Numerous xenobiotics are associated with tinnitus (Table 21-8), but the incidence is probably low and the implied relationships have usually been supported only by case reports.[34, 152, 153] Tinnitus may or may not be associated with transient or permanent hearing loss. It is probable that the agents associated with hearing loss affect cochlear function, while those that produce tinnitus without hearing loss probably act on signal transmission at the cochlear and the central nervous system. Xenobiotics that frequently produce tinnitus are streptomycin, neomycin, indomethacin, doxycycline, ethacrynic acid, furosemide, heavy

metals, and high doses of caffeine.[66 , 152 , 153] Only a few drugs, such as quinine and salicylates, consistently cause tinnitus at toxic doses.[17 , 50] These two drugs also serve as examples of how the presence of tinnitus may be an indicator of drug toxicity.

Tinnitus associated with salicylates usually begins when serum levels are in the high therapeutic or low toxic range of approximately 20â€“40 mg/dL.[113] Before the wide availability of salicylate serum measurements, physicians treating gout or rheumatoid

arthritis often titrated the salicylate dosage until tinnitus developed.[37] Tinnitus and other signs and symptoms of salicylism (Chap. 35) should be sufficient for physicians to diagnose salicylate toxicity before serum salicylate levels are available. However, tinnitus may not be evident in patients with hearing impairment despite significantly elevated salicylate concentrations.[113] The classic constellation of symptoms of quinine and salicylate toxicity, called cinchonism, includes nausea, vomiting, tinnitus, and visual disturbances.[4 , 28 , 116] Because serum quinine levels are not readily available, symptoms of quinine toxicity define the clinical diagnosis (Chap. 56).[162]

Antifungal agents: amphotericin B
Anticonvulsants: carbamazepine
Antidepressants: cyclic antidepressants, amoxapine, lithium, trancylcypromine
Antihistamines
Antimicrobials: Aminoglycosides, vancomycin, dapsone, tetracyclines, sulpha drugs, metronidazole, thiabendazole, clindamycin
Antineoplastics: cisplatin, nitrogen mustard, 6-aminonicotinamide, methotrexate, vinblastine
Antiparasitics: chloroquine, hydroxychloroquine
Antipsychotics: haloperidol, molindone

Î²-Adrenergic antagonists
Bromates
Cinchona alkaloids: quinine, quinidine, salicylates
Diuretics: furosemide, ethacrynic acid, bumetanide
Hydrocarbons: benzene
Local anesthetics: mepivacaine, bupivacaine, lidocaine
Nonsteriodal antiinflammatory drugs
Oral contraceptives
Sympathomimetics: caffeine, theophylline, metaproterenol, albuterol, methylphenidate

TABLE 21-8. Xenobiotics That Cause Tinnitus

Summary

Numerous xenobiotics commonly affect the sense of smell, taste, and hearing. They may cause significant patient morbidity. Some of the events may be foreseeable, whereas others will require monitoring and appropriate testing. Significant patient risk and discomfort may be avoided by an understanding of the basic pathophysiology of the otolaryngologic organs and by a heightened suspicion on the part of healthcare providers. Current knowledge about the pathophysiology of xenobiotics and these special organs at the molecular level is expanding rapidly. It is particularly encouraging and exciting to understand and witness the development of potential therapeutic agents.

Chapter 22
Respiratory Principles

Robert S. Hoffman

Essential Abbreviations

PO_2

Partial pressure of oxygen (in mm Hg; 1 mm Hg = 1 torr)

PAO_2

Alveolar PO_2

PaO_2

Arterial PO_2

PCO_2

Partial pressure of carbon dioxide (in mm Hg)

O_2 Sat

Hemoglobin oxygen saturation (in percent)

FiO_2

Percent oxygen in inspired air

CO

Carbon monoxide

COHb

Carboxyhemoglobin

MetHb

Methemoglobin

The primary function of the lungs is to exchange gases. Specifically, this role can be divided into the transport of oxygen (O_2) into the blood, and the elimination of carbon dioxide (CO_2) from the blood. In addition, the lungs serve as minor organs of metabolism and elimination for a number of xenobiotics, a source of insensible water loss, and a means of temperature regulation.

Cellular oxygen use is dependent on many factors, including respiratory drive; percent of oxygen in inspired air; airway patency; chest wall and pulmonary compliance; diffusing capacity; ventilationâ€“perfusion mismatch; hemoglobin content; hemoglobin oxygen loading and unloading; cellular oxygen uptake; and cardiac output. Xenobiotics have the unique ability to inhibit or impair each of these factors necessary for oxygen use and result in respiratory dysfunction. This chapter illustrates how xenobiotics acutely interact with the mechanisms of gas exchange and oxygen use. Discussion of chronic occupational lung injury is beyond the scope of this text; the reader is referred to a number of reviews for further information.[15, 80] The final section of this chapter provides a practical approach to assessing the poisoned patient.

Pulmonary Manifestations of Xenobiotic Exposures

Respiratory Drive

Respiratory rate and depth are regulated by the need to maintain a normal PCO_2 and pH. Most of the control for ventilation occurs at the level of the medulla, although this is modulated both by involuntary input from the pons and voluntary input from the higher cortices. Changes in PCO_2 are measured primarily by a central chemoreceptor, located near the exit for cranial nerves IX and X, which measures cerebral spinal fluid (CSF) pH, and secondarily by peripheral chemoreceptors in the carotid and aortic bodies, which actually measure PCO_2 . Input with regard to PO_2 is obtained from carotid and aortic chemoreceptors. Stretch receptors in the chest relay information about pulmonary dynamics, such as the volume and pressure.

Xenobiotics can affect respiratory drive in one of several ways: direct suppression of the respiratory center; alteration in the response of chemoreceptors to changes in PCO_2 ; direct stimulation of the respiratory center; increase in metabolic demands as a result of agitation or fever, which, in turn, increases total body oxygen consumption; or indirectly, as a result of the creation of acidâ€“base disorders. For example, opioids (Chap. 38) depress respiration by decreasing the responsiveness of chemoreceptors to CO_2 and by direct suppression of the pontine and medullary respiratory centers.[29 , 68 , 91] Any xenobiotic that causes a decreased respiratory drive or a decreased level of consciousness can produce bradypnea (a decreased respiratory rate), hypopnea (a decreased tidal volume), or both, resulting in hypoventilation (Chap. 3).

Methylxanthines, cocaine, and other sympathomimetics may cause an increase in respiratory drive as well as an increase in oxygen consumption. Salicylates produce hyperventilation by both central and peripheral effects (ie, respiratory alkalosis and acidemia). The net consequence of increased respiratory drive, increased oxygen consumption, or metabolic acidosis is the generation of either tachypnea (an elevated respiratory rate), hyperpnea (an increased tidal volume), or both. Whether alone or in combination,

tachypnea and hyperpnea produce hyperventilation. Tables 22-1 and 22-2 list xenobiotics that commonly produce hypo- and hyperventilation.

Baclofen
Barbiturates
Electrolyte abnormalities
Organic phosphorus compounds
Botulinum toxin
Ethanol
Poison hemlock (coniine)
Carbamates
Ethylene glycol
Clonidine
Î³-Hydroxybutyrate
Sedative-hypnotics
Colchicine
Isopropanol
Strychnine
Cyclic antidepressants
Methanol
Neuromuscular blockers
Tetanus toxin
Tetrodotoxin
Elapid envenomation
Nicotine
Opioids

TABLE 22-1. Xenobiotics that Produce Hypoventilation

Decreased Inspired FiO_2

Barometric pressure at sea level ranges near 760 mm Hg. At this pressure, 21% of ambient air is comprised of oxygen (FiO_2 = 21%), and after subtracting for the water vapor normally present in the lungs, PAO_2 (the alveolar partial pressure of oxygen) is about 150 mm Hg. Any reduction in FiO_2 decreases the PAO_2 , thereby producing signs and symptoms of hypoxemia (a low PaO_2 [the arterial partial pressure of oxygen]). At an FiO_2 of 12â€“16%, patients experience tachypnea, tachycardia, headache, mild confusion, and impaired coordination. A further decrease to an FiO_2 of 10â€“14% produces severe fatigue, cognitive impairment and decreases to between 6 and 10% are associated with nausea, vomiting, and lethargy. An FiO_2 of less than 6% is incompatible with life.[54]

This effect on FiO_2 is typically observed as elevation increases above sea level, because barometric pressure falls. By 18,000 feet, barometric pressure is only 380 mm Hg, and the PAO_2 falls to below 70 mm Hg. At 63,000 feet, the barometric pressure falls to 47 mm Hg, a level where the PAO_2 equals 0 mm Hg. Although it is important to remember this relationship, altitude-induced decreases in FiO_2 are rarely important in clinical medicine, even in commercial airline flights, where the cabins are pressurized to a maximum of several thousand feet above sea level. However, in closed or low-lying spaces, oxygen may be replaced or displaced by other gases that have no intrinsic toxicity. Common examples of these gases, referred to as simple asphyxiants (Table 22-3), are found alone or in combination with more toxic gases. Because they have little or no toxicity other than their ability to replace oxygen, removal of the victim from exposure and administration of supplemental oxygen are curative if permanent injury as a consequence of hypoxia has not already developed (Chap. 119).

