Pharmacokinetic parameters of the hypoglycemics are given in Tables 48- and 48-3 . Insulin is a peptide that is degraded in the gut and therefore i not active by the oral route. The onset and duration of action in therapeu doses varies considerably among preparations. Insulin overdose usually occurs after administration by the subcutaneous or intramuscular route. A might be predicted based on slow onset and prolonged duration of action some of the preparations, insulin overdose may result in delayed and prolonged hypoglycemia. However, hypoglycemia may also occur with sh acting forms because of some unusual toxicokinetic features. Some of th unpredicted responses may be caused by a depot effect following intramuscular or subcutaneous administration, and poor absorption may b further potentiated by the poor perfusion that can occur in hypoglycemia. [124] Further complicating the prediction of the clinical course is the delaye release of insulin from adipose tissue at the injection site(s). In diabetics the presence of insulin antibodies may explain a patient's recovery in spi of massive overdoses.[111] Because there is a finite number of insulin

receptors, insulin overdoses of varying extents probably are equivalent ir terms of the degree of hypoglycemia once receptor saturation occurs but in terms of its duration. A comparison can be made with the current treatment of diabetic ketoacidosis, in which lower doses of insulin are as effective as the higher doses used in the past.[61]

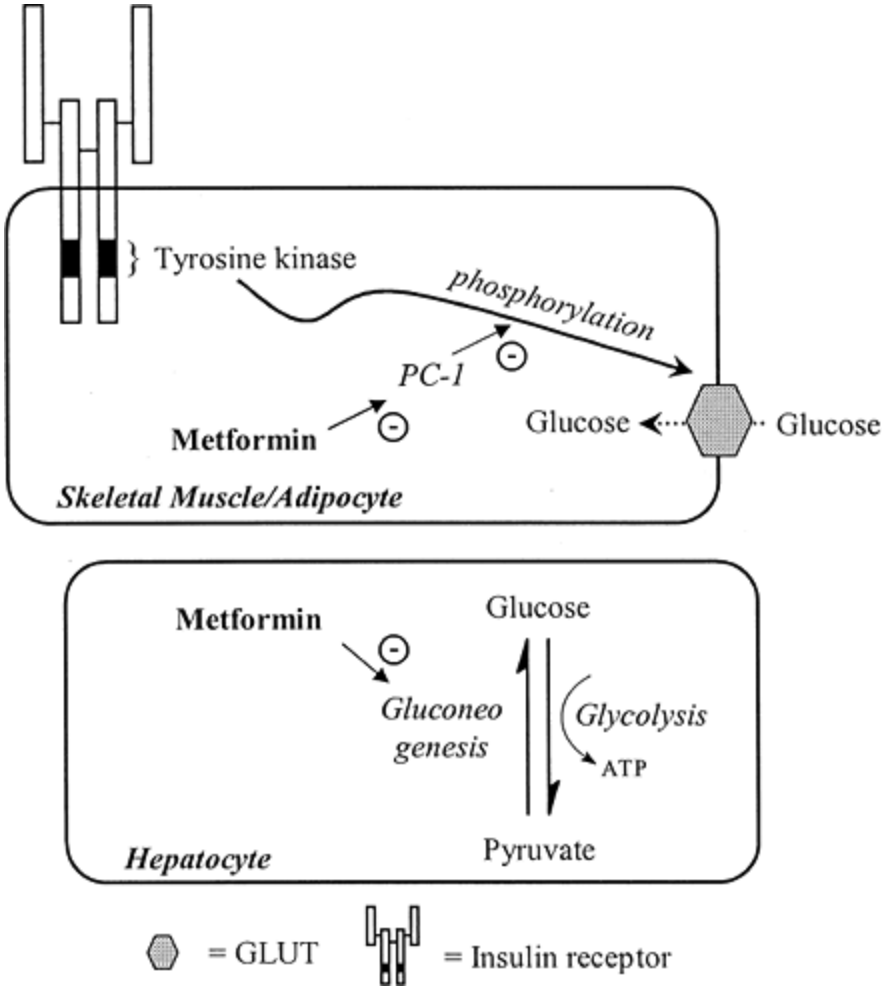

Figure 48-3. Under normal conditions, insulin binding to its receptor on myocytes and adipocytes activates tyrosine kinase, resulting in phosphorylation and activation of the membrane-bound glucose transport GLUT. Nonâ€“insulin-dependent diabetes mellitus is causally associated w an increased activity of PC-1, a glycoprotein that inhibits tyrosine kinase activity and thus reduces myocyte and adipocyte glucose uptake. Metforr reduces PC-1 activity in these cells, enhancing peripheral glucose utilizat In addition, gluconeogenesis in hepatic cells is reduced through interfere

with pyruvate carboxylase, the enzyme responsible for conversion of pyruvate to oxaloacetate.

Many of the sulfonylureas have a long duration of action, which may expl the unusually long period of hypoglycemia that can occur in both therape use and overdose. The first-generation sulfonylureas (acetohexamide, chlorpropamide, tolazamide, tolbutamide) reduce hepatic clearance of ins and produce active hepatic metabolites. These drugs are dependent on th effective urinary excretion to maintain euglycemia and prevent hypoglycemia.

Second-generation sulfonylureas (glimepiride, glipizide, glyburide) have half-lives that approach 24 hours and are characterized by substantial fe excretion of the parent drug. These agents frequently cause hypoglycemi (Table 48-2). Like insulin, the sulfonylureas may cause delayed onset of hypoglycemia following overdose.[94 , 103] The reason for the potential delayed onset of effects with sulfonylureas cannot be simply explained by known kinetic principles.

Metformin metabolism is negligible, and the majority of an absorbed dose excreted in the urine unchanged. Plasma protein binding also is negligible The kinetics of acarbose are notable for minimal systemic absorption and metabolism that occurs in the gut. As a result, serious systemic toxicity i not expected.[112] Adverse clinical effects usually are gastrointestinal. Repaglinide is a prandial glucose regulator with a short onset and short duration of action. These characteristics allow for flexible dosing in patie with irregular eating habits.[87] Despite its short half-life in therapeutic do overdose experience and toxicokinetic data for repaglinide are lacking. Whether after overdose hypoglycemia would be prolonged or delayed in onset is not clear.

Central nervous system (CNS) symptoms predominate in hypoglycemia because the brain relies almost entirely on glucose as an energy source.

adult brain can only use free fatty acids for ATP synthesis under aerobic conditions. However, during prolonged starvation, the brain can utilize ketones derived from free fatty acids. In contrast to the brain, other maj organs such as the heart, liver, and skeletal muscle often function during hypoglycemia because they can use various fuel sources, particularly free fatty acids.[117]

Emphasis on tighter diabetic control as a means of preventing microvascu effects carries with it an increased risk for hypoglycemia.[31, 32] Regulatio of glucose control to near-normal glucose concentrations, the characteris of each individual's awareness of hypoglycemia, and the individual counterregulatory mechanisms define the frequency and intensity of hypoglycemia.[116] The Diabetic Control and Complications Trial (DCCT) research group reported 62 episodes of blood glucose concentration < 50 mg/dL with CNS manifestations requiring assistance for every 100 patien years in patients undergoing an intensive insulin therapy regimen. This w in comparison to a conventional therapy group, which had 19 such episod per 100 patient-years.[31, 32] The intensive therapy group received â‰¥3 insulin injections per day or used a pump in an effort to achieve a glucos concentration as close to normal as possible, whereas the conventional therapy group received 1 or 2 daily insulin injections.

See TABLE 48-1 for list of xenobiotics that cause hypoglycemia alone.

TABLE 48-4. Xenobiotics Known To React with Hypoglycemics Resulting in Hypoglycemia

The autonomic nervous system regulates glucagon and insulin secretion, glycogenolysis, lipolysis, and gluconeogenesis. Î²-Adrenergic antagonists affect all these mechanisms and can result in hypoglycemia. In the prese of chronic renal failure, Î²-adrenergic antagonist-induced hypoglycemia is particular risk[47] secondary to increased insulin half-life and reduced rena gluconeogenesis.[95] In addition, the clinical presentation of hypoglycemia may be muted when Î²-adrenergic antagonists are present because the expected autonomic responses of tachycardia, diaphoresis, and anxiety m not occur. Although this is assumed to be true, an adverse effect on hypoglycemic awareness could not be demonstrated in healthy volunteers given metoprolol, atenolol, and propranolol.[60]

The concept of hypoglycemia-associated autonomic failure in diabetes mellitus is well described.[29] Recent episodes of hypoglycemia result in autonomic failure by causing defective glucose counterregulation and hypoglycemic unawareness. As glucose concentrations fall, normal sensin mechanisms result in decreased insulin secretion and increased glucagon and epinephrine secretion. These counterregulatory defenses against hypoglycemia are defective in most people with type I diabetes mellitus a in many with type II diabetes mellitus.

Although various xenobiotics can cause hypoglycemia (Table 48-1), salicylates and ethanol are particularly notable for their unintended hypoglycemic effects. The mechanism of ethanol-induced hypoglycemia is discussed in Chap. 75 . Salicylate inhibition of prostaglandin synthesis in Î² cell of the pancreas is postulated to result in enhanced insulin secretion.[11] Salicylates may also cause hypoglycemia by poorly defined mechanisms that do not involve enhanced insulin secretion.

Besides decreasing glucose concentrations, the hypoglycemics can produce number of adverse effects, both in overdose and in therapeutic doses. The sulfonylureas, predominantly chlorpropamide, can cause a syndrome of inappropriate antidiuretic

hormone secretion.[57] Concomitant use of sulfonylureas and ethanol can cause a disulfiramâ€“ethanol reaction, as sulfonylureas inhibit aldehyde dehydrogenase.[100]

Clinical Manifestations

Hypoglycemia and its secondary effects on the CNS are the most common adverse effects related to insulin and the sulfonylureas. Clinical hypoglycemia is the failure to maintain a serum glucose concentration that prevents signs or symptoms of glucose deficiency. The glycemic threshold is the plasma glucose concentration below which clinical manifestations develop, a threshold that is host variable. In one study, the mean glycemic threshold for hypoglycemic symptoms was 78 mg/dL in poorly controlled diabetics compared to 53 mg/dL in nondiabetics.[16]

The presentations of patients with hypoglycemia are extremely variable. Hypoglycemia must be considered with any neuropsychiatric abnormality, whether persistent or transient, focal or generalized (Table 48-5). The cerebral cortex usually is most severely affected. Categorization of these findings are as follows:[99]

- Delirium with subdued, confused, or manic behavior.

- Coma with multifocal brainstem abnormalities, including posturing an respiratory abnormalities, with preservation of the oculocephalic (dol eyes), oculovestibular (cold-caloric), and pupillary responses.
- Focal neurologic deficits simulating a cerebrovascular accident (CVA) with or without the presence of coma. During a 12-month study perio 3 (2.4%) of 125 hypoglycemic patients presented with hemiplegia.[74] There are numerous reports[3, 120] and series[114, 133] of patients with focal neurologic deficits.
- Solitary or multiple seizures, with or without a significant postictal phase.

These neuropsychiatric symptoms usually are reversible if the hypoglycer is corrected promptly. The morbidity resulting from undiagnosed hypoglycemia is related partly to the etiology and partly to the duration a severity of the hypoglycemia. Because the etiologies of hypoglycemia encompass both severe diseases such as fulminant hepatic failure and benign problems such as a missed meal by an insulin-requiring diabetic, t literature with regard to outcome is confusing. Although a study of 125 E cases of symptomatic hypoglycemia reported an 11% mortality rate,[74] on 1 death (0.8%) was attributed directly to hypoglycemia. In that same stu 9 patients (7.2%) presented with seizures (focal in one case), 3 patients (2.4%) presented with hemiparesis, and 4 survivors (3.2%) suffered residual neurologic deficits. In 1 tertiary care medical center, 1.2% of all admitted patients had hypoglycemia (defined as a serum or plasma gluco concentration < 50 mg/dL). The overall mortality was 27% for this group 94 patients.[40] The longer and more profound the hypoglycemic episode, t more likely permanent CNS damage will occur.[6]

TABLE 48-5. Manifestations of Hypoglycemia

No absolute criteria available from the physical examination or history distinguish one form of metabolic coma from another. Moreover, the find classically associated with hypoglycemia, such as tremor, sweating, tachycardia, confusion, coma, and seizures, frequently may not occur (Ta 48-5).[52] Patients may be unaware of hypoglycemia, particularly those w well-controlled IDDM. It appears that even in the presence of numerical hypoglycemia, diabetic individuals with near-normal glycosylated hemogl values maintain near-normal glucose uptake by the brain, thereby preserving cerebral metabolism and limiting the response of

counterregulatory hormones. The result of this limited response is unawareness of hypoglycemia.[15, 16] A threshold level likely is achieved below which the glucose concentration is inadequate, but this may be a l so close to that causing serious neuroglycopenia that patients have limite opportunity for corrective action.[15] Hypoglycemia unawareness is most li in diabetics with chronic exposure to hypoglycemics because of hypoglycemia-associated autonomic failure.[29] Acute ingestion of hypoglycemic agents in nondiabetics likely would cause classic signs and symptoms.

Hypoglycemia may not occur until 18 hours after lente insulin overdose[86] and may persist for up to 6 days after ultralente insulin overdose.[75] Deat after insulin overdose cannot be correlated directly with either the dose o preparation type. Some patients have died with doses estimated in the hundreds of units, whereas others have survived doses in the thousands units.[111] Mortality and morbidity may correlate better with delay in recognition of the problem, duration of symptoms, onset of therapy, and type of complications, as opposed to the absolute degree of hypoglycemia persistence of elevated insulin concentrations. A significant correlation exists between the amount of insulin injected and either the total amount dextrose used for treatment or the duration of dextrose infusion.[124] In th retrospective study of insulin overdose, 7 (41%) of 17 cases developed recurrent hypoglycemia between 5 and 39 hours after overdose despite o feeding and intravenous dextrose infusion ranging from 5â€“17 g dextros per hour.

In a retrospective review of 40 sulfonylurea overdose cases, the time fro ingestion to the onset of hypoglycemia, when known, was variable.[94] The longest delay was 21 hours after ingestion of glyburide and 48 hours afte ingestion of chlorpropamide. In a retrospective poison center review of 9 cases of sulfonylurea exposures in children, 25 patients (27%) developed hypoglycemia, with a time of onset ranging from 0.5â€“16 hours and a m of 4.3 hours.[103] In a prospective poison center study of sulfonylurea exposures in children, 56 (30%) of 185 patients developed hypoglycemia with a time of onset ranging from 1â€“21 hours and a mean of 5.3 hours. Single-tablet ingestions of chlorpropamide 250 mg, glipizide 5 mg, and

glyburide 2.5 mg can result in hypoglycemia in young children;[103] and th hypoglycemia may be delayed.[128]

Sinus tachycardia, atrial fibrillation, and ventricular premature contractio are the most common dysrhythmias associated with hypoglycemia.[67 , 91] outpouring of catecholamines, hypoglycemia itself, transient electrolyte abnormalities, and underlying heart disease appear to be the most likely etiologies. Based on their mechanisms of action, both insulin and the sulfonylureas are expected to promote the shift of potassium into cells, a hypokalemia after insulin overdose is well documented.[5 , 124] Other cardiovascular manifestations include angina and ischemia, which may be the sole manifestations of hypoglycemia.[36] Both are directly related to hypoglycemia.[13 , 98] Increased release of catecholamines during hypoglycemia increases myocardial oxygen demand and may decrease supply by causing coronary vasoconstriction at stenotic sites.

Hypothermia may occur in hypoglycemic patients.[41 , 59 , 126] If present, hypothermia usually is mild (90â€“95Â°F [32â€“35Â°C]), unless coexistir conditions such as environmental exposure, infection, head injury, or hypothyroidism are present. In a study comparing 2 groups of comatose stuporous patients, hypothermia was almost exclusively limited to the hypoglycemic patients; of these patients, 53% with demonstrated hypoglycemia showed hypothermia.[126] The central hypothalamic response hypoglycemia stimulated by the sympathetic nervous system may actuall â€œovershootâ€• normal temperatures, resulting in hyperthermia.[26]

Hypoglycemia is reported in 2 cases of metformin overdose.[130] In both cases, lactic acidosis was evident upon initial presentation. Hypoglycemia was present initially in one of the cases but did not develop until 7 hours later in the second case. Hypoglycemia is reported in a case of metformir associated lactic acidosis related to therapeutic use.[63] Insufficient evider supports the concept that metformin-associated hypoglycemia can develo in a patient who is not critically ill without lactic acidosis. Because many patients receiving metformin also take sulfonylureas, hypoglycemia shoul be anticipated after overdose. Phenformin ingestion alone rarely causes

hypoglycemia, both in overdose and with therapeutic use.[115]

The Î±-glucosidase inhibitors, thiazolidinediones, and meglitinides are ne agents for which overdose data are limited. Acarbose likely does not caus hypoglycemia based on its mechanism of action of inhibiting Î±-glucosida The most common adverse effects associated with its therapeutic use are gastrointestinal, including nausea, bloating, abdominal pain, flatulence, a diarrhea. Elevated aminotransferase concentrations were noted in clinical trials.[53] Most patients were asymptomatic, and the aminotransferase concentrations returned to normal after the drug was discontinued. In Sp the therapeutic use of acarbose in some cases reportedly led to hepatotoxicity that resolved after the drug was discontinued.[4 , 22] Althou hypoglycemia is unexpected after thiazolidinedione overdose, experience limited. The most serious adverse effect of troglitazone is the developme of liver toxicity with therapeutic doses, which in some cases was severe enough to require liver transplantation.[45 , 89] Liver toxicity related to therapeutic use of rosiglitazone[2 , 42] and pioglitazone is also reported.[73] Hypoglycemia should be anticipated after repaglinide and nateglinide ingestion.[83] A case of repaglinide-induced factitious hypoglycemia is reported.[51]

Diagnostic Testing

Suspicion of possible hypoglycemia is particularly important in the patien with an abnormal neurologic examination. The most frequent reasons for failure to diagnose hypoglycemia and mismanaging patients are the erroneous conclusions that the patient is not hypoglycemic but rather is psychotic, epileptic, experiencing a CVA, or intoxicated because of an â€œodor of alcoholâ€• on the breath (Chap. 75). Compounding the problem of misdiagnosis is the erroneous assumption that a single bolus 0.5â€“1 g/kg of dextrose 50% in water (D_{50} W) for an adult will always b sufficient.

Serum glucose concentrations are accurate, but treatment cannot be dela pending the results. Glucose reagent strip testing can be performed at th bedside. The sensitivity of these tests for detecting hypoglycemia is

excellent, but these tests are not perfect. In a comparison of reagent stri to serum glucose determinations, 87% of the reagent strips were within 0 mg/dL of the actual glucose concentration.[113] This determination was accurate for plasma glucose concentrations < 350 mg/dL. Remember that hypoglycemia is primarily a clinical and not a numerical disorder. Patients with poorly controlled diabetes in particular may become symptomatic at higher glucose concentrations than those without the disease.[16] The threshold reagent strip concentration that should be used as the basis for administration of hypertonic dextrose is debated, but based on the availa data[113] we suggest a cutoff of 90 mg/dL is appropriate. Note that toxic concentrations of acetaminophen and certain sugars (ex maltose) can produce false elevations of glucose concentrations noted by Glucometer I and Accu-Chek Advantage glucose meters.[23] Bedside glucose testing is discussed in more detail in Antidotes in Depth: Dextrose .

Several new glucose monitoring devices now are available. Alternate-site testing allows patients the convenience of using small amounts of blood obtained at sites other than the fingertip. Alternate-site testing results compare favorably with fingertip results when readings are obtained durir fasting and 2 hours postprandial, but not at 1 hour postprandial and immediately postexercise.[12] Continuous glucose monitoring devices also available. One such product is noninvasive and is worn like a wristwatch.[Another device requires the insertion of a subcutaneous sensor.[48] These monitoring systems appear to be useful for monitoring trends and detect unrecognized hypoglycemia, particularly at night. However, the delay in reporting results and the potential for error limit their use for rapid detection of hypoglycemia.

Diagnostic studies other than determinations of glucose concentrations m be indicated, depending on the clinical situation. In some instances, determination of serum ethanol concentration may be helpful in confirmir alcohol as a contributing or sole etiologic factor. Renal function tests may indicate the presence of renal impairment as a causative factor of hypoglycemia. This commonly occurs in diabetics taking insulin, who ofte develop renal failure after they have had the disease for several years. Insulin half-life increases as renal function declines. Measures of hepatic

function may be a clue to liver disease as a cause of hypoglycemia, altho liver disease may also be evident on physical examination. Seizures are commonly associated with hypoglycemia, but other studies, such as electrolytes, calcium, magnesium, and computed tomographic scanning o the brain, may be indicated if doubt about the etiology exists.

In the majority of overdose cases, laboratory testing for specific antidiabetics is not helpful. Exceptions might include malicious, surreptitious, or unintentional overdoses (discussed in the section on Evaluation of Malicious, Surreptitious, or Unintentional Overdose). Metformin concentrations in the setting of

overdose and metformin-associated lactic acidosis are variable and do no necessarily correlate with the clinical condition.[1 , 64 , 65]

[a] Insulin levels are determined during fasting hypoglycemia at low concentrations, preferably <60 mg/dL of blood glucose.

[b] Sulfonylurea ingestion is diagnosed by detection of the drugs or their metabolites in plasma or urine.

[c] The antiinsulin antibodies produced spontaneously differ from those of treated (exposed to exogenous insulin) and those of untreated insulin-dependent diabetics.

[d] The presence of antiinsulin antibodies occurs less frequently in those exposed only to human insulin.

Clinical State	Insulin[a] (Plasma) (ÂµUnit/mL)	C-Peptide (Plasma) (nmol/L)	Proinsulin (pmol/L)	Antiinsuli Antibodies

TABLE 48-6. Laboratory Assessment of Fasting Hypoglycemia

For known diabetics in whom overdose is not suspected, the clinician mus search diligently for the cause of hypoglycemia. Sometimes it is as simple a missed meal or an unusually strenuous exercise routine, but in many ca

the cause is not so clear. Numerous medical conditions, as well as a varie of medications, may be involved (Table 48-1), and diagnostic testing mu be individualized episode depending on the clinical suspicion. Diagnosing etiology as â€œidiopathicâ€• is never acceptable.

Evaluation of Malicious, Surreptitious, or Unintentional Overdose

The physical examination may provide helpful clues to the evaluation of a suspected malicious, surreptitious, or unintentional insulin overdose. A meticulous search may reveal a site that is erythematous, hemorrhagic, atypically boggy in nature, or even painful if the subcutaneous (or intramuscular) injection of insulin was particularly large. Even a simple unexplained needle puncture mark in the appropriate clinical setting may suggest insulin injection.

An understanding of how the Î² cells of the pancreas secrete insulin in response to glucose concentrations in the blood is essential to understan the investigation of fasting hypoglycemia.[30] When the plasma glucose concentration is < 45 mg/dL, insulin secretion should be almost complete suppressed, so plasma insulin concentrations should be minimal or absent.[101] Moreover, insulin is secreted as proinsulin, which is cleaved in vivo to form insulin (a double-stranded peptide) and C-peptide, which are released into the blood in equimolar quantities. Insulin is biologically act whereas proinsulin has limited activity, and C-peptide has no activity. Although insulin is normally cleared during hepatic transit, C-peptide is n For this reason, C-peptide can be utilized as a quantitative marker of endogenous insulin secretion. Commercially available exogenous human insulin does not contain C-peptide fragments (Table 48-6). When plasma glucose concentration falls to hypoglycemic concentrations (usually < 60 mg/dL), insulin secretion should fall to less then 6 ÂµUnit/mL. If hypoglycemia is caused by exogenous insulin administration, plasma C-peptide concentrations should be < 0.2 nmol/L in the presence of insulin concentrations that are substantially higher than insulin concentrations resulting from an insulinoma. With insulinoma, insulin concentrations

generally are > 6 ÂµUnit/mL in the presence of hypoglycemia. Insulinoma results in elevations of both C-peptide and insulin concentrations. Sulfonylurea overdose is expected to have similar effects, but concentrat in reported cases of sulfonylurea-induced hypoglycemia vary considerably and can be within normal ranges.[34] In the face of uncertainty, sulfonylur concentrations are readily available from reference laboratories. Animal insulin can be distinguished from human insulin by high-performance liqu chromatography.[46] However, this technique has limited use because of th virtually exclusive use of human insulin at present.

In summary, patients with chronic insulin-induced factitious or surreptitio hypoglycemia will have high insulin concentrations, the presence of insuli binding antibodies,[39] and low C-peptide concentrations. Those who have taken sulfonylureas will have high insulin concentrations, absent insulin-binding antibodies, high C-peptide concentrations, and presence of urinar sulfonylurea metabolites (Table 48-6). The issues of evidence collection that are appropriate to document malicious or surreptitious use of insulin successfully have been described[71] (Chap. 135).

Management

Treatment centers on the correction of hypoglycemia and the anticipation that hypoglycemia may recur. Symptomatic patients with hypoglycemia require immediate treatment with 0.5â€“1 g/kg concentrated intravenous dextrose in the form of D_{50} W in adults, D_{25} W in children, and D_{10} W in neonates. Occasionally, patients require a larger dose to achieve an initia response. If hypoglycemia is suspected but not confirmed, as in the abse of rapid reagent strip availability or when such readings are â€œborderline,â€• dextrose should be administered. Theoretical risks ar associated with use of concentrated dextrose in the setting of cerebral ischemia, but failure to rapidly correct hypoglycemia may lead to deleter neurologic effects. Appropriate emergency and toxicologic uses of hypert dextrose are covered in detail in Antidotes in Depth: Dextrose . When concentrated dextrose is administered with potential nutritional deprivati a dose of 100 mg thiamine hydrochloride also should be given in view of

substantial association between hypoglycemia, alcoholism, and malnutriti Correction of thiamine deficiency prevents development of Wernicke-Korsakoff syndrome.

The kinetics of intravenous administration of 25 g D_{50} W have been studi in healthy euglycemic nondiabetic volunteers,[9] limiting

extrapolation to the clinical setting. At 5 minutes postinjection, glucose concentrations rise rapidly to a mean of 244 mg/dL and return to baseline 30 minutes. No mechanism reliably extrapolates back to pre-D_{50} W concentrations.

Glucagon should not be considered as an antihypoglycemic agent except the uncommon situation where intravenous access cannot be obtained. Glucagon has a delay to onset of action and may be ineffective in patient with depleted glycogen stores, as in the elderly, cancer patients, or alcoholics. Glucagon also stimulates insulin release from the pancreas, w may lead to prolonged hypoglycemia in settings such as sulfonylurea ingestion and insulinoma.[131]

Numerous articles have evaluated approaches for treating insulin reactior with carbohydrates in tablet, solution, or gel forms in a well-defined diab population.[118] None of these forms is appropriate for the undefined, poss hypoglycemic patient. Patients who have significant clinical symptoms of hypoglycemia are at risk for grave CNS complications unless they are treated quickly and adequately with glucose.

A common occurrence involves symptomatic hypoglycemic patients who receive intravenous dextrose in the prehospital setting and subsequently refuse transport to the hospital. The authors of a retrospective review of 571 paramedic runs involving hypoglycemic patients concluded that out-c hospital treatment of hypoglycemic diabetic patients is safe and effective even when transport is refused.[119] However, of the 159 patients who agr to hospital transport, 40% were admitted. The authors of a prospective study involving 132 hypoglycemic diabetic patients who refused transport after therapy concluded that most such patients have good short-term outcome, but they still encouraged transport because of the risk of recur

hypoglycemia.[82] One patient died in each of these 2 studies. A prospectiv study in 35 patients with 38 hypoglycemic events related to insulin use concluded that most patients were successfully treated.[69] Study participa were treated in the field and not transported to a healthcare facility. However, 2 patients developed recurrent hypoglycemia that they treated themselves, and 1 of these patients required placement in a long-term ca facility for hypoglycemic encephalopathy. We emphatically encourage the further education of paramedics and restructuring of their protocols, emphasizing the importance of transporting all hypoglycemic patients to EDs.

Emesis, lavage, and catharsis are of limited benefit in the management o patients who overdose on oral antidiabetic and hypoglycemic agents. The extensive affinity between chlorpropamide, tolazamide, tolbutamide, glyburide, glipizide, and activated charcoal is demonstrated in vitro.[58] Th affinities ranged from 0.45â€“0.52 g/g activated charcoal at pH 7.5 and were higher at pH 4.9. Single-dose activated charcoal should be beneficia the management of these overdoses. Although affinity studies are lacking the other oral agents, their chemical characteristics are such that single-dose activated charcoal is expected to be beneficial for these overdoses a well. Multiple-dose activated charcoal and whole-bowel irrigation may be benefit and should be considered after overdose of modified-release oral agents.

In patients who overdose on insulin, case reports describe the use of surgical excision of the injection site.[21 , 70 , 79] However, this technique not been studied in a systematic fashion, so further data are necessary before this approach can be recommended. Needle aspiration of a depot is less invasive and should be considered.

Urinary alkalinization to a pH of 7â€“8 can reduce the half-life of chlorpropamide from 49 hours to approximately 13 hours. Urinary alkalinization is not useful for other oral antidiabetics.[90]

Maintaining Euglycemia After Initial Contro

After the patient is awake and alert, further therapy depends on the xenobiotic involved and pancreatic islet cell function. Some patients, particularly those with prolonged hypoglycemia, may have persistent alte mental status despite euglycemia. Whether the event was unintentional o intentional with suicidal or homicidal intent must be determined. One problem associated with dextrose administration occurs in individuals who can produce insulin via glucose-stimulated insulin release (nondiabetics a those with type II diabetes mellitus), placing them at substantial risk for recurrent hypoglycemia. This complication can occur with insulin overdos but is particularly problematic with overdoses of sulfonylurea or meglitini because these oral agents stimulate insulin release. Treatment with hypertonic dextrose solutions can be expected to result in dramatic yet o transient increases in glucose concentrations, with a subsequent fall in serum glucose concentration possibly back to hypoglycemic levels.

For diabetic patients who unintentionally inject an excessive amount of insulin, feeding should be initiated and intravenous access maintained wh avoiding routine dextrose infusion. In the event of recurrent hypoglycemi a concentrated dextrose bolus should be used. Overdose in the setting of suicidal or homicidal intent likely involves significant quantities of insulin Nondiabetics may be particularly prone to significant hypoglycemia becau they lack insulin resistance. Feeding should be initiated and glucose concentrations maintained in the 100â€“150 mg/dL range using a concentrated dextrose infusion (D_{10} W).

Some patients may require even more concentrated dextrose infusions, s as 20% dextrose in water (D_{20} W) augmented by repeated doses of D_{50} W Central venous lines should be used when D_{20} W infusion is instituted, because concentrated dextrose solutions are substantial venous irritants. The presence of glycosuria is not an adequate indicator of euglycemia; frequent serial blood glucose or reagent strip glucose concentrations sho be obtained. The appropriate timing of glucose monitoring varies depend on the clinical situation. Mental status must be observed. As a rough guid glucose monitoring every 1â€“2 hours after initial control is reasonable, subsequent spacing of the intervals to once every 4â€“6 hours. Phosphat concentrations should be monitored because glucose loading may lead to

hypophosphatemia.[84] Potassium concentrations should be checked becau glucose administration may lead to hypokalemia in nondiabetics and hyperkalemia in patients with impaired insulin secretion.[27] The duration o sampling necessary depends on the stability of the patient, the underlyin metabolic disorders, the extent of overdose, and the rate of improvemen When the patient begins to eat an adequate diet and the initial hypoglyce is controlled, the serum glucose concentration will rise, and the concentration and rate of infusion can be tapered. Many patients may actually develop significant hyperglycemia.

The therapeutic approach differs for patients who overdose on sulfonylur or meglitinides. After initial control of hypoglycemia with concentrated dextrose, the patient should

be fed. Intravenous access is necessary, but routine dextrose infusion should be avoided. As with insulin overdose, frequent monitoring of gluco concentrations and mental status is critical. We recommend early use of octreotide in this setting because of the significant risk of glucose-stimulated insulin release.

Octreotide, a semisynthetic long-acting analog of somatostatin with an intravenous half-life of 72 minutes, inhibits glucose-stimulated Î²-cell ins release via receptors coupled to G proteins on Î²-islet cells.[14] Somatostat is present in diverse tissues such as the hypothalamus, pancreas, and GI tract. It alters the secretion of growth hormone and thyroid-stimulating hormone, gastrointestinal secretions, and the endocrine pancreas (glucag and insulin).[106 , 107] Octreotide was compared to intravenous hypertonic dextrose and to diazoxide and concomitant dextrose in normal subjects brought to hypoglycemia using glipizide.[14] Fewer episodes of recurrent hypoglycemia occurred after octreotide therapy, and overall dextrose requirements were lower than in the dextrose-alone and dextrose-plus-diazoxide groups. Several successful clinical experiences with octreotide reported with quinine-induced hypoglycemia resulting from malaria therapy,[97] insulinoma,[50] nesidioblastosis of infancy,[33] hypoglycemia rela to therapeutic use of gliclazide,[17] and tolbutamide overdose.[14] In a retrospective study of 9 patients with hypoglycemia resulting from either

glyburide or glipizide, octreotide effectively reduced the risk of recurrent hypoglycemia.[80]

Octreotide appears to be relatively free of serious side effects. The most likely adverse effects are injection-site discomfort if the agent is administered subcutaneously and gastrointestinal symptoms such as naus bloating, diarrhea, and constipation.[72] The suggested adult octreotide do is 50 Âµg subcutaneously every 6 hours (Antidotes in Depth: Octreotide) Like octreotide, diazoxide may be effective in patients with refractory sulfonylurea-induced hypoglycemia.[56 , 94] However, because of its potent to cause hypotension, diazoxide should be considered only if octreotide is ineffective or unavailable.

Admitting Patients to the Hospital

The decision to admit a patient may be complex, but several guidelines c be followed. Admission is required for hypoglycemia related to ethanol, starvation, hepatic failure, and renal failure and for hypoglycemia of unknown etiology. Patients receiving therapeutic doses of insulin require inpatient evaluation of recurrent and unexplained hypoglycemic episodes. patients with hypoglycemia after unintentional overdose with long-acting insulin should be admitted. Hospitalization is recommended after unintentional overdose with ultrashort-acting, short-acting, or intermedia acting insulin if hypoglycemia is persistent or recurrent during a 4- to 6- observation period in the ED. Many factors may be responsible for unintentional insulin overdose, such as patient error because of impaired vision, syringe structure, and prescription error, and hospital admission r be warranted. Admission is indicated for any patient, regardless of serum glucose concentration or presence or absence of symptoms, who intentionally overdoses on a sulfonylurea or any form of insulin, because delayed, profound, and protracted hypoglycemia may result. Although ins overdose by the intravenous route is expected to result in more immedia symptoms, experience with this scenario is limited. Admission in this sett is advised unless short-acting insulin is involved. Admission is not routine indicated for patients taking therapeutic doses of insulin who become

hypoglycemic after a missed meal. Hypoglycemia related to sulfonylurea in any setting requires hospitalization.[19]

Patients with possible self-induced factitious hypoglycemia should be admitted. â€œFactitiousâ€• (intentionally self-induced) hypoglycemia is most commonly recognized by members of the medical profession. Administration of insulin to a nondiabetic child is a form of child abuse or attempt at homicide.[35] Children who have been given an inappropriate do of insulin, as well as any patient who may be a victim of attempted homicide, should be admitted.

A 4- to 6-hour observation period is recommended after metformin overdose. Further observation or hospital admission is not required for patients who remain asymptomatic during this period with no evidence of metabolic acidosis or hypoglycemia. Patients who overdose on acarbose a not expected to have delayed or serious systemic toxicity, and routine medical admission is unnecessary. Although hypoglycemia is unlikely afte thiazolidinedione overdose, experience cases is limited and admission is recommended. Significant hypoglycemia is reported with repaglinide used a factitious setting.[51] Repaglinide is a new agent that is expected to beha like a sulfonylurea. For this reason alone, hospital admission after repaglinide overdose is advisable, even when the patient is asymptomatic

Children who unintentionally ingested one or more sulfonylurea tablets should be admitted. Although this recommendation may be controversial some authors suggest shorter observation periods[20] or even home monitoring in some cases,[108] we believe that delayed effects of sulfonylu ingestion in children are well documented in the literature[103 , 121 , 128] a convincing enough to support admission in all cases. Asymptomatic childr with single-tablet exposures to sulfonylureas are perhaps best managed without prophylactic intravenous glucose, which could contribute to delay onset of hypoglycemia.[20] Such patients instead are best managed by earl feeding, frequent checks of glucose concentrations, and observation of mental status.

Metformin-Associated Lactic Acidosis

The biguanides are uniquely associated with the occurrence of lactic acidosis. Phenformin causes lactic acid production by several mechanisms interference with cellular aerobic metabolism and subsequent enhanced anaerobic metabolism. Phenformin suppresses hepatic gluconeogenesis fr pyruvate and causes a decrease in hepatocellular pH, resulting in decreas lactate consumption and hepatic lactate uptake. Metformin-associated lac acidosis occurs 20 times less commonly than that occurring with phenfor In isolated perfused rat liver, metformin inhibits both hepatic lactate upt and conversion of lactate to glucose.[104] Lactic acidosis related to metfor usually occurs in the presence of an underlying condition, particularly ren impairment.[25 , 63] In this setting, increased tissue burden of metformin, which is renally eliminated, probably occurs. Other risk factors include cardiorespiratory insufficiency, septicemia, liver disease, history of lactic acidosis, advanced age, alcohol abuse, and use of radiologic contrast media.[8 , 25] Iodinated contrast material may induce acute renal failure, leading to accumulation of metformin and subsequent risk for developme of lactic acidosis. However, the risk of developing lactic acidosis after contrast administration is low in patients taking

metformin who have normal renal function and no other risk factors.[78 , 8

Severe lactic acidosis occurs after metformin overdose[65 , 81 , 93 , 130] but appears to be uncommon. In 1 case,[81] lactic acidosis was not diagnosed until 14 hours after metformin overdose. The patient had early symptoms repeated vomiting at 1 hour postingestion. In a series of 13 metformin overdose cases reported to a French pharmaceutical company, 7 patients presented with lactic acidosis.[65] The 13 cases were selected based on the overdose history and for whom arterial pH, arterial lactate, and metformi plasma concentrations were obtained. The authors do not document the number of overdose cases not included in the study. In a larger poison center series of 65 adult cases of metformin overdose, 2 patients develop significant lactic acidosis, 1 of whom died.[122] One patient developed disseminated intravascular coagulation, and hypoglycemia occurred in 7 patients with concomitant insulin or sulfonylurea overdose. The remaining cases were described as having minimal toxicity. In a poison center series

55 children exposed to metformin, lactic acidosis was not reported, and n significant adverse effects were noted.[123] The doses ingested ranged fron 250 mg to 16.5 g, with a median of 500 mg.

A systematic review from the Cochrane Library concluded that therapeuti use of metformin is not associated with an increased risk of lactic acidosi compared with other antidiabetic treatments if no contraindications are present.[109] This conclusion was based on a review of prospective comparative trials and observational cohort studies. However, the risk of metformin-associated lactic acidosis in the setting of overdose setting or renal insufficiency was not assessed. Although lactic acidosis after overdo is not common, it does occur with sufficient frequency to require vigilanc on the part of the treating physician. Case reports were not used in the Cochrane review, and a few cases of metformin-associated lactic acidosis the setting of therapeutic use with no underlying risk factors are reported , 96 , 132

Metformin-associated lactic acidosis is a potentially lethal condition. Recognition and awareness of this disorder are important. Symptoms may nonspecific and include abdominal pain, nausea, vomiting, malaise, myal and dizziness. However, gastrointestinal symptoms are common adverse effects associated with therapeutic use of metformin and do not necessar require discontinuation of the drug. More severe clinical manifestations o metformin-associated lactic acidosis include confusion, mental status depression, hypothermia, respiratory insufficiency, and hypotension. Plas metformin concentrations can be obtained as a diagnostic aid but may no correlate with the clinical state in both the acute overdose setting and in setting of therapeutic metformin use. In a series of 13 cases with metfor overdose, 6 of 7 patients with lactic acidosis had elevated metformin concentrations.[65] Of the 6 patients without lactic acidosis, 3 had markedl elevated metformin concentrations. In a series of cases of lactic acidosis related to therapeutic use, 10 of 14 patients had elevated metformin plas concentrations.[64]

Aggressive airway management and vasopressor therapy may be required Indications for use of intravenous sodium bicarbonate in critically ill patie

with lactic acidosis of various etiologies are poorly defined and controver Rather than using an arterial pH cutoff, we recommend using sodium bicarbonate given evidence of impaired buffering capacity based on a ser bicarbonate concentration of < 5 mEq/L. Based on case reports, hemodialysis using a sodium bicarbonate buffer may be effective in improving acidâ€“base status and clinical outcome in patients with significant lactic acidosis.[49 , 63 , 66] In some of these cases, metformin concentrations were measured and remained abnormally high after dialys Clinical improvement despite inadequate removal of metformin may be related to correction of acidâ€“base status.

Summary

Numerous xenobiotics and medical conditions may cause hypoglycemia. Hypoglycemia is the predominant adverse effect related to therapeutic us and overdose of the drugs used for treatment of diabetes mellitus. Variou clinical manifestations, particularly neurologic, may occur and can be confused with conditions such as ethanol intoxication, psychosis, epilepsy and cerebrovascular accidents. The potential for delayed and prolonged hypoglycemia must be recognized in overdose situations. Although severa treatment options exist, rapid intravenous administration of glucose is th most important measure. Octreotide is useful for patients with refractory hypoglycemia following sulfonylurea or meglitinide overdose.

Dextrose (D-glucose)

Adenosine triphosphate (ATP) furnishes the metabolic energy that fuels critical cellular processes in all organs. In the adult human

brain, anaerobic and aerobic metabolism of glucose through glycolysis and the tricarboxylic acid cycle, respectively, are the primary sources of ATP (Chap. 48). Whereas the adult brain can utilize fatty acids, amino acids, and ketones as alternate substrates for ATP synthesis under aerobic conditions, glucose is the only substrate for ATP production in the brain of the fetus or neonate.[77,95] The onset of hypoglycemia is followed rapidly by cerebral dysfunction. Hypoglycemia causes neurologic effects that are clinically indistinguishable from those of a variety of toxic-metabolic and structural brain injuries, which can include focal stroke syndromes, seizures, confusion, delirium, and coma.[5,23,31,53,67,81,98,104] Hypoglycemia precipitates myocardial stress and is associated with angina, electrocardiographic changes, and dysrhythmias.[32,57,66,68,69] In most cases, these effects reverse following treatment of hypoglycemia. However, prolonged or severe hypoglycemia may result in permanent brain injury, myocardial infarction, and death.[33,84]

Administration of 0.5â€“1 g/kg concentrated intravenous dextrose immediately reverses the clinical effects of uncomplicated hypoglycemia if the duration of hypoglycemia is brief (Table A11-1). Because of the myriad presentations of hypoglycemia, the difficulties inherent in making the clinical diagnosis, and the serious consequences of failure to treat the condition, the empirical administration of hypertonic dextrose to all patients with altered mental status was a standard emergency department practice.[13,43,44] Previously only clinically insignificant or rare complications were attributed to this practice. The complications were readily accepted when contrasted with the risks of delayed recognition and treatment of hypoglycemia. For example, intravenous administration of dextrose causes hypophosphatemia that is clinically insignificant in healthy individuals.[3,48,63,76] Dextrose infusion may precipitate hyperkalemia in diabetic patients with type IV renal tubular acidosis.[3,38] Concern that the osmotic effects of hypertonic dextrose could precipitate pulmonary

edema in critically ill patients with fragile cardiac function has been expressed.[51] Rarely, administration of hypertonic dextrose is associated with lactic acidosis in cancer patients with large tumor burdens.[39] Concentrated dextrose solutions commonly cause phlebitis and sclerosis of veins; tissue necrosis follows soft-tissue infiltration of $D_{50}W$.[29] Tissue infarction follows inadvertent intraarterial injection of $D_{50}W$.[6] Inappropriately large boluses of $D_{50}W$ in children are associated with seizures, hyperosmolar coma, and death. Seizures and subdural hemorrhage followed administration of 100 mL hypertonic dextrose to a 20-kg child, whereas administration of 280 mL $D_{50}W$ to a 15-kg child resulted in death.[83] Anecdotal reports of precipitation of acute Wernicke encephalopathy by administration of dextrose led to the concomitant administration of thiamine as part of the â€œcoma cocktailâ€•[44] (Antidotes in Depth: Thiamine Hydrochloride). The most serious complications of administration of hypertonic dextrose are caused by medication errors, such as inadvertent substitution of a look-alike bolus of concentrated lidocaine or magnesium.[45]

Concerns Regarding Elevated Blood Glucose Concentrations in Patients with Cerebral Ischemia

An expanding body of clinical literature demonstrates that the presence of hyperglycemia upon admission is associated with poorer outcomes in patients with acute cerebrovascular accidents.[13,28,34,47,71,74,100] Complications include increased rates of hemorrhagic conversion,[14] larger infarction volumes,[9,20,34] higher incidence of cerebral edema,[90] and increased mortality.[15,20] In two studies, the magnitudes of blood glucose concentration elevation that persisted after an acute stroke were positively correlated with larger infarction volumes as measured by MRI, poor functional outcome, and increased death rate.[9,20]

The largest study to date is a retrospective evaluation of data from 624 patients reported in the National Institute of Neurological Disorders and Stroke (NINDS) study of thrombolysis in acute stroke. The study confirmed a strong association of hyperglycemia upon admission with a worse outcome in thrombotic stroke. The effect of admission blood glucose concentration on the outcome of acute stroke was closely related to the magnitude of blood pressure upon admission. The likelihood of a favorable outcome decreased with increased blood glucose and blood pressure upon admission. Hyperglycemic patients also had an increased risk for subsequent intracranial hemorrhage, whether or not they received thrombolytic therapy.[14] As in similar studies, examination of these data could not prove a cause-and-effect relationship between hyperglycemia and a poorer outcome in stroke.[14] A conundrum has been created by the difficulty of demonstrating a clear delineation of the primary effect of hyperglycemia on the ischemic brain from hyperglycemia that accompanies an intense sympathetic â€œstressâ€• response to severe brain injury. In the latter case, hyperglycemia may be an epiphenomenon related to more extensive or severe injury rather than a cause of injury.[20,70,105] A study supporting the contention that hyperglycemia is an independent predictor of increased infarction severity relied on the inability to measure elevated catecholamines in stroke patients with hyperglycemia.[94] In addition, no study has demonstrated that hyperglycemia is not simply a marker of increased cerebrovascular disease in diabetics.[14,74] In the NINDS study, 72% of patients with admission blood glucose concentrations > 200 mg/dL were known diabetics. Because hemoglobin A_{Ic} concentrations were not measured, the possibility

that other patients in this category had previously undiagnosed diabetes cannot be excluded.[14] A prospective randomized controlled study evaluating the effect of glycemic control on outcomes in stroke has not been performed, thus precluding an

assumption of a cause-and-effect relationship between hyperglycemia and increased brain injury. This situation is being evaluated in the Glucose Insulin in Stroke Trial (GIST).[79]

TABLE A-11-1. Dosing of Dextrose

Bolus	
Adult	
$D_{50}W$ (50% = 0.5 g/mL)	0.5â€“1.0-g/kg bolus
Child	
$D_{25}W$ (25% = 0.25 g/mL); 1:1 dilution of $D_{50}W$ with sterile water	0.5-g/kg bolus
Infant	
$D_{10}W$ (10% = 0.1 g/mL); 1:4 dilution of $D_{50}W$ with sterile water	0.5-g/kg bolus
Infusion	
Adults and Children	
$D_{10}W$ (10% = 0.1	Titrate Infusion as indicated

g/mL) D_5W (5% = 0.05 g/mL)	to maintain serum glucose in normal range

A deleterious effect of hyperglycemia appears to be independent of the presence of diabetes mellitus in some diabetic animal models. Whether the data on the adverse vascular effects of diabetes in animal models are comparable to those in humans is not clear.[48,97,99,101]

Clinical studies of global ischemia in patients with cardiac arrest demonstrate that admission hyperglycemia is a poor prognostic indicator. In 430 prehospital patients resuscitated from cardiac arrest, 276 patients who awakened had significantly lower blood glucose concentrations than 154 patients who did not (mean 262 mg/dL vs. 341 mg/dL, $p = 0.0005$). In 90 awake patients with persistent neurologic deficits, mean blood glucose concentration was 286 mg/dL compared with 250 mg/dL in patients who recovered fully ($p = 0.02$).[62] A poor prognosis is also demonstrated in head trauma patients with admission hyperglycemia.[35,54,107]

The cellular biochemical changes that occur in the setting of ischemia are extensively investigated. Global ischemia is associated with rapid depletion of brain glucose, ATP, and phosphocreatine, followed by a rapid rise in intracellular lactic acid, disruption of energy-dependent electrolyte gradients, increased intracellular calcium, activation of phospholipase, and generation of destructive free radicals.[7,48,87,88,91,97,100,102] Many researchers propose intracellular accumulation of lactic acid is a primary cause of cellular injury,[4,48,77,87,89,97,100] but this proposal is debated. A study suggests that lactate is a useful energy substrate in the reperfusion period and implicates corticosterone in the deleterious effects.[78] Other investigators have demonstrated postsynaptic glutamate (*N*-methyl-D-aspartate [NMDA]) receptor activation in the setting of hyperglycemia, which

is associated with programmed cell death in other models.[11,58,60] This debate likely will continue.

Hyperglycemia is associated with increased capillary permeability in ischemic tissue and delays in resolution of intracellular calcium elevation during recovery from ischemia.[7,30] Significant increases in neutrophil deposition are demonstrated in areas of focal brain injury associated with hyperglycemia, suggesting a role in injury production.[61] Hyperglycemia may interfere with membrane repair systems by suppressing the synthesis of â€œheat shockâ€• proteins in injured cells.[21,102] Administration of insulin to control hyperglycemia has been shown to decrease the extent of ischemic injury.[25,27,42,59,99,100] Because insulin promotes the synthesis of â€œheat shockâ€• protein in ischemic cells, it may have a protective effect that is independent of its effect on blood glucose.[93,96]

Controlled laboratory investigations of ischemic brain injury consistently demonstrate that higher blood glucose concentrations are associated with more extensive cerebral injury. Most of these studies consisted of animal models of global cerebral ischemia that used cardiac arrest or four-vessel ligation or models of focal ischemia that used one- or two-vessel ligation.[72] These studies showed deleterious effects of hyperglycemia on a variety of outcome end points, such as death, evidence of cerebral edema, and neurologic recovery.[22,25,26,37,46,55,75,85,86] The most severe injuries are evident when ischemia is incomplete or focal so that a small amount of blood flow is present, as when collateral circulation is present near an area of focal infarction.[24,49,73] Hyperglycemia, however, has not been shown to be detrimental in fetal and neonatal animal models of anoxia.[16,95] Hypoglycemia was associated with worse outcomes in all models in which it was studied.[25,49,86]

Physical Examination in Hypoglycemia

Neither the history nor the physical examination reliably detects patients who are hypoglycemic.[43,44] Symptoms of tachycardia, diaphoresis, pallor, hypertension, tremors, hunger, and restlessness tend to predominate when the decline in blood glucose concentration is rapid. However, the symptoms can be blunted by Î²-adrenergic antagonists. Central nervous system symptoms of glycopenia include headaches, visual disturbances, psychiatric disturbances, confusion, stupor, coma, seizures, and focal neurologic findings and are nonspecific.[65,81,82] In pediatric patients, the only symptom of neuroglycopenia may be lethargy or irritability.[106]

Clinical Implications of Studies of Hyperglycemia and Cerebral Ischemia

The clinical and laboratory studies have led to calls for reassessment of the standard practice of routine inclusion of $D_{50}W$ in the cocktail antidote for patients with altered mental status.[13,43] Although clinical studies do not prove that hyperglycemia is more than a stress-related epiphenomenon or a marker for diabetes-related cerebrovascular insufficiency, an overview of both clinical and laboratory studies offers a preponderance of evidence that hyperglycemia likely has an independent role in the extent of brain injury induced by ischemia. A thoughtful assessment recognizes the possible detriment of raising blood glucose concentrations in a patient whose altered mental status or focal neurologic symptoms are caused by ischemia. This must be weighed against the risk of failure to treat hypoglycemia and the potential resultant permanent neurologic injury. Without question the reversal of hypoglycemia is a sound clinical intervention in the patient who is hypoglycemic, and the failure to administer dextrose in a timely fashion to a patient with significant hypoglycemia can result in permanent neurologic injury. This dilemma remains particularly consequential in the

prehospital setting where reliable testing of blood glucose concentration is limited.

The new guidelines for management of patients with stroke recommend the avoidance of glucose-containing fluids and advocate for aggressive control of hyperglycemia while still avoiding hypoglycemia.[1,41]

Reliability of Bedside Blood Glucose Determinations

The bedside diagnosis of hypoglycemia is limited by the lack of availability of reagent strips that have the same reliability and accuracy of the chemistry laboratory. Sensitivities of commonly available reagent strips for detection of hypoglycemia range between 92% and 97% in various studies.[17,18,19,50,56,64,80] The accuracy of these tests is affected by the source of blood, whether venous or capillary,[8,36,52,92] and by the presence of shock.[8,92] Accuracy also can be altered by the hematocrit[10] and the presence of isopropyl alcohol in the sample.[40] A study of 66 critically ill newborns that defined critical hypoglycemia as < 30 mg/dL found a sensitivity of 100% for the detection of hypoglycemia for each of two different reagent strips.[64] False-positive capillary determinations of hypoglycemia have been demonstrated in patients in shock and cardiac arrest. A study of capillary samples in 50 patients with cardiac arrest identified 8 patients as hypoglycemic. The laboratory evaluations confirmed that 3 of these patients were hypoglycemic and that no results were false-negative. Reagent strip testing of venous blood correctly classified these 8 patients.[92] A critical care unit study that evaluated patients in shock showed that 32% were incorrectly diagnosed as hypoglycemic when capillary blood was used. Results of reagent strip tests of venous blood correlated well with laboratory results, correctly classifying all patients. No cases of hypoglycemia were

missed.[8]

Several studies have compared the accuracy of standard reagent strips for the detection of hypoglycemia from capillary and venous blood compared with the gold standard of the laboratory. As indicated, use of capillary blood from patients with cardiac arrest or shock is associated with an increased false-positive rate for detection of hypoglycemia. Two studies, one with 97 subjects[36] and one with 270 subjects,[52] evaluated the agreement between reagent strip determinations of capillary and venous blood glucose in healthy normoglycemic volunteers. Correlation in the normoglycemic range was poor (Pearson correlation 0.24 and 0.5, respectively), with a tendency for capillary measurements to correlate more closely with the laboratory measurements and to be higher than venous measurements. In the larger study, 18% of subjects had a > 15 mg/dL difference between capillary and venous reagent strip tests. In these ranges, capillary measurements were better correlated with the laboratory values. In the lower ranges of normoglycemia, the capillary sample appeared to underestimate its venous counterpart.[36,52] Whether these results have any clinical significance is not clear because none of the subjects fell out of the normoglycemic range. They suggest that the capillary blood glucose test has greater accuracy in the normoglycemic range.

The â€œsafeâ€• number at which no cases of symptomatic hypoglycemia are missed by reagent strip testing is a subject of debate because of the inherent risk of error from lack of sensitivity. In addition, poorly controlled diabetics experience hypoglycemic symptoms at blood glucose concentrations that normally are regarded as euglycemic. In one study where hypoglycemia was defined as a blood glucose concentration < 60 mg/dL, 2 of 33 hypoglycemic patients were not detected. A cutoff of 90 mg/dL would have detected 100% of numerically hypoglycemic patients.[56] An important study of diabetics demonstrated that the mean blood glucose concentration for

symptomatic hypoglycemia in poorly controlled diabetics was 78 Â± 5 mg/dL compared with 53 Â± mg/dL in normal controls.[12] Based on these studies, it can be argued that a bedside reagent measurement of 90 mg/dL is a conservative cutoff for assurance of clinical euglycemia in all patients.

Pharmacokinetics of Dextrose

Studies of the pharmacokinetics of dextrose are limited, so predicting the amount of dextrose required to effectively treat hypoglycemia is difficult. At equilibrium, 25 g dextrose distributed in total body water in a 70-kg adult is calculated to raise the serum glucose concentration by about 60 mg/dL.[44] In the few clinical studies performed, the magnitude of glucose elevation after oral or intravenous loading is highly unpredictable. In one study, administration of 25 g (50 mL) $D_{50}W$ to adults resulted in a mean blood glucose elevation of 166 mg/dL; however, the range of this elevation was 37â€“370 mg/dL above baseline.[2] In a human model of insulin-induced hypoglycemia, oral administration of 20 g dextrose raised serum blood glucose concentration 60 to 120 mg/dL over 1 hour, whereas 10 g raised the concentration from 60 to 100 mg/dL.[103]

Conclusion: A Rational Clinical Solution

An ideal clinical solution to the management of patients with altered mental status or focal neurologic symptoms misses no cases of significant symptomatic hypoglycemia but avoids the administration of dextrose to patients with brain ischemia. A realistic approach can be fashioned from our understanding of the reliability of reagent test strips and a risk-to-benefit assessment of the presenting problem.

Infants and neonates should receive dextrose when clinically indicated without concern for associated ischemia or anoxia

because the detrimental effect of hyperglycemia seems to be absent in this age group. The patient with coma or status epilepticus from hypoglycemia benefits greatly from empiric treatment with dextrose and suffers the greatest morbidity if not treated. Furthermore, a patient who is comatose from a major cerebrovascular accident has a very limited chance for recovery, and administration of dextrose likely will not impact heavily on the prognosis compared with a missed diagnosis of significant hypoglycemia. Administering $D_{50}W$ to patients in coma who do not have a measured blood glucose of at least 90 mg/dL determined by bedside reagent strip testing is rational. Similarly, although confusion and delirium without focal neurologic findings can occur as manifestations of structural brain injury, toxic-metabolic etiologies are more common. These altered patients should receive dextrose if the glucose concentration determined by bedside test is < 90 mg/dL. When a reliable bedside glucose determination is not readily available, all of these patients should receive $D_{50}W$ empirically.

Rapid reagent glucose samples of capillary blood are especially unreliable in the patient with hypotension or cardiac arrest; however, bedside reagent strip testing of venous blood appears to be more reliable.[8,80,92] Patients in shock or cardiac arrest should

undergo reagent testing using a venous blood sample (not a fingerstick sample) and should receive dextrose if results indicate they are numerically hypoglycemic (< 90 mg/dL). Administration of dextrose to a patient with a cardiac arrest who is euglycemic as determined by reagent strip testing should be considered only if the patient is diabetic.

Patients with focal neurologic deficits due to ischemia constitute a population that is reasonably expected to receive the greatest benefit from maintenance of euglycemia. Although focal presentations of hypoglycemia are not rare, they are infrequent relative to the numbers of patients with focal presentations who

have suffered cerebrovascular accidents. In one study, 3% of patients with hypoglycemia presented with focal symptoms.[65] In the patient with a history of diabetes who presents with focal symptoms, symptomatic hypoglycemia must be strongly considered when the reagent strip shows a blood glucose concentration < 90 mg/dL.

The patient with a clear history and evidence of significant head injury antedated by normal activity (eg, crossing the street, being struck by a car) should not be treated unless the bedside test indicates hypoglycemia (< 60 mg/dL). Diabetic patients may suffer unintentional injuries predisposed by hypoglycemic episodes. The treating physician must use his or her best judgment of the mechanism and evidence of injury, witness' reports, available medical history, and result of bedside glucose determination to decide whether to administer $D_{50}W$ to the traumatized patient with an altered concentration of consciousness.

In summary, dextrose should be administered to all patients with altered levels of consciousness and numerical hypoglycemia (glucose concentration < 90 mg/dL). Concerns regarding the negative effects of elevated blood glucose concentration on cerebral ischemia should not cause a physician to withhold dextrose in patients with neurologic impairment when symptomatic hypoglycemia cannot be promptly and reasonably excluded. Dextrose should be empirically administered when bedside reagent strips are not available. Studies indicated that the currently available reagent strips reliably demonstrate the absence of significant hypoglycemia at readings > 90 mg/dL. Profound neurological impairment likely is not the result of hypoglycemia when such concentrations are demonstrated, even in a diabetic patient.

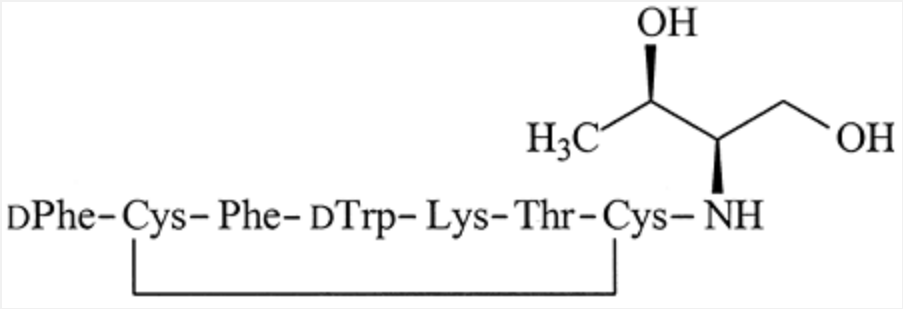
Antidotes in Depth

Octreotide

Mary Ann Howland



Octreotide is a long-acting, synthetic octapeptide analog of somatostatin that inhibits pancreatic insulin secretion. It currently is considered second only to glucose for the treatment of refractory hypoglycemia induced by overdoses of oral

hypoglycemic agents (eg, sulfonylureas) and quinine.

History

â€œSomatostatinâ€• is a collective term for shorter fragments (SRIF-28, SRIF-25, and SRIF-14) cleaved by tissue-specific enzymes from preprosomatostatin (116 amino acids) and prosomatostatin (92 amino acids).[9] Somatostatin was discovered in 1973, during the search for growth hormone releasing factor.[6] In addition to its effects on growth hormone and insulin secretion, somatostatin has far-reaching effects as a central nervous system (CNS) neurotransmitter and as a modulator of hormonal release.[26,32] Unfortunately, the role of somatostatin as a therapeutic tool is limited because somatostatin is short acting. Octreotide was purposefully synthesized in 1982 at Sandoz Labs in a quest to develop a longer-acting analog of somatostatin.[3] Octreotide currently is used therapeutically for the treatment of acromegaly, pituitary adenomas, pancreatic islet cell tumors, carcinoid tumors, portal hypertension, esophageal varices, and secretory diarrhea.[26] Octreotide is also being investigated for its inhibitory effects on tumor cell proliferation.[26,33]

Receptor Affinity

Somatostatin's effects are mediated by high-affinity binding to membrane receptors on target tissues. Five different somatostatin receptor subtypes that belong to a superfamily of G-proteinâ€“coupled receptors have been identified and assigned numbers (SSTR1â€“SSTR5) according to their order of discovery.[9] Octreotide has high binding affinity for subtypes SSTR2 and SSTR5, low affinity for subtypes SSTR1 and SSTR4, and intermediate affinity for subtype SSTR3.[26] SSTR2 is found in the pancreas, brain, pituitary, stomach, and kidney. SSTR5 is found in the brain, pituitary, heart, adrenal glands, placenta, small intestine, and skeletal muscle.[26,30,35]

Effects on Insulin Secretion and Other Hormones

Experiments using a whole-cell patch clamp technique on a hamster Î²-cell line suggest that somatostatin inhibits insulin secretion by a G-proteinâ€“mediated decrease in calcium entry through voltage-dependent Ca^{2+} channels.[20] No evidence indicates that somatostatin inhibits insulin release by promoting K^+ efflux through K^+ channels (Fig. 48-2).[27,34] However, evidence suggests that somatostatin, like epinephrine, stimulates a Gi-coupled receptor that inhibits adenylate cyclase and production of cyclic adenosine monophosphate (cAMP), thereby reducing insulin secretion.[19] Simultaneous distal reduction in protein kinase A also may be involved in reducing insulin secretion.[19] These mechanisms appear to be independent of Ca^{2+}.[19] Activation of SSTR5 on the Î²-cell of the pancreas also reduces insulin biosynthesis.[13] Experiments with somatostatin both in healthy human volunteers and in an isolated perfused canine pancreas model demonstrate the ability of somatostatin to inhibit glucose-stimulated insulin release.[1,15]

One study in human volunteers confirms the ability of somatostatin to inhibit the increased insulin response to both glucose and glucagon.[15] Intravenous (IV) infusion of 1 g tolbutamide over 2 minutes caused insulin concentrations to rise and serum glucose concentration to drop sharply. However, treatment with somatostatin blocked these changes. Similarly, in the presence of somatostatin and tolbutamide, administration of IV glucagon caused a rise in glucose concentration without the expected subsequent glucose-stimulated rise in insulin. These effects of somatostatin were short lived. Within 5 minutes of stopping the somatostatin, the insulin-releasing effects of tolbutamide continued, and within 15 minutes the serum glucose concentration fell. Peak insulin concentrations were achieved

within 25 minutes.

Studies comparing octreotide to somatostatin in rats and monkeys demonstrate that octreotide is 1.3 times as potent as somatostatin in inhibiting insulin secretion by 50%. Likewise, compared with somatostatin, octreotide was 45 times more potent in inhibiting growth hormone secretion and 11 times more potent in inhibiting glucagon release.[3] Comparable results were found using a hyperglycemic glucose clamp technique.[23] Octreotide blocks the counterregulatory response to the effects of 0.1 unit/kg IV insulin by preventing an increase in glucagon and growth hormone. In a subsequent study of the effects of octreotide on the responses of adrenocorticotropin, cortisol, prolactin, luteinizing hormone, and follicle-stimulating hormone to insulin-induced hypoglycemia, all remained intact.[27] In contrast, in this and other studies, growth hormone[12] and thyroid-stimulating hormone were significantly inhibited.[27]

Pharmacokinetics

The pharmacokinetics of IV and subcutaneous (SC) octreotide were studied in 8 healthy adult volunteers.[25] Subjects received 25, 50, 100,

and 200 Âµg IV octreotide over 3 minutes and 50, 100, 200, and 400 Âµg SC octreotide in random order. Following IV administration, the distribution half-life averaged 12 minutes, and the elimination half-life ranged from 72 Â± 22 minutes to 98 Â± 37 minutes and was linear. Vi (volume of distribution of the central compartment) was dose dependent and increased from approximately 5.7 L at 25, 50, and 100 Âµg IV to 10 L at 200-Âµg IV doses.[25] Vd (volume of distribution determined by area under the curve) was 18 Â± 6 L to 30 Â± 30 L and showed no dose dependency.[25] Renal elimination accounted for approximately 30% of the elimination and was reduced in the elderly and in those with

severe renal failure.[32]

After SC administration, bioavailability was 100%, and peak levels were achieved within 30 minutes with an absorption half-life of 5â€“12 minutes. The elimination half-life was 88â€“102 minutes. Peak plasma concentrations ranged from 2.4 ng/mL at doses of 50 Âµg to 23.5 ng/mL at doses of 400 Âµg, which represent approximately half of the intravenously administered level.[25]

The pharmacokinetics in patients with pathologic conditions may differ from the pharmacokinetics in healthy volunteers as exemplified by a lower peak concentration and a higher steady-state Vd in patients with acromegaly.[32]

The duration of action is variable. When used for tumor suppression, the duration may last up to 12 hours.[32] The duration of action for inhibition of insulin secretion is unknown.

Clinical use for Insulin Suppression

Octreotide was studied in several clinical conditions, including insulinomas and hypoglycemia of infancy.[2,16,22,37,38] In most instances, octreotide suppressed insulin concentrations, and glucose concentrations rose. However, worsening hypoglycemia is reported when glucagon suppression outlasted insulin suppression.[4,8,14,37] Octreotide currently is used for treatment of xenobiotic-induced endogenous secretion of insulin.

In controlled studies of healthy volunteers, octreotide suppressed the release of insulin associated with quinine.[36] Life-threatening hypoglycemia is a well-recognized complication of quinine treatment of *Plasmodium falciparum* malaria. In this setting, hypertonic dextrose and diazoxide therapy frequently is inadequate, with ensuing refractory hypoglycemia. In an investigation of the potential hypoglycemia-sparing effect of octreotide given for treatment of quinine-induced hypoglycemia, healthy adults were given 50 Âµg/h octreotide or placebo as a

continuous IV infusion for 4 hours, followed at the first hour by infusion of 490 mg quinine base.[36] In the control subjects, plasma insulin concentrations rose and plasma glucose concentrations fell significantly, whereas in the octreotide group, insulin concentrations fell and glucose concentrations remained constant. This effect of octreotide began within 30 minutes and persisted for 2 hours after octreotide was stopped. Octreotide was successfully used to treat refractory hypoglycemia in a woman receiving 600 mg quinine dihydrochloride IV for malaria.[36]

Several case studies and a case series of 9 patients support the efficacy of octreotide in overdoses of glipizide, glyburide, gliclazide, and tolbutamide (whether intentional or unintentional), in nonâ€“insulin-dependent diabetes or insulin-dependent diabetes, and in a pediatric patient.[5,7,10,11,17,18,21,23,28,31] In these case reports, therapeutic doses ranged considerably, and the most frequent doses were 50â€“100 Âµg subcutaneously repeated every 8â€“12 hours in the adult patients.

The efficacy of octreotide was demonstrated in a subsequent study. Eight healthy volunteers were given 1.43 mg/kg glipizide orally and randomized to receive either a variable dextrose infusion to remain euglycemic, diazoxide 300 mg IV over 30 minutes and repeated every 4 hours along with dextrose, or octreotide 30 ng/kg/min IV continuously.[5] Following administration of glipizide, hypoglycemia of 50 mg/dL was achieved within 30â€“165 minutes.[5] Insulin concentrations in the diazoxide group were comparable to those in the glipizide group, with resultant glucose concentrations slightly higher than the other groups. Four of the 8 patients in the octreotide group did not require supplemental dextrose. At the fifth hour of the protocol, an IV bolus of 50 mL 50% dextrose was given to the octreotide group to study the response to hyperglycemia. Approximately 6.5 hours was necessary for the plasma glucose concentration to drop to 85 mg/dL, whereas only 3 hours was necessary in the dextrose and diazoxide groups.[5] Diazoxide infusion was associated with higher

norepinephrine concentrations, whereas epinephrine concentrations were similar in all groups.[5] All xenobiotics were stopped at 13 hours, and plasma glucose concentrations fell to < 65 mg/dL within 1.5 hours in subjects who received the dextrose and diazoxide, whereas the plasma glucose concentrations remained > 65 mg/dL in 6 of the 8 octreotide subjects for the 4-hour observation period. Without additional octreotide, hypoglycemia continued to recur for as long as 30 hours after the initial glipizide administration.

Adverse Drug Effects

Octreotide is generally well tolerated, but experience in the toxicologic setting is limited. Adverse reactions occurring with short-term administration usually are local or gastrointestinal. Stinging at the injection site occurs in approximately 7% of patients but rarely lasts more than 15 minutes.[39] Healthy volunteers receiving octreotide noted no side effects when given IV doses of 25 or 50 Âµg or SC doses of 50 or 100 Âµg. At higher doses, early transient nausea and later-appearing but longer-lasting diarrhea and abdominal pain frequently occur.[24,25] Healthy volunteers were given IV bolus doses of octreotide as high as 1000 Âµg and infusion doses of 30,000 Âµg over 20 minutes and 120,000 Âµg over 8 hours without serious adverse effects. Single doses in healthy volunteers resulted in decreased biliary contractility and bile secretion.[32] Long-term therapy lasting weeks to months results in biliary tract abnormalities.[32,40] Product information warns of the potential for acute cholecystitis, ascending cholangitis, biliary obstruction, cholestatic hepatitis, and pancreatitis.[32]

Octreotide alters the balance among insulin, glucagon, and growth hormone. Glucose concentrations must be serially monitored. Hyperglycemia often occurs, but cases of hypoglycemia are reported. The most likely explanation is glucagon suppression

outlasting insulin suppression.[32]

Other adverse effects reported with long-term administration of octreotide include hypothyroidism, cardiac conduction abnormalities, worsening congestive heart failure (in at-risk patients with acromegaly), bradycardia, pancreatitis, altered fat absorption, and decreased vitamin B_{12} levels.[32] Anaphylactoid reactions are rarely reported.[32]

Drug interactions are expected with xenobiotics that affect glucose regulation. Octreotide may significantly decrease oral absorption of cyclosporine.[32]

Administration

Both SC and IV administration are acceptable, although the usual route is SC administration.[32] The SC administration sites should be rotated. For IV infusion, octreotide can be diluted in sterile 0.9% sodium chloride solution or D_5W and infused over 15â€“30 minutes or by IV bolus over 3 minutes.[32] Rapid IV bolus may be indicated for carcinoid crisis.[32] Refrigeration of octreotide is recommended for prolonged storage, although octreotide is stable at room temperature for 14 days when protected from light. Active warming of refrigerated octreotide is not recommended, although passive warming to room temperature prior to administration is suggested and may reduce the pain of SC administration.[29] Using the smallest volume possible reduces the pain with SC administration. A depot formula designed to last for 4 weeks is available (Sandostatin LAR Depot). Although the depot formula is useful for patients with insulinomas, its duration of action far exceeds that of any oral hypoglycemic agent, making it an inappropriate and unnecessary choice for management of xenobiotic-induced hypoglycemia.

Dosing

No controlled trials have evaluated the dose of octreotide for the management of sulfonylurea overdose. In adults, a 50-Âµg SC dose of octreotide given every 6 hours is suggested. In children, a dose of 4â€“5 Âµg/kg/d SC divided every 6 hours, up to the adult dose, can be used for initial therapy. This pediatric dose is derived from the literature on treatment of persistent hyperinsulinemic hypoglycemia of infancy.[16] In situations where compromised peripheral blood flow is expected, octreotide should be administered intravenously in the same dose but every 4 hours instead of every 6 hours. Further experience in the toxicologic setting should permit a better delineation of dosing recommendations. Several days of therapy may be required, depending on the duration of the offending agent. All patients must be carefully monitored for recurrent hypoglycemia during octreotide therapy and perhaps for 24 hours following termination of octreotide therapy before discharge. Octreotide is considered a category B drug (Table 30-2), and pregnant women must be carefully monitored for recurrent hypoglycemia. Use of octreotide should not diminish this vigilance.

Availability

Octreotide acetate (Sandostatin) injection is available in ampules and multidose vials ranging in concentration from 50â€“1000 Âµg/mL. The multidose vials contain phenol.

Summary

Octreotide is useful for treating refractory hypoglycemia induced by xenobiotics such as sulfonylureas and quinine that cause endogenous release of insulin. Octreotide is more effective than diazoxide in suppressing insulin and is much better tolerated.

Chapter 49
Thyroid and Antithyroid Medications

Nicole C. Bouchard

A 3-year-old boy was found with an empty bottle of his mother's levoth 300-Âµg tablets). The mother estimated he had ingested as many as 20 were found in the nearby area or in the child's mouth. The child cried whe â€œeatenâ€• the pills. He was brought promptly to the hospital. On initi asymptomatic and had stable vital signs: blood pressure, 100/60 mm Hg; respiratory rate, 16 breaths/min; temperature 98.6Â°F (37.0Â°C). He was (1 g/kg) mixed with juice, which he drank readily. A complete blood cou electrolytes, blood urea nitrogen, serum creatinine, urinalysis, and thyroid and the child was admitted to the pediatric intensive care unit (ICU). His 5â€“12 Âµg/dL), and total triiodothyronine (T_3) was 120 ng/dL (normal other laboratory test results were within normal limits for his age. He rem days before he was transferred to a regular pediatric ward. His behavior, examination were normal at that time. After 72 hours of observation, he from the hospital. The parents were advised to monitor for signs of hyp gastrointestinal upset, and they were taught how to measure his pulse ra immediately if the child became symptomatic.

According to his parents, the child became somewhat irritable on day 5

reported that he was more disruptive than usual in day school. That ever asleep. He was awakened at night with abdominal cramps and had 2 episo morning, his parents measured his pulse rate to be 130 beats/min. The p emergency department, where the triage nurse noted the child was â€œj follows: blood pressure, 120/80 mm Hg; pulse, 153 beats/min; respirator temperature 99.5Â°F (37.5Â°C). His physical examination was remarkable reactive pupils (bilaterally), vigorous bowel sounds, warm skin, and brisk not diaphoretic or confused. His ECG showed a sinus tachycardia.

He was readmitted to the ICU and treated with 60 mg liquid propranolol d days. His pulse rate decreased to 105 beats/min, and his blood pressure after the first dose of propranolol. He remained afebrile. He had 2 more complained of mild abdominal cramping for another 24 hours. Otherwise, well hydrated, and playful throughout. He was able to tolerate a normal revealed normal serum electrolyte concentrations and a normal complete tests revealed total T_4 of 24 Âµg/dL (normal 5â€“12 Âµg/dL), total T_3 20 ng/dL), and undetectable thyroid-stimulating hormone (TSH).

The patient remained in the ICU for 2 days (postingestion day 8) before l pediatric ward. On the ward, he required no further treatment with prop asymptomatic, except for a pulse rate of 110 beats/min. He was discharge hospital day 4 (postingestion day 9). On follow-up with his pediatrician 1 asymptomatic. His parents reported no further disruptive behavior, gastr tachycardia. His TSH concentration remained suppressed until 3 weeks a

History and Epidemiology

Long before the thyroid was recognized as a functional endocrine gland, t serve a cosmetic function, especially in women. Egyptian paintings often necks of women with enlarged thyroid glands. Other early theories on the thyroid gland include lubrication of the trachea, to protect women from â€œvexationâ€• from men and from the diversion of blood flow from the defined in historical accounts, symptoms resembling hypothyroidism and sheep thyroid were described 500 years ago. In the 16th century, Parace between goiter (thyroid gland enlargement) and cretinism.[67] A syndrome and exophthalmos was first described in 1786.[79] Graves and von Basedov

and its relationship to the thyroid gland 50 years later.[32, 35, 63, 79, 10

In 1891, injection of ground sheep thyroid extract was formally described myxedema.[35] Shortly afterward, oral administration of this therapy was c Seaweed, which contains large amounts of iodine, was used to treat goit medicine as early as the 3rd century A.D. In 1863, Trousseau[100] fortuitous Graves disease when he inadvertently prescribed daily tincture of iodine i a tachycardic, thyrotoxic young woman.

Sir Charles R. Harington described the chemical structure and performed (tetraiodothyronine [T_4]) in 1926.[81] Triiodothyronine (T_3) was not isola 1950s.[35] Prior to this time, desiccated thyroid gland from animal sources hypothyroidism. Despite becoming essentially obsolete in the modern me thyroid can be easily purchased via the Internet and in health food stores Unfortunately, the misguided use of thyroid supplements, both organic ar stimulants, and weight-loss aids has become increasingly common. Two e *thyrotoxicosis* that occurred in the United States in the mid 1980s secon beef contaminated with bovine thyroid gland demonstrated the potential sequelae following unknown thyroid hormone ingestion by a community.[4]

Today, hypothyroidism and hyperthyroidism are relatively common endoc incidence of neonatal hypothyroidism is 1 per 3000â€“4500 births. It is affects 1â€“7% of adults.[89] According to 2003 US retail pharmaceutical s prescriptions, Synthroid (T_4) was ranked second overall for total prescri 47,000â€“49,000 prescriptions written in 2003.[46, 73] Many cases of inte overdoses with thyroid hormone are reported in both adults and children. thyroid hormones on physiologic homeostasis and the widespread use and hormone, morbidity and mortality from overdose are very low overall.

Physiology

To properly understand the impact of thyroid supplements and antithyroid human body, an understanding of thyroid physiology is required. Thyroid following: (1) the hypothalamus, (2) the pituitary gland, (3) the thyroid g for the thyroid hormones (Figure 49-1).

The hypothalamus is an intermediate between cerebral centers and the p hypothalamus receives specific neurotransmitter stimulation, thyroid-releas produced. TRH is transported through the venous sinusoids to the pituita thyroid-stimulating hormone (TSH). TSH enters the circulation and stimul

of the thyroid hormones T_3 and T_4 by the thyroid gland. Thyroid physiolo autoregulation or â€œfeedback controlâ€• of hormonal function. When a released, they exert an inhibitory effect on the pituitary gland, leading to (Figure 49-1). Suppression or upregulation of TSH production is a freque the evaluation of the hyperthyroid and the hypothyroid state, respectivel

Thyroid hormones are tyrosine molecules with iodine substitutions. Two fo physiologically active: T_3 and T_4 (Table 49-1). Synthesis of these thyroid process. The amino acid tyrosine is concentrated in the follicles of the thy epithelial layer surrounding a proteinaceous colloidal substance called t contains a large amount of tyrosine. After iodide (I^-) is absorbed from t in thyroid cells by an active transport process called *iodide trapping* , wh by thyroid (iodide) peroxidase. Iodine rapidly iodinates tyrosine residues and diiodotyrosine (DIT). These substituted tyrosine molecules then combi ratio of T_3 to T_4 in thyroglobulin is 1:5. T_3 and T_4 (thyroxine) ultimately from the thyroglobulin matrix inside the follicles of thyroid gland.

Iodide trapping can be inhibited pharmacologically by monovalent anions pertechnetate (TcO_4^-), and perchlorate (ClO_4^-). Thyroid peroxidase is of intrathyroidal iodide and by thioamide drugs. High intrathyroidal iodide the release of thyroid hormone into circulation (Table 49-2).

Approximately 95% of circulating or peripheral thyroid hormone is T_4 ; th the peripheral T_3 is secreted directly by the thyroid; the balance results of T_4 to T_3 . When circulating T_4 enters the cell, it is deiodinated to T_3 . occurs by monodeiodination of either the outer ring or the inner ring by deiodinase, yielding 3,5,3â€²-T_3 and 3,3â€²,5â€²- triiodothyronine (rever approximately 3 times greater hormonal activity than T_4 . rT_3 is metaboli effects by binding to thyroid hormone receptors inside the nucleus. This receptors regulates gene transcription and protein synthesis, which ultim consumption and underlies the thermogenic effects of thyroid hormones.

Î²-Adrenergic antagonism, corticosteroids, ipodate, starvation, and severe deiodinase, which results in decreased production of metabolically active monodeiodination to metabolically inactive rT_3 (Table 49-2). This energ attenuation of the thermogenic effects of thyroid hormones in times of p

Pharmacology

T_4 and T_3

Thyroid supplementation for treatment of hypothyroidism is widespread in medicine. Thyroid hormones historically were derived from animal origin b synthetically produced. Desiccated thyroid (Armour) still is derived from both T_3 and T_4 . Because it is less pharmacologically stable and carries a thyrotoxicity from T_3 , its use has largely been supplanted by safer syn is the preparation of choice because of its low immunogenicity, 7- day ha regimen. Synthroid is the commercial name of the most commonly prescri (Cytomel or Triostat, available PO and IV) and liotrix (Thyrolar, available are seldom used secondary to their short half-lives, high cost, rare thera risk of thyrotoxicosis. The typical levothyroxine dose in adults is 1.7 Âµg patients are started on lower doses (range 12.5â€“Âµg/d [0.0125â€“0.025 sensitivity to thyroxine excess. Infants with congenital or acquired hypoth doses of 8â€“10 Âµg/kg/d (~25â€“50 Âµg/d). Older infants and children a kilogram: age > 12 years: 2â€“3 Âµg/kg once daily until the adult daily d reached; 6â€“12 years: 4â€“5 Âµg/kg/d or 100â€–150 Âµg once daily; 1â 75â€–100 Âµg once daily; 6â€–12 months: 6â€–8 Âµg/kg/d or 50â€–75 Âµ regard to suppression of TSH and elevation of T_4 is reached approximatel therapy. Doses usually are titrated in increments of 12.5 or 25 Âµg/d afte measurements. Different sources suggest that bioequivalence of Synthroi may and may not be equivalent.[17] Thyroid hormone concentrations and th should be followed when transitioning between levothyroxine formulations present an opportunity for an adverse drug reaction.

Pharmacokinetics and Toxicodynamics

In circulation, T_3 and T_4 both are highly and reversibly bound to plasma and 99.97%, respectively, in the nonpregnant adult. Thyroxine-binding gl approximately two thirds of the circulating thyroid hormones; albumin and remainder. It is estimated that only 0.4% of T_3 and 0.04% of T_4 exist in derived thyroid hormones exhibit similar binding characteristics when dosi

The amount of thyroid hormone bound to proteins varies greatly with dif pharmacologic conditions, for example, increasing in pregnancy and levo decreasing in chronic disease. Such changes in protein binding must be thyroid hormone concentrations in the blood (see Diagnostic Testing). T thyroid hormones is very large: 40 L/kg for T_3 and 10 L/kg for T_4 . Table pharmacokinetic properties of thyroid hormones.

The oral bioavailabilities of exogenous thyroid hormones are high: 80% fo Gastrointestinal absorption is thought to occur primarily in the duodenum absorption can be decreased by variations in intestinal flora and binding b containing antacids, calcium preparations, carbonate salts, sucralfate, iron cholestyramine resins, colestipol hydrochloride), and infant soy formula (

TABLE 49-1. Pharmacokinetic Properties of Thyroid Hormones

Thyroid hormones undergo their ultimate metabolism peripherally. Intra

accounts for approximately two thirds of inactivation. Most of the remain metabolism by glucuronidation or sulfation. Xenobiotics that induce hepa as rifampin, phenobarbital, phenytoin, and carbamazepine, increase the n (Table 49-2).

Inhibit TRH and TSH synthesis
Dopamine, levodopa, corticosteroids, somatostatin
No hypothyroidism
Inhibit thyroid hormone synthesis or release
Iodides (including amiodarone), lithium, aminoglutethimide
Hypothyroidism
Inhibit iodide uptake to thyroid gland
Monovalent anions (SCN^- , TcO_4^- , ClO_4^-)
Treatment for iodide-induced hyperthyroidism
Increase TBG
Estrogens, tamoxifen, heroin, methadone, mitotane
Altered thyroid hormone transport in serum
â†‘ Total measured thyroid hormone (vs. *free* hormone)
Decreased TBG
Androgens, glucocorticoids
Altered thyroid hormone transport in serum
â†“ Total measured thyroid hormone (vs. *free* hormone)
Displace T_3 or T_4 from TBG
Salicylates, mefenamic acid, furosemide
Transient hyperthyroxinemia
Inhibit thyroid peroxidase
Thioamides (methimazole, propylthiouracil)
Decrease thyroid hormone synthesis
Induction of hepatic enzymes
Phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin
â†“ Total thyroid hormone measurements
Inhibition of 5â€²-deiodinase
Iopanoic acid, ipodate, amiodarone, Î²-adrenergic antagonists, corticost
Decrease peripheral conversion of T_4 (â†“T_3 , â†‘rT_3)
Interfere with GI absorption of T_4

Cholestyramine, colestipol, aluminum hydroxide, sucralfate, ferrous sulfat infant soy formula
Decreased oral bioavailability of T_4
Induction of autoimmune thyroid disease

Interaction Xenobiotic Effect

TABLE 49-2. Xenobiotic Interactions: Effects on Thyroid Hormone

Pathophysiology

Thyroid hormones are critical for optimal physiologic growth and function. important determinant of basal metabolic rate (BMR). In addition, the th effect on many hormones, notably catecholamines and insulin.

Hyperthyroidism is a condition characterized by excess active thyroid hor carbohydrate and protein metabolism are increased in the presence of th metabolism and cholesterol synthesis are increased. The clinical picture c increased metabolism, along with tachycardia, tremor, anxiety, other beh tachydysrhythmias such as atrial fibrillation.[24, 54, 87] This constellation *thyrotoxicosis*, may result from overproduction of the hormone, increase excess exogenous hormone. Graves disease, an autoimmune disorder, is t excess thyroid hormone secretion. It accounts for approximately two thirds accompanied by exophthalmos. Severe thyrotoxicosis accompanied by dec *thyroid storm* or *thyrotoxic crisis.* Mortality in thyroid storm, even with t [24]

An increased in sensitivity to catecholamines is suggested to underscore inotropy and chronotropy produced by thyroid hormones. Plasma catecho established to be normal or decreased in hyperthyroid states.[14, 84] Altho thyroid hormones can cause decreased systemic vascular resistance leadin

cardiac output, two general mechanisms are proposed for the direct card
although their relative contributions are uncertain.[3,16,54,99] (1) T_3 in

intracellular signaling mechanisms that lead to increased catecholamine e
intracellular signaling activity involving protein kinase A, cyclic adenosine
and increased phosphorylation of thyroid hormone receptor proteins all a
degrees.[23,54,82,83,86,93,101] Enhancement of myocardial transmer
reticulum ion channel function, L-type voltage-gated Ca^{2+} channels, and
sarcoplasmic reticulum also are suggested.[50,51,72,92] Whether these
signaling represents a direct T_3 effect on intracellular signaling mediators
the individual Î²-adrenergic receptor response to catecholamines with a s
postreceptor signaling is unclear.[3]

In addition to these two mechanisms, T_3 upregulates synthesis of cardiac
TRÎ± and TRÎ² genes). Comprehensive reviews on this topic explore the
thyroid hormones and their effects on the cardiovascular system.[15,54,

with T_3 , can result in thyrotoxic symptoms. Comprehensive reviews of

Clinical Manifestation

The widespread availability and use of thyroid supplements make thyroid
in acute intentional and unintentional overdoses. In addition, chronic exc
is a relatively frequent occurrence. Symptoms of toxicity from exogenous

those of catecholamine excess. Pronounced catecholamine effects occur i especially tachycardia, tachydysrhythmias (usually atrial fibrillation or flu cardiac failure.[24, 54, 87] Interestingly, although hyperthyroid patients typ agitated, patients with thyroid storm may present with a decreased level coma.[8, 45, 57, 85, 91] Hyperthermia can occur secondary to the thermog hormones and psychomotor agitation. Hyperthermia can be extreme (ie, > tachycardia associated with thyrotoxicosis often is disproportionate to th

Acute Toxicity

Acute overdoses with thyroid hormone preparations most commonly occu Significant ingestions of levothyroxine usually do not manifest clinically u but are rarely reported to manifest as early as 2â€“3 days postingestion. peripheral conversion of T_4 to the metabolically active T_3 and the time t protein synthesis account for this clinical latency of hours to days follow administration. Acute overdoses involving preparations containing T_3 can hours days after exposure.[62]

In children, acute thyroxine overdoses almost universally are benign beca unintentional nature and lower doses ingested. Most pediatric patients re only mild symptoms. No deaths have been reported.[21, 28, 48, 58, 60, 6 with unintentional overdose, only 3 children developed mild symptoms 1 Similarly, large case series that involved 41 children (ages 1â€“5 years) thyroxine (estimated doses ranged from 40â€“800 Âµg) found mild symp tachycardia, fever, vomiting, diarrhea, diaphoresis, and flushing) in only 2 clinical outcomes. The degree of symptoms did not correlate with the am serum thyroxine concentrations (measured 1â€“5 hours postingestion) for Diagnostic Testing).[28] Two other series involving 78 and 92 cases of ur found that mild symptoms developed in only 4 and 8 patients, respective severe toxicity in children are reported: 1 child without a history of a seiz days after a levothyroxine ingestion (18,000 Âµg),[56] and another child be 12-hour period (blood pressure, 120/68 mm Hg; pulse, 200 beats/min; t hours after ingesting a large amount (3.2 g, or â€œ50 grainsâ€•) of a containing both T_3 and T_4 .[61]

Ingestions in adults have a wide range of toxicity. Many patients are asy

symptomatic.[30 , 64 , 76] Severe sequelae occur more frequently in adults resemble thyrotoxicosis and, in extreme cases, thyroid storm. Hyperther [58 , 91] and severe agitation[34] are well described. Hemiparesis,[8] muscle w respiratory failure,[26] sudden death,[7] myocardial infarction,[7] cardiac failu rhabdomyolysis with muscle necrosis,[8] delayed palmar desquamation (> and hematuria[34] are also described. Because patients are expected to be ingestion and laboratory tests correlate poorly with the degree of sympto findings early in the course of the ingestion are not reliable indicators of (see Diagnostic Testing).

Chronic Toxicity

Following chronic excessive thyroid hormone ingestions, patients may pre have a more subtle and insidious presentation. Classically, chronic ingesti occurs in patients with hypothyroidism, psychiatric disorders, and eating thyroid hormones chronically may develop significant weight loss, anxiety osteoporosis.[75] More severe manifestations, such as cardiac dysrhythmia and psychosis, also occur. As in patients with hyperthyroidism, intercurre stressors can trigger thyroid storm in these patients.

Numerous miniepidemics of hyperthyroidism and thyrotoxicosis have resul ground meat containing neck muscle contaminated with thyroid gland.[19] , these epidemics had 3 volunteers consume a single large portion of â€c implicated ground beef that previously had been frozen. Although all vo the mean serum peak T_4 (8â€“12 hours postingestion) was elevated ~15 undetectable for 4â€“17 days.[41] The practice of gullet trimming (using lar to these outbreaks has since been prohibited in US slaughter houses. The exists, especially when laryngeal muscles are used or when farmers and meat.[78] Until an exogenous source of thyroid hormone is suspected or id misdiagnosed with painless thyroiditis or thyrotoxicosis factitia.

Thyrotoxicosis factitia is a symptomatic disorder that mimics physiologic intentional chronic ingestion of exogenous thyroid hormone. The pattern surreptitious and maladaptive. Patients frequently have comorbid psychiat Munchausen syndrome or eating disorders, or are taking thyroid hormone with thyrotoxicosis factitia disorder often have access to thyroid medicatic

friends, or they can obtain the medications at their place of employment.

In recent years, thyroid hormones have gained popularity among dieters a hormones as weight-loss aids and as stimulants. Severe consequences car reported in 3 patients suspected of chronic ingestion of thyroid hormone enhancement.[7] In 2002, the heavily promoted Singaporean diet pill Slim and hyperthyroidism in numerous

patients.[39] Investigators found the proprietary herbal preparation was a amounts of the undeclared ingredients T_4 , T_3 (from thyroid gland extract banned drug). The medication was promptly withdrawn and the manufact Singapore Poisons Act.[39 , 40] Unfortunately, supplements containing thyro remain highly promoted and are readily available to the general public w Internet and in stores selling nutritional supplements (Chap. 44).[90]

Diagnostic Testing

Traditionally, thyroid testing was undertaken using combinations of measu measurement of hormone binding (T_3 uptake). Free T_4 and T_3 also can b dialysis (*free* T_4), analogue assays (ie, competitive analogs of either fre competitively bind for spaces on the serum-binding proteins), and antibo sequential assays that capture a representative portion of the free fractio Assessment of pituitary production of TSH has improved greatly in recent assays can readily detect suppression of TSH production. TSH is now relie thyroid function screening. Suppressed or elevated concentrations of TSH with a free T_4 assay and, if necessary, a free T_3 assay (Table 49-3).

The clinical manifestations of thyrotoxicosis and thyroid storm are well kn moderate, and high concentrations of T_3 and T_4 .[10] This lack of correlatio serum concentrations is also true for exogenous thyroid hormone ingestio [76 , 105] In a large case series of children with unintentional estimated in 40 and 800 Âµg), serum T_4 concentrations were drawn in 11 patients (1 Serum T_4 concentrations were normal in 5 of these children and were slig (mean 16 Âµg/dL). In this series, one infant who was estimated to have i significantly higher concentration (55 Âµg/dL at 4.5 hours) and developed diaphoresis and a â€œstaring spellâ€• 7 days postingestion. Another chil

Diagnostic Test	Normal Values[a]	Comments

TABLE 49-3. Diagnostic Tests for Thyroid Hormone and Thyroid F

Routine analysis of laboratory thyroid function tests in the setting of acu likely will not affect management. Analysis of thyroid hormone concentrat confirmation of a suspected ingestion is desired and in massive ingestions symptoms may occur. Suppression of TSH and elevated thyroid hormone serum thyroglobulin concentration may help to differentiate between thyr disease.[68]

Management

General

Based on the existing literature, conservative management is adequate in unintentional thyroxine ingestions in both adults and children. Most childr managed with home observation and follow-up appointments. In cases wh estimated to be > 4000 Âµg, patient follow-up by regular telephone conta Historically, most children with unintentional ingestions have been treated activated charcoal and/or syrup of ipecac or by gastric lavage,[28 , 48 , 56] procedures probably are unnecessary. Based on 2 large series of uninten which no toxicity was observed in the vast majority of cases, clinically si with estimated ingestions < 5000 Âµg.[78 , 102] Because children almost un minor symptoms, activated charcoal administration should be considered o Âµg thyroxine. Aspiration risks are minimal in awake, alert children who a and take activated charcoal orally, without nasogastric tube placement.[58] acute ingestions > 5000 Âµg thyroxine also should be treated with activa presentations with massive thyroxine ingestions (> 10,000â€“50,000 Âµg) ingestions of preparations containing large amounts of T_3 , gastric empty emesis and orogastric lavage are unwarranted.[8 , 34] Similarly, patients w 10,000â€“50,000 Âµg) or ingestion of T_3 -containing products should be anticipation of development of significant symptoms.[8 , 34 , 56 , 61]

Treatment should be based on the development of symptoms and should protection, and control of sympathomimetic symptoms, mental status alt Adrenergic antagonism with propranolol has been used for sympathomime cases.[28 , 48 , 56 , 60 , 76 , 95]

Empirical treatment with Î²-adrenergic antagonists is not recommended. T
for significant tachycardia, dysrhythmias, and other symptoms of catecho

Agitation

When sedation is required, parenteral benzodiazepines and barbiturates
benzodiazepines such as midazolam or diazepam should be used to contr
symptomatic patients. Phenobarbital should be considered as a sole agent
adjunct in patients requiring sedation because it offers the added theoret
enhanced hepatic elimination of thyroxine (Table 49-2). Because of the
the lack of evidence regarding the clinical use of enhanced hepatic elimi
sedation with phenobarbital for the sole purpose of enhanced elimination
antipsychotic agents such as haloperidol and droperidol should be avoide
anticholinergic properties can exacerbate thyrotoxic symptoms. In addition
drugs to prolong the QTc interval and predispose to malignant dysrhythmi
catecholaminergic patient. Antipsychotic agents should be reserved for m
strong psychiatric behavioral manifestations.

Catecholamine Excess and Cardiovascular

The principal mechanism of action of Î²-adrenergic antagonists in hyperth
receptorâ€“mediated effects.[75] In addition to their sympatholytic effects
inhibit 5â€²-deiodinase, thereby decreasing peripheral conversion of T_4 t
electrocardiographic and blood pressure monitoring are indicated when Î
used. The clinical significance of decreased peripheral conversion in the s
Propranolol is the most frequently used Î²-adrenergic antagonist in thyro
[63 , 76 , 95] Parenteral Î²-adrenergic antagonists should be used when sym
rapid control of heart rate is required. Starting doses of 1â€“2 mg IV pr
are recommended. High doses have been reported in massive thyroxine o
received 23 mg propranolol IV over 1 hour on initial presentation, then re
mg/day IV for 5 more days.[34] Oral propranolol can be used for persistent
both hemodynamically and medically stable and are not acutely agitated.
20â€“120 mg every 6 hours may be required. Other Î²-adrenergic antago
provided they do not have intrinsic sympathomimetic activity (ie, partial
receptors), such as acebutolol, oxprenolol, penbutolol, and pindolol (Chap

When Î²-adrenergic antagonists are contraindicated, as in patients with a heart failure, calcium channel blockers can be used. Among calcium chan most studied for the management of thyrotoxicosis.[71, 88] A double-blind, propranolol to diltiazem for thyrotoxic symptoms found that diltiazem was as effective as propranolol.[71] Another study successfully used diltiazem as of cardiovascular symptoms in 11 thyrotoxic patients.[88] Doses of 60â€“12 daily or 5â€“10 mg/hour parenterally have been used.[71, 88] A possible e calcium channel blockers in thyrotoxicosis is that thyroid hormone enhanc voltage-gated Ca^{2+} channels, accelerates Ca^{2+} entry into the sarcoplasm cellular Ca^{2+} storage capacity.[50, 51, 72, 92] The net effect of these chan chronotropy. Calcium channel blockers, particularly diltiazem and verapam of parenteral Î²-adrenergic antagonists in combination with parenteral cal contraindicated because of the risk for profound hypotension and cardiov

Hyperthermia

Antipyretics are recommended for hyperpyrexia, with acetaminophen being particularly high doses (1.5â€“3 g/d), should be avoided because it carrie thyrotoxicity from displacement of T_3 and T_4 from TBG (Table 49-2). No especially extreme hyperthermia (> 106Â°F [> 41Â°C]), most likely is se agitation and excess heat production from the hypermetabolic, catechola Extreme hyperthermia should be considered a medical emergency and sh treated with active external cooling with ice baths and with Î²-adrenergic benzodiazepines and/or barbiturates, and intubation with paralysis if nece

Other Therapies

Bile acid sequestrants, such as cholestyramine and colestipol, and alumir sucralfate bind to exogenous T_4 and decrease GI absorption (Table 49-2 supporting their effectiveness is poor, they are not routinely recommende overdose.[58]

Oral iodine contrast media is known to decrease peripheral conversion of PO daily are routinely used for thyroid storm. Thioamides, such as propy methimazole, and the corticosteroids are thyroid gland inhibitors that are

nonâ€“drug-related hyperthyroidism. In addition, thioamides inhibit periph Evidence from limited case reports suggests poor efficacy of both thioam overdose[8 , 26 , 58] (see Thioamides).

Although use of antithyroid drugs such as PTU, corticosteroids, and iodine overdose has theoretical benefits, these drugs are unvalidated, potentially additional benefit, or be superior, to conventional therapy with activated antagonism, and sedation. These treatments are not recommended as ac of exogenous thyroxine overdose.

Extracorporeal Drug Removal

Extracorporeal drug removal procedures, such as plasma exchange or pl transfusion (in children), and charcoal hemoperfusion, have been used in hormone overdose and thyroid storm.[1 , 8 , 9 , 26 , 42 , 58 , 62 , 69 , 74 , 97] regarding improvement of clinical condition and plasma clearances of thyr methods are

conflicting. The largest series of acute ingestions involved 6 patients who massive thyroxine ingestions of prescribed capsules containing a 1000-fol thyroxine (dose range 50,000â€“125,000 Âµg/d for 2â€“12 days). Charco plasmapheresis were used in all patients. Plasmapheresis was found to be hemoperfusion in the extraction of thyroxine. The authors suggest this in duration of thyrotoxicosis. Rebound elevations in plasma concentrations oc patients, suggesting redistribution between extravascular and intravascu redistribution is expected given the large volume of distribution for thyroi There may be a role for early plasmapheresis in the exceptional situation of thyroid hormone. Because the outcomes from most ingestions of thyroi with good supportive care, sedation, and Î²-adrenergic antagonism, the r be evaluated on case-by-case basis after consultation with a medical tox

Xenobiotics with Antithyroid Effects

Thioamides

Antithyroid drugs are used to decrease the amount of thyroid hormone ir commonly in Graves disease. Thioamides are a group of chemicals with tl Methimazole and PTU are the two principal thioamides used for treatmen Carbimazole, which is bioactivated methimazole, is available in Europe an both inhibit the activity of thyroid peroxidase in the thyroid gland.[98] PTU inactivating 5â€²-deiodinase, which decreases the peripheral conversion o active T_3 .[20 , 59] Because thioamides act primarily by decreasing thyroid release), a lag time of 3â€“4 weeks may occur before T_4 is depleted. The 50â€“80%. It is rapidly absorbed from the GI tract and may undergo first Although its plasma half-life is only 1.5 hours, its effects are long-lasting thyroid gland. PTU is inactivated by glucuronidation and is renally elimin absorbed, is concentrated in the thyroid, and is more slowly eliminated th Doses of PTU are in the range of 100 mg orally every 6â€“8 hours. Methir daily. Although PTU is 10 times less potent than methimazole, it is more for its use are mild-to-moderate hyperthyroidism.

The two thioamides traverse the placenta (methimazole more than PTU) a during pregnancy. However, they are minimally secreted in breast milk. A 3â€“12% of patients taking thioamides. The most common adverse effect rash. Methimazole, PTU, and, to a lesser extent, carbimazole can cause and age-related agranulocytosis and neutrophil dyscrasias.[61 , 70 , 80] This adverse effect can be treated by administration of granulocyte colony-sti withdrawal of thioamides can lead to rebound symptoms and thyrotoxic s

Little data exist regarding overdose with thioamides. A 12-year-old girl w who was estimated to have ingested 5000â€“13,000 mg PTU, developed c concentration and elevated alkaline phosphatase concentration (7350 mU functioning thyroid gland may have contributed to the benign course in th sequelae have been associated with acute overdose of thioamides.

Iodides

Prior to the development of thioamides, iodide salts were the principal t Iodides decrease thyroid hormone concentrations by inhibiting formation a high-dose iodides (> 2g/d) decrease thyroid hormone release and produc 2â€“7 days. Common sources of iodides include calcium iodide, sodium io

pharmaceutical preparations, oral drops commonly referred to as SSKI [s
methyl iodide (industrial preparations).

The adverse reaction to chronic ingestion of small or excessive amounts
is characterized by cutaneous rash, laryngitis, bronchitis, esophagitis, co
taste, salivation, headache, and bleeding diathesis. Immune-mediated h
consisting of urticaria, angioedema, eosinophilia, vasculitis, arthralgia, ly
anaphylactoid reactions may occur. Chronic iodide therapy has produced
rarely hyperthyroidism. As much as 10 g sodium iodide has been adminis
signs or symptoms of toxicity.

Iodide (I^-), unlike iodine (I_2) (Chap. 98), is not a caustic. KI is added
for prevention of goiter. It also is used as a prophylactic agent after expo
nuclear fallout to prevent uptake of radioactive iodine into the thyroid gla
most commonly used iodide for thyroid suppression in hyperthyroidism. Io
described but rare disorder characterized by severe sialadenitis (or paro
conjunctivitis following administration of ionic and nonionic iodine-containi
iodide salts (Table 49-4).[12, 13, 49] Although the mechanism remains unc
idiosyncratic or secondary to iodide accumulation and subsequent inflamm
the salivary gland. Symptoms tend to occur within 12 hours and resolve
hours.[12]

Iodides should be avoided in pregnancy because they readily cross the p
complications, such as cretinism and death from respiratory failure secon
reported.[22, 43, 66] Iodide salts adsorb to activated charcoal.

Methyl iodide is a methylating agent used in the chemical and pharmaceu
microscopy, as a catalyst in production of organic lead compounds, as an
in fire extinguishers, and formerly as a soil fumigant. Methyl iodide toxic
with early pulmonary congestion, lethargy, and renal failure. It also is a
degeneration, multifocal neuropathies (cranial nerve and spinal), Parkinso
persistent psychiatric symptoms (months to years).[2, 44] Chronic repeated
misdiagnoses such as multiple sclerosis. The toxicity is similar to that of
112).

Chapter 50
Antihistamines and Decongestants

Anthony J. Tomassoni

Richard S. Weisman

A 17-year-old man was brought to the emergency department by friends who noted progressive onset of drowsiness and confusion. The friends indicated the patient became progressively more disoriented and made statements that were out of context. The patient repeatedly told his friends that he was thirsty. Shortly thereafter, his friends reported he seemed to be responding to internal stimuli. Upon questioning by his friends while en route to the emergency department, the patient admitted taking â€œa bottlefulâ€• of diphenhydramine capsules in a suicide attempt between 1 and 2 hours earlier. The bottle was not located. Past medical history obtained from friends and family was negative. Family history was negative for epilepsy. Social history was positive for smoking and occasional ethanol and marijuana use. Upon initial evaluation, the patient was lethargic, he had no verbal response to questions, and when aroused with vigorous stimulation he became agitated and muttered unintelligible sounds. His initial vital signs were: blood pressure, 175/90 mm Hg; pulse, 135 beats/min;

respiratory rate, 18 breaths/min; temperature 100.0Â°F (37.8Â°C). His skin was warm, dry, and pink. Examination of the head, eyes, ears, nose, and throat was notable for 7-mm pupils that were sluggishly reactive to light and for dry mucous membranes. His neck showed no evidence of meningismus. Chest and heart examinations were normal except for tachycardia. Abdominal examination was remarkable only for absent bowel sounds. The patient's neurologic status was notable for periods of lethargy alternating with agitation upon stimulation and lack of spontaneous verbal output. During his agitation, the patient sometimes appeared to be picking at the bed sheets or the clothing of caregivers. Occasional myoclonic jerks were present. Deep tendon reflexes were symmetric and plantar reflexes were downgoing.

Oxygen was administered via nasal cannula at 2 L/min. Cardiac monitoring was instituted. Intravenous 0.9% sodium chloride solution was administered at a rate of 150 mL/h. Blood was sent to the laboratory for a complete blood count, electrolytes, glucose, toxicology screen, and acetaminophen concentration. A nasogastric tube was inserted, gastric fluid was aspirated to minimize potential for aspiration, and 50 g activated charcoal was administered. A Foley catheter was inserted, and nearly 1 L of clear urine was immediately drained. The patient's agitation improved immediately after this procedure. ECG revealed sinus tachycardia with a normal QRS duration of 0.08 seconds and normal QTc interval. Ethanol concentration was 55 mg/dL. No acetaminophen was detected, and immunoassay-based toxicology screen was negative for cyclic antidepressants and common drugs of abuse.

Approximately 3â€“4 hours after his ingestion, the patient had a grand mal, tonicâ€“clonic seizure that lasted approximately 2 minutes. As the seizure appeared to be subsiding, diazepam 5 mg was administered. Following the seizure, the patient had a brief postictal period. He then remained somnolent but arousable for 4 hours, after which he progressively became alert and oriented over the next 8 hours. His vital signs gradually returned to normal over

the same time period, and bowel sounds returned. The Foley catheter was removed, and the patient was able to void spontaneously. No significant rhabdomyolysis occurred. The patient was transferred for psychiatric assessment.

Antihistamines

History and Epidemiology

H_1 receptor antagonists were introduced into clinical use in the early 1940s. The class continues to find widespread application in the treatment of anaphylaxis, allergic rhinitis, urticaria, and other histamine-mediated disorders. The numerous functions of histamine and its receptors in the nervous system, immune system, and other organ systems have been further elucidated in recent years.

Antihistamines are available worldwide, and many do not require a prescription. They often are used for symptomatic relief of allergy symptoms and are included in many combination cold preparations. They also are found in nonprescription sleeping aids. Antihistamines are frequently ingested in suicide attempts, probably because of their ready availability. Poison center and clinical experience suggests that recreational use of antihistamines is increasing, but whether the increased use results simply from inclusion of antihistamines in cold preparations containing the widely abused cough suppressant dextromethorphan is unclear (Chap. 38). Terfenadine and astemizole were associated with cardiac dysrhythmias and are no longer approved for use in the United States[47] (Chap. 133).

Unintentional exposures to antihistamine-containing preparations are common, with > 14,000 cases involving children younger than 6 years reported annually.[32] Liquid formulations attractive to children are available, and children occasionally are administered diphenhydramine or another antihistamine as a sedative by parents and daycare workers.[3] Although ingestion is the usual route of

exposure, toxicity can also result from exposure to topical preparations containing antihistamines.[43]

Physiology of the Histamine Receptor System

Four types of histamine receptors are recognized and designated H_1 , H_2 , H_3 , and H_4 . All are helical transmembrane molecules that transduce extracellular signals via G proteins to intracellular second-messenger systems. H_1 receptors are located in the CNS, heart and vasculature, airways, sensory nerves, gastrointestinal smooth muscle cells, immune cells, and adrenal medulla. The many functions of histamine and the H_1 receptor include control of the sleepâ€“wake cycle, cognition, memory, and endocrine homeostasis. The H_1 receptor also causes vasodilation, increases vascular permeability and bronchoconstriction, and decreases atrioventricular nodal conduction when histamine is present. H_2 receptors are located in cells of the gastric mucosa, heart, lung, CNS, uterus, and immune cells. The action of histamine on H_2 receptor results in increased gastric acid secretion, increased vascular permeability, and other effects. Endogenous histamine is one of the triggers for gastric acid secretion through interaction with the H_2 receptor located on gastric parietal cells. This process results in increased adenyl cyclase and cyclic adenosine monophosphate (cAMP), with activation of the H^+ - K^+ -ATPase pump and ultimately release of H^+ into the gastric lumen.

H_3 receptors are found in neurons of the central and peripheral nervous systems, airways, and GI tract. The action of histamine on H_3 receptors of the CNS decreases further release of histamine, acetylcholine, dopamine, norepinephrine and serotonin.[64] H_3 receptors partly act to prevent excessive bronchoconstriction. H_3 receptors also are implicated in control of neurogenic inflammation and proinflammatory activity.[37] The recently identified H_4 receptor is located in leukocytes, bone marrow, spleen, lung, liver, colon, and

hippocampus. It apparently has roles in the differentiation of myeloblasts and promyelocytes and eosinophil chemotaxis. This chapter focuses on H_1 and H_2 antihistamines, as no H_3 or H_4 receptor active pharmaceuticals are currently in clinical use.

Pharmacology

Histamine Antagonists

All known H_1 histamine antagonists function as inverse agonists and not simply competitive antagonists.[54] For consistency with the medical literature and the current clinical use of these drugs, we use the terms *H_1 antihistamine* and *histamine antagonist* rather than inverse agonist to describe agents of this class.

Agonists and antagonists that act at each of the four histamine-modulated receptor sites have been identified. Through these receptors, histamine interacts with G proteins in the plasma membranes. Stimulation of H_1 receptors results in increased synthesis of inositol-1,4,5-triphosphate and several diacylglycerols (DAGs) from phospholipids located in cell membranes. Inositol-1,4,5-triphosphate causes release of calcium, which then activates calciumâ€“calmodulin-dependent myosin light-chain kinase, resulting in enhanced cross-bridging and smooth muscle contraction. The reaction at the H_1 receptors is mediated by phospholipase C. H_2 receptor stimulation is mediated by adenyl cyclase activation of cyclic AMP-dependent protein kinase in smooth muscle and in parietal cells of the stomach and results in increased gastric acidity through stimulation of the H^+ -K^+ -ATPase pump.

Six major classes of â€œfirst-generationâ€• antihistamines are traditionally recognized. They are first-generation derivatives of ethylenediamine, ethanolamine, alkylamines, phenothiazines, piperazines, and piperidines. Many of the classic antihistamines are substituted ethylamine structures with a tertiary amino group linked by a 2- or 3-carbon chain with two aromatic groups.[20] This structure

differs from histamine by the absence of a primary amino group and the presence of a single aromatic moiety. Figure 50-1 shows the structures of the pharmacologic classes of the antihistamines.

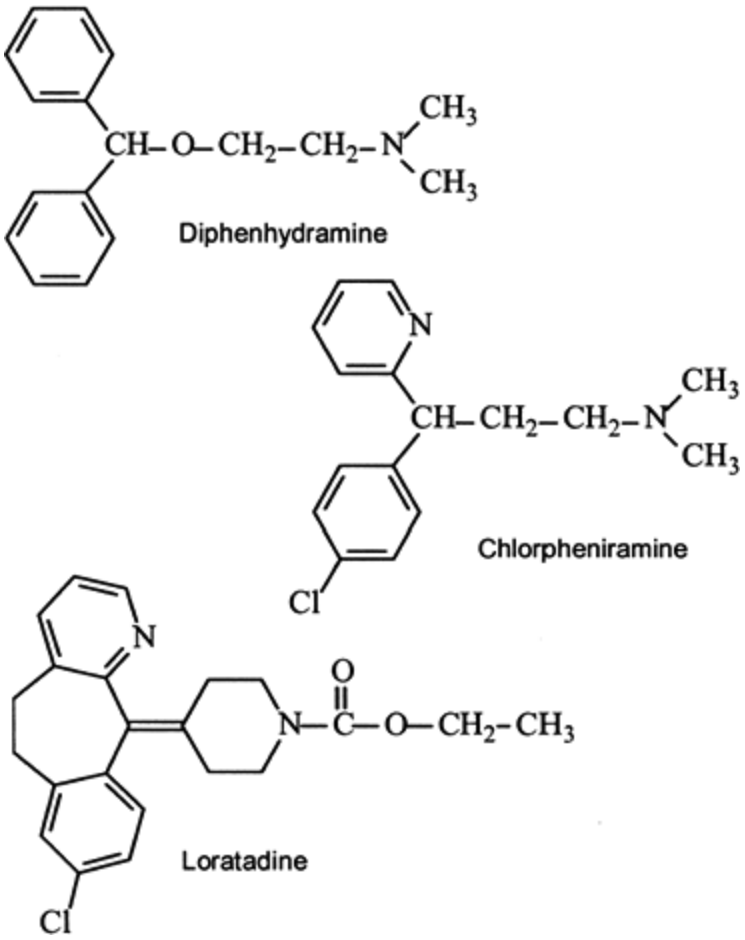

Figure 50-1. Structures of diverse H_1 receptor antagonists.

Currently, the more clinically useful classification may distinguish between the older â€œfirst-generationâ€• agents, which readily penetrate the bloodâ€“brain barrier and produce CNS effects, and the peripherally selective or â€œsecond-generationâ€• H_1 antihistamines, which have a higher therapeutic index. Central effects of the first-generation H_1 antihistamines likely result from their interference with histamine function as a neurotransmitter. The first-generation H_1 antihistamines also bind to muscarinic and

perhaps adrenergic receptors. In addition, some first-generation antihistamines are not recognized by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS. Second-generation H_1 receptor antagonists are highly specific for peripheral rather than central H_1 receptors receptors.[45] They do not penetrate the CNS well because of their hydrophilicity, their relatively high molecular weight, and recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS. Cetirizine, fexofenadine, loratadine, azelastine (nasal spray), and ebastine have lower binding affinities for the cholinergic, Î±-adrenergic, and Î²-adrenergic receptor sites than do the first-generation antihistamines. Some second-generation H_1 receptor antagonists, such as azelastine, a phthalazinone derivative, do not easily fit the standard classification scheme. Of note, using recommended doses of antihistamines, PET scanning shows that first-generation agents occupy > 70% of the H_1 receptors in the frontal cortex, temporal cortex, hippocampus, and pons. In contrast, the second-generation agents occupy < 20â€“30% of the available CNS H_1 receptors.[60, 61]

Given the absence of anticholinergic effects of the second-generation antihistamines, antihistamine therapy for patients with seasonal asthma has been reintroduced and has proved efficacious.[19] The relative incidence of anticholinergic and CNS adverse effects caused by second-generation H_1 antihistamines is similar to that produced by placebo.[2, 8] However, some patients report sedation, especially if higher-than-recommended dosages are taken.[8] Table 50-1 lists the peripheral selectivity of the antihistamine that is principally defined by the relative absence of anticholinergic and sedative properties of the H_1 antagonists.

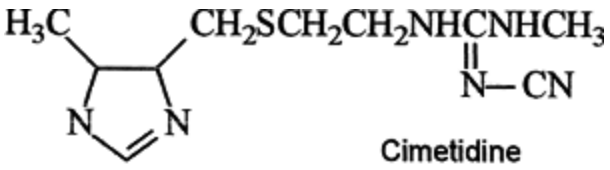
Antihistamine	Anticholinergic Class	Sedation	Duration of Action (h)	Typical Adult Dose

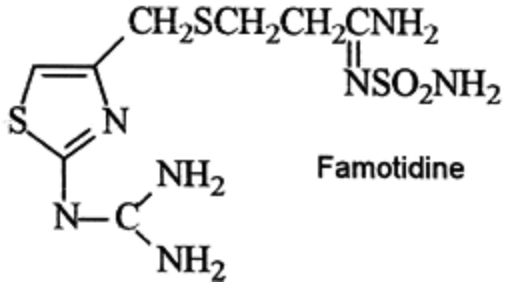
TABLE 50-1. The Pharmacologic Characteristics of Antihistamine

H_2 Receptor Antagonists

These histamine congeners are highly selective and competitively inhibit the H_2 receptor site. The original compound in this class, which retains the imidazole ring of histamine, is cimetidine (Figure 50-2). Although newer compounds, such as ranitidine and famotidine, have replaced this ring with a furan or thiazole group, respectively, they retain significant similarity to the histamine structure.[56]



Cimetidine



Famotidine

Figure 50-2. Structures of H_2 receptor antagonists.

The effectiveness of H_2 receptor antagonists in the treatment of gastroesophageal reflux disease is improved further by their concomitant alteration in the response of parietal cells to acetylcholine and gastrin, two other stimulants for gastric acid secretion (Figure 50-3). Of note, H_2 receptor antagonists have little effect elsewhere in the body, and they have weak CNS penetration secondary to their hydrophilic properties.

Reports on the effect of H_2 antihistamines on ethanol metabolism yield conflicting results. Definitive studies have not been performed, but at this time any effect at clinically relevant doses of alcohol appears insignificant. Questions regarding the effect of accelerated

gastric emptying time caused by H_2 antagonists on ethanol absorption, metabolic enzyme polymorphisms, interindividual variability of the effects of H_2 blockers on ethanol metabolism, and magnitude of the effect (if any) caused by different H_2 blockers remain to be answered.[22 , 59]

Pharmacokinetics and Toxicokinetics

H_1 Receptor Antagonists

The antihistamines are generally well absorbed following oral administration, and most achieve peak plasma concentrations within 2â€“3 hours. Although less well studied, dermal absorption appears to be consequential, especially with extensive or prolonged application to abnormal skin.[43] The maximum antihistaminic effect occurs several hours after peak serum concentrations. The durations of action range from 3 hours to > 24 hours, which is much longer than predicted from the extremely variable serum elimination half-life values of the antihistamines.

Hepatic metabolism is the primary route of metabolism for antihistamines.[48] Many Asian patients can acetylate therapeutic concentrations of diphenhydramine to a nontoxic metabolite twice as rapidly as white patients, making Asians much less sensitive to both the psychomotor and sedative effects.[58] Alterations in usual dosages may be required for patients taking other medications, those with hepatic or renal dysfunction, the young, and the elderly. Such modifications often must be made empirically because formal studies and recommendations for many agents are lacking. Drugâ€“drug interactions may be caused by modulation of CYP450 metabolism or interference with active transport mechanism (eg, P-glycoprotein).[54]

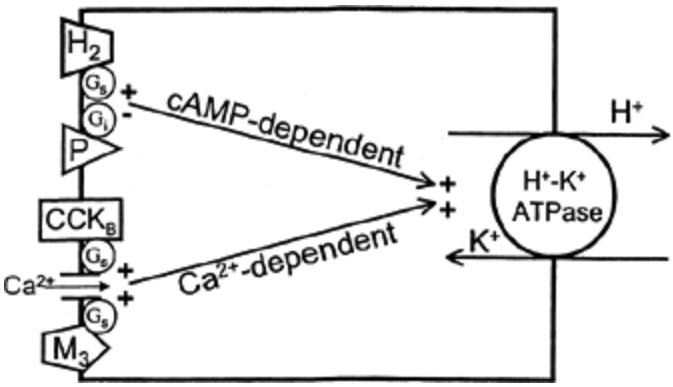


Figure 50-3. Schematic representation of a gastric parietal cell demonstrating the mechanism of hydrogen ion secretion into the lumen. Gastric acid is modulated by both calcium-dependent and cyclic adenosine monophosphate (cAMP)-dependent pathways. Histamine binding to the H_2 receptor increases gastric acidity by increasing cAMP through the stimulatory G protein G_S . Prostaglandins (P) decrease gastric acidity by decreasing cAMP through the inhibitory G protein G_i . Both acetylcholine and gastrin increase gastric acidity by increasing the influx of calcium through G_S interactions. Acetylcholine binds at the muscarinic$_3$ (M_3) receptor, whereas gastrin binds at the cholecystokinin B (CCK_B) receptor.

H_2 Receptor Antagonists

Cimetidine is the prototypical H_2 receptor antagonist. Cimetidine is rapidly and completely absorbed following oral administration. Cimetidine has a volume of distribution of approximately 2 L/kg, with 13â€“25% protein binding.[1] Up to 75% of cimetidine is eliminated unchanged in the urine, 15% is metabolized by the liver, and 10% is eliminated unchanged in the stool. The elimination half-life in patients with normal renal function is approximately 2 hours, but the half-life is substantially prolonged with impaired renal function.[1] Cimetidine is responsible for numerous drugâ€“drug interactions because it can inhibit cytochrome P450 activity, thereby impairing hepatic drug metabolism. It can reduce hepatic blood flow, resulting

in decreased clearance of drugs highly extracted by the liver. None of the other currently available H_2 receptor antagonists inhibit the cytochrome P450 oxidase system.[42] Additionally, by altering gastric pH, cimetidine and all the other H_2 antagonists may alter the absorption of acid-labile xenobiotics. Finally, cimetidine is associated with enhanced myelosuppression if it is administered with xenobiotics capable of causing bone marrow suppression.[51] Table 50-2 lists the pharmacologic properties of H_2 receptor antagonists.

TABLE 50-2. Pharmacology of Histamine H_2 Receptor Antagonists

Clinical Manifestations

H_1 Receptor Antagonists

Although dry mouth and mydriasis are common adverse therapeutic effects, sedation is of the greatest concern. Therapeutic antihistamine use may be as incapacitating as ethanol intoxication with regard to operating motor vehicles.[23] Compared with adults, children may more commonly present with excitation and irritability and may be more prone to hallucinations and seizures.

The clinical manifestations of H_1 receptor antagonist overdose are largely extensions of the adverse effects noted with therapeutic use of these agents. Following overdose with a first-generation H_1 antihistamine, patients typically present with CNS depression and an anticholinergic syndrome. Findings typically include mydriasis, tachycardia, fever, dry mucous membranes, urinary retention, diminished bowel sounds, and disorientation (Table 50-3). The patient's skin may appear flushed, warm, and dry. Hyperthermia correlates with the extent of agitation, ambient temperature and humidity, and length of time during which the patient cannot dissipate heat because of anticholinergic-mediated reduction in sweating. Ingestion of second-generation antihistamines usually does not result in significant CNS depression or anticholinergic effects. Some patients with therapeutic dosing or following overdose develop the central anticholinergic syndrome, in which CNS anticholinergic

effects, such as delirium or hallucinations, outlast peripheral anticholinergic effects. The lack of tachycardia, skin changes, or other peripheral anticholinergic manifestations complicates obtaining the correct diagnosis for antihistamine-poisoned patients who arrive late to healthcare and have a clear exposure history.[18, 65]

In a review of 136 patients with diphenhydramine overdose, somnolence, lethargy, or coma occurred in approximately 55% of patients, whereas 15% experienced a catatonic stupor.[34] Several reports suggest that young children experience more respiratory complications, CNS stimulation, anticholinergic effects, and seizures than do adult patients. In a placebo-controlled study comparing the CNS effects of first- and second-generation H_1 receptor antihistamines, the second-generation agents caused less cognitive

dysfunction and somnolence.[8, 26] This finding was corroborated in the simulated driving model, in which loratadine produced significantly less impairment than diphenhydramine.[23] Use of diphenhydramine compared with loratadine in a work setting results in significantly higher injury rates.[14]

Central Peripheral

TABLE 50-3. Anticholinergic Signs and Symptoms

Sinus tachycardia is a consistent finding following an antihistamine overdose with anticholinergic effects. Both hypotension and hypertension may occur.[39] These findings probably relate more to the patient's age, volume status, and vascular tone than to a specific class of antihistamines. As a result of sodium channel blockade following a large diphenhydramine overdose, prolongation of both the QRS complexes and QT intervals may occur.[31, 50, 52, 62] Of note, postmortem findings are generally limited to pulmonary and visceral edema, suggesting cardiogenic death.[33]

Mydriasis develops at both therapeutic and toxic doses, with most patients describing blurred vision and/or diplopia. Both vertical and horizontal nystagmus occur in patients with diphenhydramine overdose. Other CNS effects include seizures, hallucinations, acute extrapyramidal movement disorders, and psychoses.[13, 30]

Rhabdomyolysis can occur in patients with extreme agitation or seizures following an H_1 antihistamine overdose. Rhabdomyolysis is commonly noted in patients who overdose with doxylamine, even in the absence of trauma or any of the other common, etiologies such as seizures, shock, or crush injuries.[16, 35, 38] The mechanism is undefined. Rhabdomyolysis is reported as a rare adverse event following diphenhydramine overdose.[11]

Topical application of some antihistamines, particularly to children with skin lesions such as chickenpox, may produce classic systemic anticholinergic toxicity.[43] Promethazine and other H_1 antihistamines are associated with sudden infant death syndrome, although causality is not proven.[49] Cetirizine, a second-generation H_1 antihistamine, is suggested as safer for infant use, but further study is warranted.[55] Other adverse effects include pancytopenia and jaundice.

Elderly patients are more susceptible to adverse events because renal and hepatic dysfunction, which are more common in the elderly,

delays antihistamine metabolism.[26] Several infants who died of diphenhydramine overdose had serum concentrations lower than expected for adults; the implications are unclear.[3] All H_1 antihistamines cross the placenta, and some are teratogenic in animals. Because of their antimuscarinic effects, first-generation antihistamines are generally contraindicated in patients with glaucoma or prostatic hypertrophy.

H_2 Receptor Antagonists

Acute toxic effects appear to be extremely rare, even after large (20 g) oral ingestions of H_2 receptor antagonists.[28] Patients may develop tachycardia, dilated and sluggishly reactive pupils, slurred speech, and confusion.[57, 63] Bradycardia, hypotension, and cardiac arrest have followed rapid intravenous administration of cimetidine in seriously ill patients.[53] Famotidine and ranitidine produce even fewer dose-related toxicities in overdose. In addition, they are less likely than cimetidine to induce or inhibit the cytochrome P450 enzyme system, thereby producing fewer drugâ€“drug interactions.[27, 44]

Management

Patients who will develop severe complications may be indistinguishable from those who will have a benign course. The patient's vital signs and mental status must be monitored. The individual should be attached to on a cardiac monitor and observed for signs of sodium channel blockade (increased QRS duration and prolonged QT_c interval), development of seizures, and dysrhythmias. Assessment of the serum acetaminophen concentration is important because many analgesics and cough and cold products contain acetaminophen. Other laboratory studies should be obtained as indicated by history or physical signs and symptoms, such as creatine kinase in patients with seizures or doxylamine overdose. Measurement of antihistamine concentrations in body fluid is not readily available and is generally unnecessary for clinical assessment

and management. A serum pregnancy test should be obtained in women of childbearing age with ingestions.

Gastrointestinal decontamination using oral activated charcoal should be considered.[21] Orogastric lavage may be indicated in patients with massive overdose of a first-generation H_1 antihistamine. Serial assessments of the patient's vital signs, particularly temperature, and mental status should be made. The potential for clinical deterioration necessitates management of symptomatic patients in a monitored environment.

Specific Therapy

H_1 Receptor Antagonists

Hypotension generally responds to isotonic fluids (0.9% sodium chloride solution or lactated Ringer solution). If the desired increase in blood pressure is not attained, dopamine or norepinephrine can be titrated to achieve an acceptable blood pressure. In one instance, cardiogenic shock and myocardial depression resulting from a 10-g ingestion of pyrilamine maleate could be reversed only with an intraaortic balloon counterpulsation device.[17] This approach is a rarely needed but potentially useful intervention. Agitation, psychosis, or seizure generally responds readily to titration of a benzodiazepine such as diazepam or lorazepam. Cooling via evaporative methods (tepid mist via spray bottle or similar device; fan) is generally sufficient, but patients with severe hyperthermia should receive more rapid cooling using an ice bath. Hyperthermic patients should be monitored for development of disseminated intravascular coagulation and other complications. Seizures should be treated with an intravenous benzodiazepine such as diazepam 10 mg (0.1â€“0.2 mg/kg in children) or lorazepam with repeated dosing as necessary. Recurrent seizures refractory to the benzodiazepine should be treated with phenobarbital, propofol, or general anesthesia. In addition, proper fluid management and urinary

alkalinization are necessary to prevent myoglobin-induced nephrotoxicity.

The sodium channel-blocking (type IA antidysrhythmic) properties of diphenhydramine may lead to wide-complex dysrhythmias that resemble cyclic antidepressant overdose (Chaps. 61 and 71). Hypertonic sodium bicarbonate can reverse diphenhydramine-associated conduction abnormalities.[52] Cardioversion or pacing may be required for dysrhythmias. Type IA (quinidine, procainamide, disopyramide), IC (flecainide), and III (amiodarone, sotalol) antiarrhythmic drugs are contraindicated because of their capacity to prolong the QT_c interval.

Physostigmine can effectively reverse the peripheral or central anticholinergic syndrome if clinically indicated.[41] In a retrospective comparison of physostigmine and benzodiazepines, physostigmine was found to be safer and more effective for treating anticholinergic agitation and delirium.[5] Physostigmine can reverse both peripheral and central anticholinergic effects (Table 50-3). Contraindications to physostigmine use include a wide QRS complex or bradycardia noted by electrocardiography, asthma, and pulmonary disease.

The primary benefits of physostigmine use in patients with antihistamine overdose include restoration of gastrointestinal motility, elimination of agitation, and possible obviation of the need for CT scan or lumbar puncture if the patient regains a normal mental status and can provide a clear history. The anticipated benefits of physostigmine must outweigh the potential risks prior to its use.

For physostigmine administration, the patient should be attached to a cardiac monitor, and secure intravenous access should be established. Physostigmine (1â€“2 mg in adults; 0.5 mg in children) should be administered by *slow* intravenous push with continuous monitoring of vital signs, breath sounds, and oxygen saturation by pulse oximetry. The initial dose of physostigmine can be repeated at 5- to 10-minute intervals if anticholinergic symptoms are not

reversed and cholinergic symptoms such as salivation, diaphoresis, bradycardia, lacrimation, urination, or defecation do not develop. When improvement occurs as a result of physostigmine, readministration of physostigmine at 30- to 60-minute intervals may be necessary. Alternatively, sedation with benzodiazepines may be appropriate once the diagnosis is confirmed. A dose of intravenous atropine that is half the dose of physostigmine should be available at the patient's bedside to treat cholinergic toxicity if it occurs (Antidotes in Depth: Physostigmine).

H_2 Receptor Antagonists

Patients who overdose on an H_2 antihistamine should receive 1 g oral activated charcoal per kilogram body weight at most if indicated. H_2 antihistamine antagonists rarely result in significant toxicity and therefore do not warrant exposure to the risks of complications from orogastric lavage or emesis. Monitoring for uncommon complications and assessment of coingestants should be performed as clinically indicated.

Decongestants

History and Epidemiology

Decongestants are sympathomimetic agents that act on Î±-adrenergic receptors, producing vasoconstriction, shrinking swollen mucous membranes, and improving bronchiolar air movement. Ephedrine, the first agent of this class to be used pharmaceutically, is derived from *Ephedra* spp plants. Ephedrine was used in China for at least 2000 years before it was introduced into Western medicine in 1924. Phenylephrine was introduced into clinical medicine in the 1930s. Several topical imidazoline decongestants (see Figure 50-4) have since been developed for clinical use.