The potential magnitude of toxicity from simple asphyxiants was best exemplified by the disasters in Cameroon near the Lakes of Monoun and Nyos, in 1984 and 1986, respectively. For unclear reasons, Lake Nyos, a volcanic lake, released a cloud of carbon

dioxide (CO_2) gas of approximately a quarter million tons. Because CO_2 is 1.5 times heavier than air, the gas cloud flowed into the surrounding low-lying valleys, killing by asphyxia more than 1700 people, and affecting countless more people because of hypoxia. Most survivors recovered without complications.[7, 33] Smaller scale, but equally serious, toxicity from CO_2 results from improper handling of dry ice or release into a closed space.[34, 38]

Amphetamines
Gyromitra mushrooms
Paraldehyde

Propane

TABLE 22-3. Simple Asphyxiants

Chest Wall

Hypoventilation can occur as a result of a decrease in either respiratory rate or tidal volume. Thus, even when the stimulus to breathe is normal, adequate ventilation is dependent on the coordination and function of the muscles of the diaphragm and chest wall. Changes in this function can result in hypoventilation by two separate mechanisms; both muscle weakness and muscle rigidity may impair the patient's ability to expand the chest wall. Toxicologic causes of muscle weakness include botulinum toxin,[76] electrolyte abnormalities such as hypokalemia,[49, 92] or hypermagnesemia,[27] organic phosphorus compounds,[59, 77] and neuromuscular blockers.[11, 43] Patients with hypoventilation caused by muscle weakness respond well to assisted ventilation and correction of the underlying problem (Chaps. 17, 46, 66, and 109). Chest-wall rigidity impairing ventilation can occur in strychnine poisoning,[12, 47, 53] tetanus,[19, 47, 82] and fentanyl use[18, 20] (Chaps. 38 and 108). Often these patients are difficult to ventilate despite intubation and may require muscle relaxants, neuromuscular blocking agents, or naloxone (for fentanyl).

Airway Patency

The airway itself may be compromised in several ways. As a patient's mental status becomes impaired, the airway is often obstructed by the tongue.[35] Alternatively, vomitus, or either aspiration of activated charcoal or a foreign body, can directly obstruct the trachea or major bronchi with resultant hypoxia.[35, 44, 56, 60, 71, 75] Obstruction may also result from increased secretions produced during organic phosphorus compound poisoning. Laryngospasm may occur either as a manifestation of systemic reactions, such as anaphylaxis, as a result of edema from thermal or caustic injury (Chaps. 100 and 123), or as a direct response to an irritant gas (Chap. 119). Similarly, the tongue can become swollen in response to thermal or caustic injury or toxic exposure to plants such as *Dieffenbachia* spp, or as a result of angioedema from drugs such as angiotensin-converting enzyme inhibitors (Chaps. 60, 100, 114, and 123).[29] Regardless of the mechanism, upper airway obstruction results in hypoventilation, hypoxemia, and hypercapnia (hypercarbia) with the persistence of a normal A-a gradient (see discussion of A-a gradients). Upper airway obstruction is often acute and severe and requires immediate therapy to prevent further clinical compromise.

Bronchospasm may be a manifestation of anaphylaxis, as well as exposure to pyrolyzed cocaine,[74, 83, 84] smoke, irritant gases[37, 41, 66] (Table 22-4), or dust (eg, cotton in byssinosis), or as a result of occupational asthma[52, 80] and hypersensitivity pneumonitis[96] (Chaps. 119 and 123).

TABLE 22-4. Irritant Gases

Airway collapse may result from pneumothorax caused by barotrauma, which more commonly results from the manner of administration of illicit drugs than from actual drug overdose. Barotrauma may also result from nasal insufflation or inhalation of drugs. This form of barotrauma occurs most often in cocaine (particularly in the form of â€œcrackâ€•) and marijuana users, who either smoke or insufflate these drugs and then perform prolonged Valsalva maneuvers in an attempt to enhance the drug's effects (Chaps. 74 and 81).[9 , 16 , 64 , 78 , 93] The increased airway pressure leads to rupture of an alveolar bleb, and free air dissects along the peribronchial paths into the mediastinum and pleural cavities. Nitrous oxide abuse also causes barotrauma.[45] People who have access to nitrous oxide in the hospital or laboratory may siphon and abuse the agent from low-pressure tanks meant for inhalation. In contrast, at parties they inhale nitrous oxide that is used as a propellant in whipped cream cans. Tremendous pressure generated by the escaping gas from this high-pressure system is then transmitted to the airways, sometimes resulting in severe barotrauma (Chap. 65).

Ventilationâ€“Perfusion Mismatch

Ventilationâ€“perfusion (V/Q) mismatch is manifested at the extremes by aeration of the lung without arterial blood supply (as in pulmonary embolism from injected contaminants), and by a normal blood supply to the lung without any ventilation. Impaired blood supply to a normal lung and normal blood supply to an

inadequately ventilated lung constitute an infinite number of gradations that exist between the extremes. The normal response to regional variations in ventilation is to shunt blood away from an area of lung that is poorly ventilated, thereby preferentially delivering blood to an area of the lung where gas exchange is more efficient. An hypoxia-induced reduction in local nitric oxide production appears to be responsible for the regional vasoconstriction that occurs.[1] This effect, commonly known as hypoxic pulmonary vasoconstriction, is best described in patients with chronic obstructive lung disease and facilitates compensation for the V/Q mismatch associated with that disorder. It is unclear whether xenobiotic-induced alterations in pulmonary nitric oxide production are significant determinants in the V/Q mismatch that occurs in poisoning.

In toxicology, V/Q mismatch most commonly results from perfusion of an abnormally ventilated lung, as may occur following aspiration of gastric contents, a frequent complication of many types of poisoning.[44, 60] Although alterations in consciousness and loss of protective airway reflexes are predisposing factors, certain xenobiotics, such as hydrocarbons, directly result in aspiration pneumonitis because of their specific characteristics of volatility, viscosity, and surface tension (Chap. 102).

The diagnosis of aspiration pneumonitis often relies on the chest radiograph for confirmation. The location of the infiltrate depends significantly on the patient's position when the aspiration occurred. Most commonly, aspiration occurs in the right mainstem bronchus, because the angle with the carina is not as acute as it is for entry into the left mainstem bronchus. When aspiration occurs in the supine position, the subsequent infiltrate is usually manifest in the posterior segments of the upper lobe and superior segments of the lower lobe. Aspiration typically involves vomitus; but secretions, activated charcoal, teeth, dentures, food, and other foreign bodies are also frequently aspirated.

Diffusing Capacity Abnormalities

Severe impairment in diffusing capacity commonly results from local injury to the lungs in disorders such as interstitial pneumonia, aspiration, toxic inhalations, and near drowning, and from systemic effects of sepsis, trauma, and various other medical disorders.[8] When this process is acute and associated with clinical criteria including rales, hypoxemia (unspecified degree), and bilateral involvement on a chest radiograph demonstrating a normal heart size, it has been traditionally referred to as *noncardiogenic pulmonary edema* ; throughout this chapter and text, however, the term *acute lung injury* (ALI) is used instead, which reflects current nomenclature.[8] ALI is the presence of increased intraalveolar fluid in the lungs with a normal cardiac output. More rigid criteria, such as a PaO_2 /FiO_2 ratio <300 mm Hg (regardless of positive end-expiratory pressure [PEEP]), bilateral infiltrates on the chest radiograph, and either a pulmonary artery wedge pressure that is less than or equal to 18 mm Hg or no clinical evidence of left atrial hypertension, are used to further define the ALI.[8] When these same criteria are met, but the patient's PaO_2 /FiO_2 ratio is <200 mm Hg (regardless of PEEP), the term *acute respiratory distress syndrome* (ARDS) is used.[8 , 50] Approximately 150,000 Americans develop ARDS annually, many as a result of xenobiotics; ARDS has a fatality rate of almost 50%.[4]

Commonly, patients are chronically exposed to xenobiotics associated with reduced diffusing capacity by smoking tobacco and other xenobiotics or working with asbestos, silica, and coal, which cause slow pulmonary fibrosis or promote emphysema. More recent work emphasizes the ability of chronically smoked cocaine to alter pulmonary function.[84] Acutely, ALI from opioids, salicylates, or phosgene and delayed severe fibrosis from paraquat can cause profound alterations in diffusion (Chaps. 35 , 38 , 111 , and 119).[62 , 72 , 98] Associated parenchymal damage is almost

always present and causes both reduction in lung volumes and V/Q mismatch. Intravenous injection of talc, a common contaminant found in drugs of abuse,[65] and septic emboli from right-sided endocarditis[63 , 81] may result in isolated vascular defects with reduction in diffusion capacity. Similarly, cocaine-induced pulmonary spasm can obstruct vascular channels and alter pulmonary function, creating V/Q mismatch.[23]

ALI with or without progression to ARDS is a common occurrence from poisoning. The edema fluid (and the resulting hypoxia, pulmonary rales, and radiographic abnormalities) may develop in part because of increased permeability of the alveolar and capillary basement membrane.[17 , 21 , 55 , 72] Proteinaceous fluid leaks from the capillaries into the alveoli and interstitium of the lung. Several mechanisms are proposed as the cause for ALI, although there is no single unifying mechanism for all of the toxins that have been implicated. Acute lung injury may result from exposure to xenobiotics that produce hypoventilation by at least three different mechanisms: hypoxia may injure the vascular endothelial cells; autoregulatory vascular redistribution may cause localized capillary hypertension; or alveolar microtrauma may occur as alveolar units collapse, only to be reopened suddenly during reventilation.[72] These and other events may activate neutrophils and release inflammatory cytokines.[3 , 90] Other xenobiotics may be directly toxic to the capillary epithelial cells or may be partly responsible for the release of vasoactive substances.[3] The effects of salicylates and other nonsteroidal antiinflammatory agents may be mediated via effects on prostaglandin synthesis. Finally, sympathomimetic stimulants may cause â€œneurogenicâ€• pulmonary edema, which is thought to be mediated by massive catecholamine discharge. Elevated catecholamine levels are also noted in experimental opioid overdose, possibly supplying a link between hypoxia, hypercarbia, and the catecholamine hypothesis of ALI.[58]

In the 1880s, William Osler described â€œpulmonary edemaâ€• in an opium user. The opioids are still among the most common causes of ALI (Chap. 38), but it is now recognized that there are many types of xenobiotics that can cause ALI, such as the sedative-hypnotic agents, salicylates, cocaine, carbon monoxide, diuretics, and calcium channel blockers, all of which are associated with this entity (Table 22-5).[25 , 26 , 28 , 31 , 32 , 36 , 39 , 42 , 48 , 67 , 69 , 79 , 81 , 98] The route of xenobiotic administration is not usually the determining factor; ALI can result from oral, intravenous, and inhalational exposure. Because the source of the problem is increased pulmonary capillary permeability, patients with ALI have a normal pulmonary-capillary wedge pressure, unlike patients with cardiogenic pulmonary edema.

Cardiogenic pulmonary edema may also occur as the result of poisoning. Etiologies for this phenomenon include the ingestion of large amounts of a xenobiotic with negative inotropy (eg, Î²-adrenergic antagonists, type IA antidysrhythmics) or myocardial infarction (from cocaine). Because many overdoses are mixed overdoses, the distinction between cardiogenic pulmonary edema and ALI is often difficult to establish by physical examination and requires invasive monitoring techniques.

Although the treatments for cardiogenic pulmonary edema and ALI have many similarities, critical aspects of the therapy differ, and therefore an accurate diagnosis must be established. Most diagnostic tests are not helpful in differentiating between these two diseases. Physical examination reveals the presence of rales with both entities. An S_3 gallop, if present, suggests a cardiac cause of pulmonary edema, but its absence does not establish the diagnosis of ALI. In both entities, the arterial blood-gas analysis demonstrates hypoxia and the chest radiograph shows perihilar, basilar, or diffuse alveolar infiltrates. The presence of â€œvascular redistributionâ€• on the chest radiograph, however, is suggestive of a cardiogenic etiology; a normal-sized heart is more commonly associated with ALI, whereas an enlarged heart is more typical of

cardiogenic pulmonary edema. The diagnostic tests that may be useful in establishing the correct diagnosis include echocardiography, transcutaneous bioimpedance, pulmonary artery catheter pressure measurements, and radionucleotide ventriculography (â€œgated-poolâ€• scan). Although the radionucleotide scan accurately measures cardiac output, it is not routinely available in the emergency department (ED) or intensive care unit (ICU) and usually requires the transport of a critically ill patient to the nuclear medicine suite. Although echocardiography can be performed as a portable â€œbedsideâ€• technique, it is less sensitive and less specific for determinations of cardiac output. Therefore, the most definitive diagnostic procedure in the emergency setting is the insertion of a pulmonary artery catheter for hemodynamic monitoring. Although not specifically well-investigated in poisoning, recent experiences with transcutaneous bioimpedance measurements of cardiac output show promise for this portable noninvasive technique.[6 , 22 , 61] Cardiogenic pulmonary edema results from an elevated left-atrial filling pressure (elevated pulmonary-capillary wedge pressure) and a decreased cardiac output. In patients with ALI, the pulmonary artery wedge pressure and the cardiac output are normal (Table 22-6).

Vinca alkaloids

TABLE 22-5. Common Xenobiotic Causes of Acute Lung Injury

The basic treatment for ALI and ARDS is supportive care while the xenobiotic is eliminated and healing occurs in the pulmonary capillaries.[3,50] The most important specific therapeutic maneuver in patients with ALI/ARDS involves the use of low tidal-volume ventilation.[84,90] This results in reduced airway pressures which seem to â€œrestâ€• the lung and allow healing to occur. The efficacy of jet ventilators or membrane oxygenators is inadequately studied. Some studies suggested a potential role for extracorporeal membrane oxygenation in the treatment of ALI and ARDS.[46] PEEP may be particularly beneficial. The PEEP should be maintained as low as possible, in the range of 5â€“15 cm H_2O, to maintain a PO_2 of at least 55 mm Hg, or an oxygen saturation of 88%, with an inspired oxygen concentration of 40% or less. Higher PEEP settings are not always beneficial and can cause an increased incidence of pneumothorax or hypotension. An increase in PEEP may result in a modest increase in PO_2, but a larger decrease in venous return and decreased cardiac output. Therefore, with each change in PEEP, the resulting actual increase (or perhaps decrease) in oxygen delivery to the body should be determined.[4]

Hemoglobin and the Chemical

Asphyxiants

Disorders of hemoglobin oxygen content, as well as of hemoglobin loading and unloading, result in cellular hypoxia, which, in turn,

results in hyperventilation. Anemia is a common complication of the infectious diseases associated with parenteral drug use. In addition, many xenobiotics result in hemolysis or direct bone marrow suppression. Among the latter group are the heavy metals, lead, benzene, and ethanol. Hemolysis may occur in individuals exposed to lead, copper, or arsine gas, and in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency exposed to oxidants (Chap. 24).

TABLE 22-6. Pulmonary Artery Catheter Values

The oxygen-carrying capacity of blood declines in almost direct proportion to hemoglobin content,[85] as seen in Figure 22-1 . As shown in Figure 22-1A , under most normal conditions the dissolved oxygen content of the blood contributes little, and thus the last portion of the equation can be eliminated. Anemia resulting in a decrease of the hemoglobin content to 7.5 g/dL (a hematocrit of approximately 22%) decreases the oxygen content of the blood to about 10.2 mL O_2 /dL (Fig. 22-1B). Because central cyanosis is only visible with a concentration of reduced deoxyhemoglobin of at least 5 g/dL, unless an abnormal hemoglobin is present, anemia can significantly impair oxygen-carrying capacity without the development of this common physical manifestation (Chap. 122).

In contrast, as the PO_2 reaches higher values (as in hyperbaric oxygen [HBO] chambers), the dissolved oxygen content becomes significant and may be of therapeutic value, particularly when the oxygen-carrying content of hemoglobin is compromised. The PO_2 corresponding to an FiO_2 of 100% is approximately 575 mm Hg. In HBO at 3 atm and 100% oxygen, PO_2 values in excess of 1500 mm Hg can be achieved.[54] Under these conditions, the dissolved oxygen content of the blood rises dramatically (to as much as 4.5 mL O_2 /dL) and may be adequate to sustain life, even in the absence of any contribution from hemoglobin (Fig. 22-1C).

Oxygen content (O_2 content) = hemoglobin bound oxygen + dissolved oxygen

A. Normal conditions: hemoglobin (Hb) = 15 g/dL; PO_2 = 100 mm Hg, oxygen saturation (O_2 Sat) = 95%

O_2 content = [(Hb)(O_2 sat) (constant) + (another constant)(PO_2)]

= [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2 /dL/mm Hg)(PO_2)]

= [(15 g/dL)(95%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(100 mm Hg)]

= [(19.8 mL O_2/dL) + (0.3 mL O_2/dL)]

= 20.1 mL O_2/dL = 20.1 vol%

B. Anemia: Hb = 7.5 g/dL; PO_2 = 100 mm Hg, O_2 Sat = 95%

O_2 content = [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(PO_2)]

= [(7.5 g/dL)(95%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(100 mm Hg)]

= [(9.9 mL O_2/dL) + (0.3 mL O_2/dL)]

= 10.2 mL O_2/dL = 10.2 vol%

C. Hyperbaric oxygen: Hb = 15 g/dL; PO_2 = 1500 mm Hg, O_2 Sat = 100%

O_2 content = [(Hb)(O_2 sat)(1.39 mL O_2/g%) + (0.003 mL O_2dL/mm Hg)(PO_2)]

= [(15 g/dL)(100%)(1.39 mL O_2/g%) + (0.003 mL O_2/dL/mm Hg)(1500 mm Hg)]

= [(20.9 mL O_2/dL) + (4.5 mL O_2/dL)]

= 25.4 mL O_2/dL = 25.4 vol%

Figure 22-1. Oxygen content of the blood.

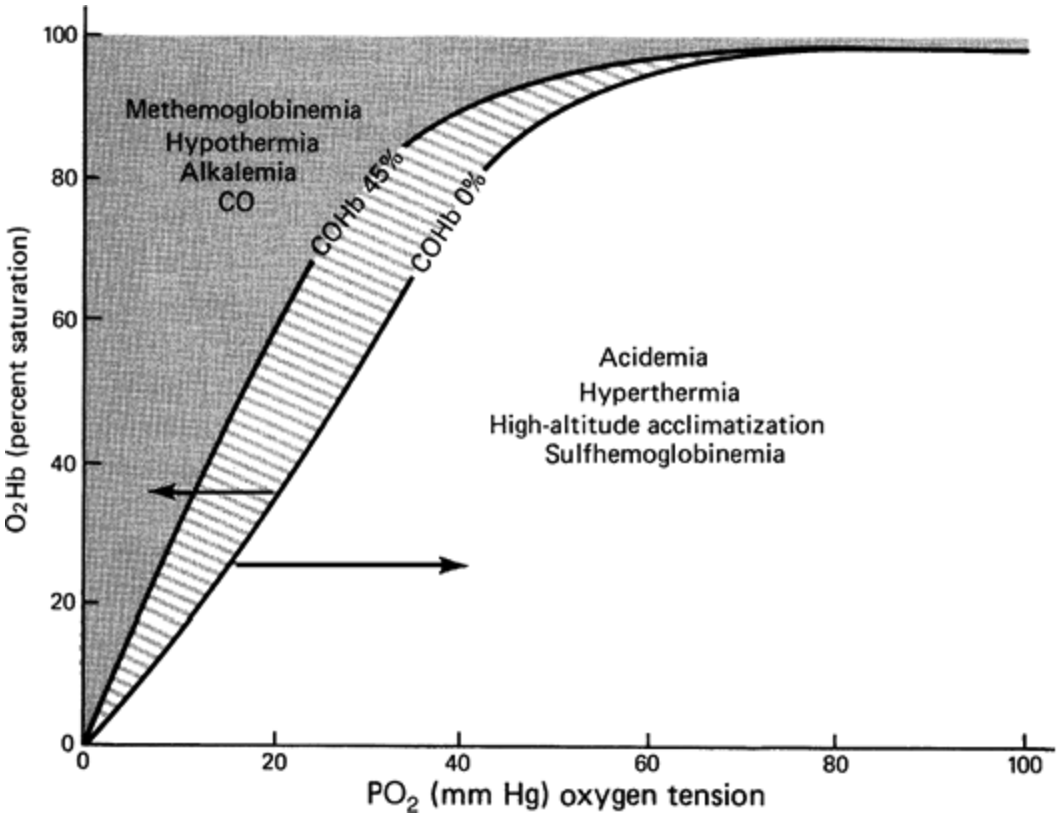

Figure 22-2. Oxyhemoglobin dissociation curve at 98.6Â°F (37Â°C) and pH 7.40. (Hematocrit does not alter this relationship.