Recreational use of ephedrine-containing stimulants is common, and

combinations of these compounds with caffeine or other herbs may be marketed as â€œherbal ecstasyâ€• (Chap. 39). The sale of dietary supplements containing Ephedra (ephedrine alkaloids) was banned by the FDA in 2004 because of concerns over their cardiovascular effects, including increased blood pressure and irregular heart rhythm. Xenobiotics that contain chemically synthesized ephedrine, traditional Chinese herbal remedies, and herbal teas are not covered by the rule.[15]

Pharmacology and Pharmacokinetics

Decongestants are pharmacologically active following topical or oral administration. Absorption from the gastrointestinal tract is rapid, with peak blood concentrations occurring within 2â€“4 hours of ingestion. Oral decongestants can affect the cardiovascular, urinary, central nervous, and endocrine systems.[4] The decongestants phenylephrine, pseudoephedrine, ephedrine, and phenylpropanolamine reduce nasal congestion by stimulating the Î±-adrenergic receptor sites on vascular smooth muscle.[29] This process constricts dilated arterioles and reduces blood flow to engorged nasal vascular beds. The $\hat{I}\pm_1$ -mediated decrease in volume ultimately lowers resistance to airflow. Prolonged topical administration may produce rebound congestion upon discontinuation; possible mechanisms include desensitization of receptors and mucosal damage. This damage is thought to be caused by $\hat{I}\pm_2$ -mediated arteriolar constriction resulting in decreased nutritional supply to the mucosa. Therefore, selective $\hat{I}\pm_1$ agonists may cause less mucosal damage.

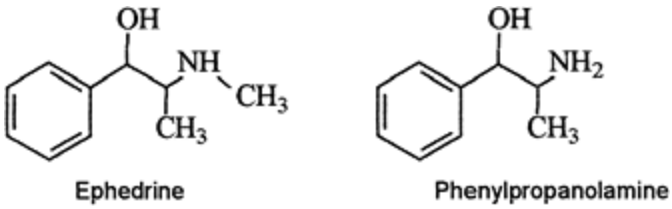

Figure 50-4. Structures of ephedrine and phenylpropanolamine.

Phenylephrine is a powerful Î±$_{1,2}$ -adrenergic receptor agonist with very little Î²-adrenergic agonist activity. Pseudoephedrine and ephedrine are direct-acting nonspecific Î±$_{1,2}$ - and Î²$_{1,2}$ -adrenergic receptor stimulants. Pseudoephedrine is the D-isomer of ephedrine and has only 25% of the adrenergic receptor activity of ephedrine.[9] Phenylpropanolamine is an Î±$_{1,2}$ -adrenergic receptor stimulant devoid of Î²-adrenergic receptor activity. Phenylpropanolamine can directly stimulate Î±$_{1,2}$ receptors and can indirectly stimulate these receptors by causing norepinephrine release (Table 50-4).

The imidazoline (I) category of sympathomimetics are generally reserved for topical application and are used for their local effects in the nasal passages and the eye. The more common medications include oxymetazoline hydrochloride, tetrahydrozoline hydrochloride, and naphazoline hydrochloride (Figure 50-5). The imidazolines are rapidly absorbed from the gastrointestinal tract and mucous membranes. The elimination half-lives of these agents range from 2â€“4 hours. Their vasoconstrictor effects are mediated by their actions as Î±-adrenergic agonists, with binding to Î±$_{1,2}$ receptors on blood vessels. The Î±$_1$ -mediated vasoconstriction is complemented by an additive effect of preferential binding to Î±$_2$ receptors located on resistance vessels regulating blood flow. In

addition, these compounds show high affinity for imidazoline receptors, which are located in the ventrolateral medulla and some peripheral tissues. Stimulation of imidazoline receptors produces a sympatholytic effect that results in bradycardia and hypotension. All imidazoline preparations have a relatively rapid onset of action, with 60% of maximum effectiveness after only 20 minutes. Oxymetazoline is the only compound with a duration of action > 8 hours. The other preparations have an average duration of action of approximately 4 hours.[25]

Decongestant Class Duration of Action Receptor Activity

TABLE 50-4. The Pharmacologic Characteristics of Decongestants

The imidazoline decongestants such as oxymetazoline and naphazoline are pure central and peripheral α_2 -adrenergic receptor agonists; tetrahydrozoline stimulates α_2 receptors and H_2 receptors. These medications are primarily used as nasal decongestants. Tetrahydrozoline is available without prescription as an ophthalmic preparation to decrease eye irritation and redness.

Clinical Manifestations

Following a decongestant overdose, most patients present with CNS

stimulation, hypertension, tachycardia, or reflex bradycardia (in response to pure Î±-adrenergic agonist-induced hypertension only). Approximately 4â€“5 times the recommended dose of pseudoephedrine[9] but less phenylpropanolamine may be required to cause hypertension.[10] An increase in sinus dysrhythmias is reported in adults with ingestion of 120 mg pseudoephedrine and moderate exercise.[4] Headache was the most common initial symptom (39%) reported by patients who later developed severe toxicity.[36] In 45 patients who developed hypertensive encephalopathy from phenylpropanolamine ingestion, 24 patients developed intracranial hemorrhages, 15 developed seizures, and 6 died.[36] In more severe exposures, seizures, myocardial infarction, bradycardia, atrial and ventricular dysrhythmias, ischemic bowel infarction, and cerebral hemorrhages are reported.[6, 12] In a review of 500 reports of adverse reactions from patients who had ingested ephedrine and associated stimulants as dietary supplements, 8 fatalities from myocardial infarction and cerebral hemorrhage were reported.[7] Symptoms of toxicity from decongestants usually resolve within 8â€“16 hours. However, symptoms may persist for > 24 hours if a sustained-release product is ingested. Acute myocardial infarction is reported with therapeutic dosing of pseudoephedrine.[40]

When ingested, the imidazoline decongestants naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline are potent central and peripheral $\hat{I}\pm_2$ -adrenergic and imidazoline receptor stimulants. In overdose, they can cause CNS depression, hypotension, bradycardia, and respiratory depression.[24, 46] Children are particularly sensitive to the effects of the imidazoline decongestants.

Management

Extreme agitation, seizures, tachycardia, hypertension, and psychosis should initially be treated with administration of oxygen and intravenous benzodiazepines, expeditiously titrated upward to effect.

A patient who remains hypertensive or is believed to have chest pain of ischemic origin (ECG indicated) may be treated with phentolamine, an Î±-adrenergic antagonist, or nitroprusside, a venous and arterial vasodilator.

A patient with a focal neurologic deficit or an abnormal neuropsychiatric examination following decongestant ingestion should be evaluated for cerebral hemorrhage by noncontrast head CT scan and, if indicated, subsequent lumbar puncture to exclude subarrachnoid hemorrhage.[36]

Patients who have overdosed on a decongestant generally should receive 1 g activated charcoal per kilogram body weight as a single dose. Activated charcoal administration may be beneficial several hours after ingestion of sustained-release decongestant preparations, and serial doses of activated charcoal may be considered in this context. Syrup of ipecac has no role, and orogastric lavage should be reserved only for life-threatening ingestions within the previous hour.

Ventricular dysrhythmias from decongestant ingestions should be treated with standard doses of lidocaine or amiodarone.[66] Refractory dysrhythmias may require antiadrenergic therapy with propranolol, but only after pretreatment with phentolamine, if possible, or with strict expectant management of the patient's blood pressure. Patients who develop hypertension following propranolol should immediately receive phentolamine. Phenylpropanolamine ingestions may cause hypertension with a reflex bradycardia and atrioventricular block that is responsive to standard doses of atropine.[68] Atropine must be used with caution because it can cause a dangerous increase in blood pressure as the reflex bradycardia reverses. Therefore, a direct-acting vasodilator such as phentolamine or nitroprusside is preferred because the stimulus for the bradycardia is corrected with reversal of the hypertension. Imidazoline-induced hypertension rarely requires therapy, but in the setting of symptomatic hypertension a short-acting Î±-adrenergic antagonist such as phentolamine may be administered.[67] However, the hypertension is generally transient and

followed by hypotension that raises the risk of antihypertensive therapy.

Summary

The popularity and availability of antihistamines and decongestants make them readily accessible for deliberate or unintentional ingestions in both adults and children. Recreational use of these agents may lead to exposure to substantial doses of these medications. Fortunately, nearly all patients exposed to excessive doses of members of these classes of medications that are currently available in the United States do well if they receive treatment early in

the course of ingestion. Patients treated with activated charcoal, continuous assessment, supportive care, management of abnormal vital signs, electrocardiography, cardiac monitoring, and mental status have an excellent outcome with little risk of adverse sequelae. Familiarity with the more severe complications of antihistamine and decongestant overdoses results in early and appropriate interventions to reduce both morbidity and mortality from these exposures.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Antidotes in Depth

Physostigmine Salicylate

Mary Ann Howland

Physostigmine is a carbamate that reversibly inhibits cholinesterases in both the peripheral nervous system and the central nervous system (CNS).[44] The tertiary amine structure of physostigmine permits CNS penetration and differentiates it from neostigmine and pyridostigmine, which are quaternary amines and thereby have limited ability to enter the CNS. This action inhibits the metabolism of acetylcholine, thereby allowing acetylcholine to accumulate and antagonize the anticholinergic effects of xenobiotics such as atropine, scopolamine,[51] and diphenhydramine. Although physostigmine previously was used as an antagonist to the anticholinergic effects of the tricyclic antidepressants and the phenothiazines, its use is no longer recommended because of a poor risk-to-benefit ratio given the potential for exacerbation of life-threatening cardiotoxicity. A review of 30 years of the literature reassessed and questioned the contraindication to physostigmine use for cyclic antidepressant ingestions. The review concluded that the safety of physostigmine use for seizures or cardiotoxicity was difficult to predict, but the

author still did not recommend physostigmine use in the setting of cyclic antidepressant toxicity.[43] Similarly, physostigmine likely will have a poor risk-to-benefit ratio in the management of presumed Î³-hydroxybutyrate (GHB) toxicity. A study in rats revealed that physostigmine did not effect arousal but increased the risk of physostigmine-induced toxicities of fasciculations and seizures.[4] Atypical antipsychotics have complex pharmacologic effects. Although some atypical antipsychotics (eg, olanzapine) have significant antimuscarinic side effects, the benefit of treating these anticholinergic effects with physostigmine in the often confusing overdose setting must be weighed against the potential risks of exacerbating cardiotoxicity.[45]

History

The history of physostigmine dates to antiquity and the Efik people of Old Calabar in Nigeria.[17,20,23,44] The chiefs in those areas used a poisonous concoction made from the beans of an aquatic leguminous perennial plant found in the area to deliver the *esere ordeal*. Esere was the word used to represent both the bean and the ritual used to test the innocence or guilt of an accused person. They also believed that the esere had the power to detect and kill those persons practicing witchcraft. Supposedly, innocent persons quickly swallowed the poison, which caused immediate emesis.[23] Vomiting allowed them to survive on their own or to be given an antidote of excrement in water. The guilty, however, hesitated swallowing, leading to speculation that sublingual absorption led to severe systemic symptoms without the benefit of vomiting. These persons were noted to develop mouth fasciculations and died foaming at the mouth. Daniell, a British medical officer stationed in Calabar, brought samples of the bean and the plant back to England in 1840.[23] John Balfour, a professor of medicine and botany at the Edinburgh Medical School, is credited with characterizing the plant, which became known as *Physostigma venenosum Balfour* (family *Leguminoseae*) in 1857. The active

alkaloid isolated from the Old Calabar, or ordeal bean, by Jobst and Hesse in 1864 was named physostigmine. Independently, 1 year later Vee and Leven also isolated the active alkaloid and named it eserine.

Christison performed the first toxicologic studies, including self-experimentation with increasing doses of the seed. Fraser, Christison's student and later successor, originated the concept of antagonism from his experiments with physostigmine and atropine. Fraser plotted the dose relationships between the effects of atropine versus physostigmine on various organs such as the eye and the heart. He demonstrated, that up to a certain dose, atropine acted as an antidote to the lethal effects of physostigmine.[17] Experiments with physostigmine paved the way for Anderson, to propose the existence of a transmitter as the mechanism of action of physostigmine in 1906. In the 1920s, Loewi proposed and then proved the theory of neurohumoral transmission. Stedman and Burger established the chemical structure of physostigmine in 1925. Julian and Pikl synthesized physostigmine in 1935. By this time, physostigmine was already used as a miotic agent for patients with glaucoma, as a treatment for patients with myasthenia gravis, as a reversal agent to the paralytic effects of curare, as an antidote to atropine, and as a prototypical insecticide. In summary, physostigmine, a prototypical carbamate insecticide, was instrumental in the development of a bioassay for acetylcholine, concepts of neurohumoral transmission, mapping of cholinergic nerves, the concept of antagonism, the kinetics of enzyme inhibition, and improved understanding of the bloodâ€“brain barrier.[20]

Chemistry and Affinity for Cholinesterase

Figure 50-6A shows the general formula for carbamate inhibitors. Figures 50-6B and C show the chemical structures of

physostigmine ($C_{15}H_{21}O_2N_3$), a tertiary amine, and neostigmine, a quaternary amine. Like acetylcholine, physostigmine is a substrate for the cholinesterases (choline ester hydrolases) erythrocyte acetylcholinesterase and plasma cholinesterase. Both acetylcholine and physostigmine bind to the cholinesterase enzymes to form a complex. Then a part of the substrate known as the *leaving group* (ie, choline for acetylcholine) is removed, and the remaining acetylated (for acetylcholine) or carbamoylated (for physostigmine) enzyme is hydrolyzed, regenerating the enzyme and freeing the acetate or carbamate groups, respectively (Figures 109-2, 109-3, 109-4). For acetylcholine, the process is extremely quick, with a turnover time of 150 ms. In contrast, the half-life for hydrolysis of the carbamoylated enzyme is 15â€“30 minutes.[44] The I_{50} (molar concentration that inhibits 50% of the enzyme) of physostigmine is 2.3 Ã— 10^{-7} M for acetylcholinesterase, which is much weaker than for other carbamates at 1 Ã— 10^{-10} M or many organic phosphorus compounds at 1 Ã— 10^{-11} M.[21] Only the S-isomer inhibits cholinesterases, with plasma cholinesterase just a little more sensitive than acetylcholinesterase.[3] Newer xenobiotics used in patients with Alzheimer

disease[11] show selectivity for the CNS and for acetylcholinesterase. They include tacrine, donepezil, and galantamine, which are reversible cholinesterase inhibitors; metrifonate, an irreversible inhibitor; and rivastigmine, a pseudo-irreversible or slowly reversible inhibitor. These xenobiotics and neostigmine[22] have undergone limited study for reversal of anticholinergic poisoning.[11,22,26,38]

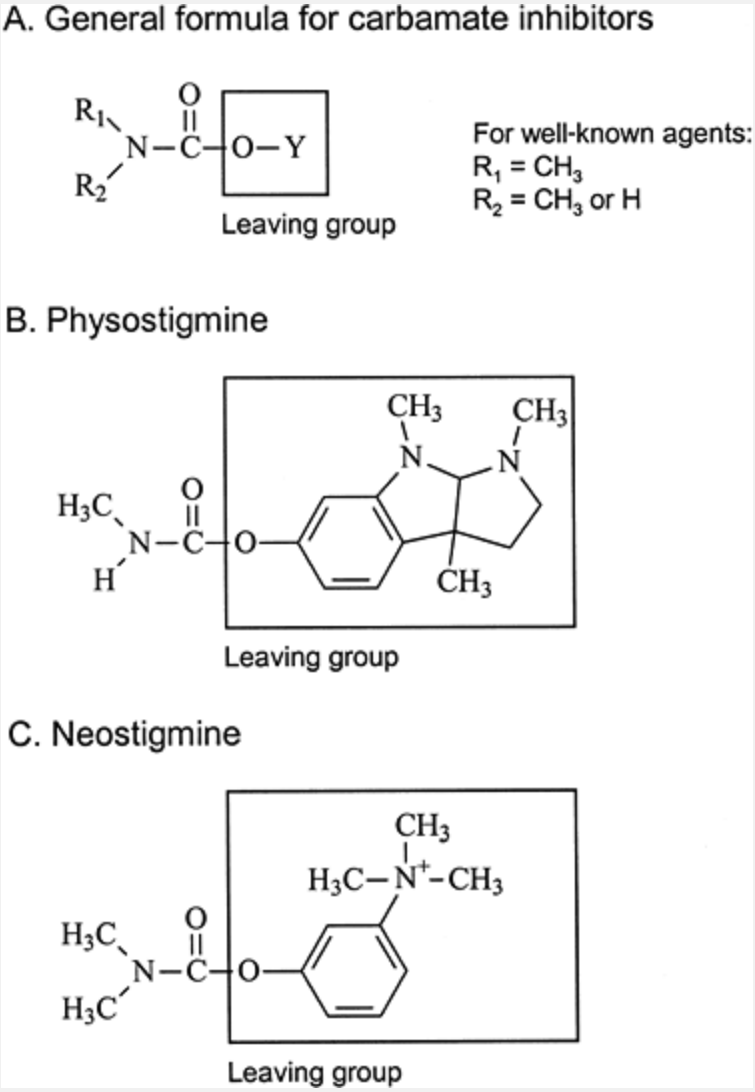

Figure A13-1. A: General formula for carbamate inhibitors. B: Structure of physostigmine. C: Structure of neostigmine.

Pharmacokinetics

Physostigmine is poorly absorbed orally, with a bioavailability of <5â€“12%.[1,31] Cholinesterases cleave the ester linkage, and very little xenobiotic is eliminated unchanged in the urine.

Pharmacokinetic parameters following IV administration of 1.5 mg over 60 minutes in 9 patients with Alzheimer disease demonstrated the following: Vd 2.4 Â± 0.6 L/kg; $t_{1/2}$ 16.4 Â± 3.2 minutes; peak plasma concentration 3 Â± 0.5 ng/mL; clearance 0.1 L/min/kg (7.7 L/min). There was a 3-fold interindividual variability in plasma physostigmine concentrations. Plasma cholinesterase concentrations demonstrated inhibition within 2 minutes of initiating the physostigmine infusion. The half-life of plasma cholinesterase inhibition was 83.7 Â± 5.2 minutes, with full recovery within 3 hours of termination of physostigmine infusion. The effects on plasma cholinesterase inhibition last approximately 5 times longer than the half-life of physostigmine.[25] All patients experienced varying degrees of diaphoresis, nausea, vomiting, headache, and generalized fatigue despite pretreatment with 2.5 mg methscopolamine.[2]

Clinical Use

Physostigmine was first used as an antidote in 1864 to counteract severe atropine poisoning.[33] Today its role is primarily in the treatment of antimuscarinic xenobiotics. More than 600 of these xenobiotics respond to physostigmine.[12] Anticholinergics fall into the categories of antimuscarinic (atropine, scopolamine, propantheline, benztropine, trihexyphenidyl), neuromuscular blockers (exemplified by curare), and ganglionic blockers (eg, trimethaphan). Other xenobiotics (eg, antihistamines, antipsychotics, and antidepressants) have anticholinergic properties that are not their primary therapeutic actions and are often considered adverse drug effects.

Clinical use of physostigmine has varied over time.[40] Enamored with its ability to cause CNS arousal, physostigmine was used in the 1970s to reverse the CNS effects of a large number of anticholinergics. It also was used inappropriately to treat toxicity from nonanticholinergics.[18,30,32,34,36] The success with regard to

anticholinergics is directly antidotal by virtue of its inhibition of cholinesterase. Effects of xenobiotics such as the benzodiazepines, opioids,[27,37,49] and GHB[4,46] result from either acetylcholine's direct action on the reticular activating system or interdependence of central neurotransmitters.[34] Few serious adverse effects are reported.[48] However, asystole followed administration of physostigmine in 2 patients with tricyclic antidepressant overdose.[35] This occurrence led to the realization that toxicity from tricyclic antidepressants is complex and consists of more than just anticholinergic effects.[35] Tricyclic antidepressant-induced sodium channel blockade causes myocardial depression, QRS and QTc interval prolongation, and ventricular dysrhythmias. Physostigmine probably augments vagal effects, thus contributing to decreased cardiac output and cardiac conduction defects. A reevaluation must conclude that the risks of physostigmine use for xenobiotics that are not primarily antimuscarinic often outweighs any benefit.

This analysis appears to hold true for reversing the effects of GHB (Chap. 78) as well.[46] GHB is rarely used alone, and its effects are highly variable. Recovery occurs spontaneously in approximately 2 hours (16 minutesâ€“6 hours).[7,8,14,28,47] Three patients in whom a presumptive diagnosis of GHB toxicity was made were treated with physostigmine.[7] The 3 patients had an improved mental status within 5â€“15 minutes. One of these patient relapsed and then fully awakened 40 minutes later. This patient was incontinent of feces, an adverse effect likely caused by the physostigmine.[7] A closer look at the patient descriptions reveals that all 3 improved with stimulation prior to physostigmine. Justification for use based upon a study performed in the 1970s in the operating room at a time when GHB was first being evaluated as an anesthetic appears illogical when caring for those who illicitly use GHB.[19]

However, in cases of anticholinergic overdose, physostigmine use clearly is beneficial. A study of 52 patients showed that physostigmine controlled agitation and reversed delirium in 96%

and 87% of patients, respectively,[6] whereas benzodiazepines controlled agitation in 24% of patients but were ineffective in reversing delirium. A shorter time to recovery following agitation was observed in those treated with physostigmine. No significant differences between these groups with regard to side effects and length of stay were noted.[6]

Indications

Indications for physostigmine use include the presence of peripheral or central anticholinergic manifestations without evidence of QRS or QTc prolongation. Peripheral manifestations include dry mucosa, dry skin, flushed face, mydriasis, hyperthermia, decreased bowel sounds, urinary retention, and tachycardia. Central manifestations include agitation, delirium, hallucinations, seizures, and coma.[16,29] The peripheral and central findings usually occur simultaneously. In the early phases of overdose, finding only central manifestations is uncommon, although they often are more remarkable.[1,5,9,13,15,21,39,42] The central findings may persist longer than the peripheral findings, particularly when a patient is recovering from an overdose of an antimuscarinic xenobiotic.

Adverse Effects

An excess of physostigmine results in accumulation of acetylcholine at peripheral muscarinic receptors, nicotinic receptors (skeletal muscle, autonomic ganglia, adrenal glands), and CNS sites.[24] Muscarinic effects produce stimulation of smooth muscle and glandular secretions in the respiratory, gastrointestinal, and genitourinary tracts and inhibition of contraction of most vascular smooth musculature. Nicotinic effects are stimulatory at low doses and depressant at high doses. For example, acetylcholine excess at the neuromuscular junction

produces fasciculations followed by weakness and paralysis. Its effect on the CNS results in anxiety, dizziness, tremors, confusion, ataxia, coma, and seizures.[24] Electroencephalograms (EEGs) demonstrate desynchronous discharges followed by higher-voltage discharges and a pattern similar to tonicâ€“clonic seizures.[24] The cardiovascular effects are dose dependent and directly related to the presence of the diverse muscarinic and nicotinic effects.[24] In addition to its inhibition of cholinesterase, physostigmine has a direct action on the nicotinic acetylcholine receptor ionic channel on the neuromuscular junction, resulting in decreased Î³-aminobutyric acid in the striatum.[41]

Physostigmine toxicity results when physostigmine is used in the absence of antimuscarinic toxicity or when an excess in relation to the antimuscarinic xenobiotic is administered. Patients overdosed with physostigmine should be managed with intensive supportive care, including mechanical ventilation if needed, intravenous atropine[50] titrated to reverse bronchial secretions, and, rarely, pralidoxime to reverse skeletal muscle effects.[10]

Relative contraindications to physostigmine use include reversible airway disease, peripheral vascular disease, intestinal or bladder obstruction, intraventricular conduction defects, and atrioventricular block. Little information is available regarding the effects of physostigmine in pregnancy. Transient muscular weakness occurred in 10â€“20% of neonates whose mothers received anticholinesterases for treatment of their myasthenia gravis.[31]

Drug interactions with cholinergic agonists (eg, ophthalmic pilocarpine), depolarizing neuromuscular blocking agents, or other anticholinesterase agents (eg, carbamates, organic phosphorous compounds, and pyridostigmine) are expected to be at least additive when these agents are taken concomitantly with physostigmine. The actions of drugs metabolized by plasma cholinesterases (eg, cocaine, succinylcholine, or mivacurium) are

expected to be prolonged.

Dosing

The dose of physostigmine is 1â€“2 mg in adults and 0.02 mg/kg (maximum 0.5 mg) in children intravenously infused over at least 5 minutes. The onset of action usually is within minutes.[21] The dose can be repeated in 10â€“15 minutes if an adequate response is not achieved and muscarinic effects are not noted. Rapid administration may cause bradycardia, hypersalivation leading to respiratory difficulty, and seizures. Although the half-life of physostigmine is approximately 16 minutes, its duration of action usually is much longer (often >1 hour) and is directly related to the duration of cholinesterase inhibition.[2] After reversal of anticholinergic symptoms is achieved, additional doses may be required if clinical relapse occurs. The effective dose depends upon the ingested dose and duration of action of the antimuscarinic xenobiotic. Although a total of 4 mg in divided doses usually is sufficient in most clinical situations,[16] significant interindividual variability exists. Atropine should be available at the bedside and titrated to effect should excessive cholinergic toxicity develop. A dose of atropine administered at half the physostigmine dose is often recommended.

Physostigmine is available as an ophthalmic ointment that can be applied topically to the conjunctival sac, where it causes miosis for treatment of acute angle-closure glaucoma. Miosis occurs within 10â€“30 minutes and persists for 12â€“48 hours.[31]

Availability

Physostigmine is available as Antilirium in 2-mL ampules, with 1 mL containing 1 mg physostigmine salicylate. The vehicle contains sodium bisulfite and benzyl alcohol.

Summary

Physostigmine has been used extensively in the fields of anesthesiology and emergency medicine. The only use of physostigmine with sound scientific support is for the management of patients with an anticholinergic syndrome, particularly those without cardiovascular compromise who have an agitated delirium. In this population, physostigmine has an excellent risk-to-benefit profile.

Chapter 51
Antimigraine Medications

Jason Chu

Neal A. Lewin

Cluster headaches were recently diagnosed in a 57-year-old man with a controlled with valsartan and hydrochlorothiazide. Indomethacin, prednis acetaminophen-caffeine, and hydrocodone were prescribed, but the patier Subsequently, his neurologist prescribed 2 therapeutic doses of 10 mg riz 2 days prior to his presentation to the emergency department (ED). Upon patient complained of nausea, vomiting, and crampy abdominal pain. His pressure, 156/93 mm Hg; pulse, 94 beats/min; respiratory rate, 22 bre 98.2Â°F (36.8Â°C); pulse oximetry, 99% on room air. Physical examinatic right-sided abdominal tenderness to palpation. A 12-lead electrocardiogra and laboratory evaluation revealed blood urea nitrogen, 23 mg/dL; creat urinalysis; and normal prothrombin and partial thromboplastin times. Cor both oral and intravenous contrast of the abdomen and pelvis revealed a of the right kidney, which was confirmed by magnetic resonance angiogra arteriogram of the renal arteries showed no evidence of renal artery dis dysplasia. He was treated with intravenous hydration and pain manageme resolved.

When the patient was examined 1 month following discharge from the ho
further episodes of cluster headaches or abdominal discomfort, and his r
normal.

A migraine headache is a neurovascular disorder often initiated by a trigg
characterized by a headache that may be associated with an aura and po
variety of multiple organ system complaints, such as visual disturbances,
urinary frequency. For an extensive review, see the diagnostic criteria for
migraine established by the International Headache Society.[32] The initiati
fully understood, but likely involves genetic abnormalities in central nervo
channels predisposing sufferers to migraine triggers. Patients with familia
which is an autosomal dominant disorder, have missense mutations in the
specific P/Q voltage-gated calcium channels, which mediate serotonin and
wave of cortical spreading electrical depression.[24] Dysfunction of the P/Q
channels, which impairs serotonin release, is theorized to trigger this spr
depression. Once triggered, an electrical wave of cortical neuronal depol
the cortex in a caudal to rostral direction, followed by a spreading wave
an aura in some migraineurs. Current theories suggest these spreading w
patients without aura. Studies have demonstrated that migraineurs have
magnesium, which is needed for proper calcium channel activity, thus len
theory of migraine as a channelopathy.

Toxicity of many of these medications are discussed in depth elsewhere ir formerly the mainstay of therapy for treatment of migraines, but the trip has essentially replaced the ergots.

Ergot Alkaloids

History and Epidemiology

Ergot is the product of *Claviceps purpurea* , a fungus that contaminates r spores of the fungus are both wind-borne and transported by insects to y germinate into hyphal filaments. When a spore germinates, it destroys th a curved body called the *sclerotium* , which is a major commercial source This fungus can elaborate diverse substances, including

ergotamine, histamine, tyramine, isomylamine, acetylcholine, and acetal

Figure 51-1. Infarction of right kidney after rizatriptan use.

In 600 B.C., an Assyrian tablet mentioned contamination of grain believed *purpurea* . In approximately 400 B.C., a contaminated grass that killed p described. In the Middle Ages, epidemics causing gangrene of the extrer of limbs, were depicted in the literature. The disease was called *holy fire* because of the blackened limbs resembling the charring from fire and the expressed by its victims. Any improvement that reportedly occurred when shrine of St. Anthony probably was the result of a diet free of contamina the journey.[27] Abortion and seizures also were reported to result with th early as 1582, midwives used ergot to assist in the childbirth process. De physician to use ergot for obstetric care in 1818. In 1822, Hosack reporte used for control of postpartum hemorrhage, but that its routine use during avoided because of the drug's toxicity.[65] Since 1950, clinical use of ergot limited almost entirely to treatment of vascular headaches. Ergonovine, is used in obstetric care for its stimulant effect on uterine smooth muscl used for postpartum uterine atony and hemorrhage. Ergot derivatives have â€œcognition enhancers,â€• [67] to help manage orthostatic hypotension,[6] secretion of prolactin.[56]

used in both roles.

Prophylactic Abortive

TABLE 51-1. Xenobiotics Used for Migraine Treatment

Presently in the United States, epidemics of ergotism are prevented by g
grain fields. A grain field that contains more than 0.3% infected grain is
sale. In some years as much as 36% of the grain is rejected.[56] Ergot toxi
animals, remains a problem elsewhere in the world.[5,36]

Pharmacology and Pharmacokinetics

The ergot alkaloids can be divided into three groups: amino acid alkaloic acid alkaloids, and amine alkaloids. All ergot alkaloids are derivatives of 6-methylergoline (Figure 51-2).

The pharmacokinetics of the ergot alkaloids are well defined from control studies, whereas the toxicokinetics are

essentially unknown (Table 51-2). Almost all of the ergots are poorly ab considerable first-pass hepatic metabolism occurs, resulting in highly va Intramuscular absorption is unpredictable, and actions often are delayed. dose is approximately 10 times the intramuscular dose.[48] Ergotamine sup bioavailability 20 times compared to orally administered doses by avoidin metabolism in oral dosing.[31 , 55] Peak plasma concentrations with oral er 45â€“60 minutes.[48] The volume of distribution is approximately 2 L/kg, a from 1.4â€“6.2 hours. Ergot alkaloids are metabolized in the liver by CYP are excreted in the bile.[4 , 56]

Compound	Interactions with Tryptaminergic (Serotonergic) Receptors	Interactions with Dopaminergic Receptors

TABLE 51-3. Pharmacology of Ergot Derivatives

Peripherally, ergotamine acts as a partial Î±-adrenergic agonist or as an dopaminergic, and serotonergic (tryptaminergic) receptors.[56] The ergopep ergot alkaloids (ergotamine, ergotoxine) exhibit Î±-adrenergic agonism, (dihydroergotamine) of the lysergic acid

nucleus increases Î±-adrenergic agonism.[56] However, their peripheral va predominate over the Î±-adrenergic antagonist effects. An additional vas be caused by direct action of ergotamine on the media of the arterioles.[5 at therapeutic doses is vasoconstriction. Table 51-3 summarizes the phar selected ergot alkaloids currently used in clinical medicine. The spectrum dosage, host response, and physiologic conditions.

The difference between therapeutic and toxic doses in peripheral vessels of ergotamine produce only mild vasoconstriction, and this effect is direct doses, extreme vasoconstriction produces the characteristic ischemic chan ergotism.

The cerebrovascular effects of ergot alkaloids are not clearly understood. for example, therapeutic doses of ergotamine produce mild vasoconstrict agonism, especially in intracranial vessels that already are dilated during vasoconstriction is one mechanism by which ergot terminates a migraine little definitive information is available regarding the effects of toxic doses on the cerebral vasculature. Cephalic vasodilation may occur, but the mec unknown. One hypothesis is that toxic doses of the drug initially produce and ischemia, just as they do in the periphery. However, because the ce tolerate hypoxia and hypercapnia, rapid vasodilation ensues and improves addition, Î±-adrenergic receptors in the CNS function differently from thos possibly CNS vascular tone cannot be maintained in the setting of local t

Clinical Manifestations

Ergotism, a toxicologic syndrome resulting from excessive use of ergot a by intense burning of the extremities, hemorrhagic vesiculations, pruritus vomiting, and gangrene (Table 51-4). Headache, fixed miosis, hallucinat cerebrovascular ischemia, and convulsions also are associated with this c called â€œ*convulsive* â€• ergotism.[27] Chronic ergotism usually presents of the lower extremities, although ischemia of cerebral, mesenteric, coron beds is well documented.[2 , 19 , 20 , 53 , 54] Ergotism also can result from with cytochrome CYP3A4 inhibitors, such as macrolide antibiotics and pro increase the area under the curve of ergots.[3 , 4]

Ergotaminism is a syndrome caused specifically by ergotamine use. Symp insufficiency, such as cold extremities, extremity pain at rest, numbness, intermittent claudication, are most commonly reported.[27] CNS manifestati ergotaminism. However, the adverse effects reported may not result from many published cases describe ingestions of combination therapeutic pre ergot alkaloid and caffeine. Restlessness, nausea, vomiting, or agitation d an acute overdose, but peripheral vasospasm may not be obvious for 24

Central Effects Peripheral Effects

TABLE 51-4. Clinical Manifestations of Ergotism

The vascular effects ascribed to ergot alkaloids are complex and sometim 3). Subintimal and medial fibrosis, vasospasm, and arteriolar and venou stasis related) are all reported.[41] Angiography can demonstrate distal, se with increased collateralization in patients with chronic ergotism. The co

ophthalmic, and mesenteric vasculature,[54] as well as the vessels of the c affected.[58] Neuropathic changes may be secondary to ischemia of the va

Bradycardia is a characteristic effect of the ergot alkaloids. Bradycardia is baroreceptor-mediated phenomenon associated with vasoconstriction, but sympathetic tone, direct myocardial depression, and increased vagal activ

One finding is particularly striking, especially considering attention to a s a recently withdrawn group of dietary aids. Myocardial valvular abnormali ergot alkaloids. Ergotamine and methysergide both cause mitral and aort and immobility resulting in valvular regurgitation.[21 , 53]

Methysergide use is limited because of its well-described adverse effects pleuropericardial, endocardial, and endovascular fibrosis.[47 , 53]

Treatment

The treatment for a patient with ergot alkaloid toxicity depends on the na findings. Gastric emptying should be used rarely, if at all, because vomitir occurrence, and the ingestion may be complicated by seizures. Shortly aft overdose, if the patient is not vomiting, activated charcoal should be adm management. If emesis is present, metoclopramide or a 5-HT_3 antagonist can be used as an antiemetic to facilitate administration of activated char characterized by minimal pain of the extremities, supportive measures su analgesia are all that is needed. With more serious cases, severe periph produce ischemic changes, including angina, myocardial infarction, cereb claudication, and mesenteric ischemia. Intravenous vasodilators, such as [7 , 46] nitroglycerin,[30] and phentolamine, are indicated to reverse the isch captopril,[69] and nifedipine[11] also have been used to achieve peripheral v with mild signs and symptoms of vasospasm, such as dysesthesias and m the digits.

Although sympathetic block, epidural block, or sympathectomyâ€”all of wh pastâ€”may relieve vasoconstriction mediated via the CNS, these modalitie antagonize the direct action of the ergot alkaloids on arteriolar smooth m corticosteroids, or low-molecular-weight dextran[57] can be used to prever subsequent clot formation. Use of thrombolytic agents in this setting has

been evaluated but may have some theoretical utility. Arteriotomy may b large clots. Hyperbaric oxygen may correct local tissue hypoxia.[17] Benzod used to treat seizures or hallucinations.

Triptans

In 1974, investigations began on new compounds that produced vasocons receptors. The first compound successfully used in this context was 5-ca CT). When applied to an isolated dog saphenous vein, 5-CT caused poter induced significant hypotension in vivo. The next compound developed, A aminoethyl)-*N* -methyl-1-H-indole-5-acetamide], also constricted dog saph more 5-HT receptor selectivity. AH25086 was effective against acute migr volunteers, but further research was stopped because the compound was development in humans.[28] Sumatriptan was synthesized in 1984, and its the rapid development of other triptans, which currently include naratrip rizatriptan, eletriptan, almotriptan, and frovatriptan (Figure 51-3 and Tab

Pharmacology

The triptans are all primarily 5-HT_{1B} and 5-HT_{1D} receptor agonists and ha HT_{1A} and 5-HT_{1F} receptors[22] (Chap. 14). In the CNS, 5-HT_{1B} receptors a vessels.[25] Stimulation of these receptors results in cerebral vasospasm[12] cerebral vasodilation. In contrast, the 5-HT_{1D} receptors are located pres neurons and act as â€œautoreceptors,â€• decreasing neurotransmitter r trigeminal nerve terminals.[34] The triptans also inhibit dural neurogenic in preventing the release of vasodilating neuropeptides from peripheral trig Peripherally, triptans cause vasospasm systemically through the 5-HT_{1B}

The available triptans are pharmacodynamically similar but have differen 51-5). Sumatriptan has an oral bioavailability of only 14% (range 10â€“ extensive first-pass hepatic metabolism. Peak plasma concentrations are a (range 0.5â€“4.5 hours).[22] An intranasal formulation is available, but the 17%.[55] Subcutaneous administration results in a much higher bioavailabil peak plasma concentrations at 10 minutes; therefore, sumatriptan is pref

subcutaneous route. The volume of distribution is 2.4â€“3.3 L/kg, and the approximately 2 hours. The newer triptans differ substantially from sumat oral bioavailability, plasma half-life, time to maximum effect, and recurre (Table 51-5).

TABLE 51-5. Pharmacokinetics of Triptans

Clinical Manifestations

With appropriate therapeutic use, the adverse effects associated with the include nausea, vomiting, dyspepsia, flushing, and paresthesias.[13,56] Hc

consequential adverse effects are related to vasospasm. Chest pressure is of sumatriptan users.[6, 50] Although triptans reduce coronary artery diam chest pressure usually is not believed to be secondary to cardiac ischem for chest pressure sensations include a generalized vasospastic disorder esophageal spasm, bronchospasm, alterations of skeletal muscle energy sensitization of pain pathways.[15] Therapeutic sumatriptan use is also ass infarction, dysrhythmias, renal infarctions, and ischemic colitis.[1, 10, 35] Although the triptans result in some degree of coronary artery constrictio hence recommendations state that routine stress tests are not necessary to therapy with triptans.[16, 38, 64]

Cephalic vasospasm is the desired effect of sumatriptan, but adverse neu from transient ischemic attacks to cerebral vascular events, hemorrhages, reported.[8, 33, 37, 41, 42] Spinal cord infarction is reported after therap and renal infarction is reported after therapeutic rizatriptan use.[23] These been reported with the other triptans, possibly because the other triptans become available.

Animal studies showed a wide margin of safety with oral sumatriptan. Su administration of 2 g/kg sumatriptan to rats was lethal. Death was prece inactivity, and tremor.[29] Dogs survived 20 mg/kg and 100 mg/kg subcuta developed hind limb paralysis, erythema, tremor, salivation, and loss of in other animals

include seizures, inactivity, reduced respiratory rate, cyanosis, ptosis, at salivation, and lacrimation.[29, 61] Dogs given oral sumatriptan 2 mg/kg/d opacities and corneal epithelial defects after 1 month of treatment.[61]

Two cases of excessive sumatriptan taken for treatment of headaches are old man took 66 doses of sumatriptan 6 mg subcutaneously over 4 weeks headaches and had no adverse effects.[62] A 43-year-old man who took 23 25 mg and 32 tablets of Midrin (a combination medication with isomethep dichloralphenazone 100 mg, acetaminophen 325 mg) over 7 days for hea occipital infarction with a right hemianopsia. Digital subtraction angiogra narrowing in multiple cerebral vessels. The hemianopsia and vessel findir cessation of the sumatriptan and Midrin and treatment with nicardipine.[42]

drugâ€“drug interactions with the triptans and other medications, such as inhibitors (MAOIs), are reported, although the potential exists because of MAO-A or P450 enzymes.

Treatment

Treatment of triptan-induced vasospasm is dependent on the route of exp system affected. Decontamination is not feasible after subcutaneous expos effective in overdoses of oral preparations. Most triptans are oral prepara rizatriptan and zolmitriptan are formulated to dissolve orally on the tongu decontamination with activated charcoal should only be performed for ing preparation of other triptans. Because vomiting is not as prominent with exposure to the ergot alkaloids, gastric emptying procedures such as orog considered early, but only after massive and early exposure.

Calcium channel blockers have been used successfully in the setting of ischemia.[42] Patients with sumatriptan-associated myocardial infarction we heparin, and intravenous nitroglycerin.[49] Thrombolytic therapy has not b setting but, rationally, should be instituted if clinically warranted after i vasoconstriction and ischemia should be reversed with a calcium channel vasodilator (eg, sodium nitroprusside or nitroglycerin), or the Î±-adrener phentolamine.

Isometheptene

Isometheptene is a mild vasoconstrictor marketed as a combination prep includes dichloralphenazone, a muscle relaxant, and acetaminophen. It has adrenergic agonist effects and minor direct Î±-adrenergic agonist effects vasculature.[63] When administered early during a migraine exacerbation, effective as sumatriptan in relieving migraine headache. Cerebral vasoco after excessive isometheptene and sumatriptan use and after therapeutic [51] Autonomic dysreflexia was reported in a man with spinal cord injury w for treatment of a migraine headache.[68] Treatment of isometheptene-ind should include discontinuation of the medication and reversal of the vaso channel blockers or vasodilators, such as sodium nitroprusside, nitroglyc

Summary

Although epidemic ergotism no longer is a common concern because of g poisoning by both unintentional and intentional ingestions continues to be the complex pharmacologic and physiologic actions of these agents and u pharmacologic antidotes enables the clinician to minimize the morbidity a associated with ergot alkaloids. The introduction of the triptans has decre alkaloids for treatment of migraine. Triptan toxicity is infrequent but, whe consequential complications. Clinicians should be aware of the pharmacolo agents, in order to anticipate and minimize the adverse effects of exposu

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 52 Antineoplastics

Richard Y. Wang

A 70-year-old woman was brought to the emergency department (ED) from an extended-care facility because of the sudden onset of epistaxis. Her vital signs were: blood pressure, 120/70 mm Hg; pulse, 100 beats/min; respiratory rate, 18 breaths/min; and temperature, 98.6Â°F (37Â°C). The patient stated that for the last 2 days she had dysphagia, progressive weakness, and intermittent shaking. She had a past medical history of rheumatoid arthritis and pulmonary emboli. Her medications include methotrexate (MTX) and Coumadin, which were both started within the last month for her underlying medical disorders. An anterior nasal packing was placed to stop the bleeding. Further examination of the oropharynx demonstrated several ulcers. The skin showed ecchymoses. Chest and abdominal findings were unremarkable. A large-bore IV line was established, and blood was drawn for a complete blood cell count (CBC) with platelets, international normalized ratio (INR), partial thromboplastin time (PTT), electrolytes, blood urea nitrogen (BUN), and creatinine. Blood was also sent for a serum MTX concentration and a type and cross-

match. The CBC showed hemoglobin, 8 g/dL; white cell count, 2000/mm^3 (81% neutrophils, 13% lymphocytes, 1% monocytes, 5% eosinophils); platelet count, 3000/mm^3 ; and INR, 2.0. PTT and renal function were normal. The extended-care facility was contacted, and it was discovered that the patient was inadvertently given methotrexate 2.5 mg daily for 1 month instead of once a week for 1 month.

The patient was transfused with packed red blood cells, platelets, and fresh-frozen plasma. Prophylactic broad-spectrum antibiotics were initiated. Leucovorin 10 mg/m^2 was started and administered every 4 hours IV. The serum MTX concentration was later determined to be zero and leucovorin therapy was discontinued. The white blood cell count (WBC) was lowest on day 3 of hospitalization and rose thereafter.

Although overdoses of antineoplastic medications are infrequent, these events are of greater consequence than overdoses of many other medications because of their narrow therapeutic margin. From 1988 to 2003, the annual number of people exposed to antineoplastic agents reported to US poison control centers was about 1000 (Chap. 130). This figure represents about 1 per 1000 cases of pharmaceutical exposures, or 1 per 2000 cases of all exposures annually reported to US poison control centers. Two-thirds of the people exposed to antineoplastic agents in these reports were adults, one-fourth were young children, and the remainder were adolescents. Between 1999 and 2003 there was an observable change in the annual trend of the proportion of exposures between adults and young children: From 1999 to 2002, the annual percent of exposures for adults increased to approximately 50â€“70%, and for children younger than 6 years old, this figure decreased from 30% to 20%. Children and adolescents between the ages of 6 and 19 years accounted for approximately 7% of the population annually exposed, and this frequency did not change between these years. The reasons for these observations are not apparent and further analysis is

warranted to define the causes of these trends. Approximately 10% of the annual exposures in this setting resulted in morbidity defined as moderate or major in severity. This was higher than expected because unintentional exposures occurred 8 times more frequently than intentional exposures. The mortality was about 1 per 1000 exposures.

A review of the 2819 orders for cytotoxic agents at a pharmacy satellite showed that 93 orders (3%) contained at least 1 error in the dosage regimen and 442 (16%) contained at least 1 error in the instructions for drug preparation.[89] Three of the errors in dosage regimen were classified as potentially lethal, 13 as serious, 5 as significant, and 72 as minor. Two of the potentially lethal overdoses of cisplatin were a result of errors in duration of administration (100 mg/m^2 for 3â€“4 consecutive days instead of for 1 day). Lack of healthcare provider familiarity with the agent and its dosing was a major cause of these events. In another study evaluating drug errors, 49% occurred at the ordering/prescribing stage. This was most commonly caused by physicians who lacked knowledge of the drug and of the intended patient.[162] Other areas in which errors occurred were during transcription and nurse administration. As more antineoplastics become available and their indications broaden, unintentional exposures and unintended dosing regimens (Chap. 134) will increase in number and frequency.

Aside from unintentional exposures, additional factors leading to increased toxicity associated with antineoplastics include age, gender, comorbidities/compromised host state, and diminished renal and hepatic function. Diminished hepatic clearance caused by altered enzyme expression can be accounted for by age, gender, smoking status, and the concurrent use of other medications. Differences in gender can contribute to varying pharmacokinetic parameters, including bioavailability, distribution, metabolism, and elimination. In a study, women treated with 5-fluorouracil (5-FU) for colon cancer were found to have a 2-fold higher frequency of

drug-related toxicity than men.[266] The manifestations included leukopenia, diarrhea, and stomatitis, which also was observed in other reports.[211, 251] Although the basis for this difference in toxicity between genders is not known, it may be

because of a decreased 5-FU clearance from diminished dihydropyrimidine dehydrogenase activity in women.[187, 211] Dihydropyrimidine dehydrogenase inactivates more than 80% of fluorouracil by metabolizing it to 5-fluorodihydrouracil, and low activity of this enzyme can result in hematologic and gastrointestinal toxicity.

Class	Antineoplastic	Adverse Effects	Overdose	Antidotes

TABLE 52-1. Classification of Antineoplastics and Their Effects

At an individual level, genetic polymorphisms can contribute to differences in xenobiotic response with resultant toxicity by altering targets, transporters, and enzyme complexes. Such variations have been characterized for several enzymes that are involved in the metabolism of antineoplastic agents. Irinotecan and amonafide are two examples that are associated with toxicity.

Irinotecan is a topoisomerase I inhibitor that works through its active metabolite, SN-38, which can cause diarrhea and neutropenia at elevated levels.[279] A genetic variant of uridine diphosphate glucuronosyltransferase (UGT1A1) containing the T7 allele glucuronidates SN-38 at a slower rate than other variants, resulting in increased SN-38 levels and toxicity.[12 , 125] Another example is amonafide, which is a topoisomerase II inhibitor; and its active

metabolite, *N* -acetyl amonafide is formed by *N* -acetyltransferase 2 (NAT2). People capable of â€œrapid acetylationâ€• have a genetic variation of NAT2 and are more likely to develop myelotoxicity than are people with a slower rate of acetylation activity.[215] There are additional polymorphisms in metabolism associated with antineoplastic agents; however, further work is necessary to define their clinical significance. Because of the narrow therapeutic index of the antineoplastic agents, the significance of such findings demonstrates the benefit of individual drug monitoring to maximize the therapeutic efficacy of the these agents while limiting host toxicity.

Most antineoplastic agents can be grouped into one of these four categories: alkylating agents, antimetabolites, antimitotics, and antibiotics (Table 52-1). The antimetabolites are grouped by the substrates with which they interfere. Methotrexate is a folate antagonist; other drugs with similar but lesser toxicity include trimethoprim and pyrimethamine. The antimitotics are plant alkaloids and they exert toxic effects by interrupting microtubule assembly. Other naturally derived agents include the antibiotics and the enzyme L-asparaginase, which can be isolated from bacteria. The alkylating agents are more commonly used than other antineoplastic agents and cause covalent binding to nucleic acids, which inhibits DNA activity. These xenobiotics include the nitrogen mustards, platinoids, and nitrosoureas. The antimetabolites and the alkylating agents are cell-cycle active,

meaning that they only affect cells undergoing cell division. Some agents are phase specific; that is, they affect the cell only at a period during cell division. The cell cycle consists of the S phase (DNA replication) and the M phase (mitosis). DNA regulation and chromosomal separation occur during the mitosis. Vincristine is M-phase specific and cytarabine is S-phase specific, in their sites of action. A new class of antineoplastics inhibits topoisomerase I, which is necessary for DNA replication because it allows for reversible DNA single-strand breaks. Because the majority of the cases of antineoplastic overdoses involve the methotrexate, vincristine, mitoxantrone (related to the anthracyclines), mustards, and cisplatin, this discussion focuses on these xenobiotics. Other sources for information regarding these agents are the American Cancer Society (http://www.cancer.org/docroot/home/index.asp) and the American Society of Health-System Pharmacists (http://www.ashp.org/).

Methotrexate

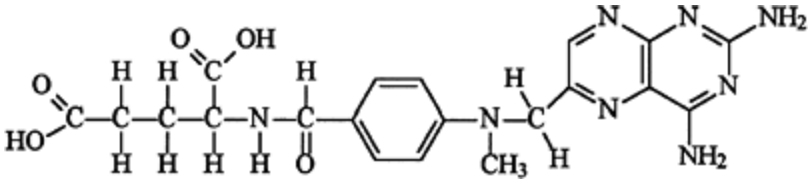

Figure. No Caption Available.

Pharmacology

Methotrexate (MTX) is an important therapeutic agent for a variety of cancers, such as non-Hodgkin lymphoma, lymphocytic leukemia, breast cancer, and small-cell lung carcinoma. Its immunosuppressive activity allows it to also be used for rheumatoid arthritis, organ transplantation, psoriasis,

trophoblastic diseases, and therapeutic abortion.[52, 133] Its therapeutic and toxic effects are based on its ability to limit DNA and RNA synthesis by inhibiting dihydrofolate reductase (DHFR) and thymidylate synthetase (Fig. 52-1). Thymidylate synthesis is inhibited by polyglutamic derivatives of methotrexate. DHFR reduces folic acid to tetrahydrofolate (FH_4), which serves as an essential cofactor in the synthesis of purine nucleotides. These reduced folates are also required by thymidylate synthetase to serve as methyl donors in the formation of thymidylate. Thymidylate is then used for DNA synthesis. MTX is a structural analog of folate and competitively inhibits DHFR by binding to this enzyme's site of action. This stops reduced folate production, which is necessary for nucleotide formation and DNA/RNA synthesis.

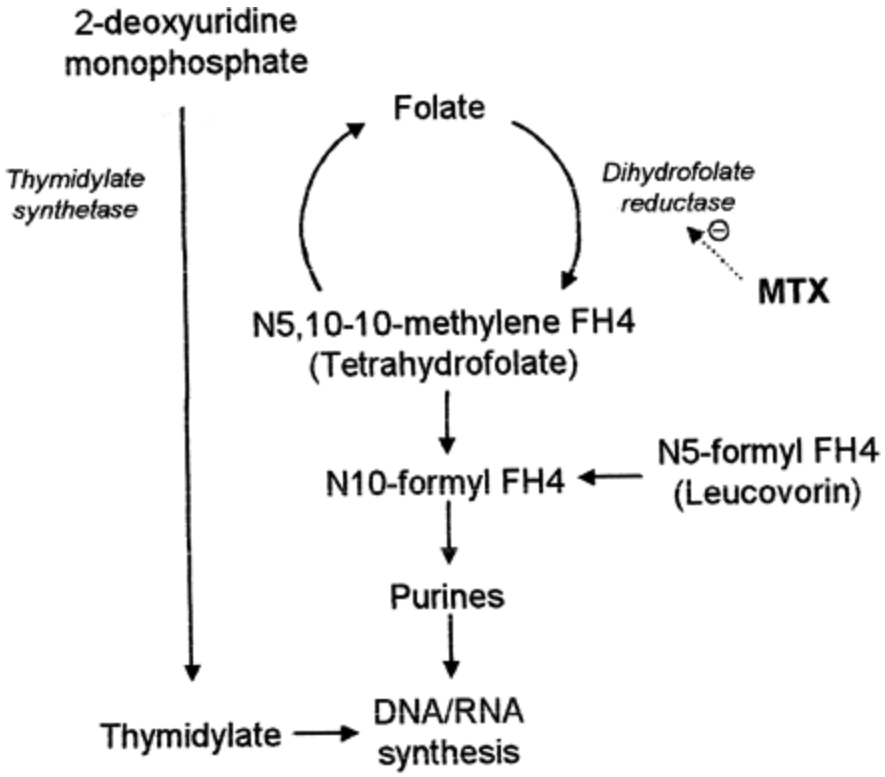

Figure 52-1. Mechanism of methotrexate (MTX) toxicity. MTX inhibits DHFR activity, which is necessary for DNA and RNA synthesis. Leucovorin bypasses blockade to allow for continued

synthesis.

The bioavailability of methotrexate appears to be limited by a saturable intestinal absorption mechanism. At oral doses less than 30 mg/m^2 , the absorption is 90%; at doses greater than 80 mg/m^2 , the absorption is less than 10â€“20%.[36] The weekly adult dose used for the treatment of psoriasis and rheumatoid arthritis is low and can be administered orally. However, the dose used to induce abortion is higher (50 mg/m^2) and must be administered parenterally to achieve effective drug concentrations. MTX dosing regimens for chemotherapy are variable, but can be generally classified as low, moderate, and high doses. Conventional intravenous doses of up to 100 mg/m^2 can be administered without leucovorin rescue. Doses of 1000 mg/m^2 are considered potentially lethal. Much higher doses (2â€“3 g/m^2) can be given when MTX is followed by leucovorin in order to prevent life-threatening toxicity. Mortality from high-dose MTX is approximately 6%, and occurs primarily when patients' MTX levels are not monitored.[86 , 255 , 275]

MTX has a triphasic plasma clearance. The initial plasma distribution half-life is shortâ€”0.75 hours. The second half-life is 2â€“3.4 hours and represents renal clearance of the drug. The third phase has a half-life of about 8â€“10.4 hours and represents tissue redistribution into the plasma. This third phase can be prolonged in the setting of renal failure and is associated with bone marrow and gastrointestinal (GI) toxicity. The kidneys eliminate 50â€“80% of MTX unchanged within 48 hours of administration. At high doses, drug and insoluble drug metabolites 7-hydroxy methotrexate and 2,4-diamino-10-methyl pteroic acid accumulate and may precipitate in the renal tubules, causing reversible acute tubular necrosis. MTX is one-tenth as soluble at a pH of 5.5 as it is at a pH of 7.5.[36 , 231] The serum concentration threshold for nephrotoxicity is 2.2 mmol/L at a urine pH of 5.5, and 22 mmol/L at a urine pH of

6.9. Patients who are either inadequately hydrated or not alkalinized are at risk for acute renal failure from high dose MTX treatment.[3,92,135] MTX is excreted unchanged in the urine by both glomerular filtration and active tubular secretion. Folic acid blocks MTX renal reabsorption and can enhance elimination during leucovorin rescue.[118] A small amount of MTX is metabolized intracellularly to polyglutamate derivatives, which inhibit DHFR and thymidylate synthetase and are believed to be responsible for the persistent cytotoxic effect of MTX.

Toxicity of MTX depends more on the duration of exposure than the dose itself. Thus, greater toxicity is expected from a 7-g (approximately 4 g/m^2 , adult) IV dose administered over 48 hours than from a 20 g (approximately 12 g/m^2 , adult) IV dose administered over 24 hours.[99] Patients with a plasma MTX concentration greater than 1.0 Âµmol/L at 48 hours posttreatment are considered at risk for bone marrow and gastrointestinal mucosal toxicity.[255] Risk factors for MTX toxicity are impaired renal function (primary route of drug elimination), third compartment spacing, ascites, and pleural effusions, use of nonsteroidal antiinflammatory drugs (NSAIDs), age, folate deficiency, and concurrent infection.[255] The contribution of NSAID use to MTX toxicity may be a result of diminished renal clearance of the drug.[153]

Clinical Manifestations

In the course of MTX therapy, a variety of disorders can occur, resulting from either increased patient susceptibility to toxicity or excessive administration. The clinical manifestations of MTX toxicity include stomatitis, esophagitis, renal failure, myelosuppression, hepatitis, and central neurologic system dysfunction. In a group of 23 patients who received 45 courses of high-dose MTX therapy with leucovorin rescue, the commonly

observed signs included increased aspartate aminotransferase (AST)/alanine aminotransferase (ALT) (81%), nausea and vomiting (66%), mucositis (33%), dermatitis (18%), leukopenia (11%), thrombocytopenia (9%), and creatinine elevation (7%).[216]

Nausea and vomiting, considered rare after low-dose cancer therapy (<40 mg/m^2), typically begin 2â€“4 hours after high-dose therapy (>1000 mg/m^2) and last for about 6â€“12 hours. Mucositis, characterized by mouth soreness, stomatitis, or diarrhea, usually occurs 1â€“2 weeks after therapy and can last for 4â€“7 days. Other gastrointestinal symptoms resulting from MTX therapy include pharyngitis, anorexia, gastrointestinal hemorrhage, and toxic megacolon.[16] Hepatocellular toxicity, as described by increased AST (>1000), ALT (>1000), and hyperbilirubinemia, can be observed with both acute and chronic therapy.[180 , 194] It is usually associated with high-dosage regimens. Laboratory abnormalities improve within 1â€“2 weeks of discontinuation of MTX. The mechanism is incompletely understood, but toxicity is attributed to reduced liver folate stores.[19] Factors associated with hepatotoxicity are sustained high plasma levels, increased cumulative dosages, chronic therapy, and host factors such as increase in age, obesity, diabetes, and alcoholism.[280]

Pancytopenia usually occurs within the first 2 weeks after an acute exposure. There are several reports demonstrating the occurrence of pancytopenia in individuals receiving chronic MTX therapy for rheumatoid arthritis and psoriasis.[74 , 147 , 180 , 222]

When used in small IV doses of 40â€“60 mg/m^2 , MTX is not associated with appreciable nephrotoxicity. However, at doses greater than 5000 mg/m^2 (approximately 130 mg/kg for an adult), several investigators report severe kidney damage, with oliguria, azotemia, and renal failure.[25] The renal function can normalize over time. Patients at risk for nephrotoxicity include the elderly, those with underlying renal disease defined as a glomerular

filtration rate of less than 50 mL/min, and those who receive concurrent drug therapy that can delay MTX excretion, which includes agents that reduce renal blood flow such as NSAIDs, the nephrotoxic agents cisplatin and the aminoglycosides, or weak organic acids such as salicylates and piperacillin.[127 , 255]

The neurologic complications associated with either high-dose systemic MTX therapy or intrathecal administration are the most consequential manifestations. The incidence of neurologic toxicity from high-dose MTX therapy is approximately 5â€“15%.[136] The manifestations usually occur from hours to days after the initiation of therapy and include hemiparesis, paraparesis, quadraparesis, seizures, and dysreflexia.[84 , 179 , 277] These events are reversible to varying degrees. The mechanisms remain unclear, but may be the result of direct toxicity to neuronal glial and endothelial cells and decreased neurotransmitter synthesis.[2] Clinical findings occurring within several hours (usually within 12 hours) of therapy are attributed to chemical arachnoiditis, and they include acute onset of fever, meningismus, pleocytosis, and increased cerebrospinal fluid (CSF) protein concentration.[119] Leukoencephalopathy is associated with the onset of behavioral disorders and progressive dementia from months to years after treatment and is irreversible.[7] CSF analysis and computerized tomography of the brain may be normal or show demyelination of white matter (especially in the anterior and frontal lobes).[7]

Management

In the event of an oral overdose of methotrexate, the initial concern should be gastrointestinal decontamination. Activated charcoal adsorbs methotrexate and should be administered as soon as possible to limit absorption.[94] The administration of multiple-dose activated charcoal and cholestyramine[84 , 242] can significantly decrease the elimination half-life of methotrexate by interrupting the enterohepatic circulation.[94 , 105] This can increase

MTX clearance when it is administered parenterally, but is of most benefit to patients with diminished renal creatinine clearance.

Adequate hydration with 0.9% sodium chloride solution as well as urinary alkalinization with IV sodium bicarbonate (to urine pH 7â€“8) (Antidotes in Depth: Sodium Bicarbonate) is also important to prevent renal failure in patients who receive inadvertent high doses. The CBC should be monitored on days 7, 10, and 14 because life-threatening complications, such as bleeding disorders and overwhelming sepsis, can occur.[159]

Patients presenting with meningismus or altered mental status following MTX therapy require an initial computed tomography (CT) scan of the brain and then CSF analysis for infection.[145] Although not considered standard, the CSF may be assayed for MTX if excessive exposure to this compartment is suspected. The CSF MTX concentration is about 0.1 Âµmol/L and lasts for 48 hours after an IV MTX dose of 1500 mg/m^2 , and 100 Âµmol/L for the peak therapeutic concentration after a 12-mg intrathecal MTX dose.[198] Magnetic resonance imaging (MRI) of the brain may demonstrate a high signal throughout the pachymeningeal (dura mater) region, which is consistent with a chemical meningitis.[93] MRI scans of the brain of patients with leukoencephalopathy shows hyperintense lesions in the white matter area.[93] This is a finding similar to that in patients presenting with subacute neurologic symptoms following MTX therapy.[179]

Antidotes

Folinic acid (leucovorin, *N* -5-formyl-tetrahydrofolate) rescue therapy allows higher doses of methotrexate to be administered therapeutically, as leucovorin limits bone marrow and gastrointestinal toxicity. The effectiveness of leucovorin depends on both the timing of administration and the dose. Leucovorin is most beneficial when administered within 1 hour of exposure, but

should still be given to patients who present in a delayed manner after an excessive exposure. The only complications associated with leucovorin administration are the possible drug interaction with anticonvulsants (phenobarbital, phenytoin, primidone) to lower seizure threshold at high leucovorin dosages[219] and hypersensitivity reactions.[120]

The initial leucovorin dose to be administered should achieve a plasma concentration equal to or greater than that of the MTX. In this manner, the reduced folate antidote can successfully compete with MTX for active transport sites on the cell membrane, displace MTX from its intracellular binding site, and, most importantly, restore reduced folate stores to allow for continued purine and subsequent DNA/RNA synthesis.[134 , 210] The lower doses of leucovorin used during MTX therapy are an attempt to protect normal body cells but not tumor cells. Under therapeutic circumstances delay leucovorin rescue as long as possible, administer the minimal effective dose, and discontinue therapy as soon as it is no longer necessary.[25] It is important to adjust the leucovorin dose according to the actual plasma MTX level for an overdose situation, and not to continue at the original rescue dose for routine therapy (Antidotes in Depth: Folic Acid and Leucovorin [Folinic Acid]).[146]

Serum MTX levels should be monitored at 12, 24, and 48 hours postexposure so that leucovorin therapy can be adjusted accordingly. Generally, leucovorin therapy is continued in patients undergoing chemotherapy if the plasma MTX level is above 1.0 Âµmol/L (1 Ã— 10^{+6} M) at 48 hours postexposure,[255] and maintained until the level is below 0.1 Âµmol/L.[264] However, for patients without cancer, the leucovorin therapy should be continued until the MTX level is less than 0.01 Âµmol/L, because DNA synthesis is impaired above this value.[53] In patients with marrow toxicity, leucovorin therapy should be considered until marrow recovery occurs, even if serum MTX is no longer detectable,[173] because intracellular MTX activity may still be

ongoing. It should be noted that trimethoprim, a folate antagonist, can cause false elevations with certain MTX assays (competitive protein binding technique, enzyme inhibition).[22] Spectrophotofluorimetric analysis may misinterpret folinic acid for MTX and should not be used as the analytic method during leucovorin therapy.[149]

Thymidine is also used to rescue cells from the cytotoxic effects of MTX by what is called *thymidylate salvage*.[82, 259] Thymidine can be converted to thymidine triphosphate by thymidine kinase, which is not inhibited by MTX, thus allowing for DNA synthesis. Thymidine rescue is not as effective as leucovorin.[185, 259] It is currently available under an investigational protocol (NCI 92-C-0134) for use by patients with high serum MTX concentration, severe manifestations of toxicity (ie, mucositis, thrombocytopenia, neutropenia, and hepatic insufficiency), and renal insufficiency from the National Cancer Institute (e-mail: ncicssc@mail.nih.gov ; tel: 888â€“624â€“1937 or 301â€–496â€–5725; fax: 301â€–881â€–8239). The investigational dose for thymidine is 8 g/m^2 /d IV, and this treatment is used in conjunction with leucovorin and carboxypeptidase.

Carboxypeptidase G_2 ($CPDG_2$) is a rescue agent that inactivates MTX by cleaving its terminal glutamate group.[292] It is a recombinant bacterial (*Pseudomonas*) enzyme that is well tolerated by patients undergoing high-dose MTX therapy.[68, 283, 284, 292] On its administration, serum MTX concentration decreases within 1 hour. Hypersensitivity reactions may occur because of this agent's bacterial origin. $CPDG_2$ is available for compassionate (protocol No. NCI 92-C-0134) use by patients with high serum MTX concentration (at least 10 Âµmol/L more than 42 hours after initiation of MTX therapy) or under investigational protocol (NCI 92-C-0137) for intrathecal (IT) overdoses (â‰¥100 mg IT MTX) from the National Cancer Institute (e-mail: ncicssc@mail.nih.gov ; tel: 888â€“624â€“1937 or 301â€–496â€–5725; fax: 301â€–881â€–8239). Leucovorin and thymidine treatments are

continued during $CPDG_2$ use because this enzyme does not enter the cell. The investigational dose for $CPDG_2$ is 50 U/kg IV and repeat administration may be necessary if the MTX concentration remains greater than 1 Âµmol/L. It is essential that the high-performance liquid chromatography (HPLC) technique be used to assay for MTX concentration after $CPDG_2$ therapy, because the enzymatic byproducts of MTX yield falsely elevated values with the routine enzyme immunosorbent assay method.[292]

Extracorporeal Elimination

There are several reports of the use of hemodialysis and/or hemo-perfusion for patients with MTX toxicity. Although the volume of distribution (0.6â€“0.9 L/kg) and protein binding (50%) suggest that methotrexate is dialyzable, clinical evidence suggests otherwise.[250] In one report, less than 10% of an initial 0.7 g dose of methotrexate was cleared in 12 sessions of hemodialysis.[261] The measured clearance was only 38 mL/min, which can be compared to 5 mL/min for peritoneal dialysis,[111] 0.28â€“24 mL/min for continuous venovenous hemodiafiltration,[137, 146] and 180 mL/min for normal renal clearance.[167] Using plasma exchange transfusion to remove MTX is not recommended because of the drug's low degree of protein binding, which limits the efficacy of this procedure.[25, 146, 261]

Acute intermittent hemodialysis with a high-flux dialyzer membrane yielded an effective mean plasma MTX clearance of 92 mL/min in 6 patients with renal failure that was a result of either chronic disease or high-dose MTX therapy.[278] These patients received high-dose MTX therapy and had a predialysis plasma MTX concentration ranging from 1.45 to 1813 Âµmol/L. The time of dialysis initiation after MTX treatment was from 1 hour to 6 days in this patient population. A plasma MTX concentration of 0.3 Âµmol/L was used as an end point for dialysis. The reported plasma MTX clearance by this technique closely approximates

normal renal MTX clearance and should be considered if it is available.

Charcoal hemoperfusion removed more than 50% of methotrexate in 4 patients with impaired renal MTX clearance during high-dose MTX therapy.[73] This was thought to have prevented severe skin and mucosal toxicity. Sequential hemodialysis and hemoperfusion were used for a patient with substantial MTX toxicity.[105] These procedures decreased the half-life of elimination from 45 hours to 7.6 hours. In experimental animals, hemoperfusion significantly reduced the terminal half-life of methotrexate. In surgically anephric dogs, hemoperfusion decreased the half-life from more than 20 hours to 1.3 hours.[126] Consequently, hemoperfusion is recommended over hemodialysis.

In vitro studies indicate that the toxic effects of 100 Âµmol/L of MTX cannot be reversed by 1000 Âµmol/L of leucovorin.[210] This suggests the need for hemoperfusion to lower persistent MTX

plasma concentrations of greater than 100 Âµmol/L.[217] It is important to perform hemoperfusion early, prior to distribution into tissues. Rebound of MTX levels from tissues may be expected after hemodialysis, which can begin at 2 hours postdialysis and plateau at 16 hours.[98, 111, 278] If hemoperfusion is not available, and the patient is in renal failure and has a plasma MTX concentration greater than 8 Âµmol/L, hemodialysis may be considered until more definitive treatment, such as enzymatic cleavage, is available.[73]

Patients who are at the greatest risk for developing MTX toxicity despite leucovorin treatment should be considered for extracorporeal elimination because they are most likely to benefit from this procedure. This includes patients with progressively diminishing renal clearance.[255] Although hemoperfusion is preferred over hemodialysis, hemodialysis can be used if it is the only choice available. Hemodialysis can offer the additional benefit

of correcting fluid and electrolyte disorders resulting from renal failure. Other treatment options, including leucovorin and urinary alkalinization, should be continued during extracorporeal MTX removal. Folic acid is water soluble and can be removed by hemodialysis.[64 , 217 , 241 , 245] This is probably also applicable for leucovorin, and replacement doses of leucovorin postdialysis should be considered.

Granulocyte Colony-Stimulating Factor

The decision to use myeloid growth factors in patients with agranulocytosis depends on the severity and nature of the neutropenia, and the anticipated speed of recovery. Granulocyte-macrophage colony-stimulating factor (GM-CSF) was used in a patient with a chronic MTX overdose and pancytopenia.[250] The patient had a serum MTX concentration of 1.25 Âµmol/L on admission and was in renal failure. Bone marrow biopsy showed promyelocytes, but no mature white cells, and a marked reduction of megakaryocytes. Because of deteriorating conditions, GM-CSF (125 Âµg/m^2 /d) was administered when the MTX level fell below the reference limit for toxicity. Seven days after the initiation of GM-CSF, the WBC count rose and reached normal values within 10 days. Typically, if promyelocytes and myelocytes are present in the bone marrow, neutrophil recovery will occur spontaneously in 4â€“7 days, following the withdrawal of the offending agent.[91] However, when granulopoiesis is completely absent, neutrophil recovery cannot be expected for at least 14 days. Using granulocyte colony-stimulating factor (G-CSF) or GM-CSF can accelerate neutrophil recovery during cytotoxic antineoplastic therapy. When myeloid precursors are present in the bone marrow, G-CSF can accelerate neutrophil recovery in 1â€“4 days. If myeloid precursors are absent, neutrophil recovery with G-CSF may take longer, but can be expected to occur sooner than without G-CSF therapy. GM-CSF is indicated for use in neutropenic patients following induction antineoplastic therapy for acute myelogenous

leukemia because this agent enhances the response of macrophages, neutrophils, and eosinophils. Serum levels of the antineoplastic should be below detection before institution of G-CSF to gain maximal response; typically, G-CSF is initiated 24 hours upon the completion of the treatment cycle. The initial dose is 5 Âµg/kg/d IV or subcutaneously (SC), and it is continued beyond the expected WBC nadir. This is usually a 2-week course; however, it can be prolonged with lomustine overdoses.[1,263] The dose may be adjusted, depending on the patient's WBC response. Therapy can be discontinued when the post nadir absolute neutrophil count is greater than 10 Ã— 10^3 cells/mm^3 . Bone pain can be anticipated from the use of these agents, presumably because of the increase in cellularity in the marrow space. Additional side effects can be expected from GM-CSF therapy, including myalgia, fevers, and pericarditis.

GM-CSF might produce a transient beneficial response in the WBC in patients with aplastic anemia.[55] However, when the anemia was severe, the GM-CSF therapy was not effective. Another hematopoietic growth factor is erythropoietin (EPO), which is approved for use in patients with anemia associated with cancer chemotherapy treatment.[100]

Vincristine and Vinblastine

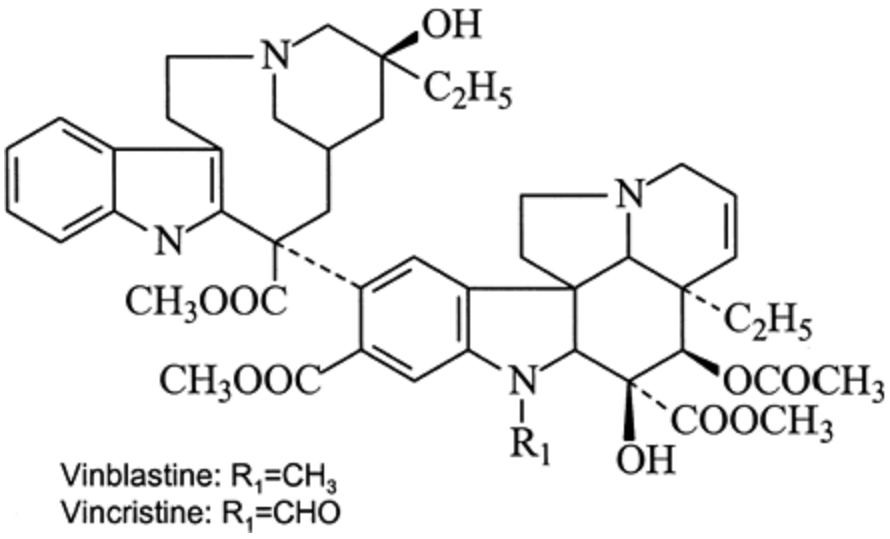

Figure. No Caption Available.

Pharmacology

Vincristine and vinblastine are derived from the periwinkle plant (*Catharanthus roseus*) and used for the treatment of leukemias, lymphomas, and certain solid tumors. Their mechanism of activity is similar to that of colchicine, podophyllotoxin, and the taxoids (eg, paclitaxel, docetaxel).[69 , 78] These xenobiotics disrupt microtubule assembly from tubulin subunits by either preventing their formation or depolymerization, both of which are necessary for routine cell maintenance. Microtubules are responsible for several basic cellular functions including cell division, axonal transport of nutrients and organelles, and cellular movement. Mitotic metaphase arrest is commonly observed because of the inability to form spindle fibers from the microtubules. Cell death quickly ensues as a result of the interruption of these homeostatic functions, accounting for the clinical manifestations.

The vinca alkaloids are primarily eliminated through the liver and have a terminal plasma half-life of about 24 hours.[193] Patients with hepatic dysfunction are susceptible to toxicity. The capacity of vincristine to be bound by plasma proteins ranges from 50% to

80%.[208]

Vincristine overdose is the most frequently reported antineoplastic overdose in the literature. This is because there are at least 4 different ways to misdose this agent, including confusing it with vinblastine, misinterpreting the dose, administering it by the wrong route, and confusing two different-strength vials. The normal dose of vincristine is 0.06 mg/kg, and a single dose is not to exceed 2.0 mg for either an adult or child.

Clinical Manifestations

Despite their similarity in structure, vincristine and vinblastine differ in clinical toxicity. Vincristine produces less bone marrow suppression and more neurotoxicity than does vinblastine. During the therapeutic use of vincristine, myelosuppression occurs in only

5â€“10% of patients.[115] However, this effect is common in the overdose setting and when it occurs the need for replacement blood products and concern for overwhelming infection is apparent.[172] The fall in cell counts begins within the first week and may last for up to 3 weeks. Other manifestations of acute vincristine toxicity are mucositis, CNS disorders, and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Central nervous system disorders are varied and unusual during therapeutic vincristine therapy because of the agent's poor penetrance of the bloodâ€“brain barrier.[131] They are, however, more common when there is delayed elimination, damage to the blood brainâ€“barrier, overdose, or inadvertent intrathecal administration. Generalized seizures from toxicity or secondary effects may occur from 1 to 7 days after exposure.[121 , 141 , 144 , 256] Treatment with benzodiazepines or phenobarbital is usually successful, and phenytoin was used successfully in a patient with barbiturate hypersensitivity.[144] Other manifestations are depression, agitation, insomnia, and hallucinations. Vincristine

stimulation of the hypothalamus may be responsible for the fevers and SIADH noted in overdosed patients.[223] The fevers begin 24 hours after exposure and last 6â€“96 hours. Serum electrolytes need to be monitored, typically for 10 days.

Autonomic dysfunction is observed, and it commonly includes ileus, constipation, and abdominal pain. Atony of the bladder, hypertension, and hypotension also can occur.[144]

Ascending peripheral neuropathies occur during vincristine therapy and can be limited by keeping the total for a single dose below 2 mg.[246] Neuropathy may appear after an overdose, starting at about 2 weeks and lasting for 6â€“7 weeks. Paresthesias, neuritic pain, ataxia, bone pain, wrist drop, foot drop, involvement of cranial nerves IIIâ€“VII and X, and diminished reflexes can be observed.[281] The incidence of paresthesia increases with dose and is reported to be 56% in patients treated at doses between 12.5 and 25 Âµg/kg.[115] At a dose of 75 Âµg/kg, the incidence of patients with a sensory disorder increased by 6-fold. The loss of reflexes, the earliest and most consistent sign of vincristine neuropathy, is maximal at 17 days after a single massive dose. Muscular weakness is a limiting point in therapy, and typically involves the distal dorsiflexors of the extremities, although laryngeal involvement is also reported.[165 , 230] These severe neurologic symptoms may be reversed by either withholding therapy or reducing dosage upon manifestation of these findings.[165] The mechanism of toxicity is not well understood, but appears to be related to inhibition of microtubular synthesis, which leads to axonal degeneration.[103 , 196] A brain biopsy of a patient suffering a vincristine-related death showed neurotubular dissociation, which is characteristic of vincristine damage in experimental animals.[40 , 57] Unlike the vinca alkaloids, Taxol-induced peripheral neuropathy is predominantly sensory and resolves faster with discontinuation of the offending agent.[170] This is because of the different effects on microtubule assembly by these agents. Nerve conduction studies and the Achilles tendon

reflex are useful in monitoring patients for toxicity after exposure.

Vincristine-induced myocardial infarctions are reported but their cause is not understood.[175 , 247 , 257 , 289] It may be related to vinca alkaloid-induced platelet aggregation, coronary artery spasm, or increased sensitivity of myocardium to hypoxia.

Management

Patients receiving an inadvertent amount of an IV dose of vincristine should be admitted to a cardiac-monitored bed and observed for 24â€“72 hours.[174] Seizures, dysrhythmias, and alterations in blood pressure can be expectantly managed, although prophylactic phenobarbital and benzodiazepine were used to prevent seizures in two patients.[54 , 152] Calcium channel-blockers (nifedipine and amlodipine) were used to control hypertension in a patient with vincristine overdose.[54] Blood counts must be monitored daily, and G-CSF may be used to treat neutropenia.[54 , 172 , 256] However, the red cell response from the use of erythropoietin may be limited because of the induction of metaphase arrest in the erythroblasts by these particular xenobiotics.[177]

If patients remain asymptomatic during the observation period, they can be discharged with followup for bone marrow suppression and SIADH; otherwise, depending upon the patients' clinical condition, continual observation for progression of neurologic symptoms is warranted.[27] The symptoms of acute toxicity usually last for 3â€“7 days, and the neurologic sequelae may last for months before some resolution is observed.

In a controlled clinical trial, for vincristine-induced peripheral neuropathy glutamic acid therapy had limited efficacy. Patients receiving vincristine therapy were given glutamic acid as 500 mg orally 3 times a day.[132] It was observed that there was a decreased incidence in loss of Achilles tendon reflex and delayed

onset of paresthesias in the glutamic acid-treated group. No reported adverse effects with glutamic acid were observed in this investigation. Animal studies involving the administration of glutamic and aspartic acid to mice poisoned with either vinblastine or vincristine demonstrate increased survival and decreased sensorimotor peripheral neuropathy.[39, 66, 130] The mechanisms of these observed effects with glutamic acid remain unclear, but several have been suggested, including glutamic acid's ability to competitively inhibit a common cellular transport mechanism for vincristine,[37, 63] its ability to assist in the stabilization of tubulin and promote its polymerization into microtubules,[41, 110] and the ability of glutamic acid to improve cellular metabolism by overcoming the inhibition by these agents in the Krebs cycle.[77, 220] Although the role of glutamic acid in acute toxicity needs further study, it is not harmful and should be considered. Glutamic acid may be initiated as 500 mg orally 3 times a day and continued until the serum drug concentration is below toxicity.[132] L-Glutamic acid is the preferred stereoisomer because it is biologically active and this product is available as a powder from various distributors in the United States.

Leucovorin may shorten the course of vincristine-induced peripheral neuropathy[107] and myelosuppression.[152] The mechanism is attributed to leucovorin's ability to overcome a vincristine-mediated block of dihydrofolate reductase and thymidine synthetase.[107] However, neither leucovorin[24, 128, 262] nor pyridoxine[129] has been shown definitely to be effective. An initial experimental investigation evaluating the efficacy of antibody therapy to limit vinca alkaloid toxicity shows promise.[108]

Enhanced Elimination

Vincristine is rapidly distributed to tissue stores and highly bound to proteins and red cells.[48] Although elimination of vincristine is via the hepatobiliary system,[48] there is no evidence demonstrating

the efficacy of multiple-dose activated charcoal in enhancing the elimination in the overdose setting. In more than 50% of children given vincristine IV, plasma concentrations were not detected 4 hours after administration.[190] Such characteristics favor early intervention and methods other than hemodialysis. Double-volume exchange transfusion was performed at 6 hours postexposure in

3 children who were overdosed with 7.5 mg/m^2 of vincristine IV.[152] This procedure replaced approximately 90% of the circulating blood volume by exchanging twice the patient's blood volume. Of the 2 survivors, their respective postexchange serum vincristine concentrations were 57% and 71% lower than their preexchange concentrations. The amount of vincristine removed was not determined. Although these patients developed peripheral neuropathies, myelosuppression, and autonomic instability, the author noted that the duration of illness was shorter than previously reported. Thus, based on the pharmacokinetic profile of vincristine and these two reports, exchange transfusion in the child is the preferred method of enhanced elimination when the patient presents soon after the administration of the drug, and plasmapheresis is the preferred method in the adult.

Plasmapheresis was attempted with vinca alkaloid overdoses.[172, 208] In an 18-year-old patient who received two 8-mg IV doses of vincristine at 12-hour intervals, the procedure was performed 6 hours after the second dose and 1.5 times the plasma volume was plasmapheresed.[208] Postplasmapheresis serum vincristine concentration was 23% lower than the starting concentration. The patient survived with myelosuppression, neurotoxicity, and SIADH.

Anthracyclines

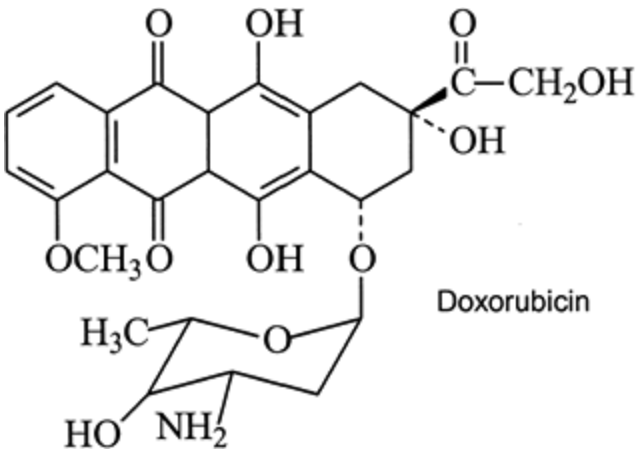

Figure. No Caption Available.

Pharmacology

The antineoplastics derived from the bacterium *Streptomyces* are dactinomycin, daunorubicin, doxorubicin, bleomycin, mitomycin, and plicamycin. Only plicamycin crosses the bloodâ€“brain barrier. The terminal elimination half-life for doxorubicin is about 30 hours.[104] Doxorubicin and daunorubicin are both eliminated by the liver and patients with hepatic dysfunction should have their dosage decreased. Delayed drug elimination contributes to increased drug area under the plasma drug concentration versus time curve (AUC) and peak serum concentration, which are associated with myelosuppression and cardiac toxicity, respectively.[166] The mechanism of therapeutic action of the anthracyclines is attributed to DNA intercalation[228] and activation of topoisomerase II.[260] These xenobiotics are metabolized to active metabolites, which have lesser degrees of activity than their parent compounds. A typical dose schedule for daunorubicin is 30â€“60 mg/m^2 daily for 3 days; for doxorubicin, 45â€“60 mg/m^2 every 18â€“21 days. Daunorubicin and doxorubicin share many common indications for cancer therapy, but they differ in that doxorubicin is used in solid tumors such as breast carcinoma.

The red anthracycline antibioticsâ€”dactinomycin and

doxorubicinâ€”are associated with cardiotoxicity, which limits their therapeutic use. The mechanism responsible for their therapeutic effects is different from that which causes cardiotoxicity.[260] The mechanism of cardiac toxicity is believed to result from the formation of free radicals.[191] Doxorubicin and dactinomycin are quinone derivatives and can be reduced to free radicals. These metabolites are extremely cytotoxic through the promotion of lipid peroxidation. Paraquat and bleomycin have similar mechanisms of toxicity. The limited efficacy of free radical scavengers (Î±-tocopherol, *N* -acetylcysteine) for anthracycline cardiotoxicity led to an understanding of the importance of iron as a cofactor for these radical-producing reactions.[192] The anthracyclines have a high affinity for metal ions. Doxorubicin has an iron (Fe^{3+})-binding constant of 10,[41] which is comparable to deferoxamine.[96] The heart's increased susceptibility to free radicals is attributed to its lack of sufficient enzyme activity responsible for free radical scavenging.[75]

Clinical Manifestations

The cardiotoxic manifestations can be divided into acute and chronic categories. The various findings described with acute toxicity include dysrhythmias, ST and T-wave changes on the ECG, diminished ejection fraction that usually resolves over 24 hours, and sudden death.[42 , 252 , 288] Abnormal findings on the ECG are present in 41% of patients receiving doxorubicin.[14 , 112 , 164 , 252 , 276 , 291 , 294] These are neither dose related nor associated with the development of cardiomyopathy. Acute pericarditis and myocarditis resulting in conduction defects and congestive heart failure are also reported.[42] Animal studies with doxorubicin demonstrate beneficial effects of adrenergic antagonists for toxicity because of elevated levels of catecholamines,[43] although the use of Î²-adrenergic antagonists in the potential setting of diminished cardiac output needs to be considered.

Significant cardiotoxicity results from elevated peak serum levels and accounts for the continuous and periodic infusions practiced in therapy. In cumulative doses, the anthracycline antibiotics cause a cardiomyopathy that results in congestive heart failure. The condition is irreversible and is associated with a 48% mortality.[212] This drug-induced congestive heart failure is associated with pathognomonic changes on electron microscopy that can distinguish it from infectious and ischemic etiologies. These histologic changes include reduced number of myocardial fibrils, and mitochondrial and cellular degeneration.[33] The potential mechanisms for cardiac failure include free radical damage and impaired intracellular calcium homeostasis.[206] The incidence of chronic cardiotoxicity for doxorubicin is between 1 and 10% when the cumulative dose is less than 450 mg/m^2 , and becomes greater than 20% when more than 550 mg/m^2 (comparable to dactinomycin, 950 mg/m^2) is administered.[274] At a cumulative dose of 720 mg/m^2 for epirubicin, the incidence of cardiac dysfunction is reported to be 19%.[186]

The best way of monitoring cardiac function during therapy is to use radionuclide cineradiography to measure the left ventricular ejection fraction.[6] Therapy should be discontinued when the ejection fraction falls below 50%. Two-dimensional echocardiography can demonstrate left ventricular wall thickening and fractional shortening from anthracycline overexposure. Newer techniques used to assess subclinical cardiac muscle pathology from these agents include cardiac-specific contractile protein troponin T and troponin I,[168] and radionuclide-tagged monoclonal antibody imaging.[49] In a small clinical trial of patients treated with doxorubicin,

serum cardiac troponin T levels did not correlate with echocardiographic findings.[150] In 21 of 24 patients, the serum troponin T level was below detection and 9 patients had abnormal echocardiographic findings. Further studies are necessary to

determine the role of these new laboratory studies in clinical management.

Factors associated with an increased risk for cardiotoxicity include mediastinal irradiation, preexisting cardiac disease in children, age more than 70 years, and the concomitant use of cyclophosphamide, paclitaxel, and other anthracycline agents.[42] Children are at risk for developing increased left ventricular afterload from doxorubicin toxicity because of the drug's ability to inhibit myocardial growth, which can lead to a disproportionate ratio of left ventricular wall thickness to left ventricular chamber size.[169] Fatalities are reported with minimum doses of 150â€“333 mg/m^2 , and occur within 1â€“16 days after exposure.[65]

Myelosuppression and mucositis are other effects associated with the use of the anthracycline agents. They typically occur in 1â€“2 weeks, and patients recover.[26] The white cells are affected more than either the red cells or platelets. Patients with diminished drug clearance (eg, liver failure) are at risk for the development of these findings.

Mitoxantrone is recognized to be less toxic than doxorubicin and daunorubicin. Major organs of toxicity remain the heart, bone marrow, and gut. Gastrointestinal effects are less severe and less frequent with mitoxantrone than with doxorubicin.[244] Four cases of mitoxantrone overdose are reported in the literature.[109 , 244] Common to these events is a 10-fold error in dosing (100 mg/m^2 instead of 10 mg/m^2), early onset of nausea with vomiting, and myelosuppression with fever. Acute decreased cardiac contractility was observed by echocardiography in 1 patient who was asymptomatic.[109] Otherwise, no patient developed dysrhythmias, congestive failure, ECG changes, or elevated creatine phosphokinase levels early after exposure. Three patients developed fatal congestive heart failure (CHF) from 1â€“4 months later.[244]

Management

There are no specific antidotes for this class of agents except for dexrazoxane; thus, management is largely supportive. Monitoring for cardiotoxicity and pancytopenia is necessary. A baseline chest radiograph, electrocardiogram, and echocardiogram to determine left ventricular ejection fraction (at rest and/or with stress) are required. Endomyocardial biopsy and cardiac catheterization can assist in distinguishing other causes of cardiac dysfunction. Left ventricular function is the best predictor for cardiomyopathy.[88, 235] A 10% absolute decrease in the left ventricular ejection fraction (LVEF) or a drop in LVEF of 50% from baseline is a significant finding for the discontinuation of further anthracycline therapy.[235] Although digoxin and furosemide should be used to manage acute CHF, a variable response can be expected.[244] Digoxin and low-dose verapamil benefit patients treated with doxorubicin; however, this benefit may be limited by the severity of the disorder.[95, 282] At higher doses of verapamil, hypotension and heart block were observed, which limited further use.[202, 254]

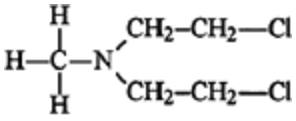
Dexrazoxane is a cardioprotectant that limits the effects of doxorubicin by chelating intracellular iron, which mediates the formation of free radical cellular damage. In clinical trials, patients receiving dexrazoxane had smaller decreases in LVEF per dose of doxorubicin, fewer histologic changes on cardiac biopsy, were better able to tolerate doxorubicin doses greater than 600 mg/m^2, and had a lower occurrence of serum cardiac troponin T elevations than did patients who were not pretreated with dexrazoxane.[169, 248] The current role of this chelator is to limit cardiotoxicity in patients receiving more than 300 mg/m^2 of doxorubicin.[238] It is administered 30 minutes before doxorubicin in a 10:1 ratio. Dexrazoxane increases the systemic clearance of epirubicin in a clinical trial, which may be an added benefit to patients with increased exposure.[23] Further investigations are required to determine the use of dexrazoxane in overdose exposures and with

other anthracycline agents.[5, 186] Other cardioprotectants under investigation include amifostine[50] and monohydroxyethylrutoside. Monohydroxyethylrutoside is a semisynthetic flavonoid that can chelate iron and scavenge free radicals. In experimental models, monohydroxyethylrutoside decreased doxorubicin-induced cardiotoxicity as measured by ST segment elevation on the ECG[268] and left ventricular function.[122] Clinical trials are lacking with this agent.

Enhanced Elimination

The anthracycline agents are highly protein bound and have a large volume of distribution, which make them unlikely candidates for hemodialysis. However, the early institution of hemoperfusion may enhance elimination. In an animal model, plasma doxorubicin clearance could be enhanced up to 20-fold with hemoperfusion.[286] Factors determining this were duration of therapy, rate of flow, and the use of a 2% acrylic hydrogel-coated cartridge. Three patients with a doxorubicin overdose were treated with hemoperfusion, 1 with an Amberlite cartridge, and all had a rapid reduction in their serum levels.[65] One survived a 10-fold error in dosing. In a patient with a mitoxantrone overdose of 98 mg IV, hemoperfusion was begun within hours, but in two trials, only 0.287 and 0.236 mg of drug were removed.[109]

Nitrogen Mustards



Mechlorethamine

Pharmacology

The nitrogen mustard agents are cyclophosphamide, ifosfamide, chlorambucil, mechlorethamine, and melphalan. Their indicated uses include immunosuppression (eg, controlling graft-versus-host rejection, collagen vascular diseases) and chemotherapy. The tumoricidal activity of these xenobiotics is the result of the formation of reactive intermediates that bind to nucleophilic moieties on the DNA chain, which inactivates DNA synthesis. Unlike the other xenobiotics, cyclophosphamide and ifosfamide require mixed function oxidation to achieve their alkylating properties. Mechlorethamine is the original compound from which all of the others were derived. It is highly reactive when it comes in contact with water and undergoes rapid chemical transformation. Local reactions caused by mechlorethamine spillage (eg, extravasation) include tissue injury and thrombophlebitis (see Extravasational Injury below). Nonenzymatic hydrolysis is the major route by which these agents are metabolized, thus accounting for their relatively short elimination half-lives (ie, less than 3 hours).[31] Cyclophosphamide,

ifosfamide, and chlorambucil have active metabolites, which prolongs their alkylating activity after administration.[142]

Clinical Manifestations

Chlorambucil and ifosfamide can produce altered mental status and seizures from therapeutic use or from an overdose.[46] Both compounds undergo *N* -dechloroethylation to produce chloroacetaldehyde, which is purported to be a nervous system toxin.[102] Encephalopathy occurs in 9% of patients receiving 5 g/m^2 of ifosfamide, and is more frequent with oral than with IV administration because of the first-pass effect and increased chloroacetaldehyde production.[181] Seizures are more commonly associated with chlorambucil. Acute overdoses reported in the literature are all from the oral route, and range in dosing from 1.5â€“6.8 mg/kg (therapeutic is 0.1â€“0.2 mg/kg).[10 , 47] The

seizures occur within 6 hours, may appear as generalized tonicâ€“clonic activity or staring spells, and can last for 24 hours. However, in one instance in which therapeutic dosing was increased, seizures occurred 17 hours later. This delay may be attributed to a lower serum concentration or a slower time to peak than in the overdose setting. A similar reasoning would explain why a patient with a chronic overdose of 4.1 mg/kg over 5 days did not sustain CNS toxicity.[81] Patients with increased likelihood to seize are those with underlying seizure disorders or with nephrotic syndrome, which can alter pharmacokinetics.[229] Electroencephalograms (EEGs) demonstrated multiple paroxysms of bilaterally symmetric 2â€“3-Hz spikes and slow high-voltage rhythmic slowing that progressed to slower bursts of rhythmic spike and wave discharge in a child with an acute overdose.[47] Myelosuppression occurs in patients with both acute and chronic overdoses, and can present as late as 41 days postexposure. Recovery is expected within 1 week of the nadir, and G-CSF treatment may be necessary.[140]

Cyclophosphamide and its analog ifosfamide induce hemorrhagic cystitis from their irritating metabolite acrolein. This occurs in approximately 5â€“10% of patients who receive therapy.[45 , 62] The incidence of cystitis does not appear to be related to the total dose and administration route, age, or gender. The course is usually self-limiting, although blood transfusions may be required. Free water retention is observed in patients receiving more than 50 mg/kg of cyclophosphamide.[70] This effect is attributed to the activity of the alkylating metabolite on the renal tubule and is observed at 6â€“8 hours after drug administration. The patient experiences decreased urinary output, increased urine osmolality, and decreased serum osmolality. This is self-limiting, lasting for about 12â€“16 hours.

In the overdose setting, cyclophosphamide can cause dysrhythmias, myocardial necrosis, and death. ECG changes are noted at doses of 120 mg/kg and heart failure and myocarditis at

doses greater than 150 mg/kg.[13 , 188] An ordering error led to the death of 1 patient and to irreversible cardiac damage in another patient from cyclophosphamide overdose. These 2 patients received 6520 mg of the agent daily for 4 consecutive days, when the amount was to be divided over 4 days.[225] The onset of heart failure can be sudden, and patients older than 50 years of age, and those with prior treatment with anthracyclines, are at greatest risk for cardiac toxicity.[253]

Management

Recommendations for patients with an acute chlorambucil exposure include routine gastrointestinal decontamination, a 6-hour observation, a baseline CBC and hepatic enzymes, and a followup CBC weekly for 4 weeks.[269] Ifosfamide-induced encephalopathy can be managed with methylene blue (50 mg IV as a 1% solution), although the mechanism by which methylene blue acts is unknown.[155 , 293] Seizures are reported to be more effectively managed with benzodiazepines and barbiturates than with phenytoin.[10 , 34 , 287]

When gross hematuria from cyclophosphamide or ifosfamide therapy persists, treatments reported to be effective in the literature can be considered. These treatments include electrocauterization, systemic vasopressin,[213] intravesical administration of silver nitrate,[154] formalin,[90 , 239] prostaglandin F-î± ,[243] and hydrostatic pressure.[116] Some of the preventive therapies that seem to reduce this occurrence include adequate hydration for dilution effect, frequent bladder emptying, IV administration of 2-mercaptoethane sulfonate sodium (MESNA), and intravesical *N* -acetylcysteine.[45] The thiol group of *N* -acetylcysteine is believed to directly interact with acrolein to limit its irritating effect on the bladder epithelium. MESNA is believed to work by inactivating acrolein to an inert thioether.[117] The IV dose of MESNA is 20% of the cyclophosphamide or ifosfamide amount

(wt/wt) and administered during therapy and again at 4 and 8 hours. MESNA is used during standard-dose therapy for ifosfamide and high-dose therapy for cyclophosphamide.

Patients with large exposures to cyclophosphamide require baseline ECGs and echocardiograms. Intravenous fluid restriction, digoxin, and furosemide were successfully used to treat a patient with cyclophosphamide-induced congestive cardiomyopathy.[273]

Pharmacology

The cytotoxic effects of the platinum-containing compounds were first recognized in 1965; since then, many types have been derived. The ones of clinical significance are cisplatin, carboplatin, and oxaliplatin.[189] These xenobiotics were designed to reduce the incidence of nephrotoxicity and to counter drug resistance. Differences in chemical structure exist. Most notably, cisplatin is an inorganic and carboplatin an organic compound. Similarities exist in their mechanism of toxicity, which is the binding of platinum to DNA to form inter- and intrastrand bonds, which lead to DNA dysfunction and strand breakage. These xenobiotics are eliminated from the body primarily in the urine and at varying rates. The amount eliminated at 24 hours is 25% for cisplatin and 90% for carboplatin. Patients with decreased creatinine clearance

(<30 mg/m^2) will have prolonged elimination half-lives of platinoids.[83]

Clinical Manifestations

The more common manifestations of toxicity with cisplatin during therapy are renal dysfunction, auditory impairment, and peripheral sensory neuropathy. The other antineoplastics recognized to cause

a peripheral neuropathy are the vinca alkaloids and the taxoids. Oxaliplatin-induced neuropathy is triggered or enhanced by exposure to cold and can subside over several months.[87] Myelosuppression is a dose-limiting factor for carboplatin and iproplatin, which does not occur with cisplatin. At a carboplatin dose of 800 mg/m^2 , 25% of patients develop marrow toxicity.[203] The marrow effects are delayed, with nadir occurring 3â€“5 weeks after the start of therapy. Patients developing an anemia within the first week of cisplatin therapy should be evaluated for hemolytic anemia.[59]

The sources of error associated with cisplatin are frequency of administration (total dose versus over a period of time), mistaking it for carboplatin, and writing the wrong dose.[60 , 209] Manifestations in the overdose setting involve neurologic, visual, hearing, bone marrow, pancreatic, and renal disorders.[242] The most common renal disorder is renal failure, which is dose-related and begins at 50 mg/m^2 . The result is irreversible distal tubular necrosis.[224 , 232] Cell death may be from intracellular glutathione depletion.[67 , 72 , 101] The presence of urinary alanine aminopeptidase and *N* -acetyl-Î²-D-glucosaminidase may be used as early indicators of renal tubular damage.[67 , 72 , 101] Saline diuresis can limit renal toxicity. Hyponatremia is an uncommon finding with cisplatin exposure and is attributed to either sodium-wasting nephropathy from renal tubular dysfunction or SIADH. At doses greater than 200 mg/m^2 , the development of seizures,

encephalopathy, and irreversible peripheral sensory neuropathy is of concern.[28 , 61 , 114 , 203 , 204] Pathologic evaluation demonstrates axonal degeneration and damage to the dorsal root ganglion. At this dose, visual impairment may occur within the first week of exposure.[58 , 178 , 285] This can include temporary visual loss, with permanent loss of color discrimination. Physical examination of the anterior chamber and fundus of the eye will be normal; however, an electroretinogram will demonstrate a disorder with the postphotoreceptor neural function. Some other ocular disorders are papilledema and retrobulbar neuritis. High-frequency (>2000 Hz) hearing loss is evident 2â€“3 days after exposure to doses greater than 500 mg/m^2 .[56]

Management

Renal protection and enhanced elimination of platinum are the two primary goals in the management of a cisplatin overdose. Expectant management for myelosuppression and neurotoxicity can follow. Sodium chloride diuresis both promotes the inactive anionic state of cisplatin and decreases the urine platinum concentration to limit nephrotoxicity during therapy.[8 , 272] Hydration with 0.9% NaCl solution and an osmotic diuretic (eg, mannitol) should be administered to achieve a high urine output (eg, 1â€“3 mL/kg/h) for 6â€“24 hours postexposure. In the setting of nonoliguric renal failure, careful hydration is recommended to maintain urinary output, because platinum renal excretion is directly related to urinary flow, and independent of creatinine clearance.[58] Aside from evaluating the BUN and creatinine, assessment of renal function can include the glomerular filtration, filtration fraction, and renal plasma flow.[106 , 183 , 184 , 197]

Amifostine and sodium thiosulfate are effective nephroprotectants. Amifostine's role is more preventative and is approved by the FDA for use to protect against cisplatin-induced nephrotoxicity. Unlike thiosulfate, amifostine is activated intracellularly by alkaline

phosphatase to scavenge free radicals, prevent cisplatin-DNA adduct formation, and facilitate DNA repair.[151] The patient requires adequate hydration during amifostine infusion because hypotension can occur. Sodium thiosulfate is effective postexposure. Thiosulfate remains in the extracellular space to bind free platinum and limit cellular damage at the renal tubules. Little or no renal toxicity occurred in patients receiving as much as 270 mg/m^2 of cisplatin when thiosulfate was given as an IV bolus of 4 g/m^2 followed by infusion of 12 g/m^2 over 6 hours.[113 , 207] Thiosulfate may offer the additional benefit of limiting neurotoxicity and should be administered to all patients after an overdose.[176 , 270] The use of thiosulfate is limited by the time in which it needs to be administered after exposure (ie, 1â€“2 hours). *N* -acetylcysteine and BNP7787 are being investigated as alternative rescue agents for cisplatin toxicity.[242]

Hemodialysis is ineffective in patients with cisplatin overdoses, likely as a result of this agent's high protein binding.[44] However, in patients with renal failure, hemodialysis may be beneficial. Plasmapheresis was performed in 2 adults and there was a fall in blood serum platinum concentrations with clinical improvement. The first patient received an overdose of 280 mg/m^2 and was plasmapheresed on day 12 of exposure.[58] After 3 daily treatments, the serum platinum concentration decreased from 2900 to 200 ng/mL and the patient had noticeable improvement in gastrointestinal and visual symptoms. On day 20, the serum platinum concentration rebounded to 700 ng/mL and the symptoms worsened. Further plasmapheresis lowered the concentration to 290 ng/mL by day 27 and symptoms improved. The other patient received 300 mg/m^2 of cisplatin and received 4 daily treatments of plasmapheresis starting on day 6 postexposure.[143] The plasma serum platinum concentration declined from 2979 to 430 ng/mL and the patient became more awake and less nauseous. On day 11, platinum concentrations rebounded to 834 ng/mL and fell to 279 ng/mL on reinstitution of

plasmapheresis. The amount of platinum removed by 3 trials was 4622 Âµg. The author of the paper contends that plasmapheresis prevented the need for hemodialysis in renal failure. Thus, plasmapheresis appears to be effective in cisplatin overdose and should be instituted immediately after exposure. Patients who remain symptomatic days later also may benefit.

Intrathecal Overdose

Intrathecal overdoses with vincristine, methotrexate, doxorubicin, daunorubicin, and cytarabine are reported in the literature.[156] Common sources of error are confusing the IV for the intrathecal agent and misidentifying the strength of the solution vial in the preparation of the medication. These events are distressing because of the disastrous consequences they bring and the immediacy with which the agent must be removed from the intrathecal space. Removal of as much of the agent as possible is the patient's only chance of having an acceptable prognosis (see Chap. 19).

Upon recognition of the occurrence, the patient needs to be placed in a gravity-dependent position to prevent upward flow of the agent towards the cisterna magnum. The upright position significantly delays the flow of an intralumbar administered agent to the cerebral ventricles, when compared with the flow in a patient lying flat or in the Trendelenburg position.[80] The lumbar puncture site needs to be maintained or reestablished so that as much of the CSF can be drained as possible. With an intrathecal MTX model, if 20 mL of CSF is removed within 30 minutes of administration, then 94% of the agent given is retrieved.[4] However, by removing the same volume at 3 hours, only 10% of the agent is recovered. CSF drainage can be accomplished in short time intervals, considering that CSF production is 30 mL/h. CSF exchange should be accomplished by lavaging the intrathecal space with lactated

Ringer solution. An equal volume of the CSF space should be used in each pass of the lavage, and 2â€“3 passes should be performed to complete the procedure. The volume of CSF in a child older than age 3 years approaches that of an adult (ie, 120 mL). For large exposures, CSF perfusion must follow. This is performed by passing solution through a ventriculostomy and out a lumbar drainage catheter. Lactated Ringer solution with 15â€“25 mL of fresh-frozen plasma added per liter of crystalloid is infused at 150 mL/h for 18â€“24 hours.[79, 290] The ventriculostomy and lumbar drain can then be removed. The thecal effluent can be collected to determine the amount of drug recovered. Depending on the antineoplastic involved, additional measures may be necessary.

Intrathecal vincristine overdoses are devastating. Only 2 of 13 patients reported in the literature survived, and their survival was attributed to the CSF evacuation of this agent within minutes of exposure as described above.[79, 290] There is no indication for the intrathecal administration of vincristine or vinblastine. This mishap is usually the result of confusing vincristine with the other medications (eg, cytarabine, MTX) that are commonly dispensed for intrathecal use. Death follows a characteristic course, consisting of back pain, meningismus, lower-limb weakness, urinary difficulty, loss of deep tendon reflexes, encephalopathy, and respiratory failure. Alteration in mental status appeared earlier when vincristine was administered intraventricularly.[182] Pathologic changes are most notable in the cerebellum, the brainstem, and the anterior horns of the spinal cord.[18] There are only 2 reported survivors from intrathecal vincristine, and the amount of vincristine recovered in one case was 95% of the 2 mg of vincristine that had been administered.[79] Additional therapies provided in these cases were glutamic acid (10 g IV over 24 hours, then 500 mg orally 3 times a day),[132] folinic acid (25 mg IV every 6 hours), and pyridoxine (50 mg IV every 8 hours). These therapies were continued for 1 week or until the neurologic

symptoms stabilized. Dexamethasone (4 mg/m^2 IV every 6 hours) may be given for meningeal inflammation. The roles of these agents are unclear, but because of the seriousness of the situation, aggressive therapy should be offered.

Intrathecal overdoses of MTX commonly occur because a more concentrated solution vial is mistaken for one that is less concentrated.[249, 163] Overdoses reported in the literature range as high as 650 mg and death is associated with amounts greater than 500 mg.[249] The therapeutic intrathecal MTX dose, according to age, is 6 mg for a patient younger than 1 year old; 8 mg for a patient between the ages of 1 and 2 years; 10 mg for a patient between the ages of 2 and 3 years; and 12 mg for a patient older than 3 years of age.[36] The neurotoxicity associated with these events includes chemical arachnoiditis, ascending neuropathy, encephalopathy, and seizures. The seizures can be treated with phenobarbital and benzodiazepines.[163, 221]

Unlike intrathecal vincristine overdoses, the prognosis for an intrathecal MTX exposure is more favorable because of the different mechanism of action and the availability of rescue therapy. Two deaths are reported with intrathecal MTX overdose after the patients received amounts greater than 500 mg.[85, 249] CSF removal of MTX is still crucial, and for amounts less than 100 mg, CSF drainage may be adequate if performed within 30â€“60 minutes of administration.[138, 198] When a longer period of time has elapsed, or a larger amount is involved, CSF exchange is necessary, and possibly CSF perfusion as well. At amounts greater than 500 mg, CSF perfusion must follow because drainage and exchange cannot remove enough MTX to prevent significant toxicity. CSF decontamination should continue until the final CSF MTX concentration is about 100 Âµmol/L, which is a peak therapeutic level for a 12-mg intrathecal MTX dose.[198] Large amounts of MTX administered intrathecally pass into the systemic circulation, which poses a threat to the bone marrow. Although there are no reports of myelosuppression resulting from such an

event, IV leucovorin is indicated. High-dose leucovorin rescue should be started upon recognition of the overdose. The following IV leucovorin regimen was used in a patient who received 600 mg of intrathecal MTX and survived: 1000 mg/m^2 , followed by 100 mg/m^2 every 3 hours until the plasma MTX concentration was less than 0.1 Âµmol/L.[198] Leucovorin is not to be administered intrathecally because seizures with resultant death can occur, and the etiology of MTX-induced neurotoxicity is chemical irritation, not folate inhibition.[138] Additional therapies are hydration and urinary alkalinization to prevent renal toxicity, and IV dexamethasone to lessen meningeal inflammation. Enzymatic agents that inactivate MTX are a new and promising form of rescue therapy for intrathecal overdoses. $CPDG_2$ dramatically shortened the MTX CSF half-life in a patient with a 600-mg intrathecal overdose.[198] The patient received the carboxypeptidase agent intrathecally, following CSF decontamination, and survived. Enzymatic cleavage may obviate the future need for CSF perfusion in large overdoses.

Extravasational Injury

Extravasational injuries are among the most consequential local toxic events. When an antineoplastic leaks into the perivascular space, significant necrosis of skin, muscles, and tendons can occur with resultant loss of function. The initial manifestations may include swelling, pain, and a burning sensation that can last for hours. Days later, the area becomes erythematous and indurated and can either resolve or proceed to ulceration and necrosis.[226] Sometimes, these early findings may be difficult to distinguish from other forms of local drug toxicity, such as irritation and hypersensitivity. Either the drug or its vehicle (ethanol, propylene glycol) can cause local irritation. The drugs associated with local irritation include fluorouracil, carmustine, bisantrene, cisplatin, and dacarbazine. The local irritation and hypersensitivity manifestations are self-limiting and typified by an immediate onset

of a burning sensation, pruritus, erythema, and a flare reaction of the vein in which the agent is being infused. Pretreatment with an antihistamine usually prevents some of the hypersensitivity manifestations upon subsequent administrations.[271] Drugs reported to cause hypersensitivity reactions include daunorubicin, doxorubicin, idarubicin, and mitoxantrone. This event is typified by the presence of pruritus. Nevertheless, when local reactions cannot be differentiated, it is always best to presume extravasation and manage the situation accordingly.

The occurrence of these inadvertent events appears to be about 50 times more frequent in the hands of the inexperienced clinician.[123] Several factors are associated with extravasational injuries from peripheral intravenous lines, including (a) patients with poor vessel integrity and blood flow, such as the elderly, those who undergo numerous venipunctures, and radiation therapy to the site; (b) limited venous and lymphatic drainage caused by either obstruction or surgical resection; and (c) use of sites over joints, which increases the risk of dislodgments because of movement.[124, 226] Extravasational injuries from implanted ports in central venous vessels can occur from inadequate placement of the needle, needle dislodgment, fibrin sheath formation around the

catheter, perforation of the superior vena cava, and fracture of the catheter.[234] When extravasation from a port is suspected and radiographic studies are not diagnostic, a CT scan of the chest with a contrast dye study is necessary for evaluation.[11]

General

Stop infusion and maintain intravenous cannula at the site.

Aspirate extravsate from the site by accessing the original intravenous cannula.

Irrigation of subcutaneous tissue at the site with normal saline by accessing the original intravenous cannula.

Minimizes amount of antineoplastic localized at the site.
Apply dry cool compresses for 1 hour, every 8 hours for 3 days.
Localizes area of involvement and diminishes cellular uptake of the antineoplastic.
Elevate extremity and administer analgesia.
Promotes drainage, prevent dependent edema, and for comfort.
Specific
Anthracyclines
Dimethyl sulfoxide (DMSO)â€”55â€“99%.
Applied topically and allowed to dry.
Every 6â€“8 hours for 3â€“10 days.
Free radical scavenger.
Dexrazoxane 1000 mg/m^2 , daily, on days 1 and 2, and then 500 mg/m^2 on day 3: IV.
Limits free radical formation.
Mechlorethamine
Sodium thiosulfateâ€”Prepare a sterile 0.17 Msolution by mixing 4 mL thiosulfate 10% weight/volume with 6 mL water for injection.
Infiltrate the site of extravasation.
Prevents tissue alkylation.
Mitomycin
DMSO applied topically.
Free radical scavenger.
Vinca alkaloids and epipodophyllotoxins
Hyaluronidaseâ€”Inject, intradermally or subcutaneously, 150â€“900 U into the site.
Degrades hyaluronic acid to enhance systemic absorption.

Dry warm compresses.
Promotes systemic absorption.

Therapy Purpose/Mechanism

TABLE 52-2. Management of Extravasational Injuries [29]

The factors associated with a poor outcome from extravasational injuries include (a) areas of the body with little subcutaneous tissue, such as the dorsum of the hand, volar surface of the wrist, and antecubital fossa, where healing is poor and vital structures are more likely to be involved; (b) concentration of extravasate; (c) increased volume and duration of contact with tissue; and (d) the type of agent.[226, 227] Vesicant agents, such as doxorubicin, daunorubicin, dactinomycin, epirubicin, idarubicin, mechlorethamine, mitomycin, and the vinca alkaloids, appear to result in more significant local tissue destruction. Mitomycin infusions can cause dermal ulcerations at venipuncture sites remote from the location of administration.[205] The anthracycline antibiotics are associated with a higher incidence of significant injuries and delayed healing, which may be a result of their slow release from bound tissue into surrounding viable tissue. Doxorubicin extravasation is associated with local tissue necrosis in approximately 25% of cases. The extravasational injuries from taxanes appear similar to the vesicant agents, but are milder in response and longer in days to presentation.[17, 214] Prevention is the best form of therapy for these injuries. Specialized nursing care and the use of indwelling central venous catheters have limited the extent of these injuries.

Management

The treatment for extravasational injuries is somewhat controversial, varying from conservative care to early surgical debridement and the use of selective antidotes.[236] This uncertainty is a result of the limited number of clinical cases available for study and the discordance between animal studies and clinical findings. However, general management guidelines for an extravasation and their theoretical foundations exist (Table 52-2).[29, 38]

Once extravasation is suspected, the infusion should be

immediately halted. A physician should be notified and the xenobiotic, its concentration, and the approximate amount infused should be noted. The venous access should be maintained so that aspiration of as much of the infusate as possible can be performed and antidote can be administered, if indicated. Injection of normal saline into the catheter to dilute the extravasate may be beneficial.[148 , 236] The intermittent local application of ice and elevation of the extremity should be done for 48â€“72 hours so as to limit further progression of the agent and the development of dependent edema. Cooling the area is believed to prevent cell injury by reducing the amount of xenobiotic absorbed by the tissue and lowering the cellular metabolic rate. It was demonstrated that, with just cold application and strict elevation, only 13 (11%) of 119 patients with mild extravasations required surgical intervention for their injuries.[160] In the past, heat was recommended to disperse the agent, but investigations with mice treated with intradermal doxorubicin demonstrated that this practice increases the area of skin ulceration.[76 , 160] However, dry, warm compresses are still recommended for the vinca alkaloids and etoposide to promote systemic uptake.[29] This is combined with the local infiltration with hyaluronidase to enhance absorption (Table 52-2). The amount of hyaluronidase administered at the site ranges from 150â€“900 U, and the working concentration of the solution depends on the area to be treated. For extravasational injuries involving a small area, the initial solution of 150 U/mL may be adequate. Otherwise, the solution may be

diluted by 10-fold with normal saline to increase the amount of volume that would be needed to treat a larger surface area. If the intravenous cannula is still accessible, 1 mL of hyaluronidase can be administered through the catheter. Wounds that are either cancerous or infected should not be treated with hyaluronidase.

The wound should be observed closely for the first 7 days, and a

surgeon consulted if either pain persists or evidence of ulceration appears.[226] However, in severe extravasationsâ€”where there is a high incidence of necrosis because of the type of drug (doxorubicin), the volume or concentration, and any area in which there may be significant long-term morbidity (over joints)â€”early surgical consultation is warranted. If tissue ulceration occurs, initial management can be with sterile dressings to prevent secondary infections. After the area of necrotic skin has evolved to the point where it can be clearly delineated from surviving tissue, surgical debridement may be beneficial to limit secondary infection. The use of intravenous fluorescein or other dye indicators can aid in identifying viable tissue.[15] The patient may require surgical reconstruction or skin grafts depending on the extent of the injury.

Antidotal therapy should be considered when the extravasate is known to respond poorly to conservative care. The vesicant-type agents are associated with a significantly worse outcome, and when the exposure is large, a more aggressive approach should be initiated. Otherwise, conservative supportive management may be adequate. The specific antidotal treatments can be divided into several categories based upon their mechanism of action, one of which is the reduction of the inflammatory response through the application of steroids. Hydrocortisone has been used in varying concentrations (50â€“200 mg) as either subcutaneous or intradermal injections for doxorubicin and the vinca alkaloids,[20 , 123 , 161 , 267] and as a topical cream.[148] Steroids may have only a limited role in doxorubicin-induced lesions because inflammatory cells are not found in predominance at the wound site.[32] The addition of steroids to doxorubicin infusions, so as to limit morbidity if extravasation should occur, is not recommended because the drugs are chemically incompatible.[265] A prophylactic approach is to inactivate the drug by affecting the pH of the environment. The administration of 5 mL of 8.4% sodium bicarbonate through the same IV line to decrease the DNA binding

of doxorubicin has been advocated.[21] The use of sodium bicarbonate should be cautious and not be considered as routine treatment because its hyperosmolarity can cause tissue necrosis.[97] Sodium thiosulfate is recommended for mechlorethamine extravasations, and is believed to work by inactivating the agent by reacting with the active ethylenimmonium ring.[124 , 199] The site is infiltrated with sterile sodium thiosulfate solution and then ice compresses are applied intermittently for 48â€“72 hours.[29] Finally, there are agents, such as dimethyl sulfoxide (DMSO), that scavenge the free radicals that are believed to cause tissue damage from doxorubicin. Dimethyl sulfoxide is beneficial for anthracycline extravasations in both animal and human clinical trials.[30 , 71 , 161 , 199 , 258] The concentration of DMSO used ranged from 55â€“99% and was applied topically with intermittent cool compresses.[29 , 161 , 198] Some of the other beneficial properties of DMSO are its antiinflammatory, analgesic, and vasodilatory effects, and its ability to promote systemic absorption of drug at local sites.[171] The systemic administration of dexrazoxane was demonstrated to limit anthracycline-induced skin lesions in a murine model[158] and used successfully in patients with doxorubicin[157] and epirubicin[139 , 157] extravasations. Dexrazoxane was given to these patients over 3 days and by the intravenous route at a starting dose of 1000 mg/m^2 . Additional clinical evidence needs to be gathered to better define the dosing regimen for this type of therapy. Although the overall incidence of extravasations with antineoplastic agents is small, the associated morbidity from any one event may be significant. Prevention is the best form of therapy.

Antineoplastics in the Workplace

A variety of workers are at risk for increased exposure to antineoplastics, including pharmacists, nurses, physicians, and others involved in the preparation and dispensation of these agents, and who may be exposed to the body fluids of patients

treated with these agents. Several studies demonstrate that these agents can be detected in the work environment and measured in workers,[233] and there is concern about the possible genotoxic effects from these exposures.[237] The worker may absorb these xenobiotics by either the dermal, inhalational, or gastrointestinal route. The factors determining the amount of worker exposure include the nature of the work, the amount of drug used, the frequency and duration of exposure, the physical and chemical nature of the drug, and the use of ventilated cabinets and personal protection equipment during the handling of these agents. The workplace guidelines for antineoplastics fall under the broader category of hazardous agents. A sample list of drugs considered as hazardous agents by National Institute for Occupational Safety and Health (NIOSH) is available for further information.[51] NIOSH defines a drug as a hazardous agent if it is either carcinogenic, teratogenic, genotoxic, associated with developmental or reproductive toxicity, or toxic to organs at low dose.

Regulatory and workplace recommendations for exposure levels and the waste management of these agents are available from various agencies and organizations. These recommendations are limited in scope because only a small number of xenobiotics or adverse health effects have been adequately studied, and many agents do not meet the current definition for inclusion. US Environmental Protection Agency (Resource Conservation and Recovery Act, 40 CFR Â§Â§260â€“279) regulates 9 antineoplastics (arsenic trioxide chlorambucil, cyclophosphamide, daunomycin, melphalan, mitomycin C, naphthylamine mustard, streptozocin, and uracil mustard) and the equipment and devices associated with their preparation or delivery, as well as their disposal, as hazardous waste.[218] The current recommendations for worker safety with these agents in the workplace includes the proper management of the work environment (eg, storage, handling, preparation, administration, use of personal protection equipment, decontamination, waste disposal) and the institution of a medical

surveillance program with approved laboratory testing.[9, 195]

Summary

The antineoplastics are a unique therapeutic class because their cytotoxicity is a direct effect. Medicine is challenged to carefully balance this measure so that there is limited damage to native cells, and thus the patient. Over the years, the number of antineoplastic exposures reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System has remained small; however, the consequences of toxicity to the patient in these reports were great. The majority of these occurrences were iatrogenic, involving misreading of the product label, and

errors in dosing and transcription of orders (Chap. 134). A key element was the lack of familiarity of the healthcare provider with the use of these select xenobiotics. The number of antineoplastics and their indicated use have increased over the years and will continue in this fashion into the future, increasing the chance for medical error and patient toxicity. The clinical manifestations of toxicity can develop in various organ systems and are primarily determined by the mechanism of action, route of administration, and duration of exposure. The gut epithelium and bone marrow are extremely susceptible to toxicity because of their high mitotic activity. They are important because their failure will lead to overwhelming sepsis and death. Treatment remains primarily supportive in nature. New additions in this area include carboxypeptidase, the antidote for MTX, and G-CSF to limit the severity of neutropenia. Further work is necessary to define the role of erythropoietin in exposures resulting in anemia. Although cytoprotectants will continue to be developed, they cannot be relied on to rescue patients from exposures because their number will be few in comparison to the quantity of available antineoplastics and their effectiveness limited to pretreatment.

Thus, prevention is the best treatment, which can be accomplished by maintaining a heightened awareness when working with these agents, educating the patient and healthcare provider regarding their use, and providing increased skilled care.

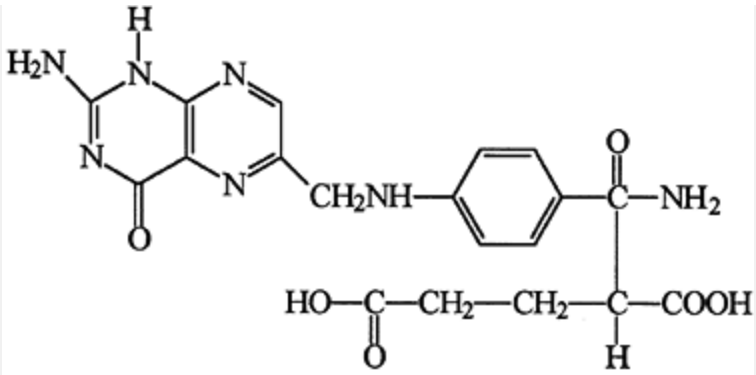
Antidotes in Depth

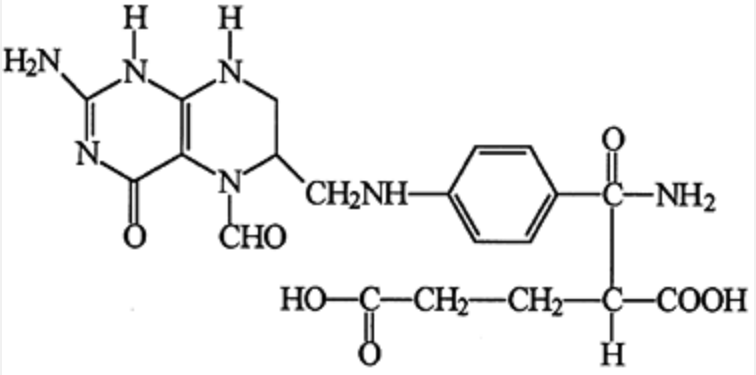
Leucovorin (Folinic Acid) and Folic Acid

Mary Ann Howland

Pharmacology



Folic Acid



Folinic Acid

Folinic Acid

Folic acid, an essential water-soluble vitamin, consists of a pteridine ring joined to PABA (*para*-aminobenzoic acid) and glutamic acid.[6] Folic acid is the most common pharmaceutical preparation of the many folate congeners that exist in nature and perform essential cellular metabolic functions. After absorption, folic acid is reduced by dihydrofolic acid reductase (DHFR) to tetrahydrofolic acid, which accepts 1-carbon groups.

Tetrahydrofolic acid serves as the precursor for several biologically active forms of folic acid, including 5-formyltetrahydrofolic acid, which is best known as folinic acid, leucovorin, and citrovorum factor. These biologically active forms of folate are enzymatically interconvertible and function as cofactors, providing the 1-carbon groups necessary for many intracellular metabolic reactions, including the synthesis of thymidylate and purine nucleotides, which are essential precursors of DNA.[21,23,27,28,32] The minimum daily requirement of folate is normally 50 Âµg, but in pregnant women and nutritionally deprived, acutely ill patients, 100 to 200 Âµg may be required.[6,7]

Role in Methotrexate Toxicity

Methotrexate, an antimetabolite, is a structural analog of folic acid, differing only in the substitution of an amino group for a hydroxyl group at the number 4 position of the pteridine ring (see Fig. 52-1). Methotrexate binds to the active site of DHFR, rendering it incapable of reducing folic acid to its biologically active forms, and incapable of regenerating the necessary active forms required for the synthesis of purine nucleotides and thymidylate. At physiologic pH the binding between methotrexate and DHFR is competitive, with an inhibition constant of about 1 Âµmol/L.[25] Leucovorin is a reduced, active form of folate. As such, it does not require DHFR for enzymatic interconversion to the form required for purine nucleotide and thymidylate formation. *Leucovorin rescue* is the term used to describe the practice of limiting the toxic effects of high-dose methotrexate therapy. Folic acid would be ineffective to counteract methotrexate toxicity because DHFR would be unavailable to convert folic acid to the necessary reduced and active forms.

Role in Methanol Toxicity

Administering folic acid to monkeys accelerates formate

metabolism.[17] Pretreatment with folic acid or leucovorin decreased formate levels and the accompanying metabolic acidosis, without affecting the rate of methanol elimination.[19] Leucovorin was still effective in hastening the elimination of formate when given 10 hours after methanol administration. Other studies demonstrate that rats and monkeys experimentally made folate-deficient develop methanol toxicity at lower methanol levels.[11]

Total folate, leucovorin, and folate dehydrogenase (which increases leucovorin levels) are all diminished in the livers of methanol-poisoned humans.[11] In an analysis[8] of a single methanol-poisoned patient who was given folate and ethanol and hemodialyzed, the half-life of formate was 1.1 hours.[20] In another methanol-poisoned patient treated without folate, the formate half-life was 2.8 hours.[8] This comparative data is inadequate to draw definitive conclusions, but may support the therapeutic role of folate, in addition to that of fomepizole and hemodialysis.

Leucovorin Pharmacokinetics

Leucovorin is naturally formed in the body as the active (*l* or â€“) isomer, whereas the commercial preparation consists of equal amounts of the inactive (*d* or +) and active (*l* or â€“) isomers. The pharmacokinetics of the racemic mixture of leucovorin and its active metabolite were studied after IV infusion, and as a constant infusion in normal human volunteers.[15,29] During constant infusion, the steady-state concentration for the active isomer was 2.33 Âµmol, the half-life was 35 minutes, and the volume of distribution was 13.6 L. The active isomer is metabolized to an active metabolite (L-5-CH3-THF). A more recent study detected no adverse effects of the inactive isomer on the intracellular uptake of the active isomer and concluded that giving the active isomer provided no pharmacokinetic advantage over the racemic mixture.[26]

The pharmacokinetics of orally administered leucovorin was studied in healthy, fasted, male volunteers in single doses ranging from 20â€“100 mg, and 200 mg IV over 5 minutes as compared to 200 mg orally.[16,22] Bioavailability decreased from 100% for the 20-mg dose to 78% for the 40-mg dose, and ultimately to 31% for the 200-mg dose. A microbiologic assay was used to measure total tetrahydrofolates (reduced and active folates). Normal plasma folate levels are approximately 0.05 Âµmol/L.[9] The 200-mg oral dose produced a peak plasma concentration of 1.82 Âµmol/L, compared to 0.66 Âµmol/L for the 20-mg oral dose and 27.1 Âµmol/L for the 200-mg IV dose.[16,22]

Leucovorin Dosing for Methotrexate Overdoses

When a patient overdoses on methotrexate, a dose of leucovorin estimated to produce the same plasma concentration as the methotrexate dose should be given as soon as possible and, preferably, within 1 hour. One mole of methotrexate weighs 455 daltons and 1 mole of leucovorin calcium weighs 511 daltons. Because of the safety of leucovorin and because of the toxicity of methotrexate, underdosing leucovorin should be avoided. Although plasma concentrations are often closely followed in patients on diverse oncologic regimens,[2,3] it is inappropriate to wait for a methotrexate plasma concentration before initiating treatment with leucovorin in the overdose setting, or in the treatment of tubal pregnancies.[1] The toxic threshold for methotrexate is reported to be 1 Ã— 10^{-8} mol/L (0.01 Âµmol/L or 10 nmol/L).[4] Normal plasma folate levels are in the range of 13â€“43 nmol/L. In a patient who is not receiving methotrexate therapeutically, there is no need to permit any methotrexate to remain unantagonized by leucovorin.

For example, if a child unintentionally ingests one hundred 2.5-mg methotrexate tablets for a total dose of 250 mg, only part of this

dose is absorbed because methotrexate absorption is saturable.[5] The bioavailability of methotrexate decreases from 100% with doses less than 30 mg/m^2 to approximately 10â€“20% with doses greater than 80 mg/m^2. In this case, it is safe to assume that a bioavailability of 50% would result in an absorbed dose of methotrexate of 125 mg. For this substantial exposure an intravenous dose of 125 mg of leucovorin could be given over 15â€“30 minutes. This dose of IV leucovorin should be repeated every 3â€“6 hours until the methotrexate concentration is less than 1 Ã— 10^8 mol/L, and preferably zero. The methotrexate half-life may vary from 5â€“45 hours, depending on the dose and the patient's renal function. For this reason, leucovorin therapy should be continued for 12â€“24 doses (3 days) or longer if methotrexate concentrations are unavailable. Patients who may develop third-space storage in ascites or pleural effusions may also require leucovorin dosing for an extended period of time. Patients with bone marrow toxicity require more prolonged dosing because plasma half-lives of methotrexate do not reflect persistent intracellular concentrations.

Unintentional overdose with intrathecal methotrexate is potentially quite serious and is dose dependent. In these cases, intravenous leucovorin should be administered. Intrathecal leucovorin was considered a major factor in the death of a child given a slightly higher dose of intrathecal methotrexate than was prescribed.[10,14] Not all intrathecal methotrexate overdoses require aggressive intervention, but consultation with experienced hematologists/oncologists and medical toxicologists is warranted.[12]

An intravenous leucovorin dose of 100 mg/m^2 every 3â€“6 hours should be effective, in all but the most severe overdoses. A constant intravenous infusion of 21 mg/m^2/h has been safely administered for 5 days. A transition to the oral administration of leucovorin depends on the plasma concentration of the methotrexate and whether adequate plasma concentrations of

leucovorin can be achieved by that route. In adults, a 200-mg oral dose produces a peak plasma concentration of 1.82 Âµmol/L as compared to 27.1 Âµmol/L with a 200-mg IV dose.

Administration of activated charcoal precludes the subsequent administration of oral leucovorin. In addition to leucovorin, other modalities to treat methotrexate overdoses should be used (activated charcoal, urinary alkalinization), or considered (carboxypeptidase G, extracorporeal removal, and thymidine) (Chap. 52).

Adverse Effects and Safety Issues

Reports of adverse reactions to parenteral injections of folic acid or leucovorin are uncommon; however, adverse reactions may include allergic or anaphylactoid reactions.[6] Seizures are rarely associated with leucovorin administration.[18] The calcium content of leucovorin warrants a slow intravenous infusion at a rate not faster than 160 mg/min in adults. Leucovorin should never be administered intrathecally.[10,13,24,31]

Dosing

The routine dose of leucovorin for â€œleucovorin rescueâ€• ranges from 10â€“25 mg/m^2 IM or IV every 6 hours for 72 hours to 100 mg/m^2 every 3 hours in patients with renal compromise. If administration to neonates is necessary, a benzyl alcohol-free preparation must be used because of the toxicity of benzyl alcohol in neonates (Chap. 53).[30] For methotrexate overdoses, a dose of leucovorin equal to that of the ingested methotrexate dose should be administered IV as soon as possible over 15â€“30 minutes, but not faster than 160 mg/min in adults.