The chemical asphyxiants that produce methemoglobin, carboxyhemoglobin, and sulfhemoglobin all interfere with oxygen loading and/or unloading to various degrees. Methemoglobin inhibits oxygen loading, producing cyanosis that is unresponsive to supplemental oxygen (Chap. 122). In addition, the oxyhemoglobin saturation curve is shifted to the left, interfering with unloading (Fig. 22-2). Carboxyhemoglobin has similar effects on oxygen loading and unloading, but carboxyhemoglobin is not associated with cyanosis (Chap. 120). Sulfhemoglobin has similar effects on oxygen loading, but actually shifts the oxyhemoglobin saturation curve to the right, favoring unloading. Cyanide, hydrogen sulfide, and sodium azide primarily affect oxygen use by interfering with the cytochrome oxidase system (Chap. 121).

Cardiac Output

Any xenobiotic that causes a decreased cardiac output or hypotension may result in tissue hypoxia and tachypnea. This occurs most frequently with overdoses of Î²-adrenergic antagonists and calcium channel blockers, antidysrhythmics, cyclic antidepressants, and phenothiazines (Chap. 23).

Approach to the Poisoned Patient

The initial assessment of every patient must involve the evaluation of upper airway patency. Adequacy of ventilation should then be determined. If concomitant injury is suspected, care must be taken to protect the cervical spine. When airway patency is in question, maneuvers to establish and protect the airway are of prime importance. Often this may simply involve repositioning the chin, jaw, or head, or suctioning secretions or vomitus from the airway. However, insertion of an oral or nasopharyngeal

airway, or nasopharyngeal or endotracheal intubation, or surgical cricothyroidotomy may be required as clinically indicated. After the airway is secured, high-flow supplemental oxygen should be provided and the depth, rate, and rhythm of respirations evaluated. An acceptable tidal breath is one that transports 10â€“15 mL of air/kg of body weight.[4]

Hypoventilation resulting from an inadequate respiratory rate or tidal volume is arbitrarily defined as PCO_2 greater than 44 mm Hg and leads to hypoxia and ventilatory failure if uncorrected.[94] The symptoms of hypoxia and or hypercarbia are nonspecific and resemble toxicity from many xenobiotics. Initially, patients appear restless and confused. Signs of sympathetic discharge, such as tachycardia and diaphoresis, may be noted. Later, patients may complain of headache, only to become sedated and subsequently comatose, as further deterioration occurs. Because these signs

and symptoms are nonspecific, arterial blood-gas analysis must be used early in the assessment of patients who present with xenobiotic overdose and possible ventilatory failure.

A trial of naloxone, hypertonic dextrose, and thiamine may be indicated for the patient with an altered mental status and or respiratory compromise (Chap. 4). Because opioid overdose and hypoglycemia are rapidly reversible, potential causes of respiratory failure, these diagnoses should be addressed before most other interventions are considered. Failure to identify and reverse these conditions may result in unnecessary diagnostic and therapeutic interventions in addition to irreversible neurologic sequelae.

Having assured an acceptable airway, the remainder of the evaluation can proceed. A rapid assessment of the remainder of the vital signs (Chap. 3) should then occur. Obtaining a history and physical examination, pulse oximetry, arterial blood-gas analysis, measured oxygen saturation, and a chest radiograph are sufficient to determine the diagnosis of pulmonary pathology in most cases. However, adjuncts, such as measurement of negative inspiratory force (NIF), invasive hemodynamic monitoring, evaluation of the arterialâ€“venous oxygen difference, xenon ventilation and technetium scanning, and CT scanning may be required.

History

A directed history must include questions on the nature, onset, and duration of symptoms; substance use and abuse; home and occupational exposures; and underlying pulmonary pathology. If the patient is suffering from a significant degree of respiratory compromise, most or all of the history may have to be obtained from friends, relatives, paramedics, coworkers, or others.

Physical Examination

The physical evaluation must include a detailed assessment of depth, rate, and rhythm of respirations, use of accessory muscles, direct evaluation of the oropharynx, position of the trachea, and presence and quality of breath sounds. Skin, nail bed, and conjunctival color must be observed for pallor or cyanosis. Funduscopic examination is a useful adjunct to the examination. Papilledema may be noted in the presence of acute hypercapnia. Additionally, because cyanide poisoning interferes with oxygen delivery to tissue, the venous oxygen saturation remains high. During the funduscopic examination, this may appear as arteriolization of the retinal veins, where the veins take on a color more characteristic of arteries (Chap. 121). A general assessment of muscle tone, with a specific emphasis on ocular and neck muscles may give clues to flaccidity or rigidity syndromes that interfere with respiration. When in doubt, a determination of the NIF will provide a rapid, objective, quantifiable bedside assessment of respiratory strength.

Pulse Oximetry

Pulse oximeters have gained widespread acceptance as rapid, noninvasive indicators of hemoglobin oxygen saturation. As defined, hemoglobin oxygen saturation is the ratio of oxyhemoglobin to total hemoglobin. By using two light-emitting diodes, the pulse oximeter is able to measure absorbance at the peak wavelengths for oxy- and deoxyhemoglobin (typically at 940 and 660 nm, respectively). Thus, the ratio of oxyhemoglobin to oxyhemoglobin plus deoxyhemoglobin (total hemoglobin) can be calculated. The clinician may then estimate the PO_2 from the oxygen saturation.

Some of the limitations of this approach require elaboration. Because the oxyhemoglobin saturation curve becomes quite flat above 90% saturation (Fig. 22-2), small changes in saturation

over 90% may represent very large changes in PO_2 . Thus, a decrease from 97% saturation to 95% saturation may represent a substantial decrease in PO_2 . Although a low saturation is an early indicator of hypoxic hypoxia, this is only one of many causes of tissue hypoxia. If total hemoglobin is low, oxygen-carrying capacity is inadequate even with excellent saturation (Fig. 22-1). Dyshemoglobinemias, such as carboxyhemoglobin, methemoglobin, and possibly sulfhemoglobin, interfere with the accuracy of pulse oximeter determinations and are of particular concern in the poisoned patient. Specifically, using a standard pulse oximeter, the presence of elevated concentrations of methemoglobin will tend to make the saturation approach 84â€“86% (Chap. 122).[5] , [73] Carboxyhemoglobin is falsely interpreted by the pulse oximeter as mostly oxyhemoglobin, thus readings tend to appear normal even with significant carbon monoxide poisoning,[86] as Table 22-7 illustrates.

Accurate response by the pulse oximeter also requires adequate blood pressure, lack of strong venous pulsations (as might occur in a patient with tricuspid regurgitation), translucent nails (some shades of nail polish may interfere), absence of circulating dyes (methylene blue), and a near-normal temperature. Finally, we are often more interested in PCO_2 than PO_2 because it is a better measure of ventilation. The pulse oximeter gives no information

with regard to PCO_2 . Although the pulse oximeter may give early clues to the presence of hypoxic hypoxia, extrapolation of oxygen saturation to standard arterial blood-gas values may be difficult because of the many possible sources of error. Pulse oximetry is therefore best used as an initial screening tool for hypoxic hypoxia and later in combination with the initial arterial blood-gas measurement, as a determination of the patient's response to therapy.

The table demonstrates limitations of the various methods for determining oxygen saturation (O_2 saturation). The arterial blood gas (ABG) calculates the O_2 saturation from the dissolved oxygen content (PO_2) and becomes abnormal only when the PO_2 falls. The pulse oximeter uses only two wavelengths of light and produces substantial errors in the presence of a dyshemoglobinemia. Because the cooximeter uses more wavelengths of light than the pulse oximeter, it can correctly identify the presence of carboxyhemoglobin and methemoglobin. The cooximeter has the additional advantage (*) of calculating the total hemoglobin and

oxygen content, so that it is useful in the setting of anemia. All techniques are acceptable for the assessment of hypoxemia.

TABLE 22-7. Sample Interpretations of Oxygen Saturations Reported from Various Sources

Blood-Gas Analysis

Arterial blood-gas analysis is an easy and rapid means of evaluating both acidâ€“base status and gas exchange. Attention must be paid to the method for determining oxygen saturation, specifically whether it is measured or calculated from PO_2 . If the measured O_2 saturation is lower than would be predicted from the PO_2 (the calculated O_2 saturation), the presence of an abnormal hemoglobin (such as carboxyhemoglobin or methemoglobin) must be suspected. A normal calculated O_2 saturation does not exclude these disorders (see Use of the Cooximeter below).

Because it is easier to obtain, venous blood-gas analysis is often used as a substitute for arterial blood-gas analysis.[13] When compared to arterial values, venous pH and PO_2 are lower, whereas PCO_2 is higher. Errors can be introduced by increased muscle activity of the extremity being tested (eg, seizures) or the prolonged placement of a tourniquet while attempting phlebotomy. Although a venous blood gas is generally acceptable for assessment of the blood pH, it cannot provide a good evaluation of gas exchange.

Mixed venous blood (defined as right-heart blood), however, is required for accurate determination of the arterialâ€“venous

oxygen extraction and is an excellent indicator of acidâ€“base status, cardiovascular function, and oxygen use. Unfortunately, a central venous catheter is required for sampling. When performing a peripheral venous blood-gas analysis, it is usually assumed that this is only an approximation of mixed venous blood.

The arterial PO_2 is generally considered adequate only if it lies within the flat portion at the upper right of the sigmoidal-shaped oxyhemoglobin dissociation curve (Fig. 22-2). That portion of the curve includes the PO_2 range from 60 to 100 mm Hg, which corresponds to oxygen saturations greater than 90%. As mentioned earlier, within this flat portion there can be discernible changes in PO_2 with little change in oxygen saturation. For instance, an arterial PO_2 of 80 mm Hg corresponds roughly to an oxygen saturation of 95%. If the PO_2 falls to 60 mm Hg, the oxygen saturation falls to 90%. This insignificant decrease in the oxygen-carrying capacity of the blood is of minimal clinical concern. If the PO_2 falls another 20 mm Hg, however, there is a more significant reduction in oxygen saturation, to approximately 70%. Thus, changes in PO_2 above 60 mm Hg are usually not of acute therapeutic significance, because the O_2 saturation is above 90%. These changes are, however, frequently of diagnostic significance.

An exception to this concept applies to the patient who is under metabolic stress, as might result from low cardiac output, impaired vascular flow, anemia, or dyshemoglobinemia. Under these circumstances even the modest gain achieved by increasing both dissolved oxygen content and hemoglobin saturation above 90% may be desirable, as discussed earlier (see Hemoglobin and Chemical Asphyxiants). Also, even if a PO_2 greater than 60 mm Hg or an O_2 saturation greater than 90% is considered acceptable in most acute settings, it is still desirable to achieve greater values, when feasible, to create a safety zone in case of clinical deterioration.

Significance of a Decreased PO_2

In a patient with a diminished PO_2 , five clinically relevant mechanisms for the hypoxemia should be considered: (a) alveolar hypoventilation; (b) V/Q mismatch; (c) shunting; (d) diffusion abnormality; and, rarely, (e) a decrease in FiO_2 . In most clinical circumstances, diffusion defects cannot be distinguished from V/Q mismatch. Usually, the responsible mechanism can be identified by calculating the alveolar-arterial (A-a) oxygen gradient. In patients with alveolar hypoventilation, the A-a gradient is completely normal (15 mm Hg or less when breathing room air). Patients with V/Q mismatch have an A-a gradient that is increased but which normalizes when 100% oxygen is administered for at least 20 minutes. A normal A-a gradient is defined as less than 100 mm Hg on 100% oxygen. The arterial PO_2 on 100% oxygen reaches approximately 575 mm Hg. In contrast, a patient with a shunt will also have an increased A-a gradient while breathing room air, but when 100% oxygen is administered, the arterial PO_2 falls substantially below 575 mm Hg and the A-a gradient does not normalize. Finally, in the case of a patient with hypoxia resulting from breathing in an environment in which the FiO_2 is less than 21%, the PO_2 should correct rapidly when the patient is removed from the environment or supplemental oxygen is delivered.

In general, a low PO_2 can be improved by supplying supplemental oxygen. Although in this instance the patient's laboratory values may be corrected, the underlying process persists. It is important to remember that the laboratory correlate of hypoventilation is hypercapnia on the arterial blood-gas analysis. If hypercapnia is associated with a low arterial pH (less than 7.35), assisted ventilation should be considered, regardless of whether the PO_2 corrects with supplemental oxygen.

Use of the Cooximeter

Routine analysis of an arterial blood-gas yields a measured pH,

measured PO_2 , and measured PCO_2 . Ordinarily, the serum bicarbonate, base excess, and percent oxygen saturation of hemoglobin are all calculated values. The oxygen saturation is of clinical significance because it usually correlates with the oxygen content of the blood, and thus the oxygen available to the tissues. However, implied in this relationship is a normal amount of functional hemoglobin. Because the oxygen saturation is calculated from the measured PO_2 using the oxyhemoglobin dissociation curve, it represents only the saturation of normal hemoglobin. Thus, in the presence of even a small percentage of abnormal hemoglobin, the calculated oxygen saturation overestimates the total oxygen content of the blood. For example, a patient with PO_2 of 95 mm Hg has a calculated oxygen saturation of 95%. If this patient also has a 30% methemoglobinemia, only 70% of the total hemoglobin is saturated to 95% and the actual saturation is only 67%. This gap is clinically important because hemoglobin saturations of less than 90% do not provide adequate oxygen delivery to the tissues. Most cooximeters spectrophotometrically measure total hemoglobin, oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin (Fig. 22-3). The resultant saturation is a measured oxygen saturation of the total hemoglobin by including four common hemoglobin variants, and thus correlates with the total oxygen content of the blood.

The difference between measured and calculated oxygen saturation represents the percentage of abnormal hemoglobin present. This gap is helpful in the diagnosis of methemoglobin and

carboxyhemoglobin, and is useful in assessing the adequacy of therapy for these disorders. Common indications for cooximetry include cyanosis that is unresponsive to oxygen (methemoglobin and sulfhemoglobin), known use of methemoglobin-forming xenobiotics (such as dapsone), smoke inhalation (carboxyhemoglobin and possibly methemoglobin), and evaluation of therapy for cyanide toxicity (methemoglobin).

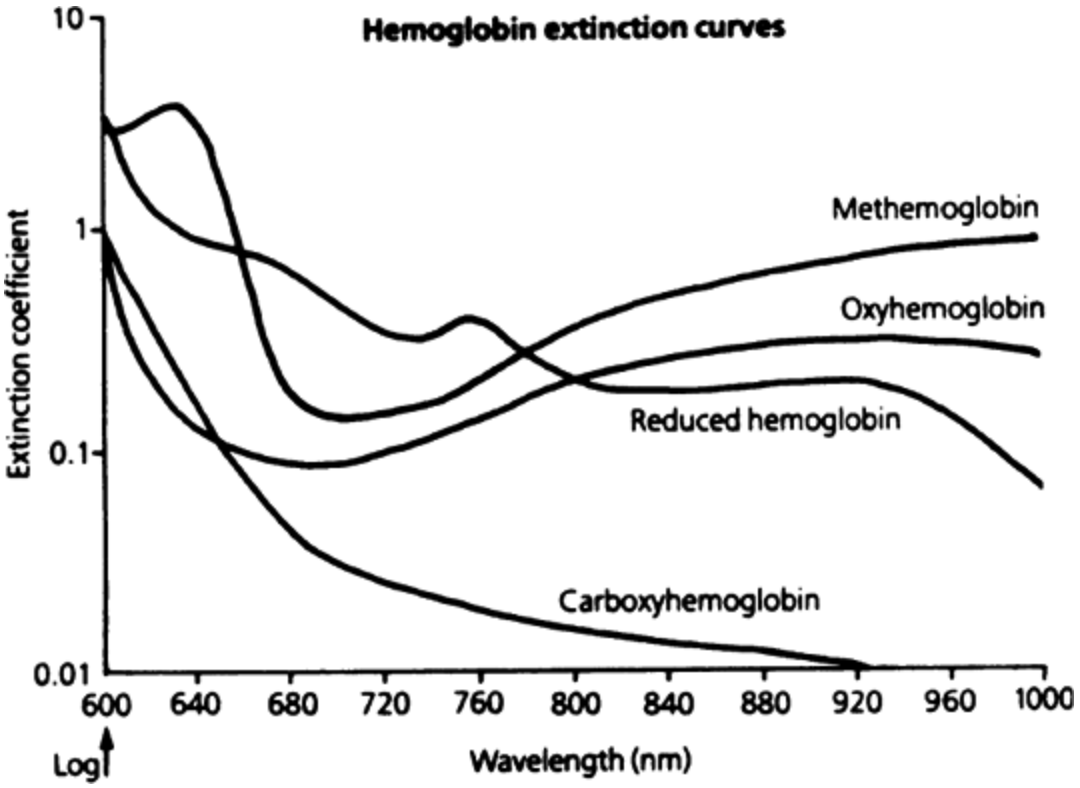

Figure 22-3. Cooximetry curves for normal and abnormal hemoglobin variants. Transmitted light absorbance spectra are shown for four hemoglobin species: oxyhemoglobin, reduced (deoxy) hemoglobin, carboxyhemoglobin, and methemoglobin. *(Adapted with permission from International Anesthesiology Clinics. Boston, Little Brown & Co., 1987;25(3):138. Tremper KK, Barker SJ: Using pulse oximetry when dyshemoglobin levels are high. J Crit Illness 1998;3:103â€“107.)*

Like so many other tools, the cooximeter is not perfect. Its biggest limitation occurs when dealing with uncommon hemoglobins. Because only four wavelengths of light are used by most cooximeters, they have the ability to define only four hemoglobin variants. Consequently, rare dyshemoglobinemias, such as sulfhemoglobin, are interpreted as one or a combination of the four common hemoglobin variants, giving erroneous results. This phenomenon is commonly noted in neonates, where fetal

hemoglobin may be interpreted as carboxyhemoglobin.[88, 95] Although this error rarely adds more than 10% to the true carboxyhemoglobin value, this amount can be significant because of the difficulties in assessing the neuropsychiatric status of infants possibly exposed to carbon monoxide. Some newer cooximeters are unaffected by fetal hemoglobin, and should be used in neonatal cases of suspected carbon monoxide poisoning.[89, 99] Similarly, these newer models are now beginning to provide measurements of sulfhemoglobin as well.[24, 97, 99] Additionally, cooximeters tend to interpret low levels (<2.5%) of carboxyhemoglobin inconsistently.[57] Fortunately, this rarely has clinical implications.