An intravenous leucovorin dose of 100 mg/m^2 every 3â€“6 hours should be effective, in all but the most severe overdoses. This dose should be continued for several days, or until the MTX serum

concentration falls below 1 Ã— 10^{-8} mol/L and no bone marrow toxicity is evident.

Either folic acid or leucovorin (folinic acid) should be administered parenterally at the first suspicion of methanol poisoning. No complications are reported with the use of 50â€“70 mg of IV folic acid every 4 hours for the first 24 hours, in the treatment of methanol-poisoned patients.[20] The precise dose necessary is unknown, but 1â€“2 mg/kg every 4â€“6 hours is probably reasonable. The folic acid should be continued until the methanol and formate are eliminated. As the first dose is usually administered prior to hemodialysis, a second dose should be administered at the completion of hemodialysis, because hemodialysis will probably remove this highly water-soluble vitamin.

Availability

Folic acid is available parenterally in 10-mL multidose vials with 1.5% benzyl alcohol in concentrations of 5 or 10 mg/mL, from a

variety of manufacturers. Once opened, this vial must be kept refrigerated.

Leucovorin (folinic acid) powder for injection is available in 50-, 100-, and 350-mg vials. Reconstitution with sterile water for injectionâ€”5 mL to the 50-mg vial, or 10 mL to the 100-mg vialâ€”results in a final concentration of 10 mg/mL. Adding 17 mL of sterile water for injection to the 350-mg vial results in a final concentration of 20 mg/mL. Because of the calcium content, the rate of intravenous administration should not be faster than 160 mg/min in adults. Leucovorin is also available orally in a variety of strengths, including 5-, 10-, 15-, and 25-mg tablets.

Summary

Leucovorin (folinic acid) is the primary antidote for a patient who receives an overdose of methotrexate. Leucovorin is the biologically active, reduced form of folic acid, the synthesis of which is prevented by methotrexate. Only leucovorin (folinic acid) is an acceptable antidote for a patient with methotrexate toxicity, but either folic acid or leucovorin is acceptable for a patient poisoned by methanol. Following a methanol overdose, folic acid enhances the elimination of formate.

Chapter 53
Pharmaceutical Additives

Sean P. Nordt

Lisa E. Vivero

A 32-year-old man was brought to the emergency department (ED) after confused and inarticulate at a motel by paramedics. The patient's tongue and he had urinary incontinence. In the ED, the patient had a blood press mm Hg, a pulse of 101 beats/min, respirations of 20 breaths/min, and a 97.4Â°F (36.3Â°C). Physical examination revealed abrasions on the left si his pupils were 6 mm, equal, and reactive to light; his lungs were clear and his abdomen was soft and nontender. A 12-lead electrocardiogram sh tachycardia, a rate of 102 beats/min, a PR interval of 200 msec, a QRS c msec, and a QTc interval of 450 msec. An old ED chart revealed that the suffered a gunshot wound to the head and subsequently had developed a disorder.

A loading dose of 1 g phenytoin equivalents of fosphenytoin was given i over 5 minutes. Immediately following the fosphenytoin, the patient beca hypotensive with a blood pressure of 85/50 mm Hg. His heart rate decrea beats/min, and his QRS interval widened to 140 msec. Atropine 1 mg was intravenously, resulting in an increase in heart rate to 82 beats/min. Int

sodium chloride solution at 1 L over 15 minutes was administered, which blood pressure to 140/60 mm Hg. Several minutes later the patient's QRS 100 msec without other intervention. Subsequently, it was realized that t unintentionally given phenytoin instead of fosphenytoin. The patient had reaction to the rapid infusion of phenytoin, which contains 400 mg/mL of glycol.

History and Epidemiology

During the last century there were several US outbreaks of toxicity assoc pharmaceutical additives (Chap. 1). The 1937 Massengill sulfanilamide d most notorious of these epidemics. Diethylene glycol, an excellent solvent nephrotoxin, was substituted for the additives propylene glycol and glycer formulation of a new sulfanilamide antibiotic because of a lower cost.[25] , result, more than 100 people died from acute renal failure.[25] More recent of acute renal failure occurred when diethylene glycol was used to solubi acetaminophen in South Africa, Bangladesh, Nigeria, and Haiti.[18] , [47] , [67]

In December 1983, E-Ferol, a new parenteral vitamin E formulation, was contained 25 U/mL of Î±-tocopherol acetate, 9% polysorbate 80, 1% pol and water for injection. At the time, no premarketing testing was required formulations of an already-approved xenobiotic. Several months after its syndrome in low-birth-weight infants, characterized by thrombocytopenia, dysfunction, cholestasis, hepatomegaly, and ascites, was described.[1] , [95] deaths and 43 cases of severe symptoms were attributed to E-Ferol. Vitar thought to be the cause and E-Ferol was recalled from the market 4 mon release. It is now believed that the polysorbate emulsifiers were respons

More recently there has been concern over potential mercury toxicity fror preservative thimerosal, a mercury derivative that has been used in pare for 70 years. Although there are a few reports of toxicity from large oral thimerosal dosages, no evidence has yet shown toxicity to result from ro vaccination. Potential concerns of toxicity, particularly autism, have spur efforts to eliminate thimerosal from vaccines, wherever possible.

Although these additive-related occurrences are rare, relative to the freq

pharmaceutical additive use, they illustrate the potential of pharmaceutic toxicity.

Pharmaceuticals are labeled specifically to focus attention on the active i a product, thus giving the misimpression that additive ingredients are ine unimportant. Additives, or excipients, as they are more properly termed, to act as vehicles, add color, improve taste, provide consistency, enhance solubility, and to impart antimicrobial properties to medicinal formulations is true that most cases of excipient toxicity involve exposure to large qua prolonged or improper use, these adverse events are nonetheless related toxicologic properties of the excipient.

Prior to selecting the specific additives and quantity necessary for a drug the drug manufacturer must consider several factors, including the active physical form, its solubility and stability, the desired final dosage form an administration, and compatibility with the dispensing container materials. active ingredient may require different excipients to impart appropriate characteristics to different dosage forms, such as in long-acting and imı formulations. Similarly, multiple-dose injection vials containing the same ingredients as single-dose vials specifically require the addition of a bact not necessary for single-dose vials.

Unlike requirements for active ingredients, there is no specific FDA appro pharmaceutical excipients. As such, the FDA determines the amount and t necessary to support the use of a specific excipient on a case-by-case ba current practice, only excipients that were previously permitted for use in pharmaceuticals are defined as *generally recognized as safe* (GRAS), or a listed.â€• All components of a pharmaceutical product, including excipien produced in accordance with current good manufacturing practice standar purity. Recently, the Safety Committee of the International Pharmaceutic Council developed guidelines for the toxicologic testing of new excipients patent protection laws, it was not until very recently that manufacturers to provide a list of inactive ingredients contained in all pharmaceutical p Although it is becoming easier to identify pharmaceutical additives in pro information on their effects and the mechanisms by which they cause ad

TABLE 53-1. Potential Toxicity by Organ System of Various Pha Excipients

This chapter summarizes the available literature on commonly used addi with direct toxicities. Data on pharmacokinetics and mechanism of toxicit where data are available. Although many additives are associated with l reactions, including anaphylaxis, these are not discussed because of their nonpharmacologic basis. However, excipients should always be considered causative agents in patients developing hypersensitivity reactions (Table

Benzalkonium Chloride

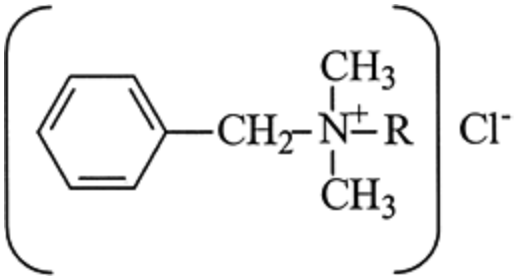

Figure. No Caption Available.

Benzalkonium chloride (BAC) or alkyldimethyl (phenylmethyl) ammonium quaternary ammonium cationic surfactant composed of a mixture of alkyl dimethyl ammonium chlorides. Although it is the most widely used ophth preservative in the United States, it is also considered the most cytotoxic).[79 , 85] Benzalkonium chloride is also used in otic and nasal formulations, small-volume parenterals. The antimicrobial activity of BAC includes Grar Gram-negative bacteria, and some viruses, fungi, and protozoa. Because onset of action, good tissue penetration, and long duration of action, BAC over other preservatives. The concentration of BAC in ophthalmic medica ranges from 0.004 to 0.01%.[85] Ingestion of strong BAC solutions (greater can be caustic (Chap. 98).

Ophthalmic Toxicity

Corneal epithelial cells harvested from human cadavers within 12 hours o exposed to a medium containing 0.01% BAC.[134] The surfactant properties resulted in intracellular matrix dissolution and loss of epithelial superficia Following exposure to the medium, mitotic activity ceased, and degenera corneal epithelium were noted. During a 24-hour observation period, epit cytokinetic or mitotic activity did not occur. Patients with a compromised epithelium may be at increased risk for the adverse corneal effects of BA

Two case reports demonstrate the potential toxicity of BAC and the difficu recognizing it. A 36-year-old woman complained of decreased vision wher inadvertently switched from Lensrins, a contact lens cleaning solution, to

isotonic boric acid solution, preserved with BAC. After 3 days, she had i pain, and decreased visual acuity. Examination of the cornea revealed m punctate erosions of the epithelium. An in vitro experiment identified sig of BAC to soft contact lenses.[53] In the second case, a 56-year-old man c keratoconjunctivitis sicca was treated with topical antibiotics and artificial containing BAC. Following 1 year of

continual use, the patient developed intractable pain, photophobia, and breakdown of the corneal epithelium. Not suspecting the BAC-containing patient continued to use the artificial tears solution for another 9 years c continued pain and decreasing visual acuity. Replacement with a preserv solution resulted in resolution of pain, photophobia, and corneal changes.

Nasopharyngeal and Oropharyngeal Toxicit

Human adenoidal tissue was exposed to oxymetazoline nasal spray preser at concentrations ranging from 0.005â€“0.15 mg/mL for 1â€“30 minutes. and broken epithelial cells were seen with all concentrations, however, it earlier and more frequently with the higher concentrations. The number c ciliary bodies also decreased as the duration and the concentrations incr Benzalkonium chloride may decrease the viscosity of the normal protectiv lining of the naso- and oropharynx, resulting in cytotoxicity.

Giving rats 1 of 3 nasal steroid sprays preserved with either 0.031% or 0 their right nostril twice daily for 21 days caused squamous cell metaplasia decrease in the number of goblet cells, cilia, and mucus.[14] No histologic

occurred in rats receiving the preservative-free steroid or in tissue expose sodium chloride solution administered into the left nostril as the control. another study, epithelial desquamation, inflammation, and edema occurre and 0.10% BAC was applied hourly to the nasal cavities of rats for 8 hou developed in the nasal cavities of rats receiving 0.01% BAC.

Benzyl Alcohol

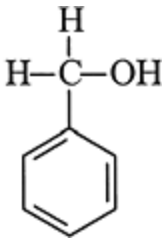

Figure. No Caption Available.

Benzyl alcohol (benzene methanol) is a colorless, oily liquid with a faint that is most commonly added to pharmaceuticals as a bacteriostatic agent In 1982, a â€œgaspingâ€• syndrome, which included hypotension, brad respirations, hypotonia, progressive metabolic acidosis, seizures, cardiov collapse, and death, was first described in low-birth-weight neonates in i units.[20 , 60 , 90] All the infants had received either bacteriostatic water or chloride solution containing 0.9% benzyl alcohol to flush intravenous cath parenteral medications reconstituted with bacteriostatic water or saline.[2 syndrome occurred in infants who had received greater than 99 mg/kg of (range, 99â€“234 mg/kg).[60] The World Health Organization (WHO) curre the acceptable daily intake of benzyl alcohol to be not more than 5 mg/kg weight.[22]

Pharmacokinetics

In adults, benzyl alcohol is oxidized to benzoic acid, conjugated in the liv and excreted in the urine as hippuric acid. The immature metabolic capac diminish their ability to metabolize and excrete benzyl alcohol.[60] Preterm greater ability to metabolize benzyl alcohol to benzoic acid than do term

unable to convert benzoic acid to hippuric acid, possibly because of glyci This results in the accumulation of benzoic acid (Fig. 53-1).[82] A fatal cas acidosis was reported in a 5-year-old girl who had received 2.4 mg/kg/h preserved with benzyl alcohol for 36 hours to control status epilepticus. benzoic acid levels were identified in serum and urine samples. The estim dosage of benzyl alcohol was 180 mg/kg.[60 , 86]

Neurologic Toxicity

Benzyl alcohol is believed to have a role in the increased frequency of ce intraventricular hemorrhages and mortality reported in very-low-birth-we

infants (weight <1000 g) who received flush solutions preserved with be
An increased incidence of developmental delay and cerebral palsy is also
same VLBW patient population, suggesting a secondary damaging effect c
alcohol.[11]

There are several case reports of transient paraplegia following the intrat
epidural administration of antineoplastics

or analgesics containing benzyl alcohol as a preservative.[8, 36, 66, 120] T
anesthetic effects are most likely responsible for the immediate parapares
duration of effects, rather than actual demyelination of nerve roots. In a
lumbosacral dorsal root action potential amplitudes were measured after
0.9% or 1.5% benzyl alcohol solutions in either 0.9% sodium chloride sol
distilled water.[66] Rats exposed to all benzyl alcohol solutions for less thar
inhibited dorsal root action potentials. This was attributed to the local ar
of benzyl alcohol. Nerve function was 50â€“90% restored after rinsing the
0.9% sodium chloride solution. Chronic intrathecal exposure to benzyl alc
7 days showed scattered areas of demyelinization and early remyelinizatic
benzyl alcohol solution-exposed dorsal nerve roots showed greater chang
widespread areas of demyelinization and fatty degeneration of nerve fibe

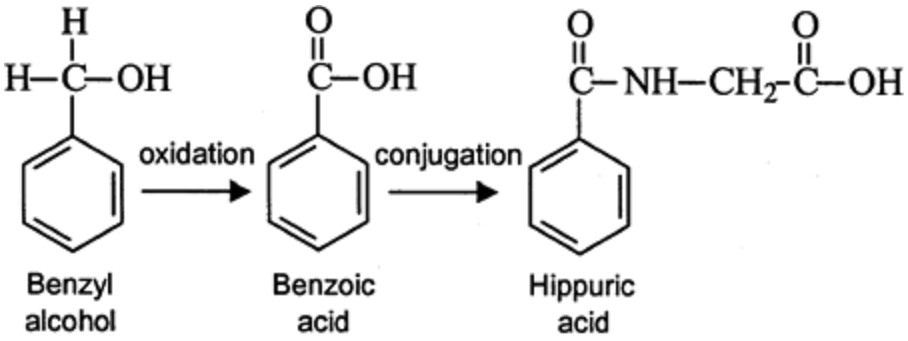

Figure 53-1. The oxidative metabolism of benzyl alcohol.

Chlorobutanol

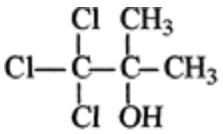

Figure. No Caption Available.

Chlorobutanol or chlorbutol (1,1,1-trichloro-2-methyl-2-propanol) is availa volatile, white crystals with an odor of camphor. Chlorobutanol has antib antifungal properties and is widely used as a preservative in injectable, and cosmetic preparations at concentrations up to 0.5% (Table 53-4). C also has mild sedative and local anesthetic properties and was formerly u therapeutically as a sedative-hypnotic.[17] Because chlorobutanol is a halo hydrocarbon, theoretically it can sensitize the myocardium to catecholam no cases of ventricular dysrhythmias are described in the literature to da human chlorobutanol dose is estimated to be 50â€“500 mg/kg.[104]

Central Nervous System Depression

Chlorobutanol has a chemical structure similar to trichloroethanol (Fig. 7 active metabolite of chloral hydrate, and is believed to exhibit similar ph properties. Central nervous system depression was reported in a 40-year male who chronically abused Seducaps, formerly available in Australia an countries, a nonprescription hypnotic containing chlorobutanol as the act ingredient.[17] On admission to the ED he had drowsiness, dysarthria, slur occasional episodes of myoclonic movements. His peak plasma chlorobuta concentration was 100 Âµg/mL, decreasing to 48 Âµg/mL over 2 weeks, v of 13 days. His speech abnormality resolved over 4 weeks. Only chlorobu detected in the patient's urine or plasma. In a second case, a possible ce system depressant effect from chlorobutanol was suggested in a 19-year- treated with high doses of intravenous morphine preserved with chlorobu received approximately 90 mg/h of chlorobutanol for several days. Her pe chlorobutanol concentration was 83 Âµg/mL, a level similar to that in the report;[17] however, the coadministration of morphine precludes the effects attributed to chlorobutanol alone.

Ophthalmic Toxicity

Chlorobutanol is a commonly used preservative in ophthalmic preparations shown to be less toxic to the eye than benzalkonium chloride.[107] Chlorob increases the permeability of cells by impairing cell membrane structure.[

experiment, using corneal epithelial cells harvested from human cadaver arrested mitotic activity following chlorobutanol exposure.[134]

Lipids

In general, there are three types of commercial intravenous lipid drug-de available: lipid emulsion, liposomal, and lipid complex (Table 53-5). Lipi immiscible lipid droplets dispersed in an aqueous phase stabilized by an egg or soy lecithin). Liposomes differ from emulsion lipid droplets in that vesicles comprised of one or more concentric phospholipid bilayers surrou aqueous core. Lipophilic drugs can be formulated for intravenous adminis partitioning them into the lipid phase of either an emulsion or liposome. capable of encapsulating hydrophilic therapeutic agents within their aqueo exploit lipid pharmacokinetic properties.[130] Attaching a therapeutic agent form a lipid complex is another way to take advantage of lipid pharmaco

Lipid carriers are biocompatible because of their similarity to endogenous membranes. They can be used to stabilize labile drugs against hydrolysis to decrease toxicity, and to enhance therapeutic efficacy by altering drug pharmacokinetic and pharmacodynamic parameters. The biodistribution, ar release and metabolism of a drug incorporated in a lipid formulation can the type and concentration of oil and emulsifier used; pH; drug concentr in the medium; the size of the lipid particle; and the manufacturing proce Intravenous formulations are usually isotonic and have a pH of 7â€“8.[130]

Medication Lipid Carrier

TABLE 53-5. Lipid Carrier Formulations of Common Medications

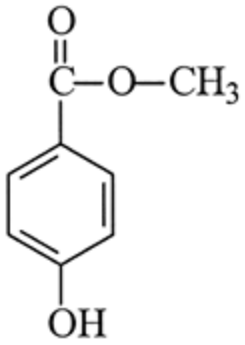
The rate of clearance of a lipid carrier from the blood depends on its phy properties, and the molecular weight of the emulsifier. Electrically charge are removed faster than neutral particles.[24,109] Smaller lipid particle siz molecular-weight emulsifiers decrease clearance. Stealth liposome formul Doxil) incorporate a polyethylene glycol coating that prevents rapid detec clearance of liposomes by the reticuloendothelial system prolonging circu Active drug targeting can be achieved by conjugating antibodies or vector chains on the emulsifier.[24,109] For a therapeutic agent available in more lipid-carrier formulation (eg, amphotericin B in AmBisome, Abelcet, and A important to note that any change in the lipid formulation can alter its p pharmacodynamic, and safety parameters; consequently, they are not ec formulations.

The physiochemical properties of lipid emulsions not only effect the thera carried by them, but the lipids themselves may also have direct pharmac on the central nervous[144] and immune systems.[84] Lipid fatty acid mediato the membrane receptor channels of *N* -methyl-D-aspartate (NMDA) recep potentiating synaptic transmission. This is supported by 1 animal[96] and s vitro[97,110,133] studies. Dogs given a medium-chain triglyceride emulsi infusion were reported to have dose-related central nervous system meta neurologic effects, accompanied by electroencephalographic changes cons encephalopathy observed when plasma octanoate concentration reached mM.[96] In an in vitro model, 3 of 9 lipid emulsions tested (Abbolipid, 20% safflower oil; Intralipid, 20% soya oil; and Structolipid, 20% structured demonstrated a dose-related activation of cortical neuronal NMDA recept

The lipid source for all but one (Omegaven, 10% fish oil) of the emulsion made up solely or partially by soya oil. The authors could not explain why lipid emulsions did not induce membrane currents. Adequate control for t constituent contribution of these emulsions is lacking. In a more recent ir the same authors found that NMDA-induced neuronal currents are reduced unknown factor in the aqueous portion of Abbolipid.[145] They suggest that may pharmacologically enhance the anesthetic effect of hypnotic agents s Propofol. The clinical relevance of these studies remains to be assessed.

Triglycerides in parenteral nutrition emulsions are implicated in altering t system, leading to an increased susceptibility to infection,[52, 142] and alt function and hemodynamics in patients with acute respiratory distress sy (ARDS).[84] Phospholipid activation of phospholipase A_2 may be an initiatir [142] however, it is not clear if these immunologic effects are a consequer other than the lipid in the emulsion.

Parabens



Methylparaben

The parabens, or parahydroxybenzoic acids, are a group of compounds w as preservatives in cosmetics, food and pharmaceuticals because of thei fungistatic, and antioxidant properties (Table 53-6).[121] A survey conduct and Drug Administration identified the parabens as the second most com in cosmetic formulations, with water being the most common.[87] Parabens in combination, because the presence of 2 or more parabens results in s action.[87] Methylparaben and propylparaben are most commonly used.[121]

paraben concentrations usually range from 0.1â€“0.3%.[115]

Widespread usage of parabens since the 1920s has shown that they have low order of toxicity;[87] however, because of their allergenic potential the considered less suit-able for injectable and ophthalmic preparations.[115] B term animal studies, the WHO has set the total acceptable daily intake of and propyl parabens to 10 mg/kg body weight.[115]

In addition to allergic reactions, parabens have the potential to cause otl effects. Bilirubin displacement from albumin binding sites occurred with of methyl and propyl paraben preserved gentamicin when serum paraber were 3â€“15 Âµg/mL.[39] Gentamicin alone has no effect on bilirubin displ Spermicidal activity was demonstrated in an in vitro study of human sem exposed to local paraben concentrations of 1â€“8 mg/mL.[127] Possible inte conception and potential adverse effects on fertility were not investigated

Phenol

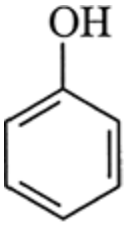

Figure. No Caption Available.

Phenol (carbolic acid, hydroxybenzene, phenylic acid, phenylic alcohol) is used preservative in injectable medications (Table 53-7). Phenol is a co pink, caustic liquid, with a characteristic odor. When exposed to air and l turns a red or brown color.[35] Phenol exerts antimicrobial activity

against a wide variety of microorganisms, such as Gram-negative and G bacteria, mycobacteria, and some fungi and viruses.[35] Phenol is well absc gastrointestinal tract, skin, and mucous membranes, and is excreted in th phenyl glucuronide and phenyl sulfate metabolites.[35] Although there are reports of phenol toxicity following intentional ingestions or unintentional exposures (Chap. 98), adverse reactions to its use as a pharmaceutical uncommon, most likely because of the small quantities used.[35]

Commercially available glucagon is a lyophilized powder that is packaged a 1-mL diluent that formerly contained phenol. According to the manufactu

used to prolong the shelf life of the glucagon solution (Lilly Pharmaceutic communication, May 2005). Reconstitution of glucagon with the sterile w preserved with 0.2% phenol and 1.6% glycerin would subsequently contai phenol. Glucagon in doses of 0.5â€“1 mg is employed in the treatment o However high doses of glucagon are used in the treatment of severe Î²-a antagonist and calcium channel-blockade poisonings. Since the total reco intravenous phenol dosage in humans should not exceed 50 mg in a 10-h because of the concerns for systemic phenol toxicity,[19 , 35 , 98] it was re that glucagon be reconstituted with either 0.9% sodium chloride solution, in water, or sterile water for injection when the dosage exceeded 10 mg.[3 Glucagon diluent no longer contains phenol.[23]

Cutaneous Absorption

Systemic toxicity from cutaneous absorption of phenol is reported. Ventr tachycardia was observed in a 11-year-old boy following administration of peel solution containing 88% phenol in water and liquid soap. The solutio to 15% of his body surface area for the treatment of xeroderma pigment Immediately following the onset of the ventricular tachycardia, the phen were irrigated with saline, an infusion of 0.9% sodium chloride solution w 2 intravenous lidocaine boluses were given followed by a lidocaine infusio dysrhythmia persisted for 3 hours. The urinary phenol concentration the was 58.9 mg/dL.[137] In a similar case, multifocal premature ventricular c (PVCs) were observed in a 10-year-old boy after application of a chemica solution of 40% phenol, 0.8% croton oil in hexachlorophene soap, and wa treatment of a giant hairy nevus.[143] The PVCs were refractory to intrave but resolved with intravenous bretylium. No phenol levels were obtained systemic absorption.

Drowsiness, respiratory depression, and blue-colored urine were noted in infant 12 hours after topical application of magenta paint over most of th seborrheic eczema.[117] Magenta paint (also known as Castellani paint) was for seborrheic eczema and contains 4% phenol, magenta, boric acid, res and methylated spirit. Further investigation found that phenol was detecte samples of 4 of 16 other infants with seborrheic eczema who had approx

11â€“15% of their body surface area painted with magenta paint for 2 da

Polyethylene Glycol

Polyethylene glycols (PEGs, Carbowax, Macrogol) include several compoun varying molecular weights (MWs) (200â€“40,000 MW).[114] They are typica mixtures designated by a number denoting their average molecular weig glycols are stable, hydrophilic substances, making them useful excipients and pharmaceuticals of all routes of administration (Table 53-8). Pegyla that modifies the pharmacokinetics of therapeutic liposomes and proteins peginterferon-Î±), is the most recent application of PEG. At room temper with molecular weights less than 600 are clear, viscous liquids with a slig characteristic odor and bitter taste. Those PEGs with molecular weights g 1000 are soluble solids and range in consistency from pastes and waxy fl powders.[114] Commercially available products such as GoLYTELY and Colyt of PEG 3350 combined with electrolytes (PEG-ELS).

The solid, high-molecular-weight PEGs are essentially nontoxic. Converse molecular-weight PEG exposures have caused adverse effects similar to t related toxic alcohols ethylene and diethylene glycol.

Pharmacokinetics

High-molecular-weight PEGs (>1000) are not significantly absorbed from gastrointestinal tract, but low-molecular-weight PEGs may be absorbed w orally.[43 , 124 , 125] Topical absorption can occur when PEGs are applied t skin.[21 , 131] The pharmacokinetics of intravenously administered PEG 3350 studied; however, it did not appear to have any systemic effects when u given by this route.[116] Once in the systemic circulation, PEGs are mainly unchanged in the urine;[43] however, low-molecular-weight PEGs are metal alcohol dehydrogenase to hydroxyacid and diacid metabolites. PEG may a broken down to ethylene glycol although the clinical consequence of this [132]

Nephrotoxicity

In rats fed various PEGs (200, 300, and 400) in their drinking water for 9 solution of 8% PEG 200 produced renal tubular

necrosis in all the animals, followed by death within 15 days; however, a solution resulted in only 2 of 9 rats dying within 80 days. A 16% PEG 40 all animals within 13 days; however, both 8% and 4% PEG 400 solutions observable effect except for a decrease in kidney weight when compared animals.[126]

TABLE 53-8. Common Medications Containing Polyethylene Glycol

Acute tubular necrosis with oliguria, azotemia and high anion gap metabo been reported after oral and topical exposures to low-molecular-weight PE 300). Acute renal failure occurred in a 65-year-old male with a history of and seizure disorder, after ingestion of the contents of a lava lamp conta 200.[44] Forty-eight hours after admission (approximately 50â€“72 hours

the patient became oliguric with an anion gap metabolic acidosis and acu Blood sample analysis confirmed traces of the lava lamp fluid; no traces in the urine. After clinical complications from ethanol withdrawal and asp pneumonitis, the patient was discharged 3 months later with residual kid attributed to the PEG component of the lamp contents. Acute tubular nec on autopsy of 6 burn patients treated with a topical antibiotic cream in a base.[21 , 131] Mass spectrometry detected hydroxyacid and diacid metaboli and urine samples. Oxalate crystals were seen in 2 cases. These effects v reproduced with the topical application of PEG for 7 days to rabbits with skin defects.[131]

Neurotoxicity

There are reports of neurologic complications, such as paraplegia and tra paralysis, following intrathecal steroidal injections containing 3% PEG as [16] In an in vitro experiment, rabbit vagus nerves were exposed to concer 3350 ranging from 3â€“40% for 1 hour.[12] Three percent and 10% PEG ha nerve action potential amplitude or conduction velocity. Twenty percent a significantly slowed nerve conduction and had varying effects on the amp action potentials. Forty percent PEG completely abolished action potential changes were reversible and thought to be related to PEG-induced osmot

Fluid, Electrolyte, and Acidâ€“Base Disturl

Hyperosmolality was reported in 3 patients with burn surface areas rangi 20â€“56%, following repeated applications of Furacin, a topical antibiotic containing 63% PEG 300, 32% PEG 4000, and 5% 1000.[21] Polyethylene g an osmotic effect that is greater than expected for its molecular weight.[1 theorized that PEG increases osmolality by sequestering water through h binding, reducing the availability of water to interact with solutes, thus i chemical and osmotic activity of the solute. Hyperosmolality following th of a PEG-containing substance may suggest systemic PEG absorption.

Two cases of metabolic acidosis were reported following administration o dosages of an intravenous nitrofurantoin solution containing PEG 300.[132]

otherwise unexplained increased anion gap was reported in 3 patients bei a topical PEG-based burn cream.[21] Metabolism of PEG by alcohol dehydro hydroxyacid and diacid metabolites can explain the metabolic acidosis.[70]

Propylene Glycol

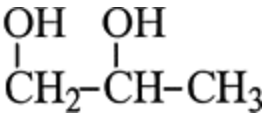

Figure. No Caption Available.

Propylene glycol (PG), or 1,2-propanediol, is a clear, colorless, odorless, liquid employed in numerous pharmaceuticals (Table 53-9), foods, and Propylene glycol is used as a solvent and preservative with antiseptic pr to ethanol. The WHO has set the daily allowable intake of PG at a maximu mg/kg,[146] or 1.8 g/d for a 70-kg person.

Pharmacokinetics

Propylene glycol is rapidly absorbed from the gastrointestinal (GI) tract f administration and has a volume of distribution of approximately 0.6 L/kg applied to intact epidermis, the absorption of PG is minimal. Percutaneou may occur following application to damaged skin (eg, extensive burn surf Approximately 12â€“45% of PG is excreted unchanged in the urine;[42] the hepatically metabolized sequentially by alcohol dehydrogenase and aldeh dehydrogenase to lactic acid. Lactic acid may be additionally oxidized to and then to carbon dioxide and water.[102] The terminal half-life of propyle reported to be between 1.4 and 5.6 hours in adults, and as long as 16.9 neonates.[42 , 128]

Cardiovascular Toxicity

Intravenous preparations of phenytoin contain 40% PG to facilitate the s phenytoin. Nine years after intravenous phenytoin became available, sev were attributed to the rapid administration of phenytoin used for the trea

cardiac dysrhythmias.[59, 135, 153]

Cardiovascular effects reported in these cases include hypotension, brad widening of the QRS interval, increased amplitude of T waves with occas and transient ST elevations. Studies in cats[89] and calves[63] confirmed PG cardiotoxin. Bradycardia and depression of atrial conduction were not

observed in cats pretreated with atropine, or in those with vagotomy foll intravenous infusion of PG, suggesting that these effects are vagally mec Amplification of the QRS complex was noted in these same pretreated cat suggesting a direct cardiotoxic effect of PG. Similar results were reported pretreated with atropine that received oxytetracycline in a PG vehicle.[63]

TABLE 53-9. Propylene Glycol Concentration of Common Medicati

Neurotoxicity

Smaller infants appear to have a decreased ability to clear PG when comp children and adults.[90] An increased frequency of seizures was reported ir weight infants who received PG 3 g daily in a parenteral multivitamin pr Seizures developed in an 11-year-old boy receiving long-term oral therap D dissolved in PG.[6] Serum calcium, magnesium, electrolytes, and blood g normal. Seizures abated after the product was discontinued. Propylene g inebriating properties similar to ethanol. Central nervous system depressi reported following an intentional oral ingestion of a PG-containing produc

A black-boxed warning was added to the product information for amprena (Agenerase), an oral protease inhibitor solution, because of concerns over (550 mg/mL) vehicle content.[119] The recommended daily dosage of amp 1650 mg/kg/d of PG. A 61-year-old man experienced visual hallucinations disorientation, tinnitus, and vertigo after receiving a 750-mg dose (474 m amprenavir solution.[76]

Ototoxicity

Otic preparations can contain up to 94% PG in solutions and 10% in susp of their vehicles.[48] In animal studies, application of high concentrations o to the middle ear can produce hearing impairment[100 , 101 , 140] and mor changes, including tympanic membrane perforation, middle ear adhesions cholesteatoma.[100 , 139 , 150] Although the effects of PG in the human mic not been studied, all medications applied to the external ear canal are c patients with perforated tympanic membranes.

Fluid, Electrolyte, and Acidâ€“Base Disturl

Patients receiving continuous or large intermittent quantities of medicati PG can develop high PG concentrations, particularly those with renal or h insufficiency.[27 , 42] Propylene glycol electrolyte and metabolic disturbance evidenced by hyperosmolality, and an elevated osmolar gap attributed to active properties of PG. In most cases, an elevated anion gap, with an o unexplained metabolic lactic acidosis, is also present. Metabolic acidosis r lactic acid produced from PG metabolism.[26] These adverse effects have b with intravenous preparations such as lorazepam,[5 , 151] diazepam,[147] eto nitroglycerin,[42] pediatric multivitamins,[61] and topical silver sulfadiazine.[1

Systemic absorption of PG from topical application of silver sulfadiazine c resulted in hyperosmolality in patients with burn surface areas greater tha body.[10 , 49 , 80] In one study, 9 of 15 burn patients had osmolar gaps (> application of the cream.[80]

Hyperosmolarity occurred in 5 infants receiving a parenteral multivitamin a daily PG dose of 3 g.[61] After 12 days, 1 premature infant had a PG con

930 mg/dL and an osmolar gap of 136. Anion gap and lactic acid concent normal. In a study of 11 intubated pediatric patients, ages 1 to 15 month receiving continuous lorazepam infusions over 3â€“14 days, accumulated concentrations of 17â€“226 mg/dL did not result in significant increases i or serum lactic acid concentrations from baseline.[31] This was attributed t function and the low cumulative PG doses received (mean 60 g).

Two small studies found a strong correlation between PG serum concentra osmolar gap in critically ill patients receiving lorazepam infusions.[5 , 151] patients on lorazepam high-dose infusions received a mean cumulative PG mg/kg/d.[5] At 48 hours the mean serum PG concentration was 200 mg/dL mg/dL), and all patients had elevated osmolar gaps (mean, 48; range, 2 patients had elevated anion gaps, although it is questionable whether this of PG because lactic acid concentrations were either not reported or were for 8 of the 9 patients. In the second study,[151] laboratory values were re patients at the time of peak serum creatinine concentrations (median, 9 receiving lorazepam infusions of 2â€“28 mg/h. Mean PG serum concentrat mg/dL (18.6â€“345 mg/dL). Elevated osmolar gaps (mean, 32; range, 1 occurred in 7 patients, and 4 of these 7 patients had high anion gaps. La concentrations were not reported for 1 patient and were high in the other

Using an elevated osmolar gap as a surrogate marker for PG accumulatio receiving lorazepam infusions, has been suggested.[5 , 151] An osmolar gap corresponds to a PG serum concentration of approximately 48 mg/dL.[5] Th should be used cautiously, as larger, more comprehensive studies are ne it. In addition, there are rare cases where PG accumulation did not result gap.[62 , 151] Anion gap and lactic acid concentration should be obtained, as concentration to eliminate other potential causes for an elevated osmolar

Nephrotoxicity

Human proximal tubular cells exposed in vitro to PG concentrations of 5(mg/dL exhibited significant cellular injury and membrane damage within 1 exposure.[102] Repeated exposure for up to 6 days produced dose-depende at lower concentrations (76, 190, and 380 mg/dL).[103]

The chronic administration of PG may contribute to proximal tubular cell subsequent decreased renal function. In a retrospective study of 8 patien developed elevations in serum creatinine while receiving continuous lora infusions, serum creatinine rose within 3â€“60 days (median, 9 days).[151] of serum creatinine rise was found to correlate with the PG serum concer duration of infusion. Serum creatinine decreased within 3 days of discont infusion. Patients with renal dysfunction are at greater risk for accumulat 45% of PG is eliminated unchanged by the kidneys;[42] the remainder is m the liver. Caution should be used when prolonged administration of a PG medication is necessary in the presence of renal or hepatic dysfunction.[10

Propylene glycol-induced renal tubular necrosis has been reported in sev Daily PG-vehicle dosages of 11â€“90 g/d over 14 days was associated wi creatinine concentrations (from 0.7 mg/dL to 2.1 mg/dL), elevated serum

concentrations, osmolar and anion gaps, and a serum PG concentration of Urine sediment analysis revealed numerous granular, muddy-brown-colore eosinophils, suggesting an acute renal tubular necrosis. A renal biopsy ar microscopy showed extensive dilation of the proximal renal tubules, with epithelial cells and mitochondria. Numerous vacuoles containing debris we A renal biopsy of another case with a serum PG concentration of 30 mg/c disrupted brush borders of the proximal renal tubules after a sudden rise creatinine (3.1 mg/dL), nonoliguric renal failure, and metabolic acidosis. attributed to an average daily PG dose of 70 g for 17 days.[68]

Sorbitol

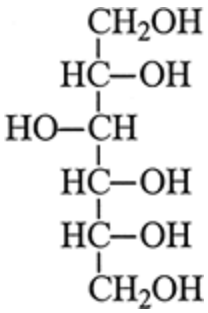

Figure. No Caption Available.

Sorbitol (D-glucitol) is widely used in the pharmaceutical industry as a s agent, moistening agent, and a diluent (Table 53-10). Sorbitol occurs na ripe berries of many fruits, trees, and plants, and was first isolated in 18 berries of the European mountain ash (*Sorbus aucuparia*).[105] It is partic chewable tablets because of its pleasant taste. In addition, it is widely us industry in chewing gums, dietetic candies, foods, and enteral nutrition Sorbitol is approximately 50â€“60% as sweet as sucrose.[105]

Pharmacokinetics

Unlike sucrose, sorbitol is not readily fermented by oral microorganisms a absorbed from the gastrointestinal tract. Any absorbed sorbitol is metabol liver to fructose and glucose.[105] Sorbitol has a caloric value of 4 kcal/g a tolerated by diabetics than sucrose; however, because some of it is meta glucose, it is not unconditionally safe for diabetics.[105]

There is a concern of potentially fatal toxicity for individuals with heredit intolerance (HFI) receiving sorbitol-containing agents.[50] HFI is an autosc disorder caused by a deficiency of fructose-1,6-bisphosphonate aldolase i kidney, cortex, and small intestine.[77] This results in the accumulation of phosphate, which causes hypoglycemia by preventing glycogen breakdowr synthesis. The prevalence of HFI is most commonly reported to be 1 in 2 but can range between 1 in 11,000 and 1 in 100,000.[2 , 75 , 77]

TABLE 53-10. Common Medications Containing Sorbitol

In individuals with HFI, the prolonged administration of sorbitol, fructose, result in death from liver or renal failure.[34,123] Dietary exclusion of fru and sorbitol prevents the adverse effects. This condition should not be co more common disorder of dietary fructose intolerance (DFI), which is caus in the glucose-transport protein 5 (GLUT5) system. This leads to the brea fructose to carbon dioxide, hydrogen, and short-chain fatty acids by colo resulting in abdominal pain and bloating.[83] Dietary fructose intolerance s minimized by limiting sorbitol, fructose, and sucrose in the diet.

Gastrointestinal Toxicity

In large dosages, sorbitol can cause abdominal cramping, bloating, flatul and diarrhea. Sorbitol exerts its cathartic effects by its osmotic properties fluid shifts within the gastrointestinal tract. In a human volunteer study, adults ingested 10 g of a sorbitol solution. Sorbitol intolerance was detect 55% of subjects.[74] One theoretical explanation for why all subjects did n the gastrointestinal adverse effects is unrecognized DFI. Diarrhea resultin sorbitol-containing medications is common and often overlooked as a pos etiology.[30,69] Ingestion of large quantities of sorbitol (>20 g/d in adults recommended (Antidotes in Depth: Whole-Bowel Irrigation and Other Int Evacuants).[105]

Thimerosal

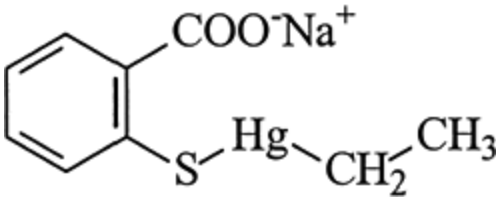

Figure. No Caption Available.

Thimerosal (Merthiolate, Mercurothiolate) or sodium ethylmercurithiosalicy organic mercury compound that is approximately 49% elemental mercury weight.[118 , 141] It is metabolized to ethylmercury and thiosalicylate. Thim wide spectrum of antibacterial activity at concentrations ranging from 0. however, higher concentrations are sometimes also used.[78 , 99] Thimerosa widely used as a preservative since the 1930s in contact lens solutions, l vaccines, particularly those in multidose containers (Table 53-11). The u thimerosal necessary for the production process of some vaccines (eg, p influenza) may leave trace amounts in the final product.[9] High-dose thim has resulted in neurotoxicity and nephrotoxicity. Over the last several ye have arisen about infant exposure to low-dose thimerosal through vaccina effects on neurodevelopment, including possible links to causes of autism

Because specific guidelines for ethylmercury exposure have not been dev regulatory guidelines for dietary methylmercury exposure have been used ethylmercury exposure from injected thimerosal-containing vaccines. Meth similar, but more toxic, organic mercury compound (Chap. 92).

Maximum daily recommended methylmercury exposures range from 0.1 Â Environmental Protection Agency [EPA]) to 0.47 Âµg Hg/kg (WHO).[3 , 29 ,

TABLE 53-11. Thimerosal Concentration of Common Medications

A 1997 FDA review of thimerosal-containing vaccines revealed that some depending on the immunization schedule, vaccine formulations, and infar might be exceeding the EPA exposure limit of 0.1 Âµg Hg/kg/d for methy the first 6 months of life, a total cumulative dose of up to 187.5 Âµg Hg thimerosal-containing vaccines was possible. The US Public Health Service the American Academy of Pediatrics (AAP) responded jointly by recommer preemptive reduction or removal of thimerosal from vaccines wherever p The WHO and European regulatory bodies have made similar recommend date, thimerosal has been removed from most US-licensed immunoglobuli vaccines routinely recommended for children younger than 7 years of age thimerosal free or contain only trace amounts (<0.5 Âµg Hg/dose), with some inactivated influenza vaccines. Multidose vials requiring thimerosal remain important for immunization programs in developing countries. Alt continue to eliminate all sources of mercury exposure, complete eliminati thimerosal from all vaccines is unlikely in the near future.[9] When a thime containing vaccine is the only alternative, the benefits of vaccination far theoretical risk of mercury toxicity.[106]

Prior to thimerosal use in pharmaceuticals, evidence for its safety and ef provided in several animal species and in 22 humans.[113] Only limited data infant mercury exposure from thimerosal-containing vaccines. Clinical stu assess the effects of thimerosal exposure on neurodevelopment and renal

immunologic function are lacking. Based on a comprehensive review of e data from the United States,[54 , 55 , 56 , 57 , 141] Denmark,[73 , 91] Sweden, United Kingdom,[4 , 71] the Institute of Medicine's (IOM) Immunization Saf Committee,[106] the Global Advisory Committee on Vaccine Safety (GACVS European Agency for the Evaluation of Medicinal Products (EMEA),[45] have that there is no causal relationship between thimerosal-containing vaccine Continued surveillance of autistic spectrum disorders as thimerosal use de conducted to evaluate any associated trends.

Pharmacokinetics

Limited pharmacokinetic data exists for thimerosal and ethylmercury. On thimerosal breaks down to form ethylmercury and thiosalicylate. Some e further decomposes into inorganic mercury in the blood, and the remainc into kidney and, to a lesser extent, brain tissue.[92 , 93] Because of its lon chain, ethylmercury is less stable and decomposes more rapidly than me leaving less ethylmercury available to enter kidney and brain tissue.[93] Et crosses the bloodâ€“brain barrier by passive diffusion.[92] Intracellular et decomposes to inorganic mercury which accumulates in kidney and brain half-life of thimerosal is estimated to be about 18 days.[93] Thimerosal is e the feces as inorganic mercury.[112]

Mercurial Toxicity

Oral Administration

A case report described a 44-year-old man who ingested 5 g (83 mg/kg) a suicide attempt; within 15 minutes he began vomiting spontaneously. G was performed and chelation therapy begun with dimercaptopropane sulf Gastroscopy revealed a hemorrhagic gastritis. Polyuric acute renal failure the day of admission and persisted for 40 days. Four days after admissior developed a fever and a maculopapular exanthem attributed to thimerosa also developed an autonomic and ascending peripheral polyneuropathy th 13 days. Chelation therapy was continued for a total of 50 days with DMF succimer. Elevated blood and urine mercury levels persisted for more thar

The patient was discharged 148 days following the ingestion with only se his toes. No other neurologic sequelae were noted.[111]

Oral absorption of thimerosal resulted in the fatal poisoning of an 18-mo from the intraotic instillation of a solution containing 0.1% thimerosal an sodium borate. Tympanostomy tubes placed 1 year earlier allowed the ir to flow through the auditory tube into the nasopharynx, and subsequently swallowed and absorbed through the oral mucosa and gastrointestinal trac 1.2 L of solution (500 mg Hg) was instilled over a 4-week period, resultin mercury poisoning. Four days after admission, the plasma mercury conce 163 Âµg/dL. The patient also received 1.7 g of boric acid. It is unclear wl contribution, if any, the boric acid made to the plasma mercury concentr therapy with *N* -acetyl-D-penicillamine was initiated on day 51. Despite i urinary mercury concentrations following administration of the *N* -acetyl- penicillamine, her neurologic function and blood mercury concentrations unchanged. The child died 3 months after admission. An autopsy was not

Intramuscular Administration

Urine mercury levels of 26 patients with hypogammaglobulinemia, who r intramuscular IgG replacement therapy preserved with 0.01% thimerosal The dosages of IgG ranged from 25â€“50 mg/kg, containing 0.6â€“1.2 mg per dose.[64] The total estimated dose of mercury administered ranged fron over a period of 6 months to 17 years. Urine mercury levels were elevate

in 19 patients ranging from 31â€“75 Âµg/L; however, no patients had cli of chronic mercury toxicity.[64]

Six cases of severe mercury poisoning resulting in 4 deaths were reporte intramuscular administration of chloramphenicol preserved with thimerosa manufacturing error produced vials containing 510 mg of thimerosal (250 instead of 0.51 mg per vial. Two adults received 4 and 5.5 g of mercury e children received 0.2â€“1.8 g each. All 6 patients had extensive tissue ne site of injection. Fever, altered mental status, slurred speech, and ataxia Autopsy identified widespread degeneration and necrosis of the renal tub creatine kinase concentrations were not reported so pigment-induced ne

cannot be ruled out. Elevated mercury concentrations were found in the tissues, and in the kidneys, livers, and brains.[7]

Topical Administration

Thirteen infants were exposed to 9â€“48 topical applications of a 0.1% t tincture for the treatment of exomphalos. Analysis for elevated mercury was performed in 10 of 13 infants who unexpectedly died. Mercury conce determined in various tissues from 6 of the infants. Mean tissue concentr samples of liver, kidney, spleen, and heart ranged from 5152 to 11,330 percutaneous absorption from these repeated topical applications.[46]

Ophthalmic Administration

Nine patients undergoing keratoplasty were exposed to a contact lens stor solution containing 0.002% thimerosal.[148] After 4 hours, the lens was re mercury concentrations of the aqueous humor and excised corneal tissues determined. Mercury concentrations were elevated in both aqueous humo 20â€“46 ng/mL higher) and corneal tissues (range, 0.6â€“14 ng higher) a eyes that had not been fitted with contact lenses. Only residual amounts remained on the contact lenses after 4 hours of wear. The authors noted the aqueous humor concentrations were in the same range as those meas patients with vision loss from systemic mercury poisoning (11â€“104 ng/ effects did not occur.

A possible drug interaction between orally administered tetracyclines and reported to result in acute, varying degrees of eye irritation in contact le using thimerosal-containing contact lens solutions who started treatment tetracycline.[38]

Summary

The benefits of pharmaceutical excipients include improved drug solubility palatability, the availability of various dosage forms, the provision of proc term storage, and the availability of multiple-dose packaging. Excipients termed â€œinert,â€• implying that they possess no pharmacologic or to

properties of their own. While excipients are essential and efficacious, the responsible for severe, and sometimes fatal, adverse effects.

The toxicity of pharmaceutical excipients should be considered for patien high dosages or prolonged administration of any medication containing e particularly those additives known to have toxicities. Individuals with dec hepatic functions or patients at the extremes of age may be at an increas accumulating excipients. Under circumstances in which there is no option continue treating a patient with a particular therapeutic agent, switching t preservative-free product, or to another brand without the offending exci obviate the need for discontinuation of an effective agent. In addition to toxicities, many excipients may also be responsible for allergic reactions. prevalence in numerous pharmaceuticals, cosmetics, and foods may allow sensitization. However, in the majority of cases, pharmaceutical excipients effective, and their benefits far exceed their potential for adverse effects administered properly.

Chapter 54

Antibiotics, Antifungals, and Antivirals

Christine M. Stork

A 56-year-old man with a past medical history significant for lumbar spinal stenosis and a recent laminectomy for chronic back pain was admitted to the hospital for a trial of intrathecal morphine. Because of a medication error, the postoperative order for intravenous cefazolin was administered into the intrathecal catheter. The error was detected when the patient complained of back pain 13 hours after initiation of the infusion; an estimated total dose of 350 mg (2.5 mL/h Ã— 13.5 h at 10 mg/mL) was infused. Soon thereafter, the patient developed generalized seizures, was intubated for airway support, and was treated using intravenous benzodiazepines, phenytoin, and phenobarbital (30 mg). Seizure activity resolved and the patient was extubated 5 days later.

History and Epidemiology

The majority of the adverse effects related to antibiotics occur as

a result of iatrogenic complications rather than intentional overdose. The origins of these complications are diverse and include dosing and decision errors, allergic reactions, adverse drug effects, and drug interactions. Prevention in the form of process improvements and information regarding population risk for adverse drug effects is required to minimize these untoward events. As dosing errors are commonly noted in neonates and infants treated with intravenous antibiotics, careful and constant diligence on the part of all healthcare providers is required to minimize such errors.

Antibiotics are more commonly associated with anaphylactic reactions than are other medications. The reason for this is unclear, but it may be a result of their high frequency of use, repeated interrupted exposures caused by intermittent prescriptive use, or because of environmental contamination. A complete and clear allergy history is essential to minimize these reactions in patients being considered for antibiotic therapy.

Many adverse effects attributed to antibiotics are difficult to predict even when given patient- and population-specific parameters. In some cases, a diluent or ancillary chemical constituent of the drug is responsible for the adverse effect, as recognized with the use of procaine penicillin G in patients with procaine allergy. Antibiotics are involved in many of the common and severe drug interactions, primarily through the inhibition of metabolic enzymes. Patients being considered for antibiotic therapy should be carefully assessed for the use of concomitant drug therapy that may be pharmacokinetically or pharmacodynamically affected by the chosen antibiotic.

Pharmacology and Toxicology

Antibiotic pharmacology is aimed at the destruction of microorganisms through the inhibition of cell-cycle reproduction or by directly altering a critical function within a microorganism.

Table 54-1 lists antibiotics and their associated mechanisms of antimicrobial activity. Often the mechanisms for toxicologic effects following acute overdose differ from the therapeutic mechanisms. Table 54-1 also lists the toxicologic effects and related mechanisms. Table 54-2 lists the pharmacokinetics of each class of drugs.

Antibacterials

Aminoglycosides

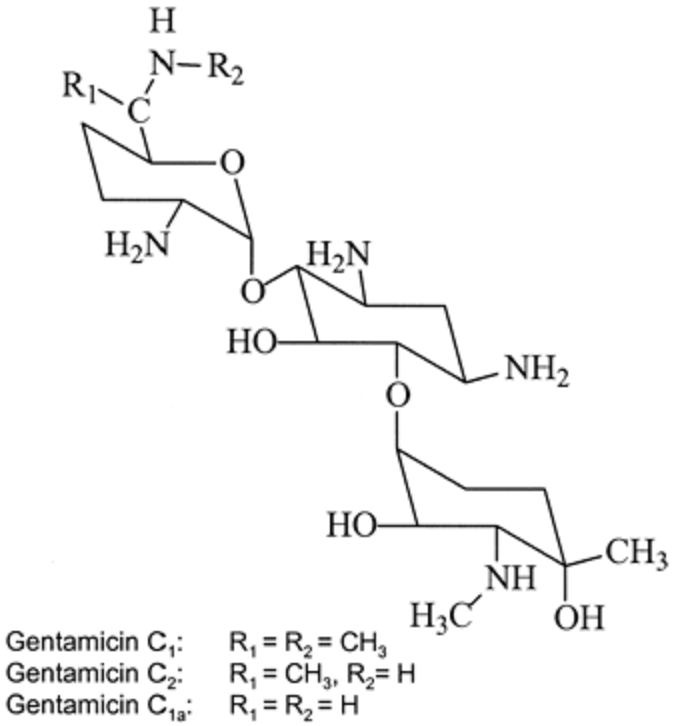

Figure. No Caption Available.

Aminoglycoside antibiotics that are in current use include amikacin, gentamicin, kanamycin, neomycin, netilmicin, streptomycin, and tobramycin.

Antibiotic
Aminoglycosides
Inhibit 30s ribosomal subunit
Neuromuscular blockade â€”inhibits the release of acetylcholine from presynaptic nerve terminals and antagonist at acetylcholine receptors
Renal toxicity/ototoxicity â€”forms an iron complex that inhibits mitochondrial respiration and causes lipid peroxidation
Penicillins, cephalosporins, and other Î²-lactams
Inhibit cell wall mucopeptide synthesis
Seizures â€”agonist at picrotoxin binding site causing GABA antagonism
Hypersensitivity â€”immune *Other* â€”see text
Chloramphenicol
Inhibits 50s ribosomal subunit and inhibits protein synthesis in rapidly dividing cells
Cardiovascular collapse
â€œGray baby syndromeâ€•
Same as mechanism of action
Fluoroquinolones
Inhibit DNA topoisomerase and DNA gyrase
Same as mechanism of action; binds to cations, particularly, magnesium, seizures
Not entirely known; binds to cations, particularly, magnesium; tendon rupture, hyper- and hypoglycemia
Linezolid
Inhibits bacterial protein synthesis through inhibition of N-formylmethionyl-t RNA
None clinically relevant
MAOI activity: pressor response to tyramine; and serotonin syndrome with SSRI and possibly meperidine
Macrolides and ketolides
Inhibit 50s ribosomal subunit in multiplying cells
Wide QTc â€”block delayed rectifier potassium channel

Not entirely known; cytotoxic effect; exacerbation of myasthenia gravis

Sulfonamides

Inhibit *para* -aminobenzoic acid and/or *para* -amino glutamic acid in the synthesis of folic acid

None clinically relevant

Hypersensitivity â€”metabolite is hapten leading to *hemolysis/methemoglobinemia* â€”exposure to UVB causes free radical formation, which results in an oxidant stress

Tetracycline

Inhibits 30s and 50s ribosomal subunits; binds to aminoacyl transfer RNA

None clinically relevant

Unknown

Vancomycin

Inhibits glycopeptidase polymerase in cell wall synthesis

â€œRed-man syndromeâ€• â€”anaphylactoid

Unknown

Antifungal

Amphotericin B

Binds with ergosterol on cytoplasmic membrane to cause pores to facilitate organelle leak

Same as mechanism of action

Nephrotoxicity â€”vehicle deoxycholate may be involved; nephrocalcinosis

Triazoles and imidazoles

Increase permeability of cell membranes

None clinically relevant

None clinically relevant

?CYP inhibition

TABLE 54-3. Predominant Aminoglycoside Toxicity

As aminoglycosides are only available in parenteral and ophthalmic forms, overdoses of aminoglycoside antibiotics are almost exclusively the result of dosing errors. Fortunately, overdoses are rarely life-threatening, and most patients can be safely managed with minimal intervention.[24 , 92 , 122 , 147] The adverse effects of aminoglycosides are generally class based, although subtle differences may exist in the potency with which the adverse effects occur (Table 54-3).

Large intravenous doses of aminoglycosides are both sufficiently effective and safe for use in single daily doses.[5] Rarely, acute aminoglycoside overdose results in nephrotoxicity, ototoxicity, or vestibular toxicity.[140, 168] In one reported case, postmortem analysis confirmed complete loss of hair cells in the inner and outer cochlear.

Aminoglycosides may infrequently exacerbate neuromuscular blockade, particularly at times corresponding to high-peak serum aminoglycoside concentrations (Chap. 66).[200, 274] These effects relate to the ability of aminoglycosides to inhibit the release of acetylcholine from presynaptic nerve terminals. This effect is mediated by antagonism by the aminoglycoside of the presynaptic calcium channel, and may be a result of the ability of aminoglycosides to block postsynaptic acetylcholine receptors.[2, 111] Risk factors for enhanced neuromuscular blockade include patients with abnormal neuromuscular junction function, such as those with myasthenia gravis and botulism, and patients receiving concomitant neuromuscular blocking drugs.[2]

Adverse Effects Associated with Therapeutic Use

Adverse effects, including nephrotoxicity and ototoxicity, correlate more closely with elevated trough serum concentrations of aminoglycosides than with elevated peak concentrations.[2, 88, 129, 177, 181] Less-common adverse effects associated with chronic aminoglycoside use include electrolyte abnormalities, allergic reactions, hepatotoxicity, anemia, granulocytopenia, thrombocytopenia, eosinophilia, retinal toxicity, reproductive dysfunction, tetany, and psychosis.[61, 65, 134, 153, 247, 262] When aminoglycosides are administered at high doses or during once-daily dosing, sepsislike reactions, including chills and malaise, can occur.[48] This is likely a result of contaminants that are delivered to the patient during the infusion.

Nephrotoxicity

The mechanism of nephrotoxicity and ototoxicity is inconclusive, but appears to include the ability of the aminoglycoside to form reactive oxygen species in the presence of iron. Mitochondrial respiration is inhibited, lipid peroxidation occurs, and stimulation of glutamate activated *N* -methyl-D-aspartate (NMDA) receptors may play a role.[113 , 232 , 241 , 269] The incidence of nephrotoxicity with aminoglycoside therapy is estimated at 5â€“10%.[10] Although the aminoglycosides are almost completely excreted prior to biotransformation in the kidney, a small fraction of filtered aminoglycoside is transported by absorptive endocytosis across the apical membrane of proximal tubular cells where it becomes sequestered within lysosomes. The aminoglycoside binds to and destroys phospholipids contained on brush border membranes in the proximal renal tubule.[10]

Clinically, acute tubular necrosis occurs after 7â€“10 days of standard-dose therapy. Laboratory abnormalities include granular casts, proteinuria, elevated urinary sodium, and increased fractional excretion of sodium. Usually the renal dysfunction is reversible; however, irreversible toxicity is reported.[9] Functional renal injury occurs days prior to elevations in serum creatinine, and for this reason, a delay in diagnosis is common.[233] Risk factors for the development of nephrotoxicity include increasing age, renal dysfunction, female sex, previous aminoglycoside therapy, liver dysfunction, large total dose, long duration of therapy, frequent doses, high trough levels, presence of other nephrotoxic drugs, and the presence of shock.[10 , 183 , 209] Because the uptake of aminoglycosides into organs causing toxicity is saturable, appropriate once-daily high-dose regimens are less problematic than several lesser doses given in a single day.

Ototoxicity

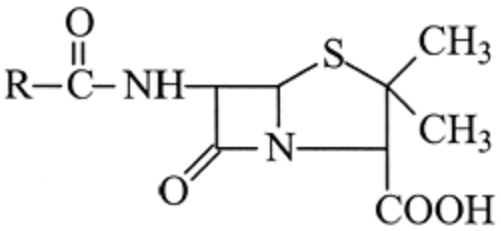
Ototoxicity can occur after acute or prolonged exposure to aminoglycosides. Both cochlear and vestibular dysfunction are correlated with high aminoglycoside trough concentrations.[41, 182] Because aminoglycosides bioaccumulate in the endolymph and perilymph spaces, they have prolonged contact time with sensory hair cells.[146] Vestibular toxicity, caused by destruction of sensory receptor portions of the inner ear or destruction of hair cells in the utricle and saccule, occurs in 0.4â€“10% of patients.[159, 182] Symptoms include vertigo or tinnitus. Table 54-3 details the relative characteristic toxicity of various aminoglycosides.

Full-tone audiometric testing may first show high-frequency hearing loss, which may subsequently progress. Given the inability of cochlear hair cells to regenerate, all hearing loss that develops is permanent. Electronystagmography is the diagnostic tool of choice for vestibular dysfunction, and up to 63% of patients with early findings of vestibular dysfunction may have improvement after discontinuation of the drug.[133] Simultaneous administration of other xenobiotics capable of causing ototoxicity enhances ototoxicity of aminoglycoside antibiotics (Chap. 21).[36, 146, 254]

Withdrawal of the offending xenobiotic is indicated in patients with either nephrotoxicity or ototoxicity caused by an aminoglycoside antibiotic. Supportive care is the mainstay of therapy. Experimental treatments in animal models include the use of deferoxamine, glutathione, and NMDA receptor antagonists in an attempt to chelate and/or detoxify a reactive intermediate.[195, 251] The antibiotic ticarcillin forms a renally eliminated complex with aminoglycosides in the blood to provide protection against tobramycin-induced renal toxicity. In humans, ticarcillin removes 50% more aminoglycoside in 48 hours than do 2 hemodialysis sessions.[80] However, ticarcillin therapy is generally of limited value because in most instances the serum concentration of the aminoglycoside has decreased before any therapeutic measures

can be employed. The use of ticarcillin should be considered only early after large overdose in patients with either demonstrated toxicity or renal failure where the risks of toxicity are significant.

Penicillins



Penicillins nucleus

Penicillin is derived from the fungus *Penicillium* and many semisynthetic derivatives have clinical utility. Penicillins, as a class, contain a 6-aminopenicillanic acid nucleus, composed of a Î²-lactam ring fused to a 5-member thiazolidine ring. Classic available penicillins include penicillin G, penicillin V, and the antistaphylococcal penicillins (nafcillin, oxacillin, cloxacillin, and dicloxacillin). Penicillins developed to enhance the spectrum of antibiotic efficacy, particularly against Gram-negative bacilli, include the second-generation penicillins (ampicillin, amoxicillin, bacampicillin, and mezlocillin), third-generation penicillins (carbenicillin and ticarcillin), and fourth-generation penicillins (piperacillin). Table 54-1 lists the pharmacologic mechanism of penicillins and Table 54-2 lists their pharmacokinetic properties.

Acute oral overdoses of penicillin-containing drugs are usually not life-threatening. The most frequent complaints following acute overdose are nausea, vomiting, and diarrhea. Rarely, hyperkalemia resulting in electrocardiographic abnormalities occurs after the rapid intravenous infusion of potassium penicillin G to patients with renal failure.

Seizures occur in persons given large intravenous or intraventricular doses of penicillins.[35, 136, 150, 175, 241] More than 50 million units intravenously are generally required to produce seizures in adults.[239] Penicillin-induced seizures appear to be mediated through an interaction of the drug with the picrotoxin-binding site on the neuronal chloride channel near the Î³-aminobutyric acid (GABA) binding site (Chap. 14). Binding of the penicillin produces an allosteric change in the receptor that prevents GABA from binding, resulting in a relative lack of inhibitory tone.[66] Penicillin analogs (such as imipenem) also cause seizures in both animal models and humans, presumably through a similar mechanism.[241]

Treatment of patients who develop penicillin-induced seizures include GABA agonists such as the benzodiazepines and barbiturates, if needed. Patients who receive an intraventricular overdose may require cerebrospinal fluid exchange to attenuate seizure activity.[150] There are rare reports of amoxicillin overdose resulting in frank hematuria and renal failure, and a single case report of penicillin-associated hearing loss.[28, 32, 98]

Adverse Effects Associated with Therapeutic Use

Penicillins are associated with a myriad of adverse effects after therapeutic use, the most common of which are allergic reactions. Penicillins are commonly implicated in immune-related reactions such as bone marrow suppression, cholestasis, hemolysis, interstitial nephritis, and vasculitis.[6, 95, 123, 187, 188, 250] Rare effects include pemphigus after penicillin use and corneal damage after the use of methicillin.[20, 278]

Acute Allergy

Penicillins are the pharmaceuticals most commonly implicated in

the development of acute anaphylactic reactions. Anaphylactic reactions are severe life-threatening immune-mediated (IgE) reactions involving multiple organ systems that occur most often immediately after exposure to a triggering agent. Table 54-4 lists the classifications of anaphylactic reactions. Anaphylaxis to penicillin is typically seen after IgE antibody formation, which can only occur after prior exposure to penicillin. Life-threatening clinical manifestations occurring after anaphylaxis can include angioedema, tongue and airway swelling, bronchospasm, bronchorrhea, cardiac dysrhythmias, cardiovascular collapse, and cardiac arrest.[81, 161] The pathophysiology of systemic anaphylaxis is complex and involves multiple pathways. IgE antibodies are cross-linked on the surface of mast cells and basophils, resulting in local and systemic release of preformed mediators of anaphylactic response, including leukotrienes C_4 and D_4, histamine, eosinophilic chemotactic factor, and other vasoactive substances, such as bradykinin, kallikrein, prostaglandin D_2, and platelet-activating factor.

I
Large local contiguous reaction (>15 cm)
II
Pruritus (urticaria) generalized
III
Asthma, angioedema, nausea, vomiting
IV
Airway (asthma, tongue swelling, dysphagia, respiratory distress, laryngeal edema)
Cardiovascular (hypotension, may progress to cardiovascular collapse)

Grade Classification Description

TABLE 54-4. Classification of Anaphylactic Reactions

The incidence of penicillin hypersensitivity is 5% overall, with 1% of penicillin reactions resulting in anaphylaxis. The risk for a fatal hypersensitivity reaction after penicillin administration is 2 per 100,000 (0.002%) patient exposures.[268] All routes of penicillin administration can result in anaphylaxis; however, it occurs most commonly after intravenous administration.

Treatment is supportive with careful attention to airway, breathing, and circulation. If the penicillin was ingested, the patient may theoretically benefit from oral activated charcoal 1 g/kg. This is unlikely to prevent anaphylaxis, as only a few molecules need be absorbed to trigger the immunologic response. Initial drug therapy for anaphylaxis includes epinephrine 0.01 mL/kg (up to 0.5 mL) of 1:1000 dilution subcutaneously (SC) every 10â€“20 minutes. Epinephrine, through Î²-receptor stimulation, results in bronchodilation and increased cardiac output. In addition, its Î±-receptor stimulation results in increased peripheral vascular tone. Oxygen and inhaled $\hat{I}^2_2$ -adrenergic agonists are warranted in severe cases, as are corticosteroids. H_1 -receptor antagonists may be sufficient in patients with mild allergic reactions who do not have pulmonary manifestations or airway concerns.

H_2 -receptor antagonism as a treatment for anaphylaxis is controversial. H_2 -receptors, when stimulated in the peripheral vasculature, cause vasodilation; in the heart, cause positive inotropy, positive chronotropy, and coronary vasodilation; and in the lung, cause increased mucus production.[227] Theoretically, H_2 -receptor antagonists can lead to a decrease in myocardial activity at a time when H_1 -receptor stimulation is causing hypotension, coronary vasoconstriction, and bronchospasm. However, in vitro and animal models demonstrate decreases in coronary circulation and decreases in the overall anaphylactic response following administration of H_1 blockers.[16 , 23] Cimetidine and ranitidine are useful for the treatment of pruritus and flushing after acute allergic reactions involving the skin.[164 , 179] Cimetidine, used

following anaphylaxis, may result in clinical improvement, particularly hypotension and tachycardia.[73 , 279] There is 1 case, however, of chronic ranitidine administration which was postulated to result in heart block after an anaphylactic response to latex.[203] Available data indicate that treatment using H_2 -receptor antagonists should only be considered when other therapies have failed and the patient is adequately H_1 -receptor blocked. Aminophylline, although mentioned in some references for the treatment of anaphylaxis, is inadequately studied and should not be routinely employed. Lastly, glucagon may be of some benefit, particularly in patients who are maintained on Î²-adrenergic antagonists.

Amoxicillin-Clavulanic Acid and Hepatitis

Intrahepatic cholestatic hepatitis occurs 1â€“6 weeks after initiation of therapy with amoxicillin-clavulanate.[7 , 54 , 114] The incidence of hepatotoxicity typically is estimated at 1.1â€“2.7 per 100,000 prescriptions.[94] The mechanism of

hepatotoxicity is not clear, but may be related to clavulanate, a Î²-lactamase inhibitor used to prevent the bacterial destruction of Î²-lactam antibiotics, or one of its metabolites. Treatment is supportive and clinical findings typically resolve after the discontinuation of therapy. However, prolonged hepatitis, ductopenia, and pancreatitis rarely occur.[50 , 215]

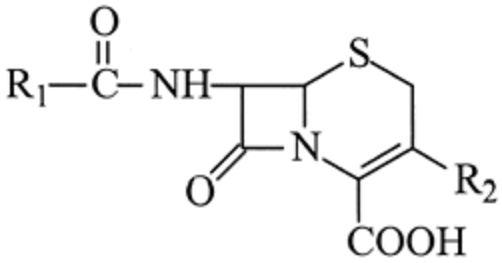
Jarisch-Herxheimer Reaction and Hoigne Syndrome

The most common adverse effects occurring after administration of intramuscular procaine penicillin G are the Hoigne syndrome and the Jarisch-Herxheimer reaction.[12 , 63 , 121 , 131 , 174 , 245 , 285] Both occur after the administration of large intramuscular or intravenous doses of penicillin G.[93 , 106] Hoigne syndrome is

characterized by extreme apprehension and fear, illusions, or hallucinations; changes in auditory and visual perception; tachycardia; systolic hypertension; and, occasionally, seizures that begin within minutes of injection.[267] These effects occur in the absence of signs or symptoms of anaphylaxis. The cause of this syndrome is unknown. Procaine is implicated as the causative agent because of this syndrome's similarity to events that occur after the administration of other pharmacologically similar local anesthetics.[229 , 240 , 264] Hoigne syndrome is 6 times more common in males than females.[244] The reason for this increased prevalence is unclear, but autosomal dominance and influences of prostaglandin and thromboxane A_2 activity in this population may be responsible.[12]

The Jarisch-Herxheimer reaction is a self-limited reaction that develops within a few hours of antibiotic therapy for the treatment of early syphilis or Lyme disease. Clinical findings include myalgias, chills, headache, rash, and fever, which spontaneously resolve within 18â€“24 hours, even with continued antibiotic therapy.[180 , 223] The pathogenesis of this reaction is likely an acute antigen release by lysed bacteria.[193]

Cephalosporins



Cephem Nucleus

Cephalosporins are semisynthetic derivatives of cephalosporin C produced by the fungus *Acremonium* , previously called

Cephalosporium. Cephalosporins have a ring structure similar to that of penicillins. Cephalosporins are generally divided into first, second, third, and fourth generations based on their antimicrobial spectrum. First-generation cephalosporins include cefadroxil, cefazolin, cephalexin, cephapirin, and cephradine. Second-generation cephalosporins include cefaclor, cefamandole, cefonicid, cefotetan, cefoxitin, cefprozil, and cefuroxime. Third-generation cephalosporins include cefdinir, ceftazidime, cefixime, ceftibuten, cefoperazone, ceftizoxime, cefotaxime, ceftriaxone, and cefpodoxime. Finally, of the fourth-generation cephalosporins, cefepime is the first to be marketed.

Effects occurring after acute overdose of cephalosporins resemble those occurring after penicillin exposure. Some cephalosporins have epileptogenic potential similar to penicillin.[98, 270] Case reports have demonstrated seizures after inadvertent intraventricular administration.[34, 156, 280] Management guidelines for cephalosporin overdose are similar to those of penicillin overdose. Table 54-1 lists the pharmacologic mechanism of cephalosporins and Table 54-2 lists their pharmacokinetic properties.

Adverse Effects Associated with Therapeutic Use

Cephalosporins rarely cause an immune-mediated acute hemolytic crisis.[25, 79] Cefaclor is the cephalosporin most commonly reported to cause serum sickness, although it can occur with other cephalosporins.[143, 167] Also like penicillins, cephalosporins are associated with chronic toxicity, including interstitial nephritis and hepatitis with first-generation agents.[187, 188, 277] Cefepime is reported in a single case to cause reversible coma and nonconvulsive seizures.[1]

Cross-Hypersensitivity

The cephalosporins contain a 6-member dihydrithiazine ring instead of the 5-member thiazolidine penicillin ring. The extent of cross-reactivity between penicillins and cephalosporins in an individual patient is largely determined by the type of penicillin allergic response experienced by the patient. The incidence of anaphylaxis to cephalosporins is between 0.0001% and 0.1%, with a 3-fold increase in patients with previous penicillin allergy.[144] Ten percent of patients with prior penicillin-related anaphylactic reactions will have positive skin test for cephalosporin hypersensitivity.[219] A negative skin test predicts a negative allergic response on oral cephalosporin challenge in penicillin-allergic patients. Lastly, the incidence of delayed hypersensitivity reactions after cephalosporin use is 1â€“2.8% in the general population and 8.1% in those with prior penicillin delayed hypersensitivity. Cross-reactivity may be greater with the first- and second-generation cephalosporins that are more structurally similar to penicillin or that are contaminated by penicillin.[8] Antibody binding after cephalosporin exposure occurs at the determinants located on the side-chain groups of the cephalosporin.[14] In fact, IgE directed against a methylene substituent linking the side chain to the penicillin molecule has been identified.[112] These determinants are quite distinct among cephalosporins, which cause the pattern of cross-hypersensitivity among cephalosporins to be much less well-defined than among the penicillins. Caution should be used when considering cephalosporins in penicillin- or cephalosporin-allergic patients; however, if a risk-to-benefit analysis demonstrates a clear benefit to the patient without equivalent alternatives, the cephalosporin should be given.

N -methylthiotetrazole Side-Chain Effects

Cephalosporins containing an *N* -methylthiotetrazole (nMTT) side chain (moxalactam, cefazolin, cefoperazone, cefmetazole, cefamandole, cefotetan) have toxic effects unique to their group

structure. As these cephalosporins undergo metabolism, they release free nMTT, which is responsible for their effects (Fig. 54-1).[176] Free nMTT inhibits the enzyme aldehyde dehydrogenase and, in conjunction with ethanol, can cause a disulfiramlike reaction (Chap. 77).[39]

The nMTT side chain is also associated with hypoprothrombinemia, although a causal relationship is controversial.[107] It is thought that nMTT depletes vitamin K-dependent clotting factors by inhibition of vitamin K epoxide reductase.[197] In a study of children 1 month to 1 year of age who were maintained on a prolonged antibiotic regimen, a significant degree of vitamin K depletion was found.[22] Treatment of patients suspected of hypoprothrombinemia caused by these cephalosporins consists of fresh-frozen plasma, if bleeding is evident, and vitamin K_1 in doses required to resynthesize vitamin K cofactors (Chap. 57).

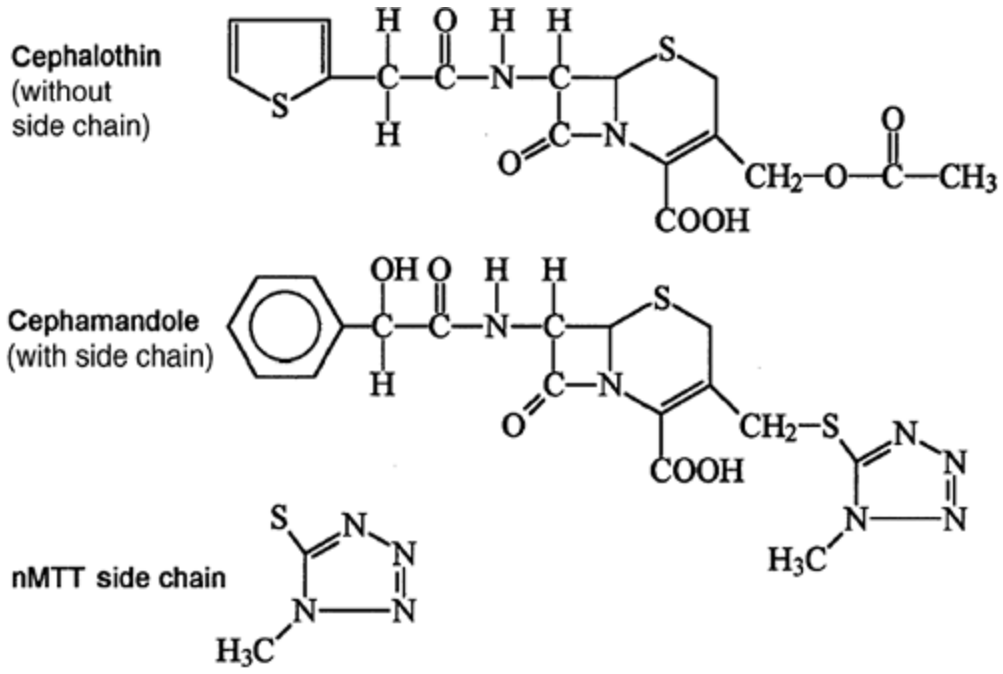


Figure 54-1. Characteristic structures of cephalosporins emphasizing the nMTT side chain.

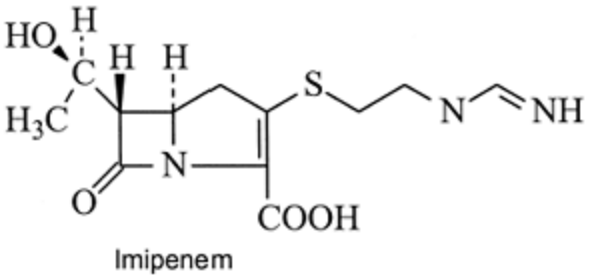
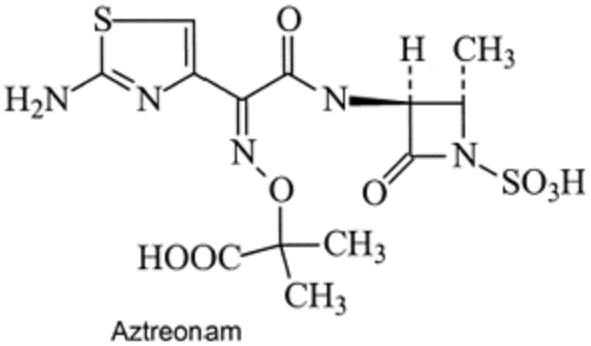
Other Î²-Lactam Antibiotics



Imipenem



Aztreonam

Figure. No Caption Available.

Included in this group are monobactams such as aztreonam and carbapenems such as imipenem and meropenem. Table 54-1 lists the pharmacologic mechanism of these drugs, and Table 54-2 lists their pharmacokinetic properties.

Effects occurring after acute overdose of other Î²-lactam antibiotics resemble those occurring following penicillin exposure. Imipenem has epileptogenic potential in both overdose and therapeutic dosing (see Adverse Effects Associated with Therapeutic Use). Management guidelines for other Î²-lactam overdoses are similar to those for penicillin overdoses.

Adverse Effects Associated with

Therapeutic Use

Imipenem, a member of the class of carbapenem compounds, can cause seizures in therapeutic doses.[45, 142, 158, 202, 249] The risk factors for seizures include central nervous system disease, prior seizure disorders, and abnormal renal function.[204] The mechanism for seizures appears to be GABA antagonism (similar to the penicillins) in conjunction with enhanced activity of excitatory amino acids.[71, 255]

Cross-Hypersensitivity

Aztreonam is a monobactam that does not contain the antigenic components required for cross-allergy with penicillins, and generalized cross-allergenicity is not expected.[230] However, aztreonam cross-reacts in vitro with ceftriaxone, thought to be the result of the similarity in their side-chain structure.[207] Cross-allergenicity has also been noted between imipenem and penicillin, although the incidence has yet to be determined.

Chloramphenicol

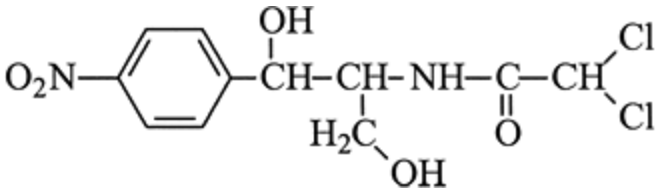


Figure. No Caption Available.

Chloramphenicol was originally derived from *Streptomyces venezuelae* and is now produced synthetically. Antimicrobial activity exists against many Gram-positive and Gram-negative aerobes and anaerobes. Table 54-1 lists the pharmacologic mechanism of chloramphenicol, and Table 54-2 lists its pharmacokinetic properties.

Acute overdose of chloramphenicol commonly causes nausea and vomiting. Effects are caused by its ability to inhibit protein synthesis in rapidly proliferating cells. Metabolic acidosis occurs as a result of the inhibition of mitochondrial enzymes, oxidative phosphorylation, and mitochondrial biogenesis.[90] Infrequently, sudden cardiovascular collapse can occur 5â€“12 hours after acute overdoses. In case series, cardiovascular compromise was more frequent in patients with serum concentrations >50 Âµg/mL.[90 , 145 , 185 , 205 , 260] Because levels are not readily available, all poisoned patients should be closely observed for at least 12 hours after exposure. Orogastric lavage may be useful for recent ingestions when the patient has not vomited, and activated charcoal 1 g/kg should be given orally.

Extracorporeal means of eliminating chloramphenicol are not usually required because of its rapid metabolism (Table 54-2). However, both hemodialysis and charcoal hemoperfusion decrease elevated plasma chloramphenicol levels and may be of benefit in patients with large overdoses, or in patients with severe hepatic or renal dysfunction.[89 , 178 , 246] Exchange transfusion also lowers chloramphenicol serum concentrations in neonates.[145 , 253] Surviving patients should be closely monitored for signs of bone marrow suppression.

Adverse Effects Associated with Therapeutic Use

Chronic toxicity of chloramphenicol is similar to that which occurs following acute poisoning. The classic description of chronic chloramphenicol toxicity is the â€œgray baby syndrome.â€• [89 , 90 , 178 , 253] Children with this syndrome exhibit vomiting, anorexia, respiratory distress, abdominal distension, green stools, lethargy, cyanosis, ashen color, metabolic acidosis, hypotension, and cardiovascular collapse. The majority (90%) of a dose of chloramphenicol is metabolized via glucuronyl transferase, forming

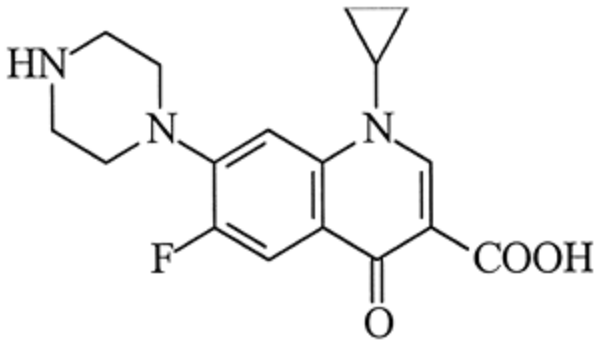
a glucuronide conjugate. The remainder is excreted renally unchanged. Infants, in particular, are predisposed to the gray baby syndrome because they have a limited capacity to conjugate chloramphenicol and, concomitantly, a limited ability to excrete unconjugated chloramphenicol in the urine.[101, 276]

Dose-dependent bone marrow depression occurs with high serum concentrations of chloramphenicol.[127, 128, 238] Clinical manifestations usually occur after several weeks of therapy and include anemia, thrombocytopenia, leukopenia, and very rarely, aplastic anemia. Bone marrow suppression is generally reversible on discontinuation

of therapy. Chloramphenicol causes bone marrow suppression by inhibiting protein synthesis in the mitochondria of marrow cell lines.[189, 190] The development of aplastic anemia after chloramphenicol use is not dose related and generally occurs in susceptible patients within 5 months of treatment (Chap. 24).[77, 282] The dehydro and nitroso bacterial metabolites of chloramphenicol cause human bone marrow cell line injury through inhibition of myeloid colony growth, inhibition of DNA synthesis, and inhibition of mitochondrial protein synthesis.[138]

Other adverse effects associated with chloramphenicol include peripheral neuropathy;[141, 211] neurologic abnormalities, such as confusion and delirium;[162] optic neuritis;[58, 141] nonlymphocytic leukemia;[243] and contact dermatitis.[151]

Fluoroquinolones



Ciprofloxacin

The fluoroquinolones are a structurally similar, synthetically derived group of antibiotics that exhibit a diverse spectrum of antimicrobial activity. The fluoroquinolones include balofloxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin, lomefloxacin, moxifloxacin, nadifloxacin, nalidixic acid, norfloxacin, ofloxacin, pefloxacin, rufloxacin, sparfloxacin, temafloxacin, tosufloxacin, and trovafloxacin. Like other antimicrobials, the fluoroquinolones rarely produce life-threatening effects following acute overdose, and most patients can be safely managed with minimal intervention.[11] Table 54-1 lists the pharmacologic mechanism of fluoroquinolones, and Table 54-2 lists their pharmacokinetic properties.

Rarely, acute overdose of a fluoroquinolone results in renal failure or seizures. The mechanism of renal failure after fluoroquinolone exposure is controversial. In animals, ciprofloxacin and norfloxacin cause pathologic changes in the kidney, especially in the setting of neutral or alkaline urine.[60, 234] In humans, renal failure is reported after both acute and chronic exposure to fluoroquinolones. A hypersensitivity reaction is postulated to explain pathologic changes consistent with interstitial nephritis.[125, 187, 188, 217, 281] Treatment includes discontinuation of the fluoroquinolone and supportive care. Improvement in renal function is usually noticed within several days.

Seizures are reported with ciprofloxacin and may be a result of the inhibition of GABA.[248, 263] Others postulate that the ability of fluoroquinolones to bind efficiently to cations, particularly magnesium, results in seizures. This hypothesis is related to magnesium's inhibitory role at the excitatory NMDA-gated ion channel (Chap. 14).[72, 235] Treatment is supportive, using benzodiazepines and, if necessary, barbiturates to increase GABAergic activity.

Adverse Effects Associated with Therapeutic Use

Several fluoroquinolones are substrates and/or inhibitors of cytochrome CYP isozymes. This can result in drug interactions, which are especially important with drugs that have a narrow therapeutic index.

Serious adverse effects related to fluoroquinolone use consist of central nervous system toxicity, as discussed, cardiovascular toxicity, hepatotoxicity, and articular/tendon toxicity.

Fluoroquinolones cause prolongation of the QTc interval and may cause torsades de pointes.[69, 135, 228] Although the mechanism of this effect is unclear, sequestering of magnesium, resulting in clinical hypomagnesemia, is postulated.[235] Treatment of patients presenting with QTc interval prolongation is supportive, with careful attention to magnesium supplementation if necessary.

The fluoroquinolones rarely result in potentially fatal hepatotoxicity.[51, 52, 91, 103, 115, 154, 169, 220] This adverse effect is most notable with trovafloxacin, although the reason for the increased risk associated with this particular fluoroquinolone is not clear. Consequently, trovafloxacin (Trovan) is now reserved only for the treatment of patients with life-threatening infections in whom the benefits are thought to outweigh the risks. In addition, the manufacturer has initiated a limited distribution

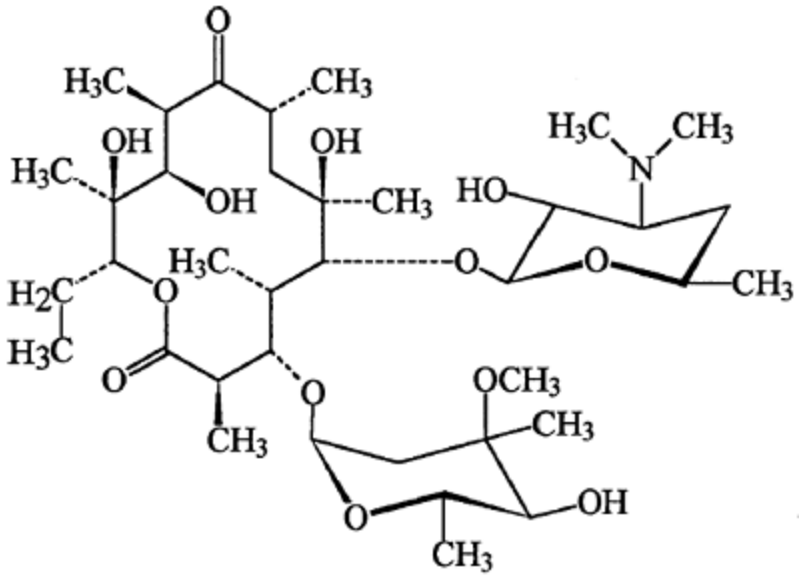
system that allows drug shipment only to pharmacies within inpatient healthcare facilities.

Fluoroquinolones should be used with caution in children and pregnant women because of their potential adverse effects on developing cartilage and bone. Damage to articular cartilage is demonstrated in young dogs and rats, although the extent varies among different fluoroquinolones.[42, 257] There are very limited data regarding damage to articular cartilage as a result of using fluoroquinolones in humans; however, children given ciprofloxacin on a compassionate basis developed complaints of swollen, painful, and stiff joints after 3 weeks of therapy.[137] All signs and symptoms abated within 2 weeks of discontinuation of therapy. However, 29 additional children treated with ofloxacin or ciprofloxacin showed no differences with respect to cartilage thickness, cartilage structure, edema, cartilage-bone borderline, or synovial fluid. Women who received quinolones during pregnancy had larger babies and more caesarean deliveries because of fetal distress than did controls.[19] However, there were no congenital malformations, delay to developmental milestones, or musculoskeletal abnormalities found.

Fluoroquinolones are also implicated as a cause of tendon rupture, which is reported to occur for up to 120 days after the start of treatment and even after the discontinuation of therapy.[206] The fluoroquinolone should be discontinued in patients, particularly athletes who complain of symptoms consistent with painful and swollen tendons.

Other adverse effects include acute psychosis, rash, tinnitus, eosinophilia, serum sickness, and, commonly, photosensitivity.[40, 108, 186, 252]

Macrolides and Ketolides



Erythromycin

The macrolide antibiotics include various forms of erythromycin (base, estolate, ethylsuccinate, gluceptate, lactobionate, stearate), azithromycin, clarithromycin, troleandomycin, and dirithromycin. Ketolides are similar in pharmacology to macrolides; telithromycin is the only available agent at this time. Table 54-1 lists the pharmacologic mechanism of macrolides and ketolides, and Table 54-2 lists their pharmacokinetic properties.

Acute oral overdoses of macrolide antibiotics are usually not life threatening and symptoms which are generally confined to the gastrointestinal tract include nausea, vomiting, and diarrhea. Erythromycin lactobionate causes QTc interval prolongation and torsades de pointes after intravenous use.[198] Oral erythromycin is also implicated in causing prolongation of the QTc interval and torsades de pointes, especially in patients concurrently taking cytochrome P450 (CYP) 3A4 inhibitors.[212] In vitro models demonstrate erythromycin's ability to slow repolarization in a concentration-dependent manner.[192] The cause of widened QTc interval was once thought to be from hypokalemia-induced

promotion of intracellular efflux of potassium.[213] Current data, however, demonstrate that the QTc interval prolongation results from blockade of delayed rectifier potassium currents (Chap. 23).[222] QTc interval prolongation and torsades de pointes are common after intravenous erythromycin lactobionate.[198] More pronounced widening occurs in patients with underlying heart disease and correlates with the infusion rate.[110] Epidemiologic studies note an increased incidence of ventricular dysrhythmias in women treated with erythromycin.[75]

Although there is no acute overdose data regarding ketolide antibiotics, effects are expected to be similar to macrolide antibiotics.

Adverse Events Associated with Therapeutic Use

Drug Interactions

Erythromycin is the prototypical macrolide and, as such, has received the most attention with respect to potential and documented drug interactions. Clarithromycin, erythromycin, and troleandomycin are all potent inhibitors of the CYP3A4 enzyme system; azithromycin does not inhibit this enzyme.[64] Erythromycin inhibits cytochrome P450 after metabolism to a nitroso intermediate, which then forms an inactive complex with the iron (II) of cytochrome P450. Chapter 9 lists substrates for the CYP3A4 system. Clinically significant interactions occur with erythromycin and carbamazepine or cisapride.[43 , 105 , 118 , 124 , 210] Inhibition of cisapride metabolism results in increased concentrations of the parent drug, which is capable of causing a widening of the QTc interval and causing torsades de pointes.[30 , 201] Cases of carbamazepine toxicity are documented when combined with the use of erythromycin.[118] Erythromycin also inhibits CYP1A2, producing clinically significant interactions with clozapine,

theophylline, and warfarin.[218]

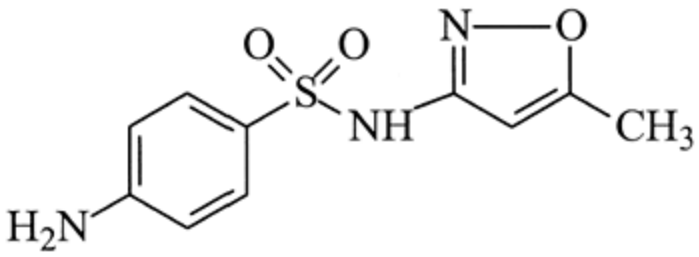
Macrolides may also interact with the absorption and renal excretion of drugs that are amenable to intestinal P-glycoprotein excretion or interfere with normal gut flora responsible for metabolism. This may be part of the underlying mechanism of cases of macrolide-induced digoxin toxicity (Chap. 62).[196]

End-Organ Effects

The most common toxic effect of macrolides after chronic use is hepatitis, which may be immune mediated.[46] Erythromycin estolate is the agent most frequently implicated in causing cholestatic hepatitis.[100 , 132]

Large doses (>4 g/d) of macrolide antibiotics are also associated with reversible high-frequency sensorineural hearing loss.[37 , 237] Renal impairment may be a risk factor.[224 , 256] There are rare case reports in which ototoxicity did not resolve following discontinuation of therapy.[78 , 160] There are insufficient data concerning the ototoxic potential of the other macrolide antibiotics. Other, rare toxic effects associated with macrolides include cataracts after clarithromycin use in animals and acute pancreatitis in humans.[83 , 266] Allergy is rare and reported at a rate of 0.4â€“3%.[70] Telithromycin contains a carbamate side chain that may interfere with the normal function of neuronal cholinesterase. It should be used cautiously in patients with myasthenia gravis, particularly those patients receiving pyridostigmine, because of the risk of cholinergic crisis.[259]

Sulfonamides



Sulfamethoxazole

Sulfonamides antagonize *para* -aminobenzoic acid or *para* -aminobenzyl glutamic acid, which are required for the biosynthesis of folic acid. Table 54-1 lists the pharmacologic mechanism of sulfonamides, and Table 54-2 lists their pharmacokinetic properties. Acute oral overdoses of sulfonamides are usually not life threatening and symptoms are generally confined to nausea, although allergy and methemoglobinemia occur rarely.[87] Treatment is similar to acute oral penicillin overdoses.

Adverse Effects Associated with Therapeutic Use

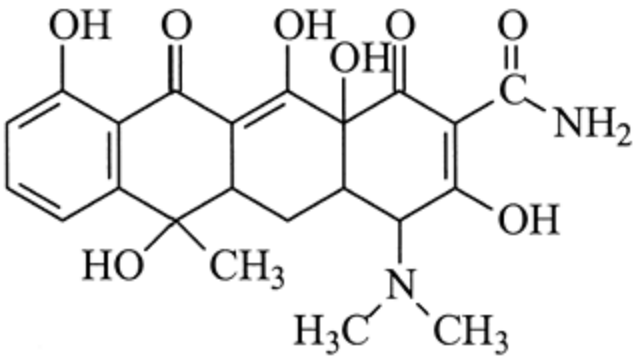
The most common adverse effects associated with sulfonamide therapy are nausea and cutaneous hypersensitivity reactions. Hypersensitivity reactions are thought to be caused by the formation of hapten sulfamethoxazole metabolites, *N* -hydroxy-sulfamethoxazole-NHOH and nitroso-sulfamethoxazole-NO. The degree of hapten binding is mitigated in vitro by cysteine and glutathione.[191] The incidence of adverse reactions to sulfonamides, including allergy, is increased in HIV-positive patients and is positively correlated to the number of previous opportunistic infections experienced by the patient.[157] This may be caused by a decrease in the mechanisms available for detoxification of free radical formation, as cysteine and glutathione levels are low in these patients.[272] Whether supplementation with a glutathione precursor such as *N* -acetylcysteine will reduce the

incidence of these reactions is unknown.[3]

Methemoglobinemia and hemolysis also rarely occur.[76 , 166] The mechanism for adverse reactions is not entirely clear. However, when sulfamethoxazole is exposed to ultraviolet B (UVB) radiation in vitro, free radicals are formed that can participate in the development of tissue peroxidation and hemolysis.[284] This finding may be of particular importance in treating patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency caused by a decrease in reducing capabilities.[4]

The sulfonamides are associated with many chronic adverse effects. Bone marrow suppression is rare, but the incidence is increased in patients with folic acid or vitamin B_{12} deficiency, and in children, pregnant women, alcoholics, dialysis patients, and immunocompromised patients, as well as in those patients who are receiving other folate antagonists. Other adverse effects include hypersensitivity pneumonitis, stomatitis, aseptic meningitis, hepatotoxicity, renal toxicity, and central nervous system toxicity.[26]

Tetracyclines



Tetracyclines

Tetracyclines are derivatives of *Streptomyces* cultures. Currently

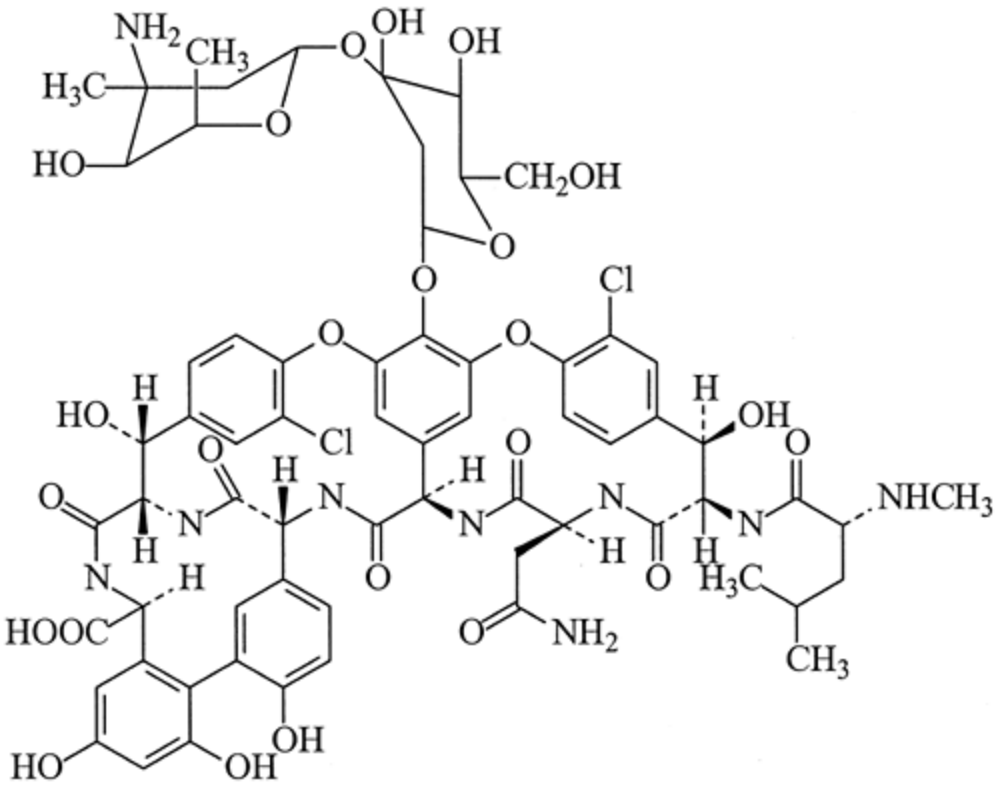
available tetracyclines include demeclocycline, doxycycline, methacycline, minocycline, oxytetracycline, and tetracycline. Table 54-1 lists the pharmacologic mechanism of tetracyclines, and Table 54-2 lists their pharmacokinetic properties. Significant toxicity after acute overdose of tetracyclines is unlikely. Gastrointestinal effects consisting of nausea, vomiting, and epigastric pain have been reported.[38]

Adverse Effects Associated with Therapeutic Use

Tetracycline should not be used in children during the first 6â€“8 years of life or by pregnant women after the 12th week of pregnancy because of the risk of development of secondary tooth discoloration in the children or developing children in utero.

Other effects associated with tetracyclines include nephrotoxicity, hepatotoxicity, skin hyperpigmentation in sun-exposed areas, and hypersensitivity reactions.[46 , 104 , 130 , 258] More severe hypersensitivity reactions, drug-induced lupus, and pneumonitis are reported after minocycline use, as are cases of necrotizing vasculitis of the skin and uterine cervix, and lymphadenopathy with eosinophilia.[171 , 236 , 242] Demeclocycline rarely causes nephrogenic diabetes insipidus.[47] Outdated older formulations, but not newer formulations, of tetracycline are reported to cause hypouricemia, hypokalemia, and a proximal and distal renal tubular acidosis.[56]

Vancomycin



Vancomycin

Vancomycin is obtained from cultures of *Nocardia orientalis* and is a tricyclic glycopeptide. Vancomycin is biologically active against numerous Gram-positive organisms. Table 54-1 lists the pharmacologic mechanism of vancomycin, and Table 54-2 lists its pharmacokinetic properties.

Acute oral overdoses of vancomycin rarely cause significant toxicity and most cases can be treated with supportive care alone. Multiple-dose activated charcoal therapy decreases the half-life of vancomycin and can be considered for patients with large overdoses when the patient is expected to have prolonged clearance.[152]

Adverse Effects Associated with Therapeutic Use

Patients who receive intravenous vancomycin may develop the â€œred man syndrome,â€• through an anaphylactoid reaction in which mast cells and basophils are directly degranulated without antibody mediation.[96] Symptoms include chest pain, dyspnea, pruritus, urticaria, flushing, and angioedema.[221] Signs and symptoms spontaneously resolve, typically within 15 minutes. Other symptoms attributable to red man syndrome include hypotension, cardiovascular collapse, and seizures.[13 , 194]

The incidence of red man syndrome appears to be related to the rate of infusion. The incidence is approximately 14% when 1 g is given over 10 minutes, whereas it is 3.4% when given over 1 hour.[194 , 199] A trial in 11 healthy persons studied the relationship between intradermal skin hypersensitivity and the development of red man syndrome. Each of the 11 subjects underwent skin testing that was followed 1 week later by an intravenous dose of vancomycin 15 mg/kg over 60 minutes. Following intravenous vancomycin, all subjects developed dermal flare responses and erythema, and 10 of 11 subjects developed pruritus within 20â€“45 minutes. After the infusion was terminated, symptoms resolved within 60 minutes.[208]

The signs and symptoms of the red man syndrome are related to the rise and fall of histamine concentrations.[117 , 163] Tachyphylaxis occurs in patients given multiple doses of vancomycin.[116 , 271] Animal models demonstrated a direct myocardial depressant and vasodilatory effect of vancomycin.[59] More serious reactions result when vancomycin is given via intravenous bolus, further supporting a rate-related anaphylactoid mechanism.[21]

Patients most often experience red man syndrome after vancomycin is administered intravenously. In rare cases, oral administration of vancomycin can also result in the syndrome.[18] Treatment includes increasing the dilution of vancomycin and slowing intravenous administration. Antihistamines may be useful

as pretreatment, especially prior to the first dose.[214] A placebo-controlled trial in adult patients studied the incidence of these symptoms in patients given 1 g of vancomycin over 1 hour, as well as the effect of diphenhydramine in the prevention of the syndrome.[271] There was a 47% incidence of reaction without diphenhydramine and a 0% incidence with diphenhydramine.

Chronic use of vancomycin may cause reversible nephrotoxicity, particularly in patients with prolonged excessive steady-state serum levels.[9, 216] Concomitant administration of aminoglycoside antibiotics may increase the risk of nephrotoxicity.[225] Vancomycin also causes, but rarely, thrombocytopenia and neutropenia.[55, 74]

Antifungals

Numerous antifungals are available. Toxicity related to the use of antifungals is variable and is based generally on their mechanism of action.

Amphotericin B

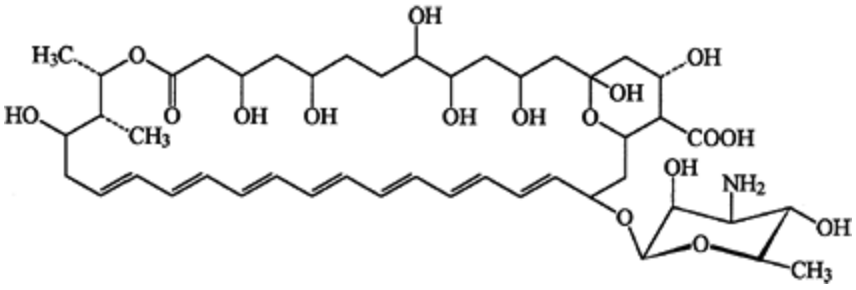


Figure. No Caption Available.

Amphotericin B is a potent antifungal derived from *Streptomyces nodosus.* Amphotericin B is generally fungistatic against fungi that contain sterols in their cell membrane. Table 54-1 lists the pharmacologic mechanism of amphotericin B, and Table 54-2 lists

its pharmacokinetic properties. Development of lipid and colloidal formulations of amphotericin B attenuate the adverse effects associated with amphotericin B.[109] In these preparations, the amphotericin B is complexed with either a lipid or cholesteryl sulfate. On contact with a fungus, lipases are released to free the complexed amphotericin B, resulting in focused cell death.[120]

There are several case reports of amphotericin B overdose in infants and children. Significant clinical findings include hypokalemia, increased aspartate aminotransferase concentrations, and cardiac complications. Dysrhythmias and cardiac arrest have occurred following doses of 5â€“15 mg/kg of amphotericin B.[31 , 57 , 148] Care should be employed in the doses of amphotericin B administered according to dosage form, as these are not interchangeable. For example, intravenous therapy for fungal infections includes a usual dose of 0.25â€“1 mg/kg/d of amphotericin B or 3â€“4 mg/kg/d of amphotericin B cholesteryl. The potential for significant dosage errors and their sequelae is readily apparent in this comparison.

Adverse Effects Associated with Therapeutic Use

Infusion of amphotericin B results in fever, rigors, headache, nausea, vomiting, hypotension, tachycardia, and dyspnea.[172] Pretreatment with acetaminophen, diphenhydramine, ibuprofen, and hydrocortisone is helpful in alleviating the febrile symptoms, as are slower rates of infusion and lower total daily doses.[99 , 265] Doses greater than 1 mg/kg/d and rapid administration of drug in less than 1 hour are not recommended. Infusion concentrations of amphotericin B greater than 0.1 mg/mL can result in localized phlebitis. Slower infusion rates, hot packs, and frequent line flushing with dextrose in water may help to alleviate symptoms.

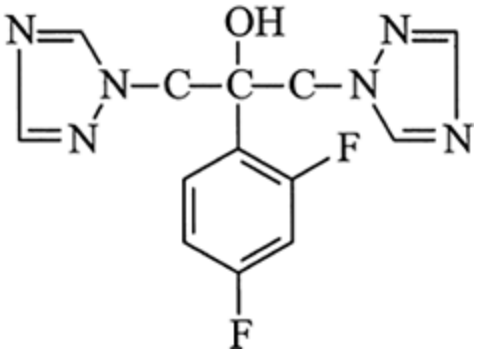
Eighty percent of patients exposed to amphotericin B will sustain some degree of renal insufficiency (Chap. 27).[44] Azotemia is

caused by distal renal tubule damage, which causes renal artery vasoconstriction as a consequence of alterations in tubular and vascular smooth muscle function.[84] Studies in animals show depressed renal blood flow and glomerular filtration rate, and increased renal vascular resistance. It is unclear why this occurs, but at this time, renal nerves, angiotensin II, nitric oxide, and tubuloglomerular feedback are excluded.[226 , 231] The toxic effects associated with amphotericin B may be caused by the vehicle deoxycholate.[283] After large total doses of amphotericin B, residual decreases in glomerular filtration rate may occur even after discontinuation of therapy. This is hypothesized to be the result of nephrocalcinosis. Potassium and magnesium wasting, proteinuria, decreased renal concentrating ability, renal tubular acidosis, and hematuria also occur.[15 , 172] Strategies to reduce renal toxicity after amphotericin B include intravenous saline or magnesium and potassium supplementation.[29 , 85 , 119] Liposomal formulations of amphotericin B resulted in fewer patients with breakthrough fungal infections, infusion-related fever, rigors, or nephrotoxicity.[273] However, chest pain is uniquely reported after use of the liposomal agent.[139]

Other adverse effects reported after treatment with amphotericin B include normochromic, normocytic anemia; decreased erythropoietin release; respiratory insufficiency with infiltrates; and, rarely, dysrhythmias, tinnitus, thrombocytopenia, peripheral neuropathy, and leukopenia.[165 , 170 , 172]

Exchange transfusion may be useful in neonates and infants and should be considered after large intravenous exposures. In adults, extracorporeal elimination is not expected to be useful because of the low water solubility and high bloodâ€“protein binding of the drug.

Azole Antifungals: Triazole and Imidazoles



Fluconazole

Common triazole antifungals include fluconazole, itraconazole, and voriconazole. Common imidazoles include clotrimazole, econazole, ketoconazole, and miconazole. Triazole antifungals are active to treat an array of fungal pathogens, whereas imidazoles are used almost exclusively in the treatment of superficial mycoses and vaginal candidiasis. Severe toxicity is not expected in the overdose setting. Hepatotoxicity, thrombocytopenia, and neutropenia are uncommon.[27] Rare case reports implicate voriconazole in the development of toxic epidermal necrolysis.[126] The majority of toxic effects noted after the use of these drugs result from their drug interactions. Fluconazole, itraconazole, ketoconazole, and miconazole competitively inhibit CYP3A4, the enzyme system responsible for the metabolism of many drugs. Table 54-5 lists other organ system manifestations associated with antifungal agents and other antibiotics.

Antibiotics Specific to the Treatment of Human Immune Deficiency Virus and Related Infections

The evaluation and management of patients infected with the human immunodeficiency virus (HIV) and associated acquired immune deficiency syndrome (AIDS) is ever evolving at a rapid

and progressive pace. Medications used to manage this disorder have increased life expectancy in these patients dramatically as new, more powerful antiviral agents and drug combinations become available. Drug therapy for HIV commonly consists of a combination of agents from different classes (nucleoside reverse transcriptase inhibitor [NRTI], nonnucleoside reverse transcriptase inhibitor [NNRTI], and protease inhibitor) in order to take advantage of the unique mechanism that each drug offers in inhibiting viral replication and minimizing drug resistance. Resistance patterns to the typical agents used in attenuating viral replication and proliferation are a substantial issue and will continue to be addressed with yet more evolution in management in

the foreseeable future. This section focuses on overdoses and major toxic effects from HIV-directed antiviral therapy, as well as from drugs that are specifically used in the management of opportunistic infections.[17] Table 54-6 lists the common antibiotic agents used to treat HIV-related opportunistic infections, and Table 54-7 lists common adverse drug effects and overdose effects, if known, for antibiotics that are specific in their use for HIV-related infections.

Drug Organ System Signs, Symptoms, Laboratory

TABLE 54-5. Consequential Organ System Manifestations Associated with Antibiotics and Antifungals

It should be noted that adverse reactions to antibiotics occur at an increased rate in HIV-infected patients. The reason for this occurrence is unclear. Drug interactions related to pharmacokinetic and pharmacodynamic causes are common and problematic in the management of HIV-positive patients.

Specific Antiretroviral Classes

Nucleoside Analog Reverse Transcriptase Inhibitors

The nucleoside analog reverse transcriptase inhibitors inhibit the reverse transcription of viral RNA into proviral DNA. Currently available

agents include abacavir (ABC), emtricitabine (FTC), didanosine (ddI), lamivudine (3TC), stavudine (d4T), zidovudine (AZT, ZDV), and zalcitabine (ddC).

Albendazole

TMX-SMX = trimethoprim and sulfamethoxazole.

Drugs Opportunistic Infection

TABLE 54-6. Antibiotics Used to Treat Common Opportunistic Infections [17]

Albendazole
No reported cases
Increased AST/ALT, nausea, vomiting, and diarrhea. Hematologic toxicity; rareâ€"encephalopathy, renal failure, rash
Antimony (pentavalent)
Acute tubular necrosis
Acute tubular necrosis. Multiorgan system failure
Atovaquone
No clinical relevant effects in reported cases[53]
Rashes, anemia, leucopenia, increased AST/ALT
Caspofungin
No reported cases
Phlebitis, headache, hypokalemia, increased AST/ALT, fever
Flucytosine

No reported cases

Bone marrow suppression, hepatotoxicity, nausea, vomiting, diarrhea, and rash

Foscarnet

No reported cases

Azotemia, hypocalcemia and renal failure are most consequential; may also result in anemia, leukopenia, thrombocytopenia, fever, headache, seizures, genital and oral ulcers, fixed-drug eruptions, nausea, vomiting, diarrhea, headaches, seizures, coma, diabetes insipidus, hypophosphatemia, hypokalemia, and hypomagnesemia

Fumagillin

No reported cases

Neutropenia and thrombocytopenia

Ganciclovir

No clinical relevant effects in reported cases[149]

Leukopenia, worsening of renal function; can also cause nausea, vomiting, diarrhea, increased AST/ALT, anemia, thrombocytopenia, headache, dizziness, confusion, seizures

Nitazoxzanide

No reported cases

Hypotension, headache, abdominal pain, nausea, vomiting; may cause green-yellow urine discoloration

Pentamidine

40 times dosing error in a 17-month-old child resulted in cardiac arrest[275]

Hypoglycemia (early) followed by hyperglycemia, azotemia; can cause hypotension, torsades de pointes, phlebitis, rash, Stevens-Johnson syndrome, hypocalcemia, hypokalemia, anorexia, nausea, vomiting, metallic taste, leukopenia, and thrombocytopenia

Primaquine

No reported cases

Granulocytopenia, hemolytic anemia, methemoglobinemia, leukocytosis; potential for hypertension

Pyrimethamine

	No reported cases	
	Agranulocytosis, aplastic anemia, thrombocytopenia, and leukopenia	
Rifabutin	High doses(>1 g daily): arthralgia/arthritis	Nausea, vomiting, diarrhea; can cause hepatotoxicity, neutropenia, thrombocytopenia, and hypersensitivity reactions
Sulfadiazine	Acute renal failure and hypoglycemia[62]	Rash, Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme; can cause headaches, depression, hallucinations, ataxia, tremor, crystalluria, hematuria, proteinuria, and nephrolithiasis
Trimetrexate	No reported cases; treat similar to methotrexate (Chap. 52)	Myelosuppression, nausea, vomiting, histaminergic reactions
Valganciclovir	No reported cases; expect to be similar to ganciclovir	Anemia, neutropenia, thrombocytopenia; nausea, vomiting, headache, and peripheral neuropathy

TABLE 54-7. Antibiotics Used in the Treatment of HIV-Related Infections [17]

Acute Overdose Effects

Many intentional overdoses of reverse transcriptase inhibitors occur without major toxicologic effect. The most serious adverse effect anticipated after acute overdose of an NRTI is the development of a lactic acidosis, which appears to be more common in women.[49 , 82 , 173] This occurs after incorporation of

the nucleoside analog into mitochondrial DNA by RNA polymerase, causing inhibition of DNA polymerase Î³. This results in decreased production of mitochondrial DNA electron transport proteins, which ultimately inhibits oxidative phosphorylation (Chap. 13). Organ system toxicity follows in addition to the development of lactic acidosis. The reported mortality in patients with NRTI-associated lactic acidosis is 33â€“57%.[82] Resolution of symptoms in survivors is 1â€“24 weeks. Patients with NRTI-associated lactic acidosis may recover more quickly after the use of cofactors such as thiamine, riboflavin, L-carnitine, vitamin C, and antioxidants.[33] The indications for the use of these agents are unclear at this time; however, because of the relative lack of toxicity of these agents, they may be considered in an attempt to attenuate toxicity.

Chronic Effects

Development of lactic acidosis is more commonly associated with therapeutic use of reverse transcriptase inhibitors than with acute overdose. The mechanism is likely identical to that described above. Other common adverse effects are somewhat agent specific and include hematologic toxicity after zidovidine,[68 , 102] pancreatitis with didanosine,[155] hypersensitivity after abacavir,[67] and sensory peripheral neuropathy after zalcitabine, stavudine, and didanosine.[184]

Nonnucleoside Reverse Transcriptase Inhibitors

Nonnucleoside reverse transcriptase inhibitors (NNRTI) bind directly to reverse transcriptase enzymes enabling allosteric inhibition of enzymatic function.[261] Delavirdine (Rescriptor), nevirapine (Viramune), and efavirenz (Sustiva) comprise the currently available agents.

There are no substantial acute overdose data on these drugs, although they generally appear to be safe in overdose. Treatment should include supportive care until more information is available. The NNRTIs are also limited in toxicity after chronic use. Nevirapine and delavirdine use commonly results in hypersensitivity reactions such as rash.[67] Efavirenz is reported to result in dizziness and dysphoria. Otherwise, toxicity can result from the ability of these drugs to either inhibit or enhance CYP isozymes in the metabolism of other drugs.

Protease Inhibitors

Protease inhibitors inhibit the vital enzyme (proteinase), which is required for viral replication.[86] Currently available agents include amprenavir (Agenerase), indinavir (Crixivan), lopinavir (Kaletra), nelfinavir (Viracept), ritonavir (Norvir), and saquinavir mesylate (Invirase).

Data after protease inhibitor overdose are limited. A review of data submitted to the manufacturer of indinavir found that of 79 reports, the complaints were nausea, vomiting, abdominal pain, and nephrolithiasis. Protease inhibitors as a class commonly result in gastrointestinal symptoms and rash.[86] A uniqe finding is an altered fat distribution pattern that, over time, results in central obesity, â€œbuffalo hump,â€• breast enlargement, cushingoid appearance, and peripheral wasting.[86]

Summary

Adverse effects attributable to antibiotics are largely related to chronic administration, although, rarely, acute toxicity does occur. Acute toxic effects of antibiotics are more common after large intravenous administration, drug interactions, or iatrogenic overdose. Careful vigilance on the part of the healthcare provider will prevent the majority of acute toxic manifestations following antibiotic use.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 55
Antituberculous Medications

Edward W. Boyer

A 15-year-old girl who had recently emigrated from Vietnam began to sei while at school. Paramedics observed two additional seizures during transport to the emergency department (ED). On arrival at the hospital, her vital signs were: blood pressure, 122/50 mm Hg; pulse, 107 beats/min; respirations, 22 breaths/ min; and temperature 99.4Â°F (37.4Â°C). Physical examination revealed an obtunded young girl without signs of head trauma, who was minimally responsive to painful stimuli. H pupils were 3 mm and sluggishly reactive. Her oropharynx showed no sig of trauma. The lungs were clear to auscultation, and she was tachycardic with no murmurs, rubs, or gallops appreciated on cardiac examination. H abdomen was soft with normal bowel sounds. Her skin was warm, dry, an well perfused. There was an abrasion on her left forearm, but no other extremity injuries.

A peripheral intravenous catheter was established, and she was placed or 100% oxygen via a nonrebreathing face mask. Pulse oximetry demonstrated an oxygen saturation of 100%. A bedside capillary glucose test revealed euglycemia. She received a total of 8 mg IV lorazepam in tl

ED but had another seizure. Additional history obtained from family members revealed that the patient had started taking medicine for a â€œlung problem.â€• On the basis of this information, she was given 5 g of intravenous pyridoxine with cessation of seizure activity. Fifty grams o activated charcoal was instilled via nasogastric tube.

Laboratory values were: a white blood cell count of 13,600/mm^3 ; hemoglobin, 12.9 g/dL; platelets, 287 Ã— 10^3 /mm^3 ; sodium, 142 mEq/L potassium, 3.7 mEq/L; chloride, 103 mEq/L; bicarbonate, 7 mEq/L; blood urea nitrogen (BUN), 7 mg/dL; creatinine, 0.6 mg/dL; serum glucose, 97 mg/dL; and anion gap, 29 mEq/L. Arterial blood gas revealed: pH 7.19; PCO_2 , 33 mm Hg; PO_2 , 105 mm Hg; and 98% oxygen saturation. Creatinine phosphokinase was 1067 U/L. Cerebrospinal fluid (CSF) showe 4 RBC (red blood cells) per mm^3 and 33 WBC (white blood cells) per mm^3 with a normal Gram stain. Cerebrospinal glucose was 76 mg/dL and prote was 27 mg/dL. Serum titers for herpes simplex virus, equine encephalitis virus, and West Nile virus were negative, as were blood and CSF cultures

She was admitted to the intensive care unit (ICU), but her level of consciousness did not improve over the next 6 hours. An electroencephalogram that was performed because of persistent depressi of consciousness showed no seizure activity. The toxicology service recommended that the patient be given an additional 5 g of intravenous pyridoxine. The patient's level of consciousness improved over the next 1 minutes, at which point she revealed that she ingested approximately 8 g of isoniazid in a suicide attempt. The remainder of her hospitalization was uneventful. A computerized tomography scan and magnet resonance imag of the brain were normal. She was discharged from the medical service a transferred to a psychiatric facility.

History and Epidemiology

The global burden of tuberculosis is enormous. Approximately 2 billion people are infected with *Mycobacterium tuberculosis;* 7.96 million new cases are diagnosed each year. An estimated 1.87 million persons die worldwide from the infection annually.[3] The introduction of isoniazid (INH

into clinical practice in 1952 caused the number of US cases of tuberculos (TB) to steadily decrease over the subsequent 30 years. However, betwe 1985 and 1991, there was a resurgence in TB cases in the United States, result of, among other factors, the human immunodeficiency virus (HIV) epidemic, homelessness, deterioration in the healthcare infrastructure, a an increased number of foreign-born persons. Concurrently, multidrug-resistant tuberculosis emerged as a serious health concern. Currently, on third of newly diagnosed cases are resistant to INH and one-fifth are resistant to both INH and rifampin, formerly the two most effective drugs for treating tuberculosis. Containment strategies, such as aggressive cas identification and directly observed therapy, were initiated to slow the spread of the infection.[21 , 22 , 43 , 57] Subsequently, the number of reported cases in the United States in 1998 decreased by 31% from the peak incidence reported in 1992. Populations that remain at risk for tuberculosis are HIV-positive patients, the homeless, intravenous drug users, healthcare workers, prisoners, prison workers, and Native Americans. In addition, the tuberculosis rate in foreign-born persons is 4â€“6 times higher than for US-born persons. The birth countries generating the highest number of US tuberculosis cases are Mexico, the Philippines, and Vietnam.[23 , 24 , 57] The emergence of multidrug-resistan tuberculosis has forced the use of multidrug regimens, as well as the reintroduction of older antituberculous drugs. This approach likely results in an increased incidence of adverse drug effects. Multidrug antitubercul regimens are associated with a 15% incidence of adverse events.[3] Hepatotoxicity, peripheral neuropathy, and ocular neuropathy are often irreversible and potentially fatal. Moreover, many patients receiving antituberculous therapy are chronically ill and have an increased risk of suicidality and intentional overdose.

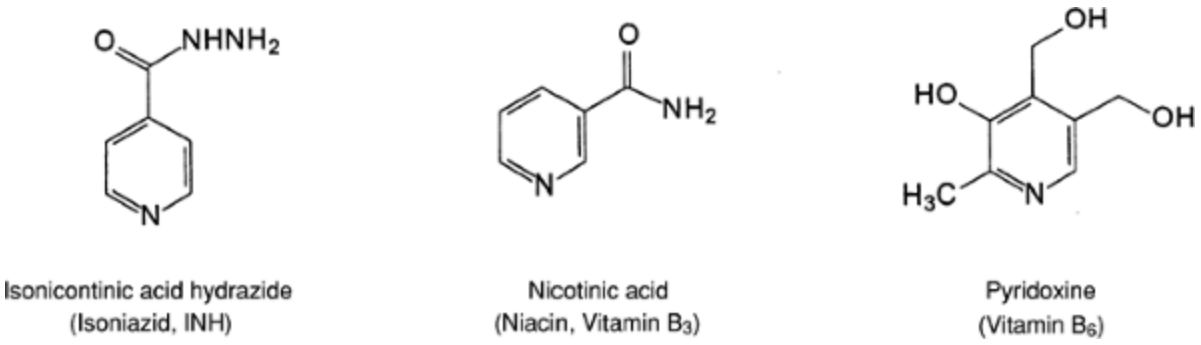

Figure 55-1. INH and related compounds.

Isoniazid

Pharmacology

Isoniazid (INH, or isonicotinic hydrazide) is structurally related to nicotinic acid (niacin, or vitamin B_3), nicotinamide-adenosine dinucleotide (NAD), and pyridoxine (vitamin B_6) (Fig. 55-1). The pyridine ring is essential for antituberculous activity. The mechanism of action of INH involves an interaction with InhA, a mycobacterial enzyme that functions as an enoyl acyl carrier protein (enoyl-ACP) reductase.[83, 84] Isoniazid itself does not directly interact with the InhA enzyme. Instead, INH is a prodrug that undergoes metabolic activation by a mycobacterial catalase-reductase, known as KatG, to produce a highly reactive intermediate.[85, 118] This activated form of INH is either an anion or radical that is stabilized by the pyridine ring. This INH-derived species enters the binding site of InhA where it reacts with the reduced form of nicotinamide adenine dinucleotide (NADH).[85] The covalently linked INH-NADH complex remains bound to the active site of InhA, irreversibly inhibiting the enzyme.[73, 83]

Enoyl-ACP reductases catalyze the NADH-dependent reduction of the double bonds in the growing fatty acid chain linked to acyl carrier protein. InhA is required for the synthesis of very-long-chain lipids known as mycolic acids (containing between 40 and 60 carbons) that are important

components of mycobacterial cell walls.

Pharmacokinetics and Toxicokinetics

When therapeutic doses of 5â€“15 mg/kg are administered orally, INH is rapidly absorbed, reaching peak plasma concentrations within 2 hours.[54] [80] , [81] Isoniazid diffuses into all body fluids with a volume of distribution approximately 0.6 L/kg and has negligible binding to serum proteins. Afte the drug penetrates infected tissue, it persists in concentrations well abo those required for bacteriocidal activity.

Isoniazid is metabolized via a cytochrome P450-mediated process, with approximately 75â€“95% of INH renally eliminated as hepatic metabolites within 24 hours of administration.[71] The primary metabolic pathway for INH is via *N* -acetylation performed by hepatocytes and gut mucosa. *N* -Acetyltransferase, the enzyme responsible for this conversion, exhibits Michaelis-Menten kinetics, although the activity of an individual's enzyme is determined by an autosomal dominant inheritance pattern. Patients wit the polymorphic forms of *N* -acetyltransferase are distinguishable phenotypically as slow and fast acetylators. The slow acetylation isoform found in 50â€“60% of American whites and African Americans, whereas t fast acetylator isoenzymes are found in 90% of Asians and Inuits.[36] Thes isoforms are distinguishable by the following characteristics: (a) Slow acetylators have less presystemic clearance, or first-pass effect, than do fast acetylators; (b) fast acetylators metabolize INH 5â€“6 times faster than slow acetylators; and (c) plasma INH concentrations are 30â€“50% lower in fast acetylators than in slow acetylators. The elimination half-life of INH is approximately 70 minutes in fast acetylators, and 180 minutes i slow acetylators. Twenty-seven percent of INH is excreted unchanged in urine by slow acetylators, as compared with excretion of 11% in fast acetylators. The clearance of INH averages approximately 46 mL/min.[11] , [112] Isoniazid is transformed either via a stepwise process to acetylhydrazine and isonicotinic acid, or directly to hydrazine. In the first instance, INH is initially acetylated to acetylisoniazid and then hydrolyzed to acetylhydrazine. This intermediate may then be oxidized by hepatic

microsomes to reactive intermediates that damage hepatocytes.[109] Figure 55-2 illustrates the metabolism of INH.

Mechanism of Toxicity

Toxic effects of INH are caused by two additive mechanisms. First, INH alters the metabolism of pyridoxine, the coenzyme needed for

transamination, transketolization, and decarboxylation, biotransformation reactions. Isoniazid creates a functional deficiency of pyridoxine by at least two mechanisms (Fig. 55-3). Hydrazone INH metabolites inhibit pyridoxine phosphokinase, the enzyme that converts pyridoxine to its active form, pyridoxal-5â€²-phosphate.[26 , 53 , 67] In addition, INH reacts with pyridoxal phosphate to produce an inactive hydrazone complex that is renally excreted.[67 , 112] Urinary excretion of pyridoxine and its metabolites increases with increasing INH dosage, reflecting the effect of INH on pyridoxine metabolism. The consequences of pyridoxine depletion include impaired activity of pyridoxine-dependent enzyme systems, as well as a decrease in catecholamine synthesis. In addition, INH either replaces nicotinic acid in the synthesis of NAD or reacts with NAD to form inactive hydrazones. Isoniazid disrupts cellular reduction/oxidation capabilities through both of these mechanisms.

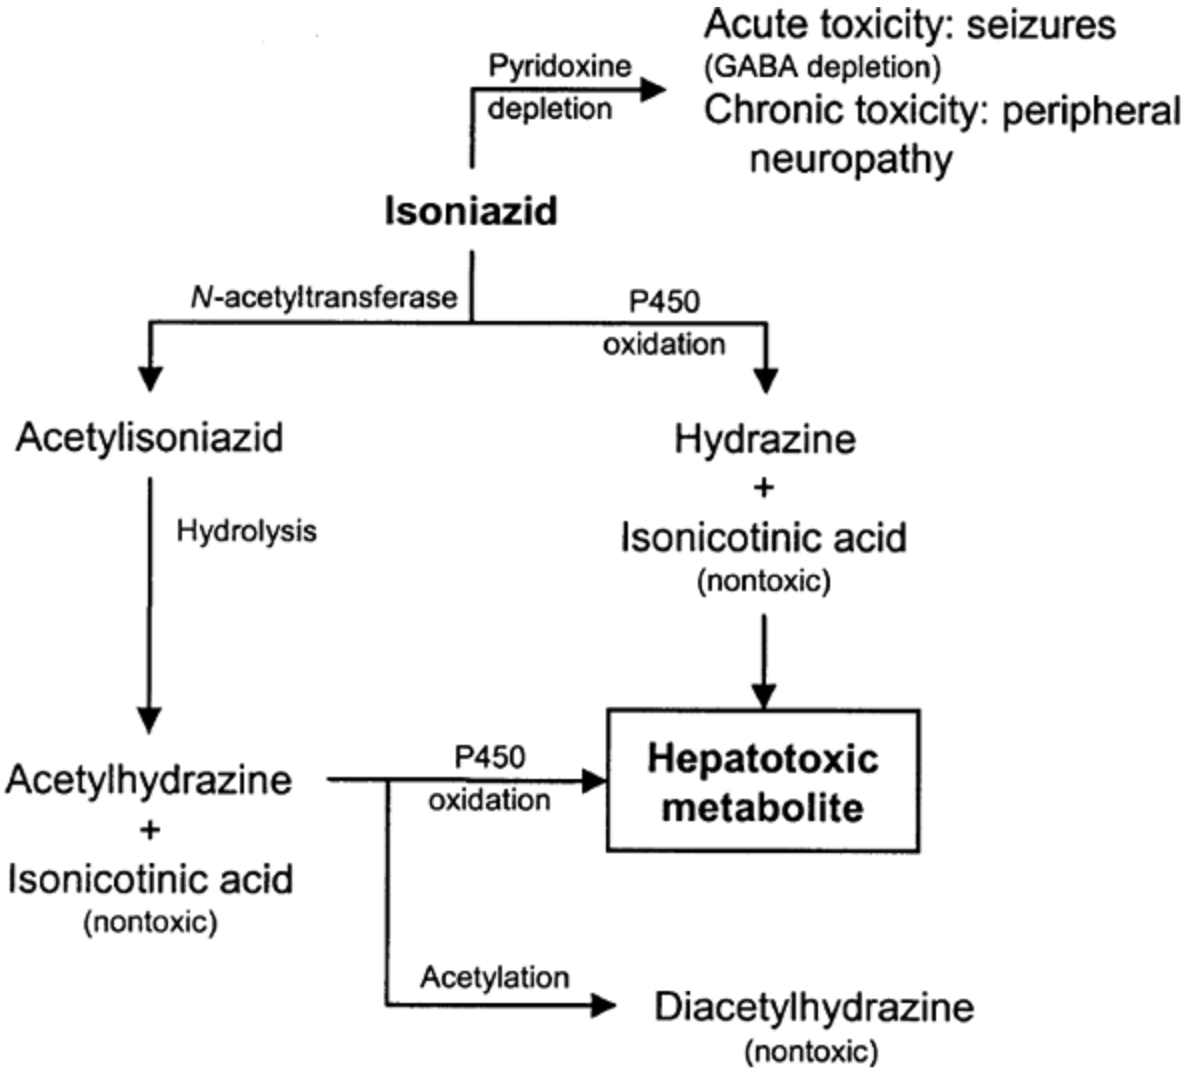

Figure 55-2. Metabolism of INH. Acetylator status is determined by polymorphism in *N* -acetyltransferase.

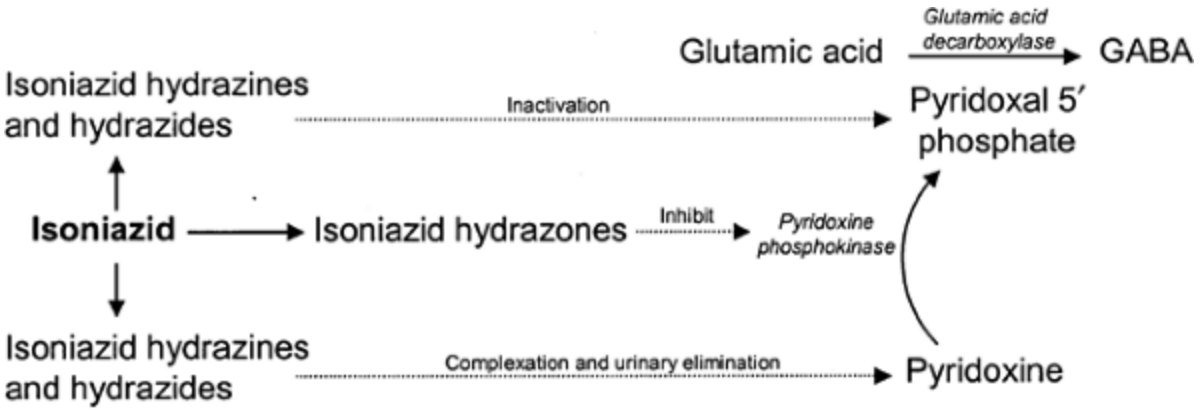

Figure 55-3. The effect of isoniazid on Î³-aminobutyric acid (GABA) synthesis.