Chest Radiography

Radiographic detection of a pneumothorax or pneumomediastinum, cardiogenic pulmonary edema, ALI and ARDS, aspiration pneumonitis, or the presence of a foreign body is crucial, but can usually be delayed until the initial evaluation is completed. Confirmation of endotracheal tube placement is necessary but initially can be ascertained by auscultating bilateral breath sounds following compression of a bag valve mask, or using a variety of marketed devices such as end tidal CO_2 detectors designed to help confirm tube placement. For patients with occupational disorders, the chest radiograph is essential to confirm and stage exposures to asbestos, silica, coal, and other causes of pneumoconiosis.

Therapeutic Options

Supplemental Oxygen

Supplemental oxygen is indicated for all patients with suspected or confirmed respiratory insufficiency. Although it is generally advisable to begin with high flow (12 L/min) via a nonrebreather mask, lower concentrations of oxygen can be used in more stable

patients. It is important to remember that a normal saturation on pulse oximetry does not imply that there is no need for supplemental oxygen. This can be determined only after a more complete assessment. Initially, there should be limited concern over worsening hypercapnia in patients with chronic obstructive pulmonary disease (COPD) and respiratory failure. This concern should not deter one from providing needed oxygen as many of these patients will require intubation for their hypoventilation. If time and the patient's clinical condition permit, an arterial blood-gas analysis should be obtained prior to administering supplemental oxygen or mechanical ventilation so that the patient's intrinsic respiratory status can be adequately defined. In many situations, the patient's condition will not permit delay, and subsequent arterial blood-gas analyses will be needed to determine the ability to decrease the FiO_2 or the need for intubation. Hyperbaric oxygen is indicated for carbon monoxide poisoning and rarely other exposures (see Antidotes in Depth: Hyperbaric Oxygen).

Additional respiratory support can be offered from bilevel positive airway pressure (BiPAP). Some experimental evidence supports the use of BiPAP for patients with acute respiratory dysfunction in the emergency department.[70] Although this technique may be useful in overdosed patients, it should be considered only as a temporizing measure for patients who are expected to recover rapidly, or while preparing for intubation.

Intubation

After the decision for mechanical ventilation has been made, the route needs to be selected. The editors of this text prefer oral intubation because it permits the use of a larger endotracheal tubeâ€”usually 8 mm or larger in adultsâ€”than does nasal intubation. If the patient later needs bronchoscopy, it can be done through the endotracheal tube. Some data suggest that

bronchoscopy with bronchoalveolar lavage may be of both diagnostic[87] and therapeutic[51] benefit for selected poisoned patients. However, in an awake patient, nasotracheal intubation done blindly or with the aid of a flexible fiberoptic laryngoscope may be more easily performed. An advantage of nasotracheal intubation over oral intubation is that orogastric lavage can be performed more easily when the oral cavity is unimpeded. After the trachea is intubated, the tube should be checked to ensure that it is correctly positioned.

All patients who sustain overdoses and show signs or symptoms of respiratory insufficiency should have chest radiographs performed. Unfortunately, intubated patients usually have portable radiographs performed and the carina may be difficult to visualize because of the poor quality of the study. When seen, the carina is visualized between T-5 and T-7 in most patients. Thus, the tip of the endotracheal tube should be above T-5 for proper (safe) placement. When a portable chest radiograph is obtained, the patient's neck may

be extended or flexed, altering the location of the endotracheal tube tip. For this reason it is essential to note the position of the neck during the radiograph, because the tip of the endotracheal tube may move up (with flexion) or down (with extension) by almost 2 cm.[10]

Mechanical Ventilation

After a patient is intubated for ventilatory support, the respirator modeâ€”assist, control, or intermittent mandatory ventilation (IMV)â€”is selected. Patients with pure hypoventilation usually require a controlled fixed rate that can be easily adjusted based on serial arterial blood-gas analyses. Patients with pulmonary parenchymal processes, such as ALI, ARDS, or pneumonia, usually do well when placed on either assist or IMV mode. With the IMV

mode, a given number of mandatory breaths is administered at the set tidal volume. The patient may take additional breaths without assistance, permitting lower mean airway pressure, which theoretically may reduce the risk of barotrauma and hemodynamic compromise. Although the lower airway pressures associated with IMV are desirable, many authorities recommend the use of the assist mode because it eliminates the patient's work of breathing.[50]

The next step is to determine the appropriate FiO_2 to be delivered to the patient. A number of formulas have been devised. One simple approach is to intubate a patient, control breathing, administer 100% oxygen, and decrease to an FiO_2 of less than 50% as quickly as possible in an attempt to prevent oxygen toxicity.[3] Although the toxic effects of oxygen are well known for paraquat (Chap. 111), evidence suggests that oxygen may be an important mediator of other xenobiotic-induced pulmonary injuries such as with iron.[40] A PO_2 of 55 mm Hg or a measured oxygen saturation greater than 88% is generally acceptable; thus, there is little reason to expose patients to much higher concentrations of oxygen once these conditions are met.[1 , 90] Many clinicians feel more comfortable establishing a â€œbufferâ€• against deterioration by increasing the PO_2 somewhat above 55 mm Hg, but prolonged exposure to higher values is rarely indicated. In patients with pure alveolar hypoventilation, the tidal volume should be set at 10â€“15 mL/kg/breath. If oxygenation cannot be maintained with FiO_2 of 50% or less, PEEP may be used, with careful reassessment of serial arterial blood-gas analyses, changes in effective compliance, and hemodynamic data with each increment in PEEP. In patients with ALI or ARDS, however, lower tidal volumes (on the order of 6 mL/kg/breath) decrease both mortality and the total number of days on the ventilator.[1]

Pharmacologic Adjuncts

Only a few pharmacologic agents have a significant place in reversing xenobiotic-induced respiratory dysfunction. Naloxone may have the greatest role. Atropine and pralidoxime may be useful for respiratory dysfunction from cholinesterase inhibitors (see Antidotes in Depth: Pralidoxime and Chap. 109). Elapid antivenom and botulinum antitoxin are rarely used but may be lifesaving. Neostigmine can reverse muscle weakness from nondepolarizing neuromuscular blockers (Chap. 66). More commonly, clinicians are required to treat bronchospasm from exposure to pulmonary irritants. The use of $\hat{I}^2_2$ -selective adrenergic-agonist bronchodilators is effective in these cases.[30] The role of corticosteroids remains controversial.[3] An inhaled solution of 2% sodium bicarbonate may provide symptomatic relief for patients with exposure to hydrogen chloride or to chlorine (See Antidotes in Depth: Sodium Bicarbonate).

Exogenous nitric oxide has been considered for a variety of pulmonary conditions. Specifically, nitric oxide may be useful as a bronchodilator,[14] a means to reverse hypoxic pulmonary vasoconstriction,[3] and as a treatment for ARDS.[2] Unfortunately, controlled studies fail to demonstrate a benefit for nitric oxide in ALI/ARDS patients.[3 , 90] Similarly, the results are disappointing for glucocorticoids, surfactants, and a variety of antiinflammatory agents.[4 , 90]

Applications in Poisoned Patients

Two 30-year-old patients who overdosed were brought to the ED. Each had ingested substantial amounts of barbiturates and diazepam. An arterial blood gas drawn from patient 1 while he was breathing room air revealed a pH of 7.18, PCO_2 of 70 mm Hg, PO_2 of 50 mm Hg, and a calculated bicarbonate of 24 mEq/L. An arterial blood gas drawn from patient 2, also breathing room air, revealed a pH of 7.31, PCO_2 of 50 mm Hg, PO_2 of 50 mm Hg, and a calculated bicarbonate of 25 mEq/L. Quick analysis showed that

patient 1 was hypercapnic with a significant respiratory acidosis. Patient 2 did not appear as ill; his PCO_2 was not very elevated and his pH was not significantly reduced. The A-a gradients were calculated to be 12.5 mm Hg for patient 1 and 37.5 mm Hg for patient 2 (Fig. 22-4A and B).

A. Arterial PCO_2 approximates alveolar PCO_2 and is substituted as:

$$PAO_2 = PiO_2 - \frac{PCO_2}{R}$$

$$PiO_2 = (FiO_2)\,(PB - PH_2O)$$

where PAO_2 is alveolar PO_2, PiO_2 is partial pressure of inspired O_2, $PaCO_2$ is arterial PCO_2, and R is the respiratory exchange ratio. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

where FiO_2 is the inspired O_2 fraction, PH_2O is water vapor pressure, and PB is barometric pressure. On room air at sea level, FiO_2 −21%. At steady state, R = 0.8. At sea level, PB = 760 mm Hg, and PH_2O = 47 mm Hg. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

$$= [(0.21)(760 - 47)] - \frac{PCO_2}{R}$$

$$= 150 - [(1.25)(PCO_2)]$$

Because the A-a gradient is equal to $PAO_2 - PaO_2$ it can be expressed as:

$$150 - [(1.25)(PCO_2)] - PaO_2 \quad \text{or} \quad 150 - [(1.25)(PCO_2) + PaO_2]$$

A normal A-a gradient is 10–15 mm Hg, but this increases with age. A rough estimate of the normal A-a gradient is one-third the patient's age.