Second, isoniazid interferes with the synthesis and metabolism of Î³-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the central nervous system. Two pyridoxine-dependent enzymes control GABA metabolism: glutamic acid decarboxylase (GAD) and GABA aminotransferase. The former catalyzes GABA synthesis, while the latter degrades the neurotransmitter. The inhibitory effects are greater on GAD which leads to decreased GABA concentrations.[7 , 114] Depletion of GABA thought to be the etiology of INH-induced seizures. Structurally similar chemicals exert similar acute toxic effects. Monomethylhydrazine, a metabolite produced from gyromitrin isolated from the *Gyromitra* species (â€œfalse morelâ€•) mushroom, and the hydrazines used in liquid rocket fuel, have a similar mechanism of action (Chap. 113).

Isoniazid, a class C drug, crosses the placenta to enter the fetal compartment and produce umbilical cord blood concentrations comparable to maternal levels.[113] Mammalian teratogen studies suggest that isoniazid is not a human teratogen, although fetal deformities following acute overdose of INH have been reported.[63 , 112] Administration of INH to pregnant women was not associated with cancer in their offspring. Isoniazid readily enters breast milk, but breast-feeding during therapy is considered acceptable.[90 , 112]

Interactions with Other Drugs and Foods

Isoniazid has an overall incidence of drugâ€“drug interactions of 5.4%.[69,94] Isoniazid potentially inhibits several cytochrome P450 (CYP)-mediated transformations, particularly demethylation, oxidation, and hydroxylation (Chap. 9). Clinically relevant adverse effects are documented with theophylline (CYP1A2), phenytoin (CYP2C9/CYP2C19), warfarin (CYP2C9/CYP2C19), valproate, and carbamazepine (CYP3A4).[52,94] Therapeutic doses of INH induce expression of the CYP2E1 cytochrome subtype. It also binds to CYP2E1 simultaneously to decrease the metabolism of substrate. The binding of INH to the active site inhibits the degradation of the enzyme itself. Intracellular concentrations of CYP2E1 are therefore increased; after INH diffuses from the CYP2E1 active site, greater-than-normal amounts of cytochrome become available to metabolize potential substrates.[94] CYP2E1 catalyzes the formation of NAPQI (*N* -acetyl-*p* -benzoquinoneimine), the acetaminophen metabolite responsible for toxicity.[25] Consequently, INH use may increase the likelihood of acetaminophen-induced hepatotoxicity, although this is unstudied.[25]

Isoniazid has numerous food interactions. Isoniazid is a weak monoamine oxidase inhibitor, and tyramine reactions to foods and serotonin syndrom from meperidine are reported in patients taking INH. Clinical effects include flushing, tachycardia, and hypertension.[31,40,62,102] Furthermore, INH inhibits the enzyme histaminase, leading to exacerbate reactions following the ingestion of histamine in scombrotoxic fish.[4,50,52,94] Table 55-1 summarizes additional INH drug and food interactions.

Clinical Manifestations of INH Toxicity

Acute Toxicity

Isoniazid produces the triad of seizures refractory to conventional therap severe metabolic acidosis, and coma. These clinical manifestations may appear as soon as 30 minutes following ingestion.[48,52,108] The case

fatality rate of a single acute ingestion may be as high as 20%.[15, 18] Although vomiting, slurred speech, dizziness, and tachycardia may represent early manifestations of toxicity, seizures may be the initial sign of acute overdose.[66] Seizures may occur following the ingestion of greater than 20 mg/kg of INH, and invariably occur with ingestions greater than 35â€“40 mg/kg. Patients with underlying seizure disorders, however, may develop seizures at lower doses.[15] Hyperreflexia or areflexia may herald INH-induced seizures. Patients may exhibit improvement in consciousness between seizures.[30, 77] Because GABA, the primary inhibitory neurotransmitter, is depleted in acute INH toxicity, seizure activity may persist until GABA concentrations are restored.

Acute INH toxicity is often associated with a wide anion gap metabolic acidosis associated with a high serum lactate. Typically, serum pH ranges between 6.80 and 7.30, although survival in the setting of an arterial pH 6.49 was reported.[48] Paralyzed animals poisoned with INH do not develop lactic acidemia, a finding that suggests the lactate arises from intense muscular activity.[26, 78] Although not borne out in clinical practice, the acidosis from INH-induced seizures has been described as resolving more slowly

than the lactic acidemia from typical seizures, the mechanism for which may be the formation of NAD hydrazones that prevent the transformation of lactate to pyruvate.[26, 113] Alternate explanations of INH-associated acidosis include the generation of acidic INH metabolites and enhanced fatty acid oxidation leading to increased serum ketoacids.[78, 112]

INH
Acute: seizures, acidosis, coma, hyperthermia, oliguria, anuria
Chronic: elevation of liver enzymes, hepatitis, autoimmune disease (arthritis, anemia, hemolysis, eosinophilia), peripheral neuropathy, optic neuritis, vitamin B_6 deficiency (pellagra)
Rifampin, PZA, ethanol: hepatic necrosis
Acetaminophen: hepatic necrosis
Warfarin: increased prothrombin time

Theophylline: tachycardia, vomiting, seizures, acidosis
Phenytoin: increased phenytoin levels
Carbamazepine: altered mental status
Meperidine: hypertension
Lactose: decreased INH absorption
Antacids: decreased INH absorption
Red wine/soft cheese: tyramine reaction
Fish (scombroid): flushing, pruritus
Liver enzymes, ANA, CBC
HIV enteropathy may decrease absorption; INH should not be given with lactose-containing drug formulations because lactose can form hydrazone and lower INH concentrations
Rifampin
Acute: diarrhea, periorbital edema
Chronic: hepatitis, reddish discoloration of body fluids
Protease inhibitors: decreased serum concentration of protease inhibitor
Delavirdine: increased HIV resistance
Cyclosporine: graft rejection
Warfarin: decreased INR
Oral contraceptives: ineffective contraception
Methadone: opioid withdrawal
Phenytoin: higher frequency of seizures
Theophylline: decreased theophylline levels
Verapamil: decreased cardiovascular effect
If administered with HIV antiretroviral agents, viral titers should be followed. Liver enzymes; monitor serum concentrations of drugs (ie, pheny- toin, cyclosporine) or clinical markers of efficacy (ie, coagulation times)
Interactions of rifampin with several HIV medications are very poorly described; changes in dosing or dosing interval for both rifampin and antiretroviral drugs may be required; has teratogenic effects
Ethambutol
Chronic: optic neuritis, loss of red-green discrimination, loss of peripheral vision

Visual acuity, color discrimination
Contraindicated in children too young for formal ophthalmologic examination
Pyrazinamide
Chronic: hepatitis, decreased urate excretion
INH: increased rates of hepatotoxicity (when extended courses or high dose pyrazinamide used)
Liver enzymes
Courses of therapy of 2 months or less recommended
Cycloserine
Chronic: depression, paranoia, seizures, megaloblastic anemia
INH: increased frequency of seizures
CBC, psychiatric monitoring

Ethionamide
Chronic: orthostatic hypotension, depression
Cycloserine: may increase CNS effects
Follow clinical signs of orthostasis

para -Aminosalicylic acid
Chronic: malaise, GI upset, elevated liver enzymes, hypersensitivity reactions, thrombocytopenia

Liver enzymes, CBC

Capreomycin
Chronic: hearing loss, tinnitus, proteinuria, sterile abscess at IM injectior sites

Audiometry, renal function tests

Drug	Major Adverse Reactions	Drug Interactionsâ€“Clinical Effect	Monitoring	Comment

TABLE 55-1. Adverse Reactions and Drug Interactions of Antituberculous Drugs

Protracted coma typically occurs with acute severe INH toxicity. Coma ma last as long as 24â€“36 hours and persist beyond the termination of seizure activity as well as the resolution of acidemia. The etiology of com is unknown.[48] Additional sequelae from acute INH toxicity include renal failure, hyperglycemia, glycosuria, and ketonuria, along with hypotension and hyperpyrexia.[6,19,112]

Chronic Toxicity

As a consequence of a myriad of INH-induced biochemical changes, chronic, therapeutic INH use is associated with a variety of adverse effec The most disconcerting is hepatocellular necrosis. Although asymptomatic elevation of aminotransferases is common in the first several months of treatment, laboratory testing may reveal the onset of hepatitis up to 1 year after starting INH therapy. In 1978, following several deaths among patients receiving INH therapy, the US Public Health Service reported the incidence of clinically evident hepatitis as 1% of those taking INH; of tha subgroup, 10% died, for an overall mortality of 0.1%.[17,60] Research performed since the resurgence of TB, however, identified a considerably lower rate of hepatotoxicity. Clinically relevant hepatitis occurred in only 11 patients in a population of 11,141 persons receiving INH, an incidence of 0.1%.[76] Additional studies suggest that the death rate from INH hepatotoxicity is only 0.001% (2 of 202,497 treated patients).[88] The decrease in mortality from INH-associated hepatitis may be a

result of improved surveillance protocols allowing for earlier cessation of therapy or decision analysis concerning continued use of INH.

Isoniazid-induced hepatitis can arise via two pathways.[34] The first involv an autoimmune mechanism resulting in hepatic injury that is thought to b idiopathic.[9 , 101 , 112 , 117] The association of hepatitis with lupus erythematosus, hemolytic anemia, thrombocytopenia, arthritis, vasculitis and polyserositis supports an immunologic process.[9 , 101 , 112 , 117] However, symptoms commonly found in autoimmune disorders such as fever, rash, and eosinophilia are usually absent, and rechallenge with isoniazid often fails to provoke recurrence of hepatocellular injury.[34] The second, more common mechanism involves direct hepatic injury by INH o its metabolites. The metabolite believed responsible for hepatic injury is acetylhydrazine, which arises from the acetylation of INH followed by its hydrolysis.[74] Hepatotoxicity is associated with chronic overdosage, increasing age, comorbid conditions such as malnutrition, and combinatio of antituberculous drugs that may serve as cytochrome inducers. Overt hepatic failure often occurs if INH therapy is continued after onset of hepatocellular injury.[34 , 35 , 38 , 47 , 72 , 97] The incidence of hepatitis is 2â€“4 times higher in pregnant women than in nonpregnant women.[39]

Peripheral neuropathy and optic neuritis are known adverse drug effects chronic INH use. Neurotoxicity is probably caused by pyridoxine deficienc aggravated by the formation of pyridoxine-INH hydrazones.[36] Peripheral neuropathy, the most common complication of INH therapy, presents in a stocking-glove distribution that progresses proximally. Although primarily sensory in nature, myalgias and weakness may occur.[98] Peripheral neuropathy is generally observed in severely malnourished, alcoholic, uremic, or diabetic patients; it is also associated with slow acetylator status, an effect which leads to increased INH levels and, consequently, increased pyridoxine depletion.[42] Optic neuritis presents as decreased visual acuity; visual field testing may reveal central scotomata.[44 , 52] Isoniazid is also associated with such findings of CNS toxicity as ataxia, psychosis, hallucinosis, and coma.[1 , 10 , 41 , 87]

Diagnostic Testing

Acute INH toxicity is a clinical diagnosis that may be inferred by history

and confirmed by measuring serum INH concentrations.[93] Acute toxicity from INH has been defined as a serum INH concentration greater than 10 mg/L 1 hour after ingestion, greater than 3.2 mg/L 2 hours after ingestio or greater than 0.2 mg/L 6 hours after the ingestion.[77] Because serum IN concentration measurements are not widely available, clinicians cannot re on serum concentrations to confirm the diagnosis or initiate therapy. Because of the risk of hepatitis associated with chronic INH use, hepatic aminotransferases should be regularly monitored once therapy is started.

Management

Acute Toxicity

The initial management requires termination of seizure activity, fluid resuscitation, and stabilization and correction of vital signs with maintenance of a patent airway. Clinicians should consider the administration of sodium bicarbonate to treat severe acidemia with a pH <7.0. Gastrointestinal decontamination should be performed by administering activated charcoal to awake patients who are able to comp with therapy.[96] Orogastric lavage and emetics are relatively contraindicated unless the patient is intubated when the risk of aspiration is diminished because of the underlying risk of seizures. Delayed absorption of INH has not been observed, suggesting that late gastrointestinal decontamination with charcoal is ineffective in preventing toxicity.[92]

The antidote for INH-induced neurologic dysfunction is pyridoxine. Pyridoxine rapidly terminates seizures, corrects metabolic acidosis, and reverses coma. The efficacy of pyridoxine is correlated with the administered dose; one study identified recurrent seizures in 60% of patients who received no pyridoxine, in 47% of those who received 10% the ideal pyridoxine dose, and in no patients who received the full dose o pyridoxine.[111] To treat acute toxicity, the pyridoxine dose in grams shoul equal the amount of INH ingested in grams, with a first dose of up to 5 g adults. Unknown quantities of ingested INH warrant initial empiric

treatment with a pyridoxine dose of no more than 5 g (pediatric dose: 70 mg/kg to a maximum of 5 g). Pyridoxine should be administered at a rate of 1 g every 2â€“3 minutes. Seizures that persist beyond administration of the initial 5-g dose should be treated by administration of an additional 5 of pyridoxine.[8]

Hospital pharmacies may stock insufficient quantities of pyridoxine to tre even a single patient with a large INH ingestion.[91] In the event that intravenous formulations are unavailable in sufficient quantities, pyridoxi tablets may be crushed and administered with fluids via nasogastric tube

Conventional anticonvulsants demonstrate variable effectiveness in terminating INH-induced seizures. Benzodiazepines may be used to potentiate the antidotal effect of suboptimal doses of pyridoxine, if gram-for-gram replacement doses of the antidote are unavailable. The benzodiazepines act synergistically with pyridoxine, as well as possess inherent GABA-agonist activity, but as single agents they may be ineffective in the treatment of acute INH poisoning.[27, 28, 52, 111] Phenytoin has no intrinsic GABAergic effect and is not recommended as therapy for INH-induced seizures.[52, 77, 86] Barbiturates, which have potent GABA-agonist activity, are expected to be as effective as the benzodiazepines, although the risk of complications is greater with this class of anticonvulsant. The efficacy of propofol in terminating INH-induc seizures has not been evaluated in humans.

Although hemodialysis has been used to enhance elimination of INH in acute overdose, with clearance rates reported as high as 120 mL/min, hemodialysis is rarely indicated. It is usually reserved for patients who develop INH-induced renal failure.[19, 112]

Asymptomatic patients who present to the ED within 2 hours of ingestion toxic amounts of INH should receive prophylactic administration of 5 g of pyridoxine. This recommendation is based on the observation that INH reaches its peak serum concentration within 2 hours of ingestion of therapeutic doses. Asymptomatic patients may be observed for a 6-hour period for signs of toxicity. Acute toxicity is unlikely to manifest more tha 6 hours beyond ingestion.

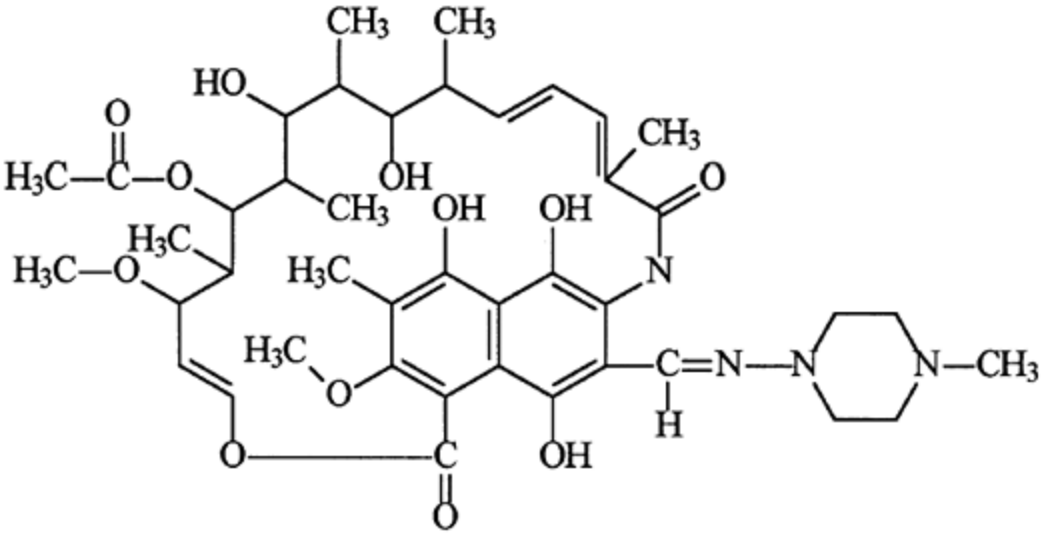
Chronic Toxicity

Hepatitis (defined as aminotransferase concentrations 2â€“3 times baseli levels) resulting from therapeutic INH administration mandates terminati of therapy; malnourished patients may require nutritional support. After resolution of liver injury, INH may be restarted, provided aminotransfera concentrations are closely monitored.[34 , 97] Pyridoxine does not reverse hepatic injury; consequently, surveillance for and recognition of hepatocellular injury remains essential. Cases of hepatitis refractory to medical therapy may require liver transplantation.[37 , 49]

Neurologic toxicity, including peripheral neuropathies, cerebellar findings and psychosis, is commonly treated with as much as 50 mg/d of oral pyridoxine, although doses as low as 6 mg/d appear

to be effective.[1 , 10 , 87 , 103] Because of its effectiveness in preventing neurologic toxicity, pyridoxine is used concurrently with INH therapy.

Rifamycins



Rifampin

Pharmacology

Rifamycins are a class of semisynthetic macrocyclic antibiotics derived fr *Streptomyces mediterranei.* Drugs in this class include rifampin, rifabutin and rifapentine, of which the first two are most commonly used.[65] Rifamp inhibits the initial steps in RNA chain polymerization through the formatic of a stable complex with RNA polymerase. Disruption of RNA synthesis interrupts protein synthesis, leading to cell death. Whereas mycobacteria RNA polymerase is susceptible to rifampin, eukaryotic RNA polymerase is not.[69]

Pharmacokinetics and Toxicokinetics

When administered orally, rifampin reaches peak plasma concentrations i 2â€“4 hours; foods, but not antacids, interfere with absorption.[81] Rifamp is secreted into the bile and undergoes enterohepatic recirculation. Although the recirculating antibiotic is deacetylated, the metabolite retai antimicrobial activity. The half-life of rifampin, which is normally betwee 1.5 and 5 hours, increases in the setting of hepatic dysfunction. After therapy is started, however, rifampin induces its own metabolism to shorten its half-life by approximately 40%. Rifampin is approximately 75 protein-bound, and distributes widely into body compartments. It imparts reddish color to all body fluids, including the CSF, leading to confusion w xanthochromia from subarachnoid hemorrhage.[52 , 69] The reddish discoloration of the skin may be removed by washing.[69] This property distinguishes rifampin from the â€œred man syndromeâ€• associated wi vancomycin, in which extreme flushing produces intense skin discoloratio (Chap. 54).[58]

Rifampin therapy carries greater teratogenic risk than other antituberculous therapies, with an incidence of malformation of 4.4%. Anencephaly, hydrocephalus, and congenital limb abnormality and dislocations are reported.[14 , 105] Rifampin is associated with hemorrhagic disease of the newborn.[14] The antibiotic is compatible with breast-feedin as only minute amounts of rifampin are secreted into breast milk.[103 , 104]

Drugâ€“Drug Interactions

Rifamycins are potent inducers of cytochrome P450 oxidative enzymes, which result in numerous drug interactions (Chap. 9). Of the rifamycins, rifampin has greater activity in inducing CYP3A4 than rifapentine; rifabut has the least inductive activity of the class.[65] In addition, rifampin is thought to induce CYP1A2, CYP2C8, and CYP2C9.[45 , 107] Concurrent administration of rifampin thus affects the metabolism of an array of drug such as warfarin, cyclosporine, phenytoin, opioids, and oral contraceptives.[45 , 95 , 107] Enzyme induction by rifampin therefore may b responsible for a variety of pathophysiologic processes, including insufficient anticoagulation in patients receiving oral anticoagulants, acut graft rejection in transplant patients, graft-versus-host disease, difficulty controlling phenytoin levels, methadone withdrawal, and unplanned pregnancy. Effects arising from CYP3A4 induction begin within 5â€“6 days after rifampin is started, and persist for up to 7 days after therapy is stopped.[70]

The cytochrome isozymes induced by rifampin also control the metabolism of drugs used in the treatment of HIV. Rifampin decreases the concentration of available protease inhibitors by 35â€“92%.[16] The antivi effect of protease inhibitors correlates best with trough concentrations.[10] Lower trough concentrations increase the frequency of drug-resistant mutations in the protease gene and promote the outgrowth of drug-resistant HIV strains. The reduction of serum concentrations of protease inhibitors is of such magnitude that it may not be overcome by increasing the dose of the protease inhibitor. Coadministration of rifampin with protease inhibitors may therefore lead to loss of HIV suppression and to the emergence of resistant HIV strains.[16]

Rifampin also decreases the serum concentrations of nucleoside reverse transcriptase inhibitors such as zidovudine. The efficacy of zidovudine an congeners is not related to the serum concentration of drug, but is, instead, related to the intracellular concentration of the active metabolite a triphosphate derivative. Even though rifampin decreases serum

zidovudine concentrations by 47%, active metabolite is present within ce in sufficient levels for activity. Rifampin, therefore, has minimal effect on the efficacy of nucleoside reverse transcriptase inhibitors. Table 55-1 list the drug interactions of rifampin.

Rifampin suppresses the transformation of antigen-stimulated lymphocyt as well as normal T-cell function, leading to decreased sensitivity to tuberculin, in turn resulting in false-negative purified protein derivative (PPD) test results.

Clinical Manifestations

Acute Toxicity

The most common side effects of acute rifampin overdose are gastrointestinal symptoms consisting of epigastric pain, nausea, vomiting and diarrhea. The presence of diarrhea distinguishes rifampin ingestion from overdose of other antimycobacterial agents.[34] Nonetheless, 3 death are associated with rifampin or rifampicin ingestion; an autopsy performe on 1 of these patients demonstrated the presence of pulmonary edema, although no causation was implied.[12, 56, 82] Other effects include flushing, angioedema, and obtundation. Children who receive an overdose of rifampin can develop facial or periorbital edema. Anterior uveitis is occasionally observed, as are neurologic effects consisting of generalized numbness, extremity pain, ataxia, and muscular weakness.[46, 69] Isolated rifamycin overdose infrequently produces serious acute effects.

Chronic Toxicity

When rifampin was originally introduced as an antituberculous agent, hepatitis was more frequently observed in patients taking combination therapy of rifampin and INH than in those taking INH alone. These findin potentially arise from rifampin's

ability to induce cytochromes responsible for INH hepatotoxicity and may

not result from direct hepatic injury by rifampin itself. Liver injury, when attributable to rifampin alone, is predominantly cholestatic, prompting suggestions that clinical surveillance for hepatic injury may be preferable to regular biochemical monitoring.[34, 79] Rifampin alters the metabolism of other xenobiotics, such as INH and acetaminophen, to increase their potential for hepatotoxicity.[34, 75] Although more prevalent in combined regimens, adverse effects are uncommon; the increased efficacy of multidrug regimens generally outweighs the risks associated with their us One report underscores the risks of the 9-month isoniazid, 2-month rifampin and pyrazinamide regimen that has resulted in 2 fatal cases of severe hepatitis following treatment for latent tuberculosis.[22]

A condition similar to a viral syndrome may result from a hypersensitivity reaction that is associated with rifampin therapy. The syndrome, which occurs in 20% of patients receiving high doses, includes fever, chills, myalgias, and a nonproductive cough. Eosinophilia, hemolytic anemia, thrombocytopenia, and interstitial nephritis can develop in severe cases.[7, 71] Intermittent dosing of rifampin is also a risk factor for renal failure, the mechanism for which is unknown. Renal failure is rarely oliguric and i usually self-limited; patients usually recover with supportive care, althou rechallenge with rifampin should be undertaken only with caution.[79]

The concomitant administration of rifampin and protease inhibitors result in increased rates of arthralgias, uveitis, leukopenia, and skin discoloration. Identical side effects occurred during the simultaneous administration of rifampin and CYP3A4 inhibitors such as clarithromycin, suggesting that toxic effects arise from elevated serum rifampin concentrations.[16] Current recommendations are that rifampin dosing be decreased when administered with nelfinavir, indinavir, and amprenavir. The administration of rifampin with ritonavir is not recommended.[16, 20]

Therapeutic Testing and Management

Management of patients with acute rifampin overdose is primarily supportive. Stabilization of vital signs and administration of activated charcoal are usually adequate, although clinicians should remain vigilant

for coingestants. For chronic toxicity, recognition of interactions between rifampin and other drugs is critical. Hepatic function should be monitored because of rifampin's ability to augment the hepatotoxicity of other pharmaceuticals and xenobiotics. Treatment for hepatic injury involves withholding rifampin therapy and reassessing the appropriateness of othe drugs administered to the patient. Supportive care for hepatotoxicity may be required. Influenzalike symptoms and renal failure secondary to rifampin may respond to decreasing the interval between administration o the drug.[79] Although rifampin interacts with protease inhibitors, the utilit of therapeutic drug monitoring is uncertain because the correlation of clinical events with serum concentrations of rifampin and antiretroviral drugs is unknown.[16]

Ethambutol

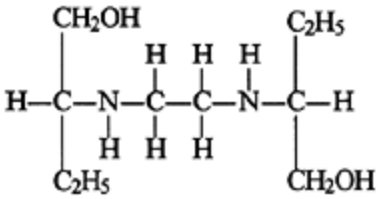


Figure. No Caption Available.

Pharmacology and Pharmacokinetics

Ethambutol, an antibiotic to which almost all strains of *M. tuberculosis* ar sensitive, has no effect on other bacteria. Ethambutol binds to arabinosyltransferases, which are enzymes that incorporate glycan subunits into cell wall polymers known as arabinogalactan and lipoarabinomannan.[64] Only the D(+) isomer is used therapeutically, but both enantiomers are bacteriocidal.[52] The drug is active only in growing cells, where bacteriostatic effects appear approximately 24 hours after ethambutol is incorporated by mycobacteria.[69]

Maximum serum concentrations are reached within 4 hours of oral

administration and are proportional to the dose. Both foods and antacids decrease absorption.[16] Ethambutol is approximately 20â€“30% protein bound and has a half-life of between 4 and 6 hours.[61, 69] Three-fourths a standard dose is excreted unchanged into the urine by a combination of glomerular filtration and tubular secretion. Consequently, ethambutol accumulates in patients with renal failure, making adjustments in dosing necessary.[69]

Ethambutol is considered safe for use during pregnancy as a first-line agent. Although a 2.2% incidence of congenital abnormalities was identified in women undergoing ethambutol therapy, no consistent patter of abnormalities occurred in their offspring.[14] Even though ethambutol is excreted into breast milk in approximately a 1:1 ratio with serum, it is compatible with breast-feeding.[14]

Clinical Manifestations and Management

Acute overdosage of ethambutol is generally well tolerated, although dea is reported.[56] More commonly, nausea, abdominal pain, confusion, visual hallucinations, and optic neuropathy occur following acute ingestions of greater than 10 g.[33] Although stabilization of vital signs and GI decontamination with activated charcoal remain the hallmarks of therapy, clinicians must remain vigilant for coingestants, particularly INH. Hemodialysis is rarely used as treatment for multidrug ingestions includir ethambutol.[33]

Although peripheral neuropathy and asymptomatic hyperuricemia occur with chronic therapy, the most significant effect of the therapeutic use of ethambutol is dose-related optic or retrobulbar neuritis, which may be unilateral or bilateral.[55, 99] Approximately 15% of patients receiving 50 mg/kg/d, 5% of patients receiving 25 mg/kg/d, and fewer than 1% of those receiving 15 mg/kg/d develop optic neuritis.[79] Patients may develo subclinical ocular disease within 30 days of starting ethambutol.[115] If clinically apparent, patients may complain of decreased visual acuity, loss of red-green discrimination, and loss of peripheral vision. The loss of peripheral vision and color discrimination that occurs in patients with opt

neuropathy caused by ethambutol distinguishes this condition from optic neuropathy secondary to INH.[52, 79]

Management of chronic toxicity from ethambutol involves cessation of therapy, although improvement may be hastened by treatment with hydroxocobalamin.[52] Recovery is less likely in older patients and is relate to the degree of visual impairment.[110]

Optic neuritis may be related to derangements in mitochondrial copper or zinc metabolism; ethambutol chelates both metals.[29] The visual abnormalities induced by ethambutol have clinical features similar to a hereditary condition known as Leber optic neuropathy. In this disorder, t mechanism of visual loss is defective mitochondrial metabolism of copper.[59] Ethambutol is suspected of mimicking this condition by binding intracellular copper, altering mitochondrial function, and producing neuronal injury.[51, 59] Alternatively, optic neuritis may be related to zinc metabolism. Ethambutol

chelates intracellular zinc to induce reversible vacuolar degeneration in retinal cultures. Progressive degeneration leads to irreversible neuronal destruction.[116] The clinical effect of this injury is a shift in the threshold for wavelength discrimination without changing the absolute sensitivity o the cone system, which patients discern as loss of red-green discrimination.[100]

Diagnostic Testing

All patients should receive neuro-ophthalmic testing prior to ethambutol therapy. The use of visual-evoked potentials is especially useful in identifying subclinical optic nerve disease. Furthermore, patients should receive regular visual acuity examinations, and clinicians should encoura patients to report any subjective symptoms related to vision. The use of ethambutol may be relatively contraindicated in children who are unable comply with an ophthalmic examination.[52, 79]

Pyrazinamide

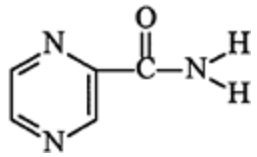

Figure. No Caption Available.

Pharmacology and Pharmacokinetics

Pyrazinamide (PZA) is a structural analog of nicotinamide whose mechanism of action is similar to that of INH. Like INH, PZA is a prodrug. Pyrazinamide requires deamidation by pyrazinamidase, an endogenous bacterial enzyme, to pyrazinoic acid, the active form of the drug. The precise cellular functions inhibited by pyrazinoic acid have not been defined, but an acid pH is required for activity. Pyrazinamide is effective against both active and dormant bacteria and its use in antituberculosis regimens shortens the course of therapy.[5] If PZA is administered during the first 2 months of treatment with INH and rifampin, a course of chemotherapy may be shortened to only 6 months, producing the shortes effective regimen.[81] After oral administration, PZA is rapidly absorbed, with maximum concentrations occurring within 1 hour of administration. The volume of distribution of PZA is 0.7 L/kg and approximately 10% remains bound to plasma protein. Pyrazinamide is metabolized to pyrazinoic acid and 5-hydroxypyrazinoic acid, which are then renally excreted. The drug has a half-life of approximately 9 hours.[69]

When introduced in the 1950s, PZA was administered in doses of 40â€“50 mg/kg for extended periods of time. The dosages produced hepatitis, witl clinical manifestations of highly elevated aminotransferase and bilirubin concentrations. Among patients taking high-dose PZA, elevations in aminotransferases were identified in 20%, and symptomatic hepatitis was identified in 10%. A small number of the latter population succumbed aft a fulminant course. As a result of these findings, PZA was believed to be

highly hepatotoxic and its use was discouraged. The resurgence of multidrug-resistant mycobacteria, however, has forced clinicians to reassess the role of PZA. Modern dosing regimens of 30 mg/kg for brief courses of 2 months infrequently produce hepatic injury, with some studi suggesting that addition of PZA to multidrug TB regimens confers no additional risk for hepatotoxicity.[34 , 80 , 81]

Pyrazinamide is rarely used in pregnancy because the risk of birth defects is poorly defined. Animal studies suggest that PZA has no teratogenic potential at therapeutic doses.[2] Pyrazinamide is minimally excreted into breast milk and is presumed safe for breast-feeding.[14]

Clinical Manifestations and Management

Proper dosing of PZA and short courses of therapy are the two most important factors in preventing toxicity. Treatment for hepatotoxicity involves cessation of PZA therapy in conjunction with supportive care.[34] Pyrazinamide inhibits the renal excretion of uric acid, and hyperuricemia observed. More than 90% of children treated with short courses develope elevated uric acid concentrations.[89] Most patients, regardless of age, remain asymptomatic and do not develop symptoms of gout, but polyarthralgias responsive to probenecid or allopurinol may be observed.[8] Toxic effects from acute overdose of pyrazinamide have not been reporte

Cycloserine

Cycloserine is used in conjunction with other tuberculostatic agents when treatment with primary agents (INH, rifampin, ethambutol, and streptomycin) has failed. Cycloserine, a structural analog of alanine, inhibits reactions in which D-alanine is required for cell wall biosynthesis. After oral doses, 70â€“90% of the drug is absorbed. Peak concentrations the drug are reached in 3â€“4 hours. Cycloserine is distributed throughou all tissues and body fluids and easily crosses the bloodâ€–brain barrier. Very little of the antibiotic is metabolized, and the drug is excreted unchanged in the urine.[69]

Toxicity, occurring in as many as 50% of patients taking cycloserine, is dose dependent. Neurologic effects consist of somnolence, headache, tremor, dysarthria, vertigo, confusion, irritability, and seizures. Psychiatr manifestations include paranoid reactions, depression, and suicidal ideation. These effects are thought to be caused by agonism of glycine B receptors by cycloserine. Cycloserine is contraindicated in patients with a history of either seizures or depression. If used, cycloserine should be introduced slowly to avoid CNS toxicity.[52, 79, 81] Toxicity is potentiated by alcohol, usually appears within the first 2 weeks of therapy, and cease upon termination of the drug. Because cycloserine is renally excreted, patients with renal failure may be predisposed to toxicity; it is removed b hemodialysis. Although no teratogenic effects were noted in 3 women exposed to cycloserine during the first trimester, cycloserine is not recommended for use during pregnancy. Cord blood concentrations are approximately 70% of serum levels, and no adverse effects occurred in breast-fed infants. Consequently, cycloserine is considered to be safe in women who are breast-feeding.[14] Reports of overdose are lacking in the English medical literature.

Other Antimycobacterials

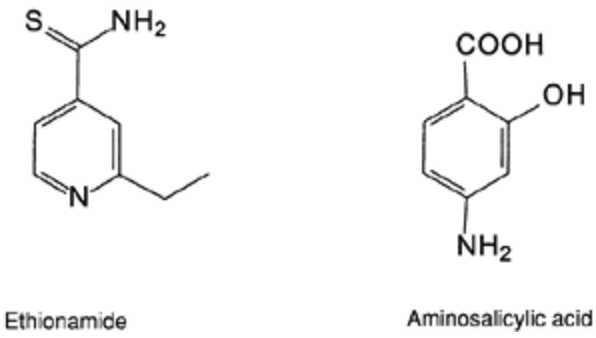

Figure. No Caption Available.

Ethionamide, a congener of INH, is thought to have a similar mechanism action to INH. Oral doses yield peak serum concentrations within

approximately 3 hours of administration. The half-life of the drug is approximately 2 hours. Toxic effects include orthostatic hypotension, depression, and drowsiness. Rash, purpura, and gynecomastia are observed, as are tremor, paresthesias, and olfactory disturbances. Approximately 5% of patients receiving ethionamide develop hepatitis. Treatment for toxicity involves withholding ethionamide therapy.[69] Birth defects were observed in 7 of 23 newborns antenatally exposed to ethionamide, although a consistent pattern of anomalies was lacking. Dat regarding the safety of ethionamide are lacking.[14] Reports of toxicity fro ethionamide overdose are absent from the English literature.[32]

para -Aminosalicylic acid (PAS) is thought to inhibit enzymes responsible for folate biosynthesis in mycobacteria but not in other organisms. PAS is readily absorbed from the gut and is rapidly distributed into all tissues, especially the pleural fluid and caseous material. *para* -Aminosalicylic aci has a half-life of minutes and is renally excreted. Adverse effects associated with PAS use include nausea, vomiting, diarrhea, sore throat, and malaise. Between 5 and 10% of patients receiving PAS develop hypersensitivity reactions characterized by high fever, rash, and arthralgias. Hematologic abnormalities of agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, and acute hemolytic anemia have been observed.[69] *para* -Aminosalicylic acid may be removed by hemodialysis in patients with renal failure.[68] Adverse effects associated with chronic therapy may be treated with withdrawal of the drug. Data regarding the safety of PAS in pregnancy and breast-feeding are lacking.[14]

Capreomycin is a cyclic polypeptide with an unknown mechanism of actio Because of poor absorption after oral dosing, capreomycin must be administered intramuscularly. Toxicity associated with capreomycin use includes hearing loss, tinnitus, proteinuria, and electrolyte disturbances, although severe renal failure is rare. Eosinophilia, leukocytosis, and rash have been described. Pain and sterile abscesses at the site of capreomyc injection have been reported.[69] Data regarding the safety of capreomycir in pregnancy and breast-feeding are lacking.[14]

Summary

In overdose antituberculous drugs represent a significant toxicologic threat. Patients acutely poisoned with INH require immediate and appropriate action to reverse seizures, acidosis, and coma. As an antidote to INH overdose, pyridoxine is effective therapy, although its action may be augmented by the use benzodiazepines. Although less common than previously believed, hepatocellular injury resulting from therapeutic dosing of INH nonetheless requires surveillance to prevent fulminant hepatic failure.

Other antituberculous agents cause significant adverse effects. In particular, rifampin has numerous drugâ€“drug interactions, including several with anti-HIV therapies. Because antituberculous therapies are common in the HIV population, potential interactions between rifampin and antiretroviral agents should remind clinicians to remain vigilant for unanticipated adverse effects. Patients receiving ethambutol, pyrazinamide, and other antituberculous agents benefit from surveillance for specific effects such as decreased visual acuity, hepatic injury, and psychiatric manifestations. Despite the toxicity of this class of drugs, poisoning is often responsive to intervention if recognized and treated appropriately.

Antidotes in Depth

Pyridoxine

Mary Ann Howland

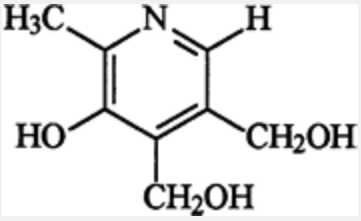

Figure. No Caption Available.

Pyridoxine (vitamin B_6), a water-soluble vitamin, is administered as an antidote for overdoses of isonicotinic acid hydrazide (isoniazid, INH), hydrazine, methylated hydrazines, and perhaps

ethylene glycol. With the exception of ethylene glycol, all of the named xenobiotics produce seizures by the competitive inhibition of pyridoxal-5â€²-phosphate (PLP) Pyridoxine overcomes this inhibition. Also, the administration of pyridoxine may enhance the less-toxic pathway of ethylene glycol metabolism to form benzoic and hippuric acid, as opposed to oxalic acid.[6] Hydrazine and methylated hydrazines (1,1-dimethylhydrazine [UDMH], monomethylhydrazine [MMH]) are used as rocket fuels, and MMH is also found in *Gyromitra esculenta* mushrooms.[3]

History

Pyridoxine deficiency was first identified in 1926 and was mistakenly attributed to the absence of vitamin B_2.[33] Ten years later, the deficiency was fully characterized and attributed to vitamin B_6.[22] A rare genetic abnormality that produced pyridoxine-responsive seizures in newborns was recognized in 1954.[5]

Chemistry

The active form of pyridoxine is the phosphate ester of pyridoxal (PLP).[27] Pyridoxine, an alcohol; pyridoxal, an aldehyde; and pyridoxamine, an aminomethyl form are all naturally occurring related compounds that are metabolized by the body to PLP.[27] Pyridoxine was chosen by the Council on Pharmacy and Chemistry to represent vitamin B_6.[27] Pyridoxine hydrochloride was chosen as the commercial preparation because of its stability.[47]

Pharmacology

PLP is an important cofactor in more than 100 enzymatic reactions, including decarboxylation and transamination of amino acids, and the metabolism of tryptophan to 5-hydroxytryptamine and methionine to cysteine.[21,27] Iatrogenic pyridoxine deficiency in animals produces seizures associated with reduced

concentrations in the brain of PLP, glutamic acid decarboxylase, and Î³-aminobutyric acid (GABA).[15]

Pharmacokinetics

Pyridoxine is not protein bound, has a volume of distribution of 0.6 L/kg, and easily crosses cell membranes; in contrast PLP is nearly entirely plasma protein bound.[47] Pyridoxine is rapidly metabolized at extrahepatic sites to pyridoxal, PLP, and 4-pyridoxic acid, with only 7% excreted unchanged in the urine.[47] After intravenous infusion of 100 mg of pyridoxine over 6 hours, PLP concentration increases rapidly in serum and in erythrocytes.[47] Pyridoxal rises from 37 nmol/L to 2183 nmol/L in serum and from undectable to 5593 nmol/L in erythrocytes, with peak levels achieved at the end of the infusion.[47] Oral pyridoxine in doses of 600 mg is 50% absorbed within 20 minutes of ingestion by a first-order process with rapid achievement of peak plasma concentrations of pyridoxine, PLP, and pyridoxal.[46] The concentration of PLP appears to be tightly controlled in the serum and related to alkaline phosphatase activity.[22,46] Oral doses of pyridoxine from 10â€“800 mg result in PLP concentrations of 518â€“732 nmol/L 4 hours after ingestion.[46] Chronic alcoholics have lower baseline PLP serum levels, as acetaldehyde enhances the degradation of PLP in erythrocytes, through stimulation of an erythrocyte membrane-bound phosphatase that hydrolyzes phosphate-containing B_6 compounds.[26]

Mechanism of Hydrazide- and Hydrazine-Induced Seizures

The antidotal role of pyridoxine in the management of INH and methylated hydrazines like MMH poisoning is based on the interference of these xenobiotics with the normal use and function of pyridoxine as a coenzyme. INH produces a syndrome resembling

cerebral vitamin B_6 deficiency, which results in seizures. Specifically, INH and other hydrazides and hydrazines inhibit the enzyme pyridoxine phosphokinase that converts pyridoxine to PLP.[21] In addition, hydrazides directly combine with PLP, causing inactivation through the production of hydrazones that are rapidly excreted by the kidney.[21] PLP is a coenzyme for L-glutamic acid decarboxylase that facilitates the synthesis of GABA from L-glutamic acid. Animal studies suggest that this interference with PLP disrupts the formation of GABA.[21,43] The decreased GABA formation reduces cerebral inhibition, which may contribute in part to the seizures resulting from exposure to INH and methylated hydrazines.[35,45]

Animal Studies

In a dog model of INH-induced toxicity, pyridoxine reduced the severity of seizures, increased the time to seizure, and prevented the mortality of a previously lethal dose of INH in a dose-dependent fashion.[12,13] Lower molar ratios prevented deaths and higher molar ratios prevented both deaths and seizures.[13] When used as a single agent, phenobarbital, pentobarbital, phenytoin, ethanol, and diazepam were ineffective in controlling seizures and mortality, but when combined with pyridoxine, each protected the animals from seizures

and death.[12] Other small-animal experiments have documented the effectiveness of pyridoxine against MMH-induced seizures when used alone[21,29,40] and when used in combination with diazepam.[18] Anticonvulsant efficacy is also demonstrated in cat[36] and monkey[38] models.

Rat studies with intraperitoneal dimethylhydrazine (UDMH) also demonstrate the protective effects of pyridoxine given intraperitoneally 90 minutes later.[14] Pyridoxine prevented seizures and death in a model that produced 94% mortality and 100%

seizures without pyridoxine.[14] When intraperitoneal UDMH and pyridoxine IV 20 minutes later were administered to rats 17% died at 24 hours, as compared to a 100% mortality without pyridoxine.[14] Other studies in dogs and monkeys also demonstrate the effectiveness of pyridoxine in preventing seizures and mortality, and in treating seizures.[4] Pyridoxine IM protected the monkeys from death and stopped the seizures caused by an IV UDMH dose.

Human Data

Clinical experience with the use of pyridoxine for INH overdose in humans demonstrates favorable results.[3,11] Rapid seizure control with no morbidity or mortality was achieved when the ratio in grams of pyridoxine administered to INH ingested ranged from 0.14 to 1.3, although in practice, most patients receive approximately gram-for-gram amounts. In 5 patients, the use of gram-for-gram amounts of pyridoxine resulted in the complete control of seizures and a resolution of the metabolic acidosis.[42] In 8 patients with intentional INH overdoses, basic poison management, intensive supportive care, and a mean dose of 5 g of pyridoxine IV resulted in no fatalities.[8] Seizures were controlled in a 22-month-old boy given 100 mg of IV pyridoxine, after an estimated INH ingestion of 5 g.[41] Variable results are reported when relatively small doses of pyridoxine are used.[28] Seizures were reported in 2 patients following the ingestion of INH-pyridoxine combination tablets, although the actual amount of pyridoxine ingested was not noted.[39]

In addition to controlling seizures, the administration of pyridoxine also appears to restore consciousness. Two patients, who remained obtunded for as long as 72 hours after the apparent resolution of the seizures, were reported to awaken immediately after 3â€“10 g of IV pyridoxine was administered.[10] A third patient who was lethargic awakened with IV pyridoxine. This work

suggests that mental status abnormalities associated with INH overdose, and conceivably hydrazine overdoses, may be responsive to pyridoxine and also may require repetitive dosing.[11,42] Patients treated with large doses of pyridoxine awaken more rapidly even after experiencing sustained seizure activity or status epilepticus.

MMH poisoning can be encountered in a variety of clinical situations. In the aerospace industry, where MMH is used as a rocket propellant, percutaneous or inhalational poisoning may occur. Ingestion of the false morel mushroom, *G. esculenta*, can also produce toxicity when its major toxic compound, gyromitrin, is metabolized to MMH (Chap. 113).

The neurologic effects of MMH poisoning are similar to those of INH toxicity and include seizures and respiratory failure. Severe liver damage similar to INH-induced hepatotoxicity is also described.[15] As in the case of INH hepatotoxicity, there is no evidence that MMH-induced hepatotoxicity can be treated by administration of pyridoxine.[9]

A patient who was exposed to hydrazine became comatose 14 hours later and remained comatose for 60 hours until 25 mg/kg of pyridoxine aroused him.[23] Another case report describes improvement in the mental status of a confused, lethargic, and restless man who had ingested a mouthful of hydrazine and was treated with a 10-g dose of pyridoxine.[20] This improvement developed over 24 hours and may have been unrelated to pyridoxine therapy. A severe sensory peripheral neuropathy lasting for 6 months developed 1 week following the overdose and was most likely a result of the hydrazine ingestion and not the pyridoxine. Six patients exposed to an Aerozine-50 (hydrazine and UDMH) spill were effectively treated with pyridoxine after developing twitching, clonic movements, hyperactivity, or GI symptoms.[17]

Ethylene Glycol

PLP is a cofactor in the conversion of glycolic acid to nonoxalate compounds (Chap. 103). Patients poisoned with ethylene glycol should receive 100 mg/d of pyridoxine IV in an attempt to shunt metabolism preferentially away from the production of oxalic acid. This approach is supported by an animal model[6] and by the study of primary hyperoxaluria,[19] but has not been studied adequately in humans with ethylene glycol poisoning.[31]

Safety Issues

Pyridoxine is clearly neurotoxic to animals and humans when administered chronically in supraphysiologic doses.[23,24,32] Delayed peripheral neurotoxicity occurred in patients taking daily doses of 200 mg to 6 g of pyridoxine for 1 month.[30,34,35] Healthy volunteers given 1 or 3 g/d developed a small- and large-fiber distal axonopathy, with sensory findings and quantitative sensory threshold abnormalities occurring after 1.5 months in the high-dose and 4.5 months in the low-dose regimens. Once symptoms occurred, the pyridoxine was immediately stopped, but symptoms progressed for 2â€“3 weeks, leading to speculation that it took time for the reversal of neuronal metabolic manifestations.[7]

Pyridoxine may also induce a sensory neuropathy when massive doses are administered, either as a single dose or over several days.[1,25,41] Ataxia occurred in dogs receiving 1 g/kg of pyridoxine.[41] Larger doses of pyridoxine produce incoordination, ataxia, seizures, and death.[41] Death after pyridoxine administration was sometimes delayed for 2â€“3 days.[41] Two patients treated with 2 g/kg of IV pyridoxine (132 and 183 g, respectively) over 3 days developed severe and crippling sensory neuropathies.[1] One year later, both patients were unable to walk. Inadequate information is available to determine the maximal single acute nontoxic dose in humans; however, there appears to be a wide margin of safety. Doses of pyridoxine ranging from

70â€“375 mg/kg or doses equivalent to the milligram-per-kilogram historical dose of ingested INH have been administered without adverse effects.[42]

Dosing

Considering all of the available data, a safe and effective pyridoxine regimen for INH overdoses in adults is 1 g of pyridoxine for each gram of INH ingested, to a maximum of 5 g or 70 mg/kg. Initial doses of pyridoxine in children probably should not exceed 70 mg/kg.[42] These doses are sufficient in the majority of patients, but the dose can be repeated if necessary. The best way to administer pyridoxine in a patient after an INH overdose has not been

established. For a patient who is actively seizing, pyridoxine may be given by slow IV infusion at approximately 0.5 g/min until the seizures stop or the maximum dose has been reached. When the seizures stop, the remainder of the dose should be infused over 4â€“6 hours to maintain pyridoxine availability while the INH is being eliminated. The dose should be repeated if seizures persist or recur, or if the patient exhibits mental status depression. In the intravenous pyridoxine, pyridoxine should be administered orally.[33]

For hydrazine and methylated hydrazines (ie, MMH, UDMH) poisoning, there is no established dose.[45] Using the same dosage regimen as for INH is theoretically reasonable, but has never been tested in humans.

Pyridoxine should not be the sole agent used for INH or MMH poisoning. A benzodiazepine should be used with pyridoxine in an attempt to achieve synergistic control of seizures. If the seizures do not respond to both of these measures, they can be repeated, followed by intravenous agents such as propofol, pentobarbital, or phenobarbital, and, if necessary, neuromuscular blockade and

general anesthesia. When neuromuscular blockade is achieved without extinguishing the central nervous system (CNS) seizure activity, irreversible neuronal damage may result. Although metabolic acidosis is probably a result of the seizures and should therefore resolve once the underlying condition is controlled, severe or refractory metabolic acidosis may require appropriate quantities of sodium bicarbonate.

Availability

Pyridoxine HCl is available parenterally at a concentration of 100 mg/mL in 1-mL ampules from various manufacturers. Thus a 5-g IV dose of pyridoxine requires fifty 1-mL ampules containing 100 mg/mL. This is an exception to the rule that appropriate doses of medications rarely require multiple dosages of this magnitude. This also emphasizes the necessity of keeping an adequate supply available in the emergency department, as well as in the pharmacy. Oral pyridoxine is available in many tablet strengths from 10â€“500 mg from various manufacturers.

Chapter 56
Antimalarials

G. Randall Bond

A 30-year-old man stumbled into the emergency department (ED) appeari agitated. However, he was quite coherent. He complained of inability to s a continuous ringing in his ears, and the sensation of â€œa train rushing

He stated that he took â€œa bunch of pills,â€• drank some wine, and we before coming to the ED. On awakening approximately 6 hours later, he w balance.

His mother related an extensive family, medical, and social history: The taking many medications. In addition, he took â€œwater pills,â€• later i control hypertension. The patient, she said, took aspirin â€œfor arthritis,â for malaria.â€• She insisted that he used no illicit drugs and seldom drar packs of cigarettes per day. She further noted that he had been extreme loss of his unemployment benefits. In addition, he had had a quarrel on t

Physical examination revealed a well-developed, talkative, anxious man, v blood pressure, 100/40 mm Hg; pulse, 100 beats/ min; respiration, 18 97.2Â°F (36.2Â°C). The skin was warm, dry, anicteric, and without pallor

Ophthalmic examination revealed fixed, widely dilated pupils (right eye 7

unresponsive to light and accommodation. Assessment of visual acuity d of distant shadows but no perception of close objects. The fundi were ea were pale and flat. There was severe arteriolar constriction starting at th vessels. The veins appeared normal in diameter. The arteriovenous ratio movements were intact.

Examination of the ears revealed normal tympanic membranes. The patien fork on each side, but could not hear the ticking of a watch. The remainc was normal except for a soft systolic ejection murmur.

Blood samples were drawn and an electrocardiogram (ECG) was obtained. with dextrose 5% in water (D_5 W), and 1 g/kg of body weight of activate orally.

The initial laboratory data revealed a hematocrit of 37.6%; a hemoglobin blood cell count (WBC) of 8600/mm^3 with 80% polymorphonuclear cells, monocytes, and 1% eosinophils. The platelet count and international norr normal.

The electrolyte analysis revealed sodium, 143 mEq/L; potassium, 4.4 mE bicarbonate, 29 mEq/L; blood urea nitrogen (BUN), 9 mg/dL; and glucose phosphokinase (10,250 IU/L), lactic dehydrogenase (700 IU/L), and aspa IU/L) were all elevated. The urinalysis was normal, with a negative urine salicylates. The ECG showed a normal sinus rhythm at 96 beats/min, an a waves in leads II, III, and aVF. Peaked T waves were present in V2 to V4 were both normal. The chest radiograph was normal. The patient was adr unit.

The ophthalmic and auditory symptoms rapidly resolved without any addi addition, the pupillary and funduscopic examination returned to normal. T vasculature and color within 24 hours. Blood pressure returned to normal abnormal auditory and visual findings entirely resolved within 48 hours. subsequently discovered that he had taken ten (300-mg) quinine tablets, treatment of the *Plasmodium falciparum* malaria.

History and Epidemiology

The malaria parasite has caused untold grief throughout human history. T

population live in areas where malaria is endemic. More than 300 million infection, and 1 million die from the infection each year.[122] Included amor infected are 50 million travelers from industrialized countries who visit th year. In spite of using prophylactic medications (Table 56-1), 30,000 wi

The bark of the cinchona tree, the first effective remedy for malaria, was than 350 years ago.[107] The toxicity of its active ingredient, quinine, was use. In this century, the need to fight wars in malaria-infested areas, and pharmaceutical advances funded largely by the military during World Wa amodiaquine, pyrimethamine) and later during the Vietnam conflict (me Chloroquine, hydroxychloroquine, primaquine, amodiaquine, mefloquine, a related to quinine, but have different patterns of toxicity. Other xenobioti include the folate inhibitors proguanil and pyrimethamine (frequently used atovaquone), the sulfonamide sulfadoxine, or the sulfone dapsone, as wel macrolides (Chap. 54).

Quinine sulfate
Not used
650 mg tid Ã— 7 days[b]
Chloroquine phosphate
500 mg/wk as single dose
1000 mg STAT then 500 mg at 6 h, 24 h, and 48 h
Hydroxychloroquine sulfate
400 mg/wk as single dose
Rarely used
Primaquine phosphate
30 mg of base/d Ã— 14 days[c]
30 mg of base/d Ã— 14 days
Halofantrine
Not used
500 mg q6h Ã— 3 doses, repeat in 7 days
Amodiaquine
Not used
10 mg of base/kg/d Ã— 3 days
Mefloquine

250 mg/wk as single dose
750 mg STAT, then 500 mg 8 h later
Pyrimethamine-sulfadoxine
Not used
75 mg pyrimethamine + 1500 mg sulfadoxine as single dose
Artemisinin
Not used
10 mg/kg Ã— 7 days
Artesunate
Not used
2 mg/kg PO BID on day 1 then 2 mg/kg/d Ã— 6[d] or

2.4 mg/kg IV on day 1 then 1.2 mg/kg/d IV or PO Ã— 6 days
Artemether
Not used
3.2 mg/kg IM on day 1 then 1.6 mg/kg/d IM or PO Ã— 6 days
Artemether-lumefantrine
Not used
80 mg artomether + 480 mg lumefantrine at 0, 8, 24, 36, 48, and 60 h
Doxycycline
100 mg/day
100 mg BID[e]
Proguanil-atovaquone
100 mg proguanil + 250 mg atovaquone once per day
400 mg proguanil + 1000 mg atovaquone per day Ã— 3 days
Proguanil-chloroquine
200 mg proguanil + 100 mg chloroquine once per day
Not used
[a] Choice, duration, and dosage may vary with malarial species and freque
geographic area.
[b] Usually with doxycycline, tetracycline, or clindamycin for chloroquine-r
[c] After leaving *P. vivax* or *P. ovale* area.
[d] Often with mefloquine 15 mg/kg in a shorter course.

[e] With quinine sulfate for chloroquine-resistant cases.

	Quinine	Chloroquine	Primaquine	Mefloquine	Halofantrine

TABLE 56-2. Pharmacokinetic Properties of Antimalarials[a]

Pathophysiology

As in the case of quinidine, the anti- and prodysrhythmic effects of quinir effect on the cardiac sodium channels and potassium channels (Chaps. 23 blockade decreases inotropy, slows the rate of depolarization, slows conc potential duration. Inhibition of the rapid inward sodium current is increas (called *use-dependent blockade*), leading to a rate-dependent widening of the potassium channels suppresses the repolarizing delayed rectifier the rapidly activating component. The resultant increase in the effective dependent, causing greater repolarization delay at slower heart rates. Th predisposes to the development of torsades de pointes. As a result, syncc occur. In addition, syncope may be the result of vasodilation from the Î- quinine.

The mechanism of quinine-induced inhibition of hearing is multifactorial.[1] of the outer hair cells of the cochlea and organ of Corti occurs.[2 , 40] Addit local prostaglandin inhibition within the organ of Corti may contribute to Inhibition of the potassium channel may also be responsible for hearing lo that the homozygous absence of gene products that form part of some p Lange-Nielson syndrome) causes deafness and prolonged QTc intervals (C

The ophthalmic toxicity of quinine is most likely a direct retinal toxic effe studies demonstrate a rapid and direct effect on the retina (decreased p doses of quinine.[37] These early retinographic changes, as well as histolo and ganglion cell layers, provide evidence of direct damage.[37] Changes ir suggesting changes in the retinal pigment epithelium, parallel changes in electrophysiologic, angiographic, or morphologic experimental evidence fo felt to be contributory) has been found.[37 , 41] Quinine may also antagoni

neurotransmission in the inner synaptic layer.

Another effect of quinine is the inhibition of the adenosine triphosphate channels of the pancreatic Î² cells, which results in the release of insulin, sulfonylureas (Chap. 48).[26] The clinical significance of quinine-induced h limited to those patients receiving high-dose IV quinine and to patients v such as concurrent malaria, pregnancy, malnutrition, and alcohol consum

Clinical Manifestations

The margin between therapeutic and toxic dosing of quinine is very smal therapeutic doses often experience a syndrome known as â€œcinchonism, nausea, vomiting, decreased hearing acuity, tinnitus, headache, vertigo, tachycardia, diarrhea, and abdominal pain.[31 , 45 , 58 , 76 , 107] The skin m

The average oral lethal dose of quinine is 8 g, although a dose as small a death.[33 , 45] Delirium, coma, and seizures are uncommon, usually occurri overdoses.[14]

Cardiovascular manifestations of quinine use are related to myocardial dru those of quinidine.[11] They manifest on the ECG as prolongation of the PR QTc interval, and as ST depression with or without T-wave inversion.[11] Pa heart block or dysrhythmias.[11] Patients on high doses of quinine must be pointes, ventricular tachycardia, and ventricular fibrillation. Quinine toxicity significant hypotension, because of vasodilation and probably a concomita contractility.

Ophthalmic presentations include blurred vision, visual field constriction, color perception, mydriasis, photophobia, scotomata, and sometimes con Onset of blindness is invariably delayed and usually follows the onset of least 6 hours. The pupillary dilation that occurs is usually nonreactive an of visual loss. Vermiform motion or tonic pupil with denervation supersen Funduscopic examination may be normal, but usually demonstrates extre associated with optic disc and retinal edema. Normal arteriolar caliber ma manifestations such as vessel attenuation and disc pallor may develop as Improvement in vision can occur rapidly, but is usually slow, occurring ov severe exposure. Initially, improvement occurs centrally and is followed la

peripheral vision. The pupils may remain dilated even after return to nor greatest exposure may develop optic atrophy.

Eighth-nerve dysfunction results in tinnitus and deafness. This causes a r acuity with a flattening of audiograms. The decreased acuity is not usua the patient recognizes tinnitus.[91] These findings usually

resolve within 48â€“72 hours, and permanent hearing impairment is unli

Although mild hyperinsulinemia may occur, hypoglycemia is rare following , [55] , [119] Hypoglycemia with elevated plasma insulin levels following therap patient with severe congestive heart failure,[55] and in a healthy patient w quantity of alcohol.[55] It also has occurred in a healthy patient following

A number of hypersensitivity reactions are described. These are the resul antiquinineâ€“hapten antibodies cross-reacting with a variety of membra Asthma sometimes occurs. Dermatologic manifestations include urticaria cutaneous vasculitis, lichen planus, and angioedema.[90] Hematologic mani are rare, but include thrombocytopenia (Chap. 24), agranulocytosis, mi anemia, and disseminated intravascular coagulation (DIC), which can lea and renal failure.[49] , [95] Hemolysis may also occur in patients with gluco deficiency. Hepatitis is a rare hypersensitivity reaction.[30] Acute respirator and a sepsislike syndrome are also reported.[52]

Diagnostic Testing

Urine thin-layer chromatography is sensitive enough to confirm the prese the ingestion of tonic water.[119] However, this test might not reliably diff quinidine, if the latter is a clinical possibility.

Immunoassay techniques are the most reliable, but quantitative serum tes available. Quinidine immunoassays cannot be substituted. In any case, no be used to determine a unique management intervention, although serum higher in individuals who develop severe toxicity, including blindness. Af serum quinine levels greater than 10 Âµg/mL are associated with tempora Âµg/mL are associated with increased risk of permanent visual damage,[11 [45] Similar levels in individuals who are severely ill with malaria do not re

because of the increase in Î±$_1$ -acid glycoprotein and consequent reductio present.[94 , 99]

Management

Although patients may frequently vomit on their own, emetic agents shoul dysrhythmias, and hypotension can occur rapidly. Because activated char quinine, orogastric lavage should only be performed for patients with rec and no spontaneous emesis. Otherwise, standard overdose management activated charcoal (1 g/kg), and supportive techniques such as oxygen, c infusion, and dextrose as needed. Because toxic manifestations are seru measures to enhance elimination may be effective in preventing or reduc

Cardiac

The cardiotoxic manifestations of quinine make the choice of serum alka intervention. In a case report of a patient with quinine overdose, alkalin was dramatically effective in narrowing the QRS complex, but torsades d perhaps because of hypokalemia combined with quinine-induced potassiu torsades de pointes was responsive in this case only to an overdrive pac should only be given if there is a clear indication of cardiotoxicity. Prolong be treated with sodium bicarbonate alkalinization to achieve a serum pH done in the patients with cardiotoxicity associated with cyclic antidepress Depth: Sodium Bicarbonate). Hypertonic sodium bicarbonate may result exacerbating the effect of potassium channel blockade. The QTc should b prolongation. If necessary, interventions for torsades de pointes, includi potassium supplementation, and overdrive pacing, should be initiated (Ch

Class IA, IC, or III antidysrhythmic agents, those with sodium channel- blocking activity, should not be used to treat a quinine-, quinidine-, or because they may exacerbate the toxin-related conduction disturbances o agents, such as lidocaine, may be useful (Chap. 61).

Extracorporeal membrane oxygenation (ECMO) was used in one case of s bradydysrhythmia and refractory hypotension[105] to stabilize the cardiovas quinidine-activated charcoal bezoar was removed, and the patient metab

A similar approach should be considered for intractable quinine toxicity.

Ophthalmic

Funduscopic examination, visual field examination, and color testing may diagnostic studies. Electroretinography, electrooculogram, visual-evoked p adaptation may be helpful in assessing the injury, but are not practicable equipment that is not portable or readily available in most clinical setting effective treatment for quinine retinal toxicity.[37 , 38] Hyperbaric oxygen (H who recovered vision, but the role of HBO in that recovery was not estab

Hypoglycemia

Serum glucose should be supported with an adequate infusion of dextrose QTc interval should be monitored during correction and maintenance. Diaz serum glucose.[80] Octreotide, a somatostatin analog that blocks insulin sec hypoglycemia. It was administered intravenously in a dose of 50 Âµg/h t hyperinsulinemia in adult malaria victims.[80 , 81] In volunteers, quinine-in suppressed within 15 minutes following a 100-Âµg intramuscular dose of Depth: Octreotide).[81]

Enhanced Elimination

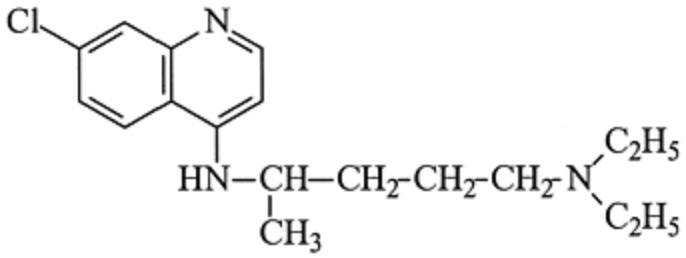
The effect of multiple-dose activated charcoal (MDAC) on quinine eliminati experimental human model as well as in symptomatic patients.[59 , 84] In t decreased the half-life of quinine from approximately 8 hours to about 4. clearance by 56%.[84] Although numerous studies show that activated char life,[8 , 57 , 84] it is unclear whether this reduction in half-life improves cl because ophthalmic, CNS, and cardiovascular toxicity are related to serur to reduce concentrations as quickly as practicable; thus, activated charco administered every 2â€“4 hours unless otherwise contraindicated.

There is conflicting evidence about a benefit of urinary acidification in en However, because of the increased potential for cardiotoxicity associated technique is never recommended. Forced diuresis is similarly not helpful a

single study, the mean half-life of quinine in the forced acid diuresis grou compared to 26.5 hours in the control group.[8]

Because quinine has a relatively large volume of distribution and is highl dialysis, hemoperfusion, hemodialysis, and exchange transfusion have only removal.[8,14,62,68,94,107] Although the blood compartment can be cl these techniques, total body clearance is only marginally altered. After tl occurs, there is little impact on the total body burden because of the rela distribution and the very extensive protein binding.

Chloroquine, Hydroxychloroquine, and Am



Chloroquine

The structurally related compounds chloroquine and amodiaquine were on malaria prophylaxis. However, with the development of resistance, they a regions. Amodiaquine is also rarely used because of a higher incidence o

Hydroxychloroquine is similar to chloroquine in therapeutic, pharmacokin properties.[32,62] The side-effect profiles of the two are slightly different, malarial prophylaxis and hydroxychloroquine use as an antiinflammatory

Pharmacokinetics and Toxicodynamics

Oral chloroquine is rapidly and completely absorbed (Table 56-2) and is tissues, particularly kidney, liver, and lung, and to erythrocytes.[13,40] Co very large apparent volume of distribution of >100 L/kg.[107] Whole-blood reflects tissue distribution and correlates with mortality.[22] About half of eliminated in the urine, as much as 70% as the parent molecule, and the

hepatic metabolites.[54, 62] An exceedingly long half-life, averaging 41 da
Hydroxychloroquine has a similarly rapid absorption and a half-life of 40
However, half-life in overdose is reported to be 15â€“30 hours.[47]

Pathophysiology

Like quinine, chloroquine has a small toxic-to-therapeutic margin. Severe
usually associated with ingestions of 5 g or more in adults, or with serur
Âµg/mL. The cardiovascular effects of chloroquine and hydroxychloroquine
quinine, including QRS prolongation, atrioventricular (AV) block, ST- and
U waves, and QTc interval prolongation, but other features of cinchonism
xenobiotics have low toxicity when used in therapeutic doses. Because of
first-line drug for malaria prophylaxis and treatment in areas where *Plasr*
changes are not described with prophylactic doses but occur rarely with
hydroxychloroquine for arthritis. The variation in individual risk for this
understood. Recent evidence suggests an early, pathological role for mer
the ganglion cells of the retina.[70] Melanin granules are also noted in the
the retina, but this occurs late.[58, 70] A related process involving skin me
pruritus frequently noted in Africans who use these drugs (8â€“20%).[58]

In some hosts, amodiaquine metabolism produces a quinone imine metabo
hapten to induce a hypersensitivity reaction.[16] This has led to reduced us
prophylactic agent, particularly among Western travelers. Nonetheless, the
tropical countries for treatment of acute and chronic malaria.

Clinical Manifestations

Symptoms usually occur within 1â€“3 hours of ingestion.[88] The range of
chloroquine toxicity is quite similar to quinine, but the frequencies of va
Nausea, vomiting, diarrhea, and abdominal pain are less common than w
depression often occurs. Apnea, hypotension, and cardiovascular compron

Hypotension is a more prominent feature than with quinine.[45] Electrocardio
associated with chloroquine use include QRS prolongation, AV block, ST-
increased U waves, and QTc interval prolongation, but these are less frec
Significant hypokalemia is invariably associated with the cardiac manifes

results from direct chloroquine-induced intracellular shifts.

The neurologic manifestations include CNS depression, dizziness, headach dystonic reactions occur.[77] Transient parkinsonism has been reported fol

The ophthalmic manifestations are infrequent in acute toxicity, usually le in nature.[45 , 58] More severe and irreversible vision and hearing changes with the use of chloroquine and hydroxychloroquine as antiinflammatory neuropathy, and cardiomyopathy also are described in this context.[5 , 114 hypersensitivity reactions similar to those associated with quinine are de oxidant stress from chloroquine may result in hemolysis in patients with dehydrogenase (G6PD) deficiency (Chap. 24).

Acute hydroxychloroquine toxicity is similar to chloroquine toxicity.[47 , 63 doses include nausea and abdominal pain, hemolysis in G6PD-deficient pa damage, sensorineural deafness, and hypoglycemia.[10 , 46 , 98] Hypersensit myocarditis and hepatitis, are described.[34 , 61]

One report of amodiaquine toxicity suggests that neurologic toxicity incl muscle stiffness, dysarthria, syncope, and seizures may occur.[45] Amodiaq hypersensitivity hepatitis and neutropenia in prophylactic use, but not th overdose experience reported.

Management

Early, aggressive management of severe chloroquine toxicity decreased th from 91% to 9%.[88] The protocol involves the use of epinephrine for ch and myocardial depression, and diazepam for possible direct cardiovascula minimize CNS-based cardiac excitation.[89] Other experiences validate this

Patients should receive early endotracheal intubation and mechanical ven used to facilitate intubation, its use immediately preceded sudden cardiac after chloroquine overdose.[22] An adequate FiO_2 , tidal volume, and venti Orogastric lavage should be performed for patients with recent and subs charcoal should be administered. During decontamination, 2 mg/kg IV dia minutes, and then 1â€“2 mg/kg/d for 2â€“4 days. Simultaneously, epine should be given IV with D_5 W, and adjusted incrementally until a systolic

100 mm Hg is achieved. Even after this initial therapy, some patients ma cardiovascular compromise and require additional epinephrine and other complex width is increased, sodium bicarbonate should be administered a potassium concentrations should be monitored and potassium supplemen aggressive replacement therapy is discouraged, because hypokalemia rep total-body potassium depletion.[21 , 45 , 47]

Because chloroquine and hydroxychloroquine have high volumes of distri binding, and long terminal elimination half-lives, enhanced elimination pr [, 45]

Primaquine

Pathophysiology

Primaquine causes RBC oxidant stress. Clinically insignificant methemoglo Methemoglobinemia and hemolysis can occur in normal individuals given toxicity of primaquine in therapeutic use has been hemolysis in G6PD-de contraindicated in pregnant women because the fetal G6PD status is unk suppression can occur.

Clinical Manifestations

Overdose with primaquine is rarely reported. Nausea, headache, and abd A case of extreme, iatrogenic overdose (1260 mg followed by 15 mg/d for hallucinations, abdominal cramps, nausea, jaundice, hepatitis, and black 7.4 mg/dL. Aminotransferases peaked at aspartate aminotransferase (AST) aminotransferase (ALT) 2654 IU/L. Renal function, hemoglobin, and white reported. Resolution occurred over 1 month.

Management

In the event of overdose, therapy should be directed at minimizing abso decontamination, reversing significant methemoglobinemia with methylene Antidotes in Depth: Methylene Blue), supporting adequate circulating red

necessary, and preventing hemoglobin-induced renal injury by maintaining alkalinizing the urine to a pH greater than 6, if necessary (Chap. 10 , Ant Bicarbonate , and Antidotes in Depth: Activated Charcoal).

Mefloquine

Pharmacokinetics and Toxicodynamics

Mefloquine is slowly absorbed (Table 56-2).[96] Absorption is enhanced wit protein bound and has a very large volume of distribution (22 L/kg).[49 , 9 in an inactive metabolite, with a terminal elimination half-life of 18 days variation occurs.[96] Because it has such a long half-life, it may take sever state, delaying the onset of toxic manifestations.

Clinical Manifestations

Common effects with prophylactic and therapeutic dosing include nausea, These effects are noted particularly in children and older adults, or with are expected in acute overdose.[90 , 116]

Mefloquine has a mild cardiodepressant effectâ€”less than that of quinine clinically significant in prophylactic dosing or with therapeutic administrat neither the PR interval nor the QRS complex is prolonged, but QTc prolo Clinically insignificant bradycardia is common.[58 , 74] Reports of torsades increase in QTc and risk of torsades de pointes are increased when meflo chloroquine, or, most particularly, with halofantrine.[58 , 73 , 74] Risk is als acute overdose. The long half-life of mefloquine, about 18 days, means th taken with therapeutic use of these xenobiotics when breakthrough mala prophylaxis, or within 28 days of mefloquine therapy. Given the lack of quinine is often used.

During prophylactic use, many patients experience insomnia, an alteration dizziness, headache, fatigue, mood alteration, and vertigo.[96 , 110] In only effects significant enough to cause the traveler to â€œfeel sickâ€• or to [97] Intolerance occurs more commonly in women.[7 , 79 , 110] Seizures occur and therapeutic use.[83 , 92] In many of these cases, there is a history of

first-degree relative, or other risk factors. Other neuropsychiatric sympto â€œcloudedâ€• consciousness, toxic encephalopathy, anxiety, depression, delirium with psychosis, comprise the bulk of serious adverse event repor related to the serum or CNS concentration. The frequency of hallucination about 1:10,000 with prophylaxis to as high as

1:200 with therapeutic dosing.[25,90] In at least one case report, the se manifestations of mefloquine were reversed with physostigmine, suggesti etiology.[102] Risk of CNS toxicity is increased by administration of quinine mefloquine. A self-resolving postmalaria neurologic syndrome including c tremor is associated with therapeutic use of mefloquine for severe malari

The effect of mefloquine on the pancreatic potassium channel is much less resulting in only a mild increase in insulin secretion.[26,27] Symptomatic h reported as an effect of mefloquine alone in healthy individuals, but has of alcohol and in a severely malnourished patient with AIDS.[4,27,58] In accompanied by alcohol use or recent starvation, this hypoglycemia may

Rare events reported with prophylaxis include urticaria, alopecia, erythem necrolysis, myalgias, mouth ulcers, neutropenia, and thrombocytopenia.[6] likely hypersensitivity reactions. It is unclear which, if any, would be sign large dose ingestion. ARDS was linked to therapeutic dosing in 1 case.[108]

In therapeutic use, mefloquine is associated with an increased incidence quinine and a group of other antimalarial medications.[75] Mefloquine was n increased incidence of abortion, low birth weight, mental retardation or implications for an overdose in the absence of malaria are not clear, but instituted.

In contrast, the consequences of excessive dosing are not only severe, b permanent. Two cases of daily mefloquine overdosing resulted in confusi speech difficulties, and high-frequency hearing loss in 1 case, and nausea depression, disorientation, and paresthesia in the other. In the first case, year, except for residual hearing loss.[56] In the second case, symptoms p another case, a man ingested 5.25 g of mefloquine over 6 days.[15] Sympto myalgia, vertigo, visual accommodation difficulties, mild hypotension (90/5 beats/min) with occasional ventricular premature complexes, minimal incre

and prolonged INR. His symptoms resolved over 5 days, except for the v 2 months. The INR corrected over 2 weeks. In this case, cardiovascular s significant than were neurologic symptoms. A fourth man ingested mefloc 3250 mg, and sulfadoxine-pyrimethamine 175 mg/3500 mgâ€”2.5 times t eachâ€”over 3 days.[18] He suffered encephalopathy that was unresolved 8 patient took mefloquine 2 g over 2 days (the usual therapeutic dose is 1: malaria.[72] At presentation he experienced nausea, constipation, and abdor headache, vertigo, insomnia, anxiety, confusion, hallucinations, and paran findings. ECG and laboratory findings were normal. No other drugs were d elevated mefloquine level of 1.8 Âµg/mL (upper limit of therapeutic 1 Âµ with only supportive care.

Management

In overdose, supportive care is the primary therapy. Decontamination wit indicated if the patient presents soon after the ingestion. Specific monito hypoglycemia, and liver injury should be provided. Patients should be foll nerve complications.

In 2 renal-failure patients taking mefloquine, prophylactic hemodialysis di Given the large volume of distribution and high degree of protein binding unlikely to be effective.

Halofantrine

Pharmacokinetics and Toxicodynamics

Halofantrine is slowly and incompletely absorbed (Table 56-2).[17 , 45] It i metabolite, *N* -desbutylhalofantrine.[17] The half-life of halofantizine is 1â€ the QTc interval is proportional to the dose and serum halofantrine conc percent of children receiving a therapeutic course of halofantrine will have msec.[101]

Clinical Manifestations

The primary toxicity from therapeutic and supratherapeutic doses is torsa fibrillation associated with prolongation of the QTc interval.[23 , 39 , 73 , 10 and syncope may occur. First-degree heart block is common, but bradyca QTc interval duration is related to serum concentration, dysrhythmias wou Dysrhythmias are also likely in the context of combined overdose or con with other drugs that cause QTc interval prolongation, particularly meflo

Other side effects, including nausea, vomiting, diarrhea, abdominal cramp headedness, which frequently occur in therapeutic use, are also expected frequently described side effectsâ€”pruritus, myalgias, and rigorsâ€”can oc seizures, minimal liver enzyme concentration elevation, and hemolysis ar Whether these manifestations are related to halofantrine or to the underl

Management

Management of halofantrine overdose should also focus on decontaminati monitoring for QTc interval prolongation and associated dysrhythmias. Trea prolonged QTc interval and torsades de pointes is discussed above under

Proguanil, Pyrimethamine, Sulfadoxine, Dap Atovaquone

Pharmacokinetics and Toxicodynamics

Proguanil, pyrimethamine, sulfadoxine, and dapsone all interfere with fola used in combination. Proguanil (chloroguanide) may be used alone, but is (Lapdap), chloroquine, or the antiparasitic atovaquone (Malarone) for pr the de novo pyrimidine synthesis that is necessary for protozoal survival unnecessary in mammalian cells. Based on the relative side-effect profile, physicians are

switching from mefloquine to atovaquone/proguanil for routine antimalari Atovaquone and proguanil may now be the most common antimalarial age Pyrimethamine is used in combination with sulfadoxine (Fansidar) or with growing malarial resistance has limited the usefulness of these two drug

for pharmacokinetic profile). Genetic polymorphism is described in the m dapsone.[48 , 87] This may be the cause of the significant hypersensitivity dapsone.[87]

Clinical Manifestations

Information on proguanil overdose is limited. The side effects of proguan nausea, diarrhea, and mouth ulcers.[58] Because of interference with folate rare complication. Folate supplementation may be required in pregnancy neutropenia, thrombocytopenia, rash, and alopecia are also noted.[25] In a hypersensitivity hepatitis was described.[25] When used to treat malaria, vomiting, sometimes severe, in a significant portion of patients (15â€“45 associated with elevated liver function tests.[90]

Atovaquone alone, primarily used to treat *Pneumocystis carinii* in AIDS p tolerated.[78] Side effects include maculopapular rash, erythema multiform complaints, and mild aminotransferase elevations. Three cases of 3- to 4 dosing have been reported.[20] No symptoms occurred in 1 case (at 3 tim Rash occurred in another, and in the third case, methemoglobinemia was overdose of dapsone.

Dapsone and the sulfonamides have a long history of causing idiosyncrat neutropenia, thrombocytopenia, eosinophilic pneumonia, aplastic anemia, [90] The rare occurrence of life-threatening erythema multiforme major, a sulfadoxine prophylaxis, has limited the use of this combination for prop

Acute ingestion of dapsone may result in nausea, vomiting, and abdomina dapsone produces RBC oxidant stress leading to methemoglobinemia and, sulfhemoglobinemia (Chap. 122).[19 , 59] The onset of hemolysis may be delayed.[121] Other symptoms, particularly tachycardia, dyspnea, dizziness seizure, syncope, and coma resulting from end-organ hypoxia, can occur. described in overdose include hepatitis and peripheral neuropathy.[45]

Overdose of pyrimethamine alone is rare. In children, it results in nausea seizures, fever, and tachycardia.[1 , 45] Blindness, deafness, and mental re Seizures were attributed to sulfadoxine-pyrimethamine in an overdose of 1 dose is 3 tablets taken once).[72] Chronic high-dose use may be associated

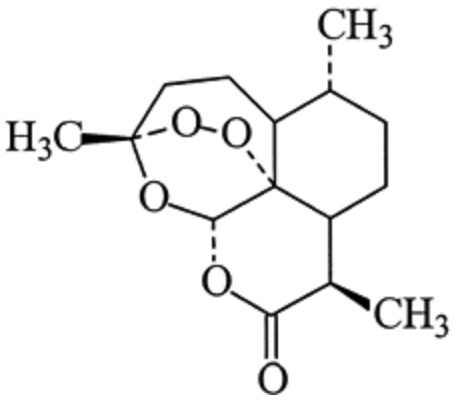
requiring folate replacement (Chap. 24 and Antidotes in Depth: Folic Acid).[1]

Management

Folate supplementation should be considered after overdose of proguanil in Depth: Folic Acid and Leucovorin [Folinic Acid]). Other efforts should

Following dapsone ingestion, clinically significant methemoglobinemia shou blue (Antidotes in Depth: Methylene Blue). Sulfhemoglobinemia is irreve insignificant portion of total hemoglobin. Both hemodialysis and multidose elimination of dapsone during therapy.[71 , 121] Multidose activated charcoa the treatment of dapsone overdose.[3] Required support may include RBC alkalinization if hemolysis is extensive (Antidotes in Depth: Sodium Bicar

Artemisinin and Derivatives



Artemisinin

Pharmacokinetics and Toxicodynamics

Artemisinin and its derivatives: artemether, arteether, dihydroartemisinin the Chinese herb qinghaosu. They were introduced in the 1980s in China and since then millions of doses have been used in Asia and Africa.

The parent drug artemisinin has poor solubility and limited bioavailablilty

absorption and some may be used parenterally, but are rapidly degraded half-life. Because these xenobiotics have a short half-life, prolonged cours prevent recrudescence of malaria. To provide a shorter, more effective tr emergence of malarial resistance, artemesinins are frequently used in co Recently the oral combination drug artemether/lumefantrine was introduc evaluating a combination of artemisinin and naphthoquine.[112]

The efficacy and toxicity of artemisinin is thought to be a result of the al core to form intracellular free radicals, particularly in the presence of hen brainstem nuclei is consistently produced following prolonged, high-dose These findings are associated with prolonged CNS exposure to parenteral xenobiotics.[35 , 90] Embryonic loss has also been observed in animals.[90]

Clinical Manifestations

In contrast to the experience with animals, the experience of more than shows that these xenobiotics have a very low incidence of side effects.[90] include nausea, vomiting, abdominal pain, diarrhea, and dizziness.

Prospective studies have failed to identify an increased incidence of adve particularly related to the brainstem.[51 , 90] Rare reports of adverse CNS suggest the possibility of CNS depression, seizures, or

cerebellar symptoms following intentional self-poisoning. In children with incidence of seizures and a delay to recovery from coma were noted in a neurologic difference was noted in long-term follow-up. In an artemether adults with severe malaria, recovery from coma was also prolonged in th number (<1%) of patients receiving an artemisinin derivative in two oth transient dizziness or cerebellar signs.[66 , 85] Most recovered within days. suffered prolonged symptoms, 1 month and 4 months, respectively, but [85] The attribution of these symptoms to artemisinin compounds, as oppos malaria, is debatable.

When serial ECGs were obtained, a small, but statistically significant fall i coincident with peak drug levels.[66] In one therapeutic trial, 7% of adult had an asymptomatic QTc interval prolongation of at least 25%.[43] Change

noted.

In contrast to the effects of quinine therapy, hypoglycemia is not reporte neutropenia, reticulocytopenia, anemia, eosinophilia, and elevated concer aminotransferases.[90]

There is little experience with the toxicity of lumefantrine alone. Lumefa related to mefloquine and halofantrine, but similar toxicity has not been product artemisinin-lumefantrine is well tolerated.[117] Studies of the com lumefantrine do not show an increase in QTc or evidence of cardiac toxic [111] Cough and angioedema were described in one case.[53]

Management

Overdose patients should be managed with supportive measures and exp cardiovascular monitoring. CNS manifestations are the most likely.

Summary

A variety of xenobiotics are used in the prevention and treatment of mala consequently, the most widely available xenobiotics, change rapidly with resistance. Most antimalarials have significant toxicity in acute overdose. are related to quinine, even within the quinine group, the pattern of prec xenobiotic dependent. Effects at the low doses associated with prophylaxi vomiting, headache, and confusion. Autoimmune-mediated idiosyncratic re most of the antimalarials. In overdose, cardiovascular, neurologic, and h predominate. Dysrhythmias are the effects that are the most life-threate derivatives and especially with chloroquine. These result from sodium ch potassium channel blockade, and myocardial depression. Other significant and neurologic injury, particularly to the special senses. Primaquine and oxidant stress resulting in methemoglobinemia. Little is known of the acu agent, artemisinin.

Decontamination, including the administration of activated charcoal, is r specific symptoms are anticipated and specific management strategies fol resulted, particularly for chloroquine poisoning. Multidose activated charc for quinine and dapsone ingestions.

Chapter 57
Anticoagulants

Mark Su

Robert S. Hoffman

A 66-year-old man presented to the emergency department with a compl of 24 hours of lower abdominal pain that radiated to his left groin. The pa had increased in intensity and resulted in syncope. His past medical histo was significant for atrial fibrillation, hypertension, congestive heart failur colonic polyps, diverticulosis, cataracts, and sciatica. His medications inc warfarin 2.5 mg daily, oxybutynin chloride 2 mg twice daily, labetalol 300 three times daily, quinapril 40 mg daily, rofecoxib 25 mg daily, and zolpi 10 mg as needed for sleep.

On physical examination, he was awake and alert, but ill appearing and p Vitals signs were blood pressure, 101/38 mm Hg; pulse, 92 beats/min; respiratory rate, 18 breaths/min; temperature, 98.6Â°F (37Â°C); symptomatic orthostasis was present. Examination of the head, eyes, ear nose, and throat was unremarkable. His chest was clear to auscultation bilaterally, and heart examination revealed an irregularly irregular rate. T patient's abdomen was noted to be moderately distended and tender in th left upper quadrant and left flank with scrotal edema. Rectal examination

testing for occult blood were negative. The skin and extremities were nor with no evidence of petechiae or ecchymoses.

The patient was immediately given 100% oxygen via a non-rebreather m treated with intravenous 0.9% sodium chloride via 2 large-bore catheters and blood was drawn for laboratory studies. An electrocardiogram demonstrated atrial fibrillation, at a rate of approximately 100 beats per minute, without evidence of acute myocardial ischemia or infarction.

Initial laboratory studies showed a white blood cell (WBC) count of $14,000/mm^3$, hemoglobin 10.3 g/dL, hematocrit 32.1%, and platelets $317,000/mm^3$. The initial prothrombin time (PT) was 66.7 seconds (international normalized ratio [INR] of 5.7), and activated partial thromboplastin time (PTT) was 81.4 seconds. Urinalysis revealed a specif gravity of 1.025; small bilirubin; trace ketones; 100 mg/dL protein; and red blood cells.

After discovering the patient's coagulopathy, he was given 10 mg of vitar K_1 subcutaneously. He was also given 4 units of fresh-frozen plasma base his weight and then taken emergently for a noncontrast abdominal compu tomography (CT) scan of the abdomen, which revealed a large retroperit hematoma, extending from the inferior pole of the spleen into the pelvis 57-1). On repeat abdominal computed tomography scan with contrast 3 hours later, the retroperitoneal hematoma was noted to have increased in size.

The patient was admitted to the surgical intensive care unit where his re coagulation studies were significant for a PT of 27 seconds, an INR of 2.3 and a PTT of 56.2 seconds. His hematocrit decreased to 22.6%, and he received an additional 6 units of fresh-frozen plasma and 6 units of packe red blood cells prior to surgery. Intraoperatively, a large hematoma with was evacuated and although no active bleeding was visualized at the time the retroperitoneal blood was believed to originate from his psoas muscle The patient had an uneventful course postoperatively and was discharged home 5 days later.

History and Epidemiology

Anticoagulants have numerous clinical applications, including the treatmer coronary artery disease, cerebrovascular events, deep venous thrombosis and pulmonary embolism.

The origins and discovery of anticoagulants are extraordinary.[1, 18, 74] The discovery of modern-day oral anticoagulants originated following investigations of a hemorrhagic disorder in Wisconsin cattle in the early 2 century that resulted from the ingestion of spoiled sweet clover silage. Th hemorrhagic agent, eventually identified as bishydroxycoumarin, would be precursor to its synthetic congener warfarin (named after the *W* isconsin lumni *R* esearch *F* oundation). This knowledge also led to the use of warf as a rodenticide. â€œSuperwarfarinsâ€• were subsequently developed as selective pressure caused rats to develop genetic resistance to warfarin. These potent agents permitted either small, repetitive ingestions or singl larger ingestions to successfully function as rodenticides.

Like warfarin, the origins of the anticoagulant heparin are equally fascina A medical student initially attempting to study ether-soluble procoagulant agents derived from porcine intestines,

serendipitously found that, over time, these apparent â€œprocoagulantsâ actually prevented the normal coagulation of blood. The phospholipid anticoagulant responsible for this effect would later be identified as an ea form of heparin. Shortly thereafter, the water-soluble mucopolysaccharid termed *heparin* (because of its abundance in the liver) was then discover *Unfractionated* heparin is a mixture of polysaccharide chains with varying molecular weights. Following the identification of the active pentasacchar segment of heparin in the 1970s, multiple *low-molecular-weight* heparins were isolated and synthetic forms created.

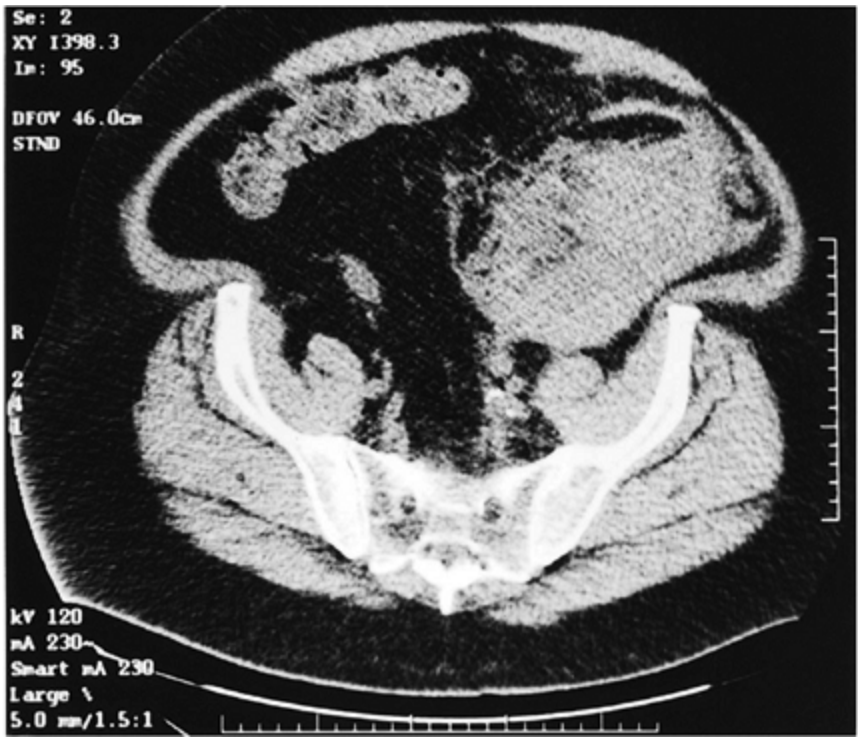

Figure 57-1. Abdominal CT scan illustrating a large left-sided retroperit hematoma in a patient with an INR of 5.7 presenting with left flank pain radiating to the groin.

In the late 19th century, human urine was noted to have proteolytic activ with a specificity for fibrin. A substance found to be an activator of endogenous plasminogen leading to the consumption of fibrin, fibrinogen, other coagulation proteins was isolated and purified and given the name *urokinase.* Streptokinase, a protein produced by Î²-hemolytic streptococc tissue plasminogen activator (t-PA), and other synthetic thrombolytic age were later discovered. Although known to exist for many years, ancrod (Arvin; a purified derivative of snake venom) and hirudin (a product of leeches) only recently gained attention as naturally occurring antithromb therapeutic agents.

The diversity of these anticoagulant and fibrinolytic agents has led to eve increasing use in many fields of medicine. Warfarin is the most common anticoagulant in use today because of its uses in patients with cerebrovascular disease, cardiac dysrhythmias, and thromboembolic dise

During the period of 1999â€“2003, the total number of cases of reported warfarin exposures to the Toxic Epidemiologic Surveillance System was 11,544 with 22 deaths (Chap. 130). Throughout this time, there was a general trend toward an increasing number of reports. Additionally, beca the common problem of excessive warfarin effects leading to hemorrhage poorly quantitated as an adverse drug reaction, it frequently goes untabulated. Thus, as long as warfarin continues to be routinely prescribe is likely that the incidence of adverse drug events will increase. Physician must be cognizant of the complications of warfarin and other anticoagula as well as their various therapeutic modalities, while balancing the poten for their risk and benefits.

Physiology

Balance Between Coagulation and Anticoagulation

An understanding of the normal function of the coagulation pathways is essential to appreciate the etiology of a coagulopathy. This section summarizes the critical steps of the coagulation cascade. For additional detail, the reader is referred to Chap. 24 and several reviews.[64 , 125 , 15

Coagulation consists of a series of events that prevent excess blood loss assist in the restoration of blood vessel integrity. Although the traditional understanding of the events that occur in the coagulation cascade,[49 , 110 discussed below, adequately describe in vitro events, the current understanding emphasizes some distinct differences that occur in vivo.[64 , 151] Despite these differences, an understanding of the traditional model most useful for interpreting the results of diagnostic tests of coagulation.

Within the cascade, coagulation factors exist as inert precursors and are transformed into enzymes when activated. Activation of the cascade occu through one of two distinct pathways, the intrinsic and extrinsic systems 57-2).[49 , 110] Once activated, these enzymes catalyze a series of reactio that ultimately converge and lead to the generation of thrombin and the

formation of a fibrin clot.

The intrinsic pathway is activated by the complexation of factor XII (Hag factor), with high-molecular-weight kininogen (HMWK) and prekallikrein, vascular subendothelial collagen. This results in sequential activation of XII, active kallikrein, active factors IX to XI, and prothrombin (factor II) 57-2). Prothrombin is converted to thrombin in the presence of factor V, calcium, and phospholipid. The integrity of this system is usually evaluate determining the partial thromboplastin time (PTT).

In the extrinsic, or tissue factor-dependent pathway, a complex is formed between factor VII, calcium, and tissue factor, which is released following injury. A calcium and lipid-dependent complex is then created between fa VII and X. The factor VII-X complex subsequently converts prothrombin t thrombin, which promotes the formation of fibrin from fibrinogen (Fig. 57 The integrity of this pathway is usually assessed by determining the prothrombin time (PT or INR).

Activation of factor X provides the important link between the intrinsic ar extrinsic coagulation pathways. Additional evidence that tissue factors ca activate both factors IX and X suggests that there are more interrelations between the two pathways.[137] Furthermore, cell surfaces facilitate the process of clotting. Platelets are also known to interact with proteins of t coagulation cascade through surface receptors for factors V, VIII, IX, and X.[67, 114, 168] As a final step, factor XIII assists in the cross-linking of fi to form a stable thrombus.

Antithrombin III (AT), protein C, and protein S serve as inhibitors, maintaining the homeostasis that is required to prevent spontaneous clot and keep blood fluid. Protein C, when aided by protein S, inactivates two plasma factors, V and VIII.[27, 41, 64] AT complexes with all the serine protease coagulation factors (factor Xa, factor IXa, and contact factors, including XIIa, kallikrein, and HMWK), except factor VII.[27, 64, 151]

Thrombolytic agents such as streptokinase, urokinase, anistreplase, and recombinant tissue plasminogen activator (rt-PA) enhance the normal processes that lead to clot degradation.[125]

Thrombosis is initiated when exposed endothelium or released tissue fact leads to platelet adherence and aggregation, the formation of thrombin, a cross-linking of fibrinogen to form fibrin

strands.[64 , 125 , 151] This results in a hemostatic plug or thrombus forma Thrombus formation, in turn, leads to generation of plasmin from plasminogen, which causes fibrinolysis and eventual dissolution of the hemostatic plug.[43 , 44] Thus the fibrinolytic system may be thought of as natural balance against unregulated coagulation. Thrombolytic therapy increases fibrinolytic activity by accelerating the conversion of plasminoge plasmin, which actively degrades fibrin.[43 , 44] Following the administration thrombolytic agents, a consequential drug-induced coagulopathy ensues, fibrin degradation products are elevated secondary to the rapid turnover clot.

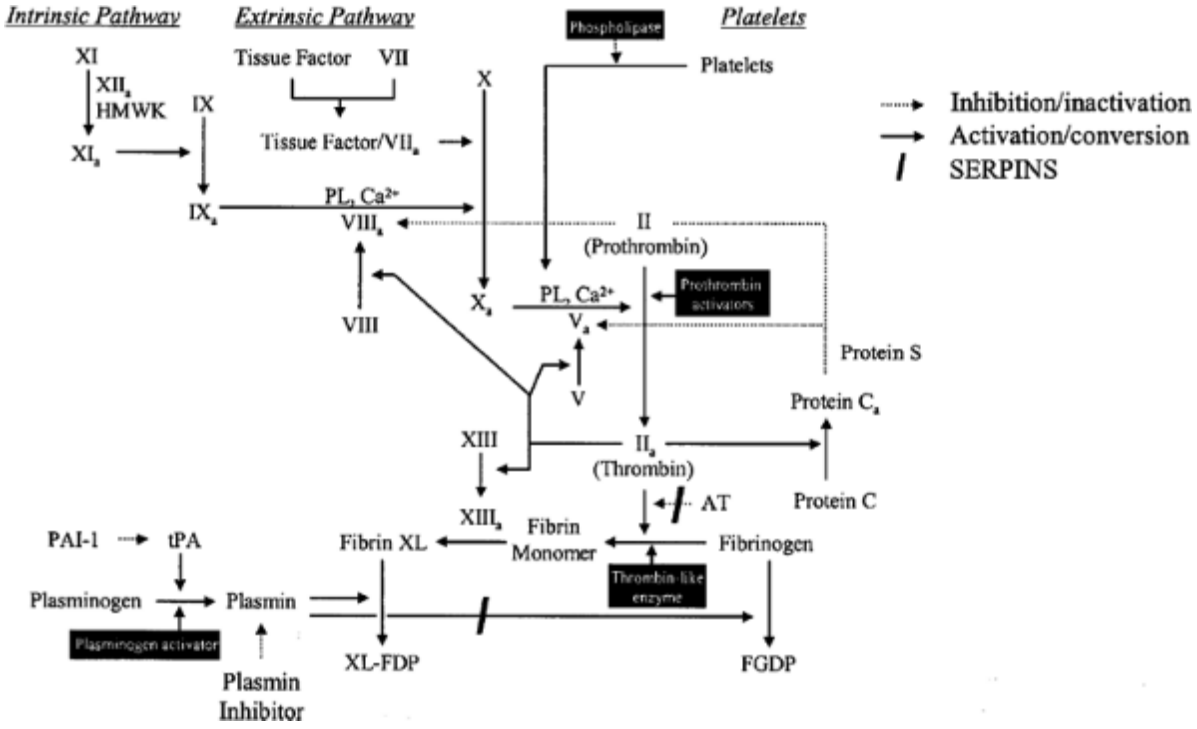

Figure 57-2. The figure presents a schematic overview of the coagulatio and fibrinolytic pathways and indicates where phospholipids on the platel surface interact with the coagulation pathway intermediates. Arrows are shown from platelets to phospholipids involved in the tissue factor VII_a a

the factor IX_a â€“$VIII_a$ interactions to avoid confusion. Interactions of selected venom proteins are indicated in the black boxes. The diagram is complete with reference to the multiple sites of interaction of the SERPIN (serine protease inhibitors) to avoid overcrowding.[115] PL = platelets; XL cross-linked.

Development of Coagulopathy

Impaired coagulation results from decreased production or enhanced consumption of coagulation factors, the presence of inhibitors of coagula activation of the fibrinolytic system, or abnormalities in platelet number function. Platelets are involved in the initial phases of clotting following b vessel injury by assisting in the formation of the fibrin plug. For the purp of this chapter, a discussion of platelet-related abnormalities is excluded. Some of this information can be found in Chap. 24 .

Decreased production of coagulation factors results from congenital and acquired etiologies. Although congenital disorders of factor VIII (hemoph factor IX (Christmas factor), factor XI, and factor XII (Hageman factor) a all reported, their overall incidence is still quite low. Clinical conditions th result in acquired factor deficiencies are much more common and result f either a decrease in synthesis or activation. Factors II, V, VII, and X are entirely synthesized in the liver,[64 , 125 , 151] making hepatic dysfunction common cause of acquired coagulopathy. In addition, factors II, VII, IX, X require postsynthetic activation by an enzyme that uses vitamin K as a cofactor,[173 , 178 , 179] such that vitamin K deficiency (from malnutrition, changes in gut flora secondary to xenobiotics, or malabsorption), or inhil of vitamin K cycling (from warfarin, as will be described), is capable of impairing coagulation.

Excessive consumption of coagulation factors usually results from massiv activation of the coagulation cascade. Massive activation occurs during s hemorrhage, or disseminated intravascular coagulation. The latter results from infection, such as sepsis, and from conditions that introduce tissue factor into the blood, such as neoplasms, snake envenomations, stagnant

blood flow, diffuse endothelial injury secondary to hyperthermia, ruptured aortic aneurysm, or aortic dissection. The hallmark of a consumptive coagulopathy is a depressed level of fibrinogen with an elevation of fibrin degradation products. This combination suggests the rapid turnover of fil in the coagulation process. In the other coagulopathic conditions, the fail to activate the coagulation cascade is associated with normal or high fibr levels and low fibrin-degradation products because of limited clot formati

Inhibitors of the coagulation cascade (circulating anticoagulants) are of t types: immunoglobulin and nonimmunoglobulin. Immunoglobulins, which often antibodies to existing coagulation factors, may occur without obviou cause. They may be part of a systemic autoimmune disorder or as a resul repeated transfusions with exogenous factors (as occurs in hemophilia).[7 105 , 163] The clinical syndromes associated with antibody inhibitors are s to those associated with deficiencies of the particular coagulation factors involved. Antibodies to factors V, VII to XI, and XIII are described in the literature.[22 , 163] Alternatively, nonimmunoglobulin neutralizers of coagulation occur in conditions associated with rapid white blood cell turnover.[22] These lysosomal cationic proteins are neutralizers that

compete with coagulation factors for negatively charged phospholipid membrane surfaces. Although they prolong in vitro coagulation times, the are rarely responsible for clinical coagulopathy because of the excess of phospholipid surface area available in vivo.[77 , 105]

Oral Anticoagulants

Warfarin and â€œWarfarinlikeâ€• Anticoagulants

Oral anticoagulants can be divided into two groups: (a) hydroxycoumarin including warfarin (commonly called by its trade name Coumadin), difenacoum, panwarfarin, warficide, coumachlor, coumafuryl, fumasol, pr ethyl biscoumacetate (Tromexan), phenprocoumon, dicumarol

bishydroxycoumarin, and acenocoumarin (Sintrom); and (b) indanediones including chlorophacinone, pindone, pivalyn, diphacinone, diphenadione, phenindione, and anisindione. Regardless of the classification, the mecha of action involves inhibition of the vitamin K cycle. Vitamin K is a cofactor the postribosomal synthesis of clotting factors II, VII, IX, and X (Fig. 57- The vitamin K-sensitive enzymatic step that occurs in the liver involves t Î³-carboxylation of 10 or more glutamic acid residues at the amino termi end of the precursor proteins, to form a unique amino acid Î³-carboxyglutamate.[54, 173, 178, 179] These amino acids chelate calcium in vivo, which allows the binding of the four vitamin K-dependent clotting fa to phospholipid membranes during activation of the coagulation cascade.[1

Vitamin K is inactive until it is reduced from its quinone form to a quinol hydroquinone) form in hepatic microsomes. This reduction of vitamin K m precede the carboxylation of the precursor factors. The carboxylation act is coupled to an epoxidase activity for vitamin K, whereby vitamin K is oxidized simultaneously to vitamin K 2,3-epoxide (Fig. 57-3).[178, 198] Th inactive form of the vitamin is converted back to the active form by two successive reductions.[54, 112, 141] In the first step, an epoxide reductase (known as vitamin K 2,3-epoxide reductase) uses reduced nicotinamide adenine dinucleotide (NADH) as a cofactor to convert vitamin K 2,3-epox to a quinone form.[133, 178] Subsequently, the quinone is reduced to the a vitamin K quinol form (see Antidotes in Depth: Vitamin K_1).

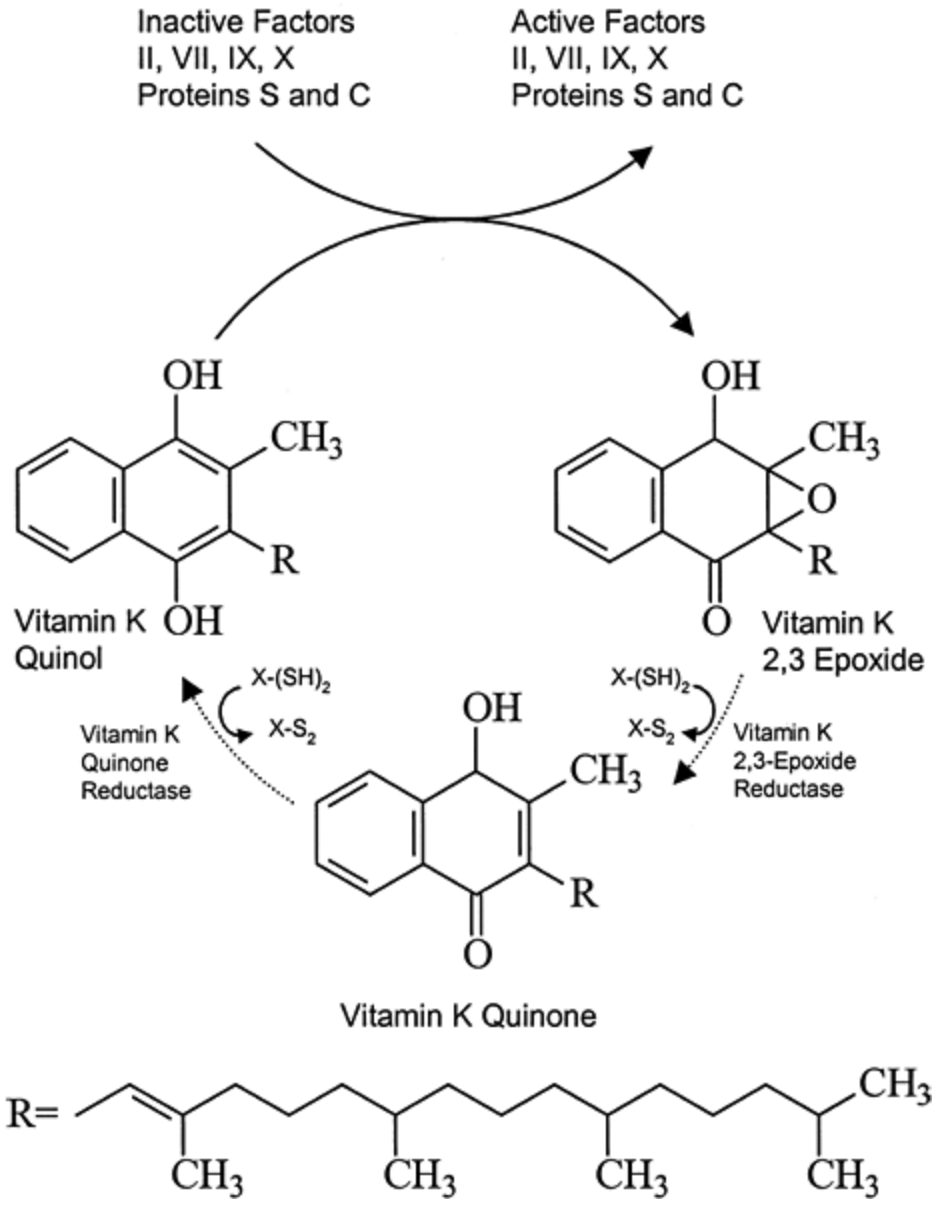

Figure 57-3. The vitamin K cycle. Dotted lines represent pathways that c be blocked with warfarin and warfarinlike anticoagulants. The aliphatic si chain (R) of vitamin K is shown below the metabolic pathway.

Warfarin is a racemic mixture of R warfarin and S warfarin enantiomers. rodents, S warfarin is 3â€“6 times more potent than R warfarin at produc hypoprothrombinemia.[30] In humans, S warfarin may only be about 1.5 ti as potent as R warfarin.[31] Warfarin and all warfarinlike compounds inhibit activity of vitamin K 2,3-epoxide reductase, as can be demonstrated by t

observation of elevated levels of vitamin K 2,3-epoxide, in orally anticoagulated subjects.[39, 201] Additional evidence suggests that another enzyme, vitamin K quinone reductase, is also inhibited by warfarin and its related compounds (Fig. 57-3).[54, 57] This reduction in the cyclic activat of vitamin K subsequently inhibits the formation of activated clotting fact

Pharmacology of Warfarin

Orally ingested warfarin is virtually completely absorbed, and peak plasm concentrations occur approximately 3 hours after drug administration.[177] Because only the free warfarin is therapeutically active, concurrent administration of xenobiotics that alter the level of free warfarin, either b competing for binding to albumin or by inhibiting warfarin metabolism, m markedly influence the anticoagulant effect.[14, 62, 177] Table 57-1 lists t xenobiotics that interfere with or potentiate warfarin's effects. Although vitamin K regeneration is altered almost immediately, the anticoagulant of warfarin, as well as other oral anticoagulant agents, is delayed until th existing stores of vitamin K are depleted and the active coagulation facto are removed from circulation. Because vitamin K turnover is rapid, this e is dependent on factor half-life ($t_{1/2}$), with factor VII ($t_{1/2}$ ~5 hours)

depleted most rapidly.[62] For a prolongation of the INR to occur, factor le must fall to approximately 25% of normal values. Assuming complete inhibition of the vitamin K cycle, this suggests that in most patients who not originally anticoagulated, at least 15 hours (three factor VII half-lives are required before warfarin's effect is evident.[62] In fact, complete inhib does not occur and hence, the onset of coagulation is even further delaye

TABLE 57-1. Common Drug Interactions With Warfarin Anticoagulation

Because the half-life of warfarin in humans is 35 hours, its duration of ac may be as long as 5 days.[30 , 62 , 177] On average, it takes approximately days of warfarin administration to reach a steady-state anticoagulant eff

R warfarin is metabolized by isozymes CYP1A2 and CYP3A4, and S warfari metabolized by CYP2C9 of the hepatic microsomal P450 enzyme system. I warfarin is metabolized by side-chain reduction to secondary alcohols tha subsequently excreted by the kidney, whereas S warfarin is metabolized hydroxylation to 7-hydroxy warfarin, which is excreted into the bile.[62 , 1 The elimination of S warfarin is more rapid than that of R warfarin.[31]

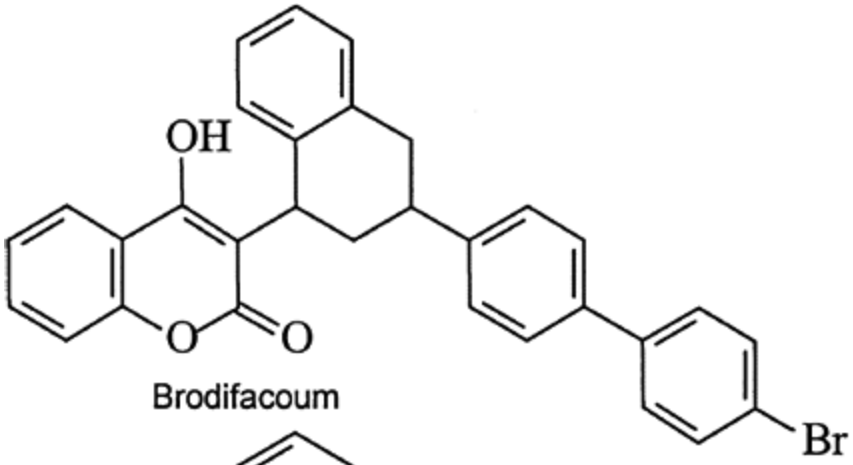
The therapeutic dose of warfarin is established for both adults and childr Typical adult recommendations are to give a starting dose of 5 mg/d with subsequent doses based on nomograms, computer programs, and/or clin experience.[65] Previous recommendations of initiating with a â€œloadingâ dose appear to be unnecessary.[3] Wide variability of maintenance dosing exists, depending on, for example, individual responsiveness, comorbid h conditions, and age. For children, the suggested starting dose of warfarin 0.2 mg/kg, followed by continued loading over 3 days, followed by a daily maintenance dose to maintain the INR between 2 and 3.[124 , 148]

Pharmacology of Long-acting Anticoagulan

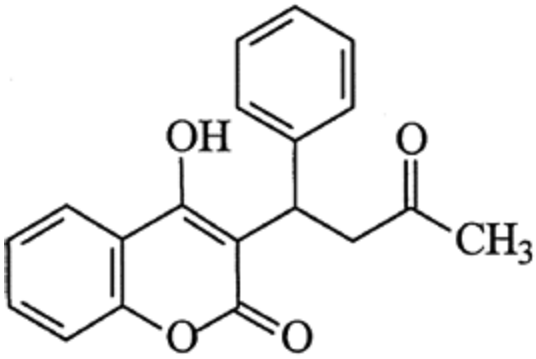
Within the coumarin group are two 4-hydroxycoumarin derivativesâ€”difenacoum and brodifacoum. These agents differ from wa by their longer, higher-molecular-weight polycyclic hydrocarbon side cha (Fig. 57-4). Together with chlorophacinone, an indandione derivative, th

are known as â€œsuperwarfarins,â€• or long-acting anticoagulants.

Long-acting anticoagulants were designed to be effective rodenticides in warfarin-resistant rodents.[109] Their mechanism of action is identical to th the traditional warfarinlike anticoagulants, as demonstrated by the measurement of increased concentrations of vitamin K 2,3-epoxide after acting anticoagulant administration.[28 , 29 , 32 , 106 , 140] The ability of th xenobiotics to perform as superior rodenticides is attributed to their high solubility and concentration in the liver.[106 , 109 , 140] They also may satu hepatic enzymes at very low levels, as demonstrated by zero-order elimination following overdose.[32] These factors make them about 100 tim more potent than warfarin on a molar basis.[106 , 109 , 140] In addition, the have a longer duration of action than the traditional warfarins.[106 , 109 , 1 For example, to obtain 100% lethality in a mouse, more than 21 days of feeding with a warfarin-containing rodenticide (0.025% anticoagulant by weight of bait) is required.[109] Similar efficacy can be achieved with a sin ingestion of brodifacoum (0.005% anticoagulant by weight of bait).[109]



Brodifacoum



Warfarin

Figure 57-4. Structural comparison of prototypical short-acting (warfari and long-acting (brodifacoum) anticoagulants.

Many animals have been poisoned with long-acting anticoagulants, either secondary to the unintentional ingestion of rodenticides, or intentionally scientific investigation. In rats, the half-life of brodifacoum is reported to 156 hours.[8] The half-life in dogs is reported to be between 6 and 120 days.[202] Horses intentionally poisoned with brodifacoum had a half-life of 1.22 days.[24] The veterinary literature is replete with reports of fatalities of animals that remained anticoagulated in excess of 1 month.[126, 175]

Likewise, many cases of intentional overdose of long-acting anticoagulant humans are also described in the literature. Table 57-2 summarizes these cases. These patients' clinical courses are characterized by a severe coagulopathy that may last weeks to months, often accompanied by consequential blood loss. The most common sites of bleeding are the

gastrointestinal and genitourinary tracts. Although initial parenteral vitar K_1 doses as high as 400 mg have been required for reversal,[34] daily oral vitamin K_1 requirements may be in the range of 50â€“100 mg. Recent experience in both animals and humans suggests that parenteral vitamin therapy might not be required (see Antidotes in Depth: Vitamin K_1).[32, 2] It should also be noted that although ingestions of these xenobiotics are most common route of exposure and subsequent cause of toxicity, derma absorption of certain xenobiotics can occur, resulting in a significant coagulopathy.[172]

Patients with unintentional ingestions must be distinguished from those w intentional ingestions, because the former individuals demonstrate a low likelihood of producing coagulation abnormalities and have only rare morbidity or mortality. Prolongation of the INR is unlikely with a single s ingestion of a superwarfarin rodenticide. Clinically significant anticoagula is even rarer. In a combined pediatric case series, prolongation of the IN occurred in only 8 of 142 children (5.6%) reported with single small ingestions of long-acting anticoagulants.[17, 94, 96, 170] Only 1 child in th group was reported to have â€œabnormal prolonged bleeding,â€• but th required no medical attention.[170] In a single case report, a 36-month-old child developed a coagulopathy manifested by epistaxis and hematuria, w anticoagulation persisting for more than 100 days after a presumed, but unwitnessed, single unintentional ingestion of brodifacoum.[183] Clinically significant coagulopathy can result, however, following small repeated ingestions. Two children reportedly became poisoned by repeated ingesti of a long-acting anticoagulant. One child presented with a neck hematom that compromised his airway, and the other with a hemarthrosis.[70] Simila a 7-year-old girl required multiple hospitalizations over a 20-month perio following repeated nonsuicidal ingestions of brodifacoum.[195] Finally, a 24 month-old child who presented with unexplained bruising and a PT >125 seconds,

was the victim of brodifacoum poisoning because of a Munchausen syndro by proxy.[7]

[a] Denotes possible repeat ingestion.

Reference	Age (y), Sex	Xenobiotic	Complications	Initial PT/INR	Duration Coagulopa

TABLE 57-2. Intentional Long-acting Anticoagulant Overdoses

Most patients (usually children) are entirely asymptomatic and have a nc coagulation profile following an acute unintentional exposure. Knowing th the risk of coagulopathy is low and that it takes days to develop, most authors recommend supportive care only.[95 , 170] Despite the fact that

significant toxicity from superwarfarins is rare, it should be recognized th the reported benign courses of pediatric exposures may be misleading. Multiple retrospective studies suggest that children with unintentional acu exposures do not require any followup coagulation studies.[33, 127, 142] However, this conclusion and approach to management may be an unjus attempt to decrease the cost of â€œunnecessaryâ€• coagulation studies. There are clearly insufficient data to justify this conclusion, as many of t â€œexposedâ€• children were never documented to have ingested long-acting anticoagulants (see Chap. 130). We recommend that clinicians continue to manage these children as possible significant exposures, and all children be followed up with daily INR

studies for at least 48 hours. A baseline INR study may also be performed determine if a child has been chronically ingesting the superwarfarin.

Clinical Manifestations

Typical warfarin rodenticides contain only small concentrations of anticoagulant, 0.025% (or 25 mg of warfarin per 100 g of product). Using data previously listed, a 10-kg child would require an initial dose of 2.5 m warfarin (or 10 g of rodenticide). These quantities are far greater than th that occur in typical â€œtastes.â€• Thus, single unintentional ingestions warfarin-containing rodenticides pose virtually no threat to either normal anticoagulated patients.[95] In contrast, intentional and large unintentional ingestions of pharmaceutical-grade anticoagulants have the potential to produce a coagulopathy and consequential bleeding. In one study describ 12 patients with surreptitious ingestion of oral anticoagulants, 9 were healthcare professionals.[134] These patients presented with bruising, hematuria, hematochezia, and menorrhagia, the typical manifestations of impaired coagulation. Hemorrhage into the neck with resultant airway compromise is a rare but life-threatening complication that has occurred.

Although intentional ingestions of warfarin-containing products are uncommon, adverse drug events resulting in excessive anticoagulation ar bleeding frequently occur. The risk of hemorrhage during oral anticoagula

therapy depends on a myriad of factors, including the intensity of anticoagulation, patient characteristics, and comorbid conditions such as hypertension, renal insufficiency, hepatic dysfunction, malignancy, length anticoagulant therapy, and indications for anticoagulationâ€”cerebrovasc disease, prosthetic heart valves, atrial fibrillation, ischemic heart disease, venous and arterial thromboembolism. Although the significance of each these clinical conditions varies among different reports, most studies demonstrate that there is a greater incidence of bleeding complications w increasing INR,[42] increasing intensity (or variation) of coagulation, advar age, a history of previous bleeding episodes while on therapeutic warfari drug interactions, impaired liver function, and dietary changes.[60 , 62 , 72 , 145 , 200] Clearly, the most serious complication of excessive anticoagula is intracranial hemorrhage, which is reported to occur in as many as 2% patients on long-term therapy.[62] This complication is associated with a fatality rate as high as 77%.[117]

An Outpatient Bleeding Risk Index was created and shown to be more accurate than physician judgment in classifying patients according to the of major bleeding.[21] The index was based on 4 independent risk factors: 65 years or older; history of cerebrovascular accident; history of gastrointestinal bleeding; and history of recent myocardial infarction, hematocrit <30%, serum creatinine >1.5 mg/dL, or diabetes mellitus. Th sum of the number of risk factors successfully predicted major bleeding a months to be 3% in low-risk (0 risk factors), 12% in intermediate-risk (1 risk factors), and 53% in high-risk (3â€“4 risk factors) patients. Because physicians had little ability to accurately estimate the probability of bleed use of the Outpatient Bleeding Risk Index seems appropriate to improve awareness and treatment of these high-risk patients.

In a study of 32 patients who developed life-threatening hemorrhage whil warfarin therapy, most patients had multiple risk factors including excess anticoagulation.[200] The gastrointestinal tract was identified as the source bleeding in 67% of the patients.[200] Sixty-six percent of patients were giv vitamin K_1 , 50% were given fresh-frozen plasma (FFP), and 7% were giv both therapies.[200]

Laboratory Assessment

Established screening tests are helpful for diagnosis. Four studiesâ€”PT (PTT, thrombin time, and fibrinogen concentrationâ€”are usually adequate Prothrombin time is calculated by adding standardized thromboplastin re (phospholipid and tissue factor) to a sample of the patient's citrated plas (the citrate removes calcium to prevent clotting). Calcium is then introdu and the time to clotting measured. With the exception of factor X, the PT unaffected by the presence or absence of factors VIII to XIII, platelets, prekallikrein, and HMWK. An individual's PT was formerly expressed as a (PT observed-to-PT control). Because this ratio is directly affected by bot laboratory methodology and the source of the thromboplastin reagent use the generated results suffered from significant variability. Thus, a standa the INR, was developed in an attempt to limit interlaboratory variability.[7] [131] The INR is derived by raising the PT ratio to a power value known as International Sensitivity Index (ISI): $(\text{PT ratio})^{\text{ISI}}$. The ISI is a measure responsiveness of the particular thromboplastin to warfarin. Although the of the INR does not completely eliminate variability,[80 , 130] it does impro the potential for standardized interpretation and limits interinstitutional variations. It should be noted that in patients taking oral anticoagulants, INR is extremely effective at monitoring the extent of anticoagulation. However, in patients with acute fulminant hepatic failure of various etiol the INR is extremely variable and occasionally misleading as a consequer of the variability in thromboplastins.[150] This may be less of a problem in United States because of the use of recombinant human preparations of thromboplastin, which results in greater consistency.[37]

The partial thromboplastin time is measured by adding kaolin or celite to citrated plasma in order to activate the â€œcontactâ€• components of th intrinsic system. This mixture is then recalcified and the time to clotting observed. Some tests use phospholipids in the reagent to activate the remaining coagulation factors, thereby giving rise to the term *activated partial thromboplastin time* (aPTT). Because the PTT and aPTT are essen interchangeable, the term PTT is used hereafter to represent the concept. PTT is not affected by alterations in factors VII, XIII, or platelets.

The thrombin time, determined by adding exogenous thrombin to citrated plasma, evaluates the ability to convert fibrinogen to fibrin, and is thus unaffected by abnormalities of factors II, V, VII to XIII, platelets, prekallikrein, or HMWK. Finally, either a fibrinogen level or a determinatic fibrin degradation products will help distinguish between problems with c formation and consumptive coagulopathy. An evaluation of the combinatic normal and abnormal results of these tests usually determines a patient's clotting abnormality (Table 57-3).

Inhibitors can be diagnosed by â€œmixing studies,â€• because only a sr percentage of the coagulation factors present in normal plasma are neces to have normal clotting studies. If the patient with an abnormal PT or PTT suffers from even a severe factor deficiency, restoration of that factor ac to 50% of normal will completely normalize the PT or PTT. Thus the pres of an abnormal PT or PTT that will not correct by incubation of the patien plasma with an equal volume of normal plasma is diagnostic of an inhibitc coagulation. Heparin-induced anticoagulation results in an elevated PTT t corrects when mixing studies are performed. More sophisticated

studies can be used to identify specific coagulation-factor deficiencies. Th reader is referred to one of several standard references for a more detail discussion of the approach to patients with abnormal coagulation studies.

PT normal, PTT prolonged, bleeding
- Deficiencies of factors VIII, IX, XI
- Von Willebrand disease

PT normal, PTT prolonged, no bleeding
- Deficiencies of factor XII, prekallikrein, high-molecular-weight-kininoge inhibitor syndrome

PT prolonged, PTT normal
- Deficiency of factor VII
- Warfarin therapy (early)
- Vitamin K deficiency (mild)

Liver disease (mild)

PT and PTT prolonged, thrombin time normal, fibrinogen normal
Deficiencies of factors II, V, IX; vitamin K deficiency (severe)
Warfarin therapy (late)

PT and PTT prolonged, thrombin time abnormal, fibrinogen normal
Heparin effect
Dysfibrinogenemia

PT and PTT prolonged, thrombin time abnormal, fibrinogen abnorm
Liver disease
Disseminated intravascular coagulation
Fibrinolytic therapy
Crotaline envenomation

TABLE 57-3. Evaluation of Abnormal Coagulation Times

Although warfarin levels may be useful to confirm the diagnosis in unkno cases and to study drug kinetics,[73 , 132] the routine use of simple and inexpensive measures such as INR determination seems more appropriat

Laboratory Evaluation of Long-acting Anticoagulants

For patients who have ingested long-acting anticoagulants and who are considered likely to develop a coagulopathy, baseline coagulation studies not usually helpful, but they may provide information about chronic exposures. If the history is reliable and the patient is healthy, baseline studies can be avoided. Serial INRs at 24 and 48 hours should identify all patients at risk of coagulopathy.[170] Depending on the social situation, th studies can be obtained while the patient remains in the home setting.

In contrast, all patients with intentional ingestion of long-acting anticoagulants should be presumed to be at risk for a severe coagulopath

fact, most patients do not seek medical care until bruising or bleeding is evident.[11,32,34,38,56,78,82,93,94,96,99,108,129,155,180] These events often occur many days after ingestion, which obviates the r for gastric decontamination unless there is a suggestion of repetitive ingestion. These patients should be managed as described below.

For patients who have suspected long-acting anticoagulant overdose, daily twice-daily INR evaluations for 2 days should be adequate to identify mos patients at risk for coagulopathy. Early detection through coagulation fac analysis may be preferred,[73] however, and levels of long-acting anticoagulants can now be measured.[59,100,132]

General Management and Antidotal Treatm

Gastrointestinal decontamination should be performed on patients who ar believed to have potentially significant life-threatening ingestions unless already present with significant bleeding. For patients who present after a hours of ingestion, gastric emptying is not indicated (see Chap. 8). Altho convincing data on the efficacy of either single- or multiple-dose activate charcoal (possible enterohepatic circulation) are lacking, at least a single dose of AC should be administered unless it is contraindicated. Oral cholestyramine can also be used to enhance warfarin elimination,[147] but studies are available that compare these two therapies or evaluate the ro combined activated charcoal and cholestyramine therapy. Although in ani models phenobarbital also enhances elimination, it is contraindicated in humans because of the decreased ability to reliably monitor the mental s of a patient who has the possibility of spontaneous intracranial hemorrha and subsequent increased risk of falling. In addition to general supportive measures, the patient should be placed in a supervised medical and psychiatric environment that offers protection against external or self-in trauma, and permits observation for the onset of coagulopathy.

Blood transfusion is required for any patient with a history of blood loss c active bleeding who is hemodynamically unstable, has impaired oxygen transport, or is expected to become unstable. Although a transfusion of packed red blood cells is ideal for replacing lost blood, it cannot correct a

coagulopathy, and thus patients will continue to bleed. Whole blood conta both the cellular elements the patient is losing and the necessary coagula factors to reverse the coagulopathy. Transfusion of whole blood may be considered in severe cases because whole blood contains many compone including platelets, white blood cells, and nonâ€“vitamin K-dependent fa However, because whole blood contains only relatively small amounts of vitamin K-dependent factors, selective use of specific blood products is generally preferred. These products include packed red blood cells, FFP, cryoprecipitate or other factor concentrates, such as factor IX complex (Konyne 80), recombinant factor VIIA (rFVIIa), and prothrombin complex concentrate.

Life-threatening hemorrhage secondary to oral anticoagulant toxicity sho be immediately reversed with FFP, followed by vitamin K_1 . FFP is rich in active vitamin K-dependent coagulation factors and will reverse oral anticoagulant-induced coagulopathy in most patients. In general, approximately 15 mL/kg of FFP should be adequate to reverse any coagulopathy.[48] However, the specific factor quantities and volume of ea unit may be varied, leading to an unpredictable response.[113] A recent stu comparing the efficacy of FFP and various clotting factor concentrates (prothrombin complex concentrate, factor VII concentrate, and Prothrom T [factors II, VII, IX and X]) in rapid reversal of anticoagulation, showed despite significant reduction in the INR, FFP had an extremely varied effe factor IX repletion. These clotting factor concentrates not only significant decreased the INR, but completely corrected it, and factor IX replacemen was much more consistent.[113] Furthermore, multiple FFP transfusions ma also be required because of the rapid degradation of coagulation factors i the absence of vitamin K.

Preliminary data using rFVIIa, a compound originally developed for the treatment of bleeding complications in patients with hemophilia, demons it to be a useful pharmacologic therapy for bleeding secondary to warfari induced excessive anticoagulation.[52 , 123] There is also a single case rep demonstrating efficacy at reversing severe bleeding caused by enoxapari Further experience with rFVIIa is necessary to determine its safety and

efficacy in anticoagulant-induced hemorrhage.

Several issues influence the decision to administer vitamin K_1 to a patien with a suspected overdose of a warfarinlike anticoagulant. Answers to the following questions should always be considered. Does the ingestion invol warfarin-containing rodenticide or a pharmaceutical preparation? Is the ingestion unintentional or intentional? Does the patient require maintena of therapeutic anticoagulation? Moreover, although vitamin K_1 administra is required to reverse the blockade of coagulation factor activation, it car be relied on for the patient with acute and consequential hemorrhage (se Antidotes in Depth: Vitamin K_1). Treatment with vitamin K_1 takes severa hours to activate enough factors to reverse the patient's coagulopathy,[11] [141] and this delay may be potentially fatal.

Repetitive, large doses of vitamin K_1 (on the order of 60 mg/d) may be required in some patients.[73] , [134] If complete reversal of INR prolongatio occurs or is desirable (as in most cases of life-threatening bleeding), and patient's underlying medical condition still requires some degree of anticoagulation, they can then receive controlled anticoagulation with he once the bleeding is controlled and they are otherwise stable. Heparin anticoagulation was used without apparent bleeding complications in 25% patients in one cross-sectional study.[200]

Vitamin K_1 is preferable over the other forms of vitamin K; the other forr are ineffective[93] , [129] , [133] , [185] and are potentially toxic.[9] (Vitamins K_3 [menadione] and K_4 [menadiol sodium diphosphate] can cause oxidative stress on neonatal erythrocytes and produce hemolysis, hyperbilirubinem and kernicterus.) Parenteral administration of vitamin K_1 (phytonadione) traditionally preferred as initial therapy by many authors, but success als can be achieved with early oral therapy.[32] In most cases reviewed, the patient was switched to oral vitamin K_1 preparations for long-term care. Vitamin K_1 can be administered intramuscularly, subcutaneously, intradermally, or intravenously. Although intravenous therapy has the mo rapid onset of action of all routes of delivery, its use as the sole therapeu agent is still associated with a delay of several hours[112] , [141] and carries added risk of anaphylactoid reactions.[149] The use of low doses and slow

of administration reduces this risk,[167] but we generally prefer that vitami be administered by other than the intravenous route (see Antidotes in De Vitamin K_1). In cases where oral administration is undesirable, for exam significant gastrointestinal hemorrhage, the subcutaneous route may be realizing that absorption may be erratic. Furthermore, if a patient is anticoagulated or overanticoagulated, administration of vitamin K_1 by the intramuscular route may result in a large hematoma. Caution should be exercised if this route of administration is chosen.

For patients with nonâ€“life-threatening hemorrhage, the clinician must consider whether anticoagulation is required for long-term care. In patien not requiring chronic anticoagulation, even small elevations of the INR m be treated with vitamin K_1 alone to prevent a deterioration in coagulation status and reduce the risk of bleeding. Because in most cases, coagulopa persists only for several days, there may be a rationale for prophylactic vitamin K_1 administration in known warfarinlike anticoagulant ingestions patients not requiring anticoagulation. In contrast to ingestions of warfar prophylactic vitamin K_1 should never be given to asymptomatic patients unintentional ingestions of long-acting anticoagulants because (a) if the patient is a child who develops a coagulopathy, it will last for weeks, and 1 or 2 doses of vitamin K_1 given will not prevent complications; (b) a gra decline in coagulation factors occurs over the first day of anticoagulation, no child would be expected to develop a life-threatening coagulopathy in 2 days; and (c) after vitamin K_1 is administered, the onset of an INR abnormality will be delayed, which could impair the clinician's ability to diagnose any coagulation abnormality, possibly requiring the patient to undergo an unnecessarily prolonged observation period.

For patients requiring chronic anticoagulation, The American College of C Physicians has issued guidelines for management of patients with elevate INRs (Table 57-4). Moreover, the use of a regression formula may assist calculating the amount of oral vitamin K_1 necessary to partially correct th INR, without completely discontinuing the oral anticoagulant. If validated, would be extremely useful prior to minor surgery or dental procedures in patients requiring chronic anticoagulation, while theoretically decreasing likelihood of thromboembolism.[197]

Treatment of Long-acting Anticoagulant Overdoses

Treatment of a patient with a long-acting anticoagulant overdose is essentially the same as the treatment of oral anticoagulant toxicity with certain exceptions.

â€¢
<5.0; no significant bleeding
Lower dose or omit next dose of warfarin
â€¢
â‰¥5.0â€“9.0; no significant bleeding
Discontinue warfarin for several doses. Alternatively, omit next dose and oral vitamin K_1 (1â€“2.5 mg) especially if at increased risk of bleeding. If more rapid reversal is necessary, give oral vitamin K_1 (â‰¤5 mg) and w 24 hours. Give additional vitamin K_1 orally (1â€“2 mg) as needed.
â€¢
â‰¥9.0; no significant bleeding
Hold warfarin therapy and give a higher dose of oral vitamin K_1 (5â€“10 and wait 24 hours. Give additional vitamin K_1 if necessary.
â€¢
Serious bleeding at any concentration or life-threatening bleeding
Hold warfarin therapy and give vitamin K_1 (10 mg by slow parenteral[b] infusion) supplemented with fresh-frozen plasma or prothrombin complex concentrate; recombinant factor VIIa may be used instead of prothrombi complex concentrate. Vitamin K_1 administration may need to be repeated h.

[a] If continued warfarin therapy is indicated after high doses of vitamin K_1 then anticoagulation with heparin or LMWH can be concomitantly given. I values >4.5 are also less reliable than values at or near the therapeutic range.

[b] Although parenteral infusion of vitamin K_1 is recommended, we urge ca with this route of administration because there may not be an appreciable

difference in onset of therapeutic effect and, although rare, may cause s anaphylactoid reactions.
Adapted from American College of Chest Physicians Consensus Conferenc 2004 guidelines.[3]

INR Recommendations

TABLE 57-4. Recommendations for Management of Elevated INF with and without Bleeding, in Patients Requiring Chronic Anticoagulation[a]

Long-acting anticoagulants are metabolized by the hepatic mixed-functior oxidase system (cytochrome P450 [CYP]).[8,133] In a rat model, the dura of coagulopathy was shortened by administering phenobarbital, a CYP3A4 inducer.[8] Although a phenobarbital effect has never been systematically studied in humans, this approach was employed by several authors in isc human cases of long-acting anticoagulant toxicity.[34,93,108,183,195] Although these anecdotal reports suggest some improvement with phenobarbital therapy, the risks of producing sedation in a patient who n be prone to bleeding complications appear consequential.

Patients with long-acting anticoagulant overdose should be followed until coagulation studies remain normal while off therapy for several days. Thi usually requires daily or even twice-daily INR measurements until the INF at the lower limit of the therapeutic range. Monitoring of serial INR measurements should allow for a gradual decrease in vitamin K_1 requirer over time. Periodic coagulation factor analysis, however, may provide an early clue to the resolution of toxicity.[82] The patient may require weeks t months of close observation for both psychiatric and medical managemer Emphasis has been placed on determining a critical superwarfarin concentration below which anticoagulation does not occur.[34] In one case report, brodifacoum was observed to follow zero-order elimination kinetic If this type of toxicokinetics is consistent in the analysis of other long-ac anticoagulants, these laboratory measurements may prove more reliable

the current empiric end points of therapy.

Parenteral Anticoagulants

Heparin

Conventional or unfractionated heparin is a heterogeneous group of mole within the class of glycosaminoglycans.[92] The heparin precursor molecule composed of long chains of mucopolysaccharides, a polypeptide, and carbohydrates. The main carbohydrate components of heparin molecules include uronic acids and amino sugars in polysaccharide chains. Heparin f pharmaceutical use is extracted from bovine lung tissue and porcine intestines.[160]

As a therapeutic agent, heparin inhibits thrombosis by accelerating the binding of the protease inhibitor antithrombin III (AT) to thrombin (factor and other serine proteases involved in coagulation.[111 , 153] Thus, factors to XII, kallikrein, and thrombin are inhibited. Heparin also affects plasminogen activator inhibitor, protein C inhibitor, and other components coagulation. Heparin's therapeutic effect is usually measured through the activated PTT. The activated blood coagulation time (ACT) may be more useful for monitoring large therapeutic doses or in the overdose situation

Low-molecular-weight heparins (LMWHs) are 4000- to 6000-Dalton fracti obtained from conventional (unfractionated) heparin.[63] As such, they sha many of the pharmacologic and toxicologic properties of conventional heparin.[26] The various LMWHs (e.g., Fraxiparine, enoxaparin, dalteparin) prepared by different methods of depolymerization of heparin; consequer they each differ to a certain extent regarding their pharmacokinetic prop and anticoagulant profiles. The major differences between LMWHs and conventional heparin are greater bioavailability, longer half-life, more predictable anticoagulation with fixed dosing, targeted activity against activated factor X, and less targeted activity against activated factor II.[2(As a result of this targeted factor X activity, LMWHs have minimal effect the activated PTT, thereby eliminating either the need for, or the usefuln

of, such monitoring. As such, they are administered on a fixed-dose sche

LMWHs have been investigated for prevention of thromboembolic disease after hip surgery and trauma, in patients with stroke or deep venous thrombosis, in pregnancy, and in other conditions where anticoagulation heparin would otherwise be indicated (e.g., at the onset of oral anticoagulation therapy). Although these xenobiotics are presumed to hav minimal risk in pregnancy[121] because they do not cross the placenta,[61 ,] they are not yet approved for treatment or prophylaxis of thromboemboli disease in pregnancy. Most studies demonstrate a lower incidence of embolization; however, there is still a trend toward increased bleeding.[19 , 107]

Pharmacology

Because of heparin's large size and negative charge it is unable to cross cellular membranes. These factors also eliminate oral administration as a therapeutic route, and heparin must be administered by either subcutane injection or continuous intravenous infusion. Following parenteral administration, heparin remains in the intravascular compartment, in par bound to globulins, fibrinogen, and low-density lipoproteins, resulting in a volume of distribution of 0.06 L/kg in humans.[55 , 135] Because of its rapi metabolism in the liver by a heparinase, heparin has a short duration of effect.[111] Although the half-life of elimination is dose dependent and ran from 1â€“2.5 hours,[111 , 118 , 135] the duration of anticoagulant effect is usually reported as 1â€“3 hours.[111] Dosing errors or drug interactions wi thrombolytic agents, antiplatelet drugs, or nonsteroidal antiinflammatory drugs may increase the risk of hemorrhage.[76]

Clinical Manifestations

Intentional overdoses with heparin are rare.[116] Most reported cases invol unintentional poisoning in hospitalized patients.[66 , 69 , 116 , 138 , 159] The cases have involved the administration of large amounts of heparin as a consequence of misidentification of heparin vials, during the process of

flushing intravenous lines, and secondary to intravenous pump malfunctio Significant bleeding complications occurred in several cases, including 1 fatality.[66]

Although no overdoses of LMWHs are reported, LMWHs are renally elimin and patients with severe renal insufficiency (creatinine clearance <30 mL/min), or end-stage renal disease, are at increased risk of toxicity.[188] Similar adverse effects to unfractionated heparins are also reported to in epidural/spinal hematoma, intrahepatic hemorrhage,[85] abdominal wall hematomas,[4] psoas hematoma after lumbar plexus block,[97] and intracrar hemorrhage in patients with malignancy in the brain.[53] These complicatio were all reported in patients who received the LMWH enoxaparin.

Evaluation and Treatment

After stabilization of the airway and breathing, and circulation are assure the physician should be prepared to replace blood loss and reverse the coagulopathy, if indicated. Because of the relatively short duration of act of heparin, observation alone might be indicated if significant bleeding ha not occurred. For the patient requiring anticoagulation, serial PTT determinations will indicate when it is safe to resume therapy. If significa bleeding occurs, either removal of the heparin or reversal of its anticoag effect

is indicated. Because heparin has a very small volume of distribution, it c be effectively removed by exchange transfusion.[159] Although this techniq has been used successfully in neonates, it is not generally applicable to c children and adults.

When severe bleeding occurs, heparin may be effectively neutralized by protamine sulfate.[2] Protamine is a low-molecular-weight protein found in sperm and testes of salmon, which forms ionic bonds with heparin and renders it devoid of anticoagulant activity.[111] One milligram of protamine sulfate injected intravenously neutralizes 100 U of heparin.[111] The dose c protamine should be calculated from the dose of heparin administered if known and assuming heparin's approximate half-life to be 60â€“90 minut

the amount of protamine should not exceed the amount of heparin expec to be found intravascularly at the time of infusion. As with other foreign proteins, protamine administration is associated with numerous adverse effects such as hypotension, bradycardia, and allergic reactions. Because approximately 0.2% of patients receiving protamine experience anaphyla a complication that carries a 30% mortality rate, most authors commonly recommend that protamine be reserved for patients with life-threatening hemorrhage (see Antidotes in Depth: Protamine).[83] It should also be no that excess protamine administration may result in paradoxical anticoagulation.

Because of the severe adverse effects associated with protamine, researc has focused on safer methods to reverse heparin anticoagulation. These agents include heparinase,[122] synthetic protamine variants,[189 , 190] and platelet factor 450, but these therapies are not widely available.

If life-threatening bleeding occurs following LMWH administration, patien should be treated supportively. The newer experimental protamine variar appear to be effective against LMWHs but are not yet unavailable.[189 , 19

Nonbleeding Complications of Anticoagular

Warfarin therapy is associated with three nonhemorrhagic lesions of the urticaria,[158] purple toe syndrome,[58] and warfarin skin necrosis.[45 , 98 , 10 120 , 187] Although warfarin skin necrosis was once thought to be a rare a idiosyncratic reaction,[98 , 102] more recent evidence suggests a link betwe this disorder and protein C deficiency.[102 , 187] Protein C is also dependen vitamin K.[41] Patients who are homozygotes for protein C deficiency have increased incidence of thrombosis and embolic events, such that they oft require long-term anticoagulant therapy.[41] Because the half-life of protein is shorter than that of many of the vitamin K-dependent coagulation fact protein C levels fall rapidly during the first hours of warfarin therapy. In protein C-deficient patient, protein C levels fall dramatically prior to a reduction in coagulation factors. This results in an imbalance that actually favors coagulation, and skin necrosis results due to microvascular throm in dermal vessels.[120 , 187] Although warfarin skin necrosis is more commo

patients with protein C deficiency, this disorder is also described in patie with protein S and AT deficiencies.[45] Unfortunately, these deficiencies are neither necessary nor sufficient to account for the incidence of warfarin necrosis.[45] If necrosis occurs, warfarin should be discontinued and hepar should be initiated to decrease thrombosis of postcapillary venules. Some patients may also require surgical dÃ©bridement.[185] The purple toe syndrome, in contrast to warfarin-induced skin necrosis, is presumed to from small atheroemboli that are no longer adherent to their plaques by

An additional major nonhemorrhagic complication of warfarin therapy rela to its use in pregnant women. Most warfarin-induced fetal abnormalities during weeks 6 to 12 of gestation, but CNS and ocular abnormalities can develop at any time during gestation.[75 , 174]

Heparin therapy is associated with a transient and mild thrombocytopenia called heparin-induced thrombocytopenia (HIT) that occurs in approximat 25% of patients during the first few days of therapy.[194] Although this syndrome results from heparin-induced platelet aggregation, a more seve form of thrombocytopenia, heparin-induced thrombocytopenia and throm syndrome (HITTS; formerly known as HIT-2 or the white clot syndrome), occurs in 1â€“5% of patients between days 7 and 14 of therapy.[112] In patients who were previously treated with heparin, these events can occu earlier than 7 days. Heparin stimulates platelets to release platelet factor which subsequently complexes with heparin to provoke an IgG response. These antibodies against the heparinâ€“platelet factor 4 complex activate platelets, which may lead to plateletâ€–fibrin thrombotic events.[6 , 111 , 2] Patients may present with either hemorrhagic or thromboembolic complications. Previously reported not to occur,[193] LMWH is also associat with thrombocytopenia (isolated HIT) and HITTS, although less frequently Consequently, once HITTS occurs, LMWH is contraindicated.[193] In addition HIT and HITTS, necrotizing skin lesions[144] and hyperkalemia from aldost suppression[136] also rarely occur in patients receiving heparin therapy.

Some additional complications of heparin use include osteoporosis, which mostly occurs in patients on long-term therapy with unfractionated hepar A small percentage of these patients may develop bone fractures if treate

continuously for more than 3 months. Data for LMWHs are limited and the incidence of osteoporosis may be less compared to unfractionated hepari

Fibrinolytic Agents and other Anticoagulan

Thrombolytic Agents

The fibrinolytic system is designed to remove unwanted clots, while leavi those clots protecting sites of vascular injury intact. Plasminogen exists a proenzyme and is converted to the active form, plasmin, by various plasminogen activators.[43, 44] t-PA is released from the endothelium and under the inhibitory control of two inactivators known as tissue plasmino activator inhibitors 1 and 2 (t-PAI-1 and t-PAI-2).[43, 44, 112, 125] Plasmi actions are nonspecific in that it degrades not only fibrin clots but also so plasma proteins and coagulation factors.[112] Inhibition of plasmin occurs through $\hat{I}\pm_2$ -antiplasmin.

With their diverse indications in acute myocardial infarction, unstable an arterial and venous thrombosis and embolism, and cerebrovascular disea the thrombolytic agents (streptokinase, urokinase, alteplase, and anistreplase) are commonly used.[16] The reader is referred to a number o reviews for specific indications and dosing regimens.[46, 104, 112, 143, 1 199] Although all xenobiotics enhance fibrinolysis, they differ in their spec sites of action and durations of effect. Alteplase (t-PA) is specific for clot does not increase fibrinolysis in the absence of a thrombus), whereas streptokinase, urokinase, and anistreplase are not clot-specific. Alteplase

has the shortest half-life and duration of effect (5 minutes and 2 hours, respectively), and anistreplase the longest (90 minutes and 18 hours, respectively).[143, 169] Streptokinase has the additional risk of severe alle reaction on rechallenge, limiting its use to once in a lifetime.

Newer thrombolytic drugs such a reteplase, and some noncommercially available agents, including monteplase, lanoteplase, pamiteplase, and staphylokinase are being evaluated for therapeutic use. These agents hav

longer half-life in plasma and may be administered via single or repeated bolus injections. They also have increased fibrin selectivity, but no improvement in long-term mortality is demonstrated.[5] Although the incid of bleeding requiring transfusion may be as high as 7.7% following high- (150 mg) alteplase and 4.4% following low-dose alteplase,[46] the incidenc intracranial hemorrhage with alteplase appears to be similar to the newe agents (monteplase, tenecteplase, reteplase, and lanoteplase).[186] The addition of heparin to the thrombolytic regimen increases the risk of blee Reviews of multiple trials suggest that life-threatening events such as intracranial hemorrhage occur in 0.30â€“0.58% of patients receiving anistreplase, 0.42â€“0.73% of patients receiving alteplase, and 0.08â€–0.30% of patients receiving streptokinase.[199] Regardless of the thrombolytic agent used the frequency of bleeding events is similar even the newer agents, with the exception that lanoteplase may have a decrea incidence of significant bleeding.[51] Supportive care is indicated for patie with minor bleeding complications; however, for patients with significant bleeding, fibrinogen and coagulation factor replacement with cryoprecipit and FFP should be administered.[156]

Snake Venoms

A detailed discussion of snake envenomations is found in Chap. 117 ; onl few specific issues are discussed here. Snake venoms may be composed c vast number of complex proteins and peptides that interact with compon of the human hemostatic system. In general, their functions may be thou of as being procoagulant, anticoagulant, fibrinolytic, vessel wall interacti platelet active, or as protein inactivators. Additionally, they may more specifically also be classified based on their specific biologic activity; som the various mechanisms include individual factor activation, inhibition of protein C and thrombin, fibrinogen degradation, platelet aggregation, and inhibition of serine protease inhibitors (SERPINS). Currently, there are m than 100 different snake venoms that affect the hemostatic system;[90 , 9] Figure 57-2 is an overview of their multiple interactions with the coagula and fibrinolytic systems.[115]

Some of these venom proteins are being used as therapeutic agents for human diseases. Ancrod, a purified derivative of the Malayan pit viper, *Calloselasma rhodostoma* (formerly known as *Agkistrodon rhodostoma*), therapeutically used because of its defibrinogenating property.[15] The mechanism of action of ancrod and other similar agents is to link fibrinog end-to-end and subsequently prevent cross-linking. It has been investiga in the treatment of deep vein thrombosis, myocardial infarction, pulmona embolus, acute cerebrovascular thrombosis, HIT, and warfarin-related vascular complications. In a multicenter study of 500 patients with acute progressing ischemic neurologic events, ancrod showed a favorable bene to-risk ratio compared to placebo.[166] As expected, an increased risk of hemorrhage is observed; however, the risk appears to be less than that v thrombolytic agents.[166] Monitoring of fibrinogen levels is essential to avo potential complications, as no specific antidote exists. For envenomation other snake venoms (such as from the Crotalinae family) that induce hemorrhage, antivenin treatment may be required.

Hirudin

Hirudin, a 65-amino-acid polypeptide produced by the salivary glands of medicinal leech (*Hirudo medicinalis*), irreversibly blocks thrombin withou need for AT.[162] Unlike heparin, the small size of hirudin allows it to enter clots and inhibit clot-bound thrombin, offering the distinct advantage of restricting further thrombus formation. Hirudin demonstrates enhanced bioavailability and a longer half-life than unfractionated heparin. In addit there are no known natural inhibitors of hirudin, such as platelet factor 4 Desirudin, is a recombinant hirudin which is used in acute coronary synd in the prevention of thromboembolic disease and in patients with heparin induced thrombocytopenia.[23 , 157 , 162] Both of these compounds appear be at least as effective as unfractionated heparin, and without increased bleeding or thrombocytopenia. However, in the Global Use of Strategies t Open Occluded Coronary Arteries (GUSTO) IIb study of patients with uns angina/nonâ€“Q-wave myocardial infarction, there was an increase in the number of blood transfusions in patients who received desirudin as comp to those who received heparin.[68]

Summary

The ever-increasing frequency of anticoagulant therapeutic use is associa with complications and adverse outcomes. A complete understanding of t normal mechanisms of coagulation, anticoagulation, and thrombolysis, combined with an understanding of the pharmacology of the agent and th patient's clinical needs, will allow the clinician to better choose among th complex therapies currently available. Supportive care is often adequate certain complications associated with these therapies; however, occasion more aggressive interventions and specific antidotes are necessary depe on the particular agent and medical condition of the patient.

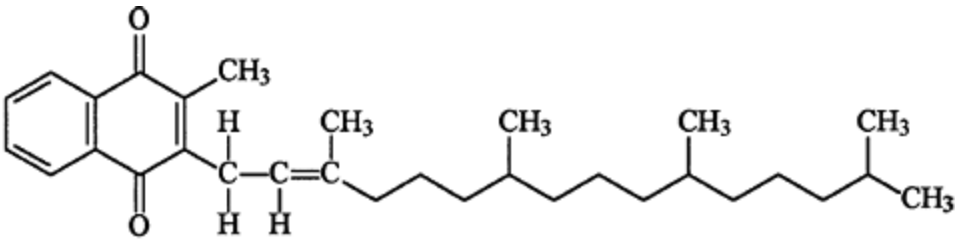
Antidotes in Depth

Vitamin K_1

Mary Ann Howland



Vitamin K_1

Vitamin K_1 (phytonadione) is indicated for the reversal of elevated prothrombin times and international normalized ratios (INRs) in patients with xenobiotic-induced vitamin K deficiency. Vitamin K deficiency is typically induced following the therapeutic administration of warfarin, or following the overdose of warfarin or the long-acting anticoagulant rodenticides (LAARs), such as brodifacoum. The optimal dosage regimen of vitamin K_1 to treat patients who develop an elevated INR while receiving warfarin has been reviewed and a revised guideline regarding the dose and route of administration published.[1,7] Oral administration of

vitamin K_1 is used safely and successfully. Because intravenous administration of vitamin K_1 is associated with anaphylactoid reactions, it should be avoided unless serious or life-threatening bleeding is present. Subcutaneous administration should only be considered an appropriate route of therapy when a patient is unable to tolerate oral vitamin K therapy yet is not clinically compromised enough to necessitate intravenous vitamin K_1 .[7]

History

It was noted in 1929 that chickens fed a poor diet developed spontaneous bleeding. In 1935, Dam and coworkers discovered that incorporating a fat-soluble substance in the diet could correct the bleeding and they named this substance a â€œkoagulation factor,â€• hence vitamin K.[19 , 28]

Chemistry

Vitamin K is an essential fat-soluble vitamin. The name *vitamin K* is actually a broad term that encompasses at least two distinct natural forms. Vitamin K_1 (phytonadione, phylloquinone) is the only form synthesized by plants and algae. Vitamin K_2 (menaquinones) is actually a series of compounds with the same 2-methyl-1,4-naphthoquinone ring structure as phylloquinone, but with a variable number (1â€“13) of repeating 5-carbon units on the side chain. Bacteria synthesize vitamin K_2 (menaquinones). Most of the vitamin K ingested in the diet is phylloquinone (vitamin K_1).

Daily Requirement

The human daily requirement for vitamin K is small; the Food and Nutrition Board set the recommended daily allowance at 1 Âµg/kg/d of phylloquinone for adults, although 10 times that amount is required for infants to maintain normal hemostasis.[27]

Extrahepatic enzymatic reactions that are vitamin K-dependent relate to carboxylation of proteins in the bone, kidney, placenta, lung, pancreas, and spleen, and include the synthesis of osteocalcin, matrix Gla protein, plaque Gla protein, and one or more renal Gla proteins.[27 , 28 , 32] Note that variations in an individual's dietary vitamin K intake while receiving chronic oral anticoagulation can significantly result in either over- or under-anticoagulation.[12]

Pharmacokinetics of Dietary Vitamin K

Dietary vitamin K in the form of phylloquinone and menaquinones is solubilized with the bile salts, free fatty acids, and monoglycerides to enhance absorption. Vitamin K, bound to chylomicrons, enters the circulation via the lymphatic system and then is taken up by the liver.[28] In the plasma, vitamin K is primarily in the phylloquinone form, whereas liver stores are 90% menaquinones and 10% phylloquinone.[28] Following 3 days of low vitamin K intake, a group of surgical patients showed a 4-fold lowering of liver vitamin K concentrations.[31] Rats given a vitamin K-deficient diet develop severe bleeding within 2â€“3 weeks.

Pharmacology

Activation of coagulation factors II, VII, IX, and X, and proteins S and C require Î³-carboxylation of the glutamate residues in a vitamin K-dependent process. Only the reduced (quinol, hydroquinone) form of vitamin K manifests biologic activity (Fig. 57-3). The quinone form of vitamin K can be activated to the quinol form directly by a nicotinamide adenine dinucleotide phosphate (NADPH)-dependent pathway that is relatively insensitive to warfarin.[28 , 32] During the carboxylation step, the K quinol form is converted to an epoxide. This 2,3-epoxide is reduced and recycled to the active K quinol in a two-step process that is inhibited by warfarin. For further detail, the reader is

referred to an in-depth model of the chemical basis of this reaction.[9 , 34]

Vitamin K Deficiency and Monitoring

Vitamin K deficiency can result from inadequate intake, malabsorption, or interference with the vitamin K cycle. Malnourishment and any condition in which bile salts or fatty acids are inadequate, such as extrahepatic cholestasis or severe pancreatic insufficiency, can lead to vitamin K deficiency. There are multifactorial etiologies that place newborns at risk for hemorrhage. Phylloquinone does not readily cross the placenta, and breast milk contains less phylloquinone than vitamin K-fortified formula. Fetal hepatic stores of phylloquinone are low and maternal anticonvulsant therapy may lead to increased vitamin K metabolism.[28 , 32] Although

menaquinones are produced in the colon by bacteria, it is unlikely that enteric production contributes significantly to vitamin K stores or that eradication of the bacteria with antibiotics, without a coexistent dietary deficiency of vitamin K, results in deficiency.[28] Determination of vitamin K deficiency is usually established on the basis of a prolonged prothrombin time (PT), which is a surrogate marker of specific coagulation factors. Measurement of the vitamin K-dependent factors, II, VII, IX, and X, appears to be an effective way to determine the adequacy of vitamin K_1 dosing.[15] Serial measurements of factor VII, the factor with the shortest half-life, allows for the early detection of inadequate vitamin K in the diet or a therapeutic regimen.[6] Direct measurement of serum vitamin K serum levels is done by high-performance liquid chromatography (HPLC) analysis. The human serum vitamin K concentration required for adequate production of activated clotting factors in the presence of LAARs is still unclear. One study in a patient who overdosed on brodifacoum suggested that a serum vitamin K concentration of 0.2â€“0.4 Âµg/mL was sufficient, in contrast to

the 1 Âµg/mL reported as necessary in rabbits.[6 , 23]

Mechanism of Action for Xenobiotic-Induced Vitamin K Deficiency

Oral anticoagulants are vitamin K antagonists that interfere with the vitamin K cycle, causing the accumulation of vitamin K 2,3-epoxide, an inactive metabolite. Warfarin is a strong irreversible inhibitor of the dithiol-dependent vitamin K reductases (epoxide reductase and quinone reductase), which maintain vitamin K in its active (quinol, hydroquinone) form.[3] The superwarfarins are even more potent vitamin K reductase inhibitors. Without exogenous interference, vitamin K is recycled and only 1 Âµg/kg is required in adults to maintain adequate coagulation. NADPH-dependent quinone reductase is a warfarin-insensitive enzyme capable of reducing vitamin K_1 to its active hydroquinone form, but it is incapable of regenerating vitamin K from vitamin K epoxide following carboxylation of the coagulation factor (Fig. 57-3).[3] Thus, in the presence of warfarin or superwarfarin, additional vitamin K_1 must be administered to supply this active cofactor for each and every carboxylation step, as it can no longer be recycled.[6] The minimum vitamin K_1 requirement in the presence of a LAAR is unknown. Other compounds have varying degrees of vitamin K antagonistic activity and include the *N* -methyl-thiotetrazole side-chain-containing antibiotics such as moxalactam and cefamandole (Chap. 54), as well as salicylates (Chap. 35).[28]

Vitamin K_1 (phylloquinone, phytonadione)
Mephyton
AquaMEPHYTON
Oral
SC, IV
5 mg
2 mg/mL

Commercial Preparation	Route of Administration	Strength	Comments
		10 mg/mL	Best for anticoagulant-induced prolonged prothrombin time. Oral route preferred; divided doses may be necessary for large requirements; IV reserved for life-threatening situations. Must be carefully diluted and slowly infused (IV) to avoid anaphylactoid reactions; SC for small doses.

TABLE A16-1. Available Vitamin K_1 Products

Availability of Different Forms of Vitamin K

Table A16-1 lists the currently marketed vitamin K products. Vitamin K_1 (phylloquinone, phytonadione) is the only vitamin K preparation that should be used to reverse anticoagulant-induced vitamin K deficiency or to treat infants, pregnant women, or patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency because of the increased risks of hemolysis with other vitamin K preparations. Vitamin K_1 is superior to the other previously commercially available vitamin K preparations because it is more active, thus requiring comparatively smaller doses, because it works more rapidly (6 vs. 12 hours), and because it has fewer associated risks.[13, 30]

Vitamins K_3 (menadione) and K_4 (menadiol sodium diphosphate) can produce hemolysis, hyperbilirubinemia, and kernicterus in neonates, and hemolysis in G6PD-deficient patients. The only advantage that menadione and menadiol sodium diphosphate have is that these preparations are absorbed directly from the intestine by a passive process that does not require the presence of bile salts. Theoretically, these agents are advantageous for patients

with cholestasis or severe pancreatic insufficiency. However, they are neither interchangeable with vitamin K_1 , nor a substitute for vitamin K_1 , when anticoagulants such as warfarin or LAAR are responsible for coagulation deficits. Therefore, for a patient deficient in bile salts who requires vitamin K_1 , exogenous bile salts, such as ox bile extract 300 mg or dehydrocholic acid 500 mg, should be given with each dose of oral vitamin K_1 .[24]

Pharmacokinetics and Pharmacodynamics of Administered Vitamin K_1

There are only a limited number of pharmacokinetic studies of vitamin K_1 .[6 , 14 , 23 , 35] One study evaluated the pharmacokinetics of vitamin K_1 in healthy volunteers, brodifacoum-anticoagulated rabbits, and a patient poisoned with brodifacoum.[23] In the volunteers and the poisoned patient, a 10-mg IV dose of vitamin K_1 had

a half-life of 1.7 hours. After oral administration of doses of 10 and 50 mg of vitamin K_1 , peaks of 100â€“400 ng/mL and 200â€“2000 ng/mL, respectively, occurred at 3â€“5 hours. Bioavailability varied significantly between patients (10â€“65%) for both doses, and in individual patients with the 50-mg dose. Oral vitamin K_1 (phytonadione, phylloquinone) is absorbed in an energy-dependent saturable process in the proximal small intestine, and this likely contributes to the variability.[23] In maximally brodifacoum-anticoagulated rabbits, IV vitamin K_1 (10 mg/kg) increased prothrombin complex activity (PCA) from 14â€“50% by 4 hours, and to 100% by 9 hours, after which it declined with a half-life of 6 hours. High doses of oral vitamin K_1 were used to treat a patient anticoagulated with brodifacoum.[6] The pharmacokinetics of oral and IM vitamin K_1 were compared in 8 healthy female volunteers. Baseline serum vitamin K

concentrations were 0.23 ng/mL. Following the oral administration of 5 mg of vitamin K, peak serum concentrations of 90 ng/mL were achieved between 4 and 6 hours. These levels dropped to a steady state of 3.8 ng/mL and exhibited a half-life of about 4 hours. The pharmacokinetics were distinctly different after IM administration and quite variable. IM administration of 5 mg of vitamin K resulted in peak serum concentrations of only 50 ng/mL with delays from 2â€“30 hours following administration and with the maintenance of a plateau for about 30 hours.[14] Consequently, IM administration is not recommended; either oral or intravenous is more appropriate and the route will be defined by the severity of bleeding. Only in the case of acute gastrointestinal disease in a patient without life-threatening overanticoagulation is subcutaneous route an appropriate alternative to the oral route.

Routes of Administration and Adverse Effects

Although vitamin K_1 can be administered orally, subcutaneously, intramuscularly, or intravenously, the oral route is preferred for maintenance therapy. When administered orally, vitamin K_1 is virtually free of adverse effects, except for overcorrection of the INR in the setting of a patient who requires maintenance anticoagulation. The only preparation available for intravenous administration is AquaMEPHYTON, which is associated with rare anaphylactoid reactions. This preparation is not available in solution but as an aqueous colloidal suspension of a polyoxyethylated castor oil, dextrose, and benzyl alcohol because of vitamin K's lipid solubility. Intravenous administration has resulted in death secondary to anaphylactoid reactions, probably as a result of the preparation's colloidal formulation.[4,8,20] Numerous anaphylactoid reactions have been reported, even when it is properly diluted and administered slowly.[22] New liposomal preparations are under development, which may become safer

alternatives.

Onset of Effect

The time necessary for the INR to return to a safe or normal range is very variable and depends on the rate of absorption of vitamin K_1 , the serum concentration achieved, and the time necessary for the synthesis of activated clotting factors. A decrease in the INR can often occur within several hours, although it may take 8â€“24 hours to reach target values.[5 , 11 , 21 , 25] Maintenance of a normal INR depends on the half-life of the vitamin K_1 , maintenance of an effective serum concentration, and the half-life of the anticoagulant involved. The IV route is unpredictably faster than the oral route in restoring the INR to a safe range.[14 , 18] A comparison of oral versus intravenous vitamin K_1 therapy for excessive anticoagulation, without major bleeding, demonstrated that those individuals with INRs 6â€“10 had similarly improved INRs at 24 hours and that the IV group was more often overcorrected to an INR <2.[18]

Dosing and Administration

The optimal dosage regimen for vitamin K_1 remains unclear. Variables include the vitamin K_1 pharmacokinetics and the amount and type of anticoagulant ingested.[26] Reported cases of LAAR poisoning have required as much as 50â€“250 mg of vitamin K_1 daily for weeks to months.[2 , 6 , 10 , 16 , 17 , 29 , 33] A reasonable starting approach for a patient who has overdosed on LAAR is 25â€“50 mg of vitamin K_1 , orally 3â€“4 times a day for 1â€“2 days. The INR should be monitored and the vitamin K_1 dose adjusted accordingly. Once the INR is <2, a downward titration in the dose of vitamin K_1 can be made on the basis of factor VII analysis. For an ingestion of brodifacoum, serial serum levels of brodifacoum may be helpful in determining the ultimate duration of treatment.[6] See Table 57-4 for the management of patients

with elevated INRs secondary to excessive warfarin.

IV administration of vitamin K_1 should be reserved for life-threatening bleeding and serious bleeding at any elevation of INR (Table 57-4).[1] Under these circumstances, patients may be supplemented with prothrombin complex concentrate; fresh-frozen plasma or recombinant factor VIIa can be considered as an alternative to prothrombin complex concentrate. A starting dose of 10 mg of vitamin K_1 is reasonable. To minimize the risk of an anaphylactoid reaction, the preparation should be diluted with preservative-free 5% dextrose, 0.9% sodium chloride, or 5% dextrose in 0.9% sodium chloride, and administered slowly, at a rate not to exceed 1 mg/min in adults. Precautions should be anticipated in the event of an anaphylactoid reaction.

Because the duration of action of vitamin K_1 is short-lived, the dose must be repeated 2â€“4 times daily. The onset of the effect of vitamin K_1 is not immediate, regardless of the route of administration.

Vitamin K_1 is available orally as a 5-mg tablet.

Antidotes in Depth

Protamine

Mary Ann Howland

History

Protamine is a rapidly acting antidote that is used for reversing the anticoagulant effects of unfractionated heparin (UFH) and potentially low-molecular-weight heparin (LMWH). The antidotal property of protamine was recognized in the late 1930s, and it was approved for use as an antidote for heparin overdose in 1968.[48] However, the largest body of literature pertaining to protamine originates from its use in neutralizing heparin following cardiopulmonary bypass and dialysis procedures.

Pharmacology

The protamines are a group of simple basic cationic proteins found in fish sperm that bind to heparin to form a stable salt. Commercially available protamine sulfate is derived from the sperm of mature testes of salmon and related species. On hydrolysis, it yields basic amino acids, particularly arginine,

proline, serine, and valine, but not tyrosine and tryptophan. The effects of protamine sulfate and protamine chloride appear to be comparable.[39] The molecular weight of heparin ranges from 3,000â€“30,000 daltons and is composed of approximately 45 monosaccharide chains.

One milligram of protamine will neutralize approximately 100 U (1 mg) of UFH (mean molecular weight [MW] ~12,000 daltons). However, there is no proven method for neutralizing LMWH. Protamine neutralizes approximately 60% of the antifactor Xa activity of LMWH. Because the interaction of protamine and heparin is dependent on the MW of heparin, the lower-molecular-weight heparin (mean MW 4500 daltons) has reduced protamine binding. This protamine-resistant fraction in LMWH is an ultralow-molecular-weight fraction with low sulfide charge.[12] It is suggested that 1 mg enoxaparin equals ~100 antifactor Xa units. There are no human studies that have robust evidence either demonstrating or refuting a beneficial effect of protamine on bleeding related to LMWH. Within the first 8 hours following administration, the recommendation for reversal of the antithrombotic effect of LMWH is to administer 1 mg protamine per 100 antifactor Xa units of LMWH. A second dose of 0.5 mg protamine should be administered per 100 antifactor Xa units if bleeding continues.[24]

In animal studies, synthetic protamine variants were effective in reversing the anticoagulant effects of LMWH and are reported to be less toxic than protamine. These agents are not available for clinical use.[24,29,59,60]

Mechanism of Action

Heparin is a large electronegative substance that is rapidly complexed by the electropositive protamine, forming an inactive salt. Heparin is an indirect anticoagulant, requiring a cofactor. This cofactor formerly called antithrombin III, now referred to simply

as AT,[24] alters its stereochemistry and thereby catalyzes the subsequent inactivation of thrombin and other clotting factors. Only about one-third of an administered dose binds to AT and this fraction is responsible for most of its anticoagulant effect.[3,41] LMWH has a reduced ability to inactivate thrombin caused by lesser AT binding, but the smaller fragments of LMWH inactivate factor Xa almost as well as the larger molecules of UFH, allowing for equal efficacy.[24] Immunoelectrophoresis demonstrates that because of its net positive charge, protamine has a greater affinity for heparin than AT, producing a dissociation of the heparinâ€“AT complex in favor of a protamine-heparin complex.[49]

Adverse Effects, Risk Factors, and Safety Issues

Since the advent of cardiopulmonary bypass surgery, protamine has been routinely employed in the neutralization of heparin at the completion of the procedure. Millions of patients are exposed to protamine each year and approximately 100 deaths are reportedly associated with the use of protamine under these circumstances. It is largely in this setting that the adverse effects of protamine are also documented and studied.[26,27,42] It is often difficult to separate the adverse effects caused by protamine from those of the protamineâ€“heparin complex and those actually related to that of heparin. Adverse effects associated with protamine include both rate- and nonâ€“rate-related hypotension,[15,16,17 and 18,20,31,34,53,56] anaphylactic[30] and anaphylactoid reactions,[33,44,46] bradycardia,[1] thrombocytopenia,[64] leukopenia, decreased oxygen consumption,[61,63] acute lung injury,[4,58] pulmonary hypertension,[6] and anticoagulant effects.[2]

The mechanisms for these adverse effects are multifactorial. The strong net-positive charge of protamine may be responsible for some of the adverse effects and probably directly injures a variety of organelles, including platelets.[9,65] The protamineâ€“heparin

complex activates the arachidonic acid pathway and the production of thromboxane is at least partly responsible for some of the hemodynamic changes, including pulmonary hypertension.[6,11,25,45,65] Pretreatment with indomethacin limits these effects.[11,25,45,65] Free protamine or protamine complexed with heparin can convert L-arginine to nitric oxide (formerly called endothelium-derived relaxing factor), which, in turn, causes vasodilation and inhibits platelet aggregation and adhesion.[50] Protamine administered in the absence of heparin, or in an amount exceeding that necessary for heparin neutralization, can act as an anticoagulant and may inhibit platelet function, resulting in weaker clot formation.[32,61] This anticoagulant effect may result from effects on factor VII and/or AT. Protamine in excess of heparin can enter the myocardium and decrease cyclic adenosine monophosphate (cAMP), causing myocardial depression.[6] Protamine and protamineâ€“heparin complexes can activate the complement pathway and contribute to vasoactive events.[6,51] Protamine stimulates mast cells in the human heart and skin to release histamine.[6] Risk factors for protamine-induced adverse reactions include prior exposure, which may occur during a previous

surgery, history of nonprotamine medication allergy, a rapid rate of infusion, or a history of allergy to fish.[51] A prospective study reported a 0.06% incidence of anaphylactic reactions to protamine in all patients undergoing coronary artery bypass, but a 2% incidence in diabetics using neutral protamine Hagedorn (NPH) insulin.[7] The resultant elevation of histamine levels, the activation of complement, and elevated IgE, IgA, and IgG concentrations are also suggested as mechanisms for the adverse effects.[40,57,66,67] Diabetic patients receiving daily subcutaneous injections of a protamine-containing insulin (NPH) have a 40â€“50% increased risk of adverse reactions.[19,22,30,38,56]

Occasionally, patients manifesting a protamine allergy are

presumed to have insulin allergy.[37] In diabetic patients receiving protamine insulin injections, the presence of serum antiprotamine IgE antibody is a significant risk factor for acute protamine reactions. Only patients with previous exposure to protamine insulin injections had serum antiprotamine IgE antibodies. However, in the group without previous protamine insulin exposure, antiprotamine IgG antibody was noted as a risk factor for protamine reactions.[67] Either naturally occurring cross-reacting antibodies, or perhaps previously unrecognized protamine exposure, was responsible for the generation of these IgG antibodies.

Alternatives to Protamine in Patients at High Risk for an Adverse Drug Reaction

There are limited options for the reversal of heparin in patients who have previously experienced anaphylaxis following protamine therapy, or in patients who are expected to be at high risk for a protamine reaction. Clotting factors may be replaced, or exchange transfusion instituted in neonates, and protamine avoided, or protamine may be used while preparing to treat anaphylaxis expectantly. Several alternatives are under investigation and include the placement of heparin removal devices in the coronary artery bypass extracorporeal circuit, as well as the use of hexadimethrine, methylene blue, platelet factor 4, and heparinase as antidotes.[7,36] Pretreatment with antihistamines and corticosteroids may be sufficient for immune-mediated mechanisms, but will probably not be beneficial for pulmonary vasoconstriction and nonâ€“immune-mediated anaphylactoid reactions.[28]

Dosing in Cardiopulmonary Bypass

Protamine is most frequently used at the end of cardiopulmonary bypass operations to reverse the effects of heparin. There are many regimens used for protamine dosing, including (a) giving an arbitrary amount of protamine (eg, 0.2 mg/kg); (b) giving protamine in a ratio of 0.6â€“1.5:1 times the initial heparin dose, resulting in an activated coagulation time (ACT) of about 480 seconds; and (c) giving protamine in a ratio of 0.75â€“2.1:1 times the total operative heparin dose.[68] Two additional methods of calculating the protamine dose to improve accuracy and avoid excess protamine are proposed.[32,68] One advocates an initial protamine dose based on ACT, with subsequent doses based on the ratio of the change in thrombin time to the heparin-neutralized thrombin time. If this ratio is greater than 12 seconds, then 10-mg incremental protamine doses should be administered.[32] The other uses a nomogram based on heparin activity in mg/kg versus ACT.[68] Both methods demonstrate efficacy with 2-mg/kg doses of protamine, about one-half of the dose previously used. With these approaches, the ACT responded to protamine within 5 minutes, decreasing in value from between 550 and 700 seconds to a control of 150 seconds. Other investigators suggest a variety of monitoring methods and dosing schemas in this setting.[13,23,54]

Heparin Rebound and Redosing of Protamine

A heparin anticoagulant rebound effect is noted after cardiopulmonary bypass and is attributed to the presence of detectable circulating heparin several hours after apparently adequate heparin neutralization with protamine. The incidence of heparin rebound and the need for additional protamine range from 4â€“42% depending on the neutralization protocol.[21,43,52] It is likely that larger heparin doses may prolong the clearance of heparin, contributing to higher than expected heparin levels.[52] When 300 U/kg of body weight doses of heparin were reversed at

the end of cardiopulmonary bypass with 3 mg/kg of protamine, a 14% incidence of small but detectable concentrations of circulating heparin was noted at 2 hours, which lasted less than 1 hour in all but 1 case.[43] The prothrombin time was prolonged and thrombocytopenia was noted, but there was no increase in blood loss.

Dosing Considerations

Approximately 1 mg of protamine will neutralize about 100 U (1 mg) of heparin (UFH). A limited number of studies suggest incomplete neutralization by protamine of the LMWHs enoxaparin, dalteparin, and tinzaparin. Present recommendations are to administer 1 mg protamine per 100 antifactor Xa units where 1 mg enoxaparin equals 100 antifactor Xa units. A second dose of 0.5 mg protamine should be administered per 100 antifactor Xa units if bleeding continues.[14] A number of tests can directly measure heparin levels or indirectly measure heparin's effect on the clotting cascade.[8,10,13] These tests may be helpful in determining the appropriate dose of protamine. Because excessive protamine can act as an anticoagulant, the dose chosen should always be an underestimation of that which is needed. In the case of unintentional overdose, the half-life of heparin should be considered, because half of the administered dose of heparin is eliminated within 60â€“90 minutes. In the case of an unintentional overdose without bleeding, the short half-life of heparin and the potential risks of protamine administration usually argue for a conservative approach of patient observation, rather than protamine reversal of anticoagulation. If protamine use is necessary to treat active bleeding, the dose must be administered intravenously over 15 minutes to limit rate-related hypotension.[35,62]

Dosing in the Overdose Setting

When faced with a patient believed to have received an overdose of an unknown quantity of heparin, the decision to use protamine should be determined by the presence of a prolonged activated partial thromboplastin time (aPTT) and the presence of persistent bleeding.

In each circumstance, the potential risks of protamine use (especially in those who have had a prior life-threatening reaction to protamine as well as in a diabetic receiving a protamine-containing insulin) and the risks of continued heparin anticoagulation should be evaluated. A baseline ACT, thrombin time, heparin-neutralized thrombin time, heparin activity, platelets, prothrombin time (PT)/partial thromboplastin time (PTT), hemoglobin, and hematocrit should be obtained. Because of the routine nature of heparin reversal following cardiopulmonary bypass, consultation with members of the bypass team may be helpful. An empiric dose of protamine may be suggested by the baseline ACT: (a) an ACT of 150 seconds necessitates no protamine; (b) an ACT of 200â€“300 seconds necessitates 0.6 mg/kg; and (c) an ACT of 300â€“400 seconds necessitates 1.2 mg/kg. These doses have not been tested outside the operating room. The ACT should be repeated 5â€“15 minutes following the protamine dose and in 2â€“8 hours (to evaluate the potential for heparin rebound), and further dosing should be based on these values.

When the ACT is not available, 25â€“50 mg of protamine can be administered to an adult and adjusted accordingly. Repeat dosing in several hours may be necessary if heparin rebound occurs. The dose should be administered intravenously slowly over 15 minutes with resuscitative equipment immediately available. Neonates should not receive protamine that has been reconstituted with bacteriostatic water containing benzyl alcohol.

Future interventions for bleeding following heparin may include activated factor VII and adenosine triphosphate. Activated factor

VII therapy was recently shown to be successful in treating postoperative bleeding in a patient with renal failure who was given LMWH and aspirin.[47] Adenosine triphosphate completely reversed clinical bleeding related to LMWH in a rat model. These agents have not been FDA approved for clinical use in this setting.[14]

Availability

Protamine is available either as a parenteral solution ready for injection or as a powder to be reconstituted with 5 mL of sterile or bacteriostatic water for injection. When the vials containing 50 mg of protamine are used, they should be shaken vigorously after the water is added. The final solution of either preparation contains 10 mg of protamine per mL.

Summary

Protamine is an effective, rapidly acting antidote used to reverse the anticoagulant effect of unfractionated heparin, while its ability to reverse the effects of LMWH is less clear. This antidote should only be used for a prolonged aPTT in the presence persistent bleeding, since potential risks of its use include hypotension, anaphylactic reactions, dysrhythmias, leukopenia, thrombocytopenia and acute lung injury. Activated factor VII and adenosine triphosphate may be used in the near future to treat heparin-induced bleeding.

Chapter 58
Calcium Channel Blockers

Francis DeRoos

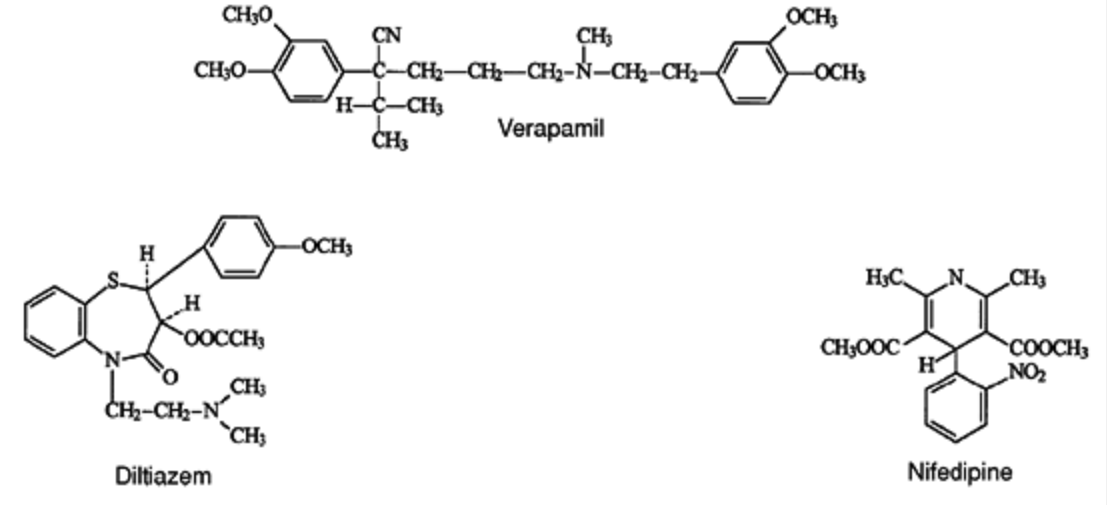

Figure. No Caption Available.

A 40-year-old woman with a history of insulin-dependent diabetes

mellitus, coronary artery disease, and depression presented to the hospital with multiple nonspecific complaints, including â€œnot feeling well,â€• dyspnea, weakness in the legs, and lightheadedness. Physical examination revealed a morbidly obese woman in no distress whose initial vital signs were: blood pressure, 120/70 mm Hg; heart rate, 100 beats/min; respiratory rate, 18 breaths/min; temperature 98.9Â°F (37.2Â°C). The lungs were clear to auscultation, and cardiac examination revealed normal S_1 and S_2, and an S_4 gallop, but no murmurs or rubs. Her abdomen was obese with active bowel sounds and no tenderness. Neurologic assessment revealed a normal mental status and no focal deficits.

Because of the nonspecific complaints in a patient with significant medical conditions, a broad diagnostic evaluation was begun that included a rapid bedside glucose measurement, a urinalysis, electrolytes, renal function testing, liver enzymes, complete blood count, and an electrocardiogram (ECG). The ECG demonstrated a sinus rhythm at 100 beats/min, with normal PR and QRS intervals, left atrial enlargement, and evidence of an old anterior wall infarction (Fig. 58-1). There was no change from previous ECGs on file at the hospital.

Approximately 4 hours into her evaluation and hospital stay, the patient complained of lightheadedness and weakness. Repeat physical examination revealed a slightly lethargic but arousable and cooperative woman. Her blood pressure was 70/30 mm Hg with a heart rate of 90 beats/min and regular. A repeat ECG revealed normal sinus rhythm and first degree heart block, with a PR interval of 240 msec (Fig. 58-2). At this time, she confided in the physician that the true reason for her visit was that she ingested 20 diltiazem (90-mg) tablets in a suicide attempt just prior to coming to the hospital.

Initial therapy included boluses of 0.9% sodium chloride, calcium chloride (2 g intravenously), glucagon (1 mg intravenously), and intravenous infusions of dopamine and isoproterenol which resulted

in transient improvement in systolic blood pressure to 98 mm Hg. One hour after her initial hypotensive episode, the patient suffered a cardiac arrest with junctional rhythm of 65 beats/min and no measurable blood pressure (Fig. 58-3). With aggressive therapy, including cardiopulmonary resuscitation (CPR), endotracheal intubation, atropine (3 mg intravenously), high-dose intravenous infusions of dopamine and isoproterenol, and a glucagon bolus (5 mg intravenously), the systolic blood pressure returned to between 40 and 65 mm Hg with a heart rate of 50â€“60 beats/min. Over the next 3 hours multiple pharmacologic agents, including repeat boluses of calcium chloride and continuous infusions of glucagon (5 mg/h), amrinone (200-mg bolus then 800 mg/h), and phenylephrine were initiated, without improvement in blood pressure. During this period the patient's serum glucose had risen from 250â€“800 mg/dL and an insulin infusion was begun.

Because of only limited improvement after multiple pharmacologic agents, a transcutaneous pacer was applied but was unable to capture. A transvenous right-ventricular pacemaker was then placed with intermittent capture at 70 beats/min, but the systolic blood pressure remained below 80 mm Hg. An intraaortic balloon pump (IABP) was placed, and within 15 minutes the blood pressure improved to 100/50 mm Hg. The patient was maintained on the IABP and transvenous pacemaker, and slowly weaned off the multiple inotropic agents and vasopressors over the next 24 hours. After a complicated 3-week hospitalization, the patient was discharged to an inpatient psychiatric facility with complete neurologic recovery.

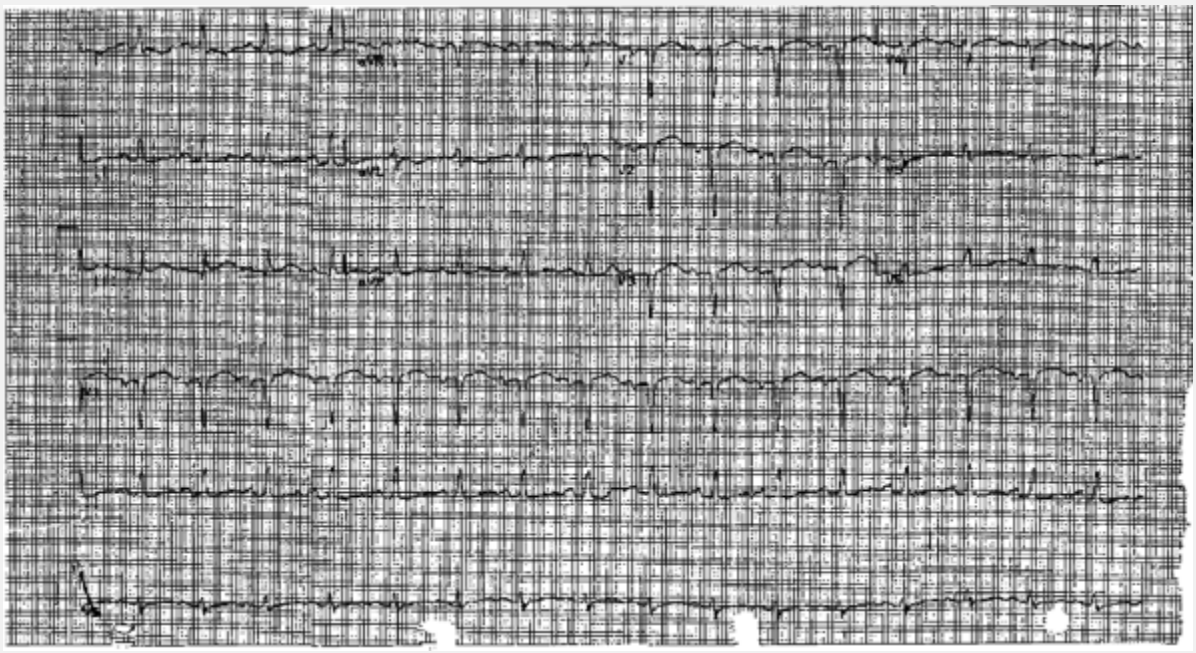

Figure 58-1. This 12-lead electrocardiogram taken 2 hours postingestion of 1800 mg of sustained-release diltiazem demonstrates a sinus tachycardia at 100 beats/min with a normal QRS axis, normal intervals, left atrial enlargement, and an old anterior wall myocardial infarction.

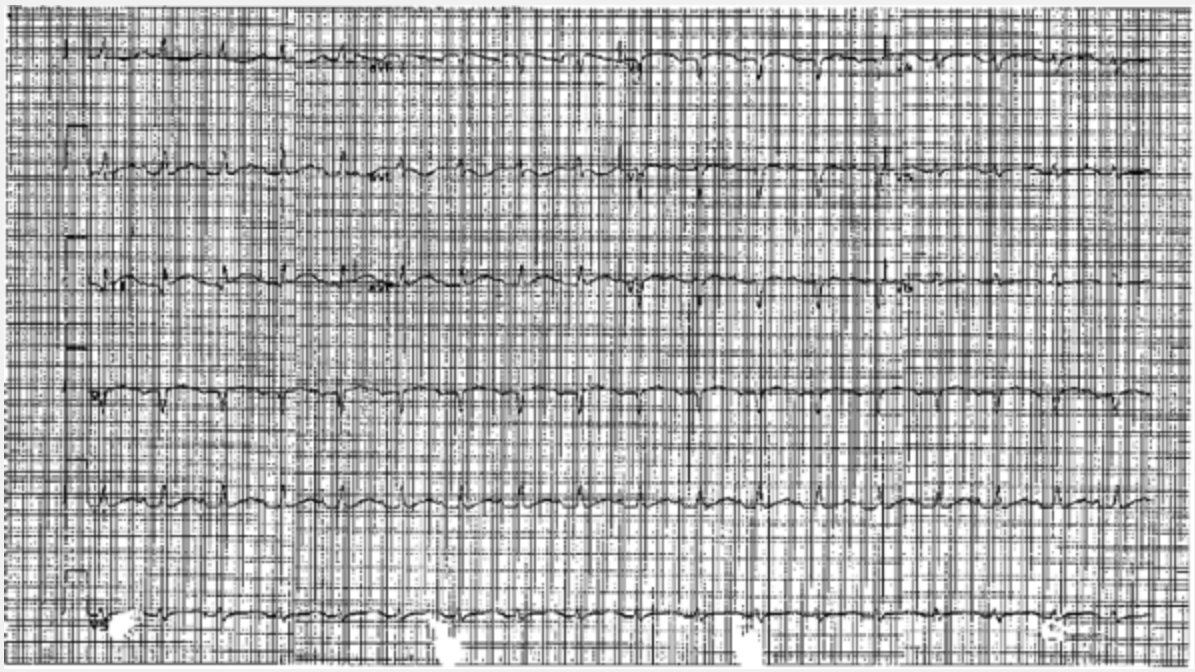

Figure 58-2. This 12-lead electrocardiogram, taken 6 hours postingestion of 1800 mg of sustained-release diltiazem, demonstrates first-degree heart block with a PR interval of 260 msec and no other changes as compared to the patient's previous electrocardiogram (Fig. 58-1).

Figure 58-3. This 3-lead rhythm strip was obtained 9 hours postingestion of 1800 mg of sustained-release diltiazem, shortly after the patient became obtunded, hypotensive, and bradycardic. The electrocardiogram demonstrates a junctional bradycardia at 65 beats/min with widened QRS interval of 130 msec and possible inferior ischemia.

Calcium channel blockers (CCBs) were first used experimentally in the 1960s, and their use has steadily risen to the point where they are some of the most frequently prescribed cardiovascular drugs.[47] Mirroring this widespread use, poisonings involving CCBs have also risen. The combination of compliance-improving sustained-release formulations and potent hemodynamic effects complicates the management of patients poisoned with these drugs. The hallmarks of toxicity include hypotension, from vasodilation and impaired myocardial contractility, and bradydysrhythmias. In severely

poisoned patients, no therapeutic intervention is demonstrated to be consistently effective. Management decisions must be made on an individual patient basis with careful assessment of the physiologic response to each treatment.

TABLE 58-1. Classification of Calcium Channel Blockers Available in the United States

Class	Specific Compounds
Phenylalkylamine	Verapamil (Calan, Isoptin, Verelan)
Benzothiazepine	Diltiazem (Cardizem, Dilacor, Tiazac)
Dihydropyridines	Nifedipine (Adalat, Procardia) Isradipine (DynaCirc) Amlodipine (Norvasc) Felodipine (Plendil) Nimodipine (Nimotop) Nisoldipine (Sular) Nicardipine (Cardene)
Diarylaminopropylamine ether	Bepridil (Vascor)
T-channel blocker	None (Mibefradil withdrawn)

Epidemiology

CCBs were first introduced to the US pharmaceutical market in the late 1970s. Currently, there are 10 CCB agents available in either regular or sustained-release formulations (Table 58-1). They are used for a variety of medical conditions, including hypertension, stable angina, dysrhythmias, migraine headaches, Raynaud phenomenon, and subarachnoid hemorrhage.

In 1986, more than 1200 exposures and 7 deaths related to CCBs were reported to the American Association of Poison Control Centers. In 2003, those figures increased to 9650 exposures, including 2042 characterized by moderate to major toxicity, and an additional 57 deaths (Chap. 130). This significant rise in fatalities is most likely the result of the increased use and access to these drugs, although the introduction of sustained-release preparations in 1988 may also play a role.

Pharmacokinetics and Toxicokinetics

All CCBs are well-absorbed orally and undergo hepatic oxidative metabolism predominantly via CYP3A subgroup of the cytochrome P450 (CYP) enzyme system.[45,62,119] Norverapamil, formed by *N*-demethylation of verapamil is the only active metabolite and retains 20% of the parent compound's activity.[78] Diltiazem is predominantly deacetylated into minimally active deacetyldiltiazem, which is then eliminated via the biliary tract.[62] In overdose, these hepatic enzymes become saturated, reducing the

potential control of the first-pass effect and increasing the quantity of active drug absorbed systemically. This saturation of drug metabolism contributes to the prolongation of the half-lives reported following overdose of various CCBs.[19,43,44,146] All CCBs are highly protein bound.[87,119] Volumes of distribution are large for verapamil (5.5 L/kg)[120] and diltiazem (5.3 L/kg),[119] and somewhat smaller for nifedipine (0.8 L/kg).[93] Although not well-studied, the substantial protein binding and the large volumes of distribution make it unlikely

that extracorporeal drug removal with hemodialysis or hemoperfusion would be of any value in overdose. Several case reports offer clinical support for this conclusion.[149,151,169]

One interesting aspect of the pharmacology of CCBs is their potential for drugâ€“drug interactions. CYP3A, which metabolizes most CCBs, is also responsible for the initial oxidation of numerous other drugs. Verapamil and diltiazem specifically compete for this isozyme and can decrease the clearance of many drugs including carbamazepine, cisapride, quinidine, various Î²-hydroxy-Î²-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, cyclosporine, tacrolimus, most HIV-protease inhibitors, and theophylline.[1,140] In June 1998, mibefradil, a structurally unique CCB, was voluntarily withdrawn following several reports of serious adverse drug interactions caused in part by mibefradil's potent inhibition of the CYP3A.[7,104] Whereas other inhibitors of CYP3A4, such as cimetidine, fluoxetine, some antifungals, macrolide antibiotics, and even the flavonoids in grapefruit juice, may raise serum concentrations of several CCBs, the clinical significance of this effect remains unclear.[1]

In addition to affecting CYP3A, verapamil and diltiazem also inhibit P-glycoproteinâ€“mediated drug transport into peripheral tissues. This inhibition results in elevated serum concentrations of drugs, such as cyclosporine and digoxin, which use this transport system.[34,72] Unlike diltiazem and verapamil, nifedipine and the other dihydropyridines do not appear to affect the clearance of other agents via CYP3A or P-glycoproteinâ€“mediated transport.[2]

Pathophysiology

Calcium plays an integral part in excitation-contraction coupling and myocardial conduction (Fig. 58-4). Initially, Ca^{2+} is driven intracellularly down large concentration and electrical gradients through calcium-specific voltage-sensitive channels. These channels, specifically identified as L-type calcium channels, are located in the plasma membrane of all types of muscle cells[81] and are composed of

homologous protein subunits, also found in some sodium and potassium channels.[85] The Î±$_{1c}$ subunit is the pore-forming portion of this channel and is where all CCBs bind to prevent Ca^{2+} transport.[64] There are many other types of calcium channels, including N, P, T, Q, and R types, that can be found either intracellularly on the sarcoplasmic reticulum or on cell plasma membranes, particularly in neuronal and secretory tissue.[153] They may be stimulated by cellular stretch (stretch-operated), specific neurohormonal binding (receptor-operated), or voltage changes (voltage-sensitive).[144] Skeletal muscle depends exclusively on intracellular Ca^{2+} stores for excitation contraction coupling, so intracellular influx of Ca^{2+} does not add much to the total Ca^{2+} pool required for contraction. In cardiac and smooth muscle cells, however, this influx is critical.

In smooth muscle, the rapid influx of calcium binds calmodulin, and the resulting complex stimulates myosin light-chain kinase activity.[3] The myosin light-chain kinase phosphorylates, and thus activates, myosin, which subsequently binds actin, causing a contraction to occur (Fig. 58-4).[82,128] In myocardial cells, this slow Ca^{2+} influx creates the plateau phase (phase 2) of the action potential.[125] The Ca^{2+} then acts as a second messenger by binding to and opening a receptor-operated calcium channel on the sarcoplasmic reticulum which releases Ca^{2+} from the vast stores of the sarcoplasmic reticulum into the cytosol.[73,74] This is often termed calcium-induced calcium release.[40,183] Calcium then binds troponin C, which causes a conformational change that displaces troponin and tropomyosin from the actin allowing actin and myosin to bind, resulting in a contraction (Chap. 23; Fig. 58-4).[84]

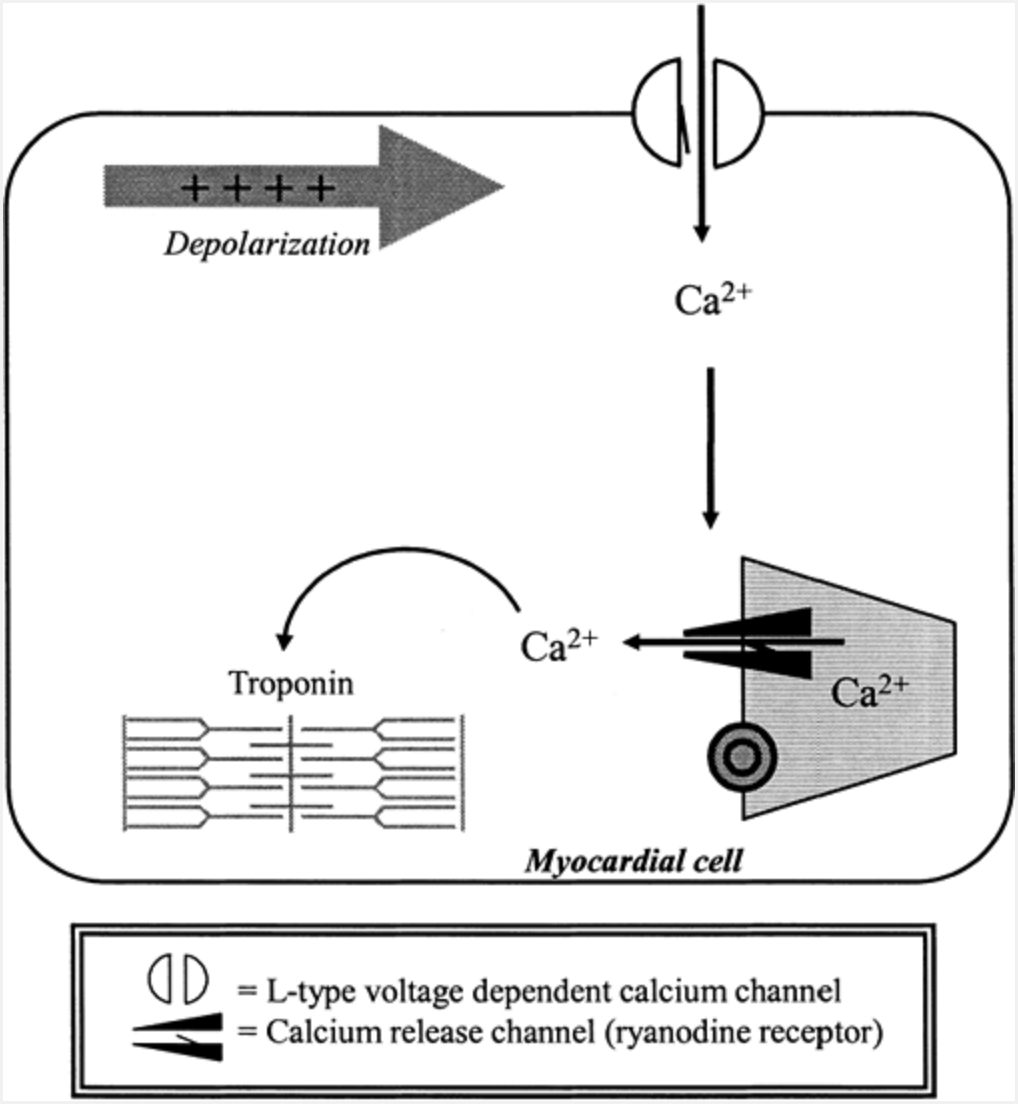

Figure 58-4. Normal contraction of myocardial cells. The L-type voltage sensitive calcium channels open to allow calcium ion influx during myocyte depolarization. These calcium ions cause the concentration-dependent release of more calcium ions from the sarcoplasmic reticulum that ultimately produce cardiac contraction.

In addition to its role in myocardial contractility, Ca^{2+} influx is also

important in myocardial conduction. Calcium influx plays an important role in the spontaneous depolarization (phase 4) of the action potential in the sinoatrial (SA) node.[125] This Ca^{2+} influx also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues particularly the atrioventricular (AV) node.[147] After opening, the rate of recovery of these slow calcium channels, in both the SA and AV nodal tissue, determines rate of conduction.[89,173]

All commercially available CCBs exert their physiologic effects by antagonizing L-type voltage-sensitive calcium channels.[83,175] The differences among their pharmacologic effects is related to a combination of specific receptor affinity and types of antagonism. This impairs Ca^{2+} influx into muscle cells, particularly the myocardial and smooth muscle, which are dependant on this influx for normal function. In the vascular smooth muscle, the cytosolic Ca^{2+} concentration maintains basal tone and any

decrease of Ca^{2+} influx results in relaxation and arterial vasodilation.[77] In the myocardium, this impaired Ca^{2+} flow results in a decreased force of contraction. In addition, the delay in recovery of the slow calcium channels in the specialized SA and AV nodal tissue results in decreased heart rate and conduction.[121]

The CCBs currently available in the United States are classified into four structural groups (Table 57-1). Each group binds a slightly different region of the $Î±_{1c}$ subunit of the calcium channel and thus has different affinities for the various L-type calcium channels, both in the myocardium and the vascular smooth muscle.[111,123,124,166,175] For several reasons, verapamil, a phenylalkylamine, has the most profound inhibitory effects on the SA and AV nodal tissue, whereas diltiazem has less profound effects and dihydropyridines have little, if any, direct myocardial effects in therapeutic dosing.[86,123,124] First, in therapeutic dosing, nifedipine does not alter the normal calcium channel recovery within the myocardium.[89,100] Second, not only do verapamil and, to a lesser extent, diltiazem impede Ca^{2+} influx and

channel recovery, but their blockade is potentiated as the frequency of channel opening increases.[55,89,137] Finally, dihydropyridines bind the calcium channel best at less-negative membrane potentials. Because the resting potential for myocardial muscle (-90 mV) is lower than that of vascular smooth muscle (-70 mV), dihydropyridines bind preferentially in the peripheral vascular tissue.[137] As a class, dihydropyridines have the most potent vasodilatory effects. Verapamil is the next most potent, followed by diltiazem. Consequently, verapamil is the most effective at decreasing heart rate, cardiac output, and blood pressure, whereas nifedipine produces the greatest decrease in systemic vascular resistance. Because nifedipine, and all the dihydropyridines, have little myocardial effect at therapeutic levels, the baroreceptor reflex remains intact and a slight increase in heart rate and cardiac output may occur.[166] Isradipine is the only dihydropyridine whose inhibitory effect on the SA node is significant enough to blunt any reflex tachycardia.[46]

These receptor-binding differences among the CCB classes determine the potential therapeutic role of each. Verapamil and diltiazem are used in the management of hypertension, to reduce myocardial oxygen demand, to achieve rate control in atrial flutter and atrial fibrillation, and to abolish supraventricular reentrant tachycardias.[2] Dihydropyridines are typically used to treat diseases with increased peripheral vascular tone such as hypertension, Raynaud phenomenon, Prinzmetal angina, esophageal spasm, vascular headaches, and post-subarachnoid hemorrhage vasospasm.[24,51,158]

Bepridil is unique because in addition to its calcium channel-blocking effects, it is a potent fast sodium channel and potassium channel blocker.[66] This impairs both myocardial contractility and conduction and results in prolongation of the effective refractory period of the AV node, the action potential itself, and myocardial repolarization.[66] Bepridil prolongs the QTc interval and may precipitate malignant ventricular dysrhythmias, including torsade de pointes.[6,66] This dysrhythmogenic effect is potentiated in the setting of hypokalemia.

Bepridil is classified and used as an antidysrhythmic agent, but because of its dysrhythmogenic potential its use is limited to patients who are refractory to all other therapy.[66]

Clinical Manifestations

The life-threatening toxicity of CCBs is manifest largely within the cardiovascular system and is an extension of their therapeutic effects. Myocardial depression and peripheral vasodilation occur, producing bradycardia and hypotension.[152] Myocardial conduction may be impaired, producing AV conduction abnormalities, idioventricular rhythms, and complete heart block.[12,42,68,75,105,113,131,139] Junctional escape rhythms frequently occur in patients with significant poisonings.[17,28,36] The negative inotropic effects may be so profound, particularly with verapamil, that ventricular contraction may be completely inhibited.[14,36,58] Patients may present initially asymptomatic but deteriorate rapidly into severe cardiogenic shock.[157,177]

Hypotension is the most common abnormal vital sign finding following an overdose.[142,143] The associated clinical findings represent the degree of cardiovascular compromise and hypoperfusion of the patient's central nervous system. Early or mild symptoms include dizziness, fatigue, and lightheadedness, whereas more severely poisoned patients may manifest lethargy, syncope, altered mental status, coma, and death.[29,60,68,99,131,148] Cases of seizures,[60,68,116,134,162] cerebral ischemic events,[150,155,179] ischemic bowel,[54,56,161,178] and renal failure,[113,139] occurring in the setting of CCB-induced cardiogenic shock, also are reported. Severe CNS depression is distinctly uncommon, and if respiratory depression or coma is present without severe hypotension, coingestants or other causes of altered mental status must be considered. Gastrointestinal symptoms, such as nausea and vomiting, are also uncommon.[70]

Although receptor selectivity is lost in overdose, and all CCBs can produce severe bradycardia, hypotension, and death,[152] there are

some subtle variations in presentation, depending on the agent. The CCBs with the most significant myocardial effects, verapamil and, to a lesser extent, diltiazem, are associated with more negative inotropic and chronotropic effects.[135,138] In a prospective, poison control center-based study, AV nodal block occurred much more frequently in the setting of verapamil poisoning.[142] In contrast, nifedipine, because of its limited myocardial binding, may produce tachycardia or a â€œnormalâ€• heart rate initially, with bradycardia developing only in patients with more substantial ingestions.[27,63,178,182] Deaths associated with dihydropyridines occur, although they are relatively uncommon.[99,108,135]

Numerous reports document hyperglycemia in patients with severe CCB poisoning.[18,29,38,60,68,113,122,139,162,177] Insulin release from the Î²-islet cells in the pancreas is dependent on calcium influx via an L-type calcium channel.[107,115] In CCB overdose, this channel is also antagonized, impairing normal calcium influx and reducing insulin release.[31] The hyperglycemic effect may be exacerbated in a diabetic patient, or if glucagon is used as inotropic therapy (Chap. 48).[170]

Acute pulmonary injury is also associated with CCB poisoning.[18,50,63,71,80,109] Although the mechanism is unknown, precapillary vasodilation may cause an increase in transcapillary hydrostatic pressure.[71,80] The elevated pressure gradient results in increased pulmonary capillary transudates and, ultimately, interstitial edema.

Several factors, including the CCB involved, the dose ingested, the product formulation, and the patient's underlying cardiovascular health, may play a role in the ultimate degree of toxicity. Coingestion with other agents that have cardiovascular activity, such as Î²-adrenergic antagonists and digoxin, may potentiate conduction abnormalities.[23,48,79,101,188]

The product formulation (immediate or regular vs. sustained release) affects the onset of symptoms and duration of toxicity. With regular-

release formulations, toxicity is often present within 2â€“3 hours of ingestion.[13,143] With sustained-release products, however, initial signs or symptoms may be delayed for 6â€“8 hours, and delays

of up to 15 hours are reported.[13,143,160,172] In addition, with ingestion of sustained-release products, the drug's apparent half-life is prolonged and toxicity may last longer than 48 hours.[9,12,36,103]

Comorbidity and age are two factors that negatively impact on both morbidity and mortality in patients with CCB poisoning. Elderly patients, and those with underlying cardiovascular disease such as congestive heart failure, are much more sensitive to the myocardial depressant effects of CCBs.[27,118] Even at therapeutic doses, these individuals may develop symptoms of mild hypoperfusion, such as dizziness and fatigue, much more frequently.[59,69,75,127]

Diagnostic Testing

All patients with a suspected CCB ingestion should be attached to a cardiac monitor and have a 12-lead ECG performed to assess both their heart rate and rhythm, as well as the presence of any conduction abnormalities. Careful assessment of the degree of hypoperfusion, if any, may include a chest radiograph, pulse oximetry, and serum chemistry analysis for metabolic acidosis. Assays for various CCB serum concentrations are not routinely available and are not used to manage patients after overdose. If a patient presents with bradydysrhythmias of unclear origin, assessment of electrolytes, particularly potassium and magnesium, renal function, and a digoxin concentration may be helpful, although careful history taking often provides the most valuable clues. If hyperkalemia is present, cardioactive steroid poisoning should be considered, particularly in the absence of renal failure. Because calcium channel antagonist poisoning can impair insulin secretion from the pancreas, hyperglycemia may be detected.

Management

Any patient with a suspected CCB ingestion should be immediately evaluated, even if there are no symptoms and the vital signs are normal. Intravenous access and continuous electrocardiographic monitoring should be initiated. A 12-lead ECG should be repeated at least every 1â€“2 hours for the first several hours. If the patient's condition normalizes, ECGs can be repeated at longer intervals subsequently. Initial treatment should begin with adequate oxygenation and airway protection (as clinically indicated), and aggressive gastrointestinal decontamination. If the patient is hypotensive and there is no evidence of congestive heart failure, an initial fluid bolus of 10â€“20 mL/kg of crystalloid should be given, and repeated as needed.

Gastrointestinal decontamination is a critical intervention. Induced emesis should be avoided because CCB-poisoned patients can rapidly deteriorate and become severely hypotensive. Orogastric lavage should be considered for all patients who present early (1â€“2 hours postingestion) after large ingestions, and for those patients who are critically ill. Although the effects of orogastric lavage in an overdose involving a sustained-release CCB have not been specifically studied, and although most of these formulations tend to be large and poorly soluble, because of their significant danger in overdose, orogastric lavage should still be strongly considered. When performing orogastric lavage in a CCB-poisoned patient, it is important to remember that lavage may increase vagal tone and potentially exacerbate any bradydysrhythmias.[171] Pretreatment with a therapeutic dose of atropine may prevent this. All patients with CCB ingestions should receive 1 g/kg of activated charcoal orally. Multiple doses (0.5 g/kg) of activated charcoal (MDAC) without a cathartic should be administered to all patients with either sustained-release pill ingestions or signs of continuing absorption. Although data are limited, there is no evidence that MDAC increases CCB clearance from the serum.[146,168] Rather, its efficacy may be a result of the

continuous presence of activated charcoal throughout the gastrointestinal tract, which adsorbs any active drug from its slow-release formulation. Whole-bowel irrigation (WBI) with polyethylene glycol solution (1â€“2 L/h via nasogastric tube in adults, up to 500 mL/h in children) should be initiated for patients who ingest sustained-release products [20,167] and may be the most effective way of achieving gastrointestinal decontamination for ingestions involving these formulations.[91] Dosing should be continued until the rectal effluent is clear.

The importance of early initiation of MDAC and WBI, even for well-appearing patients with a history of sustained-release CCB ingestion, particularly children, cannot be overemphasized. It is imperative to minimize any absorption and prevent delayed cardiovascular toxicity, which can be profound and difficult to reverse. Several reports describe patients who presented with mild signs of poisoning, in whom gastrointestinal decontamination was not performed aggressively and who subsequently displayed severe toxicity.

Pharmacotherapy should focus on maintenance or improvement of both cardiac output and peripheral vascular tone.[88] Although many agents, including atropine, calcium, insulin, glucagon, isoproterenol, dopamine, epinephrine, norepinephrine, and phosphodiesterase inhibitors, have been used with reported success in CCB-poisoned patients, no single agent has consistently demonstrated total efficacy.[68,135,138,142,143] Little prospective or basic research specifically evaluates effective treatment modalities.

Therapy should begin with crystalloids and atropine, but more critically poisoned patients will not respond to these initial efforts, and inotropes and vasopressors will be needed. Although it would be ideal to initiate each agent individually and monitor the patient's hemodynamic response, in the most critically ill patients, multiple therapies should be administered simultaneously. A reasonable treatment sequence includes calcium followed by a catecholamine such as norepinephrine, high-dose insulin infusion, glucagon, and a

phosphodiesterase inhibitor. The evidence for the use of each of these drugs is discussed below.

Atropine

Atropine is considered the drug of choice for patients with symptomatic bradycardia. In an early dog model of verapamil poisoning, atropine improved heart rate and cardiac output.[49] In one prospective study, 2 of 8 bradycardic CCB-poisoned patients also had an improvement in heart rate with atropine therapy.[142] Clinical experience, however, demonstrates atropine to be largely ineffective in improving heart rate in severe CCB-poisoned patients.[29,38,74,138,148,157,179] Initial treatment with calcium might improve the efficacy of atropine.[37,70,76] Given its availability, efficacy in mild poisonings, and safety profile, atropine should still be considered as initial therapy in patients with symptomatic bradycardia. Dosing should begin with 0.5â€“1.0 mg (0.02 mg/kg in children) IV every 2 or 3 minutes up to a maximum dose of 3 mg in all patients with symptomatic bradycardia. However, because of its limited efficacy in severely poisoned patients, treatment failures should be anticipated. In patients in whom WBI or MDAC will be used, the use of atropine must be

carefully considered, weighing the potential benefits of improved heart rate, and thus cardiac output, against the anticholinergic effects potentially decreasing GI motility.

Calcium

Pharmacologically, Ca^{2+} appears to be a logical choice to treat patients with CCB toxicity. Pretreatment with intravenous Ca^{2+}, prior to verapamil use for supraventricular tachydysrhythmias, prevents hypotension without diminishing the antidysrhythmic effects.[33,156,180] This is also observed in the overdose setting where Ca^{2+} tends to improve blood pressure more than it does the heart

rate. Although the exact mechanism is unclear, boluses of Ca^{2+} increase the extracellular Ca^{2+} concentration and increase the intracellular concentration gradient. This may drive Ca^{2+} intracellularly through unaffected calcium channels. Calcium salts are beneficial in experimental models of CCB poisoning.[37,49,58] In verapamil-poisoned dogs, improvement in inotropy and blood pressure was demonstrated after increasing the serum [Ca^{2+}] by 2 mEq/L with an intravenous infusion of 10% calcium chloride at 3 mg/kg/min.[58]

Calcium ion reverses the negative inotropy, impaired conduction, and hypotension in humans poisoned by CCBs.[21,57,61,63,105,106,110,112,126,127,136,181,184] Unfortunately, this effect is often short-lived and more severely poisoned patients may not improve significantly with calcium salt administration.[26,29,38,43,50,53,74,146,151] Some authors believe that these failures might represent inadequate dosing.[20,70,106] Unfortunately, the exact dosing of calcium salts is unclear. Reasonable recommendations for poisoned adults include an initial intravenous bolus of approximately 13â€“25 mEq of Ca^{2+} (10â€“20 mL of 10% calcium chloride or 30â€“60 mL of 10% calcium gluconate) followed by either repeat boluses every 15â€–20 minutes up to 3â€–4 doses or a continuous infusion of 0.5 mEq/kg/h of Ca^{2+} (0.2â€–0.4 mL/kg/h of 10% calcium chloride or 0.6â€–1.2 mL of 10% calcium gluconate).[88,90,135] Careful selection of the calcium salt used is critical for dosing. Although there is no difference in efficacy of calcium chloride or calcium gluconate, 1 g of calcium chloride contains 13.4 mEq of calcium, which is more than 3 times the 4.3 mEq found in 1 g of calcium gluconate. Consequently, to administer equal doses of Ca^{2+}, 3 times the volume of standard calcium gluconate is required. If repeat dosing or continuous infusions are used, the serum [Ca^{2+}] and PO_4^{-3} should be closely monitored to detect if hypercalcemia or hypophosphatemia develop. These concerns are not unfounded, and may in fact significantly limit Ca^{2+} therapy.[99] Other adverse effects of intravenous Ca^{2+} include nausea,

vomiting, flushing, constipation, confusion, and angina.[90] If there is any suspicion that a cardioactive steroid such as digoxin is involved in an overdose, Ca^{2+} should be avoided until after digoxin-specific Fab is administered because it may worsen digoxin toxicity (Chap. 62).[16]

Inotropes and Vasopressors

Catecholamines are the next line of therapy in the treatment of CCB poisoning. Numerous case reports describe the success or failure of a wide variety of vasopressors, including epinephrine (success,[8,26] failure,[60,113]), norepinephrine (success,[68,122] failure[113,116]), dopamine (success,[9,39,179] failure[8,26,35,53,60,113,122,177]), isoproterenol (success,[52,113,131,139,169] failure[8,28,60,177]), dobutamine (success,[139] failure[29,35,113]), and vasopressin.[49,97,165] Experimentally, no single therapy is consistently effective. This is not surprising given the significant variability in both the CCBs and the patients involved. Mechanistically, however, either stimulation of $\hat{I}^2_1$-adrenergic receptors on the myocardium or of $\hat{I}\pm_1$-adrenergic receptors on the peripheral vascular smooth muscle are the most logical targets, but which one depends upon the etiology of the hypotension.

$\hat{I}^2$-Adrenergic agonists activate adenylate cyclase via G_s protein.[154] This results in formation of cyclic adenosine monophosphate (cAMP), which stimulates protein kinase A to phosphorylate the $\hat{I}\pm_1$ subunit of various calcium channels (Fig. 58-6).[159] It is unclear whether this phosphorylation allows calcium channels to remain open longer,[27,145] or if it opens dormant channels within the plasma membrane.[21,90] In addition, protein kinase A also phosphorylates phospholamban, which improves calcium release from troponin after contraction.[164] In the myocardium, this multifactorial increase in intracellular calcium results in improved chronotropy, dromotropy, and inotropy (Chap. 59).

In the peripheral vascular smooth muscle, $\hat{I}\pm_1$-adrenergic receptor

agonists activate receptor-operated calcium channels. This opening of nonpoisoned calcium channels allows calcium influx (Fig. 58-5),[145] which makes Î±$_1$-adrenergic agonists such as norepinephrine and phenylephrine logical choices if the hypotension is primarily the result of peripheral vasodilation, as would occur most typically with the dihydropyridine CCBs. Based on these pharmacologic mechanisms, norepinephrine appears to be an appropriate initial catecholamine to use in hypotensive CCB-poisoned patients. Its significant Î²$_1$-adrenergic activity combats

the myocardial depressant effects, while its Î±$_1$-adrenergic effects increase peripheral vascular resistance. There is some theoretical concern about using pure Î²-adrenergic receptor agonists, such as isoproterenol and, to a lesser extent, dobutamine, because Î²$_2$-adrenergic receptor agonist-induced peripheral vasodilation may worsen hypotension, particularly at high doses.

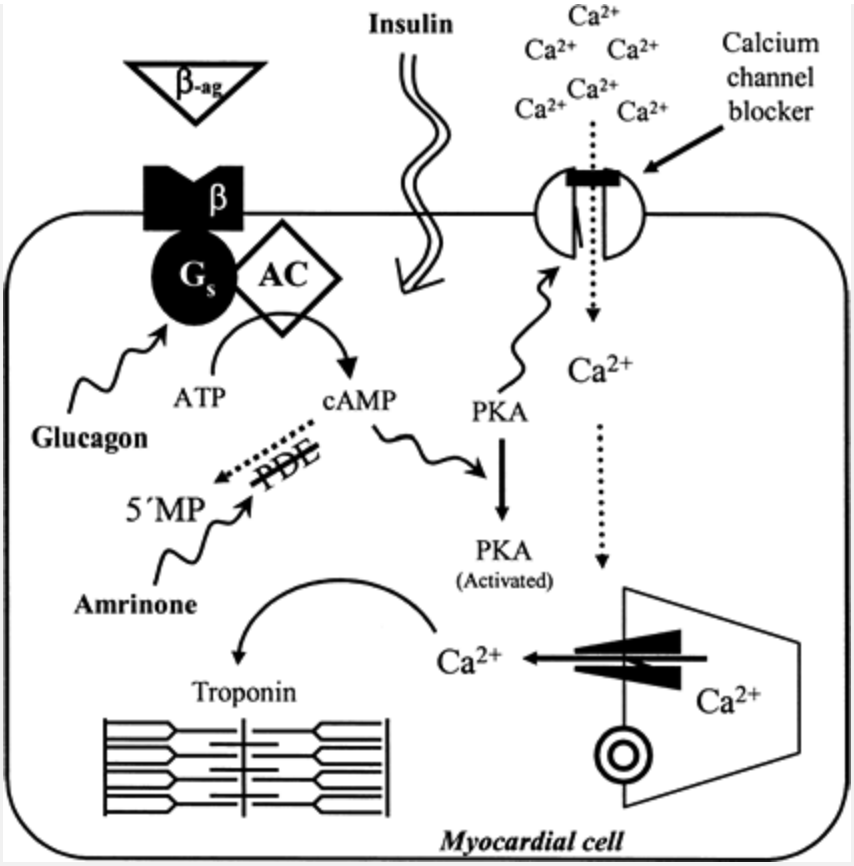

Figure 58-5. Myocardial toxicity of calcium channel blockers and antidotal therapies. Calcium channel blockers reduce ion influx through the L-type calcium channel and thus reduce contractility. Mechanisms to increase intracellular calcium include recruitment of new or dormant calcium channels by increasing cyclic adenosine monophosphate (cAMP) either by stimulating its formation by adenylate cyclase (AC) with catecholamines or glucagon (see text), or by inhibiting its degradation with amrinone. Increasing the calcium concentration gradient across the cellular membrane to futher its influx, may improve contractility. The mechanism by which insulin therapy enhances inotropy is undefined. Phophodiesterase, PDE; protein kinase A, PKA.

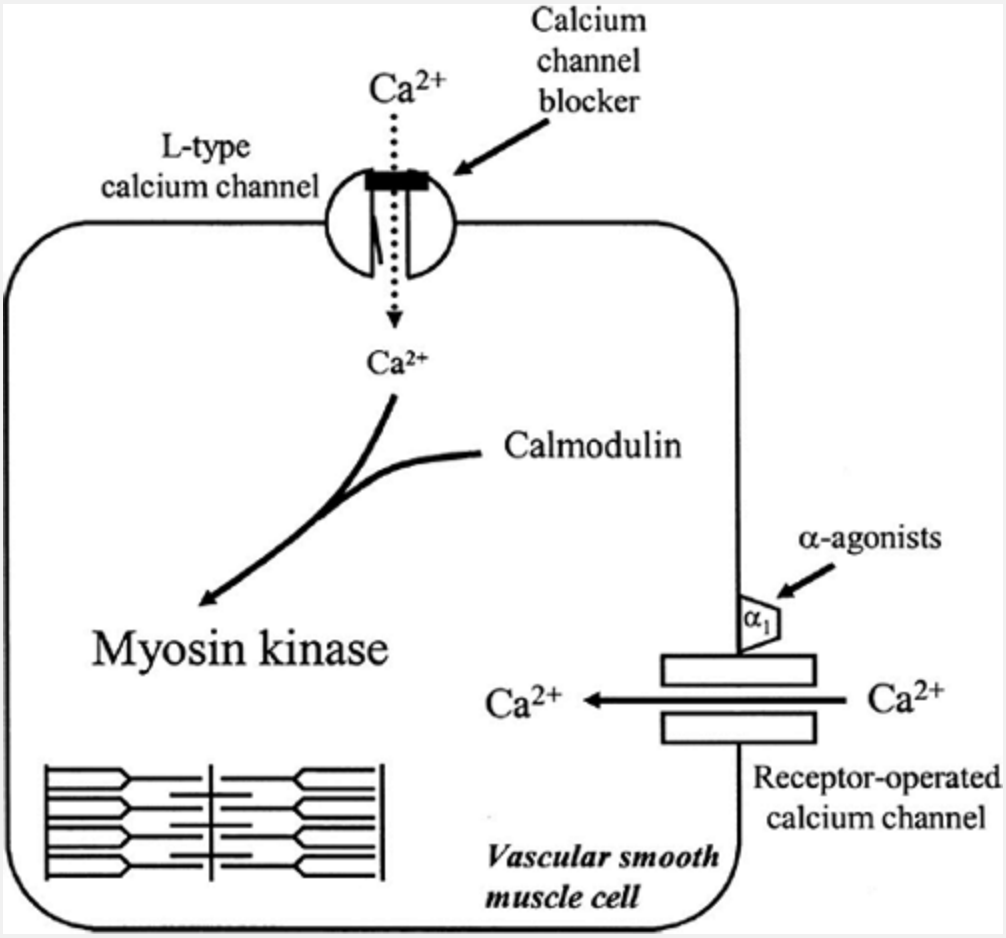

Figure 58-6. Vascular toxicity of calcium channel blockers and antidotal therapies. Calcium's entry via voltage-sensitive channels initiates a cascade of events that result in actinâ€“myosin coupling and contraction; this is inhibited by calcium channel blockers. Mechanisms to increase intracellular calcium include activation of receptor-operated calcium channels with Î±$_1$-adrenergic agonists or increasing the calcium ion gradient across the cellular membrane to further its influx.

Dopamine is predominantly an indirect acting pressor which acts by stimulating the release of norepinephrine from the distal nerve

terminal, and not by direct Î±- and Î²-adrenergic receptor stimulation.[65] This may limit its effectiveness in severely stressed patients who may have catecholamine depletion.[177] Published clinical experience of patients with severe CCB poisonings support these concerns.[8,28,35,52,60,113,122,177] Improvement in blood pressure may be noted with dopamine at high dosing, when the drug has additional direct Î±- and Î²-adrenergic effects.[65]

The choice of a sympathomimetic drug is based on numerous factors, including the pharmacologic profile of each drug, the patient's underlying physiologic condition, and the physician's familiarity and comfort with the drug. If one sympathomimetic drug is unsuccessful, determining the cardiac output and systemic vascular resistance may be helpful in assessing whether the myocardial depressant or peripheral vasodilatory effects are responsible for the hypotension.[138] This knowledge will help guide the subsequent choice of pharmacologic agents.

Insulin and Glucose

The most promising treatment for patients who are severely poisoned with CCBs may be hyperinsulinemia/euglycemia therapy. It is long known that high-dose insulin has positive inotropic effects.[41] Although some indirect evidence suggests that increased Ca^{2+} entry may be involved,[41,102] there is growing support for the hypothesis that improved myocardial use of carbohydrates is responsible for clinical improvement.[96] Verapamil poisoning alters the normal metabolism of the myocardial cell, which primarily relies on fatty acids and forces carbohydrate dependence.[95,97,98] At the same time, CCBs impede use of carbohydrates by inhibiting calcium-mediated insulin secretion from the Î²-islet cells in the pancreas,[31,129] and by somehow increasing myocardial insulin resistance.[96] In a canine model of verapamil toxicity, high-dose insulin, in conjunction with continuous dextrose infusion to maintain euglycemia, improved survival when compared to calcium, epinephrine, or glucagon.[94,98] It

is postulated that although epinephrine and glucagon increase myocardial contractility, they do so at the expense of increased myocardial oxygen consumption, and that insulin improves overall myocardial efficiency. The use of insulin is particularly interesting, because severe CCB toxicity often produces significant hyperglycemia and insulin infusions are often initiated.[38,162]

There are now several reported cases of CCB-poisoned patients in whom adjuvant high-dose insulin therapy successfully improved hemodynamic function.[17,117,187] Notably, there was little effect on heart rate in any of these patients, and in 1 patient, an improvement in ejection fraction from 10 to 50% was described.[187] Reports of the failure of this treatment have also been published,[30] but often represent initiation of therapy in terminally ill patients with multiple organ failure.

Because of the promising animal evidence, the relative lack of other demonstrably effective therapeutics, the seriousness and potentially fatal nature of CCB poisoning, and the growing clinical successes with this therapy, early initiation of hyperinsulinemia/euglycemia therapy for CCB-poisoned patients is recommended. Based on the canine data and published clinical experience, if the serum glucose is <250 mg/dL an initial bolus of 25â€“50 g of dextrose (0.5â€“1 g/kg), should be followed by a dextrose infusion of 0.25â€“0.5 g/kg/h. Then administer an initial insulin bolus of 0.1 U/kg followed by an insulin infusion at a rate of 0.5 U/kg/h, which should be increased if there is no hemodynamic response within 60 minutes. Remember that this increase should be done in a stepwise manner with concomitant increases in the dextrose infusion to maintain euglycemic control. Serum glucose levels should be closely monitored throughout therapy, particularly during the first few hours, and should be continued for several hours after discontinuation of the insulin infusion. Because insulin's hemodynamic effects are mediated via alterations in myocardial metabolism, the hemodynamic response is typically delayed for 30â€“60 minutes, necessitating the simultaneous use of catecholamines in profoundly hypotensive

patients.

Glucagon

Glucagon is an endogenous polypeptide hormone secreted by the pancreatic Î± cells in response to hypoglycemia and catecholamines. In addition, it has significant inotropic and chronotropic effects.[25,133] Glucagon is a therapy of choice for Î²-adrenergic antagonist poisoning (Chap. 59) because of its ability to bypass the Î²-adrenergic receptor and activate adenylate cyclase via a G_s protein in the myocardium.[186] Thus, glucagon is unique in that it is functionally a â€œpureâ€• $Î²_1$ agonist, with no peripheral vasodilatory effects. However in CCB poisoning, because the cellular lesion is â€œdownstreamâ€• from adenylate cyclase, glucagon offers no pharmacologic advantage over more traditional Î²-adrenergic agents (Fig. 58-6).

There are reports of CCB-poisoned patients who failed to respond to fluids, Ca^{2+}, or dopamine and dobutamine, but who had significant increases in both heart rate and blood pressure after glucagon administration.[35,132,176] Many other much more severely poisoned patients demonstrated no hemodynamic benefit with glucagon therapy.[8,28,60] Several animal models demonstrated glucagon's efficacy in improving CCB-induced myocardial depression.[10,79,163,189,190] Unfortunately, none of these studies compared other therapies, including Ca^{2+}, high-dose insulin, and catecholamines, with glucagon. Although the data are limited, given its experimental and anecdotal efficacy, glucagon should be considered in the management of refractory hypotension in patients with CCB poisoning. Dosing for glucagon is not well established. An initial dose of 3â€“5 mg intravenously slowly over 1â€“2 minutes is reasonable in adults, and if there is no hemodynamic improvement within 5 minutes, retreatment with a dose of 4â€“10 mg might be effective. The initial pediatric dose is 50 Âµg/kg. Because of

glucagon's short half-life, a maintenance infusion should be initiated, once a desired effect is achieved. Maintenance infusion dosing should begin at the â€œresponse doseâ€• of glucagon per hour. For example, if an initial dose of 4 mg of glucagon effectively improved blood pressure, the infusion should be started at 4 mg/h (see Antidotes in Depth: Glucagon). Adverse effects include vomiting and hyperglycemia, particularly in diabetics or during continuous infusion.[170]

Phosphodiesterase Inhibitors

Another class of therapeutics that have demonstrated usefulness in treating CCB poisoning are the phosphodiesterase inhibitors: inamrinone, milrinone, and enoximone. These agents inhibit the breakdown of cAMP by phosphodiesterase, thereby increasing cAMP concentrations. These noncatecholamine inotropic agents do not disproportionately increase myocardial oxygen demand and have been traditionally used for congestive heart failure.[11,15] They specifically inhibit phosphodiesterase III, the enzyme responsible for cAMP breakdown found in cardiac and vascular tissue (Fig. 58-6).[32] This inhibition results in increased cAMP, increased intracellular calcium, and improved inotropy. Inamrinone improved myocardial contractility in two canine models of verapamil poisoning.[5,114] In addition, inamrinone was clinically successful in patients with CCB poisoning when used in combination with another inotropic agent, such as isoproterenol or glucagon.[53,185] This â€œtwo-prongedâ€• approach to increase myocardial cAMP concentrations, by stimulating its formation and inhibiting its breakdown, is pharmacologically rational. However, because of inamrinone nonselective inhibition of phosphodiesterase III, cAMP is also increased in the vascular smooth muscle. This causes smooth muscle relaxation, peripheral vasodilation, and, often, hypotension, which may severely limit its usefulness in many CCB-poisoned patients.[92] Phosphodiesterase inhibitors should be used only as second-line agents, in combination with another inotropic agent, and in patients with hemodynamic

monitoring. Dosing in the treatment of CCB-poisoned patients is not well defined, but should be based on traditional dosing for congestive heart failure. For inamrinone, the experimental data and the case reports suggest that an initial bolus of 1 mg/kg over 2 minutes followed by a continuous infusion of 5â€“20 Âµg/kg/min is appropriate.[5,32,52,53,185]

Experimental Pharmaceutical Agents

Digoxin is being experimentally evaluated as a therapeutic agent in CCB poisoning. Cardioactive steroids inhibit sodium/potassium/ adenosine triphosphatase (ATPase), which increases the intracellular sodium concentration and decreases the transmembrane sodium concentration gradient. This concentration gradient is the driving force for the sodiumâ€“calcium exchanger in the cell membrane. When it is decreased, less Ca^{2+} can exit the cell in exchange for Na^{+} during cellular repolarization.[130] In a canine model of verapamil poisoning, digoxin, in conjunction with atropine improved both myocardial dromotropy and inotropy and increased peripheral vascular resistance. A trupine was added to block the vagally mediated inhibitory effects of digoxin on heart rate and AV nodal conduction.[141] However, because digoxin takes a significant amount of time to distribute into tissue, and because limited efficacy data and no safety data have yet been collected, much more work is required before digoxin should be administered to patients with CCB poisoning.

Adjunctive Hemodynamic Support

Many of the most severely poisoned patients may not respond to any pharmacologic intervention.[36,60] Transthoracic or intravenous cardiac pacing may be required to improve heart rate, as several case reports demonstrate.[39,157,177] However, in a prospective cohort of CCB poisonings, 2 of 4 patients with significant bradycardia requiring electrical pacing had no electrical capture.[142] In addition, even if

electrical pacing is effective in increasing the heart rate, blood pressure often remains unchanged.[19,67,68,131]

Intraaortic balloon counterpulsation is another invasive supportive option to be considered in cases refractory to pharmacologic therapy. Intraaortic balloon counterpulsation was used successfully to improve cardiac output and blood pressure in a patient with a mixed verapamil and atenolol overdose.[48] The synchronized inflation and deflation is dependent on regular cardiac electrical activity, so cardiac pacing is often required in addition to the intraaortic balloon.[174] It is important to understand that overdosed patients who may be candidates for intraaortic balloon counterpulsation support have a much better prognosis than do patients with severe left ventricular failure from ischemic heart disease, in whom this technology is traditionally used. Between 24 and 48 hours of assisted cardiac output allows metabolism and elimination of the CCBs and a return of baseline myocardial function.

Much more invasive and technologically demanding, emergent open and percutaneous cardiopulmonary bypass has also been used to support patients with severe CCB poisoning for days, with subsequent full recoveries.[36,60,67] The major limitation of all these technologies, however, is that they are available only at tertiary care facilities.

Disposition

Every patient who manifests any signs or symptoms of toxicity should be admitted to an intensive care setting. Because of the potential for delayed toxicity, despite some recent recommendations to the contrary,[13] any patient ingesting sustained-release products should be admitted for 24 hours to a monitored setting, even if asymptomatic. This is particularly important for toddlers and small children in whom even one or a few tablets may produce significant toxicity.[13,17,60,108,134] All admitted patients should be treated with activated charcoal, and those with a history of sustained-release

product ingestion should be treated with WBI. Only patients with a reliable history of an â€œimmediate-releaseâ€• preparation ingestion who have received adequate gastrointestinal decontamination, who have serial ECGs over 6â€“8 hours that have remained unchanged, and who are asymptomatic, can be â€œmedically cleared.â€•

Summary

Calcium channel blockers are commonly used to treat hypertension, stable and vasospastic angina, dysrhythmias, migraine headaches, Raynaud phenomenon, and subarachnoid hemorrhage. Because of the increasing frequency of use, CCB exposures continue to rise, resulting in numerous deaths from poisoning annually. Hallmarks of toxicity include bradydysrhythmias and hypotension, which are an extension of the pharmacologic effects of these agents. Although most patients develop symptoms of hypoperfusion, such as lightheadedness, nausea, or fatigue, within hours of a significant ingestion, sustained-release formulations may result in significant delays in any hemodynamic consequences and certainly may prolong toxicity. Because of the significant lethality of large ingestions of sustained-release CCBs, it is imperative to make gastrointestinal decontamination with whole-bowel irrigation a high priority. Aggressive decontamination of patients with exposures to sustained-release products should begin as soon as possible and should not be delayed by waiting for signs of toxicity. Once hemodynamic toxicity develops, in addition to supportive care, pharmacologic treatment with calcium boluses, followed by high-dose insulin and glucose infusions, should be initiated. Traditional catecholamines are also typically needed but their use alone may not be sufficient in the most critically poisoned patients. Other options include glucagon and phosphodiesterase inhibitors. Patients who fail to respond to all pharmaceutical interventions should be considered for extracorporeal mechanical support whenever available.

Chapter 59
Î²-Adrenergic Antagonists

Jeffrey Brubacher

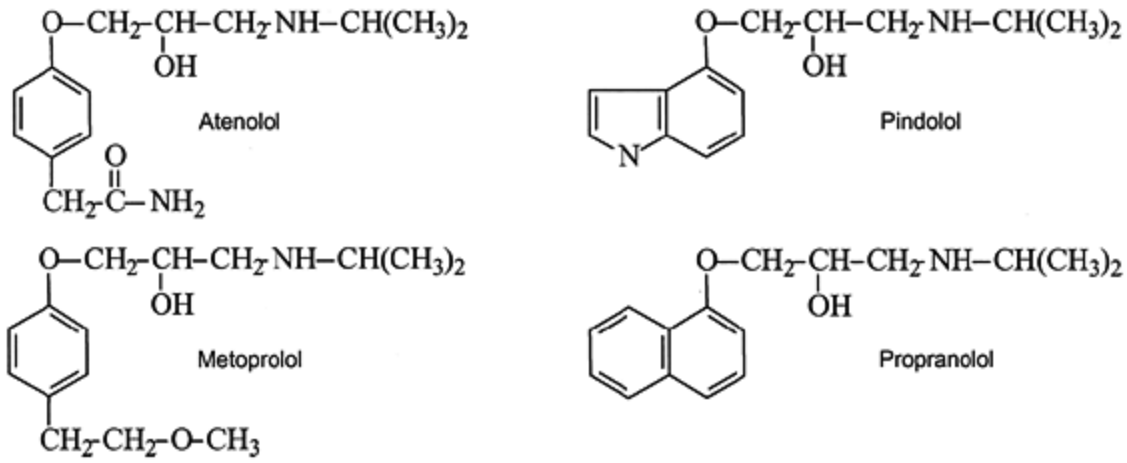

Figure. No Caption Available.

A 64-year-old man was brought to the emergency department (ED) by ar emergency medical personnel found him hypoventilating with a blood press a respiratory rate of 10 breaths/min. They intubated him and gave him 2 NaCl solution. During transport to hospital, the patient had a generalized arrival at the ED he was comatose with a blood pressure of 85 mm Hg by

96.8Â°F (36Â°C). On 100% oxygen the patient's oxygen saturation was 9
mg/dL. Physical examination was otherwise unremarkable except for occa
no murmurs. Pupils were 6 mm and reactive, skin was cool, and bowel so
dextrose IV, 100 mg thiamine IV, and 2 mg naloxone IV with no response

Blood was obtained for laboratory analysis and sent for a complete blood
phosphokinase. Arterial blood was sent for blood gas analysis. A 12-lead
of 280 msec and a QRS duration of 140 msec. During the next several m
pressure decreased to 75 mm Hg and his pulse decreased to 40 beats/min
atropine and another 500 mL of 0.9% NaCl solution, which resulted in lit
pacing was instituted, which increased his pulse to 70 beats/min, but the
discontinued. A central venous line was inserted, and dopamine was titrat

Further history was obtained from the patient's son. The patient was prev
hypertension. The patient stopped taking antidepressants several months
medication and no one else in the family took any pills. The family stated
and displayed apathy, decreased appetite, and an inability to sleep. On th
breakfast, took a shower, and went for a walk before he returned home to
his nap, but 2 hours later when the family could not arouse him for lunch
to return home and bring all medication bottles to the ED. A call was pla

The history of depression, seizures, hypotension, and widened QRS interv
bradycardia, and the patient was given an IV bolus of 100 mEq of hypert

vital signs following this, and a repeat electrocardiogram was essentially u
msec. A bicarbonate infusion was started. Because of the possibility of a
g of calcium chloride intravenously. Following this, his systolic blood pressu
beats/min.

The family physician returned the call and stated that the propranolol had
patient's daughters returned with all of the medication bottles that she c
analgesics were almost full; however, the propranolol bottle was empty. As

With this additional information, the patient was given a total of 5 mg of
blood pressure to 105/60 mm Hg and his pulse to 55 beats/min. A glucag
admitted to the intensive care unit. Laboratory analysis was negative for
complete blood count, and arterial blood gas values were all within norma

resolved on repeat analysis performed after the patient's vital signs had

By the next day, the patient regained consciousness and was able to mai stopped. He was extubated and stated that he had taken an overdose of a psychiatrist who suggested that his depression was exacerbated by th were restarted. A calcium channel blocker was prescribed for hypertension service. On followup 1 month later, he was doing well with no complaints. controlled.

History

In 1948, Raymond Alquist postulated that epinephrine's cardiovascular act the existence of two distinct sets of receptors that he generically named â€œantiepinephrineâ€• agents, such as phenoxybenzamine, reversed the epinephrine. According to Alquist's theory these drugs acted at the Î± re catecholamine-induced tachycardia. The British pharmacist, Sir James Blac potential clinical benefit of a Î²-adrenergic antagonist. In 1958, Black sy drug was briefly marketed as â€œAlderlin,â€• named after Alderly Park, was discontinued because it produced thymic tumors in mice. Propranolol incomplete anagram of Alderlin) in the United Kingdom in 1964,[19 , 155] ar adrenergic antagonists, the management of angina was limited to drugs s venous capacitance vessels and increased myocardial oxygen delivery by clinicians the ability to decrease myocardial oxygen use. This new approa ischemic heart disease.[86] New drugs soon followed, and by 1979, 10 Î²- Unfortunately, it soon became apparent that these agents were dangerous toxicity and deaths from Î²-adrenergic antagonist overdose were reporte antagonists (Table 59-1). They are commonly used in the treatment of and tachydysrhythmias. Additional indications for Î²-adrenergic antagonist benign essential tremor, panic attack, stage fright, and hyperthyroidism are also used in the treatment of glaucoma.[65]

Epidemiology

Intentional Î²-adrenergic antagonist overdose, although relatively uncommo From 1985 to 1995, there were 52,156 Î²-adrenergic antagonist exposure

of the American Association of Poison Control Centers (Chap. 130). Thes antagonists were implicated as the primary cause of death in 38. The otl antagonists because of the presence of cardioactive coingestants, such as than age 6 years accounted for 19,388 exposures, but no fatalities were this series was a 7 year old. More than half of the fatalities developed c number of exposures to Î²-adrenergic antagonists reported to TESS increas 2003. Each year in this period, Î²-adrenergic antagonist exposures resulte 20â€“40 deaths (Chap. 130).

Compared to the other Î²-adrenergic antagonists, propranolol accounts fo and deaths.[84 , 104] This may be explained by the fact that propranolol is anxiety, stress, and migraine, who may be more prone to suicide attempt and membrane-stabilizing properties.[58 , 130]

Pharmacology

The Cardiac Cycle

Normal cardiac electrical activity involves a complex series of ion fluxes Electrical activity of the heart is coupled to cell contraction and relaxatio concentrations. Cardiac electrical and mechanical activity is closely regula

In normal conditions, heart rate is determined by the rate of spontaneou sinoatrial (SA) node (Fig. 59-1). Pacemaker cells are also found in the depolarizations of pacemaker cells are a result of

several inward cation channels that are under autonomic control. Î²-Adre spontaneous depolarization of pacemaker cells by incompletely understood caused by a direct, phosphorylation-independent action of cyclic adenosir Depolarization of cells in the SA node spreads to surrounding atrial cells, initiates an electric current that spreads along specialized pathways to de cardiac excitation, is linked to mechanical activity of the heart by the p (Chap. 23).

TABLE 59-1. Pharmacologic Properties of the Î²-Adrenergic Anta

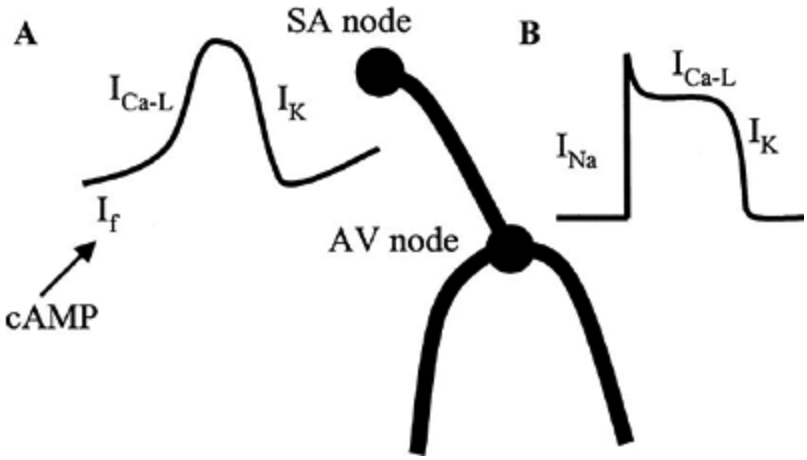

Figure 59-1. Cardiac conduction system: A. The cardiac cycle begins wh spontaneously due to inward â€œpacemakerâ€• currents (I_f). Adrenergi heart rate via a direct effect of cAMP. Cholinergic stimulation hyperpolariz pacemaker cell depolarization and hence bradycardia. Pacemaker cells lac the opening of L-type calcium channels (I_{Ca-L}) and the impulse is transr depolarization generates an impulse sufficient to open fast sodium channe specialized pathways to depolarize the atria and ventricles.

Myocyte Calcium Flow and Contractility

During systole, voltage-sensitive slow calcium channels (L-type channels) depolarization and allow extracellular calcium to flow down its concentrati channels are located primarily at the sarcolemmalâ€“sarcoplasmic reticulur channels (ryanodine receptors) in the SR. A small increase in local calciu through a single L-type calcium channel, triggers the opening of an array calcium from the SR, a phenomenon known as calcium-induced calcium r proportional to the magnitude of the calcium influx via the L-type calciun myocyte calcium concentrations. Actinâ€“myosin interaction is also mod ischemia, intracellular pH, and myofilament stretch.[12 , 16 , 138]

During diastole, several ion pumps actively remove calcium from the cyto

drop during diastole, calcium dissociates from troponin and relaxation oc calcium adenosine triphosphatase (ATPase) that pumps cytosolic calcium i exchanges 1 calcium ion for 3 sodium ions. The activity of the SR calciur

Î²-Adrenergic Receptors and the Heart

Î²-Adrenergic receptors are divided into $Î²_1$, $Î²_2$, and $Î²_3$ subtypes. The receptor, but there also are cardiac $Î²_2$ - and $Î²_3$ -adrenergic receptors. T increases with heart failure.[156] $Î²_1$ -Adrenergic receptors mediate increase protein kinases (Fig. 59-3). $Î²_1$ -Adrenergic receptors are coupled to G_s stimulated. This increases the intracellular production of cAMP, which binds dependent protein kinases.[93] Protein kinase A, in turn, phosphorylates ir voltage-sensitive calcium channels, and troponin.[56 , 160] L-type calcium the influx of calcium during each cell depolarization, triggering greater re [153] Phosphorylation of phospholamban removes its inhibition of the SR ar resulting in increased SR calcium stores and hence enhanced contractility results in more rapid removal of cytoplasmic calcium during diastole, anc phosphorylation facilitates calcium unbinding, thus improving cardiac perf Activated protein kinase A (PKA) also phosphorylates SR calcium release calcium release from the SR.[16] $Î²_1$ -Adrenergic receptors increase chronot at least in part, direct cAMP interaction with pacemaker channels.[2 , 23]

Like $Î²_1$ -adrenergic receptors, the cardiac $Î²_2$ -adrenergic receptors med subcellular mechanisms are less-well understood than for $Î²_1$ -adrenergic excitatory G_s proteins but are also coupled to inhibitory G_i proteins, and relaxation, and chronotropy, independent of global increases in cytoplasmic adrenergic-receptorâ€“induced increases in cAMP (via G_s protein stimulat receptors causes increases in cAMP and PKA activity that remain localized the G_i protein counteracts these effects elsewhere in the cytoplasm, perl down cAMP) and protein phosphatases (that counteract the action of PKA) contractility by increasing cytoplasmic pH independent of G protein activ

The role of the $Î²_3$ -adrenergic receptor in humans is incompletely underst plays a role in thermogenesis and lipolysis[35] and is also found in human mediates negative inotropy caused by G_i protein linkage

and subsequent inhibition of cAMP production and stimulation of nitric ox stimulation resulted in G_S protein stimulation and positive inotropy.[78] The substantially from that of the other Î² receptors. Whereas isoproterenol is adrenergic antagonists actually act as agonists at the $Î²_3$ -adrenergic rec

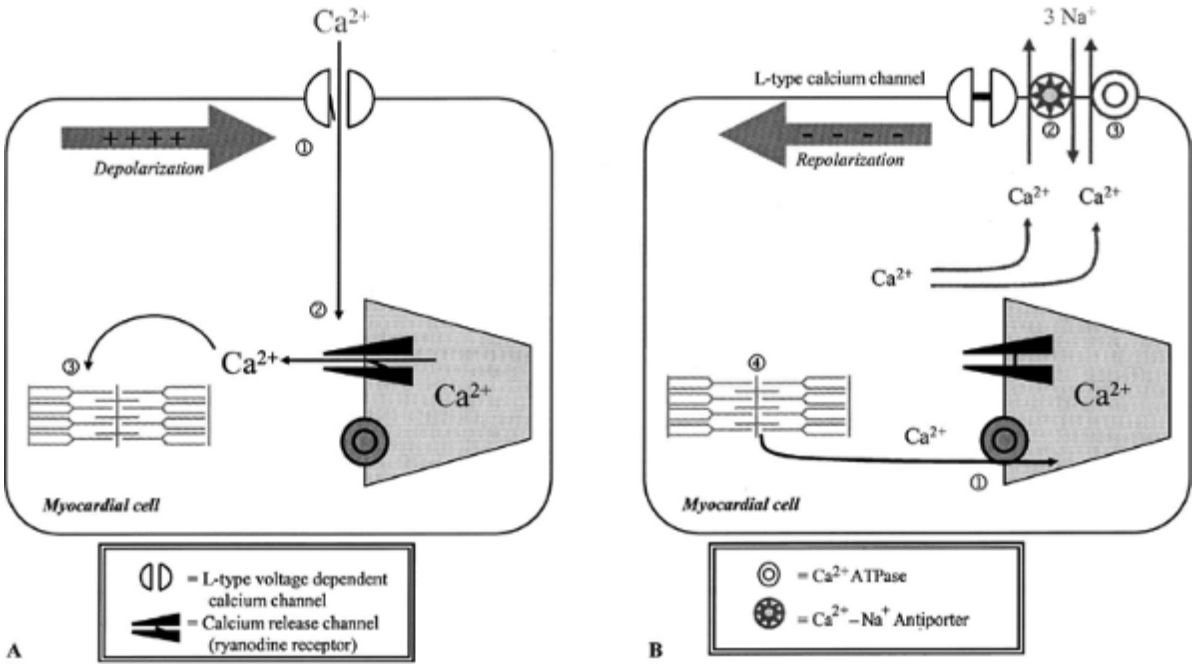

Figure 59-2. A. Fluctuations in calcium concentrations couple myocyte c relaxation. â‘ Depolarization causes voltage sensitive calcium channels to into the myocyte. â‘¡ This calcium current triggers the opening of calcium pours out of the SR. The amount of calcium released from the SR is prop of calcium stored in the SR. â‘¢ At rest, actinâ€“myosin interaction is pre inhibition is removed, and actin and myosin slide relative to each other, a actively removed from the myocyte to allow relaxation. â‘ Most calcium is calsequestrin. Calcium stored in the SR is thus available for release dur ATPase is inhibited by phospholamban. (See Fig. 59-3 .) â‘¡ The calcium sodium flow in one direction to that of a single molecule of calcium in th electrochemical gradients, which usually favor the inward flow of sodium c therefore inhibited by high intracellular sodium or extracellular calcium c conditions, the pump may â€œrun in reverse.â€• â‘¢ Some calcium is act myocyte calcium concentrations fall, calcium is released from troponin an

Noncardiac Effects of Î²-Adrenergic Recept

Î²-Adrenergic agonists have important non cardiac effects. $Î²_2$ -Adrenergi organs. Relaxation of arteriolar smooth muscle by $Î²_2$ -adrenergic stimula blood pressure. This counteracts Î±-adrenergicâ€“mediated arteriolar cons bronchodilation. Third trimester uterine tone and contractions are inhibited both $Î²_1$ - and $Î²_2$ -adrenergic stimulation.

Î² Receptors play a role in the immune system. Mast cell degranulation is epinephrine in aborting and treating severe allergic reactions. Polymorph stimulation, resulting in the increased white blood cell counts with catech epinephrine seen with pain or physiological stress.

Î²-Adrenergic agonists also have important metabolic effects. Insulin secre Despite increased insulin levels, the net effect of $Î²_2$ -adrenergic receptor skeletal muscle glycogenolysis and hepatic gluconeogenesis and glycogen from pancreatic alpha cells.[85] Î²-Adrenergic agonists act at fat cells to c adrenergic receptors results in breakdown of triglycerides and release of increased by $Î²_2$ -adrenergic stimulation, resulting in hypokalemia, explain hyperkalemia. Finally, renin secretion is increased by $Î²_1$ -adrenergic stin

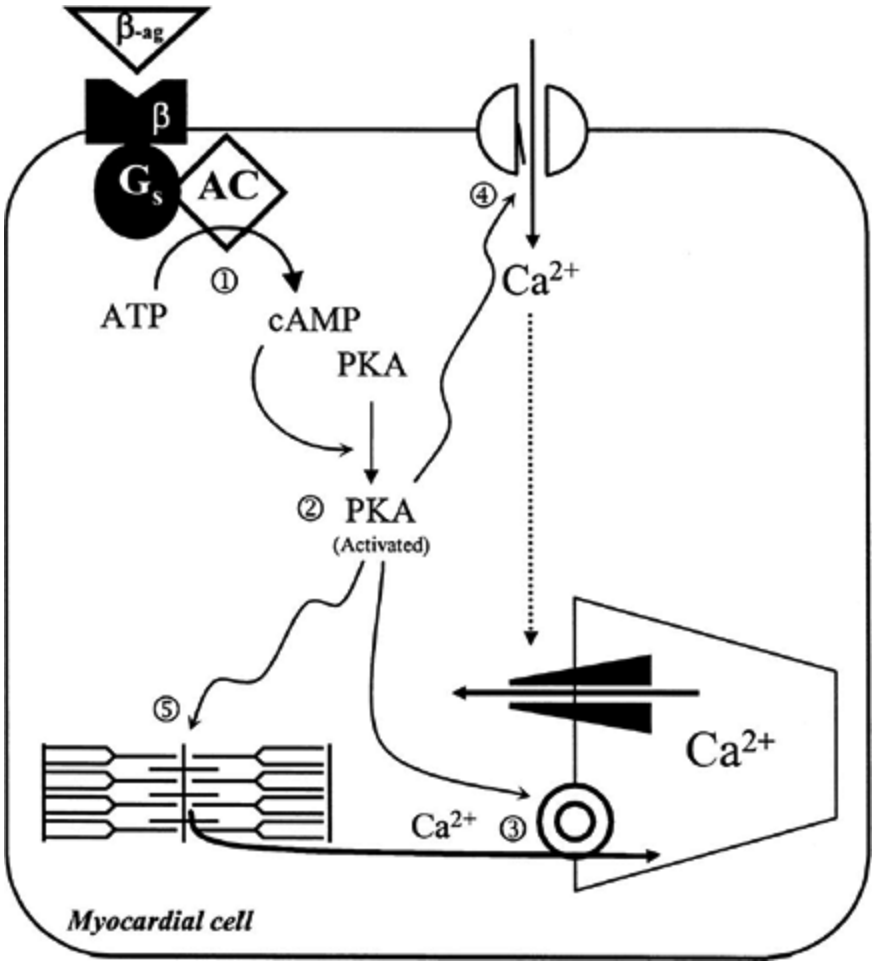

Figure 59-3. Î²-Adrenergic agonists are positive inotropes by virtue of th Adrenergic receptors are coupled to G_S proteins which activate adenyl cyc increased formation of cAMP from ATP. â‘¡ Increased cAMP levels activate receptor stimulation by phosphorylating key intracellular proteins. â‘¢ Ph reticulum (SR) calcium ATPase resulting in increased SR calcium stores a Phosphorylation of voltage sensitive calcium channels increases calcium in phosphorylation improves cardiac performance by facilitating calcium unb

Î²-Adrenergic antagonists are contraindicated in situations of catecholamin these conditions, $\hat{I}^2_2$ -adrenergicâ€“mediated vasodilation is essential to Adrenergic antagonists may result in an â€œunopposed Î±â€• adrenergi resistance (Chap. 74). Agents with combined Î±- and Î²-adrenergic ant example, is 5- to 10-fold more potent as a Î²-adrenergic antagonist than -adrenergic agonist properties can avoid the â€œunopposed Î±â€• effect, investigated.[49 , 65 , 111 , 163]

Other Preparations (Ophthalmic, Sustained

Therapeutic use of ophthalmic solutions containing Î²-adrenergic antagonis grade AV block, heart failure, bronchospasm, and depression.[20 , 42 , 115] combination of the calcium channel blocker felodipine and metoprolol has medication (Logimax, Astra-Zeneca, Wilmington, Delaware) is marketed in United States or Canada. Another combination product containing nifedipin antihypertensive.[33]

Pathophysiology

Most of the toxicity of Î²-adrenergic antagonists is a result of their abilit cardiac Î²-adrenergic receptors. The peripheral effects of Î²-adrenergic an Adrenergic Antagonists above). Î²-Adrenergic antagonists also appear to catecholamine receptors. For example, in catecholamine-depleted, spontan sotalol all decreased heart rate and contractility.[31] Surprisingly, these eff hearts,[89] suggesting that antagonism of the Î²-adrenergic receptor is not membrane-depressant effect may contribute to the cardiac depressant effe depressant effects of most of the other Î²-adrenergic antagonists. It may depression, at least in part, by an action independent of either catechola

Other investigators studied the role of extracellular ions and cardiac me

toxicity. Î²-Adrenergic antagonists interfere with calcium uptake into the stimulate calcium-sensitive outward potassium channels, and result in m bradycardia. Lowering extracellular potassium, or raising extracellular sod atenolol toxicity in isolated rat hearts.[72] In another series of experiments poisoned with Î²-adrenergic antagonists. This may have been the result o

Although cardiovascular effects are most prominent in overdose, Î²-adre effect is centrally mediated and appears to be an important cause of dea antagonism toxicity.[90] There is evidence that propranolol may interfere w effects noted in propranolol overdose.[50]

Clinical Manifestations

Toxicity generally occurs early following Î²-adrenergic antagonist poisoning the rapid development of seizures, coma, and dysrhythmias. In a retrosp antagonist overdose, there were 39 symptomatic patients with well-docum these patients had ingested a sustained-release product. Thirty-one patien symptoms at 4 hours, and everyone developed symptoms within the first documented reports of immediate-release Î²-adrenergic antagonist overdos ingestion.[96] The authors of an Australian series also noted that, in their symptoms began within 6 hours of ingestion.[130] These observations do no

delayed toxicity, or to sustained-release products.

Î²-Adrenergic antagonist overdose in healthy people is generally quite ben
Î²-adrenergic overdose remained asymptomatic.[34 , 98 , 161] This is partia
often well tolerated in healthy persons who do not rely on sympathetic s
unintentional ingestions in children rarely result in significant toxicity.[14] A
no deaths or serious cardiovascular morbidity following unintentional Î²-ad
years.[106]

Î²-Adrenergic antagonists severely impair the heart's ability to respond t
contractility caused by other xenobiotics. Therefore, even relatively benig
coingested with Î²-adrenergic antagonists.[43] According to one author, the
antagonist overdose is likely to be the presence of a cardioactive coinges
to cause symptoms in persons with congestive heart failure, sick sinus sy
stimulation to maintain heart rate or cardiac output. Nevertheless, severe
have ingested Î²-adrenergic antagonists alone.[40 , 130 , 154] In patients wi
who ingest a Î²-adrenergic antagonist with membrane-stabilizing activity.

Patients with symptomatic Î²-adrenergic antagonist overdose are usually
results in sinus bradycardia, sinus pauses, or sinus arrest. Impaired atric
high-grade AV block, occurs rarely. Prolonged QRS and QTc intervals may
Congestive heart failure often complicates Î²-adrenergic antagonist overdo
the setting of severe hypotension, but may also occur with normal blood
agents.[40 , 130] Respiratory depression and apnea may have an additional
patients with propranolol toxicity and 6% of those with atenolol toxicity h
Respiratory depression following Î²-adrenergic antagonist overdose typically
is reported in awake patients.[117] Hypoglycemia may complicate Î²-adrene
in acutely poisoned adults. In a series of 15 cases of Î²-adrenergic antag
whereas both of the 2 children had symptomatic hypoglycemia.[40] Broncho
antagonist overdose and appears to occur only in susceptible patients. In
bronchospasm,[40] and in a review of 39 cases of symptomatic adults witl
bronchospasm.[96] Clinical use of Î²-adrenergic antagonists slightly increas
rarely complicates acute overdose.

Î²â Selectivity (Acebutolol, Atenolol, Betax

In overdose, cardioselectivity is largely lost, and deaths caused by the Î² atenolol,[104] betaxolol,[18] and metoprolol,[134 , 154] are reported. There is a toxicity.[165]

Membrane-Stabilizing Effects (Acebutolol,

Propranolol possesses the most membrane-stabilizing activity of this class seizures, hypotension, bradycardia, impaired atrioventricular conduction, [104] Hypotension may be disproportionate to bradycardia, and deaths from betaxolol, and oxprenolol also possess significant membrane-stabilizing act (Table 59-1).[18 , 58 , 75 , 122 , 128]

Lipid Solubility

In overdose, the more lipophilic Î²-adrenergic antagonists may cause delir hypotension.[40 , 130] Atenolol, the least lipid soluble of the Î²-adrenergic a antagonists when taken in overdose.[58] In one series of Î²-adrenergic anta overdose

had seizures, compared with 8 of 28 patients with propranolol overdose.[1] toxicity and cardiovascular death.[104 , 124 , 157]

Intrinsic Sympathomimetic Activity (Acebu Pindolol)

There is little experience with overdose of these agents but ISA would th Î²-adrenergic antagonists. Sympathetic stimulation with mild tachycardia this drug appears to be relatively safe in overdose.[40 , 84 , 129] In addition membrane-stabilizing activity, making them dangerous in overdose.[40 , 58

Potassium Channel Blockade (Acebutolol,

In 6 patients with sotalol overdose, the average QTc interval was 172% including multifocal ventricular extrasystoles, ventricular tachycardia, an complicated by hypotension, bradycardia, and asystole,[5 , 120] and fatalitie

Sotalol overdose can cause delayed and prolonged toxicity, although elect 6 patients with sotalol overdose, all had prolonged QTc interval noted on after ingestion. We are not told whether these patients were taking sotalo the prolonged QTc on the initial electrocardiogram was present prior to t hours after ingestion and the risk of ventricular dysrhythmias was highest developed ventricular tachycardia did so after 4 hours, and in 2 patients, ingestion. One patient continued to have ventricular dysrhythmias at 48 h long as 100 hours after ingestion. In this series, the average sotalol half- the QTc interval was 82 hours.[120] Acebutolol-induced QTc interval prolong that occur with severe acebutolol toxicity.[32 , 97 , 104]

Vasodilation (Bucindolol, Carteolol, Carvedi

The Î±$_1$ -adrenergic antagonism of labetalol and carvedilol would theoreti toxicity. Conversely, the low membrane-stabilizing effect of these drugs m labetalol appears to be similar clinically to that of other Î²-adrenergic ar features.[79 , 80 , 150] Experience with carvedilol overdose is extremely lim dopamine, without significant bradycardia, and had a benign course.[54] In complicated by bradycardia, lethargy, and hypoglycemia. The patient rece has occurred following betaxolol poisoning.[18] Overdose with bucindolol, ca

Other Preparations (Ophthalmic, Sustained

There is very little published experience with overdoses of the sustained- expect that overdose will result in both a delayed onset and prolonged d antagonists is not reported. Patients who take mixed overdoses with calc difficult to manage because of synergistic toxicity.[140 , 144 , 151] Overdoses blocker preparations are not reported, but these combinations may be qu

Differential Diagnosis of Bradycardia

Bradycardia can result from numerous xenobiotic exposures and medical bradycardia are calcium channel blockers (Chap. 58), Î²-adrenergic anta Other xenobiotic causes of bradycardia include Î±$_1$ -adrenergic agonists, as clonidine and other imidazolines (Chap. 60), cholinergic agents, such

); opioids (Chap. 38); and most sedative hypnotics, such as the barbitu blockers (Chap. 71) usually cause tachycardia but can cause bradycardia bradycardia, but overdoses are rare. Many patients with xenobiotic causes Non-xenobiotic causes of bradycardia include hyperkalemia, hypothermia, episodes, intracranial hypertension, and benign physiologic bradycardia in discussed in detail in Chap. 23 .

Diagnostic Testing

All patients who intentionally overdose with a Î²-adrenergic antagonist sh monitoring. Serum glucose should be measured regardless of mental sta hypoglycemia. A chest radiograph and measurement of oxygen saturation s congestive heart failure. For patients with bradycardia of uncertain etiolo enzymes, and digoxin concentrations may prove helpful. Serum concentra routine clinical use but may prove helpful in making a retrospective diagn

Management

The initial management of the critically ill patient who ingests Î²-adrenerg is important to have an organized approach to the care of these patients

maintained with endotracheal intubation if necessary. Because laryngoscopy atropine prior to intubation of the bradycardic patient. This is particularly complication. The initial treatment of bradycardia and hypotension consists insufficient in patients with severe toxicity, but may suffice in patients w

Gastrointestinal decontamination is warranted for all persons who have i Induction of emesis is contraindicated because of the potential for catastr because vomiting increases vagal stimulation and can worsen bradycardia significant symptoms such as seizures, significant hypotension, or bradycar Orogastric lavage is also recommended for all patients who present shortl propranolol or one of the other more toxic Î²-adrenergic antagonists (ac orogastric lavage causes vagal stimulation and carries the risk of worseni

standard doses of atropine. Activated charcoal alone is recommended for

of the more water-soluble Î²-adrenergic antagonists and who present mo polyethylene glycol should be considered in patients who have ingested Bowel Irrigation and Other Intestinal Evacuants).

The following categories of toxicity are to be used as a guide only. Some require more aggressive treatment. Clinical judgement is required. See A

Asymptomatic

1. Activated charcoal
2. Consider orogastric lavage within the first hour postingestion
3. Consider whole-bowel irrigation with polyethylene glycol electrolyte la preparations

Mild Toxicity

Mild hypotension (BP <100 mm/Hg systolic) or bradycardia (HR <60 b

1. All of the above plus:
2. Atropine 1 mg for bradycardia
3. Fluid boluses (20â€“40 mL/kg of 0.9% NaCl solution) for hypotension

Moderate Toxicity

Failure of the above therapy, or

severe bradycardia (HR <40 beats/minute), or

hypotension (BP <80 mm/Hg systolic), or clinical evidence of hypope consciousness

1. All of the above plus:
2. Monitor ventilation and intubate if necessary
3. Glucagon: 3â€“5 mg IV over 1â€“2 minutes (may give up to 10 mg) t
4. Atropine up to 3 mg for bradycardia
5. Calcium salts for hypotension: 1â€“3 g calcium chloride slow IV push
6. High-dose insulin: regular insulin 1U/kg bolus followed by regular ins (eg, 10 mL/kg/h of 10% dextrose or 2 mL/kg/h of 50% dextrose); gl tapered, or increased, as required

Severe Toxicity

Failure of the above therapy, or evidence of severe hypoperfusion such

1. All of the above plus:
2. Increase glucagon infusion to 10 mg/h
3. Intra-arterial and pulmonary artery pressure monitoring and frequen
4. Catecholamine infusion: *Very high doses of the following are typicall*
   a. Isoproterenol (Î²$_1$, Î²$_2$ agonistâ€”caution for Î²$_2$ -mediated vasod
   b. Epinephrine (Î±, Î² agonistâ€”caution for â€œunopposed Î±â€• e
   c. Dobutamine (Î²$_1$ agonistâ€”theoretically useful but limited experie
   d. Norepinephrine (Î±, Î²$_1$ agonistâ€”caution for â€œunopposed Î±â€

TABLE 59-2. Management of Patients with Î²-Adrenergic Antagon

Seizures or coma associated with cardiovascular collapse are treated by a relatively normal vital signs should be treated with benzodiazepines follo seizures are rare in Î²-adrenergic antagonist overdose.