B. Referring to the two overdosed patients above, the A-a gradient for patient 1 is:

$$150 - [(1.25)(70) + 50] = 12.5 \text{ mm Hg}$$

This calculation reveals a normal gradient, indicating that the etiology for hypoxemia and hypoventilation is extrinsic to the lung itself.

In patient 2 the A-a gradient is:

$$150 - [(1.25)(50) + 50] = 37.5 \text{ mm Hg}$$

This abnormally high A-a gradient is consistent with the aspiration which was pneumonia seen on the patient's chest radiograph.

Figure 22-4. A. Derivation of the definition of alveolar-arterial (A-a) oxygen gradients. B. Using the A-a gradients.

The A-a gradient should be no more than one-third of a patient's age.[38] Patient 1 has a normal A-a gradient (12.5 mm Hg). Therefore, the mechanism for his hypoxemia must be purely alveolar hypoventilation, because that is the only mechanism that does not disrupt gas exchange. The treatment is to reverse the hypoventilation by assisting the patient's ventilation. Mechanical ventilation will reduce the PCO_2 , increase the PO_2 , and stabilize the patient until he is no longer under the influence of the xenobiotics he has ingested.

Alternatively, the A-a gradient of patient 2 (37.5 mm Hg) is significantly elevated. There are two possible mechanisms for this hypoxemia: V/Q mismatch or shunting. To discern which of these two mechanisms is responsible, the patient should be given 100% oxygen. In either case, however, the increased A-a gradient suggests that there is intrinsic pulmonary pathology causing the hypoxemia. On finding an increased A-a gradient, a chest radiograph should be examined for an intrinsic pulmonary cause of the gas exchange abnormality. Patient 2 had a significant right-lower-lobe infiltrate. He had aspirated and a pneumonitis developed, which contributed to his hypoxemia. His treatment, therefore, included antibiotic therapy and respiratory support.

Summary

Xenobiotics adversely affect tissue oxygenation at every step required for oxygen delivery. This process begins with lowering the partial pressure of inspired oxygen (simple asphyxiants) and ends with inhibition or blockade of cytochrome oxidase (carbon monoxide, cyanide, hydrogen sulfide). Although the clinical manifestations of hypoxia are constant regardless of the etiology, the history, physical examination, and some simple laboratory testing will often allow the clinician to determine the specific mechanism of hypoxia. Once the specific mechanism for hypoxia is identified, potential etiologies can be appreciated, and specific

treatments begun. While the diagnosis is being established, the first responses to tissue hypoxia always involve administration of supplemental oxygen, assisted ventilation if necessary, and assuring the adequacy of circulation.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 23
Cardiovascular Principles

Robert A Hessler

The maintenance of adequate tissue perfusion depends on the volume status and vascular resistance, cardiac contractility, and cardiac rhythm. These components of the hemodynamic system are all vulnerable to the effects of xenobiotics. Cardiovascular toxicity may therefore be manifeste by the development of (a) hemodynamic instability, (b) heart failure, (c) cardiac conduction abnormalities, or (d) dysrhythmias. The presence of these specific cardiovascular abnormalities might be helpful in determinir the type of toxic exposure. Even when multiple cardiovascular abnormalities occur, the specific pattern of the anomalies (toxicologic syndrome or â€œtoxidromeâ€•) may suggest a particular class or type o xenobiotic.

Mechanisms of Cardiovascular Toxicity

An alteration in hemodynamic functioning may be a result of either indire metabolic effects or direct effects on the nervous system, heart, or blood vessels. Poisoning may lead indirectly to hemodynamic changes secondar to the development of acidemia, alkalemia, hypoxia, or electrolyte

abnormalities. In these patients, supportive care with ventilation, oxygenation, and fluid and electrolyte repletion will usually improve the cardiovascular status. These cardiovascular abnormalities are caused by metabolic changes and are generally not useful in the identification of a specific ingested xenobiotic.

Xenobiotics can also cause specific hemodynamic abnormalities as a resu of direct effects on the myocardial cells, the cardiac conduction system, o on the arteriolar smooth muscle cells. These effects are frequently mediated by interactions with cellular ion channels or cell membrane receptors. A rational approach to treatment of xenobiotic-induced hemodynamic effects is based on the underlying pharmacology and pathophysiology of the neurohormonal receptors, membrane ion channels intracellular calcium regulation, and the autonomic nervous system.

Ion Channels of the Myocardial Cell Membrane

Electrophysiologic studies have identified the functional types of membrane receptors and ion channels. Molecular genetic studies have identified the gene coding for the key cardiac ion channels and have elucidated the structural and physiologic relationships that lead to toxicologic effects of many xenobiotics. These channels are critical for maintenance of the intracellular ion concentrations necessary for action potential development, impulse conduction throughout the heart, and myocyte contraction.

Potassium Channel

Ion channels that change their conductance of current with changes in th transmembrane voltage potential are called *rectifying channels.* The voltage sensitive potassium channels are categorized based upon their speed of activation and their voltage response. These include the â€œdelayed rectifierâ€• potassium currents, particularly the I_{Kr} (rapidly activating) and the I_{Ks} (slowly activating) channels.[80]

The various voltage gated potassium channels share an underlying structural similarity. The Î± subunit is a protein molecule with 6 membrane-spanning Î±-helical domains, termed S1â€“S6 (Fig. 23-1A). The pore domain is located between the S5 and S6 regions of the Î± subunit, and the S4 region is the voltage sensor region.[53 , 93] Four of these Î± subunits assemble with Î² subunits to form the functional potassium channel complex. Four of the Î± subunits encoded by the KvLQT1 gene assemble with Î² units encoded by the minK gene (originally thought to be the minimal potassium channel subunit) to form the I_{Ks} potassium channel.[53] HERG (human ether a-go-go related gene) encodes the Î± subunit that assembles with Î² subunit proteins encoded by the MiRP1 (minK related protein 1) gene to form the I_{Kr} potassium channel. The C-terminus region of the Î± subunit encoded by HERG has a cyclic nucleotide binding domain and an N-terminus region similar to domains involved in signal transduction in cells.[53]

Many xenobiotics interact with the HERG-encoded subunit of the potassiu channel to reduce the current through the I_{Kr} channel and prolong the action potential duration. The HERG Î± subunit of the channel is particularly susceptible to xenobiotic-induced interactions due to two important differences from the other channels. First, the S6 domain of th HERG channel has aromatic domains on the inner cavity pore that can bir to aromatic xenobiotics. Additionally, the inner cavity and entrance of the HERG channel is larger than the other voltage-gated potassium channels.[53] This larger pore can accommodate larger xenobiotics that are then trapped within the pore when the channel closes.[53 , 92 , 93 , 114]

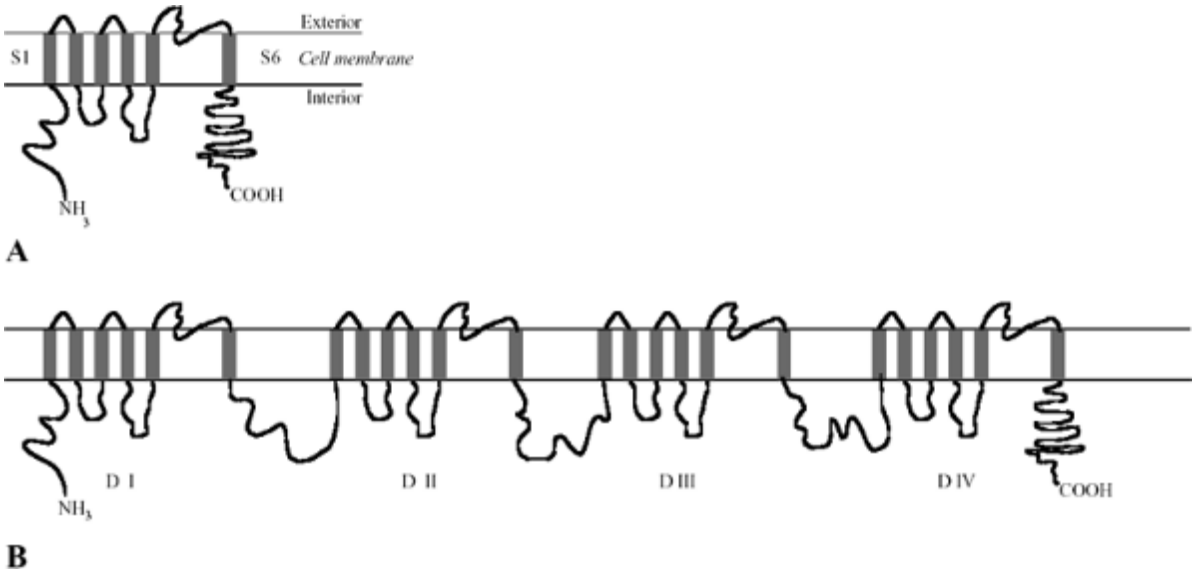

Figure 23-1. Structure of the potassium and sodium ion channels. A . Th structure of the Î± subunit of the voltage-gated potassium channel. The protein molecule has 6 membrane-spanning regions (S1â€“S6); the voltage-sensitive region is S4 and the actual ion channel is located between S5 and S6. Four of these Î± subunits assemble with 4 Î² subunit to form the potassium channel complex. B . The structure of the Î± subunit of the sodium channel. The protein molecule has 4 domains (D Iâ€”D IV), each analogous to one of the potassium channel Î± subunits. One of these molecules assembles with Î² subunits to form the membrane sodium channel.