Specific Management

Patients who fail to respond to atropine and fluids require management w time permits, it is preferable to introduce new medications sequentially so by calcium, high-dose insulin, a catecholamine pressor, and, if this fails, the critically ill patient, there may not be enough time for this approach, Advanced hemodynamic monitoring, when available, is advisable to guide phosphodiesterase inhibitors. Mechanical life support with intraaortic ballo medical management fails.

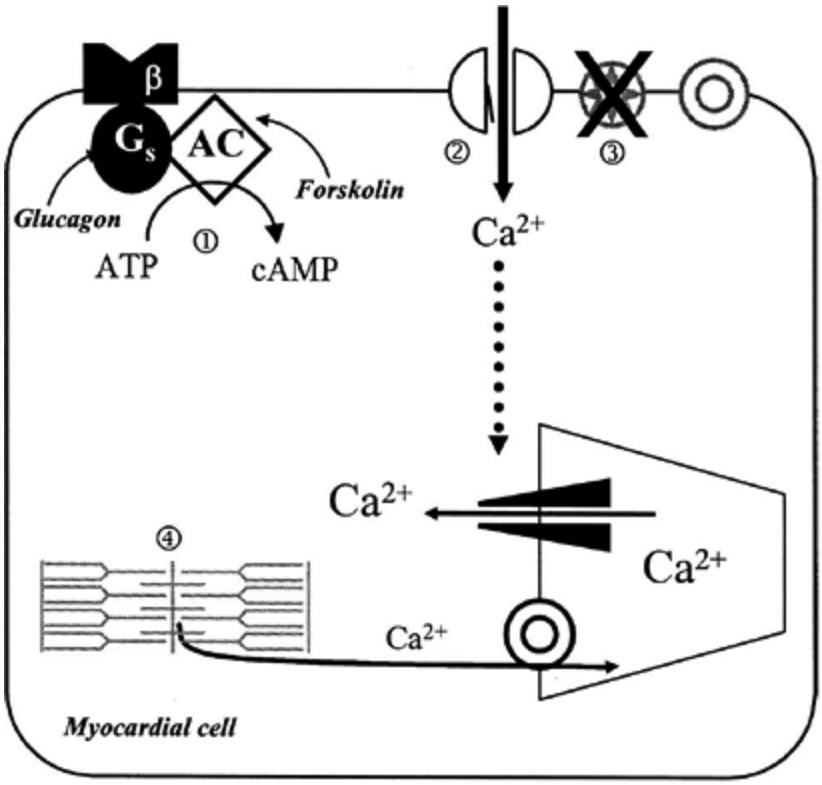

Figure 59-4. Positive inotropes improve cardiac function by a number o calcium. â‘ xenobiotics that increase cAMP: Glucagon receptors and Î²-ac binding increases cAMP by activation of adenyl cyclase. Phosphodiesterase Forskolin increases cAMP by directly activating adenyl cyclase. â‘¡ Calcium depolarization and result in higher intracellular calcium stores. â‘¢ xenobi exchange pump: Digoxin and sodium channel openers that increase intra prolong the action potential duration alter the electrochemical gradients in that increase the sensitivity of the contractile elements to calcium: Angiot alkalosis. Experimental xenobiotics that directly increase the sensitivity of

Glucagon

Humans have cardiac glucagon receptors[174] that, like Î²-adrenergic recept adenyl cyclase activity, independent of Î²-adrenergic receptor binding.[181] phosphodiesterase and thereby prevent cAMP breakdown.[114]

A recent comprehensive review found no controlled trials of glucagon in Nevertheless, with more than 30 years of clinical use,[82 , 171] glucagon is

adrenergic antagonist toxicity.[126 , 161 , 175] This is supported by several glucagon is also effective in correcting symptomatic bradycardia and hyp use.[105] Glucagon is a vasodilator, and in animal models of propranolol p output, and heart rate than in restoring blood pressure.[11 , 103]

The initial adult dose of glucagon for Î²-adrenergic antagonist toxicity is 3 pediatric dose is 50 Âµg/kg. If there is no response to the initial dose, hig response occurs, a glucagon infusion is started. Most authors recommend recommend glucagon infusions as high as 10 mg/h. Glucagon infusion sho example, if the patient receives 7 mg of glucagon before a response occu full dose of glucagon fails to restore blood pressure and heart rate, and we would still recommend starting an infusion of glucagon at 10 mg/h, a Glucagon may cause vomiting with the risk of aspiration. Other side effec hypocalcemia,[68] both of which should be treated appropriately if they de

Calcium

Calcium salts effectively treat hypotension from calcium channel-blocker o but not heart rate, in animal models of Î²-adrenergic antagonist toxicity.[8 patients with Î²-adrenergic antagonist overdose,[24 , 124] and in combined toxicity.[59] The adult starting dose of calcium chloride is 1 g of the 10% s calcium chloride initially. Calcium gluconate contains one-third as much ele proportionately higher. Calcium gluconate is less irritating and is generally calcium gluconate is always preferred for children. The initial pediatric dose repeated up to a total of 180 mg/kg (see Antidotes in Depth: Calcium). significantly higher doses, serum calcium concentrations should be asses

Insulin and Glucose

High-dose insulin combined with glucose and potassium improves cardiac myocardial infarction.[36 , 108 , 109 and 110] High-dose insulin is effective in for patients with severe calcium channel blocker poisoning (Chap. 58). of glucose, proved effective in a series of 5 patients with severe calcium benefit of high-dose insulin for severe calcium channel-blocker toxicity.[21] understood, but may involve inhibition of fatty acid metabolism, enhanced

calcium handling.

There is evidence that high-dose insulin, combined with sufficient glucose antagonist poisoning. In a canine model of propranolol toxicity, all 6 anim of 6 in the glucagon group, 1 of 6 in the epinephrine group, and no survi atenolol and amlodipine had a beneficial response to high-dose insulin.[182] glucose is monitored), and does not require invasive monitoring. There is severely poisoned with calcium channel antagonists. For these reasons, a antagonist poisoning, we recommend using insulin and glucose infusions t fluids, atropine, and glucagon. We recommend a bolus dose of regular ins start at 0.5 U/kg/h. This can be increased up to 1.0 U/kg/h until the pa Glucose should be given at an initial rate of 1 g/kg/h, monitored every 30 euglycemia. The response to insulin is typically delayed for 15â€“60 minu infusion before the full effects of insulin are apparent. Insulin can cause as necessary. Insulin can also cause hypophosphatemia. The effects of ins deterioration is unlikely to occur. It is important to continue monitoring g discontinued.

Catecholamines

Patients who do not respond to the preceding therapies usually require a somewhat controversial. Theoretically, the pure Î²-adrenergic agonist isopro overcome Î²-adrenergic blockade without causing any Î±-adrenergic effec drawbacks that limit its efficacy. In the presence of Î²-adrenergic antago catecholamines are frequently required.[128, 133, 161, 167] One author su the usual effective rate may be required.[28] Individual case reports docum these high doses, the $\hat{I}^2_2$ -adrenergic effects of isoproterenol cause perip Furthermore, isoproterenol is very dysrhythmogenic and is thus potentiall causes of hypotension and bradycardia. Nevertheless, in some animal mo even more effective than glucagon in reversing Î²-adrenergic antagonist validated this in humans. In a review of reported cases, glucagon increase time.[175] In contrast, isoproterenol was effective in increasing heart rate or time. Epinephrine was more effective than isoproterenol.[175] The selective associated with isoproterenol; it has been used successfully to treat Î²-a expected to be especially effective following overdose of the cardioselec

approved and prenalterol therapy is limited, as its relatively long half-life adrenergic agonist, with relatively little effect on vascular resistance, that and dobutamine is not always effective in patients with Î²-adrenergic an antagonism, catecholamines with substantial Î±-adrenergic agonist proper improving contractility, resulting in acute cardiac failure. Severe hypertensi vasodilation is another potential adverse reaction from this so-called un problems, we recommend that catecholamine use be guided by hemodyn bioimpedance techniques or echocardiographic) monitoring of cardiac perf usual rates and then increased rapidly until a clinical effect is obtained. I adrenergic antagonist overdose is fairly certain, it is reasonable to begin monitoring of the patient's blood pressure and clinical status. The infusion hypotensive or develops congestive heart failure.

Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors (PDIs) amrinone, milrinone, and enoxim overdose because they inhibit the breakdown of cAMP by phosphodieste PDIs increase inotropy in the presence of Î²-adrenergic antagonism, in bo appear to be as effective as glucagon in animal models of Î²-adrenergic to demonstrate an additional benefit of these agents over glucagon.[102] , therapy and, in fact, are used clinically to treat Î²-adrenergic antagonist hypotension secondary to peripheral vasodilation. Furthermore, these drug (30â€“60 minutes for milrinone, 2â€“4 hours for amrinone, and approxim PDIs should generally only be considered for patients who have arterial

Ventricular Pacing

Ventricular pacing is not a particularly useful intervention in patients with heart rate in some patients.[71] Unfortunately, there will frequently be failur increase in cardiac output or blood

pressure.[4] , [84] , [87] , [161] In fact, some authors have noticed that ventricu secondary to loss of organized atrial contraction, or impaired ventricular

Extracorporeal Removal

Extracorporeal removal is ineffective for the lipid-soluble Î²-adrenergic an
Hemodialysis may remove water-soluble renally eliminated Î²-adrenergic
hemodialysis is technically difficult in these patients because of hypotens
indicated in patients with Î²-adrenergic antagonist overdose but may be

Mechanical Life Support

It is important to remember that the patient with severe hypotension fro
ventilation and circulation can be maintained until the xenobiotic is elimin
appropriate to consider the use of an intraaortic balloon pump or extrac
recoveries following the use of these therapies for refractory Î²-adrenerg
antagonist and calcium channel blocker overdose.[39 , 178] A recent case s
membrane oxygenation) for patients with cardiac arrest caused by cardiov
were attributed to delayed institution of ECMO. The other 4 patients surv

Experimental Treatment

Aminophylline increases heart rate and contractility by several mechanis
and, at supratherapeutic doses, phosphodiesterase inhibition. Aminophylline
was effective in a dog model of propranolol poisoning.[176] Aminophylline w
atenolol, quinapril, and fluvoxamine.[135]

Antidotes in Depth

Glucagon

Mary Ann Howland

Glucagon is a polypeptide counterregulatory hormone with a molecular weight of 3500 daltons, secreted by the Î± cells of the pancreas. Glucagon was discovered in 1923, 2 years after the discovery of insulin.[8] Previously animal derived, the current FDA-approved form is synthesized by recombinant DNA technology since 1998. Its traditional role was to reverse life-threatening hypoglycemia in diabetic patients who were unable to ingest dextrose in the outpatient setting. In medical toxicology, however, glucagon is used in the management of Î²-adrenergic antagonist and calcium channel blocker overdoses.

Mechanism of Action

Administration of ^{125}I-labeled glucagon to cats demonstrates the presence of a specific glucagon receptor, and binding is closely correlated with activation of cardiac adenylate cyclase.[25] A large number of glucagon binding sites are demonstrated, and as little as 10% occupancy produces near maximal stimulation of adenylate

cyclase. Glucagon receptors are identified in the human heart and brain, and resemble those on the pancreas.[65] The binding of glucagon to its receptor results in coupling with two isoforms of the G_S protein, catalyzing the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the Î± subunit of the G_S protein.[24,53,70] One isoform is coupled to Î² agonists, while both isoforms are coupled to glucagon.[70] The GTP-G_S units stimulate adenylate cyclase to convert adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP).[34,42] In addition, it now appears that in human atrial heart tissue glucagon, along with $Î²_2$ agonists, histamine, and serotonin (but not $Î²_1$ agonists), also activates G_i, which inhibits cAMP formation.[29]

Stimulation of glucagon receptors in the liver and adipose tissue increases cAMP synthesis, resulting in glycogenolysis, gluconeogenesis, and ketogenesis.[34] Other properties of glucagon include relaxation of smooth muscle in the lower esophageal sphincter, stomach, small and large intestines, common bile duct, and ureters.[21,24,32]

Pharmacokinetics and Pharmacodynamics

The volume of distribution of glucagon is 0.25 L/kg. The elimination half-life is 8â€“18 minutes, and the plasma, liver, and kidney extensively metabolize glucagon. After a single IV bolus, the effects of glucagon on the heart in human volunteers begin within 1â€“3 minutes, are maximal within 5â€“7 minutes, and persist for 10â€“15 minutes.[48] The time to maximal glucose concentration is 5â€“20 minutes, with a duration of action of 60â€“90 minutes.[19] Smooth muscle relaxation begins within 1 minute and lasts 10â€–20 minutes.[19]

Tachyphylaxis or desensitization may occur with continual dosing. Experimental heart preparations exposed to glucagon for varying

lengths of time demonstrated a decrease in the amount of cAMP generated.[27,71] Calcium or isoproterenol administration after glucagon desensitization improved contractility and cAMP rose. Possible explanations for tachyphylaxis include uncoupling from the glucagon receptor and or phosphodiesterase (PDE) hydrolysis of cAMP.[27,67,71,74] Other experiments demonstrated a transient effect of glucagon on contractility and hyperglycemia, also suggesting tachyphylaxis.[23,28]

Cardiovascular Effects

Investigations of the mechanism of action of glucagon on the heart have been performed on cardiac tissue obtained from patients during surgical procedures and in a variety of in vivo and ex vivo animal studies. The results are often species specific and are affected by the presence or absence of congestive heart failure. The inotropic action of glucagon appears to be related to an increase in cardiac cAMP levels.[13,34,42] Resulting positive inotropic[2,17,40,48] and chronotropic[2,13,17,30,32,40,42,48,68] actions of glucagon are very similar to those of the Î²-adrenergic agonists, except that they are not blocked by Î²-adrenergic antagonists.[70] Although in some canine experiments glucagon was associated with ventricular tachycardia, glucagon was not found to be dysrhythmogenic in studies in patients with severe chronic congestive heart failure or myocardial infarction-related acute congestive heart failure, or in postoperative patients with myocardial depression.[28,36,41,44] The effects of glucagon are markedly diminished as the severity and chronicity of congestive heart failure increases.[48]

Evidence now suggests an additional mechanism of action for glucagon, independent of cAMP, and dependent on arachidonic acid.[59] Cardiac tissue metabolizes glucagon, liberating mini-glucagon, an apparently active smaller terminal fragment.[59,67] Mini-glucagon stimulates phospholipase A_2, releasing arachidonic

acid. Arachidonic acid acts to increase cardiac contractility through an effect on calcium. The effect of arachidonic acid, and therefore of mini-glucagon, is synergistic with the effect of glucagon and cAMP.[58]

Volunteer Studies

The cardiovascular effects of glucagon were extensively studied in 21 patients with heart failure who were given varied doses and durations.[49] Eleven patients who received 3â€“5 mg via IV bolus had increases in the force of contraction, as measured by maximum dP/dT (upstroke pattern on apex cardiogram), heart rate, cardiac index, blood pressure, and stroke work. There was no change in systemic vascular resistance, left ventricular end-diastolic pressure (LVEDP), or stroke index. Additionally, glucose increased by 50% and the potassium fell. A study of 9 patients demonstrated a 30% increase in coronary blood flow following a 50 Âµg/kg IV dose.[44] Patients who received 1 mg via IV bolus also had an increase in cardiac index, but systemic vascular resistance fell, probably secondary to splanchnic and hepatic vascular smooth muscle relaxation.[49] Patients who received an infusion of 2â€“3 mg/min for 10â€“15 minutes responded similarly to those who received the 3â€“5-mg IV

boluses, but those patients receiving boluses experienced significant dose-limiting nausea and vomiting.[49]

Role in Overdoses with Î²-Adrenergic Antagonists

Overdoses with Î²-adrenergic antagonists are particularly dangerous and are manifested by hypotension, bradycardia, prolonged atrioventricular conduction times, depressed cardiac output and cardiac failure. Other noncardiovascular effects include

alterations in consciousness, seizures, and, rarely, hypoglycemia.[1,11,14,16,22,66] Management is often complicated and many drugs, including atropine, isoproterenol, epinephrine, norepinephrine, dopamine, dobutamine, and various combinations, are used with variable success.[15] Animal studies document the ability of glucagon to increase contractility, restore the sinus node function after sinus node arrest, increase atrioventricular (AV) conduction, and improve survival.[38,48,56] Glucagon has successfully reversed bradydysrhythmias and hypotension in patients unresponsive to the aforementioned drugs, and should be administered early in the management of patients with severe overdoses.[9,11,14,30,55,64] By increasing myocardial cAMP concentrations independent of the Î² receptor,[34,42] glucagon is able to increase the inotropic[2,17,40,48] and the chronotropic[2,17,30,40,48,68] activity of the heart.

Glucagon successfully reversed the bradycardia, low-output heart failure, and hypotension that developed in a premature newborn, presumably as a result of an inappropriately large prenatal dose of labetalol given to the mother. This neonate, delivered at 32 weeks gestation and weighing 1.8 kg, received 0.3 mg/kg glucagon intravenously initially and 5 additional doses of 0.3â€“0.6 mg/kg over the next 5 hours, with improvement in heart rate, blood pressure, and perfusion. Epinephrine and diuretics were also used.[60]

Combined Effects with Phosphodiesterase Inhibitors and Calcium

Strategies for enhancing the beneficial effects of glucagon have involved combining it with the phosphodiesterase III inhibitor (PDI III) amrinone (inamrinone) and its derivative milrinone and most recently rolipram (PDI IV). In a canine model of propranolol

toxicity, both amrinone (inamrinone) and milrinone alone were comparable to glucagon,[38,57] but the combination of amrinone and glucagon resulted in a decrease in mean arterial pressure. A tachycardia occurred when milrinone was used with glucagon.[37,56] In an ex vivo model using strips of rat ventricular heart, rolipram enhanced the inotropic effect of glucagon and limited glucagon tachyphylaxis.[27]

The relationship between calcium and the chronotropic effects of glucagon was demonstrated in rats.[6] Maximal chronotropic effects of glucagon are dependent on a normal circulating ionized calcium. Both hypocalcemia and hypercalcemia blunt the maximal chronotropic response.[5,6]

Role in Calcium Channel Blocker Overdose

Calcium channel blocker overdoses produce a constellation of clinical findings similar to those recognized with Î²-adrenergic antagonist overdoses, including hypotension, bradycardia, heart block, and myocardial depression. Animal studies[26,54,61,62,72,73] demonstrate the ability of glucagon to reverse the myocardial depression produced by nifedipine, diltiazem, and verapamil. Human case reports demonstrate similar benefit.[10,12,43,46,47,63] Some authors suggest that the addition of amrinone to glucagon therapy is beneficial.[69]

Reversal of Hypoglycemia

Glucagon was once proposed as part of the initial treatment for all comatose patients.[52] Glucagon stimulates the breakdown of glycogen to glucose in the liver by interacting with G_S. The theoretical rationale for this approach is only partially sound: Hypoglycemic patients may present in coma or with an altered mental status and hypoglycemia can be present concomitantly with

a drug overdose. Immediately restoring the patient's blood glucose level may be lifesaving. Glucagon, however, requires time to act and may be ineffective in a patient with depleted glycogen stores. Patients with type 2 diabetes are more likely to respond than are patients with type 1 diabetes. The intravenous administration of 0.5â€“1.0 g/kg of 50% dextrose in adults rapidly reverses hypoglycemia and does not rely on glycogen stores for its effect. Intravenous dextrose, therefore, is preferred over glucagon as the initial substrate to be given to all patients with an altered mental status presumed to be related to hypoglycemia (see Antidotes in Depth: Dextrose). Glucagon retains a role as a temporizing measure, until medical help can be obtained, in settings such as in the home, where IV dextrose is not an option.

In patients with insulinoma, glucagon may actually worsen hypoglycemia, after an initial hyperglycemic response, as the result of a feedback rise in insulin.

Adverse Effects and Safety Issues

Side effects associated with glucagon include dose-dependent nausea, vomiting,[41] hyperglycemia, hypoglycemia, and hypokalemia; relaxation of the smooth muscle of the stomach, duodenum, small bowel, and colon; and, rarely, urticaria, respiratory distress, and hypotension.[18] The hyperglycemia is followed by an immediate rise in insulin, which causes an intracellular shift in potassium, resulting in hypokalemia.[23,41,48] It is unclear whether stimulation of the Na^+-K^+-adenosine triphosphatase (ATPase) in skeletal muscle also contributes to the hypokalemia as occurs with Î²-adrenergic agonists.[31,51]

Glucagon can also increase the release of catecholamines in a patient with a pheochromocytoma, resulting in a hypertensive crisis,[23] which can be treated with phentolamine.[18] Continuous prolonged treatment with glucagon might lead to a dilated cardiomyopathy, as was reported in a patient with a

glucagonoma.[4] Glucagon is a pregnancy category B drug.

Dosing

An initial IV bolus of 50 Âµg/kg, infused over 1â€“2 minutes, is recommended (3â€“5 mg in a 70-kg person).[16] If clinically acceptable, a longer duration of infusion may be used to limit vomiting. Higher doses may be necessary if the initial bolus is ineffective, and up to 10 mg can be used in an adult.[25] Using too small a dose can potentially decrease systemic vascular resistance.[49] In many cases,

the bolus dose has been followed by a continuous infusion of 2â€“5 mg/h (up to 10 mg/h) in 5% dextrose in water, which can be tapered as the patient improves.[1,24,25,50,55,66] This dosing regimen has never been studied and is based on case reports. Experimental heart preparations clearly demonstrate tachyphylaxis with continuous administration. Whether this occurs in humans is unclear, but might plead for repeated bolus infusions over 1â€“5 minutes rather than continuous infusion.[27,71]

Availability

Glucagon (rDNA origin) by Eli Lilly and Company is available as a 1-mg (1-unit) lyophilized powder for injection, with an accompanying 1 mL of diluent in a disposable syringe.[18] The diluent contains 12 mg/mL of glycerin water for injection, and hydrochloric acid, if needed, for pH adjustment. Glucagon (rDNA origin) as GlucaGen by Novo Nordisk A/S is available as a 1-mg (1-unit) lyophilized powder for injection. It should be reconstituted with 1 mL of sterile water for injection. Concentrations greater than 1 mg/1 mL should not be used. An adequate supply of glucagon in the emergency department is at least twenty 1-mg vials, with assurance of another 30 mg in the pharmacy.[7,39]

Summary

Glucagon can produce positive inotropic and chronotropic effects despite Î²-adrenergic and calcium channel antagonism. Glucagon is beneficial in the treatment of patients with severe overdoses of Î²-adrenergic antagonists and calcium channel blockers. The effects of glucagon may not persist and other therapies, such as insulin and dextrose, should also be considered (Chaps. 58 and 59). The relatively benign character of an IV bolus of glucagon in the patient with a serious overdose of a Î²-adrenergic antagonist or calcium channel blocker should lead the clinician to use glucagon early in patient management. Clinicians should be prepared for vomiting and the attendant risk for aspiration.

Chapter 60
Other Antihypertensives

Francis DeRoos

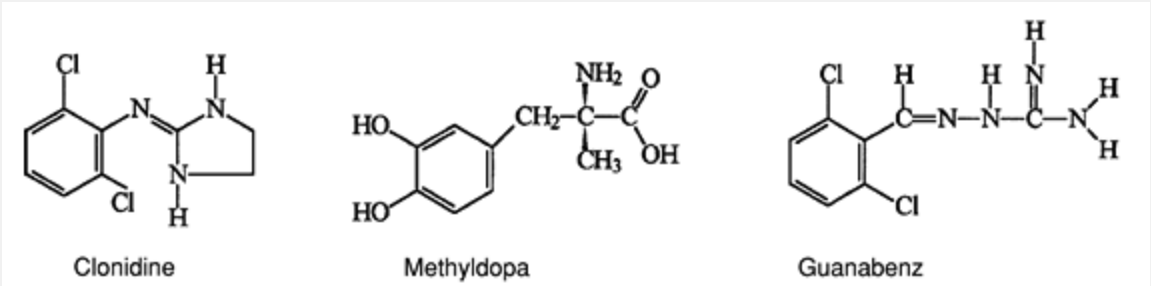

Figure. No Caption Available.

Case 1 A 2-year-old boy was brought to the emergency department because of lethargy. The patient had no medical history, but shortly before this event he was playing with a bottle

of clonidine tablets. Physical examination revealed a lethargic but well-developed child whose initial vital signs were: blood pressure, 110/70 mm Hg; heart rate, 55 beats/min at rest and 80 beats/min with stimulation; respiratory rate, 16â€“20 breaths/min, with intermittent deep, sighing respirations; temperature, 97.9Â°F (36.6Â°C). The head and neck examination was significant for 2-mm pupils that were slightly reactive to light. Lung and abdominal examinations were normal. Heart examination was notable for a regular bradycardia. Neurologic evaluation revealed a somnolent child with poor muscle tone and slight hyporeflexia. The gag reflex was intact. Of note, the patient became much more active, and at times agitated, with tactile stimulation, and he had strong, purposeful movements when intravenous access was initiated.

Supplemental oxygen and an initial intravenous dose of 0.5 mg of naloxone, followed by a second dose of 1.5 mg, were administered without clinical response. Activated charcoal (12.5 g) was given via nasogastric tube. An electrocardiogram (ECG) revealed sinus bradycardia at a rate of 60 beats/min with no conduction abnormalities. Laboratory tests included an arterial blood gas with a PH 7.36, PCO_2 of 42 mm Hg, and PO_2 of 113 mm Hg. The patient was admitted to the pediatric intensive care unit for close observation and cardiac monitoring. Over the next 16 hours the patient's blood pressure remained stable, his heart rate increased to 90 beats/min, and his mental status returned to normal.

As our understanding of the medical complications of chronic hypertension have grown along with the evidence supporting the conclusion that its treatment improves long-term morbidity and mortality, more and more antihypertensive drugs have become available. Two of the most popular classes of antihypertensives, calcium channel blockers and Î²-adrenergic antagonists, were discussed in Chaps. 58 and 59, but numerous other drugs are also marketed in the United States and are discussed here.

Although overdoses involving these drugs are rarely reported,

either because of limited use (eg, the older agents such as reserpine, trimethaphan, and methyldopa) or limited toxicity (eg, diuretics and angiotensin II receptor antagonists), poisoning does occur. Most of the adverse effects and toxicity in overdose are exaggerated pharmacologic effects.

Clonidine and other Centrally Acting Antihypertensives

Clonidine is an imidazoline compound that was synthesized in the early 1960s. Because of its potent peripheral Î±$_2$-adrenergic agonist effects, it was initially studied as a potential topical nasal decongestant. However, hypotension was a common side effect, which redirected its consideration for other therapeutic applications.[87] Clonidine is the best understood and the most commonly used of all the centrally acting antihypertensives, a group that includes methyldopa, guanfacine, and guanabenz. Although these drugs differ chemically and structurally, they all decrease blood pressure in a similar mannerâ€"by reducing the sympathetic outflow from the central nervous system. The imidazoline compounds, oxymetazoline and tetrahydrozoline, which are used as ocular topical vasoconstrictors and nasal decongestants, produce similar systemic effects when ingested[87] (Chap. 50).

Since 1985, the increased efficacy and improved side-effect profiles of the newer antihypertensives have diminished the use of the Î±$_2$-adrenergic agonists in routine hypertension management. However, clonidine use is increasing as a result of a wide variety of applications, including attention deficit hyperactivity disorder (ADHD), peripheral nerve and spinal anesthesia, and as an adjunct in the management of opioid, ethanol, and nicotine withdrawal.[94,107,113,116,194] In addition, abuse of clonidine may be a growing problem in opioid-dependant patients and it has been

used in criminal acts of chemical submission.[17,129]

Although clonidine exposure is relatively uncommon, it may cause significant toxicity, particularly in children. One report from 2 large pediatric hospitals identified 47 children requiring hospitalization for unintentional clonidine ingestions over a 5-year period.[234] Significant clonidine poisoning resulting from formulation and dosing errors are also reported.[181,210]

Pharmacology and Pharmacokinetics

Clonidine is well absorbed from the gastrointestinal tract (approximately 75%) with an onset of action within 30â€“60 minutes. The plasma concentration occurs at 2â€“3 hours and lasts as long as 8 hours.[48] Clonidine has 20â€“40% protein binding and an apparent volume of distribution of 3.2â€–5.6 L/kg.[127] The majority of clonidine is eliminated unchanged via the kidneys.[127]

Guanabenz and guanfacine are structurally and pharmacologically very similar to each other. They are well absorbed orally, achieving peak levels within 3â€–5 hours, and both have large volumes of distribution (4â€–6 L/kg for guanfacine, 7â€–17 L/kg for guanabenz).[92,204] Guanabenz is metabolized predominantly in the liver and undergoes extensive first-pass effect, whereas guanfacine is eliminated equally by the liver and kidney.[92,204] Neither drug has significant active metabolites.

Whereas clonidine, guanabenz, and guanfacine are all active drugs, with direct Î±$_2$-adrenergic agonist effects, methyldopa is a prodrug. It enters the CNS, probably by an active transport mechanism, before it is converted into its pharmacologically active degradation products.[19] Î±-Methylnorepinephrine is the most significant of its metabolites, although Î±-methyldopamine and Î±-methylepinephrine may also be important.[58,84,180] These metabolites are direct Î±$_2$-adrenergic agonists and impart their hypotensive effect just like the other centrally acting

antihypertensives. Approximately 50% of an oral dose of methyldopa is absorbed and peak plasma concentrations are achieved in 2â€“3 hours.[148] However, because methyldopa requires metabolism into its active form, these concentrations have little correlation with its clinical effects. Methyldopa has a small volume of distribution (0.24 L/kg), with little protein binding (15%).[148] It is eliminated in the urine, both as parent compound and after hepatic sulfation.[154]

Clonidine is available in both oral and patch form. The patch, referred to as the clonidine transdermal therapeutic system (TTS), allows slow, continuous delivery of drug over a prolonged period of time, typically 1 week. Similar delivery systems are effective in management of chronic pain with fentanyl and in the cessation of smoking tobacco with nicotine. This formulation, however, offers new clinical challenges. Each patch contains significantly more drug than is typically delivered during the prescribed duration of use. For example, a patch that delivers 0.1 mg/d of clonidine contains 2.5 mg total, whereas the 0.3 mg/d product contains 7.5 mg.[28] Even after 1 week of use, between 35 and 50% and, in some instances, as much as 70%, of the drug remains in the patch.[28,80] Puncturing the outer membrane layer or backing opens the drug reservoir and allows a significant amount of the drug to be released rapidly. In addition, patients do not perceive this delivery system as a medication, and may not exercise appropriate precautions. For example, discarding a used patch in an open wastebasket provides toddlers, who often are fascinated with stickers and other adhesive objects, an opportunity to remove the patch and apply, taste, or ingest it. Numerous reports of toxicity in both adults and children have resulted from dermal exposure, mouthing, or ingesting one clonidine patch, emphasizing this concern.[28,38,80,85,110,174,175]

Pathophysiology

Clonidine and the other centrally acting antihypertensives exert their hypotensive effects primarily via stimulation of presynaptic Î±$_2$-adrenergic receptors in the brain.[167,187,225] This central Î±$_2$-adrenergic receptor agonism enhances the activity of inhibitory neurons in the vasoregulatory regions of the CNS, notably the nucleus tractus solitarius in the medulla, resulting in decreased norepinephrine release. This results in decreased sympathetic outflow from the intermediolateral cell columns of the thoracolumbar spinal tracts into the periphery[1,224] and reduces heart rate, vascular tone, and, ultimately, arterial blood pressure.[168,236] This centrally mediated sympatholytic effect is modulated by nitric oxide and Î³-aminobutyric acid (GABA), which may explain some of the clinical variability that occurs among patients who have overdosed with clonidine.[29,69,202,229]

In therapeutic oral dosing, clonidine and the other centrally acting antihypertensives have little effect on the peripheral Î±$_2$ receptors, the peripheral sympathetic nervous system, or the normal circulatory responses that occur with exercise or the Valsalva maneuver.[147,158] However, when serum concentrations rise above 2 ng/mL, as in the setting of intravenous administration or oral overdose, peripheral postsynaptic Î±$_2$-adrenergic stimulation can occur, causing increased norepinephrine release and producing vasoconstriction and hypertension.[36,42,150,212] This hypertension is short-lived, however, as the potent centrally mediated sympathetic inhibition becomes the predominant effect and hypotension ensues.[4,47,121,134,192]

Imidazoline-specific binding sites are identified both in the ventrolateral medulla of the brain and in other tissues, and may be important in the clinical effects of these agents.[192,217] Direct stimulation of these receptors appears to lower blood pressure, independent of central Î±$_2$-adrenergic effects.[20] Therefore, although their precise physiologic relationship has not been clearly elucidated, more evidence supports the concept that both imidazoline and Î±$_2$-adrenergic receptors modulate the ability of

clonidine, and presumably other centrally acting antihypertensives, to inhibit central norepinephrine release and the cardiovascular effects.[21,81,143]

Clinical Manifestations

Although the majority of the published cases involve clonidine, the signs and symptoms of poisoning with any centrally acting antihypertensive are similar. The central nervous system (CNS) and cardiovascular toxicity reflect an exaggeration of their pharmacologic action. Common signs include CNS depression, bradycardia, hypotension, and, occasionally, hypothermia.[6,165,197,221] Most patients who ingest clonidine, or the other similarly acting drugs, will manifest symptoms rapidly, typically within 30â€“90 minutes.[234] The exception may be methyldopa, which requires metabolism to be activated, possibly delaying toxicity for hours.[197,238]

CNS depression is the most frequent clinical finding and can vary from mild lethargy to coma.[38,74,132,134,144,146,152,157,173] In addition,

severely obtunded patients may suffer from decreased ventilatory effort and hypoxia.[4] Respirations may be slow and shallow, with intermittent deep sighing breaths. Various other terms are used to describe this phenomenon, including gasping, Cheyne-Stokes respirations, and periodic apnea.[6,10,110,134,135] This hypoventilation is typically responsive to tactile stimuli alone, although mechanical ventilation may be required in severe cases.[4,6,86,110,144] The associated CNS depression typically resolves over 12â€“36 hours,[10,82,157] although prolonged coma is rarely reported.[164] Other manifestations of this CNS depression include hypotonia, hyporeflexia, and irritability.[36,134,207] The cranial nerve examination often demonstrates miotic pupils that may remain reactive to light.[4,6,160,214] Two unusual case reports

describe seizures in the setting of clonidine poisoning,[95,130] the mechanism of which is unclear.

Hypothermia is associated with overdoses involving centrally acting antihypertensives.[6,134,135,165] This is thought to be a consequence of Î±-adrenergic effects within the thermoregulatory center, although others suggest that these drugs activate central serotonergic pathways that alter normal thermoregulation.[122,142] Although this phenomenon may last several hours, it rarely requires treatment and responds well to passive rewarming.[36,165]

Sinus bradycardia may occur in up to 50% of patients who ingest clonidine.[207,234] Although usually associated with hypotension, it can be an isolated finding. Plausible explanations for this bradycardia include an exaggerated centrally mediated sympatholytic effect, a centrally mediated increase in vagal tone, or a direct stimulation of $Î±_2$-adrenergic receptors on the myocardium.[44,118,224,235]

Other conduction abnormalities, including first-degree heart block, Wenckebach block, 2:1 atrioventricular block, and complete heart block, are described both in overdose and after therapeutic dosing.[68,109,157,189,191,222,235] It appears that very young patients and patients who have underlying sinus node dysfunction, concurrent sympatholytic drug therapy, or renal insufficiency are at greatest risk of developing bradydysrhythmias after central antihypertensive agent ingestion.[24,207,216]

Hypotension is the major cardiovascular manifestation of central antihypertensive toxicity.[6,28,144,157,207,234] This typically occurs within the first few hours after exposure.[61] Paradoxically, severe hypertension may be noted early in dosing, particularly during intravenous administration, or in massive overdoses.[4,42,47,95,121,134,212] This is the result of peripheral $Î±_2$-adrenergic agonism. Typically, as the central sympatholytic effects become predominant, the hypertensive effect is short-lived.[95] However, in patients with massive ingestions, hypertension may be

protracted and require pharmacologic intervention.[4,47,134,207]

There is no clear association between the amount of any centrally acting antihypertensive ingested and the clinical manifestations. In children, clonidine ingestions as small as 0.2 mg have resulted in clinically severe poisoning.[157] Fatalities from any of these agents are rare with few published reports within the Toxic Exposure Surveillance System (TESS) database (Chap 130).[197] This may be because these drugs effectively block all sympathetic outflow from the CNS and this physiologic effect is not essential for life. The CNS depression resulting in hypoventilation, hypoxia, and poor airway protection may be more pronounced in fatalities.

As a result of Food and Drug Administration postmarketing surveillance and a case report that identified 4 deaths of children who received clonidine, a question was raised about whether there was an association between patients with ADHD who were being treated with combination clonidine-methylphenidate therapy and sudden death.[27,56] However, close scrutiny of these cases revealed significant confounders and an investigation by the Food and Drug Administration concluded that there was inadequate evidence to confirm this association.[56,171,211,233]

Withdrawal

Abrupt cessation of central antihypertensive therapy may result in withdrawal that is characterized by excessive sympathetic activity. Symptoms include agitation, insomnia, tremor, palpitations, and hypertension that begins between 16 and 48 hours after cessation of therapy.[79,176,209] Ventricular tachycardia and myocardial infarction may occur in patients with clonidine withdrawal.[16,149,166] The frequency and severity of symptoms appear to be greater in patients treated with higher doses for several months and in those with the most severe pretreatment hypertension.[176] However, cases occur even when the dosing is gradually reduced.[25,226] Although this phenomenon is associated

with all centrally acting Î±$_2$-agonists, it appears to be most prominent in the shorter-acting drugs such as clonidine and guanbenz.[1,23,64,172,237] The mechanism for this hyperadrenergic phenomenon appears to involve an increase in CNS noradrenergic activity in the setting of decreased Î±$_2$-receptor sensitivity.[52] Reasonable treatment strategies include administering clonidine, via either the oral or intravenous route, followed by a closely monitored tapering of the dosing over several weeks, or benzodiazepines. Animal and human data suggest that Î²-adrenergic antagonists, including labetalol, are harmful in the setting of clonidine withdrawal and their use is contraindicated.[9,104]

Diagnostic Testing

Clonidine and other centrally acting antihypertensives are not routinely included in serum or urine toxicologic assays. Consequently, management decisions should be based on clinical parameters. No electrolyte or hematologic abnormalities are associated with this exposure. Because of the potential for bradydysrhythmias and hypoventilation, a 12-lead ECG and continuous cardiac and pulse oximetry monitoring are strongly recommended during the assessment.

Management

Appropriate therapy begins with particular focus on the patient's respiratory and hemodynamic status. Administration of activated charcoal is the primary mode of gastrointestinal decontamination in most ingestions. However, as in the initial case, in patients manifesting significant toxicity, the risks of placing a nasogastric tube and instilling activated charcoal may not exceed the potential benefits. Induction of emesis is contraindicated because of the possibility of rapid deterioration in mental status. Orogastric lavage has limited utility, because these drugs are rapidly

absorbed. Patients often present following the onset of symptoms rather than immediately after ingestion, and patients respond well to supportive care. In cases involving clonidine patch ingestions, whole-bowel irrigation appears to be an effective intervention.[85]

All patients with CNS depression should be evaluated for hypoxia and hypoglycemia. Respiratory compromise, including apnea, often responds well to simple auditory or tactile stimulation.[4,6,86,110] Significant arousal during preparation for intubation often precludes the need for mechanical ventilation.[4] Endotracheal intubation may be required, however, for the most severely poisoned patients.

Isolated hypotension should initially be treated with intravenous boluses of crystalloid. Bradycardia is typically mild and

usually does not require any therapy if adequate peripheral perfusion exists. If the bradycardia is severe, however, standard doses of atropine are often effective, but redosing may be required.[4,6,132,207] Dopamine may be beneficial in patients with recalcitrant bradycardia or hypotension.[4,6,28,70,132]

Naloxone was probably first used in clonidine poisoning because of the similarity of its clinical findings to those of opioid toxicity, namely CNS and respiratory depression and miosis. Several clonidine-poisoned patients have had significant arousal after naloxone administration, as well as increased respiratory effort, heart rate, and blood pressure.[10,114,214] However, the exact reason for this physiologic response remains unclear. Animal models suggest that endogenous CNS opioids may modulate sympathetic outflow.[54,103,192]

This concept is supported by a clinical study in which clonidine was administered to hypertensive patients for 3 days resulting in a significant decrease in blood pressure. Subsequent administration of 0.4 mg naloxone parenterally reversed the decrease in blood pressure and heart rate in almost 60% of the patients.[55] Because

of the short duration of effects of naloxone (20â€“60 minutes), redosing or continuous infusion may be required. As with some synthetic opioids, such as propoxyphene and fentanyl, clinical improvement may occur only after high doses (4â€“10 mg) of naloxone,[110,133] and some patients have no response regardless of dosing.[11,132,234] If, in fact, naloxone acts as a nonspecific sympatholytic agent, it may also be beneficial in poisoning involving other Î±-adrenergic agents; however, there is a paucity of published clinical experience. In 1 adult with severe guanabenz poisoning, 7 mg of naloxone failed to improve her clinical status.[165] Rarely, naloxone administration in the setting of clonidine overdose can precipitate significant hypertension, so continuous hemodynamic monitoring is indicated.[110,234]

The use of Î±-adrenergic antagonists such as tolazoline and yohimbine, as specific antidotes for patients with Î±-adrenergic agonist overdoses, is controversial. Although some patients have had significant clinical improvements,[144,157,178,188] tolazoline was ineffective in other patients.[4,207] The adult dose is 5â€“10 mg intravenous infusion every 15 minutes, up to a total maximum of 40 mg.[36] Given that tolazoline treatment is variably successful and that most physicians are unfamiliar with it, it cannot be recommended in the primary management strategy for centrally acting antihypertensive poisoning.

The early onset hypertension is typically self-limited, and therapy should be cautiously undertaken, with the expectation that the hypertension will be self-limited. If hypertension is severe or prolonged, treatment with an infusion of sodium nitroprusside is appropriate.[134] Other short-acting antihypertensives, such as esmolol, may exacerbate this paradoxical hypertension in a manner similar to that which occurs when these drugs are used in cocaine toxicity, by inducing unopposed $\hat{I}\pm_1$-receptor stimulation (Chap. 74). Although oral nifedipine has been used,[47] its lack of titratability and its unpredictable efficacy make its use inappropriate as well.

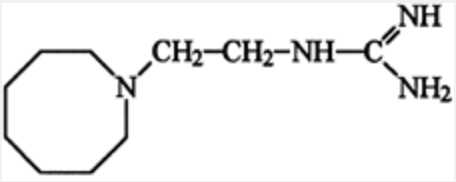
Other Sympatholytic Antihypertensives

Several other drugs also exert their antihypertensive effect by decreasing the effects of the sympathetic nervous system. Often termed *sympatholytics*, they can be classified as either ganglionic blocking agents, presynaptic adrenergic blocking agents, or Î±$_1$-adrenergic antagonists, depending on their mechanism of action. These drugs are rarely used clinically and little is known about their effects in overdose.

Ganglionic Blockers

Ganglionic blockers such as trimethaphan inhibit impulse transmission down both the postganglionic sympathetic and parasympathetic nerves, decreasing vascular tone, cardiac output, and blood pressure. These drugs were used more frequently in the 1950s and 1960s in Europe, but because of their significant side effects, they were quickly replaced with other drugs. Side effects stem from the unpredictable degree of sympathetic, as well as additional parasympathetic, blockade and include paralytic ileus, constipation, urinary retention, impotence, dry mouth, and blurred vision.[154] Trimethaphan is the only ganglionic blocker available in the United States and it is administered intravenously. Although there are no cases of intentional overdose reported, there are cases of cardiopulmonary arrest associated with administration of continuous doses and with a 10-fold pediatric dosing error while treating hypertensive crisis.[41,78] In overdose, the exaggerated hypotensive response should respond well to intravenous crystalloid boluses and, if needed, a direct-acting vasopressor such as norepinephrine.

Presynaptic Adrenergic Antagonists



Guanethidine

These drugs exert their sympatholytic action by decreasing norepinephrine release from presynaptic nerve terminals. Guanethidine and guanadrel interfere with the action potential that triggers norepinephrine release,[194] whereas reserpine depletes norepinephrine and other catecholamines from the presynpatic nerve terminals, probably by direct binding and inactivation of catecholamine storage vesicles.[65] Adverse effects of these drugs limit their clinical usefulness. These effects include a high incidence of orthostatic and exercise-induced hypotension, diarrhea, increased gastric secretions, and impotence.[154] In addition, this hypotensive effect may be prolonged for as long as 1 week.[106,195] Because of its ability to cross the bloodâ€“brain barrier, reserpine may also deplete central catecholamines and produce drowsiness, extrapyramidal symptoms, hallucinations, or depression.[126] In overdose, an extension of their pharmacologic effects is expected. Severe orthostatic hypotension should be anticipated and treated with intravenous crystalloid boluses and a direct acting vasopressor. If reserpine is involved, significant CNS depression should also be anticipated.[126]

Peripheral Î±$_1$-Adrenergic Antagonists

The fourth group of sympatholytic agents is the selective Î±$_1$-adrenergic antagonists, which include prazosin, terazosin, and doxazosin. The Î±$_1$ receptor is a postsynaptic receptor primarily located on vascular smooth muscle, although they are also found in the eye and in the gastrointestinal and genitourinary tracts.[39] In fact, this class of drugs provides first-line pharmacologic therapy for patients with urinary dysfunction secondary to benign prostatic hyperplasia. These drugs produce arterial smooth muscle relaxation, vasodilation, and lowering of the blood pressure. Although better tolerated than ganglionic blockers and peripheral adrenergic neuron blockers, these drugs may still produce significant symptoms of

postural hypotension, including lightheadedness, syncope, or palpitations, particularly after the first dose or if the dosing is rapidly increased.[15] Hypotension and CNS depression ranging from lethargy to coma are reported in overdose cases.[120,124,186] In addition, priapism can occur.[124,177] Treatment with supportive care, including intravenous fluid boluses and a vasopressor such as dopamine, was effective in the few overdose cases reported.[120,124,137]

Direct Vasodilators

Nitroprusside

Hydralazine, Minoxidil, Diazoxide

Early work established that these drugs produce vascular smooth muscle relaxation independent of innervation or known pharmacologic receptors.[49,111,112] More recently, this vasodilatory effect has been attributed to stimulation of nitric oxide release from vascular endothelial. The nitric oxide then diffuses into the underlying smooth muscle cells, stimulating guanylyl cyclase to produce cyclic guanosine monophosphate (cGMP). This second messenger indirectly inhibits calcium entry into the smooth muscle cells, producing vasodilation.[185] As this vasodilation occurs, the baroreceptor reflexes, which remain intact, produce an increased sympathetic outflow to the myocardium, resulting in an increase in heart rate and contractile force. Typically, these drugs are used therapeutically in patients with severe, refractory hypertension and in conjunction with a Î²-adrenergic antagonist to diminish the reflex tachycardia. Hydralazine, minoxidil, and diazoxide are effective orally, whereas sodium nitroprusside is only used intravenously. Minoxidil is also used topically, in a 2% solution, to promote hair growth, and significant poisoning has occurred in

suicidal adults who have ingested this formulation.[141] Diazoxide, although previously used to rapidly reduce blood pressure in hypertensive emergencies, is rarely used for this indication now as a consequence of its poor titratability and its variable, and occasionally profound, hypotensive effect.[111]

Adverse effects associated with daily hydralazine use include several immunologic phenomenon such as hemolytic anemia, vasculitis, acute glomerulonephritis, and, most notably, a lupuslike syndrome.[169] Minoxidil may cause electrocardiographic changes, both in therapeutic doses and in overdose. Sinus tachycardia, ST segment depressions, and T-wave inversions are reported.[77,170,201] The significance of these changes is unknown; they typically resolve with either continued therapy or as other toxic manifestations resolve.[77,201]

The common toxic manifestations of these drugs are an extension of their pharmacologic action. Symptoms can include lightheadedness, syncope, palpitations, and nausea.[3,131] Signs may be isolated to tachycardia alone,[96,170,201] flushing, or alterations in mental status, which is related to the degree of hypotension.[141] Based on American Association of Poison Control Centers annual poison data, it appears that in recent years, the majority of reported exposures to this class of drugs involve the topical formulation of minoxidil (Chap. 130).[53]

After appropriate gastrointestinal decontamination, routine supportive care should be performed, with special consideration to maintaining adequate mean arterial pressure. If intravenous crystalloid boluses are insufficient, a peripherally acting Î±-adrenergic agonist vasopressor such as norepinephrine or phenylephrine, is an appropriate next therapy. Dopamine and epinephrine should be avoided, to prevent an exaggerated myocardial response and tachycardia from Î²-adrenergic stimulation.

Nitroprusside

Sodium nitroprusside exerts its vasodilatory effects after spontaneously releasing into the blood the vasodilator nitric oxide. The nitroprusside molecule also contains 5 cyanide radicals that, although gradually released, on occasion produce cyanide toxicity.[153,190] Physiologic methemoglobin can bind the liberated cyanide. The binding capacity of physiologic methemoglobin is about 175 Âµg/kg of cyanide, corresponding to a little less than 500 Âµg/kg of infused sodium nitroprusside. These cyanide moieties are rapidly cleared, both by interacting with various sulfhydryl groups in the surrounding tissues and blood, and enzymatically in the liver by rhodanese, which couples them to thiosulfate-producing thiocyanate.[59] This cyanide detoxification process in healthy adults occurs at a rate of about 1 Âµg/kg/min, which corresponds to a sodium nitroprusside infusion rate of 2 Âµg/kg/min.[40,190] It is limited by the sulfur donor availability, so factors that reduce these stores, such as poor nutrition in infants and toddlers, critical illness, surgery, and diuretic use, place patients at risk for developing cyanide toxicity.[40,99] Therefore, depending on the balance of cyanide release (eg, the rate of sodium nitroprusside infusion) and the rate of cyanide detoxification (eg, the sulfur donor stores), cyanide toxicity can develop within hours. Infusion of nitroprusside at a rate of more than 1.5 mg/kg, administered over a few hours, or more than 4 Âµg/kg/min, for more than 12 hours, may overwhelm the capacity of rhodanese for detoxifying cyanide. Signs and symptoms of cyanide toxicity include alteration in mental status, anion gap metabolic acidosis, and, in late stages, hemodynamic instability. (Chapter 121 has a complete discussion of cyanide.)

One method of preventing cyanide toxicity from sodium nitroprusside is to expand the thiosulfate pool available for detoxification by the concomitant administration of sodium thiosulfate.[35,40,75,99,190] Recommendations include infusing 500

mg sodium thiosulfate (the standard 50-mL bottle of 25% sodium thiosulfate found in the Cyanide Antidote kit). Unfortunately, the thiocyanate that is formed may accumulate, particularly in patients with renal insufficiency, and produce thiocyanate toxicity.[59,99]

Thiocyanate is almost exclusively renally eliminated with an elimination half-life of 3â€“7 days. It is postulated that a continuous sodium nitroprusside infusion of 2.5 Âµg/kg/min in patients with normal renal function could produce thiocyanate toxicity within 7â€“14 days, although it may be as short as 3â€“6 days or as little as 1 Âµg/kg/min in patients with chronic renal insufficiency who are not receiving hemodialysis.[190] The symptoms of thiocyanate toxicity begin to appear at serum concentrations of 1 mmol/L (60 Âµg/mL), are very nonspecific, and may include nausea, vomiting, fatigue, dizziness, confusion, delirium, and seizures.[59] Thiocyanate toxicity may produce life-threatening effects, such as hemodynamic and intracranial pressure elevation, when serum concentrations are above 200 Âµg/mL.[40,59,75,218] An anion gap metabolic acidosis or hemodynamic instability does not occur with thiocyanate toxicity. Although cyanide or thiocyanate concentrations are not typically useful in the management of cyanide toxicity, they may be beneficial for

monitoring critically ill patients who are at risk of thiocyanate poisoning. Hemodialysis is the treatment of choice for patient with severe clinical manifestations of thiocyanate toxicity.

Diuretics

Diuretics can be divided into three main groups: (a) the thiazides and related compounds, including hydrochlorothiazide and chlorthalidone; (b) the loop diuretics, including furosemide, bumetanide, and ethacrynic acid; and (c) the potassium-sparing diuretics, including amiloride, triamterene, and spironolactone. Two other groups of diureticsâ€”the carbonic anhydrase inhibitors,

such as acetazolamide, and osmotic diuretics, such as mannitolâ€”are not used as antihypertensive agents.

The thiazides produce their diuretic effect by inhibition of sodium and chloride reabsorption in the distal convoluted tubule. Loop diuretics, in contrast, inhibit the coupled transport of sodium, potassium, and chloride in the thick ascending limb of the loop of Henle. Although their exact antihypertensive mechanism is unclear, an increased urinary excretion of sodium, potassium, and magnesium results from the use of loop diuretics. Potassium-sparing diuretics act either as aldosterone antagonists, such as spironolactone, or as renal epithelial sodium channel antagonists, such as triamterene, in the late distal tubule and collecting duct.[100]

The majority of toxicity associated with diuretics is metabolic and occurs during chronic therapy or overuse.[232] Hyponatremia develops within the first 2 weeks of initiation of therapy in more than 67% of susceptible patients.[203] Patients who are elderly, female, malnourished, or taking thiazides are at greatest risk.[8] With severe hyponatremia (<120 mEq/L), symptoms can include headache, nausea, vomiting, confusion, seizures, or coma. Pontine demyelination has been reported during rapid correction of severe hyponatremia secondary to diuretic abuse (Chap. 17).[37]

Other electrolyte abnormalities associated with diuretic use include hypokalemia and hypomagnesemia, which may precipitate ventricular dysrhythmias and sudden death. This is an extremely controversial topic, with several excellent studies providing conflicting results.[18,60,161,198,199] Although it is unclear how great a risk, if any, diuretic use may be, it remains prudent to monitor and correct the patient's potassium levels.[91,198,231] This is particularly important in elderly patients, and for those patients who concomitantly use digoxin, in which setting hypokalemia is clearly associated with dysrhythmias (Chap. 62).[22,208] Potassium-sparing diuretics can cause hyperkalemia, particularly in the

setting of renal insufficiency or when combined with other hyperkalemia-producing drugs such as angiotensin-converting enzyme inhibitors (ACEIs).[105]

Thiazide diuretics are associated with inducing hyperglycemia, particularly in patients with diabetes mellitus. This is a result of depletion of total-body potassium stores. Because insulin secretion is dependant on transmembrane potassium fluxes, this decrease in potassium concentration reduces the amount of insulin secreted.[128] This effect is dose dependant and reversible either by potassium supplementation, or discontinuation of the thiazide diuretic.[31,83] However, a recent prospective study was unable to identify an increased risk of developing diabetes mellitus in patients treated with thiazide diuretics.[72]

Thiazide diuretics are also associated with inducing hyperuricemia, uric acid, renal calculi, and gout. Uric acid is the end product of purine metabolism and its renal elimination is significantly dependant on intravascular and urinary volume. Diuretic-induced volume depletion decreases uric acid filtration and increases its reabsorption in the proximal tubule.[196,206] Several studies support the association with hyperuricemia and the development of gout.[26,76] One study found a link between thiazide diuretic use and the likelihood of the need for subsequent antigout therapy.[73]

Several unusual reactions are associated with thiazide diuretic use, including pancreatitis, cholecystitis, and hematologic abnormalities such as hypercoagulability, thrombocytopenia, and hemolytic anemia.[50,51,182,184,220,230]

Despite the widespread use of these drugs, acute overdoses are distinctly rare.[123] Major signs and symptoms include gastrointestinal distress, brisk diuresis, possible hypovolemia and electrolyte abnormalities, and altered mental status.[123] Typically, the diuresis is short lived because of the limited duration of effect and the rapid clearance of the majority of diuretics. Assessment should focus on fluid and electrolyte status, which should be

corrected as needed. If hyperkalemia is unexpectedly discovered, either the ingestion of a potassium-sparing agent should be considered or, more likely, an overdose of potassium supplements, which are frequently prescribed in conjunction with thiazide and loop diuretics.[93,97] Altered mental status, including coma, may result from diuretic overdose, without evidence of any fluid or electrolyte abnormalities.[14,123,183] Postulated mechanisms include a direct drug effect and induction of transient cerebral ischemia.[155]

Case 2 A 56-year-old man presents to the hospital complaining of progressive lip and tongue swelling. The patient had a history of nonâ€“insulin-dependent diabetes mellitus and hypertension. His medications include aspirin, glyburide, and hydrochlorothiazide, and a new antihypertensive which he began three weeks earlier. Physical examination revealed a well-appearing male in mild distress with obvious swelling of lips, face, and tongue. Initial vital signs were: blood pressure, 154/88 mm Hg; heart rate, 90 beats/min; respiratory rate, 18 breaths/min; temperature, 97.8Â°F (36.6Â°C). Head and neck examination was remarkable for marked swelling of lips, slight protrusion of tongue forcing the mouth open at rest, and left cheek swelling. Lung examination revealed no wheezes or rhonchi, with good air movement. No stridor was noted, although his voice was muffled. Heart, abdominal, and neurologic examinations were unremarkable. A diagnosis of angiotensin-converting enzyme inhibitor-induced angioedema was made and a nasopharyngeal airway was immediately placed. Diphenhydramine (50 mg IV) and methylprednisolone (125 mg IV) were administered, without significant improvement. Although the patient's upper airway was patent, the rapidity of the onset of such significant oropharyngeal swelling threatened his respiratory status. Topical anesthetics and systemic anxiolytics were used, and direct fiberoptic nasopharyngeal intubation was performed. The patient remained intubated for 36 hours. After the swelling had decreased, the patient tolerated extubation without difficulty. He

was discharged from the hospital with specific instructions to discontinue his new antihypertensive, enalapril, and instead to use verapamil.

Angiotensin-Converting Enzyme Inhibitors

ACEIs are among the most widely prescribed antihypertensive drugs. At the time of this writing there were 10 ACEIs approved by the US Food and Drug Administration for the treatment of hypertension (Table 60-1). In general, these drugs are well absorbed

from the gastrointestinal tract, reaching peak plasma levels within 1â€“4 hours. Enalapril and ramipril are prodrugs and require hepatic metabolism to produce their active forms. These drugs are primarily eliminated via the kidneys.

TABLE 60-1. Classification of Antihypertensives Available in the United States

Î²-Adrenergic antagonists (Chap. 59)
Calcium channel blockers (Chap. 58)
Sympatholytics
  Central α_2-adrenergic agonists
    Clonidine, guanabenz, guanfacine, methyldopa
  Ganglionic blocking agents
    Trimethaphan
  Peripheral adrenergic neuron antagonists
    Guanethidine, guanadrel, metyrosine, reserpine
  Peripheral α_1-adrenergic antagonists
    Prazosin, terazosin, doxazosin

Diuretics

Thiazide

Bendroflumethiazide, chlorthalidone, chlorothiazide, hydrochlorothiazide, hydroflumethiazide, indapamide, methyclothiazide, metolazone, polythiazide, trichlormethiazide

Loop diuretics

Bumetanide, ethacrynic acid, furosemide, torsemide

Potassium sparing

Amiloride, eplerenone, spironolactone, triamterene

Vasodilators

Hydralazine, minoxidil, diazoxide, nitroprusside

Angiotensin-converting enzyme inhibitors

Benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril

Angiotensin II receptor blockers

Candesartan cilexetil, eprosartan, irbesartan, losartan, telmisartan, valsartan

All ACEIs have a common core structure of a 2-methylpropanolol-L-proline moiety.[63] This structure binds directly to the active site of angiotensin-converting enzyme, which is found in the lung and vascular endothelium, preventing the conversion of angiotension I to angiotensin II. Because angiotensin II is a potent vasoconstrictor and stimulant of aldosterone secretion, vasodilation, decreased peripheral vascular resistance, decreased blood pressure, increased cardiac output, and a relative increase in renal, cerebral, and coronary blood flow occur.[63] This hypotensive response may be severe in select patients after their initial dose, resulting in syncope and cardiac ischemia.[33,88] Patients with renovascular-induced hypertension and patients who are hypovolemic from concomitant diuretic use appear to be at greatest risk.[88] Overall, however, these drugs are well tolerated and have a very low incidence of side effects. Some reported

adverse effects include rash, dysgeusia, neutropenia, hyperkalemia, chronic cough, and angioedema.[46,63,215] Because of their interference with the reninâ€“angiotensin system, ACEIs are potential teratogens and should never be used by a pregnant woman or a woman who intends to become pregnant.[13]

ACEI-Induced Angioedema

Angioedema is an inflammatory reaction in which there is increased capillary blood flow and permeability, resulting in an increase in interstitial fluid. If this process is confined to the superficial dermis, urticaria develops, whereas, if the deeper layers of the dermis or subcutaneous tissue are involved, angioedema results. Angioedema most commonly involves the periorbital, perioral, or oropharyngeal tissues.[179] This swelling may progress rapidly over minutes and result in complete airway obstruction and death.[62,66,193] The pathogenesis of acquired angioedema involves multiple vasoactive substances, including histamine, prostaglandin D_2, leukotrienes, and bradykinin. Because angiotension-converting enzyme (ACE) also inactivates bradykinin and substance P, ACE inhibition results in elevations in bradykinin concentrations that appear to be the primary cause of both ACEI-induced angioedema and cough (Fig. 60-1).[5,98] There is no evidence that the ACEI-induced angioedema phenomenon is IgE-mediated.[5]

Although the literature is replete with reports of ACEI-induced angioedema, the overall incidence is only approximately 0.1%.[57,98,102,200] One-third of these reactions occur within hours of the first dose and another third within the first week.[200] It is important to remember that the remaining one-third of cases can occur at any time during therapy, even after years.[32] Patients with a history of idiopathic angioedema, and possibly atopy, may be at greater risk.[159] There does not appear to be any doseâ€“response relationship.

Treatment varies depending on the severity and rapidity of the swelling. Because of its propensity to involve the tongue, face, and oropharynx, the airway must remain the primary focus of management. A nasopharygeal airway is often helpful. If there is any potential for, or suggestion of, airway compromise, endotracheal intubation should be performed. Severe tongue and oropharyngeal swelling may make orotracheal or nasotracheal intubation extremely difficult, if not impossible. If this is a concern, fiberoptic nasal intubation may be an attractive option, provided that the resources are available. Other techniques, including retrograde intubation over a guidewire that was passed through the cricothyroid membrane, and emergent cricothyrotomy, should also be considered.[179] The most important aspect of airway management in patients suffering from ACEI-induced angioedema, however, is early risk assessment for airway obstruction and rapid intervention prior to the development of severe, obstructive swelling.

Because of the potential for rapid, life-threatening airway obstruction, pharmacologic therapy for ACEI-induced angioedema should be aggressive and include standard agents used for anaphylaxis, such as subcutaneous epinephrine, intravenous diphenhydramine, and corticosteroids. However, because ACEI-induced angioedema is not an antibody-mediated allergic phenomenon, these

interventions will probably be ineffective, so their efficacy should not be assumed or relied on, to avoid definitive airway protection.

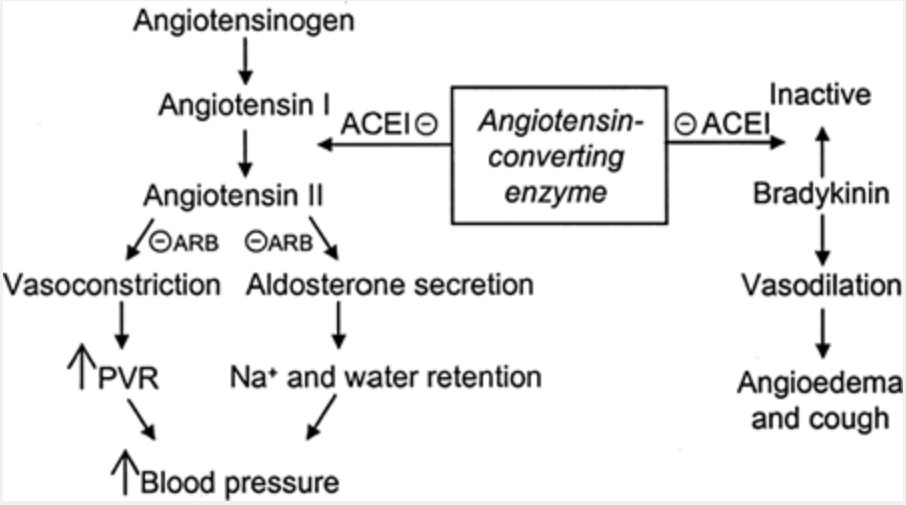


Figure 60-1. An overview of the normal function of angiotensin II and the mechanisms of action of angiotensin-converting enzyme inhibitors and the angiotensin II receptor antagonists. PVR = peripheral vascular resistance.

All patients with mild or quickly resolving angioedema should be observed for several hours to assure that the swelling does not progress or return. Outpatient therapy with a short course of oral antihistamines and corticosteroids is appropriate. Such patients should be instructed to discontinue ACEI therapy permanently and to consult their primary care physician about other antihypertensive options. Because this is a mechanistic and not allergic adverse effect, the use of any other ACEIs is contraindicated.

ACEI Overdose

The toxicity of ACEIs in overdose appears to be limited.[34,90,125,205] Althought several reports of overdoses involving ACEIs have been published, the majority of the cases reported manifested toxicity of a coingestant.[43,71,101,219,231]

Hypotension can occur in select patients,[12,117] but deaths are rarely reported in isolated ACEI ingestions.[162,228] Other patients may remain asymptomatic despite high serum drug concentrations.[119] Two studies suggest that clinical effects are uncommon in children with unintentional exposures to adult therapeutic doses.[90,205]

Treatment should focus on supportive care and on identifying any coingestants that may be more toxic, particularly other antihypertensives such as Î²-adrenergic antagonists and calcium channel blockers. In most cases, activated charcoal alone is sufficient gastrointestinal decontamination. Intravenous crystalloid boluses are often effective in correcting hypotension, although in rare cases, catecholamines may be required.[7]

Naloxone may also be effective in reversing the hypotensive effects of ACEIs. ACEIs may inhibit the metabolism of enkephalins and potentiate their opioid effects, which include lowering blood pressure.[45,145] In a controlled human volunteer study, continuous naloxone infusion effectively blunted the hypotensive response of captopril.[2] In one case report, naloxone appeared to be effective in reversing symptomatic hypotension secondary to a captopril overdose.[227] In another published case, naloxone was ineffective.[12] Although its role in the setting of ACEI overdose remains unclear, naloxone may obviate the need for large quantities of crystalloid or vasopressors and should therefore be considered.

Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) were first introduced in 1995 and currently 6 members of this class are marketed in the United States. These drugs are rapidly absorbed from the gastrointestinal tract, reaching peak plasma concentrations in 1â€“4 hours, and then are either eliminated unchanged in the feces, or, after undergoing hepatic metabolism via the mixed

function oxidase system, eliminated in the bile.[136,138,139 and 140,156]

Although these drugs are similar to ACEIs, in that they decrease the effects of angiotensin II rather than decrease the formation of angiotensin II, they act by antagonizing angiotensin II at the type 1 angiotensin (AT-1) receptor (Fig. 60-1).[108] This allows the drugs to inhibit the vasoconstrictive- and aldosterone-promoting effects of angiotensin II without interfering with bradykinin degradation,[136] significantly reducing or eliminating the risk of adverse effects, such as cough or angioedema, compared to ACEI therapy.[115,163,213] However, rare cases of angioedema associated with ARB therapy are reported.[30,223]

Like ACEIs, ARBs should never be used by a pregnant patient because of their teratogenic potential.[13] In addition, 0.5â€“1% of patients develop first-dose orthostatic hypotension.[67]

There are no published reports of overdoses involving these drugs, but hypotension should be anticipated and treated with intravenous crystalloid therapy and traditional catecholamines.

Summary

Numerous medications are currently marketed for the treatment of chronic hypertension, including centrally acting drugs, other sympatholytics, direct vasodilators, diuretics, ACEIs, and ARBs. Although these drugs are not typically associated with severe poisonings, either because of limited use, as with many of the sympatholytics and direct vasodilators, or because of limited toxicity, as with diuretics, ACEIs, and ARBs, severe poisonings have occurred and will probably continue to occur. Although centrally acting drugs, such as clonidine, may produce significant CNS depression and bradycardia, most of these drugs only produce hypotension in overdose. Management of ingestions involving these antihypertensives should focus on appropriate

gastrointestinal decontamination, typically oral activated charcoal, and hemodynamic monitoring and support with intravenous crystalloids and catecholamines. Naloxone may be used in clonidine- or ACEI-poisoned patients, but its efficacy is variable. Sodium nitroprusside use can result in cyanide toxicity if the infusion rate exceeds the body's thiosulfate stores. Although cyanide toxicity can be prevented with concomitant infusion of sodium thiosulfate, thiocyanate toxicity may develop, particularly in patients with renal dysfunction.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 61
Antidysrhythmics

Neal A. Lewin

Lewis S. Nelson

A 27-year-old man presented to the emergency department after attempt bottle of his prescription disopyramide that was prescribed for paroxysma awake but lethargic on arrival and had the following vital signs: blood pre pulse, 140 beats/min; respirations, 26 breaths/min; temperature, 98.6Â°F exact nature of his overdose was unclear, he was intubated for airway pr glucose determination was 70 mg/dL. His electrocardiogram revealed a sir complex duration of 140 msec.

On physical examination the patient was intubated and sedated. His skin prominently on his face, and there was no moisture in his axilla. The pupi and minimally reactive to light. His heart sounds were normal though rap examination were normal. Laboratory evaluation, including a serum ace were normal.

He received sodium bicarbonate 100 mEq by rapid intravenous infusion, of his QRS complex duration to 90 msec; his blood pressure remained no placed and aspiration of 300 mL of gastric contents was performed prior t of activated charcoal. A sodium bicarbonate infusion was initiated at a rate

continued for 16 hours. On discontinuation of the infusion, the QRS comp patient was extubated on the second hospital day and made an uneventfu was transferred to the care of the inpatient psychiatry service.

The term *dysrhythmia* encompasses an array of abnormal cardiac rhythms significance from merely annoying to instantly life-threatening. Antidysrhy that are used to treat any of the various dysrhythmias. The importance in the modern practice of medicine cannot be overstated, as dysrhythmias common causes of preventable sudden cardiac death.[38 , 60] However, des understanding of the underlying mechanisms of dysrhythmia formation, a antidysrhythmics have been developed, each attempting to alter specific components of the cardiac impulse generating or conducting system. In a mechanism-based adverse effect of each agent, unique and often unantic Experience with overdose of many of these drugs is limited, and manager the underlying pharmacologic principles, existing case reports, and the

History and Epidemiology

Until recently, antidysrhythmics were considered among the most rational medications. This well-earned reputation related to their high efficacy at malignant dysrhythmias. Similarly, they are effective at controlling nuisa However, this approach changed dramatically following publication of the Suppression Trials (CAST and CAST II)[37 , 62 , 63] and, more recently, with interventions, such as ablation therapy and implantable defibrillators. CAS antidysrhythmic agents to suppress asymptomatic ventricular dysrhythmias of malignant dysrhythmias. The original CAST study was discontinued pre was noted that encainide and flecainide, 2 of the examined drugs, not on death but actually increased overall mortality. The CAST II trial noted sir moricizine.[63] It has since become clear that the enhanced mortality asso antidysrhythmics is a result of their prodysrhythmogenic effects, and that group carry such risk.[110]

This chapter focuses on the drugs that serve their primary clinical role a the exception of lidocaine, have few other medicinal indications. Chapter description of the various dysrhythmias and a discussion of their genesis. channel blockers and Î²-adrenergic antagonists, also used as antidysrhyt

separately in Chaps. 58 and 59 .

Classification of Antidysrhythmic Agents

Antidysrhythmic agents modify impulse generation and conduction by inte membrane sodium, potassium, and calcium ion channels. Generally, anti electrophysiologic effects either through blockade of the channel pore or, modification of its gating mechanism (described in Fig. 61-1).[66] Unfortuna complex mechanisms of action of the antidysrhythmics, the descriptive

terms used to explain their molecular selectivities are not always comple the description of an antidysrhythmic as a specific â€œchannel blockerâ€ opener,â€• although representative of a specific action of that drug, is many of these drugs are active at other channels or on other cells. Nonsp membrane ion channel may modify several different proteins within the b anticipated target.

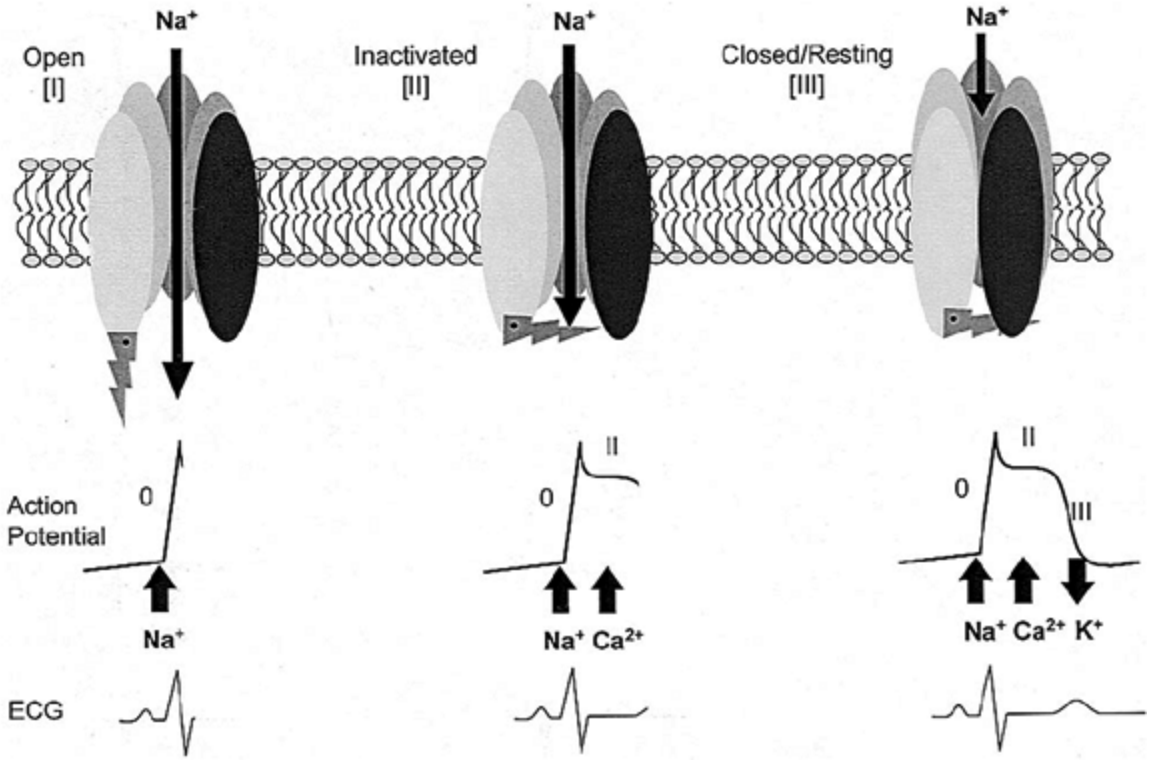

Figure 61-1. Sodium channel blockade. On appropriate signal, sodium c

which time the sodium channel converts from the resting [III] state to th sodium ion influx to initiate phase 0 of the action potential, or cellular d channels subsequently assume the inactivated state by closure of an inact voltage-dependent phenomena and occurs concomitantly with, although m activation. Cellular depolarization is maintained for a period of time by ot the plateau of the action potential. Prior to reactivating, sodium channels resting state, which also occurs in a voltage-dependent fashion. Many ar inactivated state of the channel and, by slowing conversion to the resting reopening, reducing the excitability of the cell. As this is a population ph dependent effects on channel blockade; thus, more drug interferes with certain xenobiotics, such as ciguatoxin and aconitine, stabilize the open s and produce persistent depolarization.

The Vaughan-Williams classification of antidysrhythmics by electrophysio the connection between the basic electrophysiologic actions and the anti Although initially proposed as a descriptive model for electrophysiologic a effects, the Vaughan-Williams classification is commonly invoked as a us therapy. In 1991, a competing system known as â€œthe Sicilian Gambitâ task force of European cardiologists based on the mechanisms by which dysrhythmogenic mechanisms. Although perhaps more contemporary in th classification system is complex and is therefore not widely implemented. classification would match the electrophysiologic effects of the antidysrhy interactions on different regions of the various ion channels, such as char conductance.[66]

This discussion of antidysrhythmics uses the Vaughan Williams classificat shortcomings delineated above.[131]

Class I Antidysrhythmics

All antidysrhythmics in Vaughan-Williams class I (A, B, and C) alter Na^+ voltage-gated, fast inward Na^+ channels (Table 61-1). These agents bind slow their recovery from the open or inactivated state to the resting state conversion must occur before the channel can reopen and participate in Consequently, as the proportion of drug-bound Na^+ channels increases, f

capable of reactivation on the arrival of the next depolarizing impulse. As excitability of the myocardium, abnormal rhythms are both prevented an

Blockade of these sodium channels slows the rise of phase 0 of the cellu correlates with a reduction in the rate of depolarization of the myocardial conduction through the myocardium is slowed, producing a measurable pr complex on the surface electrocardiogram. Correspondingly, slowed intra associated with reduced contractility, manifesting as negative inotropy. M results from effects of reduced intracellular Na^+ on Na^+ -Ca^{2+} exchange.[intracellular Ca^{2+} concentrations, normal levels of which are required for

The differences among class I drugs are directly related to their pharma Na^+ channel. However, it is noteworthy that the original subdivision of cla clinical observations, not current pharmacologic awareness, accounting fo ordering of the class I subdivisions.[131] Type IB drugs have their highest are in the inactivated state. This occurs at the end of depolarization, dur during periods of myocardial ischemia, all situations in which the myocar These drugs also have rapid â€œon-offâ€• binding kinetics and are thus late systole, the period during which the Na^+ channels are predominantly They are almost exclusively unbound during diastole, which is the major at normal heart rates. However, the degree of binding increases as the h because the duration of diastole decreases and the relative proportion of increases; this is termed *use dependence* (Chap. 23). Because they do r channels, class IB drugs do not affect the rate of rise of phase 0 of the a have no effect on the electrocardiogram in therapeutic doses.[130] Alternativ either prefer activated Na^+ channels or they release from the Na^+ channe still bound during the next cardiac cycle.[130] This prolonged channel block reactivation results in greater pharmacologic effects and toxicity, even at these drugs reduce V_{max} and prolong the QRS complex on the electrocard between the other two subclasses.

Although by the Vaughan-Williams classification class I drugs are conside channel blockers, many of the represented drugs, particularly those in cla effects on cardiac potassium channels. These channels are critical to mai action potential and repolarization of the myocardial cell. Slowing of pota the duration of the action potential and accounts for the persistence of r

during which the cell is incapable of re-depolarization. This effect produce

surface electrocardiogram, and predisposes to the triggering of polymorp tachycardia.[111] Because they have no effect on myocardial potassium cha alter refractoriness or the QTc interval. In fact, class IB drugs often redu duration, shortening refractoriness. Further discussion of potassium chann Chap. 23 and below in the discussion of class III antidysrhythmics.

Drug	Route	Primary Route of Elimination	Vaughan-Williams Classification	Channel Blockade	Adverse Effects and Complicatir Factors

TABLE 61-1. Antidysrhythmics: Pharmacology, Pharmacokinetics,

Class IA Antidysrhythmics: Procainamide, Disopyramide

Procainamide

Procainamide (Fig. 61-2) can be used to suppress either atrial or ventr Although absorption from the GI tract is rapid and relatively complete fol (75â€“95%), it may be delayed in overdose situations. A sustained-relea Importantly, procainamide undergoes hepatic biotransformation by acetyl acetylprocainamide (NAPA), the rate of which is genetically determined. A

channel-blocking activity of procainamide, it prolongs the action potential of the K^+ rectifier currents, and for this reason is classified as a class II acecainide.[55] Both procainamide and NAPA are renally eliminated and ma with renal insufficiency.[35, 83] However, NAPA's main advantage over proc propensity to produce a drug-induced lupuslike syndrome caused by the antibodies.[55]

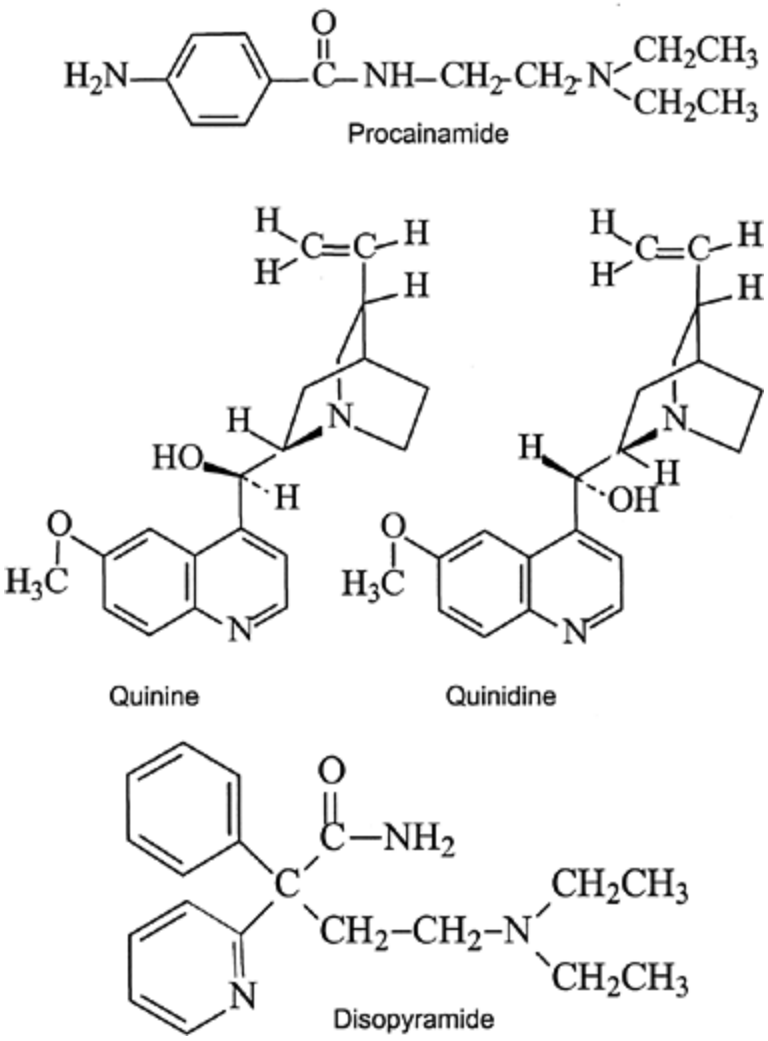

Figure 61-2. Structures of class IA antidysrhythmics and quinine.

Rapid intravenous dosing of procainamide is potentially dangerous because distribution is smaller than its final volume of distribution. Because this the heart, myocardial effects may be unexpectedly pronounced. Thus, to

infusion, the intravenous loading dose should be administered by slow int electrocardiogram monitoring. Although the chronic use of procainamide i the development of antinuclear antibodies or drug-induced systemic lupu syndrome is not associated with acute poisoning. Other reported adverse antimuscarinic effects with acute overdose[133] and myopathic pain, throm agranulocytosis following long-term use.

Both procainamide and NAPA serum concentrations should be determined therapeutic serum concentrations (5â€“20 Âµg/mL) and in patients with Because the elimination half-life of procainamide is 3â€“4 hours, which is that of NAPA (6â€“10 hours), chronic overdosing typically results in NAPA the QTc interval, a reflection of K^+ channel blockade, correlates directly, correlates inversely, with the degree of poisoning. Severe effects usually (procainamide plus NAPA) serum concentrations are greater than 60 Âµg/ structural similarity with amphetamine (Fig. 61-3), patients with procain false-positive urine enzyme-multiplied immunoassay test (EMIT) for amp

Quinidine

Quinidine (Fig. 61-2), the *d* -isomer of quinine, is derived from the bark Because it is a weak base, it is typically formulated as the sulfate or gluc management of atrial or ventricular dysrhythmias. Quinidine undergoes h and both active and inactive metabolites are renally eliminated. Thus, th ($t_{1/2}$) of approximately 6â€“8 hours is prolonged by both liver disease (t failure (to 9â€“12 hours).

Quinidine has substantial acute cardiotoxicity following overdose that in conduction abnormalities and an increased QTc interval. â€œQuinidine sy on therapeutic doses of quinidine experience paroxysmal, transient loss o frequently a result of torsades de pointes.[40 , 64 , 124] Many of the ECG ch hypokalemia.

Because quinidine shares many pharmacologic properties with quinine (Ch that patients may occasionally suffer from cinchonism following either chr overdose. This syndrome includes abdominal symptoms, tinnitus, and alte Quinidine also produces peripheral and cardiac antimuscarinic effects, wh the atrioventricular (AV) node. Thus, quinidine may actually exacerbate t

atrial flutter, explaining the need for rate control prior to chemical cardio quinidine.[61] Furthermore, as with quinine, quinidine-induced blockade of islet cells may cause uncontrolled insulin release, leading to hypoglycemi

Serum quinidine concentrations greater than 14 Âµg/mL are associated evidenced by a 50% increase in either the QRS or QTc interval. However, procainamide, quinidine is associated with an increased QTc at both sub serum concentrations.[40]

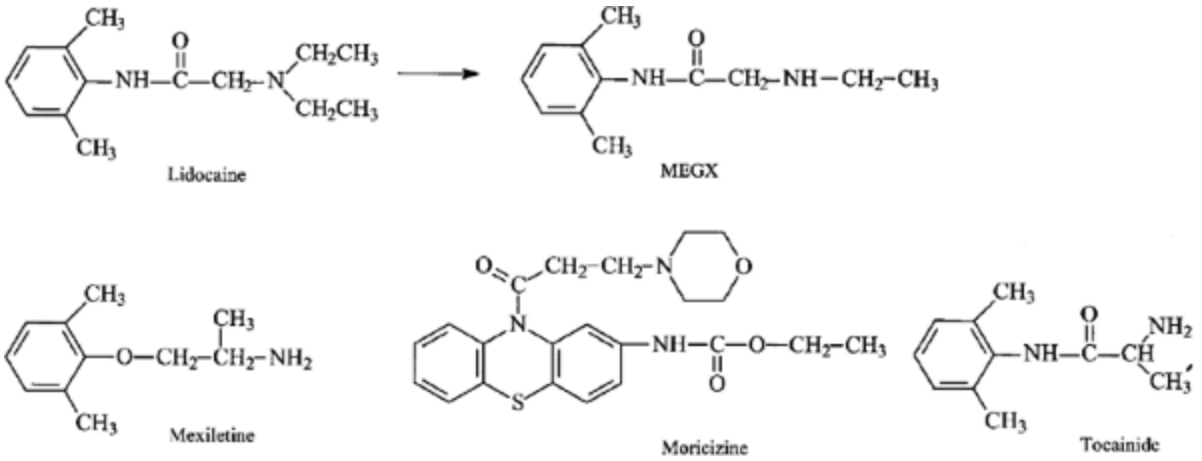

Figure 61-3. Structures of the class IB antidysrhythmic agents lidocaine tocainide, mexiletine, and moricizine.

Disopyramide

Disopyramide (Fig. 61-2) is more likely than the other class IA antidysr inotropy and congestive heart failure. This effect may be noted both in p dosing,[125] and in those who overdose. This propensity may relate in part block myocardial calcium channels.[59] Disopyramide's mono-*N* -dealkylated most pronounced anticholinergic effects of the class, accounting for the o disopyramide to treat neurocardiogenic syncope.[19]

Electrophysiologic abnormalities similar to those associated with poisoning can occur, including atrioventricular and intraventricular conduction abno pointes, and other ventricular dysrhythmias. Disopyramide frequently ca

hypoglycemia through its antagonism of K^+ channels in the pancreatic isl

Patients who overdose on disopyramide frequently develop classic antic including mydriasis, urinary retention, and gastrointestinal stasis.[105, 11(hallucinations may be prominent.

Class IA Management

Management centers on assessment and correction of cardiovascular dys evaluation and intravenous line placement, the 12-lead ECG and continuo paramount importance. Appropriate gastrointestinal decontamination is re patient is stabilized and should include whole-bowel irrigation if a sustai involved.

For patients with widening of the QRS complex duration, bolus administra hypertonic sodium bicarbonate is indicated. Depolarization is accelerated a duration is reduced, by enhancing rapid sodium ion influx through the m However, hypokalemia from the use of sodium bicarbonate may further p requiring careful monitoring of the serum K^+ and ECG. Class IA antidys is treated primarily with rapid 0.9% NaCL infusion, in order to expand th volume and to simultaneously increase myocardial contractility (ie, enhar Hypotension in the setting of QRS complex duration prolongation may res hypertonic sodium bicarbonate, which enhances inotropy by both acceler raising intravascular volume. Dopamine, dobutamine, isoproterenol, nore balloon pump insertion may also be required, but their use has not beer Because disopyramide also blocks calcium channels, calcium administratio although evidence to support this antidotal effect is lacking. Glucagon e depression in canine models, but it has not been evaluated in humans.[95]

Patients with stable ventricular dysrhythmias occurring in the setting of poisoning are usually treated with hypertonic sodium bicarbonate or lidoca counterintuitive to administer another class I antidysrhythmic to a patient class I antidysrhythmic, there is sound theoretical and experimental litera practice.[135] That is, because lidocaine is a class IB drug with rapid on-of displace the â€œslowerâ€• class IA drug from the sodium channel, effe blockade. Sodium bicarbonate enhances conduction through the myocard termination of the ventricular dysrhythmia. Magnesium sulfate and overdri

treating torsade de pointes.[72] Drugs that must be avoided in treating pa associated with class IA poisoning include other class IA and IC drugs, as antagonists and calcium channel blockers, all of which may exacerbate

The roles of activated charcoal hemoperfusion, hemofiltration, and conti hemodiafiltration are inadequately defined, but may be most beneficial fo [83] There is no clinical evidence to support the use of hemodialysis or he disopyramide poisoning.

Class IB Antidysrhythmics: Lidocaine, Toca Mexiletine, and Moricizine

Lidocaine

Lidocaine (Fig. 61-3), known internationally as lignocaine, is an aminoacy derivative of cocaine. Its predominant clinical uses are as a local anesthe

and, for mechanistically similar reasons, as a drug to control ventricular may prevent myocardial reentry by preferentially suppressing conduction Following an intravenous bolus, lidocaine rapidly enters the central nervou redistributes into the peripheral tissue with a distribution half-life of app Lidocaine is 95% dealkylated by hepatic cytochrome P450 (CYP) 3A4 to a monoethylglycylxylidide (MEGX) and, subsequently, to the inactive glycine further metabolized to monoethylglycine and xylidide.[123] MEGX, although channel blocker than the parent drug,[13] may bioaccumulate because of it life.

Patients with lidocaine toxicity develop both central nervous system and generally in that order. Because of its rapid entry into the brain, acute l produces central nervous system dysfunction, particularly seizures, as its Concomitant respiratory arrest generally occurs. Shortly following the cer depression in the intrinsic cardiac pacemakers leads to sinus arrest, AV conduction delay, hypotension, and/or cardiac arrest.[6] If the patient is s the drug distributes from the heart, and spontaneous cardiac function re

Nonmassive acute lidocaine toxicity is generally related to excessive or

dosing. Common settings include intravenous administration when the int subcutaneous, inadvertent excessive subcutaneous administration during swallowing of viscous oral lidocaine. The typical CNS manifestations of n poisoning include drowsiness, weakness, a sensation of â€œdrifting awa diplopia, decreased hearing, paresthesias, muscle fasciculations, and seizu these effects develop when serum lidocaine concentrations exceed 5 Âµg/ by paresthesias or somnolence. Any of these symptoms should, therefore, examine the patient's medication administration history or drug-infusion r well as hypotonia in neonates, are reported to result from lidocaine toxicit serum concentrations.[108]

Chronic lidocaine toxicity most commonly occurs as a therapeutic misadve therapeutic infusions, generally in a critical care unit. Hepatic blood flow influence the rate of lidocaine metabolism, and only a small percentage is kidney. Consequently, toxicity following appropriate therapeutic dosing is patients with congestive heart failure, shock, liver disease, or concomitan inhibitors such as cimetidine.[91 , 127] Adverse reactions to lidocaine also i decreasing body weight, and increasing infusion rate.[33] Lidocaine toxicity patients receiving infusions at 3 mg/min.[117] Partly for this reason, lidocai used to prevent dysrhythmias in the immediate postmyocardial infarction

When used as an antidysrhythmic, lidocaine must be administered parent first-pass hepatic metabolism associated with oral ingestion. However, n unequivocally demonstrate the toxicity associated with orally administere gastrointestinal tract absorption only one-third of the drug is bioavailable primary metabolite, MEGX, is nearly as toxic as lidocaine itself, substantia following ingestion. Because of their small size and the relatively high co lidocaine (typically 4%), children seem overrepresented in reports of oral little as 15 mL of 2% viscous lidocaine in a 3-year-old child (estimate, 30 may cause seizures.[57 , 114]

It should be noted that when lidocaine is absorbed from the oropharynx surfaces, skin, or subcutaneous tissues, hepatic metabolism is bypassed, systemic bioavailability of the parent compound. Thus, seizures are repor application of lidocaine used for bronchoscopy,[138] as well as intrauretera ureteroscopic stone extraction.[99] Furthermore, deaths related to tumesce

reported.[107] In this technique, a large volume of dilute lidocaine is used prior to liposuction. Although in some reports the cause of death was co lidocaine concentrations were commonly elevated, and it is likely that lid involved in the adverse events.[68, 107] Interestingly, proponents of this p lidocaine doses up to a maximum of 55 mg/kg are safe,[97] whereas the c limit for subcutaneous lidocaine with epinephrine is 5â€“7 mg/kg. Of sign recommended doses used for liposuction procedures do not consider the saturate the CYP3A4 hepatic microsomal enzymes. When saturation occur absorption and lidocaine toxicity may result.

The high frequency of lidocaine-related medication errors relates in part t diverse â€œampsâ€• of lidocaine designed for varying indications includ preparation of infusions, and local anesthesia.[67] With the reduced emphas current advanced cardiac life support (ACLS) protocols, one important set poisoning may be eliminated.[27]

Tocainide

Tocainide (Fig. 61-3) is indicated for the treatment of ventricular dysrhy for oral administration. Although a lidocaine analog, it does not undergo therefore almost 100% orally bioavailable.[77] Tocainide has pharmacologic identical to lidocaine.[77, 112] Both renal failure and congestive heart failu considerably. The few overdoses reported with tocainide are associated w complications similar to those that occur with lidocaine overdose.[10, 34, associated with hepatotoxicity and blood dyscrasias, which, although rare, widespread use.

Mexiletine

Mexiletine (Fig. 61-3), originally developed as an anorectic agent, was fo antidysrhythmic, local anesthetic, and anticonvulsant activity.[23] It is curr for the management of ventricular dysrhythmias. Its chemical structure properties are similar to those of lidocaine. Mexiletine, a base, is absorbe therefore, its absorption is increased when the gastric contents are alkal failure and cirrhosis, as well as therapy with cimetidine or disulfiram, dec mexiletine.[76] Its metabolism, predominantly through CYP2D6, is accelerat

phenobarbital, rifampin, and phenytoin.[76]

Adverse therapeutic effects are primarily neurologic and are similar to tho lidocaine. The few reported cases of mexiletine overdose describe promi

such as complete heart block, torsades de pointes, and asystole.[31, 47] Ne overdose includes self-limited seizures, generally in the setting of cardiot case report described a patient with mexiletine poisoning who experience any hemodynamic or electrocardiographic abnormalities.[93] The use of oth antidysrhythmics, such as lidocaine or tocainide, may potentiate the neu Mexiletine may produce a false-positive result on the amphetamine immu

Moricizine

Moricizine (Fig. 61-3) is a phenothiazine derivative that possesses the g drugs, but is difficult to specifically subclassify. It depresses Na^+ current the other class IA drugs,[30] but has other properties that more appropriate or IC. It is historically discussed as a class IB drug, as it is here. The pa extensive and rapid metabolism. Dose-related increases in PR and QRS in hemiblocks, bundle-branch blocks, and sustained ventricular tachydysrhyt drug during the CAST II trial, in the setting of myocardial infarction, sugg prodysrhythmic.[63] Clinical experience with overdose of this drug is limited similar to other class I antidysrhythmics.

Class IB Management

The focus of the initial management for intravenous lidocaine-induced car cardiopulmonary resuscitation to allow lidocaine to redistribute away from setting, management of hemodynamic compromise includes fluid replacem strategies. Resistant hypotension may require dopamine or norepinephrin insertion of an intraaortic balloon assist pump.[50] Bradydysrhythmias typica atropine, requiring the administration of dopamine, norepinephrine, or is or insertion of a transvenous pacemaker may be useful,[94] but the myocar electrical capture. Lidocaine-induced seizures, and those related to lidoca brief in nature and do not require specific therapy. For patients requiring benzodiazepine generally suffices; rarely, a barbiturate is required.

Following oral poisoning by a class IB drug, administration of activated c
Enhanced elimination techniques are limited following intravenous poisonin
time course of poisoning. Cardiopulmonary bypass, which does not direct

clearance of tocainide, but its indications remain unclear.[134] Mexiletine's
its rapid metabolism make it a poor candidate for extracorporeal drug re

Class IC Antidysrhythmics: Flecainide and

Flecainide

Flecainide, a fluorobenzamide derivative of procainamide, is used orally t
and ventricular dysrhythmias, particularly atrial fibrillation.[2 , 71] Seventy-
metabolized hepatically by CYP2D6 to two major metabolites, one active a
remaining 25% is excreted renally.[12] Thus, renal insufficiency, drug inter
heart failure all decrease its clearance. Additionally, alkaluria reduces its
through enhanced tubular reuptake of nonionized drug. Patients using the
left ventricular dysfunction with worsening congestive heart failure. This is
flecainide's negative inotropic effect, which itself may relate to its antago
channels. Furthermore, sudden dysrhythmic death may occur, particularly
ischemic heart disease.[136]

Reported overdose experience is limited to case reports that uniformly i
overdose. A 50% increase in QRS duration, a 30% prolongation of the PR
in the QTc interval occurs with flecainide toxicity.[88] The expected consequ
electrophysiologic disturbances include bradycardia, premature ventricular
ventricular fibrillation.[5] The combination of marked QRS and PR interval
minimal QTc interval prolongation, is characteristic of flecainide toxicity a
described with other antidysrhythmic agents.[29]

Propafenone

Propafenone bears a structural resemblance to propranolol,[51] as well as

quantitative, electrophysiologic properties.[87] Propafenone blocks fast inwa weak Î²-adrenergic antagonist, and is an L-type calcium channel blocker. result of first-pass metabolism by CYP2D6 to 5-OH-propafenone, the prir The long half-life allows the accumulation of parent compound, particularly metabolizer pharmacogenetic variant of CYP2D6, which may cause exces antagonism.[78 , 119] The activity of a second metabolite, *N* -depropylpropa Propafenone overdose produces sinus bradycardia, as well as ventricular inotropy.[45]

Acute overdose typically produces wide complex tachycardia, right bundl AV block, and prolongation of the QTc interval, as well as generalized se administration of phenytoin to a child with propafenone poisoning was as prolongation of the QRS interval, which initially responded to sodium bica subsequently developed bradyasystolic arrest.[86] Massive overdose in a yc the subsequent development of a mild cardiomyopathy and a left bundle-

Class IC Management

Initial stabilization should include standard management strategies for hy Additionally, therapy for hypotension, and for the electrocardiographic ma poisoning, includes intravenous hypertonic sodium bicarbonate to overcom blockade.[70] An animal study documents the beneficial effects of hyperton flecainide-induced ventricular dysrhythmias, and 3 reports of human over narrowing in response to hypertonic sodium bicarbonate administration.[18 loading with hypertonic saline may be similarly effective, it remains unpr of flecainide is reduced by urinary alkalinization, suggesting that sodium may ultimately prove superior to sodium bicarbonate.[89] The administration antidysrhythmics is clearly contraindicated because of their additive blocka However, amiodarone has been successful in the setting of ventricular fil therapy.[120] The efficacy of an external or internal pacemaker may

be limited because of the drug-induced increased electrical pacing thresho therapy with cardiopulmonary bypass[32] or extracorporeal membrane oxy and should be considered if readily available.

Extracorporeal removal is not expected to be beneficial for patients with

fact, has been unsuccessful. Although hemodialysis was successful in rer overdose, additional studies are needed to determine its clinical benefit.[2]

Class III Antidysrhythmics

Amiodarone, Dofetilide, and Ibutilide

The class III antidysrhythmics prevent and terminate reentrant dysrhythm potential duration and effective refractory period without slowing conducti or 1 of the action potential. This drug-induced effect on the action potent blockade of the rapidly activating component of the delayed rectifier pota responsible for repolarization.

The class III antidysrhythmics in use today prolong repolarization of both Thus, common electrocardiographic effects of the class III drugs at thera prolongation of the PR and QTc intervals and abnormal T and U waves. Ch discussion of the pharmacologic mechanisms of this class. Chapters 23 ar

Amiodarone

Amiodarone (Fig. 61-4) is an iodinated benzofuran derivative that is stru thyroxine, and procainamide. Forty percent of its molecular weight is ioc of patients with out-of-hospital cardiac arrests, caused by refractory ver resulted in a higher rate of survival until hospital admission.[36] Furthermor the ACLS guidelines places tremendous emphasis on the early intravenou amiodarone.[27] This, along with its ability to terminate or prevent atrial increased use of this drug despite its association with potentially severe few reported cases of amiodarone overdose.[52]

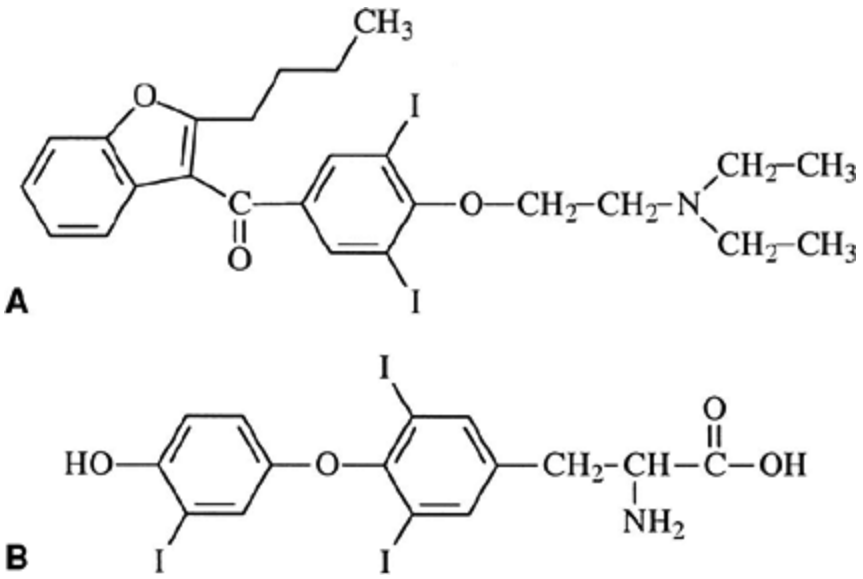

Figure 61-4. Structures of amiodarone (A) compared with triiodothyroni amiodarone is nearly 40% iodine by weight.

Although amiodarone has multiple pharmacologic effects, its efficacy as a primarily a result of its class III antidysrhythmic effects. It also has weak antagonist activity and can block both L-type calcium channels and inact Amiodarone is slowly absorbed by the oral route and concentrates in the tissue. Its oral bioavailability is extremely variable among individuals, as of approximately 66 L/kg.[28] Steady-state pharmacokinetics may not occur and the elimination half-life is 2 months. Amiodarone is metabolized via desethylamiodarone, which has comparable activity to the parent compou biliary excretion and virtually none is renally cleared.

The electrocardiographic effects of amiodarone differ, based on the route Therapeutic oral doses prolong PR and QTc intervals but not the QRS co may produce a prolongation of the PR interval, but has few other electr Ventricular dysrhythmias and sinus bradycardia are the most serious card therapeutic doses of amiodarone.[137] Prodysrhythmic monomorphic and p tachycardias resistant to cardioversion and pharmacologic interventions a surprisingly uncommon, given the frequency and extent to which QTc int Amiodarone's ability to compete for P-glycoprotein is responsible for sev effects, including elevated digoxin and cyclosporin levels and enhanced

of warfarin.[141]

The diverse complications associated with long-term therapy do not occu intravenous use. Chronic therapy with oral amiodarone is associated with thyroid, corneal, hepatic, and cutaneous toxicity, organs in which it bioa effects appear to be dose related, but because of the wide range of bioa patterns among different patients, as well as the overlap between therape concentrations, therapeutic drug monitoring is of limited benefit. Pneumo consequential extracardiac adverse effect, effects up to 5% of patients ta therapeutically. Amiodarone pneumonitis may develop within days of init typically occurs following years of therapy. Its occurrence may be dose re in those taking <200 mg daily) and the recent focus on using the minima the incidence of pneumonitis.[98] Oxygen supplementation may speed the which may explain the initial belief that patients with chronic lung disease amiodarone pneumonitis. Manifestations of pneumonitis include dyspnea, hypoxia, and radiographic changes.[24] CT scan is the most helpful initial pneumonitis, but is not used for monitoring purposes (this is often done CO).[54] Bronchoalveolar lavage typically reveals interstitial pneumonitis wit characteristic finely vacuolated foamy cytoplasm, but confirmation of the lung biopsy.

Thyroid dysfunction, either amiodarone-induced thyrotoxicosis (AIT) or hypothyroidism (AIH), occurs in approximately 4% of patients.[25] AIH is r iodine intake is sufficient.[84] AIH is likely caused by an exaggerated Wolf iodine, in this case from amiodarone, inhibits the organification and relea appears to exist in two distinct forms: type I AIT, which occurs in patien glands and iodine-induced excessive thyroid hormone synthesis and relea

type II AIT, in which destructive thyroiditis leads to release of thyroid ho follicular cells. The relative prevalence of the two forms of AIT is unknown ambient iodine intake. Amiodarone may also reduce the effect of thyroid tissue.[46] The diagnosis is confirmed with standard thyroid function testin

Corneal microdeposits are extremely common during chronic therapy and Abnormal elevation of hepatic enzymes occurs in more than 30% of those hepatotoxicity may be associated with progression to cirrhosis. Periodic

aminotransferases is typically recommended.[104] Slate gray or bluish disco common, particularly in sun-exposed portions of the body.[113]

Dofetilide

Dofetilide is a newer class III antidysrhythmic that is FDA approved for c or atrial flutter to a normal sinus rhythm. Dofetilide increases the effecti substantially in atrial tissue than in ventricular fibers, accounting for this many of the other antidysrhythmics, it may reduce the morbidity of atria congestive heart failure, and is still used despite the move from rhythm t fibrillation.[41 , 132] Dofetilide has no known effect on calcium or sodium ch Î²-adrenergic antagonism. Dofetilide increases the QTc intervals, but does interval or QRS complex in humans. Heart rate and blood pressure are a

Although limited data are available, the expected and reported adverse c ventricular tachycardia, particularly torsade de pointes.[41 , 137] The appro de pointes in patients receiving high therapeutic doses of the drug is 3%. and Drug Administration has in place strict requirements for the use of c

Overdose data reported by the manufacturer include 2 cases. One patien capsules and experienced no events, whereas a second patient inadverter supratherapeutic doses 1 hour apart and experienced fatal ventricular fib dose.[100]

Ibutilide

Ibutilide is an antidysrhythmic with predominant class III activity. It is m conversion of atrial fibrillation and flutter to normal sinus rhythm. Becaus metabolism, ibutilide can only be administered parenterally. Its metabolic understood, but they do not involve the isoenzymes CYP3A4 or CYP2D6. far do not indicate that age, sex, hepatic, or renal dysfunction necessitat recommended dosage. In addition to its effects on the delayed rectifier c concentrations, ibutilide activates a slow inward sodium current that is u channel blockers.[90]

Ibutilide can increase the QTc interval and cause torsade de pointes, esp congenital long-QT syndrome (Chap. 23). Although ibutilide can enhance

cardioversion for atrial fibrillation, its use in patients with ejection fractio with a increased incidence of sustained polymorphic ventricular tachycard failure, including biopsy-identified crystals, is reported in association with causal relationship is not yet definitive.[48] Acute overdose information, onl through the manufacturer, suggests that ventricular dysrhythmias and hi abnormalities should be expected.[101]

Class III Management

Treatment experience with class III drug overdose is limited. Isoproteren successfully treated amiodarone-induced torsades de pointes.[118] Administ antidysrhythmics or propranolol for the control of monomorphic ventricul reported, cannot be recommended on theoretical grounds. Paradoxically, â€œtorsadogenicâ€• effects of the other class III antidysrhythmics.[121] T by the beneficial effects of amiodarone on the dispersion of myocardial r channel-blocking activity (Chap. 23).

Hemodialysis is not expected to be beneficial in general, either because or because of large volumes of distribution. Multiple-dose activated charc hemoperfusion may be helpful if used immediately following overdose, bu been studied in humans.

Unclassified: Adenosine

Adenosine, a nucleoside found in all cells, is released from myocardial ce pathophysiologic conditions. It is administered as a rapid IV bolus to ter supraventricular tachycardia.[8] The effects of adenosine are mediated by protein-coupled adenosine (A_1) receptors that activate acetylcholine-sens the atrium, sinus nodes, and AV nodes. The resultant hyperpolarization re firing. Adenosine also reduces the Ca^{2+} currents, and its antidysrhythmic effect in increasing AV nodal refractoriness and from inhibiting delayed by sympathetic stimulation.[79]

Adverse effects of adenosine administration are very common and includ dyspnea, chest tightness, flushing, hypotension, and atrial fibrillation. Al following intrapulmonary administration, it is not reported following intrav

probably chest tightness, is related to stimulation by adenosine of the pu Fortunately, most of the adverse effects of adenosine are transitory becau to inosine by both extracellular and intracellular deaminases. The clinical dipyridamole, an adenosine uptake inhibitor, and by denervation hyperse recipients. Methylxanthines may produce adenosine receptor blockade. In larger-than-usual doses of adenosine are required to produce an antidysr adenosine is not reported. Treatment is supportive because of the rapid e

Summary

There are many antidysrhythmics presently in clinical use. In the overdos B, and class C drugs are associated with sodium channel blockade, which dysrhythmias and morbidity if not treated judiciously. The class IC drugs than the other class I drugs, although even the class IB drugs may be le

The class III antidysrhythmics in overdose can cause malignant dysrhyth de pointes. Amiodarone has may noncardiac effects, particularly pneumon limit its therapeutic usefulness. The clinical effects following overdose are class III drugs, but will likely manifest as an exaggeration of the therap It is only by understanding the pharmacokinetics and toxicokinetics of the management can be accomplished.

Chapter 62
Cardioactive Steroids

Jason B. Hack
Neal A. Lewin

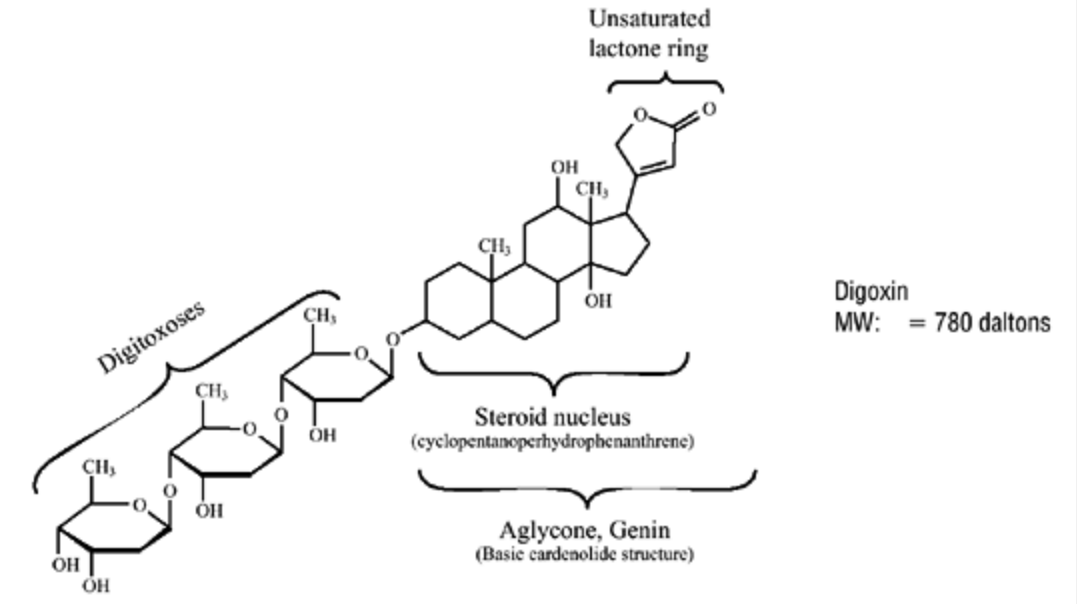

Figure. No Caption Available.

A 92-year-old woman was brought to the hospital by her grandson. The grandson stated that she had lost her appetite for several days, refused her medications for 2 days, and had begun to vomit on the day of admission. The woman complained of being weak and having no appetite because of her constant nausea. Her past medical history was significant for congestive heart failure and hypertension, for which she was chronically treated with digoxin, furosemide, and enteric-coated aspirin. Her grandson reported that 5 days prior to admission, she had initiated a course of clarithromycin for sinusitis.

On presentation to the emergency department (ED), the patient was not in acute distress, and was alert and oriented to place and person but not to time. Her vital signs were: blood pressure, 140/95 mm Hg; pulse, 50 beats/min and regular; respiratory rate, 16 breaths/min; and rectal temperature, 98.8Â°F (37.1Â°C). The woman weighed 121 lbs (55 kg). Her neck was supple with no jugular venous distension or carotid bruits appreciated. Auscultation of the lungs revealed bibasilar crackles. Cardiac auscultation revealed a normal S_1, S_2, and an S_3 gallop, with no audible murmurs. Abdominal examination revealed a soft abdomen with increased bowel sounds and without masses or bruit. Examination of the patient's lower extremities revealed 1+ pitting edema without clubbing or cyanosis, and all pulses were 2+. Neurologic examination was nonfocal.

The patient was attached to a cardiac monitor with continuous pulse oximetry. An IV line was inserted, and blood samples were obtained for complete blood count (CBC); electrolytes, including calcium and magnesium; blood urea nitrogen (BUN); creatinine; glucose; liver enzymes; lipase; digoxin; and salicylate levels. The electrocardiogram (ECG) revealed high-degree heart block with a ventricular rate of 30â€“50 beats/min (Fig. 62-1), which then converted spontaneously to atrial flutter with variable block and a

ventricular response rate of 30â€“40 beats/min (Fig. 62-2). Transcutaneous pacer pads were placed on the patient in standby mode, while 5 vials of digoxin-specific Fab were requested. Stat laboratory results revealed serum sodium, 142 mEq/L; chloride, 114 mEq/L; potassium, 3.6 mEq/L; bicarbonate, 24 mEq/L; BUN, 12 mg/dL; creatinine, 1.4 mg/dL; glucose, 98 mg/dL; calcium, 9.8 mg/dL; magnesium, 2.0 mEq/L. Liver enzymes, lipase, and CBC were all normal. A serum digoxin concentration was pending.

Fifteen minutes after the examination was completed, the patient vomited. Although her heart rate decreased to 30 beats/min, her blood pressure remained at 130/80 mm Hg. Atropine 1 mg IV was

administered for the bradycardia but did not increase heart rate; subsequently, 5 vials of digoxin-specific Fab IV were administered over 15 minutes. Within 20 minutes of the infusion, her heart rate had increased to 86 beats/min. The initial serum digoxin concentration was 3.8 ng/mL (therapeutic range: 0.5â€“2.0 ng/mL).

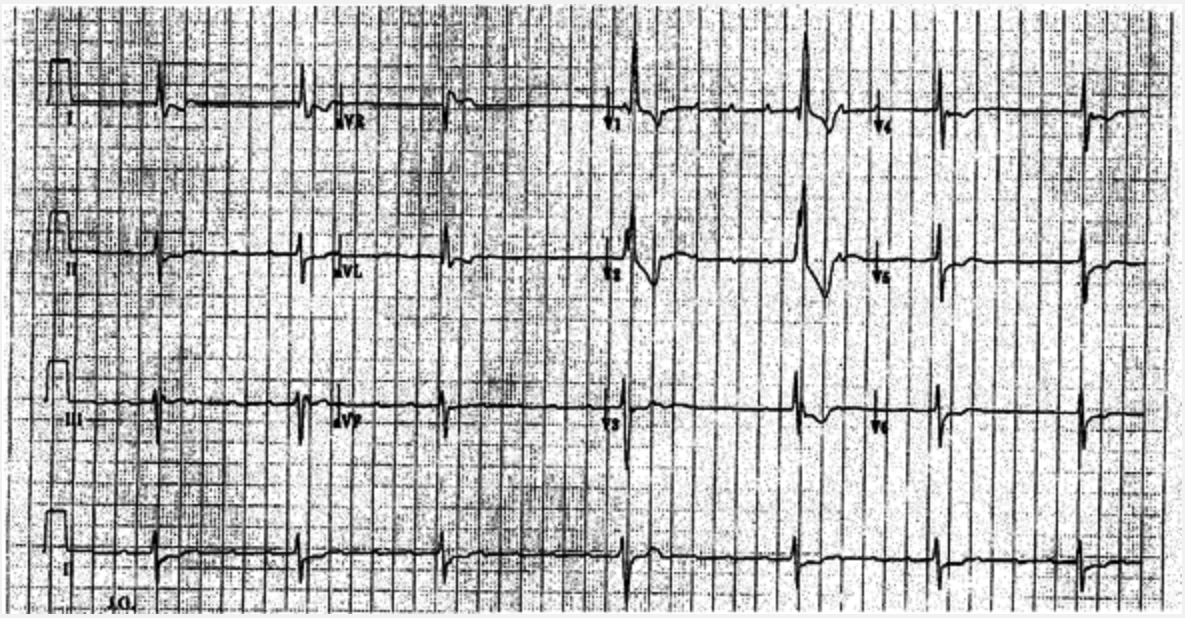

Figure 62-1. Electrocardiograph of a 92-year-old woman

demonstrating a high-degree heart block with a ventricular rate of 30â€“50 beats/min.

History and Epidemiology

Although there is evidence in the *Ebers Papyrus* (Papyrus Smith) that the Egyptians used plants containing cardioactive steroids at least 3000 years ago, it was not until 1785, when William Withering wrote the first organized account about the effects of the foxglove plant, that the use of cardioactive steroids was more widely accepted into the Western apothecary. The discussion and case reports of the 163 patients for whom Withering prescribed foxglove and his correspondence with other physicians on the subject, comprise the first work related to the medical use of cardioactive steroids. Foxglove was initially used as a diuretic and for the treatment of â€œdropsyâ€• (edema), and Withering eloquently described its â€œpower over the motion of the heart, to a degree yet unobserved in any other medicine.â€• [122]

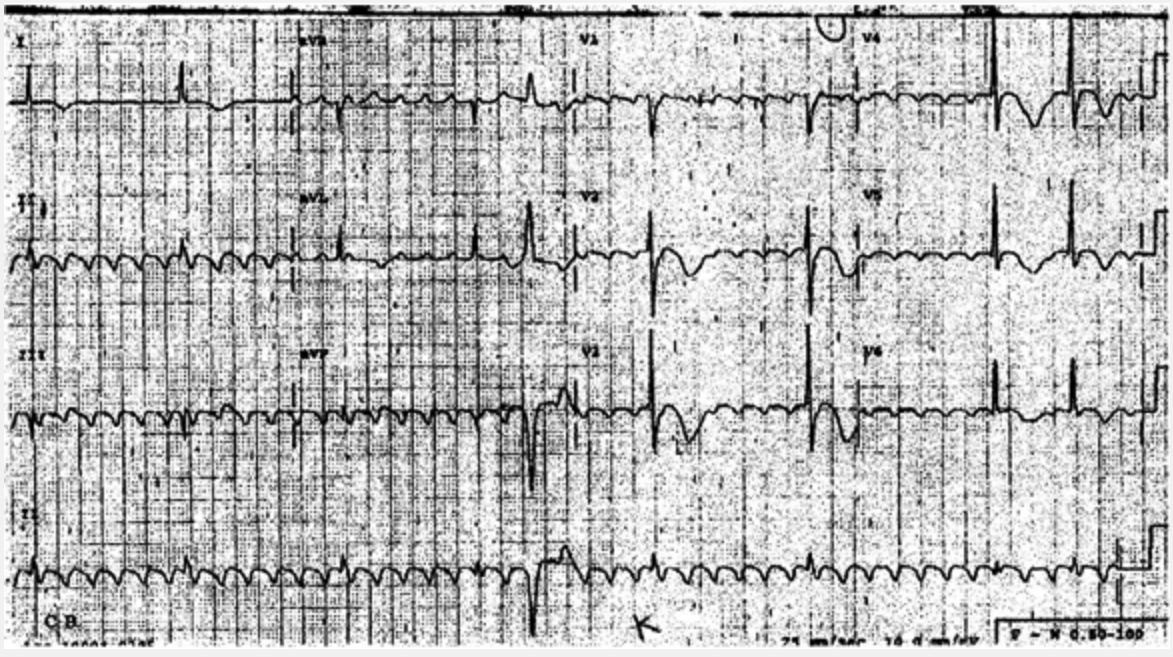

Figure 62-2. Electrocardiograph of the patient in Figure 62-1 after subsequently converted to atrial flutter with variable block and a ventricular rate of 30â€“40 beats/min.

Subsequent to these reports, cardioactive steroids became the mainstay of treatment for congestive heart failure, and to control the ventricular response rate in atrial tachydysrhythmias. Because of their narrow therapeutic index and widespread use both acute toxicity and chronic toxicity remain important problems.[82] According to the American Association of Poison Control Centers data, between the years 1999 and 2003 there were approximately 10,800 exposures to cardioactive steroid-containing plants with no attributable deaths, and 13,900 exposures to cardioactive steroid containing pharmaceuticals resulting in 73 deaths (Chap. 130).

Toxicity is typically encountered in the very young or the very old. In children, most acute overdoses are unintentional, resulting from dosing errors, often a decimal point error resulting in 10 times the appropriate dose. Adult patients more often have acute

exposures related to intentional ingestions. Older adults are at particular risk for toxicity, either from interactions of the cardioactive steroids with their chronic regimen of other medications, or indirectly, as a consequence of an alteration in the absorption or elimination kinetics of their therapeutic cardioactive steroid. Drugâ€“drug interactions may change cardioactive steroid clearance in the liver or kidney, may alter protein binding, or may result in increased bioavailability.

The most commonly prescribed cardioactive steroid in the United States is digoxin; other, internationally available but much less commonly used preparations are digitoxin, ouabain, lanatoside C, deslanoside, and gitalin. Cardioactive steroid toxicity may also result

from exposure to certain plants or animals. Documented plant sources of cardioactive steroids include oleander (*Nerium oleander*); yellow oleander (*Thevetia peruviana*), which has been implicated in the suicidal deaths of thousands of patients in Southeast Asia;[24] foxglove (*Digitalis* spp); lily of the valley (*Convallaria majalis*); dogbane (*Apocynum cannabinum*); and red squill (*Urginea maritima*). Cardioactive steroid poisoning may result from plant branches (oleander); teas containing seeds of these plants; and water and herbal products contaminated with plant cardioactive steroids (Chap. 43).[15,18,50,77,88,95,114] Toxicity also results from ingestion, instead of the intended topical application, of a purported aphrodisiac derived from the dried secretion of the *Bufo marinus* toad, which contains a bufadienolide-class cardioactive steroid.[9,11,12] Although there are no reported human exposures, fireflies of the *Photinus* species (*P. ignitus*, *P. marginellus*, and *P. pyralis)* contain a cardioactive steroid designated lucibufagin that is similar in structure to the bufadienolides.[29,63]

Chemistry

Cardioactive steroids all contain an aglycone or â€œgeninâ€• nucleus structure with a steroid core, and an unsaturated lactone ring attached at C-17. Cardiac glycosides contain additional sugar groups attached to C-3 (see illustration at beginning of chapter). Cardenolides are plant-derived aglycones with a 5-member unsaturated lactone ring. The bufadienolide and lucibufagin groups of cardioactive steroid molecules are mainly animal derived (with such notable exceptions as scillaren from red squill) and contain a 6-member unsaturated lactone ring. When the aglycone digoxigenin is linked to 1 or more hydrophilic sugar (digitoxoses) residues at C-3, it forms digoxin, a cardiac glycoside. The sugar residues confer increased water solubility and enhance the ability of the molecule to enter cells. Digitoxin's aglycone differs from digoxin's by the lack of a hydroxyl group on C-12, and ouabain differs from digoxin by both the absence of a hydroxyl group on C-12 and the addition of hydroxyl

groups on C-1, -5, -10, and -11. The cardioactive components in toad venom are genins, and lack sugar moieties.

Pharmacokinetics

The correlation between clinical effects and serum concentrations is based on steady-state concentrations, which are dependent on many absorption, distribution, and elimination factors (Table 62-1). Although not proven with other cardioactive steroids, they likely follow the distribution pattern of digoxin or digitalis in that obtaining a serum concentration before 6 hours after an ingestion (the time at which the tissue concentration has peaked) gives a misleadingly high serum concentration, resulting from its biphasic distribution. After therapeutic dosing, the intravascular distribution and elimination of digoxin from the plasma are best described using a two-compartment model that is achieved over approximately 36â€“48 hours in patients with normal renal function. The distribution or Î± phase represents the rapid rise of drug concentration intravascularly, which is dependent on whether the method of administration is intravenous or oral. An exponential decline occurs as the drug is rapidly distributed from the blood to the peripheral tissues with a 30-minute distribution half-life. During the distribution phase, most of the intravascular cardioactive steroid leaves the blood and is found in the tissues, resulting in a large volume of distribution (Vd) (eg, digoxin's Vd is 5.0 L/kg with therapeutic use). The Î² or elimination phase with a half-life of approximately 36 hours represents the drug's total-body clearance, which for digoxin is achieved primarily by the kidneys (70% in a person with normal renal function).[16,44] After a massive acute digoxin overdose, the half-life may be shortened to as little as 13â€“15 hours because of elevated serum concentrations, resulting in greater renal clearance prior to distribution to the tissues.[49,109] Even with therapeutic administration of cardioactive steroids, adjustments to the dosing regimen must be made for physiologic changes associated with age, hypothyroidism, hepatic disease, and renal diseases if the physiologic changes are associated with a

decreased creatinine clearance, alkalosis, chronic hypoxemia, myocardial disease, and cor pulmonale, and for electrolyte abnormalities, including hypomagnesemia, hypercalcemia, hypernatremia, and, commonly, hypokalemia, to avoid toxicity. Hypokalemia resulting from a variety of mechanisms, such as the use of loop diuretics, poor dietary intake, diarrhea, and the administration of potassium-binding resins, enhances the effects of cardioactive steroids on the myocardium and is associated with dysrhythmias at lower serum cardioactive steroid concentrations. Chronic hypokalemia reduces the number

of Na^+-K^+-adenosine triphosphatase (ATPase) units in skeletal muscle, thereby potentially decreasing the volume of drug distribution.[2,61]

TABLE 62-1. Pharmacology of Selected Cardioactive Steroids

Pharmacology	Digoxin	Digitoxin
Onset of Action		
Oral	1.5â€“6 h	3â€“6 h
IV	5â€“30 min	30 minâ€“2 h
Maximal effect		
Oral	4â€“6 h	6â€“12 h
IV	1.5â€“3 h	4â€–8 h

Intestinal absorption	40â€“90% (mean 75%)	>95%
Plasma protein binding	25%	97%
Volume of distribution	6â€“7 L/kg (adults) 16 L/kg (infants) 10 L/kg (neonates) 4â€“5 L/kg (adults with renal failure)	0.6 L/kg (adults)
Elimination half-life	1.6 days	6â€“7 days
Route of elimination	Renal (60â€“80%), with limited hepatic metabolism	Hepatic metabolism (80%)
Enterohepatic circulation	7%	26%

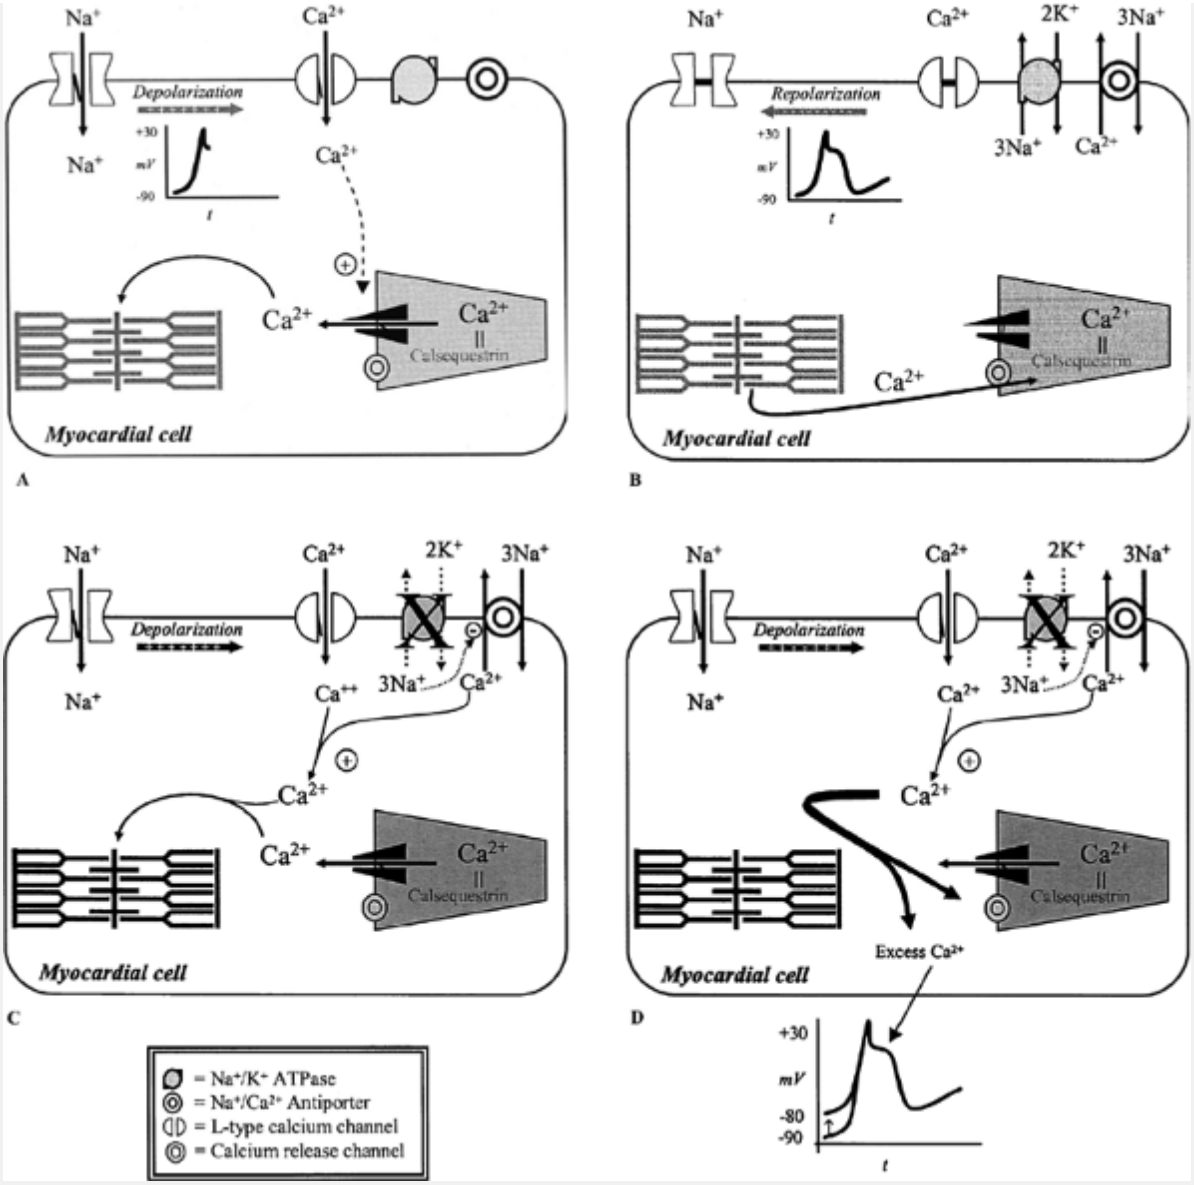

Figure 62-3. A. Normal depolarization. Depolarization occurs following the opening of fast Na^+ channels; the rise in intracellular potential opens voltage-dependent Ca^{2+} channels; and the influx of Ca^{2+} induces the massive release of Ca^{2+} from the sarcoplasmic reticulum, producing contraction. B. Normal repolarization. Repolarization begins with active expulsion of Na^+ ions in exchange for K^+ using an ATPase. This electrogenic (3 Na^+ for 2 K^+) pump creates an Na^+ gradient that is used to

expel Ca^{2+} via an antiporter. The sarcoplasmic reticulum resequesters its Ca^{2+} load via a separate ATPase. C. Pharmacologic cardioactive steroids. Digitalis inhibition of the Na^{+}-K^{+}-ATPase raises the intracellular Na^{+} content, preventing the antiporter from expelling Ca^{2+} in exchange for Na^{+}. The net result is an elevated intracellular Ca^{2+}, resulting in enhanced inotropy. D. Toxic cardioactive steroids. Excessive elevation of the intracellular Ca^{2+} elevates the resting potential, producing myocardial sensitization, and predisposes to dysrhythmias. The addition of exogenous Ca^{2+} may overwhelm the capacity of the sarcoplasmic reticulum to sequester this ion, resulting in systolic arrest. X = cardioactive steroid.

Drug interactions between digoxin and quinidine, verapamil, diltiazem, carvedilol, amiodarone, and spironolactone are common.[19,22,43,66,91] These interactions occur because of a reduction of the protein binding of the cardioactive steroids, increasing their availability to the tissues; a reduction in excretion as a consequence of a decrease in renal perfusion; or as a result of interference with their secretion by the kidneys and intestines because of inactivation of P-glycoproteins. In approximately 10â€“15% of those patients receiving digoxin, a significant amount of digoxin is inactivated in the gastrointestinal tract by enteric bacterium, primarily *Eubacterium lentum.* Inhibition of this inactivation by the alteration of the gastrointestinal flora by many antibiotics, particularly the macrolide antibiotics, may result in increased bioavailability.[71] Indeed, the use of certain antibiotics may produce as much as a 2-fold increase in serum cardioactive steroid concentration.[90]

Mechanisms of Action and Pathophysiology

Electrophysiologic Effects on Inotropy

The cardioactive steroids increase the force of contraction of the heart (positive inotropic effect) by increasing cytosolic Ca^{2+} during systole. Both Na^{+} and Ca^{2+} ions enter and exit cardiac muscle cells during each depolarization and contraction. Sodium entry heralds the start of the action potential (phase 0) and carries the inward, depolarizing positive charge. Calcium subsequently enters the cardiac myocyte through L-type calcium channels during the plateau phase of the action potential, and this Ca^{2+} triggers the release of more Ca^{2+} into the cytosol from the sarcoplasmic reticulum. During repolarization and relaxation (diastole), Ca^{2+} is both pumped back into the sarcoplasmic reticulum by a local Ca^{2+}-ATPase and is pumped extracellularly by an Na^{+}-Ca^{2+} antiporter and a sarcolemmal Ca^{2+}-ATPase (Fig. 62-3; Chap. 23).[76]

Cardioactive steroids inhibit active transport of Na^{+} and K^{+} across the cell membrane during repolarization by binding to a specific site on the extracytoplasmic face of the a subunit of the membrane Na^{+}-K^{+}-ATPase. This inhibits the cellular Na^{+} pump activity, which decreases Na^{+} extrusion and increases Na^{+} in the cytosol, thereby decreasing the transmembrane Na^{+} gradient. Because the Na^{+}-Ca^{2+} antiporter derives its power not from adenosine triphosphate (ATP) but rather from the Na^{+} gradient generated by the Na^{+}-K^{+} transport mechanism,[28] the dysfunction of the Na^{+}-K^{+}-ATPase pump reduces Ca^{2+} extrusion from the cell. The additional cytoplasmic Ca^{2+} enhances the Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum during systole and by this mechanism increases the force of contraction of the cardiac muscle.

Effects on Cardiac Conduction

At therapeutic serum concentrations, cardioactive steroids also increase automaticity and shorten the repolarization intervals of the atria and ventricles (Table 62-2). There is a concurrent decrease in the rate of depolarization and conduction through the sinoatrial (SA)

and (atrioventricular) AV nodes, respectively. This is mediated both indirectly via an enhancement in vagally mediated parasympathetic tone, and directly by depression of this tissue. These changes in nodal conduction are reflected on the ECG by a decrease in ventricular response rate to suprajunctional rhythms and by PR interval prolongation (part of â€œdigitalis effectâ€•). The effects of cardioactive steroids on ventricular repolarization are related to the elevated intracellular resting potential caused by the enhanced availability of Ca^{2+}, and manifest on the ECG as QTc interval shortening and ST segment and T-wave forces opposite in direction to the major QRS forces. The last effect results in the characteristic scooping of the ST segments (the second part of which is referred to as *digitalis effect*) (Fig 62-4). Excessive increases in intracellular Ca^{2+}, caused by excessive cardioactive steroid effects, result in delayed afterdepolarizations. These are fluxes in membrane potential caused by spontaneous Ca^{2+}-induced Ca^{2+} release, which is caused by the excess Ca^{2+}, and appear on the ECG as U waves. Occasionally, these may initiate a cellular depolarization that manifests as a premature ventricular contraction (Chap. 23).[27,58]

TABLE 62-2. Electrophysiologic Effects of Cardioactive Steroids on the Myocardium

	Atria and Ventricles	AV Node	ECG
Excitability	â†‘	â€”	Extrasystoles, tachydysrhythmias
Automaticity	â†‘	â€”	Extrasystoles, tachydysrhythmias
Conduction velocity	â†“	â†“	â†‘ PR interval, AV block
Refractoriness	â†“	â†‘	â†‘ PR interval, AV block, decreased QTc interval

Hypokalemia inhibits Na^+-K^+-ATPase activity and contributes to the pump inhibition induced by cardioactive steroids, enhances myocardial automaticity, and, as a consequence, increases myocardial susceptibility to cardioactive steroid-related dysrhythmias. This may be partly a result of decreased competitive inhibition between the cardioactive steroid and potassium at the Na^+-K^+-ATPase exchanger.[93] Severe hypokalemia (<2.5 mEq/L) reduces the rate of sodium pump function, slowing the pump and exacerbating concomitant sodium pump inhibition, because of cardioactive steroids.[58]

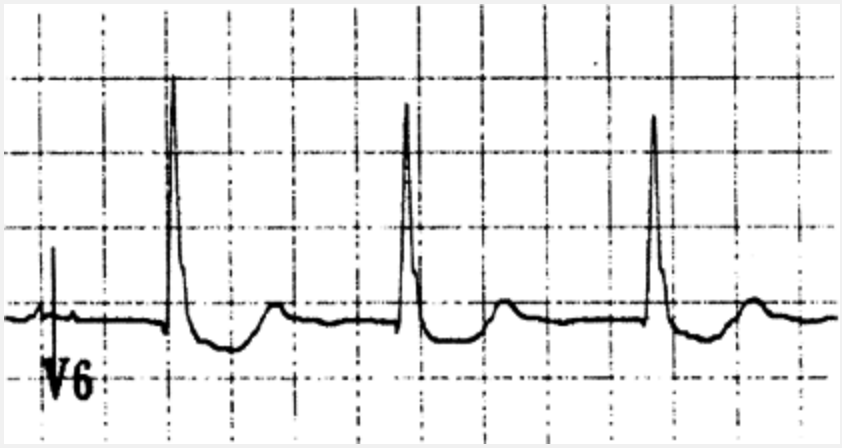

Figure 62-4. Digitalis effect noted in the lateral precordial lead, V6. Note the prolonged PR interval and the repolarization abnormality (scooping of the ST segment).

Effects of Cardioactive Steroids on the Autonomic Nervous System

Cardioactive steroids affect the parasympathetic system by increasing the release of acetylcholine from vagal fibers,[73,112] possibly through augmentation of intracellular calcium. Cardioactive steroids affect the sympathetic system by increasing efferent sympathetic discharge,[83,107] which, in turn, may exacerbate dysrhythmias.

Clinical Manifestations

Both adults and children with acute cardioactive steroid poisoning present in a similar manner, as do adults and children with chronic poisoning. However, the clinical manifestations in both adults and children vary based on the chronicity of the exposure.

Noncardiac Manifestations

Acute Toxicity

An asymptomatic period of several minutes to several hours may follow a single, orally administered, toxic dose of cardioactive steroid. The first symptom is typically nausea, vomiting, or abdominal pain. Central nervous system effects of acute toxicity can include lethargy, confusion, and weakness that are not caused by hemodynamic changes.[15]

Chronic Toxicity

Chronic toxicity is often difficult to diagnose as a result of its insidious development and protean manifestations. Symptoms may include those that occur with acute poisonings; however, they are often less obvious. Gastrointestinal symptoms include anorexia, nausea, vomiting, abdominal pain, and weight loss. Neuropsychiatric disorders include delirium, confusion, disorientation, drowsiness, headache, hallucinations, or rarely, seizures.[15,36,37] Visual disturbances include transient amblyopia, photophobia, blurring, scotomata, photopsia, decreased visual activity, and aberrations of color vision (chromatopsia), such as yellow halos (xanthopsia) around lights.[67,68]

Electrolyte Abnormalities

Elevated serum potassium concentrations frequently occur in patients with acute cardioactive steroid poisoning.[58,61] Hyperkalemia has important prognostic implications, as the serum potassium concentration is a better predictor of lethality than either the initial ECG changes or the serum cardioactive steroid concentration.[4,5] In a study of 91 acutely digitoxin-poisoned patients, conducted before digoxin-specific Fab was available, approximately 50% of the patients with serum potassium concentrations of 5.0â€“5.5 mEq/L

died. Although a serum potassium concentration lower than 5.0 mEq/L was associated with no deaths, all of the 10 patients with serum potassium concentration above 5.5 mEq/L died.[4] This hyperkalemia causes further hyperpolarization of myocardial conduction tissue, in particular, increasing AV nodal block, thereby exacerbating cardioactive steroid-induced bradydysrhythmias and conduction delays.[58] However, correction of the hyperkalemia alone does not increase patient survival,[4] as it is a marker of, not the cause of, the morbidity and mortality associated with cardioactive steroid poisoning. Elevation of the serum potassium concentration after administration of cardioactive steroids is a result of cardioactive steroid inhibition of the Na^+-K^+-ATPase pump, which results in the inhibition of potassium uptake in exchange for Na^+ by skeletal muscle (the largest potassium reservoir). The interrelationships between intracellular and extracellular potassium and cardioactive steroid therapy are complex and incompletely understood.

Cardiac Manifestations

The alterations in cardiac rate and rhythm occurring with cardioactive steroid poisoning can produce almost every known type of dysrhythmia with the exception of the rapidly conducted supraventricular tachydysrhythmias. In 10â€“15% of cases, the appearance of an ectopic ventricular rhythm is the first sign of toxicity, and this is the most frequent rhythm disturbance noted.[92] Although no dysrhythmia is pathognomic of cardioactive steroid toxicity, toxicity should be suspected when there is evidence of increased automaticity in combination with depressed conduction through the SA and AV nodes.[58] Bidirectional ventricular tachycardia is nearly diagnostic, although it can also occur with poisoning by aconitine and a few other uncommon xenobiotics[103] (Fig. 5-13). These dysrhythmias result from the complex electrophysiologic influences on both the myocardium and conduction system of the heart resulting from direct, vagotonic, and other autonomic actions

of the cardioactive steroids. The effects of digoxin vary with the dose, and differ, depending on the type of cardiac tissue involved. The atrial and ventricular myocardial tissues exhibit increased automaticity and excitability, resulting in extrasystoles and tachydysrhythmias. Conduction velocity is reduced in both the atrial conducting system and nodal tissue, resulting in an increased PR interval and AV nodal block. Indeed, AV junctional blocks of varying degrees, associated with increased ventricular automaticity, are the most common manifestations, occurring in 30â€“40%, of patients with cardioactive steroid toxicity.[74] Atrioventricular dissociation can result from suppression of the dominant pacemaker with escape of a secondary pacemaker, or from inappropriate acceleration of a ventricular pacemaker. Hypotension, shock, and cardiovascular collapse can ensue. Table 62-3 summarizes these phenomena.

Acute Toxicity

The initial increased vagal tone at the SA and AV nodes results in an atropine-responsive bradydysrhythmia. There are a multitude of cardiac dysrhythmias associated with cardioactive steroid toxicity unified by a sensitized myocardium and a depressed AV node (Table 62-3).

TABLE 62-3. Cardiac Dysrhythmias Associated with Cardioactive Steroid Poisoning

Myocardial irritability
- Atrial flutter and atrial fibrillation with block
- Nonparoxysmal atrial tachydysrhythmias with block
- Premature ventricular contractions
- Nonsustained ventricular tachycardia
- Delayed afterdepolarizations
- Bidirectional ventricular tachycardia
- Ventricular bigeminy
- Ventricular fibrillation

Conduction system dysfunction
- AV dissociation
- Exit blocks
- High-degree AV block
- His-Purkinje dysfunction
- Junctional tachycardia
- SA nodal arrest
- Sinus bradycardia

Chronic Toxicity

Bradydysrhythmias that appear later in acute poisonings, and those that occur in patients with chronic cardioactive steroid toxicity, occur by direct actions of the drug on the heart and often are minimally responsive to, or cannot be corrected by, atropine administration. Ventricular tachydysrhythmias are more common in patients with chronic or late acute poisoning than in patients with early acute poisoning.

Diagnostic Testing

Properly obtained and interpreted serum digoxin concentrations significantly aid in the management of patients with suspected

digoxin toxicity, as well as in the management of patients poisoned by several other cardioactive steroids. Although most institutions report a therapeutic range for serum digoxin concentration from 0.5â€“2.0 ng/mL (SI units: 1â€“2.6 nmol/mL), current research suggests lowering the upper limit to 1.0 ng/mL to maintain benefit while lowering the risk of toxicity.[96,105] Regardless of the therapeutic serum concentration range used, it must be interpreted in relation to the clinical condition of the patient; the relationship of the time of obtaining the blood sample to that of the last dose; and to other metabolic abnormalities and medications, including hypokalemia, hypomagnesemia, hypercalcemia, hypernatremia, alkalosis, hypothyroidism, hypoxemia, and catecholamines, and the use of calcium channel blockers, quinidine, amiodarone, or diuretics.

Although cardioactive steroid poisoning is multifactorial, resulting from the interactions of the many diverse factors previously mentioned, there is a significant correlation between the clinical condition and the serum concentration. In general, patients with pharmaceutical cardioactive steroid toxicity have mean serum concentrations above 2 ng/mL, measured at least 6 hours postingestion for digoxin, and above 40 ng/mL for digitoxin.[57] The significance of these concentrations depends on when the value is obtained in relation to an acute ingestion and the distribution phase of the drug (as discussed above). A value of 15 ng/mL of digoxin is, therefore, more ominous 6 hours after an ingestion than 1 hour after an ingestion. Because there are multiple determinants of digoxin toxicity, there is an overlap in serum digoxin concentrations between toxic and nontoxic patients, and it may be inaccurate to use the therapeutic range of digoxin of 0.5â€“2.0 ng/mL as the sole indicator of toxicity.[99]

In most hospitals, â€œdigoxin levelsâ€• are the only estimation available to physicians in the acute setting when evaluating a patient for presumed cardioactive steroid poisoning. The polyclonal assays typically used in most institutions frequently, but unpredictably, cross-react with other plant- or animal-derived cardioactive steroids.

Although only digoxin is accurately detected by monoclonal digoxin immunoassay, an elevated serum digoxin concentration in the correct clinical setting may qualitatively assist in making a presumptive diagnosis of nondigoxin cardioactive steroid poisoning (Chaps. 43 and 114).[13,86] For example â€œdigoxinâ€• concentrations are recorded from serum spiked with oleandrin and oleandrigenin from *Nerium oleander*, from patients after exposure to *Thevetia peruviana* (yellow oleander) or toad secreted bufadienolides, using various techniques including high-performance liquid chromatography (HPLC) and monoclonal and polyclonal antibody analysis.[9,25,52] With the use of more specific analytic technology, patients with cardioactive steroid poisoning from plant- or animal-derived cardioactive steroids may have low or nonexistent digoxin concentration (Chaps. 43 and 114).

Serum concentrations of digoxin are measured in one of two ways: free digoxin and total digoxin. The most common method of quantifying total digoxin in the serum is by fluorescence polarization immunoassay (FPIA). Under normal circumstances, measuring total digoxin in the serum is sufficient, as serum concentrations are predictive of cardiac concentrations.[23] However, after the use of digoxin-specific Fab (which remains almost entirely within the intravascular space [Vd of 0.40 L/kg]), there is a large elevation in total cardioactive steroid concentrations because the cardioactive steroid is drawn from the tissues and complexes with the antibody fragment, thus trapping the cardioactive steroid in the intravascular space. When this bulk movement is reversed by binding with Fab fragments, a tremendous increase, often approaching an order of magnitude, in total serum digoxin concentrations, occurs. In this situation, methods that detect only unbound digoxin, including treatment with Fab denaturing agents, ultrafiltration, and equilibrium dialysis, allow the quantification of free digoxin in the serum.[34] Paradoxically, excess digoxin antibody can cause a false elevation in the apparent â€œdigoxin concentrationâ€• (Chap. 7).

Endogenous Digoxinlike Immunoreactive Substance

Some patients who are not receiving a cardioactive steroid may have a positive digoxin assay as a result of an endogenous substance that is structurally and functionally similar to the prescribed cardioactive steroids.[43] This finding is described in patients with increased inotropic need or reduced renal clearance, including neonates;[115] and patients with renal insufficiency,[10,38,51] liver disease,[79] subarachnoid hemorrhage,[121] congestive heart failure,[40,100] insulin-dependent diabetes,[33] stress,[37,116] acromegaly,[24] hypothermia;[115] after strenuous exercise;[116] and in pregnancy.[31,39,48] An endogenous Na^+-K^+-ATPase inhibiting dihydropyrone-substituted bufenolide cardioactive steroid has been isolated from human placenta. It differs from the toad bufadienolides solely by a single double-bond pyrone ring. Because bufenolides are not normally found in either healthy humans or edible plants, a synthetic pathway to produce dihydropyrone-substituted steroids in humans may be responsible for this endogenous digoxinlike immunoreactive substance (EDLIS). Further research is necessary to confirm this pathway.[48] The use of ultrafiltration techniques, while altering incubation time and temperature at which the digoxin assay is performed, can eliminate the contribution of EDLIS.[32] The clinician suspecting this problem should consult the clinical laboratory. Clinical observations indicate that the serum digoxin concentration contributed by endogenous digoxinlike immunoreactive substances is usually less than 2 ng/mL. Other endogenous substances, such as bilirubin,[79] and exogenous substances, such as spironolactone,[101] can cross-react with the digoxin assay and cause a false-positive result.

Therapy

Management Overview

Initial treatment of a patient with acute cardioactive steroid poisoning includes providing general supportive care, discontinuing cardioactive steroid therapy, preventing further exposure, preventing further gastrointestinal (GI) absorption, monitoring for

dysrhythmias, determining electrolyte and digoxin concentrations, administering digoxin-specific antibody fragments, and treating specific complications such as dysrhythmias and electrolyte abnormalities.

Gastrointestinal Decontamination

Initial treatment should be directed toward prevention of further GI absorption. Emesis or lavage may be considered only rarely, because efficacy is limited, secondary to rapid absorption from the gut and to the emetic effects of the drug itself. Patients with chronic ingestion do not usually benefit from these GI decontamination techniques, because of the limited availability of drug in the gastrointestinal tract for removal. Because many cardioactive steroids, such as digitoxin and digoxin, are recirculated enterohepatically and enteroenterically, both late and repeated activated charcoal administration (1 g/kg of body weight every 2â€“4 hours for up to 4 doses) may be beneficial in reducing serum concentrations.[16,65,69,84,119] Steroid-binding resins such as cholestyramine and colestipol,[47,89] like activated charcoal,[20] can prevent reabsorption of cardioactive steroids from the GI tract and reduce the serum half-life by interrupting both enteroenteric and enterohepatic circulation, and may be used in cases where digoxin-specific Fab is not immediately available, or when renal function is inadequate.[20,47]

Advanced Management

Digoxin-Specific Antibody Fragments

The standard of care for patients with life-threatening cardioactive steroid toxicity is the use of digoxin-specific antibody fragments.[1,32,34,85,88,95,104,110,123] Purified digoxin-specific Fab causes a sharp decrease in free serum digoxin concentrations, a concomitant, but clinically unimportant, massive increase in total serum digoxin, an increase in renal clearance of cardioactive steroid, and a decrease in the serum potassium level.[1] In addition, the administration of digoxin-specific Fab is pharmacoeconomically sound.[21] Although the drug itself is expensive, its expense is far outweighed by obviating the need, risk, and expense of long-term ICU stays, and of repetitive evaluation of potassium and digoxin levels. Table 62-4 lists the indications for administering digoxin-specific Fab. Extensive discussion is found in Antidotes in Depth: Digoxin-Specific Antibody Fragments (Fab).

Additional Cardiac Therapies

In the event that digoxin-specific fragments are not immediately available, the secondary drugs for the management of ventricular irritability include phenytoin and lidocaine. These drugs depress the enhanced ventricular automaticity without significantly slowing, and perhaps enhancing, AV nodal conduction.[94] In fact, phenytoin may reverse digitalis-induced prolongation of AV nodal conduction while suppressing digitalis-induced ectopic tachydysrhythmia, without diminishing myocardial contractile forces.[46] In addition, phenytoin can terminate supraventricular dysrhythmias induced by digitalis more effectively than lidocaine.[94] Underlying atrial fibrillation and flutter typically do not convert to a normal sinus rhythm with administration of phenytoin or lidocaine. When used, phenytoin should be infused slowly intravenously (~50 mg/min) or in boluses of 100 mg repeated every 5 minutes until control of the dysrhythmias is achieved or a maximum of 1000 mg has been given in an adult, or 15â€“20 mg/kg in a child.[8,78] Fosphenytoin has not been evaluated

in this setting. Maintenance oral doses of phenytoin 300â€“400 mg/d in an adult, and 6â€“10 mg/kg/d in a child, should be continued until digoxin toxicity is resolved. Lidocaine is given as a 1.0â€–1.5-mg/kg IV bolus followed by continuous infusion at 1â€–4 mg/min in an adult, or as a 1.0â€–1.5-mg/kg IV bolus followed by 30â€–50 Âµg/kg/min in a child, as required to control the rhythm disturbance. (Chap. 61).

TABLE 62-4. Indications for Administration of Digoxin-Specific Antibody Fragments

Any potential digoxin-related life-threatening dysrhythmia
Potassium concentration >5.0 mEq/L in setting of acute digoxin poisoning
Chronic digoxin poisoning with dysrhythmias, significant gastrointestinal symptoms, or acute onset of significantly altered mental status, or renal insufficiency
Serum digoxin concentration (SDC) â‰¥15 ng/mL at any time, or â‰¥10 ng/mL 6 h postingestion
Ingestion of 10 mg in adult
Ingestion of 4 mg in a child
To aid in treatment of suspected cardioactive steroid poisoning without a confirmatory level
Poisoning by nondigoxin cardioactive steroid
Digoxin-specific Fab dosing (round up vial calculation)

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{Pt Wt (kg)}}{100}$$

$$\text{No. of vials} = \frac{\text{Amount ingested (mg)}}{0.5\ \text{(mg/vial)}} = 80\%\ \text{bioavailability}$$

Empiric therapy for acute poisoning:
10â€–20 vials (adult or pediatric)
Empiric therapy for chronic poisoning:

Adultâ€”3â€“6 vials
Pediatricâ€”1â€“2 vials

Class IA antidysrhythmics are contraindicated in the setting of cardioactive steroid poisoning because they may induce or worsen AV nodal block and decrease His-Purkinje conduction at slow heart rates, and because of their Î±-adrenergic receptor blockade and vagal inhibition significant hypotension and tachycardia may occur. Class IA antidysrhythmics are also prodysrhythmogenic and their safety in the setting of cardioactive steroid poisoning is unstudied. Additionally, quinidine reduces renal clearance of digoxin and digitoxin.

In patients with symptomatic supraventricular bradydysrhythmias or high degrees of AV block, atropine 0.5 mg should be administered intravenously to an adult, or 0.02 mg/kg with a minimum of 0.1 mg to a child. Atropine should be titrated to block the vagotonic effects of the cardioactive steroid. The dose may be repeated at 5-minute intervals if necessary. Therapeutic success is unpredictable, because the depressant actions of cardioactive steroids are mediated only in part through the vagus nerve. The use of isoproterenol should be avoided in cardioactive steroid-induced conduction disturbances, as there may be an increased incidence of ventricular ectopic activity in the presence of toxic levels of cardioactive steroids.

Pacemakers and Cardioversion

External or transvenous pacemakers have limited indications in the management of cardioactive steroid poisoning since digoxin-specific Fab became available. In one retrospective study of 92

digitalis-poisoned patients, 51 patients were treated with cardiac pacing and/or digoxin-specific Fab, and the overall mortality rate was 13%.[111] Prevention of life-threatening dysrhythmias failed in 8% of

patients treated with immunotherapy and in 23% of patients treated with internal pacemakers. The main reasons for failure of digoxin-specific Fab was pacing-induced dysrhythmias and delayed or insufficient doses of digoxin-specific Fab. Iatrogenic complications of pacing occurred in 36% of patients. Thus, overdrive suppression with a temporary transvenous pacemaker should not be used to abolish ventricular tachydysrhythmias in the presence of cardioactive steroid poisoning.[5,111] Pacemakers have limited utility and substantial risks in patients with cardioactive steroid toxicity making the use of digoxin-specific Fab first-line therapy.[111]

Transthoracic electrical cardioversion for atrial tachydysrhythmias, in the setting of digoxin poisoning, is both clinically and experimentally associated with the development of potentially lethal ventricular dysrhythmias. The dysrhythmias are similar to digoxin toxic rhythms,[97] and related to the degree of toxicity, and the amount of administered current in cardioversion.[97] In cardioactive steroid-poisoned patients with unstable rhythms, such as hemodynamically unstable ventricular tachycardia and ventricular fibrillation, cardioversion and defibrillation, respectively, are indicated.

Electrolyte Therapy

Potassium

Hypokalemia and hyperkalemia can exacerbate cardioactive steroid cardiotoxicity. When hypokalemia is noted in conjunction with tachydysrhythmias or bradydysrhythmias, potassium replacement should be administered with serial monitoring of serum potassium, because iatrogenic hyperkalemia is detrimental. In this setting, digoxin-specific Fab administration generally should not be used until the hypokalemia is corrected because the reinstitution of Na^+-K^+-ATPase function may cause profound hypokalemia.

In the presence of acute cardioactive steroid toxicity, when potassium exceeds 5.0 mEq/L, digoxin-specific antibodies are

indicated. When marked hyperkalemia develops in conjunction with ECG evidence of hyperkalemia, and if digoxin-specific Fab is not available immediately, an attempt should be made to lower the serum potassium with IV insulin, dextrose, sodium bicarbonate, and oral administration of the ion-exchange resin sodium polystyrene sulfonate. Similar caution, as stated above, should be applied to the subsequent administration of digoxin-specific Fab because of concern for profound hypokalemia. Calcium chloride is beneficial in most hyperkalemic patients, but in the presence of cardioactive steroid, poisoning by calcium salts may be disastrous, as intracellular hypercalcemia is already present. Although a 2004 study was unable to show an adverse effect,[41] a number of experimental studies cite the additive or synergistic actions of calcium and cardioactive steroids on the heart, resulting in dysrhythmias,[35,81,102] cardiac dysfunction[59] (eg, hypercontractility, or the so-called stone heart, hypocontractility), and cardiac arrest.[70,102,117] Furthermore, 3 case reports[7,62] of deaths in cardioactive steroid-poisoned patients following calcium administration support the withholding of calcium administration in the setting of hyperkalemia. The purported mechanism is augmented intracellular cytoplasmic Ca^{2+}, which results from an increased transmembrane concentration gradient that further inhibits calcium extrusion through the Na^{+}-Ca^{2+} exchange and/or increased intracytoplasmic stores.[57] This additional cytoplasmic calcium may result in altered contraction of myofibril organelles,[59] less negative intracellular resting potential that allows delayed afterdepolarizations to reach firing threshold,[45,57,81] altered function of the sarcoplasmic reticulum,[59,93] or increased calcium interfering with myocardial mitochondrial function (see Chap. 23).[59] Although some investigators suspect that the rate of administration of the calcium may be a factor in the subsequent cardiac toxicity,[70,81] calcium administration should be avoided, as there are better, safer, alternative treatments available for cardioactive steroid-induced hyperkalemia (eg, digoxin-specific Fab, insulin and sodium bicarbonate).[7,35,62,81,102]

Magnesium

Hypomagnesemia may also occur in cardioactive steroid-poisoned patients, secondary to the contributory factors mentioned with hypokalemia, such as long-term diuretic use to treat congestive heart failure. Concomitant hypomagnesemia may result in refractory hypokalemia, despite potassium replacement.[120] The theoretical benefits of magnesium therapy include blockade of the transient inward calcium current, antagonism of calcium at intracellular binding sites, decreased cardioactive steroid-related ventricular irritability, and blockade of potassium egress from cardioactive steroid-poisoned cells.[3,30,53,87,98,108,120] Although hypomagnesemia increases myocardial digoxin uptake and decreases cellular Na^+-K^+-ATPase activity, there is conflicting evidence on whether magnesium â€œreactivatesâ€• the cardioactive steroid-bound Na^+-K^+-ATPase activity.[79,98,108]

The successful use of intravenous magnesium sulfate in the treatment of ventricular tachydysrhythmias, caused by digoxin toxicity, is reported, even in the presence of elevated serum magnesium levels.[60] The mechanism of efficacy of magnesium may be its ability to suppress delayed afterdepolarizations, prolong refractory period by decreasing calcium uptake and potassium efflux,[108] activate Na^+-K^+-ATPase as an essential metallo-coenzyme, or antagonize digoxin at the sarcolemma Na^+-K^+-ATPase pump. However, this treatment is only temporizing, until digoxin-specific Fab is available for definitive therapy, and is not advocated as first-line therapy. The precise dosing of magnesium sulfate in cardioactive steroid-poisoned patients is not established.[3,30,53,60,87,98,120] A common regimen uses 2 g of magnesium sulfate IV over 20 minutes in an adult (25â€“50 mg/kg/dose to a maximum of 2 g in a child). Following stabilization, an adult patient with severe hypomagnesemia may require a magnesium infusion of 1â€“2 g/h (25â€“50 mg/kg/h to a maximum of 2 g in a child), with serial monitoring of serum magnesium levels, telemetry, respiratory rate (observing for

bradypnea), deep-tendon reflexes (observing for hyporeflexia), and monitoring of blood pressure. Magnesium is contraindicated in the setting of bradycardia or atrioventricular block, preexisting hypermagnesemia, and renal insufficiency or failure.

Extracorporal Removal

Forced diuresis,[64] hemoperfusion,[75,118] and hemodialysis[118] are ineffective in enhancing the elimination of digoxin because of its large volume of distribution (4â€“10 L/kg), which makes it relatively inaccessible to these techniques. Because of its high affinity for tissue proteins, approximately 10 times less digoxin is found in the serum than is found at the tissue level, and of that amount, approximately 20â€“40% is protein-bound.[55]

Various investigations into new methods of extracorporal removal are under investigation. Plasmapheresis may have a role for removing retained Fab-digoxin complexes to prevent rebound toxicity after digoxin overdose treatment in anuric patients, but its usefulness has not been clearly defined.[14,85] Additionally, there is a suggestion that hemoperfusion through a Î²$_2$-microglobulin adsorptive column might be useful for treating acute digoxin toxicity.[53,113]

Summary

Digoxin and digitoxin are the most commonly prescribed members of the drugs classified as cardioactive steroids, which share common structural similarities and functions at the cellular level. Cardioactive steroids have a narrow therapeutic index. Signs and symptoms of cardioactive steroid toxicity range from subtle to profound. Both cardiac and noncardiac effects follow cardioactive steroid poisoning. Patients with acute toxicity often have a higher serum concentration of the drug and may present with profound nausea, vomiting, bradycardia, atrial and ventricular ectopy with block, or

hyperkalemia. Patients with chronic toxicity often have a lower serum concentration of cardioactive steroids and may present similarly, but more often the symptoms are more proteanâ€”loss of appetite, headache, weakness, nausea, alteration in mental statusâ€”all of which may be combined with similar ectopic rhythms as with acute toxicity. In addition to overt overdose, an elevation in the serum cardioactive steroid concentrations and an exacerbation of the clinical drug effect leading to toxicity may occur from drug interactions or from deterioriating metabolic processes such as with declining renal function, or from electrolyte abnormalities such as hypokalemia, and hypomagnesemia. A systematic approach toward treating patients using basic supportive and decontamination management techniques, supplemented by the early administration of digoxin-specific Fab immunotherapy can significantly reduce morbidity and mortality in these high-risk patients.

Antidotes in Depth

Digoxin-Specific Antibody Fragments (Fab)

Mary Ann Howland

Digoxin-specific antibody fragments are indicated for the management of patients with toxicity related to digoxin, digitoxin, and all natural cardioactive steroids, such as oleander, squill, and toad venom. Digoxin-specific antibody fragments have an excellent record of efficacy and safety, and should be administered early in both established and suspected cardioactive steroid poisoning.

History

The production of antibody fragments to treat patients poisoned with digoxin followed the development of digoxin antibodies for measuring serum digoxin concentrations by radioimmunoassay (RIA).[11] The RIA technique permitted the correlation between serum digoxin concentration and clinical digoxin toxicity.

In 1967, Butler and Chen suggested that purified antidigoxin

antibodies with a high affinity and specificity should be developed to treat digoxin toxicity in humans.[11] The digoxin molecule alone, with a molecular weight of 780 daltons, was too small to be immunogenic. But digoxin could function as a hapten when joined to an immunogenic protein carrier such as albumin. These investigators immunized sheep with this conjugate to generate antibodies. The immunized sheep subsequently produced a mixture of antibodies that included antialbumin antibodies and antidigoxin antibodies. The antibodies were separated and highly purified to retain the digoxin antibodies, while removing the antibodies to the albumin and all other extraneous proteins. The antibodies that were developed have a high affinity for digoxin, and sufficient cross-reactivity with digitoxin to be clinically useful for the treatment of both poisonings. On the other hand, the specificity is so high that endogenous steroids, which resemble digoxin structurally, are not affected by antibody administration.

Intact IgG antidigoxin antibodies reversed digoxin toxicity in dogs. Unfortunately, the urinary excretion of digoxin was delayed, and free digoxin was released after antibody degradation occurred. Furthermore, concern for hypersensitivity reactions also existed. To make these antibodies safe and effective in humans, whole IgG antidigoxin antibodies were cleaved with papain, yielding two antigen-binding fragments (Fab), with a molecular weight of 50,000 daltons each, and one Fc fragment.[12] The Fc fragment does not bind antigen, but it does increase the potential for hypersensitivity reactions and was eliminated. The advantages of digoxin-specific antibody fragments when compared to whole IgG antibodies include larger volume of distribution, more rapid onset of action, smaller risk of adverse immunologic effects, and more rapid elimination.[12,46,48] Ultimately, the first commercial product, Digibind, a relatively pure, very safe, and extremely effective Fab product, was produced. Another commercial product, DigiFab, is currently available.

Pharmacology

Immediately following IV administration, digoxin-specific antibody fragments bind intravascular free digoxin. Unbound antibodies then diffuse into the interstitial space, binding free digoxin there. A concentration gradient is then established, which facilitates movement of the free intracellular digoxin, and digoxin that is dissociated from its binding sites (the external surface of Na^+-K^+-adenosine triphosphatase [ATPase] enzyme) in the heart and in skeletal muscle, into the interstitial or intravascular spaces.[68] The dissociation rate constant of digoxin for Na^+-K^+-ATPase, therefore, affects the time course for binding to digoxin-specific antibody fragments and, consequently, the onset of action.[50,69]

The binding affinity of digoxin-specific antibody fragments for digoxin and digitoxin are about 10^9â€“10^{11} M^{-1} and 10^8â€“10^9 M^{-1}, and are greater than the affinity of digoxin or digitoxin for the Na^+-K^+-ATPase pump receptor.[21]

Pharmacokinetics

The pharmacokinetics of Digibind versus DigiFab (previously named DigiTAb) were compared in human volunteers.[85] Each subject received 1 mg of digoxin intravenously as a 5-minute bolus, followed 2 hours later by a 30-minute intravenous infusion of 76 mg (equimolar neutralizing dose) of Digibind or DigiFab. Free and total digoxin (free plus digoxin-specific antibody fragment bound) were assayed using an ultrafiltration method over 48 hours. At 30 minutes after infusion of either digoxin-specific antibody fragment, the free digoxin serum concentration was below the level of detection of the assay and remained so for several hours. A few patients had free digoxin concentrations rebound to peak concentrations of 0.5 ng/mL at approximately 18 hours. The area under the plasma drug concentration versus time curve (AUC) for 2â€“48 hours, for free digoxin, was similar for both treatment groups. The elimination half-life of total digoxin

averaged 19.5 hours. The distribution half life was 1 hour for each digoxin-specific antibody fragments, and the volumes of distribution were 0.3 L/kg for DigiFab versus 0.4 L/kg for Digibind.[21,22] The systemic clearance of DigiFab was higher than Digibind and accounted for the shorter elimination half life of DigiFab (15 hours versus 23 hours).[85] Urine sampling over the first 24 hours demonstrated mostly free digoxin and very little digoxin-specific antibody fragments. The authors postulate that during renal excretion, the digoxin-specific antibody fragments-digoxin complex is metabolized in the kidney by the proximal tubular cells, releasing free digoxin and unmeasured digoxin-specific antibody fragments metabolites.

Similar findings were described by Smith and associates in 1976, following the first clinical use of digoxin-specific antibody fragments in a patient who gave a history of ingesting 90 (0.25 mg) digoxin tablets.[75] Total serum digoxin concentration, which was 17.6 ng/mL before digoxin-specific antibody fragments were given, rose to 226 ng/mL one hour after the start of the digoxin-specific antibody fragments infusion and remained there for 11 hours, before falling over the next 44 hours, with a half-life of 20 hours.[75] Fab concentrations peaked at the end of the infusion and then apparently exhibited a biphasic or triphasic decline, probably reflecting distribution into different compartments, as well as excretion and catabolism. Free serum digoxin concentrations were undetectable for

the first 9 hours, then rose to a peak of 2 ng/mL at 16 hours, and fell to 1.5 ng/mL at both 36 hours and 56 hours at which time sampling stopped. An analysis of renal elimination based on an incomplete collection suggested that digoxin was excreted only in the bound form during the first 6 hours, but by 30 hours after Fab administration all digoxin in the urine was free digoxin.

In order to better match availability of digoxin-specific antibody fragments to liberated digoxin, one study compared a loading dose

of digoxin-specific antibody fragments followed by an infusion to the total digoxin-specific antibody fragments dose infused over a short amount of time.[65] The former strategy increased the ratio of digoxin bound to unbound digoxin-specific antibody fragments from 50 to 70%.[65] The authors hypothesized that too rapid an infusion regimen would permit digoxin-specific antibody fragments elimination to occur before they could optimally bind digoxin being redistributed from tissue sites.[65]

Digoxin takes several hours to distribute from the blood to the tissue compartment. As expected, a rodent model demonstrated that digoxin-specific antibody fragments were more effective when administered prior to complete distribution of digoxin.[62] Once distribution is complete, increasing the dose of digoxin-specific antibody fragments improved efficacy as measured by comparing the area under the time-versus-concentration curve (AUC) of digoxin to that of the Fab-digoxin complex.[62]

Pharmacokinetic studies in patients with renal failure demonstrate that the half-life of digoxin-specific antibody fragments is prolonged 10-fold, with no change in the apparent Vd.[79] Digoxin-specific antibody fragment serum concentrations remain detectable for 2â€“3 weeks. Total digoxin serum concentrations generally follow digoxin-specific antibody fragments. There is no evidence for dissociation of digoxin-specific antibody fragments-digoxin complex over time.[86] In contrast, case reports demonstrate that free digoxin levels reappear up to 10 days following administration of digoxin-specific antibody fragments to patients with severe renal dysfunction, as compared to 12â€“24 hours in patients with normal renal function.[27,41,52,53,71,73,79,80,81,86] In one series of patients with end-stage renal disease, the maximum average concentration of free digoxin was 1.30 Â± 0.7 ng/mL and occurred at 127 Â± 40 hours.[81] The mechanism for this rebound is unclear. Following the peak, there is a slow decline that parallels the elimination of digoxin-specific antibody fragments.

Efficacy

A large study evaluating adults and children with acute and chronic digoxin toxicity established the efficacy of digoxin-specific antibody fragments.[1] Of the 150 patients treated, 148 were evaluated pretreatment for cardiovascular manifestations of toxicity: 79 patients (55%) had high-grade atrioventricular (AV) block, 68 (46%) had refractory ventricular tachycardia, 49 (33%) had ventricular fibrillation, and 56 (37%) had hyperkalemia. Ninety percent of patients had a response to digoxin-specific Fab within minutes to several hours of Digibind administration. Complete resolution of all signs and symptoms of digoxin toxicity occurred in 80% of cases. A partial response was observed in 10% of patients, and of the 15 patients who did not respond, 14 were moribund or actually found not to be digoxin toxic. The spectacular success of digoxin-specific antibody fragments for patients with digoxin toxicity is demonstrated by the fact that of the 56 patients who had cardiac arrest caused by digoxin, 54% survived hospitalization, as compared with 100% mortality before the advent of these fragments.[1,5] Newborns, infants, and children have all been successfully treated with Digibind.[5,39,70]

Adverse Effects and Safety

Digoxin-specific antibody fragments are effective, as well as very safe. Reported adverse effects include hypokalemia as a consequence of reactivation of the Na^+-K^+-ATPase, withdrawal of the inotropic or atrioventricular nodal blocking effects of digoxin leading to congestive heart failure or a rapid ventricular rate in patients with atrial fibrillation, and, rarely, allergic reactions.[21,22] In the multicenter study of 150 patients, the only acute clinical manifestations were hypokalemia in 6 patients (4%), worsening of congestive heart failure in 4 patients (3%), and transient apnea in a several-hours-old neonate.[1] There were no other reactions reported in any of the patients in this series. In a postmarketing

surveillance study of Digibind that included 451 patients, 2 patients with a prior history of allergy to antibiotics reportedly developed rashes.[57] One of these patients developed a total body rash, facial swelling, and a flush during the infusion. The other experienced a pruritic rash. Two other adverse reactions (thrombocytopenia and rigors) were probably unrelated to the use of Digibind.[57] One patient received Digibind on 3 separate occasions over the course of 1 year for multiple suicide attempts, with no adverse effects.[8]

During the clinical trials with DigiFab, 1 patient developed pulmonary edema, bilateral pleural effusion, and renal failure, most likely caused by the loss of the inotropic and chronotropic digoxin effects.[22] Phlebitis and postural hypotension were related to the infusion of DigiFab in two healthy volunteers.

Both products warn that patients with allergies to papain, chymopapain, or other papaya extracts may be at risk for an allergic reaction because trace amounts of these residues may remain in the digoxin-specific antibody fragments.[22,48] Manufacturers of DigiFab state that because some literature suggests a resemblance between dust mite allergens and some latex allergens with the antigenic structures of papain, patients may exhibit cross-allergenicity. Patients with an allergy to sheep protein or those who have previously received ovine antibodies or ovine Fab may also be at risk for allergic reactions, although this is not reported.

Indications for Digoxin-Specific Fab

Digoxin-specific antibody fragments are indicated for life-threatening, or potentially life-threatening, digoxin, digitoxin, or other xenobiotic resulting in cardioactive steroid toxicity.[21] Patients with progressive bradydysrhythmias, including symptomatic sinus bradycardia, or second- or third-degree heart block unresponsive to atropine, and those patients with severe

ventricular dysrhythmias, such as ventricular tachycardia or ventricular fibrillation, should also be treated with digoxin-specific antibody fragments. Ventricular tachycardia with a fascicular block is likely to be a digoxin-toxic rhythm.[47] Any patient with a potassium concentration exceeding 5 mEq/L that is attributable to a cardioactive steroid in the presence of other manifestations of digoxin toxicity should also be treated. Acute ingestions greater than 4 mg in a healthy child (or more than 0.1 mg/kg), or 10 mg in a healthy adult, require digoxin-specific antibody fragments, with the threshold lower in patients with significant medical

illness. Serum digoxin concentrations are not representative of myocardial concentrations until tissue distribution takes place. Following ingestion, a time delay of 4â€“6 hours is usually required for digoxin to achieve distribution from the serum to the myocardium. Serum concentrations of â‰¥10 ng/mL, at steady state after an acute ingestion, are an indication for treatment with digoxin-specific antibody fragments. Because the elderly appear at greatest risk of lethality, the threshold for treating those older than 60 years of age should be lowered.[7] Before the advent of digoxin-specific antibody fragments, mortality in patients older than 60 years of age was 58%, as compared to 8% in patients younger than 40 years of age, and to 34% in patients between the ages of 40 and 50 years of age.[7] A rapid progression of clinical signs and symptoms, such as cardiac and gastrointestinal toxicity and an elevated or rising potassium level, in the presence of an acute overdose, suggests a potentially life-threatening ingestion and the need for digoxin-specific antibody fragments.

In a patient with an unknown ingestion who is clinically ill with characteristics suggestive of poisoning by a cardioactive steroid, a calcium channel-blocking agent, or a Î²-adrenergic antagonist, digoxin-specific antibody fragments should be administered early in the management, and always prior to calcium use. If digoxin or another cardioactive steroid is involved, the effects can be

reversed, obviating the need to administer calcium and avoiding the danger of giving calcium to a cardioactive steroid-toxic patient. Cardioactive steroid toxicity causes intracellular myocardial hypercalcemia, and the administration of exogenous calcium may further exacerbate conduction abnormalities and potentially result in cardiac arrest, unresponsive to further resuscitation. Also, when it is difficult to distinguish clinically between digoxin poisoning and intrinsic cardiac disease, the administration of digoxin-specific antibody fragments can help establish the diagnosis.

A recent computer-based simulation model compared the treatment of non-lifethreatening digoxin toxicity with standard therapy. The authors concluded that treatment with digoxin-specific antibody fragments could decrease length of hospitalization by 1.5 days.[20]

Onset of Response

In the multicenter study of 150 patients, the mean time to initial response from the completion of the digoxin-specific antibody fragments infusion (accomplished over 15 minutes to 2 hours) was 19 minutes (range, 0â€“60 minutes), and the time to complete response was 88 minutes (range, 30â€“360 minutes).[16] Time to response was not affected by age, concurrent cardiac disease, or presence of chronic or acute ingestion.[1]

Dosing

The dose of digoxin-specific antibody fragments depends on the total body load (TBL) of digoxin. Adult and pediatric patients receiving digoxin therapeutically who develop chronic digoxin toxicity require small doses of digoxin-specific antibody fragments because their total body burden of digoxin is smaller when toxicity develops. Children with acute overdoses require digoxin-specific

antibody fragments doses based on the amount of digoxin ingested, in a manner similar to adults with acute ingestions.

Estimates of digoxin TBL can be made in three ways: (a) estimate the quantity of digoxin acutely ingested and assume 80% bioavailability (mg ingested Ã— 0.8 = TBL); (b) obtain a serum digoxin concentration (SDC), and, using a pharmacokinetic formula, incorporate the apparent volume of distribution (Vd) of digoxin and the patient's body weight (in kg); or (c) use an empiric dose based on the average requirements for an acute or chronic overdose in an adult or child.

TABLE A19-1. Sample Calculation Based on History of Acute Digoxin Ingestion

Adult
Weight: 70 kg
Ingestion: Fifty (0.25-mg) digoxin tablets
Calculation:
0.25 mg Ã— 50 = 12.5 mg ingested dose
12.5 mg Ã— 0.80 (80% bioavailability) = 10 mg (absorbed dose)

$$\frac{10\ \text{mg}}{0.5\ \text{mg/vial}} = 20\ \text{vials}$$

Child
Weight: 10 kg
Ingestion: Fifty (0.25-mg) digoxin tablets
Calculation: Same as for adult. Child will require 20 vials

Each of these methods of estimating the dose of digoxin-specific antibody fragments has limitations. History of ingestion is often unreliable, and empiric doses based on averages may overestimate or underestimate Fab requirements. Using the pharmacokinetic

formula assumes a steady-state Vd of 5 L/kg. This is not accurate in the acute setting. In addition, the 5 L/kg Vd is a population average that varies both with each individual and in certain disease states, such as the decreases that occur in patients with renal disease and hypothyroidism.[87]

Sample calculations for each of these methods are shown in Tables A19-1, A19-2, and A19-3. Each vial of digoxin-specific antibody fragments contains 38 mg (Digibind) or 40 mg (DigiFab)

of purified digoxin-specific antibody fragments that will bind approximately 0.5 mg of digoxin or digitoxin. If the quantity of ingestion cannot be reliably estimated, it is safest to use the largest calculated estimate. Alternatively, the clinician should be prepared to increase dosing, should resolution be incomplete.

TABLE A19-2. Sample Calculations Based on the Serum Digoxin Concentration (SDC)

Adult

Weight: 70 kg

SDC = 10 ng/mL

Volume of distribution = 5 L/kg

Calculation[a]:

$$\text{No. of vials} = \frac{\text{Total body load (mg)}}{0.5\ \text{mg/vial}} = \frac{\text{SDC} \times V_d \times \text{Pt Wt (kg)}}{1000 \times 0.5\ \text{mg/vial}}$$

$$\text{No. of vials} = \frac{10\ \text{ng/mL} \times 5\ \text{L/kg} \times 70\ \text{kg}}{1000 \times 0.5\ \text{mg/vial}}\ \text{(Round up)}$$

No. of vials = 7

Child

Volume of distribution: 5 L/kg
Calculation[a]:

$$\text{No. of vials} = \frac{10\ \text{ng/mL} \times 5\ \text{L/kg} \times 10\ \text{kg}}{1000 \times 0.5\ \text{mg/vial}}\ \text{(Round up)}$$

No. of vials = 1

Quick Estimation (for Adults and Children)

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{Pt Wt (kg)}}{100}\ \text{(Round up)}$$

[a] 1000 is a conversion factor to change ng/mL to mg/L.

TABLE A19-3. Empiric Dosing Recommendations

Acute Ingestion
Adult: 10â€“20 vials
Child[a]: 10â€“20 vials
Chronic Toxicity
Adult: 3â€“6 vials
Child[b]: 1â€“2 vials

[a]Monitor for volume overload in very small children.
[b]The prescribing information contains a table for infants and children, with corresponding serum concentrations.

Administration

According to the manufacturer, Digibind should be administered IV over 30 minutes via a 0.22-micron membrane filter.[21] The 38-mg

vial must be reconstituted with 4 mL of sterile water for IV injection, furnishing an isoosmotic solution. This preparation can be further diluted with sterile isotonic saline for injection (for small infants, addition of 34 mL to the 4 mL [for 38 mL total] achieves 1 mg/mL). After Digibind is reconstituted, it should be used immediately, or if refrigerated, it should be used within 4 hours.[21] Although slow IV infusion over 30 minutes is preferable, Digibind may be given by IV bolus to a critically ill patient.

Each vial of DigiFab should be reconstituted with 4 mL of sterile water for IV injection and gently mixed to provide a solution containing 10 mg/mL of digoxin-specific antibody fragments.[22] The reconstituted product should be used promptly or, if refrigerated, it should be used within 4 hours. This preparation can be further diluted with sterile isotonic saline for injection. DigiFab should be administered slowly as an intravenous infusion over at least 30 minutes unless the patient is critically ill, in which case the DigiFab can be given by IV bolus. If a rate-related infusion reaction occurs, the infusion should be stopped and restarted at a slower rate. For infants and small children, the manufacturer recommends diluting the 40-mg vial with 4 mL of sterile water for IV injection and administering the dose undiluted using a tuberculin syringe. For very small doses, this preparation can be further diluted with an additional 36 mL of sterile isotonic saline for injection (for a total of 40 mL) to achieve a 1 mg/mL concentration.

Availability

Digoxin-specific antibody fragments are available as Digibind or DigiFab. Vials contain 38 mg or 40 mg of purified lyophilized digoxin-immune ovine immunoglobulin fragments, respectively. Digibind is prepared using digoxin as the hapten. DigiFab is prepared using a digoxin derivative (digoxin-dicarboxymethoxylamine) as the hapten. Affinity chromatography is used to isolate and purify the digoxin-specific antibody

fragments following papain digestion.

Measurement of Digoxin Serum Concentration after Digoxin-Specific Antibody Fragments Administration

Many laboratories are not equipped to determine free serum digoxin concentrations. Therefore, after digoxin-specific antibody fragments are administered, total serum digoxin concentrations are no longer clinically useful, because they represent free plus bound digoxin.[21,31,36,44,77] The type of test employed can either result in falsely high or falsely low serum concentrations, depending on which phase (solid or supernatant) is sampled.[35,49] If the correct dose of digoxin-specific antibody fragments is administered, the free serum digoxin concentrations should be near zero. Free digoxin concentrations begin to reappear 5â€“24 hours or longer after Fab administration, depending on the antibody dose, infusion technique, and the patient's renal function. Newer commercial methods, employing ultrafiltration or immunoassays, make free digoxin measurements easier to perform and, therefore, more clinically useful, but they remain associated with errors in the underestimation or overestimation of the free digoxin level.[30,37,54,60,78,82] Free digoxin concentrations are particularly useful in patients with severe renal dysfunction. Independent of the availability of these data, the patient's cardiac status must be carefully monitored for signs of recurrent toxicity.

Other pitfalls in the measurement and utility of serum digoxin concentrations include endogenous and exogenous factors. Endogenous digoxinlike immunoreactive substances (EDLISs) have been described in infants, in women in the third trimester of pregnancy, and in patients with renal and hepatic failure.[29,32,33,38,40,50,83,84] When EDLISs are free or weakly bound, as in these circumstances, they are measurable by the

typical RIA and can account for factitiously high reported serum digoxin concentrations in the absence of digoxin treatment. The role of EDLIS in the body has not been fully elucidated, but it does have an effect on both the Na^+-K^+-ATPase pump and the cardioactive steroid receptor site.[33] EDLISs are implicated as a causative factor in hypertension and renal disease. Exogenous factors relate primarily to measurement techniques and interpretation.[42] Digoxin is metabolized to compounds with varying levels of cardioactivity.[45] Some metabolites cross-react and are measured by RIA, while others are not. The in vivo production of these metabolites varies in patients, and may depend on intestinal metabolism by gut flora as well as renal and liver clearance.

Role of Digoxin-Specific Antibody Fragments with other Cardioactive Steroids

Digoxin-specific antibody fragments were designed to have high-affinity binding for digoxin and digitoxin. There are structural similarities, however, between all cardioactive steroids. In fact, RIA-determined digoxin concentrations have been reported in patients following poisoning with nondigoxin cardioactive steroids,[27,47,61] suggesting that cross-reactivity exists between digoxin-specific antibody fragments and other cardioactive steroids. Thus, digoxin-specific antibody fragments may have some efficacy in all natural cardioactive steroid poisonings, including oleander, yellow oleander, squill, and toad venom.[3,9,10,14,26,28,63] In vitro studies also suggest the binding affinity of Digibind for cardioactive steroids.[18,19,58]

The successful reversal, by Digibind, of cardiotoxicity resulting from ingestion of *Nerium oleander* was reported.[72] This patient responded to 5 vials (200 mg) of Fab, but larger doses may be

required in other cardioactive steroid poisonings because of the lower affinity binding of Digibind for these toxins. DigiFab is expected to have similar affinity binding toward cardioactive steroids. Both products are polyclonal, contributing to their broad spectrum of affinity for nondigoxin cardioactive steroids. Treatment decisions should be based on empirical grounds, with initial therapy consisting of 10â€“20 vials. Subsequent doses can be based on clinical response.

Chapter 63

Methylxanthines and Selective Î²2-Adrenergic Agonists

Robert J. Hoffman

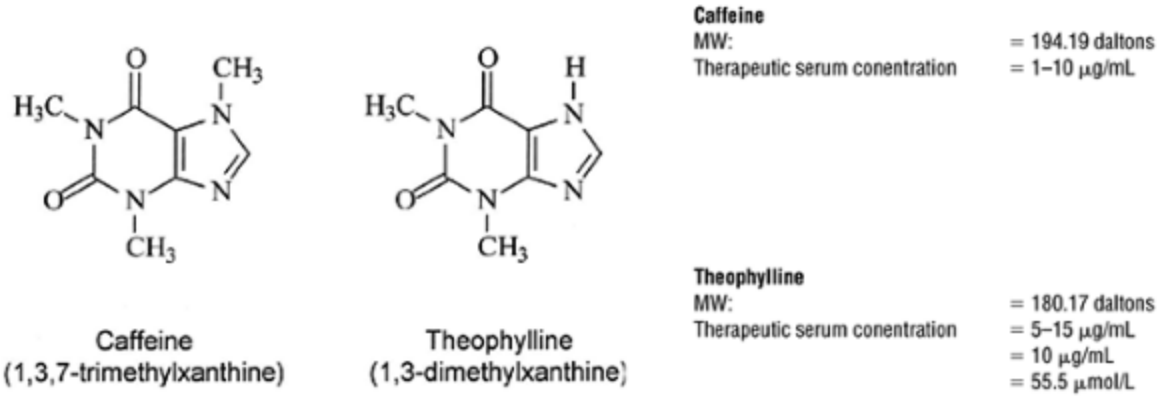

Figure. No Caption Available.

A 17-year-old girl presented to the emergency department reporting that she ingested thirty-five (200-mg) tablets of caffeine approximately 2 hours earlier. She complained of nausea,

vomiting, and palpitations. Her vital signs were: blood pressure, 115/66 mm Hg; pulse 142 beats/min; respiratory rate, 20 breaths/min; and temperature, 100.2Â°F (37.9Â°C). The patient was attached to a cardiac monitor. She was anxious, disoriented, and cooperative. Significant physical findings included mydriasis, tachycardia, tremor, and diaphoresis. A 12-lead ECG demonstrated a sinus tachycardia, with frequent unifocal premature ventricular contractions (PVCs). Fifty grams of activated charcoal with sorbitol was given orally, but she immediately vomited. Metoclopramide (10 mg IV) was administered, and 30 minutes later 50 g of activated charcoal with sorbitol was orally administered again, but vomiting recurred.

At admission the patient's serum electrolytes were: sodium, 140 mEq/L; potassium, 3.0 mEq/L; chloride, 107 mEq/L; bicarbonate, 16 mEq/L; BUN, 8 mg/dL; creatinine, 1 mg/dL; and glucose, 248 mg/dL. One liter of 0.9% NaCl solution was administered intravenously over 30 minutes, and potassium chloride (40 mEq IV) was administered twice by infusion over 1 hour. The patient's serum electrolytes 3 hours after admission and subsequent to potassium repletion were: sodium, 141 mEq/L; potassium, 2.8 mEq/L; chloride, 110 mEq/L; and bicarbonate, 17 mEq/L. The patient continued to have a sinus tachycardia with frequent unifocal PVCs, and the blood pressure decreased to 98/50 mm Hg. Two liters of lactated Ringer solution was administered by bolus over 1 hour, and the blood pressure increased to 108/56 mm Hg. Fifty grams of activated charcoal with sorbitol was orally administered again, this time without ensuing emesis. Approximately 4 hours after presentation

and 6 hours after ingestion, a serum sample for a quantitative caffeine concentration was obtained. The treating institution lacked the capability to determine a quantitative caffeine concentration, and the blood sample was sent to a reference laboratory. Serum electrolyte assays were repeated at

approximately 7 hours postingestion. Although the bicarbonate had increased to 20 mEq/L, the potassium was still 2.8 mEq/L. The patient again received potassium chloride (40 mEq IV) by infusion over 1 hour. The severity and persistence of hypotension and hypokalemia combined with a lack of intensive care capabilities necessitated transfer to the intensive care unit in a nearby children's hospital.

At the receiving institution, her vital signs had improved to blood pressure, 110/64 mm Hg; pulse, 110 beats/min; respiratory rate, 18 breaths/min; and temperature, 99.0Â°F (37.2Â°C). Fifty grams of activated charcoal without sorbitol was readministered. The patient experienced anxiety and agitation that responded to lorazepam (3 mg IV). She was awakened during the night to be reevaluated and to receive another dose of activated charcoal orally. Otherwise, the patient remained sedated through the night. She awoke in the morning with a normal mental status and reported feeling ill but much improved. Repeat electrolyte assays were normal except for a potassium of 3.1 mEq/L. Her serum caffeine concentration at that time, approximately 18 hours postingestion, was 88 Âµg/mL. Caffeine concentration assays were repeated twice that day, with results of 56 Âµg/mL and 40 Âµg/mL, at which time further assays were deemed unnecessary. Serum electrolyte assays repeated that evening, and at all subsequent times, were normal. The patient was discharged from intensive care and admitted to a psychiatric service. The serum sample for the 6-hour caffeine concentration drawn at the initial institution was later determined to be 149 Âµg/mL.

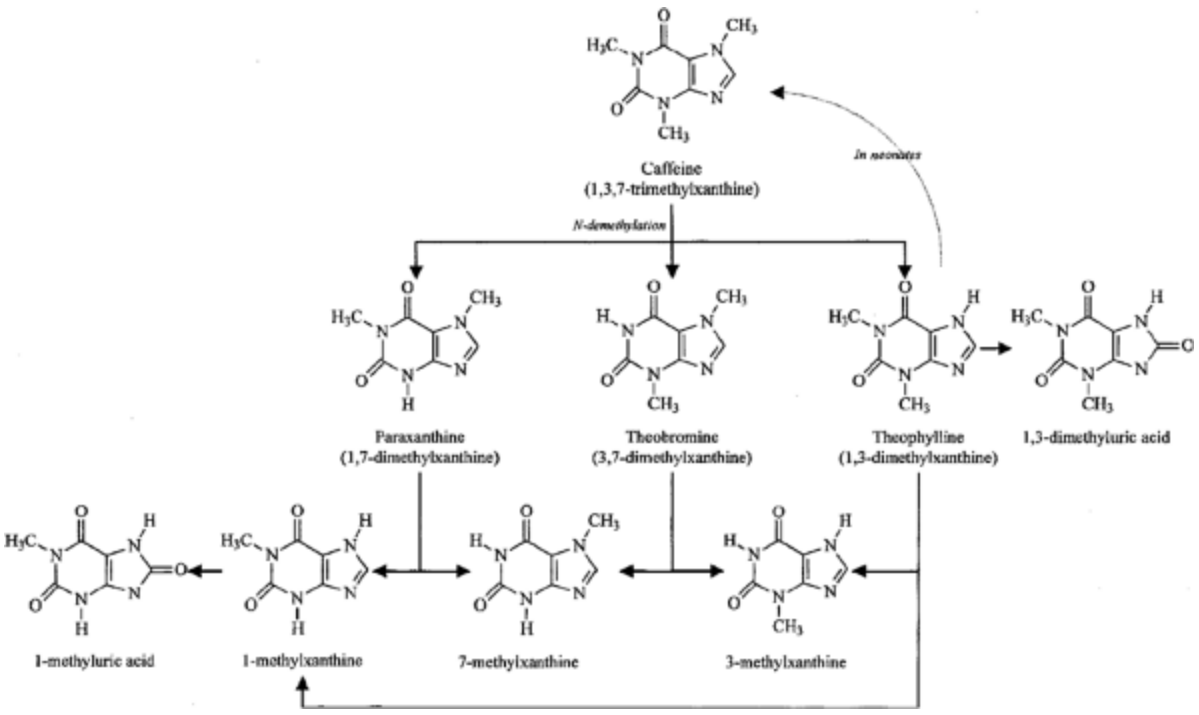

Figure 63-1. Metabolism of caffeine and other methylxanthines by the hepatic P450 enzyme system.

Methylxanthines, which include caffeine (1,3,7 trimethylxanthine), theobromine (3,7-dimethylxanthine), and theophylline (1,3-dimethylxanthine), are so named because they are methylated derivatives of xanthine (Fig. 63-1). Members of this group of plant-derived alkaloids have very similar pharmacologic properties and cause similar clinical effects. Methylxanthines are used ubiquitously throughout the world, most commonly in beverages imbibed for their stimulant, mood elevating, and fatigue abating effects. *Coffea arabica* and related species are used to make coffee, a beverage rich in caffeine. Cocoa and chocolate are derived from the seeds of *Theobroma cacao* , which contains theobromine and, to a lesser extent, caffeine. *Thea sinensis* , a bush native to China but now cultivated worldwide, produces leaves from which various teas, rich in caffeine and containing small amounts of theophylline and theobromine, are brewed.

Selective Î²2 -adrenergic agonists have been developed for the treatment of bronchoconstriction. Their selectivity has improved therapy for bronchoconstriction, allowing avoidance of the adverse effects of epinephrine, an Î±- and Î²-adrenergic agonist, as well as isoproterenol, a Î²1 - and Î²2 -adrenergic agonist. All Î²2 -adrenergic agonists have nearly identical clinical effects and the principal differences are their pharmacokinetics. This chapter does not examine each Î²2 -adrenergic agonist individually; rather, they are discussed as a class. The Î²2 -adrenergic agonists include albuterol, bitolterol, clenbuterol, formoterol, pirbuterol, salmeterol, terbutaline, and ritodrine.

Epidemiology

From 1998 to 2003, the American Association of Poison Control Centers (AAPCC) reported the following trends in methylxanthine exposures. Theophylline exposures decreased from 2609 involving 20 deaths in 1998 to 861 exposures and 10 deaths in 2003. Caffeine exposures decreased from 7390 exposures in 1998 to 6086 exposures of pharmaceutical and herbal caffeine in 2003, but increased from no deaths in 1998 to 5 deaths in 2003. The decrease in theophylline exposures presumably reflects continued decrease in use of theophylline as a therapeutic agent. The number of caffeine exposures, has essentially remained stable, reflecting steady use of caffeine, particularly caffeine in substances other than coffee, tea, and soft drinks.

There were 11,397 selective Î²2 -adrenergic agonists exposures and 1 death in 1998, and 10,501 exposures and 1 death in 2003. The number of selective Î²2 -adrenergic agonists exposures has remained stable, presumably from consistent use of these agents, but death remained uncommon. Chapter 130 discusses poison exposure data.

The overwhelming preponderance of caffeine consumed is in

beverages, and a lesser portion in foods and tablets or capsules. Users typically seek the stimulant and psychoactive effects of caffeine. Caffeine is also increasingly advocated for use as a weight-loss agent.[15, 72] The use of guarana, a plant with a very high caffeine content, for weight loss and athletic performance enhancement, has increased dramatically in recent years. With some scientific evidence demonstrating benefit in athletic performance, caffeine is advocated as a concentration[97, 156] and â€œenergyâ€• booster and as athletic performance enhancer.[33, 96] Despite the limited experience with overdose from these combination preparations, formulations containing caffeine/guarana combined with ephedrine/ma huang cause illnesses such as myocardial infarctions and death.[79] Formulations containing phenylpropanolamine and caffeine, also once marketed as an anorexiant diet aid, were removed from US markets because of adverse drug events, and a demonstrated lack of benefit from the inclusion of caffeine and a sympathomimetic agent for the purpose of appetite suppression.[82] (Chapter 39 discusses dietary supplements.)

Medicinally, caffeine is used to treat neonatal apnea and bradycardia syndrome; as an analgesic adjuvant, particularly when combined with relatively mild analgesics such as acetaminophen, aspirin, and ibuprofen; and as an adjuvant treatment for migraine headaches, as well as postlumbar puncture headaches.

Theophylline, or its water-soluble salt aminophylline, is rarely used to treat respiratory conditions. Theophylline was used to treat reversible bronchospastic airway disease, particularly asthma and chronic obstructive pulmonary disease. Theophylline was once the mainstay of therapy for such diseases, but more selective agents with fewer side effects, such as albuterol and other selective $\hat{I}^2_2$ -adrenergic agonists, are now more commonly used. However, because antiinflammatory and other beneficial effects of theophylline have been described, its role in the treatment of pulmonary disease may again expand.[102] In neonates,

theophylline and aminophylline are used similarly to caffeine to treat neonatal apnea and bradycardia syndrome. The result of such treatment is increased respiratory rate, decreased apnea, increased cardiac chronotropy and inotropy, and increased cardiac output.[31]

Caffeine and theophylline toxicity may result from either iatrogenic or self-administration, and acute or chronic toxicity can occur in either circumstance. Chronic toxicity from caffeine is most typically described as a result of the frequent self-administration of caffeine. A particular syndrome associated with chronic caffeine use consisting of headache, palpitations, tachycardia, insomnia, and delirium is termed *caffeinism* . Chronic theophylline toxicity results from the use of theophylline as a medicinal therapeutic agent. Neonates receiving caffeine therapy may develop either acute or chronic caffeine toxicity.[7 , 17]

Most reported cases of theobromine poisoning occur in animals and typically result from small animals ingesting cocoa or chocolate.[50 , 54 , 80] Theobromine has become an ingredient of numerous â€œenergyâ€• drinks used for stimulation and athletic enhancement. No reports of human toxicity exist, but it would not be unexpected if toxicity from these sources are soon reported.

Use of Î²2 -adrenergic agonists is widespread. Adverse effects are associated with both therapeutic dosing and overdose. Excessive use of Î²2 -adrenergic agonists can result in tachyphylaxis, a phenomenon in which downregulation of receptors occurs and the effects from this drug diminishes as a result of excessive use.[43 , 92] Consequently, patients may require higher doses to achieve the same clinical effect they previously experienced at lower doses, resulting in more profound systemic side effects. The most common manifestation of selective Î²2 -adrenergic agonist toxicity occurs in children who ingest oral albuterol. Toxicity of terbutaline and ritodrine are infrequent but well-reported.

Pharmacology

Methylxanthines

Methylxanthines cause the release of endogenous catecholamines, resulting in stimulation of Î²$_1$ and Î²$_2$ receptors. The resulting adrenergic agonism is important in both their therapeutic effects and in their toxicity.[179] Levels of endogenous catecholamines are extremely elevated in patients with acute methylxanthines poisoning.[21]

Methylxanthines are structural analogs of adenosine and also function pharmacologically as adenosine antagonists. Adenosine is believed to modulate histamine release and cause bronchoconstriction, which may explain the clinical efficacy of adenosine antagonists in the treatment of bronchospasm. Additionally, adenosine antagonism results in release of norepinephrine, and to a lesser extent epinephrine.

At supratherapeutic doses, methylxanthines also inhibit phosphodiesterase, the enzyme responsible for degradation of intracellular cyclic adenosine monophosphate (cAMP). Phosphodiesterase inhibition was long considered to be the primary therapeutic mechanism of the methylxanthines, but clinically significant elevations in cAMP levels are not achieved until serum methylxanthine levels are well above the therapeutic range. This likely occurs as a result of the structural similarity of cAMP and methylxanthines. cAMP is involved in the postsynaptic second messenger system of Î²-adrenergic stimulation. Thus, elevated cAMP levels cause clinical effects similar to adrenergic stimulation, including smooth muscle relaxation, peripheral vasodilation, myocardial stimulation, and CNS excitation.

Selective Î²$_2$ -Adrenergic Agonists

Selective Î²$_2$ -adrenergic agonists act quite specifically at Î²$_2$ -

adrenergic receptors, resulting in an increase in intracellular cAMP. The effects of $\hat{I}^2_2$ agonism include relaxation of vascular, bronchial, and uterine

smooth muscle, glycogenolysis in skeletal muscle, and hepatic glycogenolysis and gluconeogenesis. These receptors are located in other areas, such as type II alveolar cells, mast cells, and lymphocytes, but their significance is unknown. Selective $\hat{I}^2_2$ -adrenergic agonists are characterized as either directly activating the $\hat{I}^2_2$ receptor, such as albuterol, being taken up into a membrane depot, such as formoterol, or interacting with a receptor-specific auxiliary binding site, such as salmeterol. These differences do not appear to be relevant in acute toxicity.[95]

Pharmacokinetics and Toxicokinetics

Caffeine

Pharmacokinetics

Caffeine is bioavailable by oral, intravenous, subcutaneous, intramuscular, and rectal routes of administration. Oral administration, which is by far the most common route of exposure, results in nearly 100% bioavailability of the drug. The presence of food in the gut does little to affect peak concentration. However, food in the gut does delay time until the peak plasma concentration is reached, which is typically 30â€“60 minutes in the absence of food. Caffeine rapidly diffuses into the total body water and all tissues, and readily crosses the bloodâ€“brain barrier and the placenta. The volume of distribution is 0.6 L/kg, and 36% is protein bound. Caffeine is secreted in breast milk.[177]

Caffeine exhibits Michaelis-Menten kinetics and is metabolized via the microsomal cytochrome P450 (CYP) system, primarily by the isozyme CYP1A2. The major pathway involves demethylation to

1,7-dimethylxanthine (paraxanthine) followed by hydroxylation or repeated demethylation followed by hydroxylation. To a lesser extent, caffeine is also metabolized to 3,7-dimethylxanthine (theobromine) and 1,3-dimethylxanthine (theophylline). Neonates demethylate caffeine, producing theophylline, and also possess the unique ability to convert theophylline to caffeine by methylation.[3,11,12,30,67] By approximately 4â€“7 months of age, infants metabolize and eliminate caffeine in a manner similar to adults.[10] All people metabolize some quantity of caffeine to active metabolites, including theophylline and theobromine. The degree to which this occurs is dependent on the age, cytochrome P450 enzyme induction status, and other factors. For this reason, there may be a role for assessment of serum theophylline concentration in the management of patients with suspected caffeine overdose, but such role is not clearly defined and obviously limited.

Less than 5% of caffeine is excreted in the urine unchanged. The half-life of caffeine is highly variable and dependent on several factors. Generally speaking, younger patients, particularly infants, as well as patients with cytochrome P450 inhibition, such as pregnant patients and patients with cirrhosis, have longer caffeine half-lives than the 4.5-hour half-life in healthy, adult, nonsmoking patients.[32,47,51,171]

Toxicokinetics

Caffeine toxicity is a dose-dependent phenomenon. Unfortunately, the range of toxicity reported in different references varies greatly, and no definite conclusions can be drawn regarding serum levels and symptomatology in overdose. Therapeutic dosing in adults is 100â€“200 mg orally every 4 hours; in neonates, a typical loading dose is 20 mg/kg, with daily maintenance dosing of 5 mg/kg. Based on case reports and series, lethal dosing in adults is estimated at 150â€“200 mg/kg, and death is associated with serum concentrations >80 Âµg/mL. Although numerous fatalities

occur with serum concentrations <200 Âµg/mL, survival of a patient with an acute caffeine overdose and a serum concentrations >400 Âµg/mL is also reported.[175] Infants survive toxicity with greater serum concentrations of caffeine than are tolerated by children and adults.

Theophylline

Pharmacokinetics

Theophylline is approximately 100% bioavailable by the oral route. Many of the available oral preparations are sustained-release, designed to provide stable serum concentrations over a prolonged period with less-frequent dosing. Peak absorption generally occurs 6â€“10 hours after ingestion. However, following overdose of sustained-release preparations, the time to peak absorption may take twice as long as that of the immediate release preparations.

Similar to caffeine, theophylline rapidly diffuses into the total body water and all tissues, readily crosses the bloodâ€“brain barrier and placenta, and is secreted into breast milk.[14 , 104 , 190 , 192] Theophylline's volume of distribution is 0.5 L/kg, and 56% of it is protein bound.

Theophylline is metabolized via the microsomal cytochrome P450 system, primarily by the isozyme CYP1A2. The major pathway is demethylation to 3-methylxanthine, in addition to being demethylated or oxidized to other metabolites. Less than 10% of theophylline is excreted in the urine unchanged.

Similar to caffeine, the half-life of theophylline is highly variable, and is dependent on several factors. In healthy, adult, nonsmoking patients, the half-life is 4.5 hours. Theophylline's half-life in infants and the elderly, as well as in patients with cytochrome P450 inhibition, pregnant patients, and patients with cirrhosis, is longer than in healthy children and adult nonsmoking patients.[88 ,

[117 , 170] Factors that induce cytochrome P450, such as cigarette smoking, and others that inhibit cytochrome P450, such as exposure to cimetidine, erythromycin, and oral contraceptives, can significantly alter theophylline clearance.[75 , 116 , 131 , 132 , 147 , 181] Decreased theophylline or caffeine metabolism or reversal of enzyme induction predisposes to the development of chronic toxicity.

Toxicokinetics

Like caffeine, theophylline exhibits Michaelis-Menten kinetics.[146] At higher doses and in overdose, it undergoes zero-order elimination, and only a fixed amount of the drug can be eliminated in a given time because of saturation of metabolic enzymes.[144]

Therapeutic serum concentrations of theophylline are 5â€“15 Âµg/mL; higher concentrations are considered toxic. Morbidity and mortality occur with relatively lower concentrations in chronic toxicity. Although morbidity and mortality are not always predictable based on serum concentrations, life-threatening toxicity, including seizures, ventricular dysrhythmias, and death, is associated with serum concentrations of 80â€“100 Âµg/mL in acute overdoses and serum concentrations of 40â€“60 Âµg/mL in chronic toxicity.

Theobromine

As is the case with the other methylxanthines, theobromine is well absorbed from the gut, and is 80% bioavailable when administered in solution. It is bioavailable orally, intravenously, and rectally. Theobromine has 21% protein binding, a volume of distribution of 0.62 L/kg, and a plasma half-life of 6â€“10 hours.[55 , 141] Theobromine undergoes hepatic metabolism by the CYP system similarly to

caffeine and theophylline.[29] Like the other methylxanthines,

theobromine is excreted in breast milk, and consumption of chocolate results in measurable concentrations in breast milk. Toxic concentrations of theobromine in animals are known, but comparable human data is lacking.

Selective Î²â‚‚ -Adrenergic Agonists

Pharmacokinetics

These agents are used inhalationally, orally, and parenterally. They are bioavailable by both the inhalational and enteral route, and much of â€œinhaledâ€• Î²â‚‚ -adrenergic agonists may actually be swallowed and absorbed from the GI tract. Absorption, distribution, and elimination vary among these agents. The half-life of albuterol is approximately 4 hours. Less than 5% crosses the bloodâ€“brain barrier. It is metabolized extensively in the liver, and excreted in urine and feces as albuterol and metabolites.[2]

Terbutaline is partially metabolized in the liver, mainly to inactive conjugates. With parenteral administration, 60% of a given dose is excreted in the urine unchanged.[1]

Toxicokinetics

Ingestion of Î²â‚‚ -adrenergic agonists, which happens predominantly in young children treated with oral albuterol preparations, can cause significant symptomatology.[101] For oral albuterol poisoning, 1 mg/kg appears to be the dose threshold for developing significant toxicity.[186]

Methylxanthine Pathophysiology

Caffeine, theobromine, and theophylline affect the same organ systems and cause qualitatively similar effects.

It should be noted, however, that there are distinct differences in the activity and effects of the various methylxanthines, particularly in therapeutic dose. The major clinical effects at both therapeutic doses and in overdose result from adenosine antagonism, release of endogenous norepinephrine and consequent Î²-adrenergic receptor stimulation, and phosphodiesterase inhibition. Toxicity affects the gastrointestinal, cardiovascular, central nervous, and musculoskeletal systems, in addition to causing a constellation of metabolic derangements. Polypharmacy poisoning with methylxanthines and other agents that result in adrenergic stimulation, such as ephedrine, amphetamines, or cocaine, may be particularly severe.[52 , 184]

Theobromine toxicity is exceedingly rare. There are limited human data, and most published cases are actually veterinary. Animals with theobromine poisoning may experience emesis, incontinence, restlessness, excitement, tachycardia, seizures, coma and death. These characteristic symptoms, as well the pharmacologic similarity between theobromine and other methylxanthines, dictates that management principles for caffeine and theophylline be applied in cases of theobromine toxicity.

Toxicity

Gastrointestinal

In overdose, methylxanthines cause nausea, and most significant acute overdoses result in severe and protracted emesis. Emesis occurs in 75% of cases of acute theophylline poisoning, whereas only 30% of cases of chronic poisoning are characterized by emesis.[163] This emesis is often quite severe and may be difficult to control despite the use of potent antiemetics. This is especially evident with sustained-release theophylline preparations.[5]

Methylxanthines cause an increase in gastric acid secretion and smooth muscle relaxation. These factors contribute to the gastritis

and esophagitis reported in chronic methylxanthine users.[42] Gastritis is noted in drinkers of decaffeinated coffee, so some of the adverse gastric effects associated with coffee drinking may be a result of ingredients other than caffeine alone.

Cardiovascular

Methylxanthines are cardiac stimulants that result in positive inotropy and chronotropy. Dysrhythmias, particularly tachydysrhythmias, are common in methylxanthine overdose. As a result of their adenosine antagonism, supraventricular tachycardias (SVTs) commonly occur in overdose. Tachydysrhythmias, particularly ventricular extrasystoles, are uncommon following therapeutic doses, whereas they are common in overdose.[39 , 124 , 157] In the setting of acute poisoning, generally benign sinus tachycardia is nearly universal in patients without antecedent cardiac disease. In any patient, particularly a patient with underlying cardiac disease, a sinus tachycardia can degenerate to a more severe rhythm disturbance, which is the most common cause of fatality associated with methylxanthines poisoning. Both atrial and ventricular dysrhythmias including SVT, multifocal atrial tachycardia, atrial fibrillation, premature ventricular contractions, and ventricular tachycardia, can result from methylxanthine toxicity.[20 , 160] Electrolyte disturbances, particularly hypokalemia, may be a contributing factor in the development of dysrhythmias. Dysrhythmias occur more commonly and at lower serum concentrations in cases of chronic poisoning. Consequential dysrhythmias occur in 35% of chronic theophylline poisonings, but in only 10% of acute poisonings.[160] These dysrhythmias occur at serum levels of 40â€“80 Âµg/mL in chronic theophylline overdoses, and most commonly at serum levels greater than 80 Âµg/mL in acute overdose. Neonates born to mothers who consumed >500 mg/d of caffeine are more likely to have dysrhythmias than are neonates born to mothers who consumed <250 mg/d of caffeine.[76] Myocardial ischemia and

myocardial infarction may result from acute caffeine or theophylline poisoning.[61, 81, 119]

Tolerance to the pressor effects of methylxanthines develops after several days of use and rapidly disappears after relatively brief periods of abstinence.

At elevated serum concentrations, methylxanthines will result in peripheral vasodilation, causing a characteristic widened pulse pressure. One major mechanism by which hypotension occurs is $Î^2_2$ -adrenergic agonism. In cases of acute theophylline overdose, serum concentrations >100 Âµg/mL are usually associated with severe hypotension.

In therapeutic doses, methylxanthines cause cerebral vasoconstriction, which is a desirable effect when caffeine is used to treat a migraine headache. However, in overdose, this effect likely exacerbates CNS toxicity by diminishing cerebral perfusion.[119] Methylxanthines cause renal vasodilation, which, in addition to the increased cardiac output, results in a mild diuresis.[133]

It has been noted that dietary caffeine use is associated with a slight, but relevant, increase in blood pressure that may contribute to population levels of morbidity and mortality.[91]

Pulmonary

Methylxanthines stimulate the CNS respiratory center, causing an increase in respiratory rate. For this reason, caffeine and theophylline are used to treat neonatal apnea syndromes. Caffeine and theophylline overdose can cause hyperventilation, respiratory alkalosis, respiratory failure, respiratory arrest, and acute lung injury.

Neuropsychiatric

The stimulant and psychoactive properties of methylxanthines, particularly caffeine, elevate mood and improve performance of manual tasks.[24, 34, 90] These stimulant effects are typically considered desirable, and are one reason why caffeine is so widely used. CNS stimulation is an effect sought by users of coffee, tea, cocoa, and chocolate, but CNS stimulation resulting from therapeutic use of theophylline is generally considered to be an undesirable side effect. Caffeine is an effective analgesic adjuvant, possibly because of the stimulant properties of the drug.[123, 125, 154, 155]

Although at low doses methylxanthines improve cognitive performance and elevate mood, with increasing doses they result in adverse effects. Headache, anxiety, agitation, insomnia, tremor, irritability, hallucinations, and seizures can occur with caffeine or theophylline poisoning. In adults, caffeine doses of 50â€“200 mg result in increased alertness, decreased drowsiness, and lessened fatigue, and caffeine doses of 200â€“500 mg produce adverse effects. Children tend to develop CNS symptoms at lower serum theophylline concentrations than adults, and this excitation is a significant clinical disadvantage of theophylline use.

Seizures are a major complication of methylxanthine poisoning. The additional methyl group possessed by caffeine (1,3,7-trimethylxanthine) affords this agent greater CNS penetration relative to theophylline and theobromine, which are dimethylxanthines. Caffeine's ability to both promote and prolong seizures is well recognized, and caffeine has been used to prolong therapeutically induced seizures in electroconvulsive therapy.[49, 99] Seizures resulting from methylxanthines overdose tend to be severe and recurrent, and may be refractory to treatment. Antagonism of adenosine, the endogenous neurotransmitter responsible for halting seizures, contributes to the profound seizures associated with methylxanthine overdose.[56, 62, 161, 191]

When studied prospectively, chronic theophylline toxicity results in seizures in 14% of patients, whereas 5% of acutely poisoned patients experience seizures. In cases of chronic and acute-on-chronic toxicity, seizures are more likely to occur, and they typically occur at lower serum concentrations.[135] Patients at extremes of age, younger than 3 years and older than 60 years, are also more likely to experience seizures with overdose.

Musculoskeletal

Methylxanthines increase intracellular calcium content and increase striated muscle contractility, secondarily decreasing muscle fatigue. They also increase muscle oxygen consumption and increase the basal metabolic rate. These effects are sought by users of methylxanthines to enhance or improve athletic performance or lose weight.[9, 18, 41, 57, 71, 70] Theobromine has the most potent activity on the muscles, over 100 times that of caffeine, and theophylline has the least muscle-stimulating activity. All methylxanthines cause smooth muscle relaxation.

Tremor is the most common adverse effect from methylxanthines. Skeletal muscle excitation, which may include fasciculation, hypertonicity, myoclonus, or even rhabdomyolysis, can occur with methylxanthine overdose.[105, 115, 137, 149, 189] Mechanisms by which rhabdomyolysis may result include increased muscle activity, particularly from seizures, and direct cytotoxicity from excessive sequestered intracytoplasmic calcium. Interestingly, there are multiple case reports of compartment syndrome with rhabdomyolysis resulting from theophylline overdose.[114, 176]

Metabolic

Numerous metabolic derangements may result from acute methylxanthine toxicity, and are similar to other states of excess adrenergic agonism or increased metabolism.[75, 78, 153, 162]

Severe hypokalemia can result from Î²2 -adrenergic stimulation.[178] This results from influx of extracellular potassium into the intracellular compartment despite normal total body potassium content. Both electrocardiographic and neuromuscular complications of hypokalemia may develop. Other effects of Î²2 -adrenergic agonist poisoning include hypomagnesemia, hypophosphatemia.[28 , 101 , 183]

Transient hypokalemia resulting from Î²2 -adrenergic agonism occurs in 85% of patients with acute theophylline overdose, and typically the serum potassium concentration falls to approximately 3 mEq/L.[4 , 165] Stimulation of Na^+ -K^+ -adenosine triphosphatase (ATPase) results in a shift of serum potassium to the intracellular compartment of skeletal muscle. This hypokalemia is only a shift of potassium from the extracellular to the intracellular compartment, not a loss of potassium, and total body potassium stores are unchanged. The significance of hypokalemia in patients with methylxanthine overdose is unclear. Vomiting and renal losses do not contribute significantly to hypokalemia, but these may result in fluid loss. Hyperkalemia may result from overly aggressive repletion of potassium or from rhabdomyolysis.

Metabolic acidosis with increased serum lactate levels is commonly noted as a complication of theophylline overdose.[23 , 109] Tachypnea and respiratory alkalosis secondary to stimulation of the respiratory center may be contributory.

Hyperglycemia, with serum glucose of approximately 200 mg/dL, is common and occurs in 75% of acute theophylline overdoses. Hypophosphatemia, hypomagnesemia, hypocalcemia, hypercalcemia, and ketosis may also result from methylxanthines toxicity.[151] Hyperthermia caused by increased metabolic and muscle activity may result from caffeine and theophylline overdose. Leukocytosis, probably secondary to the high levels of circulating catecholamines, results from acute methylxanthine overdose. This phenomenon apparently lacks clinical significance.

In the absence of seizures or protracted emesis, chronic methylxanthine poisoning does not typically lead to metabolic derangements because such toxicity is an ongoing, compensated process.

Chronic Toxicity

The major difference between acute and chronic toxicity is the duration of exposure to the drug. Patients with chronic toxicity may manifest subtle signs such as anorexia, nausea, palpitations, or emesis, although they may also present with seizures or dysrhythmias.

The patient chronically receiving theophylline or caffeine has higher total body stores, and also often has underlying medical disorders, and may develop toxicity with a smaller amount of additional theophylline or caffeine. Chronic methylxanthine poisoning typically occurs in the setting of therapeutic use of theophylline, and may occur with iatrogenic administration of caffeine or from frequent, chronic consumption of caffeinated products. Patients often manifest subtle signs of illness, such as anorexia, nausea, palpitations, or emesis. However, the initial presentation in these patients, even with theophylline concentrations in the 40â€“60 Âµg/mL range, may be a seizure. In children chronically overdosed with theophylline, the peak serum theophylline concentration may fail to identify those who will progress to life-threatening toxicity. In the absence of protracted emesis or seizures, the initial electrolytes and blood gases are expected to be normal in patients with chronic methylxanthine toxicity.

Chronic Use

An inconclusive link to cancer, heart disease, osteoporosis, hyperlipidemia, and hypercholesterolemia are associated with

use.[60, 63, 74, 145, 187] Excessive consumption of caffeine-containing beverages can cause hypokalemia.[148]

Debate centers on the psychiatric and cognitive effects of chronic theophylline use, particularly in children.[113] To date, evidence suggests that although theophylline may acutely result in excessive CNS stimulation and hyperactivity, chronic use of methylxanthines does not adversely affect children's cognitive development.[19]

Caffeinism

Caffeinism is a syndrome of chronic toxicity resulting from excessive caffeine consumption. It may involve anxiety, palpitations, tremulousness, tachycardia, diuresis, headache, and diarrhea.[180] Patients suffering caffeinism also experience withdrawal symptoms upon abstinence. The chronic toxicity from excessive caffeine use, caffeinism, is a distinctly different entity from caffeine withdrawal.

Caffeine Withdrawal

Caffeine induces tolerance and a withdrawal syndrome, including headache, yawning, nausea, drowsiness, rhinorrhea, lethargy, irritability, nervousness, a disinclination to work, and depression, may result on abstinence.[173] Caffeine withdrawal symptoms are described in neonates born to mothers with consequential caffeine use.[121] The onset of caffeine withdrawal symptoms begins 12â€“24 hours after cessation of caffeine use, and lasts up to 1 week.[73] In a double-blind trial, 52% of adults with moderate caffeine intake developed a withdrawal syndrome on caffeine abstinence.[168]

Reproduction

Massive doses of methylxanthines are teratogenic, but the doses of typical use are not associated with birth defects. Decreased fecundity and adverse fetal outcome are noted in animals with chronic exposure to methylxanthines.[64, 68, 120] Human studies of fertility, fetal loss, and fetal outcome produce divergent results, and the effects of methylxanthines use during gestation are unclear.[87, 94, 126, 130]

Selective Î²2 -Adrenergic Agonist Pathophysiology

Gastrointestinal

Nausea and emesis are common adverse effects of selective Î²2 adrenergic agonist toxicity. Gastrointestinal symptoms of selective Î²2 -adrenergic agonist toxicity are not as severe as those resulting from methylxanthine toxicity and are not expected to require antiemetic therapy.

Cardiac

These drugs increase chronotropy and, in both therapeutic dose and overdose, result in tachycardia. Cardiac dysrhythmias, although described with Î²2 -adrenergic agonist poisoning, are usually supraventricular in origin and clinically inconsequential. Dysrhythmias other than sinus tachycardia should not be routinely attributed to Î²2 adrenergic agonist toxicity until other causes have been excluded.

Myocardial infarction is associated with both albuterol and isoproterenol.[58] Isoproterenol, once a common asthma therapy prior to widespread use of selective Î²2 -adrenergic agonists, has Î²1 - and Î²2 -adrenergic agonist activity and is a well-reported

cause of myocardial infarction. Given the frequency of use of selective Î²2 -adrenergic agonists, as well as toxicity and adverse effects, it seems that myocardial infarction is unlikely to occur with toxicity, but these reports clearly warrant caution about the possibility.

Elevation of the muscle fraction enzyme of creatine phosphokinase (CPK-MM) and of the myocardial band enzymes of creatine phosphokinase (CPK-MB) after large doses of Î²2 -adrenergic agonists, particularly terbutaline infusions and continuous albuterol nebulization, is well described.[44 , 45 , 174] The clinical significance of increased CPK-MB and cardiac troponin in patients receiving terbutaline infusions is unclear and has not been demonstrated to correlate clinically with adverse effects.[40]

Metabolic

Severe hypokalemia can result from Î²2 -adrenergic stimulation because of an influx of extracellular potassium into the intracellular compartment, despite normal total body potassium content. Both electrocardiographic and neuromuscular complications of hypokalemia may develop. This hypokalemia is only a shift of potassium from the extracellular to the intracellular compartment, not a loss of potassium, and total body potassium stores are unchanged. Other effects of Î²2 -adrenergic poisoning include hypomagnesemia and hypophosphatemia.

Diagnostic Testing

An ECG, serum electrolytes, and a serum caffeine or theophylline concentration, as appropriate, are indicated in cases of suspected methylxanthine toxicity. Because toxicity is dose related in acute overdose, serum concentrations of caffeine and theophylline may be loosely applied as a correlate with toxicity.

Some degree of methylation and demethylation of methylxanthines

may occur in patients of all ages, and one methylxanthine poisoning may result in a small elevation in the serum concentration of another methylxanthine metabolite. Overdose of caffeine may result in a spuriously elevated serum measurement for theophylline.[59 , 95] However, the utility of a serum theophylline concentration in cases of caffeine toxicity is undemonstrated; consequently, at this time, such concentrations should not be obtained.

Theophylline concentrations, and to a lesser extent caffeine concentrations, may be used to guide management of poisoning with the respective agents. For these concentrations to be maximally useful, it is important to know whether they reflect acute or chronic poisoning. In the setting of toxicity, serum methylxanthines concentrations should be obtained immediately and then serially every 1â€“2 hours until a downward trend is evident.

Unfortunately, serum caffeine concentrations are usually readily available only in institutions in which neonates are therapeutically treated with caffeine. Serum theophylline concentration is a more readily available laboratory assay, and the greater clinical experience with theophylline in therapeutic dose and in overdose provides a more established correlation between serum theophylline concentration and symptomatology.

Likewise, serum electrolytes, particularly potassium, should be monitored serially as long as the poisoned patient remains symptomatic and such values are in a range that may warrant treatment. Cardiac monitoring should continue until the patient is free of dysrhythmias other than sinus tachycardia, the patient has a decreasing serum methylxanthine level, and the patient is stable. In

patients with systemic illness, hyperthermia, or increased muscle tone, assessing serum creatine phosphokinase (CPK) and urinalysis

to detect rhabdomyolysis are also indicated.

Management

General Principles and Gastrointestinal Decontamination

After assuring adequacy of airway, breathing, and circulation, supportive care and maintenance of vital signs within acceptable limits are the mainstay of therapy for methylxanthine and selective Î²2 -adrenergic agonist toxicity. Decisions regarding gastrointestinal decontamination, including orogastric lavage, administration of activated charcoal, and whole-bowel irrigation, depend on the dosage and type of preparation involved, time since exposure, and the patient's physical condition. Activated charcoal is the only gastrointestinal decontamination that should be routinely considered for selective Î²2 -adrenergic agonist ingestions.

Emesis

Induced emesis is not indicated for selective Î²2 -adrenergic agonist ingestion and should only rarely be considered for minimally symptomatic patients whose methylxanthine ingestions occurred less than 1 hour earlier. A simulated overdose, controlled, volunteer study with sustained-release theophylline was unable to demonstrate reduction of absorption of theophylline in patients treated with syrup of ipecac.[130] Seizures are possible with any significant methylxanthine poisoning, and emesis in a patient experiencing a seizure is an obvious danger. Because the benefits of emetics are undemonstrated and emesis interferes with administration of activated charcoal, induced emesis is rarely considered for methylxanthine poisoning.[6 , 158]

Orogastric Lavage

Orogastric lavage may be considered for patients with potentially toxic methylxanthine ingestions and in patients who require endotracheal intubation. Orogastric lavage may not be effective in removing theophylline tablets, probably because of the large size of the tablets relative to the lumen of the orogastric tube. Selective Î²$_2$ -adrenergic agonist liquid ingestion that occurs within 1 hour prior to treatment may warrant aspiration through a nasogastric tube.

Ingestion of sustained-release theophylline tablets is associated with the formation of bezoars that may be difficult to remove or dislodge. Treatment in such cases has included endoscopic removal.[37]

Activated Charcoal

Activated charcoal may play an important role in the treatment of methylxanthine poisoning and selective Î²$_2$ -adrenergic agonists present in the GI tract prior to absorption, limiting the absorption of a given dose. Although multiple-dose activated charcoal (MDAC) is helpful in the management of methylxanthine toxicity, it is not indicated for selective Î²$_2$ -adrenergic agonist ingestion. MDAC enhances elimination of theophylline by gut dialysis. Such enhanced elimination by gut dialysis is not demonstrated, experimentally or otherwise, for caffeine or theobromine toxicity. Because caffeine is to some extent metabolized to theophylline, in cases of caffeine poisoning, MDAC would, at the very least, enhance elimination of theophylline metabolites. The pharmacologic similarity of the methylxanthines and the relative safety of MDAC therapy warrant the use of such treatment for any methylxanthine toxicity. MDAC is discussed in â€œEnhanced Eliminationâ€• later in this chapter.

Whole-Bowel Irrigation

Treatment of patients with significant ingestions of sustained-release pills may include whole-bowel irrigation (WBI) with a balanced electrolyte solution to enhance gastrointestinal elimination (Antidotes in Depth: Whole-Bowel Irrigation and Other Intestinal Evacuants). Polyethylene glycol electrolyte lavage solution used for WBI may displace theophylline already bound to charcoal.[84] This may be a particular problem in patients who have taken several doses of activated charcoal prior to WBI, in which desorption of methylxanthines from activated charcoal can result in a bolus of methylxanthines available for gastrointestinal absorption. Also, WBI is experimentally demonstrated to provide no additional benefit to activated charcoal in treatment of sustained-released theophylline ingestion.[36] Despite this data, WBI remains the recommended treatment of a patient with an ingestion of sustained-release theophylline.

Selecting a Method of Decontamination

The use of decontamination methods that involve more than minimal risk, specifically orogastric lavage, should only occur after careful consideration of the indications. Potentially life-threatening acute ingestions occurring not more than 1 hour earlier can be treated with orogastric lavage.

Treatment of Gastrointestinal System Toxicity

Phenothiazine antiemetics are contraindicated in methylxanthine poisoning because they are typically ineffective and may lower the seizure threshold. Metoclopramide may be used, but a more potent 5-HT_3 antagonist antiemetic such as ondansetron or granisetron may be required.[48 , 142 , 152] Histamine (H_2) blockers or proton pump inhibitors may be administered to any patient with

hematemesis. Cimetidine is contraindicated because it inhibits CYP450, delaying clearance of methylxanthines.

Treatment of Cardiovascular Toxicity

Hypotension should initially be treated by administration of isotonic intravenous fluid, such as 0.9% sodium chloride solution or lactated Ringer solution, in bolus volumes of 20 mL/kg. If acceptable blood pressure cannot be maintained despite several fluid boluses, or if there are contraindications to fluid bolus, vasopressor therapy should be considered.

Methylxanthine and selective Î²$_2$ -adrenergic agonist toxicity may cause hypotension via Î²$_2$ -adrenergic agonism, therefore administration of vasopressors with Î²$_2$ -adrenergic agonist effects such as epinephrine, dobutamine, or isoproterenol are not preferable. A pure Î±-adrenergic agonist such as phenylephrine is the first-line pressor of choice in such a situation, although norepinephrine is also acceptable (Table 63-1).

Hypotension may be refractory to treatment with intravenous fluid and vasopressor therapy, and in such cases the administration of a Î²-adrenergic antagonist may be warranted.[53] Administration of a Î²-adrenergic antagonist to a hypotensive patient may seem counterintuitive. Methylxanthine-induced hypotension is to a significant extent mediated by Î²$_2$ -adrenergic vasodilation. Nonselective Î²-adrenergic antagonists suppress Î²$_2$ -adrenergic stimulation. In addition, Î²$_1$ -adrenergic antagonism treats tachycardia and any decreased cardiac output that may result from inefficient cardiac

activity. In canines with aminophylline-induced tachycardia and hypotension, administration of esmolol results in a return to normal heart rate and blood pressure, and does not exacerbate hypotension.[65] Propranolol, esmolol, and metoprolol have been used successfully to treat methylxanthine-induced hypotension.[25] ,

[139] It is most appropriate to use a Î²-adrenergic antagonist with a brief duration of action, such as esmolol at least initially, in such circumstances. In the event of an adverse reaction or side effect such as hypotension or bronchospasm, the duration of such a Î²-adrenergic antagonist will be relatively brief. Ideally, any Î²-adrenergic antagonist therapy should be preceded and accompanied by measurement of cardiac output and central venous blood pressure with a device such as a pulmonary artery catheter or a transcutaneous bioinpedance device.[100]

System	Indication	Therapeutics	Comments

TABLE 63-1. Therapeutics for Methylxanthines and Selective Î²2 -Adrenergic Agonist Poisoning

In situations where drug toxicity is not in question, adenosine or electrical cardioversion are the preferred treatment for SVT, but this is not so for SVT resulting from methylxanthine toxicity. Because of the antagonist effects, administration of adenosine should not be expected to convert a methylxanthine-induced SVT. However, even if adenosine is successfully used to convert an SVT, the effect is likely to be transient. Because methylxanthine toxicity has a global effect on the myocardium, cardioversion, which is effective in electrically â€œreorganizingâ€• depolarization, is unlikely to work, as this SVT does not result from a single locus of aberrant electrical activity.

Primary treatment for methylxanthine-induced SVT includes administration of benzodiazepines, which work to abate CNS stimulation and concomitant release of catecholamines. More focused pharmacologic therapy to treat SVT would be through administration of a conduction-attenuating calcium channel blocker such as diltiazem.

In animal models, treatment of acute theophylline toxicity with the calcium channel blockers verapamil, diltiazem, and nifedipine results in decreased cardiac-related deaths and prevents dysrhythmias, hypotension, myocardial necrosis, and seizures.[185] In addition to their cardiovascular benefit, calcium channel blockers may also afford some neurologic protection and prevent seizures. In the nonasthmatic patient, methylxanthine-induced supraventricular tachycardia and other tachydysrhythmias may be treated by administration of a Î²-adrenergic antagonist.

Correction of hypokalemia may be crucial in methylxanthine poisoning associated with ventricular dysrhythmias. Hypokalemia is a well-described consequence of excess adrenergic agonism, including poisoning from methylxanthines and sympathomimetic

agents. In the absence of associated dysrhythmia, the clinical significance of such hypokalemia is unclear. Such hypokalemia has been experimentally demonstrated to respond to treatment with Î²-adrenergic antagonists.

Treatment of Central Nervous System Toxicity

Administration of a benzodiazepine, such as diazepam or lorazepam, is appropriate treatment for anxiety, agitation, or seizure. The seizures associated with methylxanthine toxicity are severe and often refractory to treatment. Seizures not controlled with one or two therapeutic doses of a benzodiazepine should be treated with a barbiturate such as pentobarbital or phenobarbital, or another suitable sedative-hypnotic such as propofol. No delay should occur before administering such medications. Unsuccessful treatment of methylxanthine-induced seizures with any particular drug should quickly be abandoned in favor of treatment with an additional or more efficacious anticonvulsant. The administration of barbiturates may result in or exacerbate hypotension. Treatment of any aforementioned problem with benzodiazepines, barbiturates, or other sedative-hypnotic may require repeated dosing until clinical effect is achieved.

Administration of phenobarbital to prevent seizures in theophylline-poisoned rabbits and mice increased survival by decreasing the incidence of seizures.[46, 69] Although historically phenobarbital was the recommended drug for such prophylaxis, use of a benzodiazepine, such as lorazepam, seems preferable. Patients at risk for seizure include patients older than 60 years or

younger than 3 years of age; those with chronic overdose and a serum concentration of 40â€“60 Âµg/mL; and acutely overdosed patients with serum levels >100 Âµg/mL.

Phenytoin and fosphenytoin are of no benefit in controlling methylxanthine-induced seizures and they have no role in such treatment.[83 , 118] Retrospective review of human cases demonstrated phenytoin to be ineffective in treating seizures in 21 of 22 cases.[89] Phenytoin is ineffective in the treatment of seizures, results in the occurrence of seizures at an earlier time after overdose, and results in higher mortality when administered to theophylline-poisoned mice.[26]

Treatment of Metabolic Derangements

Patients with symptomatic hypokalemia or hypocalcemia should be treated accordingly. Most cases of mild hypokalemia are well tolerated, but any patient with symptomatic hypokalemia, particularly those associated with ECG changes of T waves or QTc prolongation, should be treated. The frequency of ventricular dysrhythmias in methylxanthine poisoning, may be exacerbated by hypokalemia coupled with increased intrinsic catecholamine release. There is no specific level of hypokalemia that absolutely necessitates treatment.

Cautious administration of potassium to treat symptomatic hypokalemia may be indicated, but this is distinct from higher doses of potassium used in total body potassium repletion. In cases of hypokalemia secondary to Î²-adrenergic agonism, after the Î²-adrenergic agonism returns to baseline, an efflux of potassium from the intracellular compartment occurs along with a concomitant rise of the serum potassium concentration. Overly aggressive attempts to correct hypokalemia may result in hyperkalemia after the Î²-adrenergic agonist effects abate. Acute methylxanthine-induced hypokalemia may be treated with potassium supplementation, but because of the nature of the

problem, excess Î²-adrenergic agonism, potassium supplementation is typically ineffective.

Experimentally, administration of propranolol to theophylline-poisoned dogs prevented or partially reversed hypokalemia, hypophosphatemia, hyperglycemia, and metabolic acidosis, as well as hypotension.[98] Prevention or correction of the metabolic derangements associated with theophylline toxicity by administration of a Î²-adrenergic antagonist is congruent with the fact that these derangements, particularly hypokalemia, are the consequence of Î²-adrenergic agonism. The efficacy of Î²-adrenergic antagonists as therapy for hypokalemia resulting from acute methylxanthine poisoning in humans has not been studied.

The importance of treating hypomagnesemia, hypophosphatemia, and hypocalcemia must be addressed depending on the extent and clinical manifestation as they would for other patients experiencing them. As with hypokalemia, QTc prolongation is an absolute indication for treatment.

Hyperglycemia, likely resulting from increased circulating catecholamines, is common. This hyperglycemia does not necessitate treatment with any type of hypoglycemic agent, both because it is a transient effect and because, in other situations of hyperglycemia resulting from adrenergic agonism, a rebound hypoglycemia may occur.

Treatment of Musculoskeletal Toxicity

The use of benzodiazepines is appropriate treatment for fasciculations, hypertonicity, myoclonus, or rhabdomyolysis. Rhabdomyolysis necessitates aggressive intravenous fluid therapy, possibly with sodium bicarbonate (Antidotes in Depth: Sodium Bicarbonate).

Enhanced Elimination

Fortunately, methylxanthine toxicity lends itself well to several methods of enhanced elimination, including gut dialysis with MDAC, charcoal hemoperfusion, and hemodialysis, as well as lesser-used methods such as continuous arteriovenous hemoperfusion (CAVHP), and plasmapheresis.[16 , 106 , 112]

Infants with methylxanthine poisoning may be too ill, unstable, or small to be treated with hemodialysis or hemoperfusion. Both MDAC and exchange transfusion are effective methods of enhanced elimination in infants, and may be the preferred method of treatment in these patients.[136 , 138 , 166 , 164]

The therapeutic effects of activated charcoal in such cases are much greater than simply limiting absorption of ingested methylxanthines. Activated charcoal, particularly MDAC, allows elimination of theophylline, by way of gastrointestinal dialysis.[13] MDAC is extremely effective in enhancing elimination of theophylline.[22 , 66 , 111 , 134] Experimentally in dogs, rabbits, and human volunteers, activated charcoal administered after IV aminophylline administration resulted in increased systemic clearance and decreased half-life of theophylline.[86 , 103 , 122 , 140] The pharmacologic similarity of the methylxanthines suggest that MDAC may be effective in gut dialyzing caffeine or theobromine, and MDAC certainly will be effective in eliminating any theophylline generated from metabolism of caffeine or theobromine. The efficacy of MDAC, combined with the safety and ease with which this therapy can be administered, makes MDAC the mainstay of enhanced elimination in methylxanthine toxicity. Severe emesis associated with methylxanthine poisoning may result in intolerance of MDAC, and in case series has been shown to necessitate abandonment of MDAC for definitive enhancement of methylxanthine elimination by charcoal hemoperfusion (Antidotes in Depth: Activated Charcoal).[159]

Charcoal hemoperfusion is an effective method of enhanced

elimination of methylxanthines, decreasing theophylline's half-life to 2 hours and increasing its clearance possibly up to 6-fold.[35, 129, 150, 188] Variations of charcoal hemoperfusion, including albumin colloid hemoperfusion, resin hemoperfusion, and charcoal hemoperfusion, in series with hemodialysis, are reported.[38, 85, 107, 143, 172]

Charcoal hemoperfusion in series with hemodialysis may be superior to either method alone because it extends the life of the charcoal hemoperfusion cartridge, increases overall methylxanthine extraction and clearance, and allows fluid and electrolyte abnormalities to be corrected. Charcoal hemoperfusion is typically less readily available and somewhat more complicated than hemodialysis, which may influence selection between charcoal hemoperfusion and hemodialysis as therapy options. Combined hemodialysis and MDAC is an easily performed regimen that provides superior theophylline clearance to hemodialysis alone.

Although employed as an effective treatment modality, hemodialysis has always been less efficient than hemoperfusion in the extracorporeal removal of methylxanthines.[8, 108, 110, 169] Traditionally, hemodialysis was not preferred because methylxanthine elimination rates by hemodialysis were much lower than that those achieved by charcoal hemoperfusion and even lower than MDAC, a much safer, easier, noninvasive method.

Improvement of hemodialysis equipment allows blood flow rates as much as 2 times greater than in the recent past, and has tremendously increased the potential rates of methylxanthine clearance by hemodialysis. As a result, the difference in elimination achieved by hemoperfusion and hemodialysis is insignificant. This fact, in combination with the ability of hemodialysis to correct fluid and electrolyte imbalances, the greater availability of hemodialysis, greater technical ease, and lower complication rates, are resulting in a paradigm shift from considering charcoal hemoperfusion to be the definitive treatment

for significant methylxanthine toxicity to one in which charcoal hemoperfusion and hemodialysis are considered equivalent treatment options.[167]

In the treatment of methylxanthine poisoning, the specific indications for therapy to enhance elimination are not agreed upon. Several studies and clinical experience are the basis for the following suggested indications for extracorporeal elimination by charcoal hemoperfusion, hemodialysis, combined charcoal hemoperfusion/hemodialysis or combined hemodialysis and MDAC.

Most cases of methylxanthine toxicity and overdoses occur with theophylline, and theophylline concentrations tend to be both readily available and to correlate with toxicity. Therefore, many recommendations regarding hemoperfusion and/or hemodialysis for theophylline toxicity use serum theophylline concentration as a guideline. Serum concentrations may not be available in instances of caffeine poisoning and do not exist for theobromine poisoning. The clinical aspects of theophylline management guidelines can be generalized to all methylxanthines.

When indicated, charcoal hemoperfusion and/or hemodialysis should be initiated while patients are still hemodynamically stable, or considered alternately, while they are stable. Charcoal hemoperfusion and/or hemodialysis therapy should be considered for chronic theophylline poisoning associated with a serum theophylline concentration >40â€“60 Âµg/mL or with a deteriorating clinical status.

Charcoal hemoperfusion and/or hemodialysis should be performed any time a methylxanthine exposure results in a serum theophylline concentration >90 Âµg/mL and symptoms, regardless of clinical stability (Table 63-2). Any methylxanthine exposure resulting in a serum theophylline concentration >40 Âµg/mL that is associated with ventricular dysrhythmias, seizures, hypotension unresponsive to fluids, or emesis unresponsive to antiemetics should also be treated with charcoal hemoperfusion and/or

hemodialysis.

TABLE 63-2. Methylxanthine Poisoning: Indications for Charcoal Hemoperfusion and/or Hemodialysis

Seizures, dysrhythmias, or hemodynamic instability are not contraindications for extracorporeal drug removal. To the contrary, these events make administration of such therapy more critical to ensure survival of the patient.

Treatment of Chronic Methylxanthine Toxicity

Treatment of chronic methylxanthine toxicity is determined by the patient's clinical status and by the efficacy of MDAC. The precise serum theophylline or caffeine concentration at which patients with chronic theophylline or caffeine toxicity should receive activated charcoal hemoperfusion or hemodialysis is controversial. For a hemodynamically stable patient without signs of life-threatening methylxanthine toxicity such as ventricular dysrhythmias or seizures, therapy with MDAC may be sufficient. If the serum theophylline or caffeine concentration does not decline following the administration of activated charcoal, or if the patient's clinical status deteriorates, charcoal hemoperfusion or hemodialysis is indicated.

Treatment of Acute-On-Chronic

Methylxanthine Toxicity

Patients chronically receiving theophylline or caffeine who acutely overdose should be initially managed in the same manner as patients with acute overdose, although action concentrations for dialysis are the same as for chronic toxicity. Because total body stores of the methylxanthines are higher in patients who are chronically exposed, the threshold for toxicity may be reached at lower serum concentrations.

Summary

Selective $Î^2_2$ -adrenergic agonists are widely used for the treatment of bronchospasm. Methylxanthines are ubiquitously used by cultures throughout the world. Selective $Î^2_2$ -adrenergic agonist toxicity results from medicinal use of these xenobiotics, and methylxanthine toxicity results from the use of xenobiotics as well as from consumption of methylxanthine-containing foods and beverages. There are significant differences in the clinical presentation and management of patients with acute and chronic methylxanthine poisoning. Supportive care and treatment of gastrointestinal, cardiovascular, CNS, metabolic, and musculoskeletal toxicities are the mainstay of therapy. The unique properties of methylxanthines necessitate specific therapies for the gastrointestinal, cardiovascular, and CNS toxicities of methylxanthines. With some unique exceptions, selective $Î^2_2$ -adrenergic agonist toxicity is usually well tolerated and only requires supportive care. Methods of enhanced elimination, particularly extracorporeal elimination by activated

charcoal hemoperfusion, hemodialysis, or activated charcoal hemoperfusion and hemodialysis in series, as well as gut dialysis with MDAC, are effective treatments for methylxanthine toxicity.

Chapter 64
Local Anesthetics

David R Schwartz

Brian Kaufman

A 30-year-old woman presented to the emergency department 4 hours after she had undergone a laser epilation treatment. In preparation for the procedure, 150 g EMLA (eutectic mixture of local anesthetics) cream (5 tubes) was applied to her lower extremities under occlusive dressings. One hour later, she began to experience light-headedness, dyspnea, tongue numbness, and muscular twitching. The only medications she was taking were sertraline and an oral contraceptive. On physical examination she was alert and in mild respiratory distress with both perioral and acral cyanosis, which was unresponsive to supplemental oxygen. Her vital signs were: blood pressure, 130/80 mm Hg; heart rate, 120 beats/min; respiratory rate, 20 breaths/min; temperature 98.6Â°F (37Â°C). Her height was 163 cm, and she weighed 74 kg. Her lungs were clear, and her heart sounds were normal. Her abdomen was soft and nontender with normal bowel sounds. Bilateral pretibial first-degree burns were still present from a prior laser treatment. The remainder of her physical examination was

normal. Pulse oximetry revealed 84% saturation while she was breathing 100% oxygen. An arterial blood gas (ABG) obtained on 100% oxygen was: pH, 7.45; PCO_2 , 36 mm Hg; PO_2 , 385 mm Hg. Her methemoglobin level was 20% by cooximetry. The patient received methylene blue 70 mg IV over 5 minutes, and all symptoms and signs improved within 1 hour. A repeat methemoglobin level was 2.7%. Her lidocaine concentration, drawn several hours after initial placement of the EMLA cream, was 0.68 Âµg/mL, confirming systemic absorption from the EMLA cream. The patient remained stable and was discharged home.[41]

Local anesthetics are drugs that block excitation of, and transmission along, a nerve axon in a predictable and reversible manner. The anesthesia produced is selective to the chosen body part in contrast to the nonselective effects of a general anesthetic. Local anesthetics do not require the circulation as an intermediate carrier, and they usually are not transported to distant organs. Therefore, the actions of local anesthetics are largely confined to the structures with which they come into direct contact. Local anesthetics may provide analgesia in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or via instillation within the epidural or subarachnoid spaces. The various local anesthetic agents differ with regard to potency, duration of action, and degree of effects on sensory and motor fibers. Toxicity may be local or systemic. With systemic toxicity, the central nervous system (CNS) and cardiovascular systems typically are affected.

History

Until the 1880s, the only drugs available for pain relief were centrally acting depressants such as alcohol and opioids, which blunted the perception of pain rather than attacking the root cause. The coca shrub (*Erythroxylon coca*) was brought back to Europe from Peru by Karl Von Scherzer, an Austrian explorer, in

the mid-1800s. Some of the coca leaves were analyzed by the chemist Albert Niemann, who in 1860 successfully extracted and named the active principle, the *alkaloid cocaine* (Chap. 74). Although Niemann noted that cocaine crystals numbed his tongue, it was not until 1868 that the Peruvian army surgeon Moreno y Mayz initially suggested that cocaine might have medical applications as a local anesthetic. Sigmund Freud was interested in the analeptic actions of cocaine, which he hoped would help cure morphine addiction. Freud obtained a supply of cocaine from the manufacturing firm Merck and shared the supply with his good friend Carl Koller, who was a junior intern in the Ophthalmological Clinic at the University of Vienna. After dissolving coca powder in distilled water, Koller instilled the solution in the conjunctival sacs of a frog, a rabbit, and a dog. He then was able to touch their cornea without any evidence of a reflex blink. He then experimented on his own eye and that of his laboratory assistant, and he demonstrated that the eye became insensitive to touch and injury within 1 minute. In 1884, Koller performed an operation for glaucoma with topical cocaine anesthesia. Four days later, his findings were presented at the Congress of Ophthalmology in Heidelberg. Dr. Henry Noyes, an American who attended the Heidelberg meeting, reported the discovery in a letter to the *New York Medical Record* , and the news

spread rapidly. Within 1 year, cocaine was in worldwide use as a pain-relieving drug for surgery of the eye and was being tested on other mucous membranes, such as the upper airway.

After the 1884 publication of Noyes' letter, several surgeons investigated the direct injection of cocaine into tissues. One year after Koller's discovery, Halsted reported on more than 1000 cases in which cocaine infiltration anesthesia was used at the Johns Hopkins Hospital.[42] Bier reported human spinal anesthesia and the associated spinal headache in 1899.

Although the clinical benefits of cocaine anesthesia were great, so

were its toxic and addictive potential. At least 13 deaths were reported in the first 7 years following the introduction of cocaine. Within 10 years following the introduction of cocaine as a regional anesthetic, reviews of â€œcocaine poisoningâ€• appeared in the literature.[65, 83] The toxicity of cocaine, coupled with its tremendous advantages for surgery, led to a search for less toxic substitutes. After the elucidation of cocaine's chemical structure (the benzoic acid methyl ester of the alkaloid ecgonine) in 1895, other benzoic acid esters were examined. Synthetic compounds with local anesthetic activity were introduced, but they either were highly toxic or irritating or had an impractical brief clinical effectiveness. In 1904, Einhorn synthesized procaine, but its short duration of action limited its clinical utility. Research then focused on synthesis of drugs with more prolonged duration of action.

The potent, long-acting local anesthetics dibucaine and tetracaine were synthesized in 1925 and 1928, respectively, and were introduced into clinical practice. However, these anesthetics could not be used safely for regional anesthetic techniques because of systemic toxicity. From the large volumes of drug that were required. These drugs were very useful, however, for spinal anesthesia.

Lofgren synthesized the prototypical local anesthetic lidocaine from a series of aniline derivatives in 1943. This amino amide combined high tissue penetrance and moderate duration of action with acceptably low systemic toxicity. Additionally, the metabolites of lidocaine did not include *para* -aminobenzoic acid, which was the reported cause of allergic reactions to the amino ester anesthetics. Subsequent to lidocaine's release in 1944, several other amino amide compounds were synthesized and introduced into clinical practice. These include mepivacaine in 1956, prilocaine in 1959, bupivacaine in 1963, etidocaine in 1971, and ropivacaine in 1996.

Epidemiology

Considering the frequency with which local anesthetics are administered, both within and outside healthcare facilities, clinically significant toxic reactions are few and usually iatrogenic. In a report of 1106 fatalities resulting from toxic exposures reported to US Poison Control Centers in 2003, 3 were secondary to local anesthetics.(See Chap. 130) Most poisonings result from inadvertent injection of a therapeutic dose into a blood vessel, repeated use of a therapeutic dose, or unintentional administration of a toxic dose. The amide local anesthetics have largely replaced the esters because of increased stability and relative absence of hypersensitivity reactions. Differences in metabolism of these agents, however, result in a much higher likelihood of systemic toxicity. Bupivacaine, a potent and long-acting amide anesthetic, has the highest potential for cardiovascular toxicity, which can be refractory to conventional therapy. Its pure S-enantiomer levobupivacaine and the structurally similar amide ropivacaine are alternatives having similar anesthetic properties and less potential for cardiovascular toxicity.

Poisoning from topical benzocaine is relatively common because of the large number of nonprescription products available for treatment of teething and hemorrhoids and because of the widespread use of benzocaine, mostly as a spray, for topical mucosal anesthesia prior to intubation, upper endoscopy, and esophageal echocardiography. Methemoglobinemia accounts for the majority of adverse events. With nonprescription use, toxic effects following exposure typically are mild, and death rarely occurs. Toxicity usually occurs as a therapeutic misadventure, but child abuse or neglect should be considered if the patient is younger than 2 years, and suicide should be considered in older children and adults. On the other hand, benzocaine spray may be the most important cause of severe acquired methemoglobinemia in the hospital setting.[3] Between November 1997 and March 2002,

the US FDA received 198 reported adverse events secondary to benzocaine products. One hundred thirty-two cases (66.7%) involved definite or probable methemoglobinemia; most were serious adverse events, and 2 deaths occurred.[74] In these cases, a single spray of unspecified duration of 20% benzocaine was the dose most commonly reported. Because of the difficulty in limiting the dose to the manufacturer's recommendation given the current formulations available, these authors recommend a metered dosing preparation and prominent package warnings.

Pharmacology

Chemical Structure

Local anesthetics fall into 1 of 2 chemically distinct groups: amino esters and amino amides (Figure 64-1). The basic structure of all local anesthetics has three major components. A lipophilic, aromatic ring is connected by an ester or amide linkage to a short alkyl, intermediate chain that is bound to a hydrophilic tertiary (or, less commonly, secondary) amine. The amine is a base (proton acceptor) that is partially charged in the physiologic pH range.

Mode of Action

All local anesthetics function by reversibly binding to specific receptor proteins within the membrane-bound sodium channels of conducting tissues. These receptors can be reached only via the cytoplasmic side of the cell membrane, that is, by intracellular drug. Blockade of ion conductance through the sodium channel eventually leads to failure to form and propagate action potentials. The analgesic effect results from inhibiting axonal transmission of the nerve impulse in small-diameter myelinated and unmyelinated nerve fibers carrying pain and temperature sensation. Conduction block of these fibers occurs at lower concentrations than in the

larger fibers responsible for touch, motor function, and proprioception.[22] This likely occurs in myelinated nerves because smaller fibers have closer spacing of the nodes of Ranvier. Given that a fixed number of nodes must be blocked in order for conduction failure to occur, the shorter critical length of nerve is reached sooner by the locally placed anesthetic in small fibers.[36] For unmyelinated fibers, the smaller diameter limits the distance that such fibers can passively propagate the electrical impulse. In addition, differential nerve block may relate to voltage and time dependence of the affinity of local anesthetics to the sodium channels. The sodium channel can exist in three states. (See Chap. 23 .) At resting membrane potential or in the hyperpolarized membrane, the channel is closed to sodium conductance. With an appropriate

activating stimulus, the channel opens, allowing rapid sodium influx and membrane depolarization. Milliseconds later, the channel is inactivated, terminating the fast sodium current. Blockade is much stronger for channels that are activated (open) or inactivated than for channels that are resting. Pain fibers have a higher firing rate and longer action potential (ie, more time with the sodium channel open or inactivated) than other fiber types and therefore are more susceptible to local anesthetic action.[48]

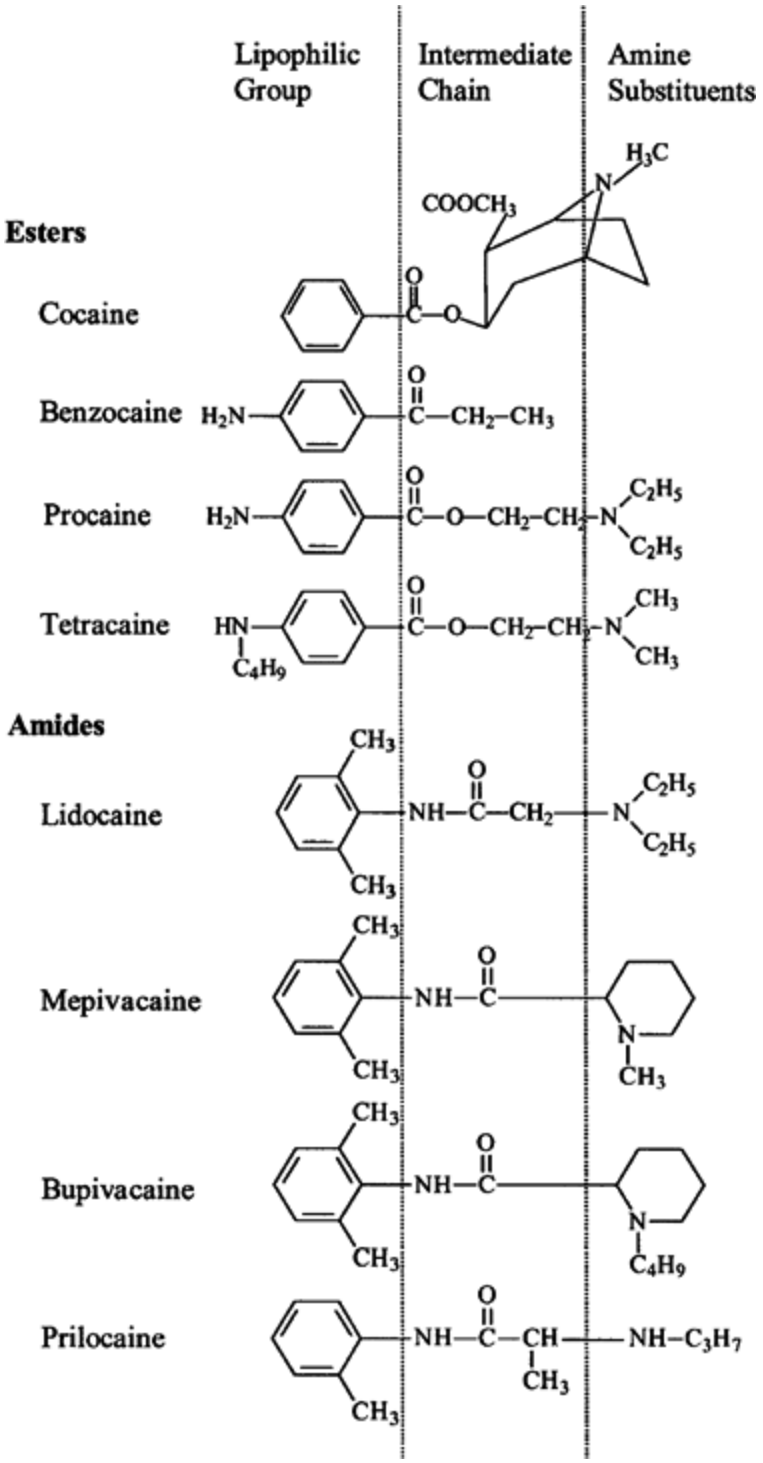

Figure 64-1. Representative local anesthetics in common clinical use.

These effects also occur in other conductive tissues in the heart and brain that rely on sodium current. As such, sodium channel blockade initially was believed to be the sole cause of systemic toxic reactions. However, the mechanisms of toxic effects are more complex, especially in the heart, and can occur at systemic concentrations lower than previously thought.[67] Local anesthetics may interact with other cellular systems at clinically relevant concentrations. For example, lidocaine inhibited muscarinic signaling in *Xenopus* oocytes at <50% of the concentration required for sodium channel blockade.[47] Growing evidence indicates that local anesthetics can directly affect many other organ systems and functions (eg, coagulation, immune, and respiratory systems) at concentrations much lower than those required to achieve sodium channel blockade.[16, 46, 47] Study of these less well-described effects may help elucidate both therapeutic and toxic phenomenon that are incompletely explained.

Physicochemical Properties

The primary determinant of a local anesthetic's onset of action is pK_a which affects the drug's lipophilicity (Table 64-1). All of the local anesthetics are weak bases, with a pK_a between 7.6 and 9.1. At physiologic pH (7.4), drugs with a lower pK_a have more uncharged molecules that are free to cross the nerve cell membrane, producing a faster onset of action than drugs with a higher pK_a . Onset of action also is influenced by the total dose of local anesthetic administered, which affects the concentration available for diffusion.

Local anesthetic potency is highly correlated with the drug's lipid solubility. Therefore, the aromatic side of the anesthetic is the primary determinant of potency. The hydrophilic amine is important in occupying the sodium channel, which involves an ionic interaction with the charged form of the tertiary amine. The

length of the intermediate chain is another determinant of local anesthetic activity, with 3â€“7 carbon-equivalents providing maximal activity.[22] Shorter or longer intermediate chain length is associated with rapid loss of local anesthetic action, suggesting that a critical length of separation of the aromatic group from the tertiary amine is required for sodium channel blockade to occur.

The degree of protein binding influences the duration of action of a local anesthetic. Drugs with greater protein binding remain associated with the neural membrane for a longer time interval and therefore have a longer duration of action.[22] When high plasma concentrations are achieved, a higher degree of protein binding increases the risk for cardiac toxicity.

Pharmacokinetics

A distinction must be made between local disposition (distribution and elimination) and systemic disposition. Local distribution is influenced by several factors, including spread of local anesthetic by bulk flow, diffusion, transport via local blood vessels, and binding to local tissues. Local elimination occurs through systemic absorption, transfer into the general circulation, and local hydrolysis of amino ester anesthetics. Systemic absorption decreases the amount of local anesthetic that is available for anesthetic effect, thereby limiting the duration of the block. Systemic absorption is dependent on the avidity of binding of local anesthetics to tissues near the site of injection and on local perfusion. Both of these factors vary with the site of injection.

Because of their lipophilicity, local anesthetics readily cross cell membranes, the bloodâ€“brain barrier, and the placenta. Once absorbed, systemic tissue distribution is highly dependent on tissue perfusion. After local anesthetics enter into the venous circulation, they pass through the lungs where significant uptake may occur, thereby lowering peak arterial concentrations. Thus, the lung may serve as a buffer to systemic toxicity.[58] This

mechanism, however, has saturable kinetics. Part of the reason why most local

anesthetic-induced seizures result from unintentional intravascular injection rather than absorptive uptake is that lung uptake of these drugs appears to exceed 90%. The very high peak venous concentrations produced by rapid injection usually are necessary to produce toxic arterial drug concentrations.

TABLE 64-1. Pharmacologic Properties of Local Anesthetics

All local anesthetics, except cocaine, cause peripheral vasodilation by direct relaxation of vascular smooth muscle. Vasodilation enhances vascular absorption of the local anesthetic. Addition of epinephrine (5 Âµg/mL or 1:200,000) to the local anesthetic solution decreases the rate of vascular absorption, thereby improving the depth and prolonging the duration of local action. An epinephrine/local anesthetic mixture also decreases bleeding into the surgical field and serves as a marker for inadvertent intravascular injection when a test dose of the mixture is injected through a needle or catheter.[71]

Significant drawbacks to epinephrine use include uncomfortable side effects such as palpitations and tremors, local tissue ischemia (eg, if used in the digits), and life-threatening systemic adverse reactions in susceptible patients (eg, myocardial ischemia, hypertensive crisis). Inadvertent intravascular injection of local anesthetics mixed with epinephrine can be fatal.[62]

The two classes of local anesthetics undergo metabolism by different routes (Chap. 74). The amino esters are rapidly metabolized by plasma cholinesterase to the major metabolite *para* -aminobenzoic acid (PABA). The amino amides are metabolized more slowly in the liver to a variety of metabolites unrelated to PABA.[21] Patients with atypical or low concentrations

of plasma cholinesterase are at increased risk for systemic toxicity from ester local anesthetics. Factors that decrease hepatic blood flow or impair hepatic function increase the risk for toxic reactions to the amino amides and make management of serious reactions more difficult. The patient's age, as it relates to liver enzyme activity and plasma protein binding, influences the rate of metabolism of local anesthetics. The lidocaine half-life following intravenous administration averaged 80 minutes in volunteers aged 22â€“26 years, whereas the half-life was 138 minutes in those aged 61â€“71 years[79] (Chap. 61). Newborn infants with immature hepatic enzyme systems have prolonged elimination of amino amides, which is associated with seizures when high continuous infusion rates are used.[1 , 68]

Lidocaine elimination is reduced by congestive heart failure or coadministration of xenobiotics that reduce hepatic blood flow, thus explaining the increased risk of toxicity with cimetidine and propranolol.[89] Propranolol also potentially decreases hepatic enzyme activity. Administration of one local anesthetic increases the free plasma fraction of another drug by displacement from protein-binding sites.[51]

Local anesthetics are often mixed to take advantage of desirable pharmacokinetics. Ideally, rapid-acting, relatively short-duration drugs such as chloroprocaine or lidocaine can be combined with longer latency, long-acting drugs such as tetracaine or bupivacaine. In practice, the advantages of the mixtures are small and toxicities are additive.[5]

Local anesthetics usually cannot penetrate intact skin in sufficient quantities to produce reliable anesthesia.[11] Efficient skin penetration requires the combination of a high water content and a high concentration of the water-insoluble base form of the local anesthetic. This combination of properties has been achieved by mixing lidocaine and prilocaine in their base forms in a 1:1 ratio (eutectic mixture of local anesthetics (EMLA).[14] Application for at

least 45 minutes is required to achieve adequate dermal analgesia. Local anesthetic uptake continues for several hours during application. A liposomal formulation of 4% lidocaine (ELA-Max) facilitates skin absorption. It is as effective as EMLA for topical anesthesia and is not associated with methemoglobinemia or significant systemic lidocaine absorption.[31]

Clinical Manifestations of Toxicity

Toxic Reactions

Regional Side Effects and Tissue Toxicity

All local anesthetics, at some concentration, are directly cytotoxic to nerve cells. However, in clinically relevant doses, these drugs rarely produce localized nerve damage.[55, 78] Significant direct neurotoxicity can result from intrathecal injection or infusion of local anesthetics for spinal anesthesia. In this setting, studies suggest lidocaine has increased risk for both persistent lumbosacral neuropathy and a syndrome of painful but self-limited postanesthesia buttock/leg pain or dysesthesia referred to as *transient neurologic symptoms*.[50] Nerve damage often is attributed to use of excessively concentrated solutions or inappropriate formulations. Several reports of cauda equina syndrome are associated with use of hyperbaric 5% lidocaine solutions

for spinal anesthesia. Hyperbaric solutions are more dense than cerebrospinal fluid. This neurotoxicity appears to be a phenomena that occurs when the anesthetic is injected through narrow-bore needles or through continuous spinal catheters. This process can result in very high local concentrations of the anesthetic that might pool around the sacral roots because of inadequate mixing.[90] The mechanism of this neurotoxic effect is unknown but

is believed to be independent of sodium channel blockade.[50] Because an equally effective block can be achieved with injection of larger and volumes of less concentrated drug, 5% lidocaine should be avoided and bupivacaine used instead.

Similar severe neurotoxic reactions have occurred following massive subarachnoid injection of chloroprocaine during attempted epidural anesthesia.[87] The neurotoxicity initially appeared to be associated with use of the antioxidant sodium bisulfite and the low pH of the commercial solution rather than use of the anesthetic per se.[105] Although chloroprocaine has been reformulated without bisulfite, new animal data suggest that the anesthetic itself may have been responsible for the neurotoxicity.[101] Skeletal muscle changes are observed following intramuscular injection of local anesthetics, especially the more potent, longer-acting agents. The effect is reversible and muscle regeneration is complete within 2 weeks following injection of local anesthetics.[8]

Systemic Side Effects and Toxicity

Allergic Reactions

Allergic reactions to local anesthetics are extremely rare. Less than 1% of all adverse drug reactions caused by local anesthetics result from true immunoglobulin (Ig)E-mediated allergic reactions.[39] In fact, in a study designed to determine the prevalence of true local anesthetic allergy in patients referred to an allergy clinic for suspected hypersensitivity, skin prick and intradermal testing were negative for all 236 subjects tested.[9] The amino esters are responsible for the majority of true allergic reactions. When hydrolyzed, the amino ester local anesthetics produce PABA, a known allergen. Cross-sensitivity to other amino ester anesthetics is common. Some multidose commercial preparations of amino amides may contain the preservative methylparabens, which is chemically related to PABA and is the

most likely cause of the much rarer allergic reaction to amino amides. Thus, preservative-free amino amides, including lidocaine, can be used safely in patients who have reactions to drug preparations containing methylparabens, unless the patient is specifically sensitive to lidocaine. If the patient with a history of prior allergic reaction to a particular drug requires a local anesthetic, a drug from the opposite class can be chosen because there is no cross-reactivity between the amides and esters.

Methemoglobinemia

Methemoglobinemia is reported frequently as an adverse effect of topical and oropharyngeal benzocaine use and occasionally with lidocaine, tetracaine, or prilocaine use. The diagnosis can be made by direct measurement of methemoglobin concentration with a cooximeter. Most reports of methemoglobinemia associated with local anesthetics are the result of an excessive dose, a break in the normal mucosal barrier for topical anesthetics, or deficiency of a congenital reducing enzyme such as methemoglobin reductase (Chap. 122).

Benzocaine is metabolized to aniline and then further metabolized to phenylhydroxylamine and nitrobenzene, all potent oxidizing agents (Chap. 122). Although reports describe methemoglobinemia resulting from standard doses of benzocaine topical oropharyngeal spray given for laryngoscopy or gastrointestinal upper endoscopy,[29 , 74] affected patients commonly have abnormal mucosal integrity, as occurs with thrush or mucositis. Prilocaine is an amino ester local anesthetic primarily used in obstetric anesthesia because of its rapid onset of action and low systemic toxicity in both mother and fetus. Use of large doses of prilocaine can lead to development of methemoglobinemia.[45 , 60] Prilocaine is an aniline derivative that, when metabolized in the liver, produces *ortho* -toluidine, another oxidizing agent.[45] A direct relationship exists between the amount

of epidural prilocaine administered and the incidence of methemoglobinemia. A dose greater than approximately 8 mg/kg is generally necessary to produce symptoms, which may not become apparent until several hours after epidural administration of the drug. Standard doses of EMLA cream used for circumcision in term neonates are associated with minimal production of methemoglobin, but risks may be increased in the neonate with metabolic disorders.[99] EMLA-associated methemoglobinemia is reported in children and, rarely, in adults. When clinically indicated, affected patients with symptomatic methemoglobinemia should be treated with intravenous methylene blue (Chap. 122 and Antidotes in Depth: Methylene Blue).

Other Reactions

The most common adverse reactions to local anesthetics are vasovagal reactions.[103]

Systemic Toxicity

Systemic toxicity for all local anesthetics correlates with plasma concentrations. Factors that determine the concentration include (1) dose of the drug, (2) rate of administration, (3) site of injection (absorption occurs more rapidly and completely from vascular areas, such with neck blocks and intercostal blocks), (4) presence or absence of a vasoconstrictor, and (5) drug-specific factors such as the degree of tissueâ€“protein binding, fat solubility, and pK_a of the drug.[72] The brain and heart are the primary target organs for systemic toxicity because of their rich perfusion, moderate tissueâ€“blood partition coefficients, lack of diffusion limitations, and presence of cells that rely on voltage-gated sodium channels to produce an action potential. Recommendations for maximal local anesthetic doses designed to minimize the risk for systemic toxic reactions have been published.[97] These maximal recommended doses aim to prevent

infiltration of excessive drug. However, because most episodes of systemic toxicity from local anesthetics, with the exception of methemoglobinemia from topical drug, occur secondary to unintentional intravascular injection rather than from overdosage, limiting the maximal dose is irrelevant for preventing most toxic systemic reactions.[96] Toxicity also is related to the metabolism for a given local anesthetic. The rapidity of elimination from the plasma influences the total dose delivered to the CNS or heart. The amino esters are rapidly hydrolyzed in the plasma and eliminated, explaining their relatively low potential for systemic toxicity. The amino amides have a much greater potential for producing systemic toxicity because termination of the therapeutic effect of these drugs is achieved through redistribution and slower metabolic inactivation.[35] Another factor that creates difficulty in specifying the minimal toxic plasma concentration of lidocaine results from the fact that its *N* -dealkylated metabolites are pharmacologically active. These factors make it difficult to establish safe doses of local anesthetics. Table 64-2 summarizes the estimates of minimal toxic doses of various local anesthetics.

Local Anesthetic	Minimum IV Toxic Dose of Local Anesthetic in Humans (mg/kg)

TABLE 64-2. Toxic Doses of Local Anesthetics

CNS Toxicity

Systemic toxicity in humans usually presents with CNS symptoms. Intravenous infusion studies in volunteers demonstrated an inverse relationship between the anesthetic potency of various local anesthetics and the dosage required to induce signs of CNS toxicity.[95] A similar relationship exists between the convulsive serum concentration of various local anesthetics and their relative anesthetic potency. In humans, seizures are reported at serum concentrations of approximately 2â€“4 Âµg/mL for bupivacaine and etidocaine. Concentrations in excess of 10 Âµg/mL usually are required for production of seizures when less potent drugs such as lidocaine are administered. Despite the strong relationship between local anesthetic potency and CNS toxicity, several other factors influence the CNS effects, including the rate of injection, drug interactions, and acidâ€“base status.[24]

The rapidity with which a particular serum concentration is achieved influences the toxicity of the anesthetic. Volunteers could tolerate an average dose of 236 mg etidocaine and a serum concentration of 3 Âµg/mL before onset of CNS symptoms when the anesthetic was infused at a rate of 10 mg/min. However, when the infusion rate was increased to 20 mg/min, the same individuals could tolerate only an average of 161 mg of the drug, which produced a serum concentration of approximately 2 Âµg/mL.[94]

Centrally acting drugs can modify the clinical presentation of a systemic toxic reaction. In general, CNS-depressant drugs minimize the signs and symptoms of CNS excitation (raise the threshold for local anesthetic-induced seizures), whereas flumazenil increases the sensitivity of the CNS to the amino amide anesthetics.[13]

Both metabolic and respiratory acidosis increase local anesthetic-induced CNS toxicity. Acidemia decreases plasma protein binding, increasing the amount of free drug available for CNS diffusion despite promoting the charged form of the amine. The convulsive threshold of various local anesthetics is inversely related to arterial PCO_2 .[26 , 32 , 33] Hypercarbia can lower seizure threshold by several mechanisms: (1) increased cerebral blood flow, which increases drug delivery to the CNS; (2) increased conversion of the drug base to the active cation in the presence of decreased intracellular pH; and (3) decreased plasma protein binding, which increases the amount of free drug available for diffusion into the brain.[15 , 26 , 32 , 33]

A gradually increasing lidocaine serum concentration produces a common pattern of symptoms and signs (Figure 64-2). In the awake patient, the initial symptoms are subjective and include tinnitus, light-headedness, circumoral numbness, disorientation, confusion, auditory and visual disturbances, and lethargy. Subjective side effects occur at serum concentrations between 3 and 6 Âµg/mL. Significant psychological effects of local anesthetics also are reported. Near-death experiences and delusions of actual death have been described as specific symptoms of local anesthetic toxicity.[63] Thus, appearance of psychologic symptoms during administration of local anesthetics should not be disregarded as unrelated nervous reactions or effects of sedatives given as premedication but rather as a possible early sign of CNS toxicity.

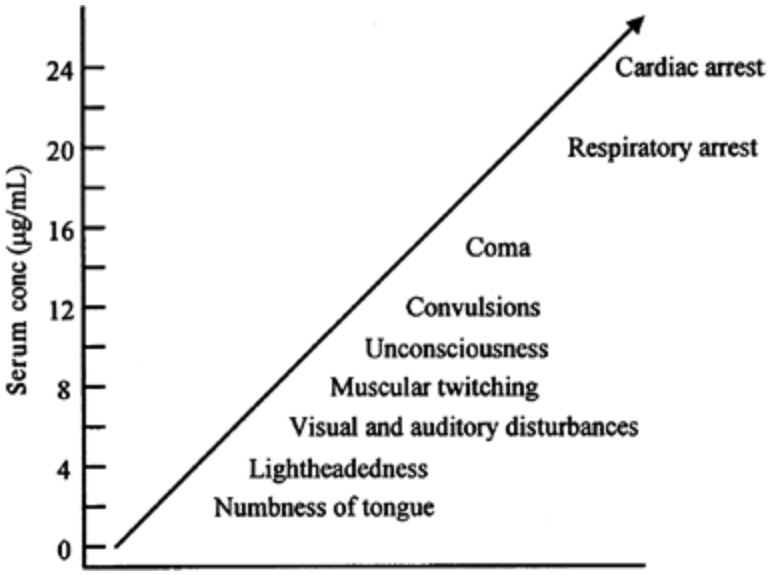

Figure 64-2. Relationship of signs and symptoms of lidocaine toxicity to lidocaine serum concentrations.

Objective signs, usually excitatory, then develop and include shivering, tremors, and ultimately generalized tonicâ€“clonic seizures. Objective CNS toxicity usually is evident at concentrations between 5 and 9 Âµg/mL. Seizures can occur at concentrations above 10 Âµg/mL, with higher concentrations producing coma, apnea, and cardiovascular collapse. The excitatory phase has a wide range of intensity and duration, depending on the chemical properties of the local anesthetic. With the highly lipophilic, highly protein-bound drugs, the excitement phase is brief and mild. Toxicity from a large intravenous bolus of bupivacaine can even present without any CNS excitement and with bradycardia, cyanosis, and coma as the first signs.[92] Rapid intravascular injection of lidocaine can produce a brief excitatory phase, followed by generalized CNS depression with respiratory arrest. Seizures may follow even a small dose injected into the vertebral or carotid artery (as may occur during stellate ganglion block).[54] A relative overdose produces a slower onset of symptoms (usually within 5â€“15 minutes of drug injection), with irritability progressing into seizures.

The mechanism of the initial CNS excitation involves a selective block of cerebral cortical inhibitory pathways in the amygdala.[100, 104] The resulting increase in unopposed excitatory activity leads to seizures. As the concentration rises further, both inhibitory and excitatory neurons are blocked, and generalized CNS depression ensues.

Treatment of Local Anesthetic CNS Toxicity

At the first sign of possible CNS toxicity, administration of the drug must be discontinued. One hundred percent oxygen should be supplied immediately, and ventilation should be supported if necessary. Minor symptoms usually do not require treatment,

provided adequate respiratory and cardiovascular function are maintained. The patient must be followed closely so that progression to more severe effects can be detected.

Although most seizures caused by local anesthetics are self-limited, they should be treated quickly because the hypoxia and acidosis produced by prolonged convulsions may increase both CNS and cardiovascular toxicity.[75, 77] Intubation is not mandatory, and the decision to intubate must be individualized. Maintaining adequate ventilation is of proven value, but modest hyperventilation in theory might decrease CNS toxicity. By decreasing CNS extraction of drug, lowering extracellular potassium, and hyperpolarizing the neuronal cell membrane, normalizing (lowering) PCO_2 may decrease the affinity or accelerate separation of the local anesthetic from the sodium channel. Barbiturates and benzodiazepines have been used for treatment of local anesthetic-induced seizures. An induction dose of thiopental can rapidly terminate a seizure and acts more quickly than benzodiazepines, but any of these agents can exacerbate

circulatory and respiratory depression.[24, 70] Propofol 1 mg/kg IV was as effective as thiopental 2 mg/kg IV in stopping bupivacaine-induced seizures in rats and has been used successfully in a patient with uncontrolled muscle twitching secondary to local anesthetic toxicity.[10, 44] However, propofol can cause significant bradydysrhythmias and even asystole, especially when propofol is used with other drugs that cause bradycardia. Whether propofol interacts with local anesthetics to enhance their bradydysrhythmic effects is not known, and it is not possible to generally recommend propofol over barbiturates and benzodiazepines for treatment of local anesthetic CNS toxicity. Neuromuscular blocking agents have been proposed as adjunctive treatment for local anesthetic-induced seizures. They block muscular activity, decreasing oxygen demand and lactic acid production. However, neuromuscular blocking agents should never be used to treat seizures per se because they have no anticonvulsant effect and can make clinical diagnosis of ongoing seizures problematic by abolishing muscle contractions. To avoid this potentially lethal complication, chemical paralysis should be used only to facilitate endotracheal intubation if needed. Use of short-acting drugs is desirable to allow for subsequent repeated neurologic assessments. Succinylcholine may not be the ideal drug because of its significant side effects, including hyperkalemia and dysrhythmias. Newer short-acting nondepolarizing agents with less potential for cardiac side effects, such as rocuronium, should be considered (Chap. 66).

When severe systemic toxicity occurs, the cardiovascular system must be monitored closely because cardiovascular depression may go unnoticed while the seizures are being treated. Because local anesthetic-induced myocardial depression can occur even with preserved blood pressure, it is important to be aware of early signs of cardiac toxicity, including ECG changes.

If toxicity results from an oral ingestion, activated charcoal and orogastric lavage are indicated but unproven therapeutic considerations. Induction of emesis is contraindicated even after

oral administration because of the risk of seizures and aspiration. Contaminated mucous membranes should be washed off. Hemodialysis probably is not useful. Hemoperfusion might be useful for severe lidocaine toxicity but is difficult to perform in the presence of significant cardiovascular depression.

Cardiovascular Toxicity

Cardiovascular side effects are the most feared manifestations of local anesthetic toxicity. Shock and cardiovascular collapse may be related to effects on vascular tone, inotropy, and dysrhythmias related to indirect CNS and direct cardiac and vascular effects of the local anesthetic. Animal studies and clinical observations clearly demonstrate that, for most local anesthetics, CNS toxicity develops at lower serum concentrations than those needed to produce cardiac toxicity, that is, they have a high CV/CNS toxicity ratio. When cardiac toxicity occurs, management can be exceedingly difficult. Some of the discrepancy between the incidence of CNS and cardiac toxicity may result from a detection bias. Not only can the treating physicians fail to recognize cardiac effects because of preoccupation with CNS manifestations of toxicity, but significant early cardiac toxicity may be quite subtle. An experimental study attempting to identify early warning signs of bupivacaine-induced cardiac toxicity in pigs evaluated bupivacaine-induced changes in cardiac output, heart rate, blood pressure, and ECG.[82] A 40% reduction in cardiac output was not associated with any significant change in heart rate or blood pressure, the latter secondary to a direct vasoconstrictive effect of bupivacaine at the concentrations produced. Typical changes on the ECG parallel the drop in cardiac output.[17]

Changes in systemic vascular tone induced by local anesthetics may be mediated by direct effect on vascular smooth muscle or indirectly via effects on spinal cord sympathetic outflow. Predictably, sympathetic blockade after spinal anesthesia or

epidural anesthesia above the T5 dermatome results in peripheral venodilation and arterial dilation. Shock can result when high doses of anesthetic are used in hypovolemic patients. Local anesthetics have a biphasic effect on peripheral vascular smooth muscle. Whereas lower doses produce direct vasoconstriction, higher doses are associated with severe cardiovascular toxicity and cause vasodilation, contributing to cardiovascular collapse.

All local anesthetics directly produce a dose-dependent decrease in cardiac contractility, with the effects roughly proportional to their peripheral anesthetic effect. Although the classic anesthetic action of sodium channel blockade in heart muscle accounts in large part for the negative inotropy by affecting excitationâ€“contraction coupling, it does not explain the entire difference in myocardial depression produced by different anesthetics.[28] Poorly understood effects on calcium handling or effects of the intracellular drug directly on contractile proteins or mitochondrial function may be operable.[28]

Blockade of the fast sodium channels of cardiac myocytes decreases maximum upstroke velocity (V_{max}) of the action potential (Chap. 23 and Fig. 61-1). This effect slows impulse conduction in the sinoatrial and atrioventricular nodes, the His-Purkinje system, and atrial and ventricular muscle.[20] These changes are reflected on ECG by increases in PR interval and QRS duration. At progressively higher drug concentrations, hypotension, sinus arrest with junctional rhythm, and eventually cardiac arrest occur.[4] Asystole is described in patients who received unintentional intravenous bolus injections of 800â€“1000 mg lidocaine.[4, 34] Cardiovascular toxicity of local anesthetics usually occurs following a sudden increase in serum concentration, as in unintentional intravascular injection. Cardiovascular toxicity is rare in other circumstances because a large dose of the drug is necessary to produce this effect, and because CNS toxicity precedes cardiovascular events, thus providing a warning. Cardiac toxicity usually is not observed with lidocaine use in humans until

the serum lidocaine concentration greatly exceeds 10 Âµg/mL, unless the patient is also receiving drugs that depress sinus and atrioventricular nodal conduction (eg, calcium channel blockers, Î²-adrenergic antagonists, or cardioactive steroids).

Bupivacaine is significantly more cardiotoxic than most other local anesthetics in common use. Inadvertent intravascular injection produces near-simultaneous signs of CNS and cardiovascular toxicity.

Animal studies have compared the dosage or serum concentrations of local anesthetics required to produce irreversible circulatory collapse to those necessary to produce seizures.[25 , 76 , 77] This cardiovascular collapse/central nervous system toxicity ratio (CC/CNS) for lidocaine is approximately 7; therefore, CNS toxicity should become evident well before potentially cardiotoxic concentrations are reached. In contrast, the CC/CNS ratio for bupivacaine is 3.7. Bupivacaine produces myocardial depression out of proportion to its anesthetic potency and, more importantly, can cause refractory ventricular dysrhythmias.[93] Enhanced cardiovascular toxicity may relate to enhanced CNS effects at cardiovascular centers,[102] direct effects on myocyte metabolism, and important differences related to sodium channel blockade. Although lidocaine and bupivacaine both block sodium channels in the open or inactivated state, lidocaine quickly dissociates from the channel at diastolic potentials, allowing rapid recovery from block during diastole (fast onâ€“fast off). Therefore, sodium channel blockade with lidocaine is much more pronounced at rapid heart rates (accounting for the antidysrhythmic effects for ventricular tachycardia). On the other hand, at high concentrations bupivacaine rapidly binds to, and slowly dissociates from, sodium channels (fast onâ€“slow off), with significant block accumulating at all physiologic heart rates.[20] Accordingly, at heart rates of 60â€“150 beats/min, approximately 70 times more lidocaine is needed than bupivacaine to produce an equal effect on V_{max} .

Enhanced conduction block in Purkinje fibers and ventricular muscle cells can set up a reentrant circuit responsible for the ventricular tachydysrhythmias induced by bupivacaine.[69]

Bupivacaine has an asymmetrically substituted carbon, and the kinetics of sodium channel binding are stereospecific.[56] The S (levo)-enantiomer is significantly less cardiotoxic than the R (dextro)-enantiomer.[6, 67] Consequently, bupivacaine, the racemic mixture of both enantiomers, is more cardiotoxic than levobupivacaine, which contains only the levo-enantiomer.[40] The stereospecific effect on sodium channels seems to differ between the heart and the peripheral nerves, however, because the local anesthetic potency of levobupivacaine is the same as, or perhaps even greater than, that of bupivacaine.[30, 80] Ropivacaine is a pure enantiomer and is less cardiotoxic than bupivacaine, but it also is slightly less potent as an analgesic.[84, 85]

Effects other than sodium channel blockade may contribute to cardiac toxicity. Lipophilic local anesthetics such as bupivacaine can directly impair mitochondrial energy transduction via two mechanisms: (1) uncoupling of oxygen consumption and adenosine triphosphate (ATP) synthesis and (2) inhibition of complex 1 in the respiratory chain.[98] This effect is related to the lipophilic properties of the drug rather than to stereospecific effects on ion channels. Lidocaine has no effect on mitochondrial respiration, and ropivacaine has less effect compared to bupivacaine.[107] There is no difference between the two bupivacaine enantiomers. These effects occur with higher concentrations of the drug, as occur after unintentional intravascular injection.

Low-dose bupivacaine-induced cardiotoxic effects are described in humans under certain circumstances and at concentrations that are not associated with seizure activity in pigs.[52, 106] Severe cardiac toxicity has been described after injection of a small subcutaneous dose of bupivacaine in a patient with secondary carnitine deficiency.[106] Myocytes are highly dependent on

oxidation of fatty acids for energy turnover. Interference with this mechanism via bupivacaine-induced inhibition of carnitine-acylcarnitine translocase has been proposed to contribute to the cardiotoxicity of lipophilic local anesthetics[106] (Chap. 47 and Fig. 47-2). Bupivacaine may produce dysrhythmias by blocking GABAergic neurons that tonically inhibit the autonomic nervous system.[43] In addition to its other effects on the heart, bupivacaine can induce a marked decrease in cardiac contractility by altering Ca^{2+} release from sarcoplasmic reticulum.[61]

In a large series of patients receiving bupivacaine published in 1978, systemic toxicity occurred in only 15 of 11,080 nerve blocks.[73] Of these patients, 80% convulsed; the other 20% had milder symptoms. However, during the late 1970s and early 1980s, a series of cases were described in which bupivacaine use, particularly at 0.75% concentration, was associated with severe cardiovascular depression, ventricular dysrhythmias, and even death. Pregnant women were disproportionately affected. Some of these cases required prolonged and difficult resuscitation.[88] In 1983, 49 incidents of cardiac arrest or ventricular tachycardia that occurred over a 10-year period were presented to the US FDA's Anesthetic and Life Support Advisory Committee. Among these cases, 0.75% bupivacaine was used in 27 obstetric patients with 10 deaths, and 0.5% bupivacaine was used in 8 obstetric patients with 6 deaths. Among the 14 nonobstetric patients, 5 died. The overall mortality was 21 of 49 (43%). Partly as a result of these reports, in 1984 the US FDA withdrew approval of bupivacaine 0.75% for use as obstetric anesthesia.[88]

Acidâ€“base and electrolyte status influence the cardiac toxicity of a given drug because all depressant properties are potentiated by acidosis, hypoxia, or hypercarbia.[12] Table 64-3 outlines the spectrum of acute local anesthetic reactions.

Laboratory

In cases of possible local anesthetic toxicity, an ECG should be obtained to detect dysrhythmias and conduction disturbances. Serum electrolytes, blood urea nitrogen (BUN), and creatinine should be obtained to help assess the cause of cardiac dysrhythmias. A methemoglobin level should be obtained in patients in whom significant methemoglobinemia is clinically suspected. Rapid sensitive assays are available for measuring concentrations of lidocaine and its monoethylglycylxylidide (MEGX) metabolite. When properly interpreted, the results of these assays can be used to prevent lidocaine toxicity and to identify lidocaine toxicity in the nontherapeutic setting. Assays for determining serum concentrations of other local anesthetics are not routinely available. Treatment should never be delayed while waiting for results of drug concentration determinations.

Etiology	Major Clinical Features
Local anesthetic toxicity (intravascular injection)	Immediate seizure and/or cardiac toxicity
Reaction to catecholamine	Tachycardia, hypertension, headache
Vasovagal reaction	Rapid onset and recovery, bradycardia, hypotension, pallor
Allergic reaction	Anaphylaxis
High spinal or epidural block	Bradycardia, hypotension, respiratory distress, respiratory arrest

TABLE 64-3. Types of Local Anesthetic Reactions

Treatment

Treatment of Local Anesthetic Cardiac Toxicity

Treatment of cardiovascular complications of local anesthetics is complicated by the complex effects of local anesthetics on the heart. Initial therapy should focus on correcting the physiologic derangements that may potentiate the cardiac toxicity of local anesthetics, including hypoxemia, acidosis, and hyperkalemia.[12, 91] Prompt support of ventilation and circulation will limit hypoxia and acidosis. Early recognition of potential cardiac toxicity is critical to achieving a good outcome because cardiac toxicity that goes unrecognized for any interval is more difficult to resuscitate.[7] If a potentially massive intravascular local anesthetic injection is suspected, maximizing oxygenation of the patient before cardiovascular collapse occurs is critical.

Despite multiple small studies suggesting the efficacy of various individual pharmacologic approaches, no convincing data suggest deviation from standard advanced cardiac life support (ACLS) protocols when dealing with most episodes of local anesthetic cardiac toxicity. Hypotension in sinus rhythm results from both peripheral vasodilation and myocardial depression and should be treated with Î±- and Î²-adrenergic agonists. Atropine supplemented with electrical pacing should be used to treat bradycardia. The effectiveness of epinephrine in reversing local anesthetic-induced cardiac depression is inconsistent in various animal models. The dysrhythmic effects of epinephrine are of particular concern. Amrinone, a phosphodiesterase III inhibitor, was evaluated for treatment of bupivacaine-induced cardiac toxicity.[38, 57] Anesthetized pigs with cardiovascular collapse induced by bupivacaine infusion survived when they were treated with amrinone; all of the control animals died of irreversible cardiac arrest.[57] A phosphodiesterase III inhibitor would be a good choice for reversing bupivacaine-induced cardiac depression.[94]

Bupivacaine-induced dysrhythmias often are refractory to cardioversion, defibrillation, and pharmacologic treatment. Lidocaine, phenytoin, magnesium, bretylium, amiodarone, calcium channel blockers, and combined therapy with clonidine and dobutamine have all been used in animal models, with variable results.[27 , 64 , 66] Therapy for bupivacaine toxicity should be directed toward dissociating bupivacaine from the myocardial sodium channel, thereby reversing the drug's effects on cardiac conduction. Lidocaine competes with bupivacaine for cardiac sodium channels and at high doses may displace it. Anecdotal reports suggest that lidocaine has occasionally helped in this application.[23] However, concern persists about additive CNS effects when lidocaine is used to treat bupivacaine cardiac toxicity, and we do not recommend its routine use.

With toxicity from the longer-acting, highly lipid-soluble, protein-bound amide local anesthetics (bupivacaine and etidocaine), if the patient does not respond promptly to therapy, cardiopulmonary resuscitation can be expected to be difficult and prolonged (1â€“2 hours) before depression of the cardiac conduction system spontaneously reverses as a result of redistribution and metabolism of the drugs.[2 , 86] Vital organ perfusion is seriously compromised during cardiopulmonary resuscitation despite optimal chest compression. The significance of this problem increases with the duration of resuscitation; therefore, rapid initiation of cardiopulmonary bypass should be considered, if practical. Its use has resulted in a successful outcome in some cases of lidocaine and bupivacaine overdose.[37 , 59] Cardiopulmonary bypass provides circulatory support that is far superior to that provided by closed-chest cardiac massage. The improved perfusion prevents tissue hypoxia and the development of metabolic acidosis, which in turn decreases the binding of local anesthetics to myocardial sodium channel receptors. Hepatic blood flow is better maintained, enhancing local anesthetic metabolism, and increased myocardial blood flow helps redistribute local anesthetics out of the

myocardium.[59]

Cardiac pacing was used successfully for treatment of cardiac arrest following unintentional administration of a 2-g bolus of lidocaine into a cardiopulmonary bypass circuit as the patient was being removed from bypass.[81] Pharmacologic therapy was unsuccessful, and resumption of bypass was necessary. Forty-five minutes after the injection, atrioventricular pacing restored perfusion and permitted discontinuation of bypass.

Use of sodium bicarbonate early in resuscitation to prevent acidosis-mediated potentiation of cardiac toxicity may have been beneficial in some cases,[23] but paradoxical effects on intracellular pH during cardiopulmonary resuscitation suggest against its use in the absence of strong experimental or clinical data.

Although human studies do not exist, small animal trials suggest a possible future role for infusions of lipid or insulin/glucose to treat serious cardiac toxicity induced by bupivacaine. A 20% lipid infusion and internal cardiac massage given 10 minutes after cardiac arrest induced by a bupivacaine bolus in dogs produced 100% survival in a model that was otherwise lethal.[108] The authors postulate that extracellular or intracellular lipid prevented or reversed interaction of the lipophilic local anesthetic with intracellular targets. In another canine model, an infusion of 2 mL/kg 50% dextrose plus 1 unit/kg insulin was superior to saline or dextrose alone in reversing bupivacaine-induced cardiac depression.[19] Effects on potassium current, calcium handling, and myocardial energy utilization all may have contributed to the salutatory effects of the insulin infusion.

Prevention of Systemic Toxicity of Local Anesthetics

Despite the development of new, relatively less toxic amide local anesthetics such as levobupivacaine and ropivacaine, severe CNS

and cardiovascular effects are not eliminated. Several cases of ropivacaine-induced cardiac arrest have been reported.[18, 49, 53] In these cases, both asystolic arrest and ventricular fibrillation-associated arrest were successfully resuscitated. Nonetheless, it is clear that prevention is more prudent and effective than treatment of toxicity. The keys to prevention are to use the lowest possible anesthetic concentration and volume consistent with effective anesthesia and to avoid a significant intravascular injection. The latter is accomplished by careful slow aspiration of a needle or catheter prior to injection, injection of a small test dose of anesthetic mixed with epinephrine to assess a cardiovascular response, if injection is intravascular, and use of slow fractional dosing of large-volume injections with vigilance for early signs of CNS or cardiac toxicity.

Summary

Local anesthetics are frequently used drugs that provide surgical analgesia and acute and chronic pain relief. The analgesic effect of local anesthetics is primarily caused by inhibition of neural conductance secondary to sodium channel blockade. Systemic toxicity, which primarily effects the heart and brain, is also largely related to

sodium channel blockade. Severe systemic toxicity usually occurs secondary to inadvertent intravascular injection. In most cases of systemic toxicity, CNS manifestations precede cardiovascular events. If cardiovascular collapse and cardiac arrest occur, resuscitation may be difficult and prolonged. Cardiopulmonary bypass may be useful because it provides cardiovascular support, limits exacerbating factors such as tissue hypoxia and acidosis, and improves hepatic blood flow, thereby increasing local anesthetic metabolism. Avoidance of intravascular injection and vigilance for early signs of CNS or cardiac toxicity are keys to preventing serious adverse events.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 65
Inhalational Anesthetics

Brian Kaufman

Martin Griffel

A 40-year-old dentist was found unresponsive in his procedure room by his office staff. The paramedics noted that the mask on his face was attached to a supply of nitrous oxide and oxygen. The oxygen tank was empty. His vital signs were: blood pressure, 140/90 mm Hg; pulse, 120 beats/min; respiratory rate, 22 breaths/min and regular. In the emergency department, his oxygen saturation by pulse oximetry was 63%. His pupils were dilated and minimally reactive. He remained unresponsive to painful stimulation. His rapid bedside glucose concentration was 110 mg/dL. His serum electrolytes and complete blood count were normal, as was a noncontrast CT scan of the head. A presumptive diagnosis of anoxic encephalopathy secondary to inhalation of pure nitrous oxide was made. Neurologic improvement did not occur.

General anesthesia occurs as a result of reversible changes in neurologic function caused by drugs that modulate synaptic neurotransmission. The commonly accepted elements of general

anesthesia include hypnosis, amnesia, analgesia, inhibition of noxious reflexes, and skeletal muscle relaxation.[8] However, precise definitions for some of these terms are lacking. In addition, different effects occur at varying concentrations of inhaled agents. Side effects of the drugs may be redefined as toxicity, depending on the clinical situation.

History

Modern anesthetic practice often is stated to have begun in 1846 at the Massachusetts General Hospital, when the dentist William Morton gave the first public demonstration of the ability of inhaled ether vapor to alleviate the pain of surgery. Following this feat, John C. Warren, the chief of surgery, remarked to the assembled gallery, â€œGentleman, this is no humbug.â€• Oliver Wendell Holmes then chose the Greek-related noun *anesthesia* (without feeling) to characterize the process.

The earliest description of the use of an inhalational anesthetic was made by Paracelsus, a Swiss physician and alchemist who prepared a mixture of diethyl ether, alcohol, and water called sweet oil of vitriol. He described how he gave this preparation to hens who fell into a deep sleep from which they recovered unharmed. In 1735, Wilhelm Froben gave this substance its modern name of â€œether.â€• Ether was used topically, particularly via the intranasal route, as a treatment of headache, nervous diseases, and fits.

Observations on the circulatory and respiratory physiology eventually led to an understanding of the effects of inhalation gases and vapors. In the last decade of the 18th century, centers for the pneumatic treatment of disease were established in Birmingham and Bristol, England. Experiments with ether that was inhaled via a funnel and with nitrous oxide were conducted at these institutions. After Humphry Davy described his own pleasurable and exhilarating experience when he inhaled the â€œlaughingâ€• gas, many of his colleagues and friends inhaled nitrous oxide to experience its

inebriating effects. Davy also described how inhalation of nitrous oxide relieved headache and the pain of an erupting molar tooth. Although Davy recognized the analgesic properties of nitrous oxide and its possible application for surgery, he failed to pursue the idea.

The public soon took up the use of nitrous oxide in the form of nitrous oxide frolics. Audiences to itinerant medicine shows volunteered to experience the exhilarating effects of nitrous oxide inhalation. At one such show in 1844 in Hartford, Connecticut, a man under the influence of nitrous oxide injured his leg but did not feel any pain. Dr. Horace Wells, a dentist in the audience that day, inhaled nitrous oxide the following day and had his partner painlessly remove a troublesome tooth. A subsequent public demonstration of the use of nitrous oxide for dental extraction went poorly, impeding the general acceptance of this agent as a surgical anesthetic.

In Great Britain in 1847, James Simpson, an obstetrician, first used ether to relieve the pain of labor. He subsequently adopted chloroform for this purpose because of its more pleasant odor and more rapid induction and emergence. The clergy and other physicians opposed the concept of relieving pain during childbirth, but the method ultimately was accepted after Queen Victoria gave birth to Prince Leopold with chloroform given by John Snow.

Over the next century, several volatile anesthetics were introduced, including ethyl chloride in 1848, divinyl ether in 1933, trichloroethylene in 1934, and ethyl vinyl ether in 1947. All of these agents had significant safety problems associated with their use, including combustibility and direct organ toxicity.

Advances in fluorine chemistry led to the cost-effective incorporation of fluorine into molecules used in the development of modern anesthetics. Fluroxene was the first of the new fluorinated anesthetics to be widely used clinically. However, this anesthetic was flammable and hepatotoxic. It was largely replaced by the nonflammable halothane, which was synthesized in 1951 and introduced into clinical practice in 1956. Methoxyflurane was

evaluated in humans in 1960 but is no longer used because of nephrotoxicity and hepatotoxicity. Other halogenated hydrocarbons with improved

clinical properties have been introduced, including enflurane, isoflurane, desflurane, and sevoflurane (Figure 65-1). The inert gas xenon has been shown to be a useful anesthetic and is being studied. Although xenon is environmentally friendly compared to presently used anesthetics, its toxicity is relatively unknown.

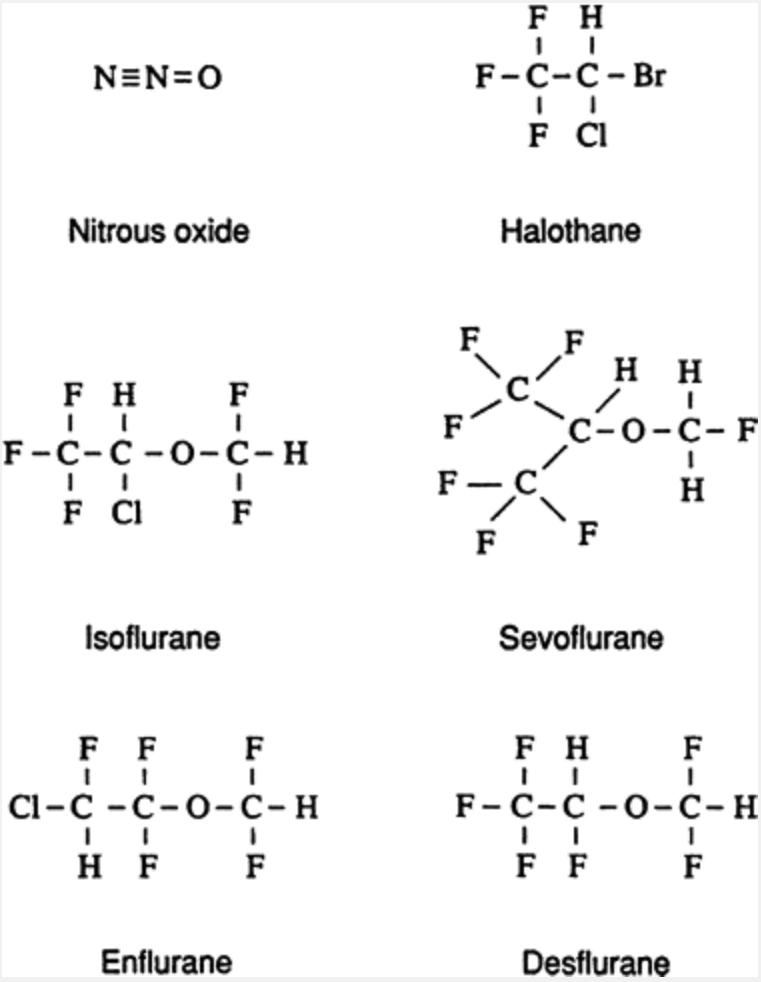

Figure 65-1. The inhalational anesthetics.

Pathophysiology

Because a wide range of chemically distinct compounds can produce anesthesia, a unique receptor for the inhaled anesthetics is improbable. More likely, the volatile anesthetics cause general anesthesia by modulating synaptic function from within cell membranes. Anesthetics are known to interact with many proteins. The most likely, but not yet proven, target for the inhalational agents are the ion channels that control ion flow across the cytoplasmic membrane. An in-depth discussion is beyond the scope of this chapter, but several concepts are important to consider. First, more than 20 different ion channels are identified, each controlling various anion and cation flows. The results of these ion channel effects include release of inhibitory neurotransmitters and inhibition of excitatory neurotransmitters. In fact, each anesthetic type has variable actions. The receptor for Î³-aminobutyric acid type A ($GABA_A$) is the best studied and plays an important role because $GABA_A$ is an inhibitory neurotransmitter. Finally, the interaction of all of these effects from a single anesthetic produces the condition we refer to as *general anesthesia.* Many of the side effects of the inhalational anesthetics result directly from ion channel effects in nonneural tissue, primarily cardiac cell membranes.

Reversible changes in neurologic function cause loss of perception and reaction to pain, unawareness of immediate events, and loss of memory of those events. The exact mechanism by which the inhaled (volatile) anesthetics produce general anesthesia is uncertain, but experimental data support several theories. The pharmacologic mechanisms for general anesthesia include the physicalâ€“chemical behavior of volatile hydrocarbons within the hydrophobic regions of biologic membrane lipids and proteins.

Pharmacokinetics

The potency of the various inhaled anesthetics correlates with their physicochemical properties. The dominant theories of the molecular mechanisms by which volatile agents affect membrane function are based on the lipid solubility of the drugs and experimental demonstration of pressure reversal of anesthesia. The anesthetic potency of volatile anesthetics correlates directly with the relative lipid solubility of each drug, which suggests that the primary molecular actions of anesthetics occur in the lipid portion of cell membranes. This mechanism is known as the *Meyer-Overton lipid solubility theory.* Potential membrane regions for anesthetic action include the hydrophobic areas of proteins and proteinâ€“lipid interface regions, as well as the phospholipid matrix. High pressures (100â€“200 atm) can reverse the anesthetic effects of several drugs, which suggests that the drugs cause anesthesia by increasing membrane volume at normal atmospheric pressure, an effect known as the *volume expansion theory*.

Because the inhaled anesthetics enter the body through the lungs, the factors that influence their absorption by blood and distribution to other tissues include the solubility of the drug in blood, blood flow through the lungs, blood flow distribution to the various organs, solubility of the anesthetic in tissue, and the mass of the tissue. The goal of inhalation anesthesia is to develop and maintain a satisfactory partial pressure of anesthetic in the brain, the primary site of action.

The pharmacokinetics of anesthetics can be linked to their pharmacodynamics by considering anesthetic potency. The linkage exists because anesthesia strives to achieve and maintain a desired alveolar concentration. For the inhaled drugs, potency is commonly referred to as the *minimum alveolar concentration* (MAC) of the anesthetic. MAC is the alveolar concentration at 1 atm that prevents movement in 50% of subjects in response to a painful stimulus. MAC

is used when comparing the effects of equipotent doses of anesthetics on various organ functions.

Nitrous Oxide

Nitrous oxide is the most commonly used inhalational anesthetic in the world. Its advantages include a mild odor, absence of airway irritation, rapid induction and emergence, potent analgesia, and minimal respiratory and circulatory effects. When administered in a modern operating room using current standards of monitoring to prevent unintentional hypoxia, nitrous oxide is a remarkably safe agent. Unfortunately, nitrous oxide also has a potential for abuse, particularly among hospital and dental personnel.[26] Death and permanent brain damage are reported but do not result from direct toxic effects; instead they are secondary to asphyxia.[13] If a patient who is exposed to nitrous oxide fails to regain consciousness within several minutes after breathing fresh air or oxygen, other etiologies for the altered mental status (eg, hypoxic encephalopathy or a concomitant central nervous system [CNS]â€“depressant xenobiotic) should be suspected.

Death may occur when patients receive commercially prepared nitrous oxide from tanks contaminated with impurities such as nitric oxide or nitrogen dioxide. Pulmonary toxicity resulting from similar contaminants produced by individual preparation of nitrous oxide by combustion of ammonium nitrate fertilizer is reported.[32]

Injury can result from the physical properties of this anesthetic. Nitrous oxide is 35 times more soluble in blood than is nitrogen. When nitrous oxide is inhaled, any compliant air-containing space, such as bowel, increases in size, whereas noncompliant spaces, such as the eustachian tubes, exhibit an increase in pressure. These effects occur because nitrous oxide diffuses along the concentration gradient from the blood into a closed space much more rapidly than nitrogen can be transferred in the opposite direction. Clinical

consequences include rapid progression of a pneumothorax to tension pneumothorax, tympanic membrane rupture with hearing loss, bowel distension, and tracheal or laryngeal trauma caused by increased endotracheal cuff pressure resulting from replacement of air by a larger volume of nitrous oxide. Nitrous oxide can be particularly dangerous in patients who have suffered air emboli, and its use should be immediately discontinued upon recognition of these events. When intracranial or neuraxial air is injected during placement of an epidural catheter, it also can theoretically expand upon subsequent exposure to nitrous oxide.

Hematologic Effects

Bone marrow depression was first recognized as a complication of long-term nitrous oxide exposure in the 1950s, when the gas was used to sedate intubated patients who had severe tetanus.[25] Leukopenia with hypoplastic bone marrow and megaloblastic erythropoiesis typically developed 3â€“5 days after initial exposure and was followed by thrombocytopenia. Recovery usually occurs within 4 days after the anesthetic is discontinued. Healthy patients undergoing routine surgical procedures demonstrate mild megaloblastic bone marrow changes after 12 hours of exposure to 50% nitrous oxide and marked changes after 24 hours.[36] Critically ill patients may be more sensitive to the effects of nitrous oxide on the bone marrow, with megaloblastic changes described after only 1 hour of exposure.[3]

The hematologic effects of exposure to nitrous oxide strongly resemble the biochemical characteristics of pernicious anemia.[2,34,35] Vitamin B_{12}, or cyanocobalamin, is a bound coenzyme of cytoplasmic methionine synthase. The cobalt moiety in the enzyme functions as a methyl carrier in its transfer from 5-methyltetrahydrofolate to homocysteine to form methionine (Figure 65-2). Nitrous oxide oxidizes the cobalt, converting vitamin B_{12} from the active monovalent form (cob(I)alamin) to the inactive bivalent form

(cob(II)alamin), which irreversibly inhibits methionine synthase.[34] The metabolic consequences of this block are significant because methionine and tetrahydrofolate are required for both DNA synthesis and myelin production. This interference is responsible for the development of bone marrow depression and polyneuropathy resembling those that occur in pernicious anemia.[34]

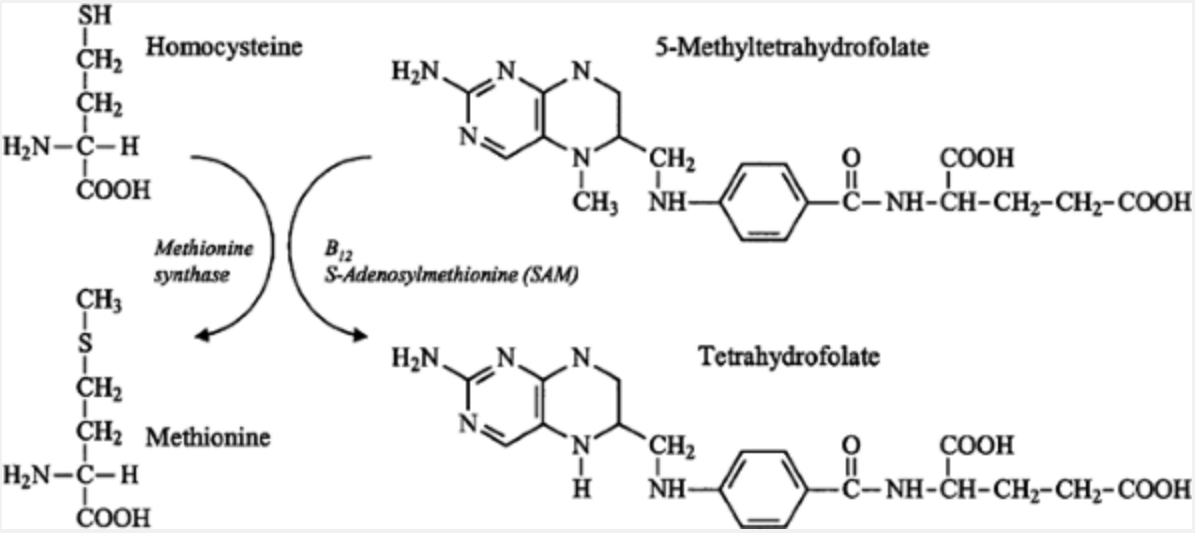

Figure 65-2. Hematologic effects of exposure to nitrous oxide resemble those characteristic of pernicious anemia and are related to oxidation and inactivation of vitamin B_{12}. The irreversible blockade of methionine synthase is consequential with regard to DNA synthesis and myelin production.

Neurologic Effects

Disabling polyneuropathy in healthcare workers who habitually abused nitrous oxide was first described in 1978.[26] The neurologic disorder improved slowly when the patients abstained from further nitrous oxide abuse. As discussed, this neuropathy is clinically indistinguishable from subacute combined degeneration of the spinal

cord associated with pernicious anemia. The syndrome of nitrous oxide neuropathy is characterized by sensorimotor polyneuropathy, often combined with signs of posterior and lateral spinal cord involvement. Signs and symptoms include numbness and paresthesias in the extremities, weakness, and truncal ataxia. Neurologic changes develop only after several months of frequent exposure to nitrous oxide. Those at risk include individuals who chronically abuse the gas and those who are occupationally exposed to grossly contaminated environments for prolonged periods.[4] This scenario is highly unlikely in the modern operating room, where inhalational anesthetics are scavenged, but it may occur in poorly ventilated dental offices, where personnel are exposed to >1000 parts per million (ppm) nitrous oxide. This problem probably is markedly underdiagnosed because the neurologic changes that occur in mild cases mimic other more common neurologic conditions.[7]

Chronic Exposure to Trace Levels of Nitrous Oxide

Dentists and dental assistants are often exposed to greater concentrations of waste anesthetic gases than are individuals working in well-vented operating rooms. Animal studies demonstrate that methionine synthase may be inactivated by exposure to >1000 ppm of nitrous oxide, a level often exceeded in dental procedure rooms. An epidemiologic survey compared 15,000 dentists who used and 15,000 dentists who did not use nitrous oxide in their practices.[7] A

1.2- to 1.8-fold increase in liver, kidney, and neurologic disease was found in the dentists and their chairside assistants who were chronically exposed to trace levels of nitrous oxide. For those with heavy office use of nitrous oxide, a 4-fold increase in the incidence of neurologic complaints compared to the nonexposed group was observed. Female dental assistants who were exposed to nitrous

oxide had a 2- to 3-fold increase in spontaneous abortion rates, reduced fertility, and a higher rate of congenital abnormalities in their offspring.

Treatment

General

Removal of the acutely affected person from the toxic environment should be the initial intervention. Individuals who have developed toxicity from abuse of the gas should be educated about the relationship between their recreational activities and their clinical findings.

Specific

Vitamin B_{12} may help patients with a masked vitamin B_{12} deficiency who develop megaloblastic anemia and neurologic dysfunction after brief exposure to nitrous oxide, but it is not beneficial in patients who have toxicity resulting from more chronic exposure.[38] The reason for the ineffectiveness of vitamin B_{12} in this situation is uncertain.

The bone marrow abnormalities associated with nitrous oxide toxicity may be reversed by administration of a single 30-mg, intravenous dose of folinic acid (the active form of folate)[31] (Antidotes in Depth: Folic Acid and Leucovorin). In primates, a methionine-supplemented diet greatly reduced demyelination and neurologic damage from chronic exposure to 15% nitrous oxide.[39]

Halogenated Hydrocarbons

The inhaled anesthetics initially were considered biochemically inert drugs. Initial reports of toxicity following their administration were poorly explained and attributed to direct effects on susceptible organs. It now is clear that the inhalational anesthetics are not inert

but are metabolized in vivo, and that their metabolites are responsible for acute and chronic toxicity.

Halothane Hepatitis

Two distinct types of hepatotoxicity are associated with halothane use. The first is a mild dysfunction that develops in approximately 20% of exposed patients. Patients often are asymptomatic but exhibit modestly elevated serum aminotransferase concentrations within a few days of anesthetic exposure. Recovery is complete.[32] In contrast, a life-threatening hepatitis occurs in approximately 1 in 10,000 exposed patients and produces fatal massive hepatic necrosis in 1 of 35,000 patients.[42] Because the histologic findings of massive hepatocellular necrosis are indistinguishable from those of viral hepatitis,[46] differentiating halothane hepatitis from other causes of hepatitis in the postoperative period is difficult without positive serologic studies. Jaundice, which is common after anesthesia and surgery, usually results from factors such as preexisting liver disease, blood transfusion, sepsis, or other causes of hepatitis. Thus halothane hepatitis is a diagnosis of exclusion.

Factors that may increase the risk of developing hepatotoxicity from halothane include multiple exposures, obesity, female gender, age, and ethnic origin.[33]

Several studies report an association between multiple exposures to halothane and subsequent development of hepatitis.[45,50] In 1 study, 95% of cases of halothane hepatitis followed multiple exposures, 55% of which involved reexposure within 4 weeks.[50] Under these circumstances, liver dysfunction usually is more severe and the latency before clinical presentation usually is shorter than when the syndrome develops after initial exposure to halothane.[45]

Obesity is a risk factor commonly implicated in halothane hepatotoxicity.[1,47] Increased fat stores may act as a â€œreservoirâ€• for halothane, with slow and prolonged release into

the circulation and subsequent increase in production of potentially hepatotoxic metabolites.

Most cases of halothane hepatitis occur in middle-aged patients, with women having twice the risk.[22] Genetic factors may play a role in some patients, as indicated by a report of this syndrome in three pairs of related women of Mexican-Indian or Mexican-Spanish ancestry.[21]

Mechanism of Toxicity

Halothane is the most extensively metabolized inhalational anesthetic. Approximately 20% of the absorbed drug undergoes oxidative metabolism, principally by cytochrome P450 in the liver, to trifluoroacetic acid. Reduction to trifluorochloroethane and difluorochloroethylene (Figure 65-3) is a minor route of halothane metabolism that requires the absence of oxygen and the presence of an electron donor. These volatile metabolites are free radicals, which may directly produce acute hepatic toxicity by irreversibly binding to and destroying intracellular structures in the hepatocyte. Alternatively, by acting as haptens they may trigger an immune-mediated hypersensitivity response.[37,48] The high percentage of patients with halothane hepatitis who had recent prior exposure to the drug is most consistent with the latter mechanism.[22]

Enflurane, used extensively in North America since 1966 but rarely used now, is weakly associated with hepatotoxicity. Some authorities believe the evidence does not support the existence of enflurane-induced hepatic necrosis.[14,16,41] Isoflurane, desflurane, and sevoflurane all appear to have low hepatotoxic potential. The immune form of hepatitis has been reported with all agents except sevoflurane. Cross-sensitivity may be operable, such that prior exposure to one anesthetic triggers hepatotoxicity upon subsequent exposure to a different anesthetic.

Nephrotoxicity

The kidneys are the only other organ at risk for toxicity from modern inhalational anesthetics. Methoxyflurane is an anesthetic introduced in 1962. By 1966, it was linked to the development of vasopressin-resistant polyuric renal insufficiency (nephrogenic diabetes insipidus) in 16 of 94 patients receiving prolonged methoxyflurane anesthesia for abdominal surgery[11] (Chap. 17). Polyuria was associated with a negative fluid balance; elevated serum sodium, osmolality, and urea nitrogen concentrations; and a fixed urinary osmolality close to that of serum. Renal abnormalities lasted from 10â€“20 days in most patients but persisted for more than 1 year in 3 patients. Subsequent studies demonstrated that renal toxicity was caused by inorganic fluoride (F) released during biotransformation of methoxyflurane.[44] The risk of toxicity was highly correlated with both the total dose of methoxyflurane (concentration times duration) and the peak serum (F^-) concentration.[10,31] The nephrotoxic serum fluoride concentration is 50â€“60 Âµmol/L.[10] Factors that enhance biotransformation (obesity, enzyme induction) increase the risk of toxicity. Although the precise mechanism

by which fluoride produces its toxic effect on the kidney is not clear, one hypothesis is that fluoride inhibits adenylate cyclase, thereby interfering with the normal action of antidiuretic hormone on the distal convoluted tubules.

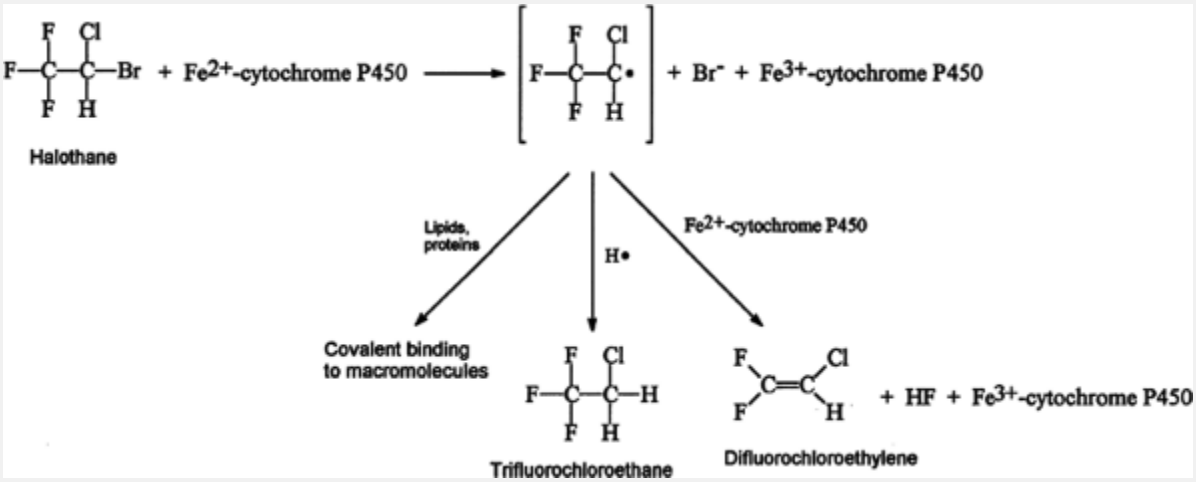

Figure 65-3. Reductive metabolism of halothane results in formation of trifluorochloroethane and difluorochloroethylene.

Although methoxyflurane is no longer used, lessons learned regarding its toxicity are applied when evaluating the nephrotoxic potential of other fluorinated anesthetics. Of the currently used anesthetics (halothane, isoflurane, enflurane, desflurane, sevoflurane), only enflurane and sevoflurane undergo biotransformation by defluorination.

Approximately 5% of sevoflurane is metabolized. This process occasionally results in sufficient serum fluoride concentrations to produce transient decreases in urine-concentrating ability.[24] However, clinically evident renal impairment almost never occurs with use of either enflurane or sevoflurane.[18] In addition, volunteer studies failed to show any urine-concentrating defect after exposure to sevoflurane that resulted in high fluoride plasma concentrations. In patients with preexisting renal insufficiency, the risk of postoperative renal dysfunction is believed to be worse with exposure to inhalational agents. However, studies demonstrate that deterioration of renal function does not occur after exposure to desflurane and isoflurane,[28] possibly because intrarenal fluoride

concentrations are more important than plasma fluoride concentrations in the development of nephrotoxicity.

Pharmacokinetics

Chronic use of isoniazid induces CYP2E1, the enzyme responsible for enflurane metabolism. This induction results in elevated serum fluoride concentrations in approximately 50% of isoniazid-treated patients who receive an enflurane anesthetic.[31] The fluoride concentrations, however, are neither high enough nor sustained enough to produce clinically significant renal dysfunction. Nonetheless, a prudent course is to avoid prolonged use of enflurane in patients taking isoniazid or other xenobiotics, such as ethanol, phenobarbital, and phenytoin, which elevate the hepatic activity of cytochrome CYP2E1 (Chap. 9).

Unusually high serum fluoride concentrations are reported in morbidly obese patients anesthetized with enflurane.[9] This finding may be related to a large storage capacity for fat-soluble anesthetics. Although prolonged postoperative release and metabolism of enflurane may occur, renal dysfunction is not reported with enflurane use even in obese patients.

Sevoflurane reacts with the alkali within carbon dioxide absorbers to produce several degradation products, including a vinyl ether called compound A ($CF_2C(CF_3)OCH_2F$), which is nephrotoxic and hepatotoxic in rats.[23,49] The site of compound A-induced nephrotoxicity in the rat is the renal tubule, especially at the corticomedullary junction.[23] The extent of nephrotoxicity is determined by both the concentration of compound A and the duration of exposure. Compound A is also conjugated, and its breakdown products are nephrotoxic.

Technical Issues

Extensive clinical experience with sevoflurane involving several million patients and 4000 closely studied volunteers failed to

demonstrate nephrotoxicity.[30] Higher levels of compound A are generated during low-flow anesthesia, use of high concentrations of sevoflurane, fresh Baralyme use, and increased temperature conditions. A high fresh-gas flow rate dilutes the concentration of compound A. Concern that higher compound A concentrations are generated when a low fresh-gas flow rate (eg, <2 L/min) is used in a closed circuit led to the current sevoflurane package labeling, which warns the anesthesia care provider against fresh-gas flow rates <2 L/min in a circle absorber system.[29]

Some controversy exists regarding the safety of low-flow sevoflurane anesthesia. Although there are no clinical reports of sevoflurane-induced nephrotoxicity as measured by changes in blood urea nitrogen (BUN), serum creatinine, or creatinine clearance, clinical data demonstrate transient nephrotoxicity when more subtle measurements of glomerular and tubular function are used.[15,20] For example, when young healthy patients without underlying renal disease were anesthetized with low-flow sevoflurane for a mean of 6.7 hours, transient but statistically significant increases in urinary glucose and protein excretion were documented without any changes in BUN, creatinine, or creatinine clearance.[20] The clinical significance of such transient abnormalities in renal function is uncertain. Regardless, it seems prudent to not use low-flow sevoflurane

in patients with preexisting renal disease until clinical data document the safety of this practice. Newer carbon dioxide absorbents that are free of strong alkali have been identified and studied in an attempt to find products that generate less compound A.

Inhalational Anesthetic-Related Carbon Monoxide Poisoning

Pharmacology

Desflurane, enflurane, and isoflurane contain a difluoromethoxy moiety that can be degraded to carbon monoxide (CO). This process occasionally results in patient exposure to toxic CO concentrations and, in rare instances, severe CO poisoning.[6] The true incidence of CO exposure during clinical anesthesia is unknown, and no adequate means for routine detection of intraoperative exposure are available at this time.

CO production is inversely proportional to the water content of CO_2 absorbents. Soda lime and Baralyme, the two most frequently used CO_2 absorbents, are sold wet (13â€“15% water by weight), but wet absorbents may dry with high gas-inflow rates. Higher levels of CO are most apt to be present during the first case following a weekend because of drying of CO_2 absorbent from a continuous inflow of dry oxygen over the weekend.[17]

Other factors influence the concentration of CO that may result from anesthetic degradation, including temperature (higher temperature increases CO formation), type of absorbent, choice of anesthetic, and concentration of anesthetic. Strong alkalis, such as potassium and sodium hydroxide, initiate the reaction that forms CO. Baralyme, which contains potassium hydroxide, forms more CO than does soda lime, which contains a combination of both.

In one experiment, Baralyme was exposed to 48 hours of dry gas flowing at 10 L/min. Nine swine were then anesthetized with desflurane. Three of the animals died of cardiac arrest within 20 minutes; the other 6 were successfully resuscitated with intravenous epinephrine and discontinuation of desflurane.[19] Extremely high concentrations of CO (mean peak concentration 37,000 ppm) were detected in the circuit within 15 minutes of initiating desflurane anesthesia. All the animals had carboxyhemoglobin concentrations >80%, with a concentration >90% in 7 of the swine. Lower CO concentrations were detected when the CO_2 absorbent was exposed to only 24 hours of dry gas and when soda lime was substituted for Baralyme.

Clinical monitors routinely used in the operating room cannot detect CO. Mass spectrometry (available in some operating rooms) cannot directly detect CO because its molecular weight is equivalent to that of nitrogen, a gas usually present in much greater amounts. In addition, detection of CO by fragmentation products is not possible by mass spectrometry because CO_2 is present in greater amounts and has similar fragmentation products. However, the presence of CO should be suspected if the mass spectrometer shows the presence of enflurane when this agent is not being administered.

Trifluoromethane is produced by degradation of isoflurane and desflurane and is responsible for the false readings for enflurane.[54] Simultaneous production of trifluoromethane and CO during chemical decomposition of isoflurane and desflurane allows the false reading of the former as enflurane by mass spectrometry to serve as a gross CO monitor and allows for interventions to prevent further CO production and enhance CO elimination. The overall incidence of CO exposure from anesthetic degradation was 6 of 1372 (0.44%) first cases of the day in which either isoflurane or desflurane was administered.[54] Mass spectrometry is a useful monitor for indirect detection of CO poisoning in the clinical setting.[53]

Although no case reports document patient morbidity or mortality from intraoperative CO exposures, carboxyhemoglobin levels reportedly as high as 36% can cause morbidity and mortality in patients with concurrent disease.[6] Unfortunately, the diagnosis of CO poisoning during anesthesia is difficult because the main clinical features of toxicity are masked by anesthesia, and no routinely available means can identify CO within the breathing circuit or detect when the CO_2 absorbent has been desiccated. Delayed neurologic sequelae from intraoperative CO poisoning will be likely missed on the anesthesiologist's postoperative patient evaluation.[52]

The product labels of desflurane and isoflurane have been altered to include a precaution that the CO_2 absorbent should be replaced if a practitioner suspects the absorbent is desiccated. However, the

problem associated with this warning is the lack of a reliable method for determining when the absorbent is fully or partially desiccated.

If an anesthetic machine is found with the fresh-gas flow â€œonâ€• at the beginning of the day, a reasonable practice is to replace the absorbent. Changing from Baralyme to soda lime use also should be considered as a protective measure. Newer CO_2 absorbents that are less likely to degrade anesthetics are being evaluated but are not yet available in the United States.

Extreme heat and fires within the anesthesia circuits have been reported in a warning distributed by the manufacturer of sevoflurane. The cases involved desiccated carbon dioxide absorbents, high sevoflurane concentrations, and primarily but not exclusively Baralyme adsorbent. The exact mechanisms have not been entirely elucidated but again point to the need to change absorbent when it is dry or routinely every Monday morning prior to the first case.

Abuse of Halogenated Volatile Anesthetics

Fatal or life-threatening complications occur when halogenated inhalational anesthetics are used for nonanesthetic purposes (suicide attempts, mood elevation, topical treatment of herpes simplex labialis). When ingested, halothane usually produces gastroenteritis with vomiting, followed by depressed consciousness, hypotension, shallow breathing, bradycardia with extrasystoles, and acute lung injury. Coma usually resolves within 72 hours.[12,51] The diagnosis should be suspected when these features occur in a patient with the sweet/fruity odor of halothane on the breath. Supportive care, including endotracheal intubation and nasogastric lavage, should be provided with protection for potentially exposed staff. Full recovery can occur without permanent organ injury.

Intravenous injections of halothane may occur as a suicide attempt or unintentionally during anesthesia induction. A young patient who

was found unconscious and hypotensive with acute lung injury following IV injection of halothane was not successfully resuscitated.[5] A 16-year-old girl received an unintentional IV injection 2.5 mL halothane during anesthesia induction.[43] She became unconscious and apneic within 30 seconds but began to awaken within 2â€“3 minutes. Four hours later she developed respiratory distress from acute lung injury but subsequently made a full recovery. Transient coma and apnea probably are secondary to a halothane bolus reaching the brain on its first pass through the

bloodstream. Redistribution then occurs, explaining the rapid awakening. The acute lung injury that develops following injection of halothane may result from a direct toxic effect of high concentrations of this hydrocarbon drug on the pulmonary vascular bed. Following injection, the anesthetic likely travels as a bolus during the first passage through the pulmonary circulation because of its poor solubility in blood.

Hospital personnel are involved in most reported cases of halothane abuse by inhalation.[40] Inhalation of halothane produces a pleasurable sensation similar to that described with glue sniffing. Death may result from upper airway obstruction following loss of consciousness or from dysrhythmias. Death occurred in a student nurse anesthetist who applied a full 250-mL bottle of enflurane over 3 hours to â€œcold soresâ€• on her lower lip.[27]

Summary

Inhalational anesthetics remain popular choices for maintenance of general anesthesia. Their advantage over intravenous drugs is that their drug level within the body can be increased or decreased at will. Toxicity with use of these drugs may result through a variety of mechanisms, including excessive physiologic drug effect, direct drug effects on metabolic pathways, and toxic effects of drug metabolites. Although life-threatening adverse reactions occur infrequently,

physicians who use these drugs should be knowledgeable about their pharmacology and potential toxicity.

Chapter 66
Neuromuscular Blockers

Kenneth M. Sutin

Brian Kaufman

Sanford M. Miller

A 28-year-old otherwise healthy man presented to the emergency department (ED) complaining of palpitations and dry mouth that develope shortly after he intentionally consumed a marijuana-laced cookie. Althoug he was having troubling illusions, he had no true hallucinations. He had n chest pain, dyspnea, dizziness, abdominal pain, or extremity pain. His in vital signs were: blood pressure, 154/80 mm Hg; pulse, 126 beats/min; respiratory rate, 18 breaths/min; and he was afebrile. On physical examination the patient was in no distress, his lungs were clear to auscultation bilaterally, and his heart sounds were rapid but regular and otherwise normal. His extremities were normal. He was neurologically int except for occasional drifts in attention during mental status testing. An electrocardiogram demonstrated sinus tachycardia. Serum chemistry ana and blood count were normal.

Approximately 1 hour after arrival, the patient had persistent complaints anxiety and troubling illusions. The treating physician ordered lorazepam

mg IV, which was administered promptly by the patient's nurse. Approximately 5 minutes later, the same nurse noted the patient was unresponsive to painful external stimulation. His repeat vital signs were: blood pressure, 210/102 mm Hg; pulse, 145 beats/min; respiratory rate, The patient had normally reactive pupils, but his protective reflexes, including gag reflex, and his muscle tone were absent. Naloxone 1 mg an flumazenil 0.2 mg were administered intravenously with no response whi the patient was ventilated by bag-valve-mask. Because of apnea, the pat was intubated and placed on mechanical ventilation.

Approximately 2 hours later, the patient was awake and extubated by the physician in the ED. Following extubation, the patient reported that he ha been fully aware of his surroundings and all activity and conversations during the entire previous period of â€œunresponsivenessâ€• although h was unable to move. He stated that he felt himself being intubated and w extremely frightened.

A count of the contents of the narcotics cabinet at the nurses station revealed that an excess of lorazepam was available compared to the amo that had been signed out. Further investigation noted that a vial of pancuronium that was located nearby in the locked portion of the medica refrigerator was missing. The vials of pancuronium and lorazepam were o identical size and shape, both had similar labels (a green outline with bla lettering), and both contained 2 mg/mL of drug. The cap colors were different. The event was reported to the hospital leadership.

History

Curare is the generic term for the resinous arrowhead poisons used to paralyze hunted animals.[102] The curare alkaloids are derived from the ba of the ligneous *Strychnos* vine, and the most potent alkaloids, the toxiferines, are derived from *Strychnos toxifera* . Fortunately for the hun who used curare, ingestion of their prey did not cause paralysis. Sir Walt Raleigh discovered the use of curare in Guyana in 1595, and he was the person to bring curare to Europe. In 1898, King's American Dispensatory stated, â€œCurare is a frightfully poisonous extract, prepared by the

savages of South America.â€• Today, curare is available in a purified for as tubocurarine.

Curare played a pivotal role in the discovery of the mechanism of neuromuscular transmission. In 1844, Claude Bernard placed a small piec of dry curare under the skin of a live frog and observed that the frog bec limp and died.[7] He performed an immediate autopsy and discovered the heart was beating. Because direct muscle stimulation produced contractio whereas nerve stimulation did not, Bernard concluded that curare paralyz the motor nerves. He later observed that bathing the isolated nerve did r affect neuromuscular transmission, leading Bernard to conclude â€œcura must act on the terminal plates of motor nerves.â€•[13] Curare was also u by Nobel Laureate physiologists Charles Sherrington, John Eccles, and Bernard Katz to further elucidate neuromuscular physiology. Its first clin use was described in 1878 when Hunter used curare to treat tetanus and seizures.[102] In 1932, Raynard West used curare to reduce the muscular rigidity of hemiplegia.

More recent uses of succinylcholine have been less benign.[2] The anesthesiologist Dr. Carl Coppolino was accused of murdering his wife in 1965 by succinylcholine injection. Her autopsy revealed an abnormally hi concentration of succinylcholine metabolites (succinic acid and choline) ir the brain and liver.[69] Although this assay was not in general use in the medical community, the evidence was deemed admissible.

In 1983, Dr. Michael Swango began his internship at Ohio State Universit Hospital. Shortly after he started his neurosurgery rotation, patients beg dying inexplicably, and he was relieved of his duties.[94] The elusive trail o Dr. Swango followed almost 14 years, through multiple residencies and j and extended as far as Mnene Hospital in Zimbabwe. At one point, the Federal Bureau of Investigation (FBI) estimated Dr. Swango might have murdered 35â€“60 people. The authorities disinterred several victims wh they believed most likely were murdered. Toxicologic analysis of the 7-ye old remains of Thomas Sammarco revealed succinylcholine in the liver an gallbladder and its metabolite succinylmonocholine in multiple organs. Th findings helped the prosecution to secure Swango's guilty plea for the

murder of three victims.

With the advent of new modalities of drug delivery, the toxicologist must attuned to possible malicious intent. Emergency personnel responding to 911 call observed the widow removing an insulin pump reservoir from he dead husband's body with the stated intent to donate the costly equipme A natural cause of death was presumed, yet surprisingly, subsequent forensic analysis revealed etomidate and laudanosine (a metabolite of atracurium) in the victim's liver.

Mechanism of Neuromuscular Transmission and Block

The purpose of a neuromuscular blocker (NMB) is to reversibly inhibit transmission at the skeletal neuromuscular junction (NMJ). All NMBs poss at least 1 positively charged quaternary ammonium moiety that binds to postsynaptic nicotinic acetylcholine (nACh) receptor at the NMJ, inhibiting normal activation by acetylcholine (ACh). The nACh receptor is a ligand-gated ion channel that consists of 4 different protein subunits in a pentameric structure surrounding a central channel. The nACh receptor found in human skeletal muscle is present in 2 primary forms: a mature found at the NMJ (Î±Î±Î²eÎ´) or as a fetal (immature) type found on mus at extrajunctional regions of the muscle fiber (Î±Î±Î²Î³Î´). Before discus the mechanism of neuromuscular block, it is helpful first to describe norn neuromuscular transmission and excitationâ€“contraction coupling (Figure 66-1).

Therapeutic and toxicologic skeletal muscle paralysis can occur by severa mechanisms. For example, tetrodotoxin blocks voltage-sensitive sodium channels, preventing action potential conduction by the motor neuron. On the other hand, botulinum toxin blocks ACh release from the presynaptic neuron by inhibiting the binding of ACh-containing vesicles to the neuron membrane in the region of the synaptic cleft. Modulation of postsynaptic receptor activity at the NMJ can produce paralysis by 1 of 2 mechanisms:

depolarizing (phase I block) and nondepolarizing (phase II block). Succinylcholine is the only depolarizing neuromuscular blocker (DNMB) in current clinical use. Nicotine at high doses can also cause a depolarizing block. The other agents discussed are all nondepolarizing neuromuscular blockers (NDNMBs).

The process of DNMB requires several steps. First, 2 molecules of succinylcholine must bind to each Î± site of the nACh receptor. This actic causes a prolonged open state of the nACh receptor ion channel. The init depolarization causes a muscle action potential and usually causes brief contractions (fasciculations). In contrast to ACh, succinylcholine is not hydrolyzed efficiently by junctional (true) acetylcholinesterase (AChE); th the effect of succinylcholine lasts much longer than ACh. The persistent presence of succinylcholine at the ACh receptor causes a sustained local muscle endplate depolarization that, in turn, causes the voltage-gated sodium channel in the perijunctional region to remain in a prolonged inac state, inducing a desensitization block. The muscle is temporarily refracto to presynaptic release of ACh (phase I block).

The NDNMBs cause skeletal muscle paralysis by competitively inhibiting t effects of ACh and thus preventing muscle depolarization. One molecule o an NDNMB bound to a single nACh receptor (on the Î± site) competitively inhibits normal channel activation. The NDNMBs do not block voltage-gate sodium channels on the muscle membrane, and direct electrical stimulati of muscle contraction is still possible. The NDNMBs are classified by dura of action as ultrashort, short, intermediate, and long. They also are classified by chemical structure as either synthetic benzylisoquinolinium drugs or aminosteroids (Table 66-1), which are derived from plant alkal

NDNMBs also block nACh receptors on the prejunctional nerve terminal ar inhibit ACh-stimulated ACh production and release.[85] This effect reduces available pool of ACh and augments the extent of neuromuscular block.[9]

Pharmacokinetics

The NMBs are highly water soluble and relatively insoluble in lipids. Thus,

they are rapidly distributed in the extracellular space and very slowly permeate lipid membranes such as the placenta and the normal bloodâ€“brain barrier. For this reason, they are devoid of central nervous system (CNS) effects. Because these drugs distribute in the extracellular space, their dosage is based on ideal body mass. Dosing according to the total body mass in obese patients can result in an exaggerated or prolon drug effect.

The speed of onset of an NMB is inversely related to its molar potency (ie ED_{95} expressed as Âµmol NMB drug per kilogram body weight).[56 , 57] Sta differently, the greater the affinity of the NDNMB for the ACh receptor, th fewer molecules per kilogram of tissue are required to produce a given degree of ACh receptor occupancy. Atracurium is the only drug that does follow this generalization because it is a mixture of isomers each having a different receptor affinity.

In general, small, fast contracting muscles such as the extraocular muscl are more susceptible to neuromuscular block than are larger, slower mus such as the diaphragm. This is the so-called *respiratory sparing effect.* Following an IV bolus of NDNMB, paralysis of the diaphragm is coincident with paralysis of laryngeal muscles because their high perfusion results in rapid drug diffusion into the NMJ.[20] Recovery from NMB is fastest for the diaphragm and intercostal muscles, intermediate for the large muscles of trunk and extremities, and slowest for the adductor pollicis, larynx, phary and extraocular muscles.[20]

Complications of Neuromuscular Blockers

Complications associated with the use of NMBs include (1) problems associated with the care of a patient who is therapeutically or otherwise paralyzed (eg, undetected hypoventilation resulting from ventilator or air problems, impaired ability to monitor neurologic function, unintentional patient awareness, peripheral nerve injury, deep vein thrombosis, and sk breakdown); (2) immediate side effects; and (3) effects occurring followi prolonged drug exposure.[75 , 76]

Patient Awareness

The NMB drugs do not affect consciousness, yet misconceptions about the drugs persist.[66] The pupillary light reflex, an important

indicator of midbrain function, is preserved in healthy subjects who receive NDNMBs[41] because pupillary function is mediated by muscarinic cholinergic receptors, for which the NMBs have no affinity. Atropine paralyzes the papillary constrictors and produce fixed mydriasis. Many drugs used in combination with NMBs, such as sedatives, opioids, and inhalational anesthetics, increase the amplitude of pupillary constriction in response to light, but do not produce paralysis.

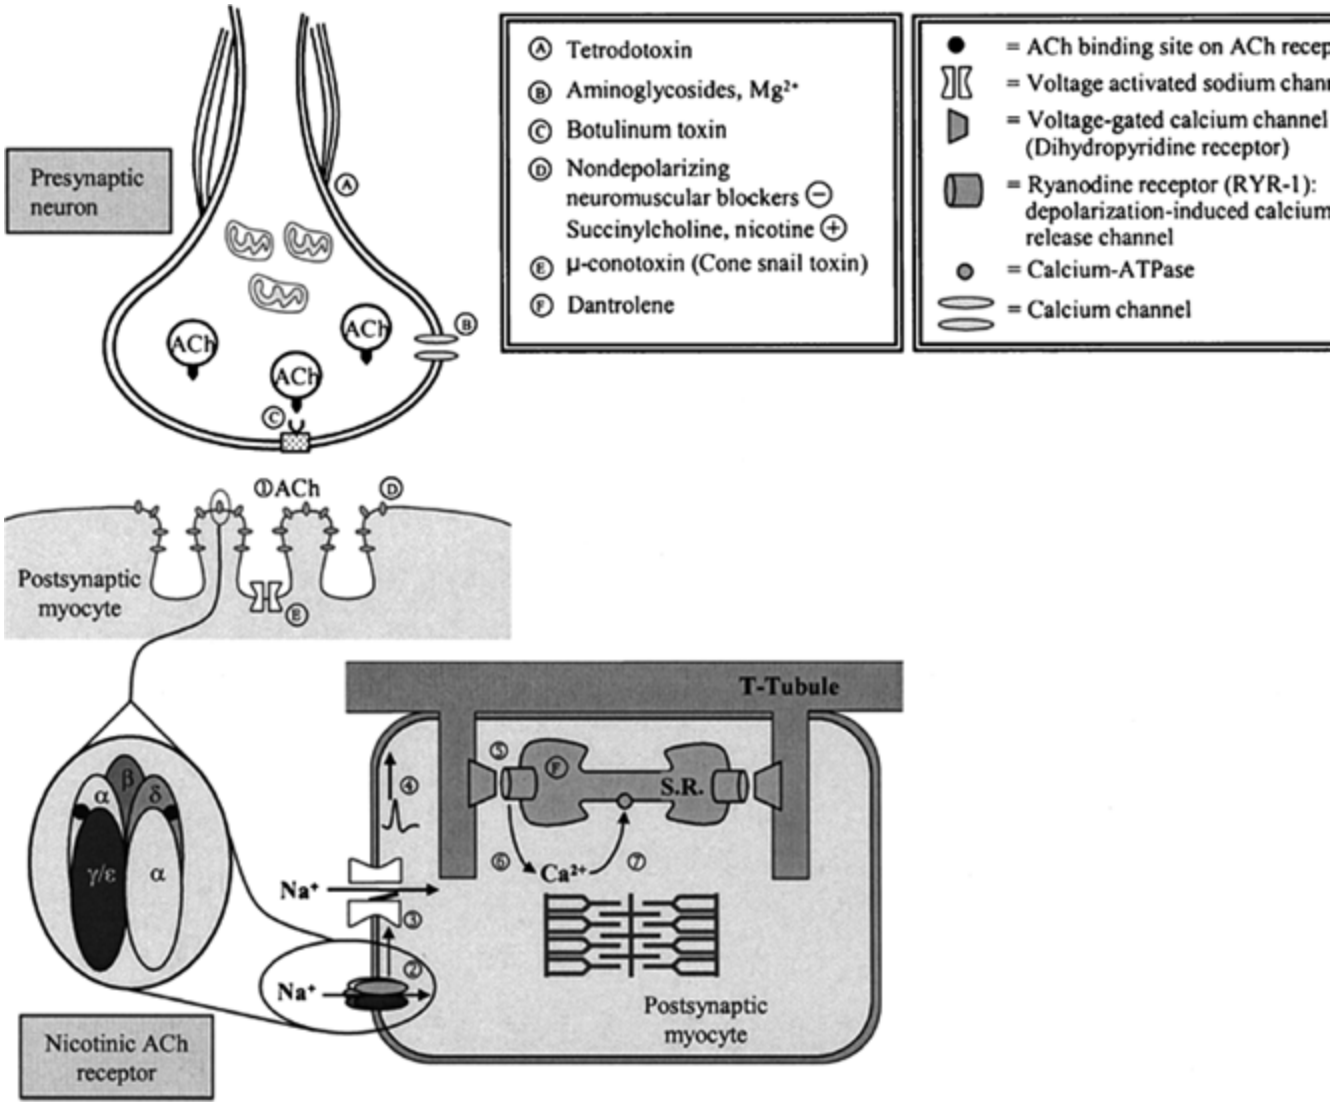

Figure 66-1. Excitationâ€“contraction coupling in skeletal muscle. At the neuromuscular junction (NMJ), acetylcholine (ACh) released from the presynaptic nerve terminal â‘ crosses the 50-nm synaptic cleft to reach t nicotinic ACh receptor â‘¡. The basal lamina, a thin layer of connective tissue, extends into the synaptic cleft and is associated with acetylcholinesterase (AChE). There are two types of receptors, a mature receptor (Î±Î±Î²ÎµÎ´) found in normal adult NMJ and a fetal or immature receptor (Î±Î±Î²Î³Î´) found on the muscle at extrajunctional sites. Proliferation of immature receptor occurs during normal embryonic development and during certain pathologic states, such as denervation injury. On the nicotinic ACh receptor, there are two negatively charged s

that can bind ACh; one at the Î±â€“Î³ interface and one at the Î±â€“Î´ interface. All neuromuscular blockers (NMBs) possess at least 1 positively charged quaternary ammonium group that can competitively bind with the ACh binding site. Only when agonist simultaneously occupies both receptor sites does the ion channel open, becoming nonselectively permeable to monovalent cations and resulting in an influx of Na^+ and an efflux of K^+ . This produces local membrane depolarization (endplate potential) that, in turn, opens voltage-activated Na^+ channels â‘¢. A depolarization of sufficient amplitude generates a propagated muscle action potential (MAP â‘£), which is conducted along the muscle membrane and down the transverse (T) tubules. In the T tubule, the MAP triggers a voltage-activated calcium channel (dihydropyridine receptor [DHPR], â‘¤), which then activates the skeletal muscle ryanodine receptor/channel (RYR-1, ⑥). To allow the fast activation of mammalian skeletal muscle, calcium diffusion is not necessary for activation of RYR-1; instead there is a direct electrical (protein) linkage between the DHPR and RYR-1.[29] This intimate association of DHPR, RYR-1, and junctional sarcoplasmic reticulum (SR) is called the *calcium release u* In contrast, in cardiac muscle, calcium entry through the DHPR is required for activation of the cardiac ryanodine receptor RYR-2. In the skeletal muscle calcium leaves the SR through the RYR-1 channel to enter the myoplasm where it binds to troponin C, activating the contractile actinâ€“myosin protein complex to produce muscular contraction. Active ATPase-driven reuptake of calcium into the longitudinal SR ⑦ terminates muscle contraction. Many factors influence the activity of the RYR-1 channel such as Ca^{2+} , Mg^{2+} , and anesthetic drugs such as inhalation agents that accelerate Ca^{2+} release in persons susceptible to malignant hyperthermia

Histamine Release

The benzylisoquinolinium muscle relaxants (Table 66-1) produce direct, nonimmunologic dose- and rate-related histamine release

from tissue mast cells. The approximate rank order for histamine release is tubocurarine > atracurium and mivacurium > succinylcholine.[27]

Name[a]	Class	Duration	Initial Dose (mg/kg)[b,c]	Onset (min)[d]	Clinical Duration (min)[e]	Recovery Index 25–75% (min)[f]
Succinylcholine	Depolarizer	Ultrashort	0.6–1	1–1.5	3–7	2
Atracurium	Nondepolarizer, benzylisoquinolinium	Intermediate	0.4	2–4	20–40	11
Cisatracurium		Intermediate	0.1	2–4	35–50	10–15
Doxacurium		Long	0.05	4–6	90–120	30–45
Mivacurium	Nondepolarizer, aminosteroid	Short	0.16	2–4	15–20	6–12
Tubocurarine		Long	1	4–6	60–90	48
Pancuronium		Long	0.14	3–6	60–100	55
Rocuronium		Intermediate	0.6	1.5–3	30–40	10–15
Vecuronium		Intermediate	0.1	2–4	20–40	10–15

	Renal Excretion (%)[g]	Biliary Excretion (%)[h]	Effect of Renal Failure	Effect of Hepatic Failure	Active Metabolite	Histamine Release	Effect on HR	Prolonged Block Reported
Succinylcholine	<10	Minimal	Minimal	Minimal	? Succinic acid	Minimal	(Rare) severe bradycardia	Atypical/deficient plasma AChE, phase II Block
Atracurium	5–10	Minimal	No effect	Minimal to none	No, but laudanosine	Minimal	No	Yes
Cisatracurium	10–20	Minimal	No effect or minimal	No effect	No, but laudanosine	No	No	Yes
Doxacurium	50–70	Minimal	Duration	Minimal	?	No	No	Yes
Mivacurium	<10	Minimal	Duration	Duration	No	Minimal	No	Atypical/deficient plasma AChE
Tubocurarine	40–50	10	Duration	Minimal	No	Marked	Tachycardia	No
Pancuronium	40–60	10–20	Duration drug and metabolites	Mild	3-Desacetyl-pancuronium	No	Tachycardia	Yes
Rocuronium	10–20	50–70	Minimal duration	Duration	No	No	Tachycardia at high dose	Yes
Vecuronium	20–40	40–70	Duration drug and metabolites	Duration drug and metabolites	3-Desacetyl-vecuronium	No	No	Yes

[a] Generic name (trade name, year introduced): succinylcholine (Anectine, 1951), atracurium (Tracrium, 1983), cisatracurium (Nimbex, 1995), doxacurium (Nuromax, 1991). Mivacurium (Mivacron, 1992), pancuronium (Pavulon, 1972), rocuronium (Zemuron, 1994), tubocurarine (Curare, 1942), vecuronium (Norcuron, 1984).
[b] Cisatracurium is labeled as mg of base per mL. Other drugs are labeled and packaged as mg of salt per mL.
[c] Typical initial dose is approximately $2 \times ED_{95}$ (mg/kg).
[d] Onset = time from bolus to 100% block.
[e] Clinical duration = time from drug injection until 25% recovery of single twitch height.
[f] Recovery Index = time from 25% to 75% recovery of single twitch height.
[g] % Renal excretion in first 24 hours of unchanged drug.
[h] % Biliary excretion in first 24 hours of unchanged drug.

TABLE 66-1. Pharmacology of Selected NMB Drugs

Anaphylaxis

Of the anaphylactic reactions occurring during general anesthesia, approximately 60% are the result of NMBs, whereas only 17% are the re of latex.[72] Rocuronium is responsible for 43% and succinylcholine for 23% all NMB-associated anaphylaxis. Pancuronium is the agent least associate with serious allergic reactions.[101]

Control of Respiration

At subparalyzing doses, NDNMBs blunt the hypoxic ventilatory response (HVR) but not the ventilatory response to hypercapnia.[25, 26] HVR returns normal when the chemical paralysis is completely reversed. Hypoventilati resulting from blunting of the HVR, especially when combined with the residual effects of other drugs used during anesthesia (eg, opioids or inhalational anesthetics), can cause delayed respiratory failure.

Autonomic Side Effects

Neuronal nACh receptors found in autonomic ganglia, such those at the N are pentamers composed of Î± and Î² subunits. In general they are less susceptible to block by NMBs.[6,7] There is one notable exception. At the sa dose that produces neuromuscular block, tubocurarine also blocks nACh receptors at the parasympathetic ganglia, causing tachycardia, and at the sympathetic ganglia, blunting the sympathetic response.[8,8] In combinatio with tubocurarine-related histamine release, the sympathetic block can cause significant hypotension, especially in patients with heart failure or hypovolemia.[10]

Aminoglycosides (eg, amikacin, gentamicin)
Potentiates
Potentiates
Dose-related decrease in presynaptic ACh release. May decrease postjunctional response to ACh. Partially reversible with calcium supplementation. Effect of neostigmine unpredictable.
Anticholinesterase, peripheral acting: neostigmine, edrophonium
Prolongs succinylcholine (except edrophonium)
Inhibits, prolongs mivacurium (except edrophonium)
Neostigmine, pyridostigmine, and physostigmine inhibit plasma AChE and prolong mivacurium and succinylcholine block. Edrophonium does not inh plasma cholinestarase.
Anticholinesterase, centrally acting: donepezil
Potentiates

Potentiates mivacurium

Inhibits AChE (junctional >> plasma), long half-life (70 h)

Î²-Adrenergic antagonist: propranolol

Potentiates in cats, effects in humans uncertain

Potentiates

Given alone may unmask myasthenic syndrome. Blocks ACh binding at postsynaptic membrane. Reversal of block with neostigmine can cause severe bradycardia.

Î²-Adrenergic antagonist: esmolol

? Mild prolongation

Slows onset of rocuronium and mivacurium

Competes for plasma AChE, slows degradation of mivacurium.

Botulinum toxin

Early potentiation, delayed resistance

Single case report: Acutely, subclinical systemic denervation leads to vecuronium hypersensitivity. Subsequent NMJ remodeling and ACh recept upregulation leads to vecuronium resistance.

Calcium channel blockers: nifedipine, verapamil

Potentiates

Potentiates

Causes calcium channel block pre- and postjunctionally. Verapamil has lo C-I effect on nerve. May inhibit block reversal by cholinesterase inhibitor.

Carbamazepine

?

Inhibits, shortened duration

Chronic therapy causes resistance to NDNMB, except for mivacurium and atracurium.

Dantrolene

?

Potentiates

Blocks excitationâ€“contraction coupling by blocking ryanodine calcium channel in sarcoplasmic reticulum of skeletal muscle.

Digitalis

More prone to cardiac dysrhythmias
Pancuranium increases catecholamines and may cause dysrhythmias

Furosemide

Biphasic dose response in cats; protein kinase inhibition at low doses and phosphodiesterase inhibition at high doses. Diuretic-related hypokalemia potentiates pancuronium in cats.

<10 Âµg/kg
Potentiates
Potentiates
1â€“4 mg/kg
Inhibits
Inhibits
Glucocorticoids

Inhibits
Chronic steroid use induces resistance to pancuronium and decrease plas cholinesterase activity by 50%. Steroids Â± NDNMB associated with myopathies.
Inhalational anesthetics: isoflurane
Potentiates
Potentiates
Decrease CNS activity and potentiates NMB in dose-dependent fashion (postsynaptic and muscle effects). Halothane causes less muscle relaxati than isoflurane.
Lidocaine
Potentiates
Low-dose lidocaine potentiates block. High-dose lidocaine inhibits nerve terminals and blocks ACh binding site at postsynaptic membrane.
The fast Na^+ channel blockers decrease action potential propagation, ACh release, postsynaptic membrane sensitivity, and muscle excitability. Wea inhibitor of plasma cholinesterase.
Lithium carbonate

Prolongs onset and duration
Prolongs effect of pancuronium
Inhibits synthesis and release of ACh. Lithium alone may cause myasther reaction.
Magnesium
Potentiates, may block fasciculations
Potentiates, may also prolong block
Decreases prejunctional ACh release, postjunctional membrane sensitivity and muscle excitability.
Nondepolarizing neuromuscular blocker: pancuronium
â€œPrecurarizationâ€• with NDNMB shortens the onset and decreases si effects of succinylcholine. Tubocurarine decreases and pancuronium increases block duration.
Chronic NDNMB induces resistance to their effect. Mixing different NDNMB may cause greater than additive effects, especially combining pancuroniu with tubocuranine or metocurine
Prior NDNMB inhibits plasma AChE and prolongs mivacurium and succinylcholine block. Rank order: pancuronium > vecuronium > tubocura > atracurium. Heterozygote for atypical plasma AChE may develop phase block when given succinylcholine and pancuronium.
Organic phosphorus compounds echothiophate
Potentiates

Irreversible plasma AChE inhibitor. May totally block enzyme activity.
Phenelzine (MAO inhibitor)
Prolongs

Decreases plasma AChE activity.
Phenytoin
?
Resistant, shortened duration
Acutely, potentiates NDNMB paralysis. With chronic use (except for mivacurium and atracurium) phenytoin induces resistance to NDNMB and increases drug metabolism. This increases the initial dose and decreases

repeat dosing interval.
Polypeptide antibiotics: polymyxin
Potentiates
Potentiates
Can cause severe weakness. May induce postsynaptic neuromuscular bloc
Neostigmine increases block.
Succinylcholine
Self-taming dose of succinylcholine may be used to limit muscular fasciculations.
Tubocurarine, pancuronium, and vecuronium slightly prolonged by prior succinylcholine

Theophylline

Inhibits
Pancuronium and theophylline can increase cardiac dysrhythmias.
Tricyclic antidepressants (TCA)

Pancuronium and TCA may cause cardiac dysrhythmias due to sympatheti effects.

Drug	Response to Succinylcholine	Response to Nondepolarizer	Commer

TABLE 66-2. Effect of Prior Administration of Many Drugs on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers (NDNMBs)

The muscarinic receptors (M_1 â€“M_5) are members of the seven-transmembrane G-proteinâ€“coupled receptor family. As such they are structurally unique and mostly unaffected by NMBs. At clinical doses,

pancuronium elicits dose- and injection rate-related increases in heart ra blood pressure, cardiac output, and sympathetic tone.[89 , 91 , 95] This is attributed to a selective block of parasympathetic transmission at the ca muscarinic receptors (atropinelike effect),[89] block of presynaptic muscari receptors at sympathetic nerve terminals, and perhaps an indirect norepinephrine-releasing effect at postganglionic fibers.[91] Sympathetic stimulation from pancuronium may increase cardiac dysrhythmias, espec when combined with halothane and a tricyclic antidepressant.[24]

Dysrhythmias including bradycardia, junctional rhythms, ventricular dysrhythmias, and cardiac arrest occur rarely after succinylcholine. This situation most likely results from stimulation of the cardiac muscarinic receptors and can be prevented by pretreatment with atropine 15â€“20 Âµg/kg IV. Bradycardia is uncommon, but it may be especially severe in children during anesthetic induction when large or repeated doses of succinylcholine are given. For this reason, atropine is generally given beforehand.

Interactions of Muscle Relaxants with Othe Drugs and Pathologic States

NMB has significant interactions with many medications (Table 66-2) and coexisting medical conditions. These interactions can affect the neuromuscular system at any level from the CNS to the muscle itself.[81 , For example, potent inhalation anesthetics depress CNS activity, local anesthetics inhibit propagation of nerve action potentials, chronic lithium therapy inhibits presynaptic synthesis of ACh, magnesium and aminoglycoside antibiotics inhibit presynaptic release of ACh, donepezil inhibits AChE, polypeptide antibiotics (eg, polymyxin) inhibit the postjunctional muscle membrane, and dantrolene inhibits calcium release from muscle sarcoplasmic reticulum. All of these drugs potentiate the eff of NMBs.

In most neuromuscular diseases, such as muscular dystrophy, Guillain-BarrÃ© syndrome, myasthenia gravis, and postpolio syndrome, sensitivity

NDNMB is increased, so a small dose of NMB produces a profound degree block.[1,11,45] Persons with myasthenia gravis typically demonstrate resistance to the effects of succinylcholine.[1,11] In individuals with myopathy of unknown etiology, a prudent course is to avoid succinylcholi because of the potential for malignant hyperthermia (MH), hyperkalemia, rhabdomyolysis and to use a short-acting NDNMB to help decrease the possibility of prolonged weakness.

Many systemic pathologic states potentiate the duration or intensity of NDNMB, such as respiratory acidosis, hypokalemia, hypocalcemia, hypermagnesemia, hypophosphatemia, hypothermia, shock, and liver or kidney failure.[84] Alternatively, acute sepsis and inflammatory states are associated with mild resistance to the effect of NDNMB.[77]

Pharmacology of Depolarizing Neuromuscular Blocking Drugs (Succinylcholine)

Succinylcholine is a bis-quaternary ammonium ion composed of 2 ACh molecules attached by their acetate groups.[22] Following a conventional IV induction dose (1 mg/kg), typical serum concentrations are approximately Âµg/mL.[79]

Succinylcholine is hydrolyzed mostly by plasma (pseudo) cholinesterase (ChE) and to a slight extent by alkaline hydrolysis. Hydrolysis is a 2-step reaction; first succinylmonocholine and choline and then succinic acid and choline are formed (both are normal products of intermediary metabolism The first reaction is approximately 6 times faster than the second reactio Less than 3% of the administered dose is excreted unchanged in the urin Following an IV bolus, the serum succinylcholine concentration rises abru and there is a rapid onset of NMJ block. Later the serum succinylcholine concentration undergoes a rapid decline as a result of drug redistribution extravascular tissues and hydrolysis in the serum. Finally succinylcholine leaves the NMJ to reenter the serum as a result of reversal of the

concentration gradient.[38 , 52]

Succinylcholine 1 mg/kg IV usually increases cerebral blood flow, cortical electrical activity, intracranial pressure,[58] and intraocular pressure, especially in lightly anesthetized patients. These effects, when they occur usually are modest.

Toxicity of Depolarizing Neuromuscular Blockers

The important adverse drug reactions associated with succinylcholine inc (1) anaphylaxis, (2) prolonged drug effect, (3) hyperkalemia, (4) acute rhabdomyolysis in patients with muscular dystrophy, (5) MH in susceptibl patients, (6) muscle spasms or trismus in myotonia congenita, and (7) cardiac dysrhythmias.

Prolonged Effect

The effects of succinylcholine may last for several hours if metabolism is slowed because of decreased plasma ChE, abnormal plasma ChE activity (genetic variant or drug inhibition), or a phase II block.[15] Plasma ChE deficiency may be caused by hepatic disease, malnutrition, plasmapheres and pregnancy.[15] Inactivation of plasma ChE can be caused by fluoride intoxication, organic phosphorus compounds, and carbamates. On the oth hand, even with only 20â€“30% of normal plasma ChE activity, the effec duration of succinylcholine is less than doubled.[31]

Many genetic variants of plasma ChE are known. The most common atypi plasma ChE (atypical type, homozygous incidence 1:3000) can be assayed its resistance to inhibition by the local anesthetic dibucaine.[82] A history o uneventful exposure to succinylcholine excludes the possibility of atypical plasma ChE, except in case of hepatic transplantation. Dibucaine inhibits ability of normal plasma ChE to hydrolyze benzoylcholine by >70% (ie, dibucaine number >70), heterozygous atypical enzyme by 40â€“60%, and homozygous atypical enzyme by â‰¤30%. Fresh-frozen plasma or plasm ChE concentrates can be infused to hasten recovery in the case of a gene

enzyme defect or an acquired ChE deficiency. However, to avoid the risks transfusion, it is best to simply keep the patient sedated, intubated, and ventilated until the drug is metabolized. In this setting, spontaneous rev usually requires 3â€“4 hours, although in rare cases full recovery require up to 12 hours.[15] When the duration of succinylcholine is very prolonged, blood samples should be drawn for measurement of plasma ChE concentration and activity.

Prolonged nondepolarizing block can occur when large doses of succinylcholine (2â€“8 mg/kg IV) are given over a short period. This is c *phase II block.* It can be partially reversed by neostigmine.

Hyperkalemia

Succinylcholine 1 mg/kg IV typically causes serum [K^+] to increase by approximately 0.5 mEq/L in normal individuals and in persons with renal failure. The acute hyperkalemic response to succinylcholine is exaggerate with coexisting myopathy or proliferation of extrajunctional muscle ACh receptors. However, the mortality is highest (30%) when rhabdomyolysis occurs.[42] Severe, precipitous, potentially life-threatening hyperkalemia occurs following succinylcholine administration in several conditions associated with proliferation of ACh receptors. These conditions include denervation (head or spinal cord injury, stroke, neuropathy, prolonged us of NDNMBs), muscle pathology (direct trauma, crush or compartment syndrome, muscular dystrophy), critical illness (hemorrhagic shock, neuropathy, myopathy, prolonged immobility), thermal burn or cold injur and sepsis lasting several days (eg, intraabdominal infections). Following neurologic injury, susceptibility to hyperkalemia begins within 4â€“7 days and may persist indefinitely. In patients who have been in the ICU for mo than 1 week, a prudent course is to avoid succinylcholine altogether beca of the risk of hyperkalemic cardiac arrest, which is associated with a mortality rate of at least 19%.[6 , 8 , 42 , 43] Severe hyperkalemia is modif but not prevented, by a dose of an NDNMB sufficient to prevent succinylcholine-induced muscle fasciculations.

Severe or even fatal hyperkalemia has been reported in a few patients wh

received succinylcholine immediately following exsanguinating hemorrhag or massive trauma. The mechanism for this condition is not the same as following neurologic injury because of inadequate time for proliferation of extrajunctional ACh receptors. Succinic acid, a tricarboxylic acid cycle intermediate (which is also a metabolite of succinylcholine), facilitates activation of voltage-gated sodium channels in a dose-dependent fashion, increasing skeletal muscle excitability.[46] In hemorrhagic shock, accumula of succinic acid as a result of cell breakdown and anaerobic metabolism possibly augments the potassium-releasing effect of succinylcholine.

Rhabdomyolysis

Severe hyperkalemia rarely occurs in the absence of a clinical history tha readily discloses an obvious risk factor, with one important exception. Ac or delayed onset of rhabdomyolysis, hyperkalemia, ventricular dysrhythn cardiac arrest, and death have been reported in apparently healthy childı who subsequently were found to have a myopathy.[59] Since March 1995, a black box warning on the package insert has stated that succinylcholine should be avoided in elective surgery in children, particularly those youn than 8 years, because of the small risk of a previously undiagnosed skele myopathy, especially Duchenne muscular dystrophy. Sudden cardiac arre occurring immediately following succinylcholine should always be assumed be caused by hyperkalemia. If fever, muscle rigidity, hyperlactatemia, or metabolic and respiratory acidosis also is present, the presumptive diagr of MH should prompt immediate therapy with dantrolene.

Malignant Hyperthermia

Malignant hyperthermia is a heterogeneous syndrome that typically affec individuals who are otherwise healthy, although it may be associated with certain myopathies, including Duchenne muscular dystrophy, central core disease, King-Denborough syndrome, osteogenesis imperfecta, and myotonia. The disorder is associated with a

defect of a skeletal muscle regulatory/receptor protein. Inheritance is

autosomal dominant with variable penetrance.[68] In humans, multiple pro defects are causally associated with MH, which may account for the heterogeneity of its inheritance and clinical presentation. In human MH, 1 at least 42 different mutations in the skeletal muscle ryanodine receptor type 1 (RYR-1, chromosome 19q13.1) is present in 50â€“80% of patients (Figure 66-1).[96] RYR-1 is present in both fast-twitch and slow-twitch skeletal muscle, whereas only RYR-2 is found in cardiac muscle. This situation may explain why the myocardium is hyperdynamic and relatively spared in the early phase of MH.[86] Of practical importance, the existence multiple mutations across multiple alleles means that genetic testing like will not prove useful in detecting all susceptible individuals.

The incidence of MH is approximately 1/20,000 in children and 1/50,000 adults. MH most often occurs in the operating room shortly after initial exposure to anesthetic agents, but it may commence several hours after general anesthetic is given[74] or as long as 12 hours after surgery. In addition, recurrence can occur 24â€“36 hours after an initial episode.

Malignant hyperthermia is caused inconsistently by exposure to certain anesthetic agents that trigger abnormal calcium release from the skeletal muscle sarcoplasmic reticulum. In patients who are MH susceptible, clinic manifestations develop less than half the time following exposure to triggering agents. For this reason, a previous uneventful anesthetic expo does not preclude development of MH on subsequent exposure.[3]

Drugs associated with precipitating an attack of MH include succinylcholin and volatile inhalational anesthetics (the prototypical agent is halothane) Drugs that can be administered safely to individuals considered susceptib to MH include NDNMBs, nitrous oxide, propofol, ketamine, etomidate, benzodiazepines, barbiturates, opioids, and local anesthetics.

The immediate systemic manifestations of MH result from skeletal muscle hypermetabolism. Uncontrolled release of calcium from the terminal cisternae of the sarcoplasmic reticulum causes skeletal muscle contractio Muscular rigidity is a specific sign of MH, but it is not consistently observ Futile cycling of calcium in the skeletal myocyte by sarcoplasmic Ca^{2+} - ATPase causes depletion of cellular ATP, hypermetabolism, excess heat

production, core hyperthermia, increased O_2 consumption and CO_2 production, venous O_2 desaturation and hypercarbia, anaerobic metabolis and lactic acid generation.[47] The extreme elevation of metabolic rate cau severe mixed venous oxygen desaturation (far below the normal of 75%) Cardiac dysrhythmias, hyperkalemia, rhabdomyolysis, and disseminated intravascular coagulopathy may occur.

The earliest signs of MH include an early and rapid increase in CO_2 production and arterial, venous, and end-tidal CO_2 ; tachycardia; tachypı hypertension or labile blood pressure; and skeletal and jaw muscle rigidit Despite the name of the syndrome, hyperthermia is not a universal findin MH. Moreover, when it occurs, it is often a late sign.[99] Acute potassium release from muscle cells may result in life-threatening hyperkalemia. Subsequent rhabdomyolysis can exacerbate the problem by causing renal failure. In late-stage MH, cardiac decompensation results from hyperkale heart failure, vascular collapse, and/or myocardial ischemia (especially w coexisting coronary artery disease).

The differential diagnosis of MH includes neuroleptic malignant syndrome propofol infusion syndrome, serotonin syndrome, thyroid storm, pheochromocytoma, baclofen withdrawal, malignant syndrome in Parkinso disease, tetanus, meningitis, poisoning by salicylates, amphetamines, cocaine or antimuscarinics, unintentional intraoperative hyperthermia, he stroke, and transfusion reactions. Of note, early septic shock is also associated with hypermetabolism, increased cardiac output, and fever, bu typically the mixed venous O_2 saturation is >75%.

Rarely, MH is triggered by severe exercise in a hot climate, IV potassium (which depolarizes the muscle membrane), antipsychotic drugs, and infection.[18 , 51] Patients with hypermetabolism or rhabdomyolysis have responded to dantrolene, but this finding does not necessarily confirm th patients have MH. Such confirmation requires a muscle biopsy.

One theory of the pathogenesis of MH states that MH-triggering agents interact with an abnormal RYR-1 channel, causing it to stay in a prolonge open state and leading to rapid efflux of calcium from the skeletal muscle sarcoplasmic reticulum into the myoplasm. Succinylcholine triggers a

prolonged muscle depolarization leading to elevated myoplasmic calcium. This action initiates accelerated calcium-activated calcium release from t myoplasmic reticulum.[44] However, not all cases of MH can be explained b an RYR-1 mutation.[35] For example, the association of defects in skeletal muscle sodium channels in certain myotonic disorders has generated inte in the role of the sodium channel in MH.[35] Also, certain MH-susceptible persons manifest increased skeletal muscle fatty acid production, and fat acids augment halothane-induced sarcoplasmic calcium release.[32 , 33 and Although definition of one pathogenic mechanism is not yet possible, any unitary hypothesis must account for these observations.

By partially blocking calcium release from skeletal muscle sarcoplasmic reticulum, dantrolene rapidly reverses the signs and symptoms of hypermetabolism: fever, mottled skin, dysrhythmias, muscle rigidity, tachycardia, metabolic acidosis, and hypercapnia. Before the discovery of dantrolene, the mortality rate from MH was 70%. When acute MH is treat immediately with dantrolene, volume resuscitation, active cooling, control hyperkalemia, and supportive care, the mortality is <5%. Therefore, the most important aspects of MH therapy are rapid initial diagnosis and immediate therapy (within minutes) with dantrolene. Even if administrati is delayed for hours or days, dantrolene may still improve survival follow an acute episode. Significant dysrhythmias can be treated with standard antidysrhythmic agents; however, calcium channel blockers must *not* be given with dantrolene because they may precipitate hyperkalemia and se hypotension[87] (Table 66-3).

Persons who have experienced a possible episode of MH or have a positiv family history can be considered for muscle biopsy and muscle testing. Th fresh tissue specimen is placed in a tissue bath perfused with Krebs solut and halothane or caffeine is added. According to the North America Malignant Hyperthermia Group, an MH-susceptible individual has a positiv muscle contraction in response to either halothane or caffeine.

Muscle Spasms

Masseter muscle rigidity (MMR) is observed in 0.3â€“1% of pediatric pati

induced with succinylcholine and halothane. MMR is clinically significant because it may complicate airway management and herald the onset of MH.[80]

When administered to persons genetically predisposed to myotonia, succinylcholine can precipitate tonic muscular contractions, ranging from trismus (which may prevent orotracheal intubation) to severe generalized myoclonus and chest wall rigidity (which may prevent ventilation).[28] Because the myotonic contractions are independent of neural activity, the cannot be aborted by an

NDNMB. Usually the contractions are self-limited, but occasionally they ca be life-threatening if an airway cannot be established and hypoxemia ensues.

Acute Phase Treatment of Malignant Hyperthermia (MH)

1. Call for help. Immediately summon experienced help when MH is suspected.
2. Stop triggering agents, including volatile inhalational anesthetics a succinylcholine.
3. Hyperventilate with 100% O_2 .
4. Administer dantrolene sodium. Give the initial bolus of 2.5 mg/kg rapidly, followed by additional boluses until signs of MH are controlled (tachycardia, rigidity, increased end-tidal CO_2 , hyperthermia). Typic total dose of 10 mg/kg controls symptoms, but occasionally up to 3 times this dose may be required.
5. Monitor core temperature closely. Excessive treatment may lead t hypothermia.
6. Actively cool the hyperthermic patient , simultaneously with the above.
    - Immersion in ice-water slurry is best. Peritoneal or gastric lavage can also be useful.
    - Surface cool with ice and hypothermia blanket.
7. Aggressively treat hyperkalemia. Hyperkalemia is common and sh be treated with hyperventilation, sodium bicarbonate, intravenous

glucose, and insulin. Severe hyperkalemia can also be treated with calcium administration. Hypokalemia should treated with great cautio because hyperkalemia may occur due to rhabdomyolysis.

8. Monitor end-tidal CO_2 , arterial and mixed venous blood gases, ser potassium and calcium, clotting studies, and urine output.
9. Administer sodium bicarbonate to correct metabolic acidosis as guided the arterial blood gas.
10. Dysrhythmias usually respond to dantrolene and correction of acidosi and hyperkalemia. If dysrhythmias persist or are life-threatening, standard antidysrhythmics can be used.
    - Calcium channel blockers should *not* be used (especially verapamil) to treat dysrhythmias because they can cause hyperkalemia and cardiovascular collapse.
11. Ensure adequate urine output by hydration and/or administration of mannitol of furosemide. Consider central venous or PA monitoring.
12. For emergency consultation to help with patient management (http://www.mhaus.org/hotline.html) call the MH Emergency Hotline:
    - Inside United States or Canada call: 800-MH-HYPER (800-644-9737)
    - Outside the United States and Canada call: 001 315-464-7079

Postacute Phase Treatment of Malignant Hyperthermia

1. Observe the patient in an ICU setting for at least 24â€“48 hour because recrudescence of MH occurs in 25% of cases, particularly following a fulminant case resistant to treatment.
2. Administer dantrolene 1 mg/kg IV q4â€“6h for 24â€“48 hours after the episode.
3. Follow arterial blood gases, creatine phosphokinase, potassium, calci phosphorus, urine and serum myoglobin, PT, PTT, platelet count, and core body temperature until they return to normal values (eg, q6h). Central temperature (eg, rectal, esophageal) should be monitored continuously.
4. Counsel the patient and family regarding MH and further precautions.

- For nonemergency patient referrals, contact MHAUS: 888-274-7899, 11 East State Street, PO Box 1069, Sherburne, NY 13460.
- Report patients who have had an acute MH episode to the North American MH Registry of MHAUS: 412-692-5464
- Alert family members to the possible dangers of MH and anesthesia.

5. Recommend an MH medical ID for the patient and have the individual wear it at all times.

Notes:

1. Each vial of dantrolene contains 20 mg of dantrolene and 3 g mannitol (to improve water solubility). Each vial should be reconstituted with 5 mL distilled sterile water for injection. Dissolution of the lyophilized solution in water is slow and requires thorough mixing.
2. The guideline above may not apply to every patient and of necessity must be altered according to specific patient needs.
3. Sudden unexpected cardiac arrest in children: Children younger than about 10 years who experience sudden cardiac arrest after succinylcholine in the absence of hypoxemia and anesthetic overdose should be treated for acute hyperkalemia first. In this situation, calcium chloride should be administered along with other means to reduce serum potassium. They should be presumed to have subclinical muscular dystrophy, and a neurologist should be consulted.

TABLE 66-3. Suggested Therapy for Malignant Hyperthermia

Pharmacology of Nondepolarizing Neuromuscular Blocking Drugs

Table 66-1 lists the details of the pharmacology and toxicity of these drugs.[50, 70, 71, 76]

Atracurium is composed of 10 different isomers, each having its unique

pharmacokinetic and pharmacodynamic profile, whereas cisatracurium contains only the 1R-*cis* 1â€²R-*cis* isomers. Both atracurium and cisatracurium exhibit organ-independent elimination and are rapidly metabolized by spontaneous (nonenzymatic) temperature- and pH-depen Hofmann degradation and, to a lesser extent, by ester hydrolysis. The la is catalyzed by nonspecific plasma esterases, distinct from the plasma Ch that hydrolyzes succinylcholine. In addition, significant drug metabolism elimination occurs in the liver and kidney.[30]

Toxicity of Nondepolarizing Neuromuscular Blocking Drugs

The most important toxic effects of the NDNMB are accumulation of laudanosine and persistent weakness. In general, limiting the drug dose a monitoring the drug effect with a portable nerve stimulator reduce the incidence of prolonged weakness.

Laudanosine

When metabolized, each atracurium molecule generates, on average, <2 molecules of laudanosine and an acrylate moiety, neither of which posses neuromuscular blocking activity.[78] Cisatracurium is an improvement over atracurium; it is 3 times more potent and generates approximately one th as much laudanosine.[37 , 55] Laudanosine is excreted primarily in the bile and, to a lesser extent, by the kidney; thus

its elimination is prolonged in patients with liver disease, biliary obstruct and renal insufficiency.[83] Laudanosine crosses the bloodâ€“brain and placental barriers.[23] In the CNS, laudanosine has an inhibitory effect at t Î³-aminobutyric acid, nACh, and opioid receptors. At high plasma concentrations in experimental animals, laudanosine causes dose-related neuroexcitation, myoclonic activity (>14 Âµg/mL), and generalized seizu (>17 Âµg/mL).[12 , 37] In humans, the toxic plasma laudanosine concentra is unknown, and seizures directly attributable to atracurium have not bee

observed even following prolonged drug infusion in the ICU.[37 , 103] In ICU patients who received a 72-hour infusion of atracurium 1 mg/kg/h), the highest plasma laudanosine concentrations (10â€“20 Âµg/mL) were obse in patients with renal insufficiency.[62]

Persistent Weakness Associated with Nondepolarizing Neuromuscular Blockers

Short-term use of an NDNMB usually results in prompt termination of the block. When an NDNMB is administered for more than 48 hours, there is a risk that weakness will persist longer than anticipated based on the kinet of drug elimination. In addition, critical illness is associated with dysfunc of the peripheral nerve, NMJ, and muscle (Table 66-4). For instance, in t ICU, persistent weakness is observed in 68â€“100% of patients with seps or multiple organ failure[17 , 36 , 98] and in 20â€“30% of patients who rece NDNMB for only 48â€“72 hours.[64] Persistent weakness is multifactorial a associated with illness severity (Acute Physiology and Chronic Health Evaluation [APACHE] III score), sepsis, acute respiratory distress syndro multiorgan failure, hyperglycemia, NDNMB, systemic glucocorticoids, mus injury, thermal injury, and electrolyte, endocrine, and nutritional disorders.[16 , 21 , 48 , 63] Many drugs given to patients in the ICU can caus weakness by themselves or potentiate the effects of NDNMB.[49 , 81] Progressive weakness and acute respiratory failure have been described *following* discharge from the ICU and can present a life-threatening situa if not immediately recognized.[60] Patients who develop persistent weakne have a 2.5- to 3.5-fold increase in ICU mortality[64] and ICU stay.

TABLE 66-4. Acute Neuromuscular Pathology Associated with Critical Illness and/or NDNMB

Pharmacology of Reversal Agents

Termination of NMB effect initially results from drug redistribution and la from drug elimination, metabolism, and/or chemical antagonism. Pharmacologic antagonism of a partial NDNMB is achieved by giving a reversal agent that inhibits junctional AChE and increases ACh at the NM This increase in ACh can overcome the competitive inhibition caused by residual NDNMB. The commonly used anti-ChEs are polar molecules that possess a quaternary ammonium (Table 66-5). Neostigmine and pyridostigmine are hydrolyzed by ChE and form carbamyl complexes ($t_{1/2}$ 15â€“20 minutes) with the esteratic site of the enzyme.[5] The half-life of carbamylâ€“ester complex is much less than the plasma half-life of neostigmine or pyridostigmine, which explains why the latter determines duration of clinical effect. In contrast, edrophonium is not hydrolyzed by ChE. Rather, it forms an electrostatic interaction and a hydrogen bond wi the cationic site of ChE that is both competitive and reversible. In additic neostigmine and pyridostigmine, but not edrophonium, inhibit plasma ChE and thus prolong the effects of drugs metabolized by this enzyme, such a succinylcholine and mivacurium.[19 , 31]

Toxicology of Reversal Agents

The most common and troublesome clinical side effect of ChE inhibition is bradycardia, which usually is prevented by coadministration of an antimuscarinic drug.[14] Bradydysrhythmias may be severe and lead to noc or idioventricular rhythm, complete heart block, or even asystole.[65] Thes side effects occur more frequently in patients with preexisting bradycardia those receiving chronic

Î²-adrenergic antagonist therapy. They are not necessarily prevented by

prior administration of atropine.[93] Other problems that may result from excess ChE inhibition are hypersalivation, bronchospasm, increased bron secretions, abdominal cramping from intestinal hyperperistalsis, cell divis tearing, and increased bladder tone. Side effects of excess antimuscarinic administration include tachycardia, bronchodilation, pupillary dilatation, a increased intraocular pressure. Following general anesthesia, use of anticholinesterases may increase the incidence of nausea, vomiting, and abdominal cramps.[54] Because atropine crosses the bloodâ€“brain barrier, can produce central anticholinergic syndrome.

Diagnostic Testing

Quantitative methods for analysis of blood and tissue NDNMB and metab concentrations using high-performance liquid chromatography and mass spectrometry are described.[53, 90]

Succinylcholine and succinylmonocholine can be assayed by gas chromatography and mass spectrometry in blood, urine, or the site of intramuscular injection.[79, 92] Less than 3% of administered succinylchol and 10% of its metabolite succinylmonocholine are excreted in the urine.

However, both parent drug and metabolite undergo spontaneous hydrolys especially in alkaline conditions.[97] Historically, detection of succinylcholir has proved difficult because of its rapid hydrolysis. However, techniques detecting this parent compound in tissues even after embalming are described.[40] Because succinic acid is a product of intermediary metabolis assay of this metabolite is not useful for positive identification of prior succinylcholine exposure.[73] Surprisingly, the presence of succinylmonocholine in forensic samples also cannot prove prior exposure succinylcholine. Succinylmonocholine in concentrations of 0.01â€“0.20 Âµ has been detected in tissues of 6 autopsy cases with no history of succinylcholine exposure.[61]

Summary

The two types of NMBs are depolarizing (DNMB) and nondepolarizing (NDNMB). Succinylcholine is the only DNMB in current clinical use. The primary action of an NMB is to reversibly inhibit transmission at the skele NMJ. Immediate side effects include dose- and rate-related histamine rel and modulation of autonomic tone.

Acute and potentially fatal hyperkalemia can occur after succinylcholine administration. Succinylcholine is contraindicated in certain myopathies (Duchenne muscular dystrophy) because of the risk for MH, rhabdomyolys and hyperkalemia. In MH, acute onset of severe hypermetabolism causing acidosis, rhabdomyolysis, hyperkalemia, and death occurs if treatment w dantrolene and aggressive cooling is not given. The effect of succinylchol is prolonged when there is an atypical genetic variant of plasma cholinesterase, when it is inhibited (eg, by pancuronium, organic phosph compounds, or donepezil), or when it is deficient (eg, from liver disease plasmapheresis).

The most important complications associated with use of NDNMBs arise fr problems with patient care: undetected hypoventilation and prolonged dr effect. At subparalyzing doses, NDNMBs blunt the hypoxic ventilatory response without affecting the response to hypercapnia. NMBs have clini important interactions with many xenobiotics and coexisting medical

conditions. In most neuromuscular diseases, sensitivity to NDNMB is increased. In renal failure, active metabolites of pancuronium and vecuronium can accumulate and cause prolonged block.

Quantitative methods for analysis of blood and tissue NMB and metabolite concentrations have been described. Postmortem detection of succinylmonocholine or succinic acid cannot confirm the presence of premortem succinylcholine.

Antidotes in Depth

Dantrolene Sodium

Kenneth M. Sutin

Brian Kaufman

Sanford M. Miller

Dantrolene is an intracellular muscle relaxant. As such, it is the only drug proven to be effective for treatment and prophylaxis of malignant hyperthermia (MH). Although dantrolene is a hydantoin derivative that is structurally similar to local anesthetics and anticonvulsants, it possesses none of their properties.[16,29]

History and Epidemiology

Dantrolene was first synthesized in 1967.[25] Four years later, the drug was first used clinically to treat muscular spasticity.[6] Dramatic reversal of the course of porcine MH was described in 1975,[11] and shortly thereafter dantrolene was studied in humans.[15]

Pharmacokinetics

Dantrolene is lipophilic and relatively insoluble in water. In plasma, dantrolene is reversibly bound to plasma proteins, especially albumin. The drug is metabolized in the liver by hydroxylation of the hydantoin ring or by reduction of the nitro group.[29] Up to 25% of administered dantrolene is excreted in the urine as the 5-hydroxydantrolene metabolite, which is about half as potent as the parent drug.[29] The elimination half-life is 4â€“8 hours for dantrolene and 15 hours for its primary metabolite. Dantrolene exhibits variable absorption by the small intestine, and peak blood concentrations are achieved 3â€“6 hours after ingestion. Oral bioavailability can be as high as 70%.[16] Quantitative analysis of dantrolene and its metabolites has been performed using high-performance liquid chromatography.[17] After a 2.4 mg/kg dose, the mean whole blood dantrolene concentration was 4.2 Âµg/mL.[9]

Mechanism

Dantrolene acts at the skeletal muscle ryanodine receptor type 1 (RYR-1), causing dose-dependent inhibition of both steady and peak components of sarcoplasmic calcium release,[26] reducing free myoplasmic calcium and thereby directly inhibiting excitationâ€“contraction coupling.[18] Dantrolene causes weakness but not total paralysis, and this plateau effect may be related to its poor solubility in water. In normal adults, a plateau in the twitch depression of the adductor pollicis muscle is reached at a dantrolene dose of 2.4 mg/kg IV, at which point the twitch suppression is 75% of baseline.[9] Dantrolene does not change the electrical properties or excitation of nerve, neuromuscular junction (NMJ), or muscle, and it does not alter sarcoplasmic calcium reuptake. Because dantrolene does not bind to the cardiac ryanodine receptor RYR-2, it has minimal effects on the myocardium.[10,28,32] It does not affect smooth muscle.

Data indicate that the dantrolene binding site is at the N-terminus

of the RYR-1 receptor, specifically at the epitope composed of amino acids 590â€“609.[20] [^{3}H]Dantrolene and [^{3}H]ryanodine appear to bind to the same sites on sarcoplasmic reticulum membrane fractions. At therapeutic concentrations, dantrolene inhibits binding of [^{3}H]ryanodine to the RYR-1 receptor.[10]

Indications

Dantrolene is indicated for treatment of fulminant skeletal muscle hypermetabolism characteristic of MH and following an acute episode of MH to prevent recrudescence. Long-term oral dantrolene therapy is used rarely to treat chronic spasticity.[14] Historically, dantrolene was used prophylactically in MH-susceptible individuals; however, current practice is simply to avoid exposure to MH-triggering drugs during anesthesia.

Dantrolene should be considered for patients with severe hyperthermia when the diagnosis of MH cannot be excluded with certainty, especially with coexisting metabolic acidosis, coagulopathy, or rhabdomyolysis.[8] Atypical presentations of MH in the presence or absence of triggering anesthetics are reported, especially in susceptible persons. In typical fulminant MH, the diagnosis is not subtle, and the course of treatment is obvious once the diagnosis is considered. This is not true when the clinical presentation is atypical. MH should be considered when hyperthermia is associated with severe hypermetabolism, increased CO_2 production, lactic acidemia, hyperkalemia, and/or rhabdomyolysis, especially when the course is fulminating and refractory to supportive therapy. One important caveat: dantrolene given for hyperthermic disorders is not a substitute for aggressive cooling. For example, in heat stroke, the lowering of body temperature by active cooling alone is not accelerated when dantrolene is added.[2,4]

There are reports of dantrolene use for treatment of acute hyperthermia of other etiologies, including neuroleptic malignant

syndrome,[1,24] heat stroke, monoamine oxidase inhibitor overdose,[12] methylenedioxymethamphetamine (â€œecstasyâ€•) overdose,[22] intrathecal baclofen withdrawal,[13] and thyroid storm.[5] There is only anecdotal support for these indications, and scientifically rigorous proof that patients with any of these syndromes benefit from dantrolene therapy is lacking. However, it is worth emphasizing that the diagnosis of heat stroke[7] or hyperthyroidism[19] does not necessarily exclude the diagnosis of MH.

Dosing

Dantrolene is supplied as a sterile lyophilized solution in a 70-mL vial that contains 20 mg dantrolene sodium and 3 g mannitol. Following reconstitution with 60 mL sterile water for injection, the pH is approximately 9.5. The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2â€“3 mg/kg IV. It is repeated every 15 minutes until the signs of hypermetabolism are reversed or until a total dose of approximately 10 mg/kg has been administered. Occasionally higher doses are required. Following initial treatment, at least 1â€“2 mg/kg IV or PO should be given every 6 hours for 1â€“3 days to prevent recrudescence of the syndrome. Initial dosing probably should be determined by total body weight

given that dantrolene is lipophilic; however, its pharmacokinetics in obesity are not determined.[9] The key point is that the total dose of dantrolene is determined by titration to a metabolic endpointâ€”resolution of skeletal muscle hypermetabolism. When an effective dose of dantrolene is given, signs of muscle hypermetabolism start to normalize within 30 minutes.[15]

Side Effects and Toxicity

Following dilution, dantrolene has an alkaline pH and can cause

venous irritation and thrombophlebitis. No evidence indicates allergic cross-reactivity with dantrolene in patients with prior phenytoin allergy.

Dantrolene and verapamil used in combination can cause hyperkalemia and decreased cardiac output; therefore, these drugs should not be combined.[16,21] The mechanism of their interaction is unclear.[23]

Dantrolene given to healthy persons or for MH prophylaxis caused subjective skeletal muscle and diaphragm weakness (experienced as dyspnea) but not muscle paralysis.[30,31] In healthy volunteers, dantrolene 2.5 mg/kg does not depress peak expiratory flow rate or vital capacity or alter end-tidal CO_2 or respiratory rate.[9] However, dantrolene may precipitate respiratory failure in patients with impaired respiratory reserve.[16]

Oral dantrolene may cause gastrointestinal upset, nausea, and vomiting. Other reported side effects include dizziness, light-headedness, ptosis, difficulty focusing, and difficulty swallowing.[9,31] When dantrolene is given orally for more than 2 months for treatment of muscular spasticity, there is a 1.8% risk of dose- and duration-related chronic hepatic inflammation, including elevated aminotransferase concentrations, hyperbilirubinemia, or jaundice[27] that may not be reversible after dantrolene is discontinued.[3]

Chapter 67
Antipsychotics

David Juurlink

A lethargic 41-year-old woman was brought to the emergency department paramedics. Her husband found her unresponsive in the bedroom with an bottle at her side. He stated that she had a history of delusions and was of a psychiatrist.

The patient was moderately obese, somnolent, and difficult to rouse. Her were: blood pressure 95/50 mm Hg; pulse 128 beats/min and regular; re 10 breaths/min; and rectal temperature 100.6Â°F (38.1Â°C). The patient' flushed, and her mucous membranes and axillae were dry. Gag reflex was there was no evidence of tongue biting or trauma. Both pupils were 3 mm and minimally responsive to light. The fundi could not be visualized. Exar cardiovascular and respiratory systems was unremarkable. Her abdomina revealed diminished bowel sounds but no tenderness or masses. The patie respond to verbal commands, but she moaned and moved all extremities vigorous sternal rub. Deep tendon reflexes were normal, the plantar resp flexion, and no clonus was present.

Two successive 2-mg boluses of naloxone were given intravenously (IV) w response. Thiamine 100 mg IV also was given. When 2 L of 0.9% sodium

solution was administered IV, the blood pressure rose to 110/70 mm Hg. blood gases determined on 40% oxygen were: pH, 7.38; PCO_2 , 43 mm H mm Hg; and HCO_3^- , 24 mEq/L. Blood samples were sent for determinati electrolytes, glucose, creatinine, creatine kinase (CK), complete blood co acetaminophen.

A nasogastric tube was inserted. An abdominal radiograph showed a non gas pattern. The tip of the nasogastric tube was seen in the distal stomac activated charcoal was instilled. An electrocardiogram revealed sinus tach normal QRS duration but a slightly prolonged QTc interval (QTc 450 msec treating physician was preparing to intubate the patient, she roused som became agitated. Her speech was unintelligible, and she began thrashing stretcher.

The patient was placed in loose restraints to prevent her from injuring he medical staff. Review of the patient's medication history revealed she wa with olanzapine 10 mg daily, in addition to omeprazole, a transdermal ni and multivitamins. The olanzapine bottle was empty, and approximately 3 mg) were unaccounted for. Suspecting olanzapine overdose with promine anticholinergic features, the physician administered 0.5 mg physostigmine reviewing the electrocardiogram for widening of the QRS complex.

The patient received 2 more doses of physostigmine 0.5 mg over the nex Her agitation lessened dramatically, and her heart rate fell to 92 beats/m she remained somnolent, she became much more communicative and beg admitted to deliberately ingesting all of her olanzapine tablets following a dispute regarding financial difficulties.

The restraints were removed, and the patient was transferred to an obse where she was observed closely overnight. She received 3 additional 0.5- physostigmine over the next 12 hours, during which time her vital signs and her mental status improved considerably. The following day she was the inpatient psychiatry ward for further evaluation and treatment.

History and Epidemiology

Prior to the introduction of chlorpromazine in 1950, patients with schizop

treated with nonspecific sedative agents such as barbiturates. Highly agi were housed in large mental institutions and often placed in physical rest approximately 500,000 patients with psychotic disorders were hospitalized States. The advent of the antipsychotics in the 1950s revolutionized the c patients. These drugs, originally termed *major tranquilizers* and subsequ *neuroleptics* , dramatically reduced the characteristic hallucinations, delu paranoia that were characteristic of schizophrenia.

Shortly following the introduction of these drugs, however, it became app were potentially dangerous in overdose (a common occurrence in mentall and that they caused

a host of adverse drugs effects, principally involving the endocrine and r The latter included the extrapyramidal syndromes (EPS), a constellation c were relatively common, sometimes irreversible, and occasionally life-th

The search for new drugs led to the development of several antipsychotic potencies and differing adverse effect profiles. The novel antipsychotic cl first synthesized in 1959, but it did not enter widespread clinical use until 1970s. Clozapine was not only relatively free of EPS, it was an extremely antipsychotic even in patients who had not responded well to other drugs unlike its predecessors, it often improved the negative symptoms of schi as avolition, alogia, and social withdrawal. Reports of agranulocytosis, sc led to the withdrawal of clozapine from the market in 1974, although it w in 1990.[9 , 43] However, clozapine's unique therapeutic and pharmacologic rendered it an *atypical* antipsychotic, the forerunner and prototype of mor compounds that have collectively become the most widely used antipsych past decade.

Most antipsychotic drug toxicity occurs by 1 of 2 mechanisms. Following (intentional or unintentional), toxicity is dose related and reflects an exte drug's effects on neurotransmitter systems and other biologic processes. idiosyncratic adverse reactions also can occur in the context of routine t This toxicity results from individual susceptibility, usually is pharmacogen and generally is unrelated to the antipsychotic dose. In both instances, th illness can range from minor to life threatening, depending on a host of

including concomitant drug exposures, comorbidity, and access to medica

The true incidence of antipsychotic drug reactions is not known with cert patients may not seek medical attention, whereas others may be misdiag among those who seek medical attention and are correctly diagnosed, nc poison centers or other adverse event reporting systems is discretionary (Chap. 130). With these limitations in mind, a few observations can be r

In 2003, poison information centers in the United States were contacted antipsychotic drug exposures. Of these reports, 32,422 were related to a antipsychotic agents and 4704 to phenothiazines.[99] Other antipsychotics a reported. By comparison, in 1993 phenothiazines were the sole category antipsychotics and were the subject of 10,975 calls, despite 27% fewer to poison centers.[60] The changing pattern of antipsychotic overdose reflects of antipsychotic drug prescribing trends over the past decade.[25 , 31 , 67]

The vast majority of poison center calls pertain to intentional overdoses i years or older. Most of these patients have a good outcome. However, 94 reported in 2003, and only a minority of them occurred in patients with antipsychotic overdose. A substantial body of clinical experience and son data suggest that the low-potency, typical antipsychotics, such as thiorid chlorpromazine and mesoridazine, are associated with greater toxicity tha antipsychotics.[16 , 18 , 37] Inferences based upon aggregated population d fatal toxicity should be extrapolated to individual patients with caution,[16] least one well-done retrospective cohort study supports the notion that t associated with greater adverse cardiovascular toxicity than other antips

Pharmacology

Classification

Antipsychotics can be classified in a variety of ways, according to their c structure, their receptor binding profiles, or as â€œtypicalâ€• or â€œat antipsychotics. Table 67-1 outlines the taxonomy of some commonly use Classification by chemical structure was most useful prior to the 1970s, v phenothiazines and butyrophenones constituted most of the antipsychotic

clinical use. Currently, the surfeit of different compounds and their struc heterogeneity renders this scheme cumbersome and of limited use to clin worth noting, however, that the phenothiazine antipsychotics bear a high structural similarity to the tricyclic antidepressants (TCAs) (Figure 67-1) share many of their manifestations in overdose. The phenothiazines can l subclassified according to the nature of the substituent on the nitrogen a 10 of the center ring as aliphatic, piperazine, or piperidine compounds.