Sodium Channel

The voltage-responsive sodium channels are responsible for the initiation of depolarization of the myocardial membrane. All currently identified voltage-responsive channels, including the sodium and calcium channel, have structures similar to the functional potassium channel assembly. The sodium channel gene encodes a single protein that contains 4 functional domains (D Iâ€”D IV). Each of these domains has the 6 membrane-spanning regions characteristic of the voltage-gated potassium channel

and is structurally similar to an Î± subunit of the potassium channel (Fig. 23-1). The single, large Î± subunit of the sodium channel assembles wit regulatory Î² subunits to form the functional unit of the sodium channel. The best characterized of the sodium channels, the SCN5A gene-encoded Î± channel, is inactivated by xenobiotic interactions between the D III ar the D IV domains to physically block the inner mouth of the sodium channel pore.[53]

Calcium Channel

Calcium channel conductivity across the myocardial cell membrane is critical for appropriate duration of cell membrane depolarization and for initiation of cellular contraction. The best characterized of the calcium channels are the slow L-type, the fast T-type, and the ryanodine receptor calcium channel (encoded by the RyR2 gene). This RyR2 channel is structurally similar to the sodium channel with 4 pore domain units in a single protein chain.[53] The RyR2 calcium channel is located on the membrane of the sarcoplasmic reticulum (SR) and mediates calcium release from the SR in myocardial cells. Calcium that enters the cell through the plasma membrane L-type calcium channels during depolarization activates the RyR2 channels on the SR. This triggers the release of large amounts of calcium from the SR into the cell cytosol to initiate myofibril contraction.

Ion Channels and the Myocardial Cell Actio Potential

An understanding of the basic electrophysiology of the myocardial cell is essential to understand the toxicity of xenobiotics and to plan appropriate therapy. Figure 23-2 shows the typical action potential of myocardial cell depolarization, the electrolyte fluxes responsible for the action potential, and the resulting ECG complex. The action potentials of the contractile ar the conductive cells are depicted.

The action potential is divided into 5 phases: phase 0, depolarization;

phase 1, overshoot; phase 2, plateau; phase 3, repolarization; and phase 4, resting. Phase 0 begins when the cell is excited either by a stimulus from an adjoining cell or by spontaneous depolarization of a pacemaker cell. Selective voltage-gated fast sodium channels (I_{Na^+}) open, resulting in rapid depolarization of the membrane. At the end of phase 0, the voltage-sensitive sodium channels close and a transient outward potassium current (I_{T0}) occurs, resulting in a partial repolarization of the membrane.

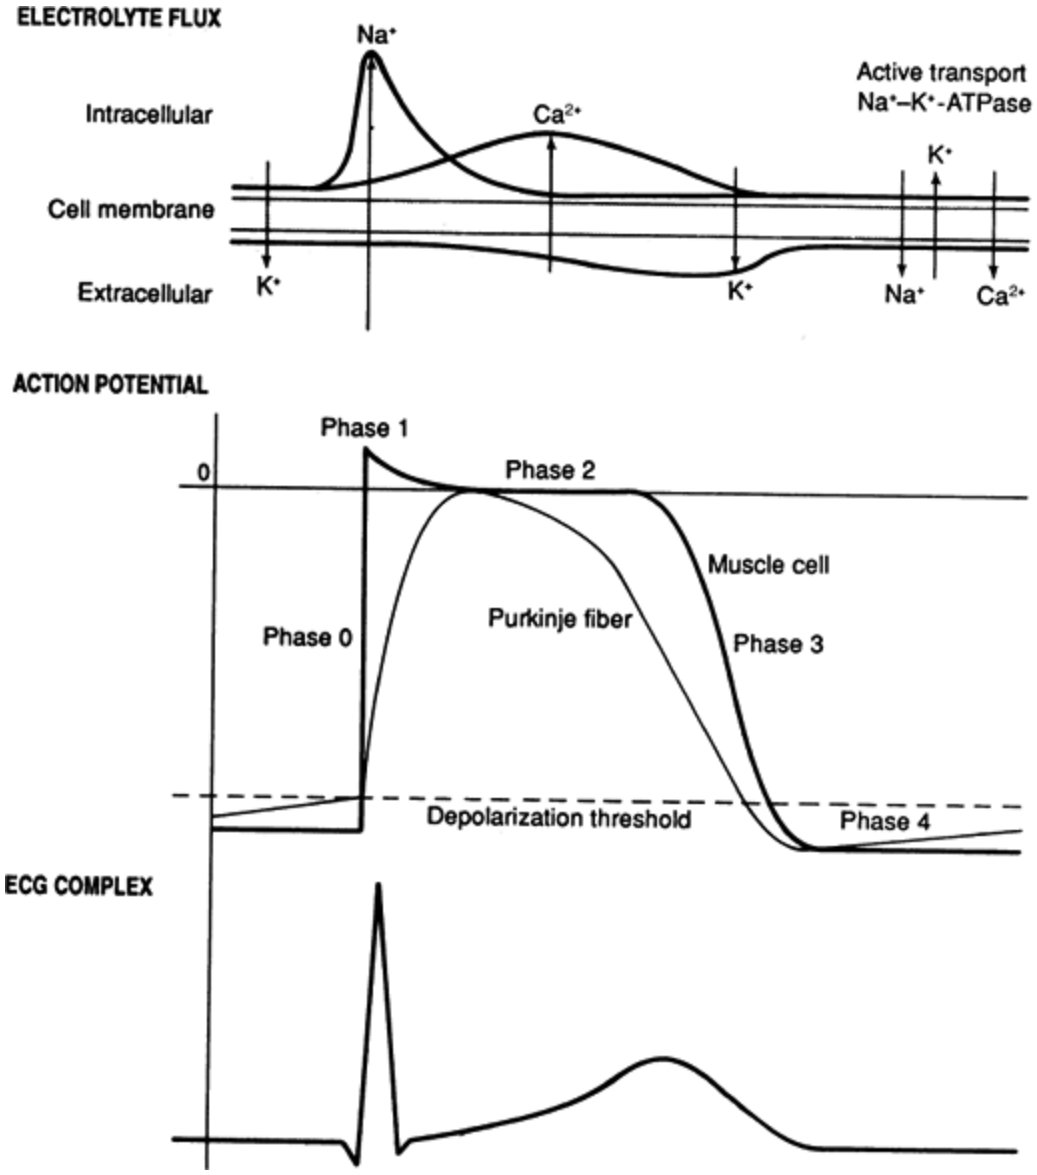

Figure 23-2. Relationship of electrolyte movement across the cell

membrane to the action potential and the ECG.

During phase 2 (plateau phase), the inward depolarizing calcium currents are largely balanced by the outward repolarizing potassium currents. Voltage-sensitive calcium channels open that allow Ca^{2+} movement down the concentration gradient into the cell. The intracellular Ca^{2+} concentration is 5â€“10,000 times lower than the extracellular concentration. The voltage-gated calcium channels that allow movement Ca^{2+} down its concentration gradient into the cell are categorized based on their conductance (fast or slow) and their sensitivity to voltage changes.[100, 116] The calcium currents (mostly the â€œlong-lastingâ€• current) gradually decrease as the channels inactivate. Simultaneously, the outward potassium â€œdelayed rectifierâ€• currents, particularly the I_{Kr} (rapidly activating) and the I_{Ks} (slowly activating) currents, increase terminating the plateau phase of the action potential and initiating cellular repolarization (phase 3). Other, smaller, outward potassium currents (not shown in Fig. 23-2) play a lesser role in the duration of the action potential and development of phase 3, including I_{Kur} (ultrarapid), I_{Kp} (plateau), $I_{K\text{-}Ach}$ (acetylcholine-dependent), and $I_{K\text{-}ATP}$ (adenosine triphosphate-dependent) currents.

Phase 4 is the resting state for much of the myocardium, except the pacemaker cells, and corresponds to diastole in the cardiac cycle. During phases 3 and 4, active transport of Na^+ , K^+ , and Ca^{2+} against their electrochemical gradients return the myocyte to the baseline resting state. The immense transmembrane electrochemical gradient is maintained during the resting state by a Ca^{2+} -Na^+ exchange mechanism and by ATP-dependent pumps in the membrane that together move Ca^{2+} out of the cells.[83, 84, 85 and 86] In the pacemaker cells, during phase 4 of the action potential, gradual electrical depolarization of the membrane occurs due to potassium currents (called the I_f for â€œfunnyâ€• or the I_h for â€œhyperpolarization-activatedâ€• current). The membrane potential gradually increases in these pacemaker cells until the threshold potential is reached, the fast inward sodium channels open, and the I_{Na} current

initiates the next phase 0. This electrical impulse is then propagated via the His-Purkinje conducting system of the heart. Electrophysiologic and molecular genetic studies have identified multiple subtypes of the sodium potassium, and calcium channels.

During phases 0â€“2, the cell cannot be depolarized again with another stimulus; the cell is *absolutely refractory.* During the latter half of phase 3, as the calcium channels convert from their inactivated to their resting state, an electrical stimulus of sufficient magnitude may cause another depolarization; the cell is *relatively refractory.* During phase 4, the cell is no longer refractory and any appropriate stimulus that reaches the threshold level may cause depolarization.

Calcium, Calcium Channels, and Cell Contraction

The contraction and relaxation cycle of the myocyte is controlled by the flux of calcium into and out of the SR into the cytoplasm.[6 , 59] Only a small proportion of the Ca^{2+} involved in myofibril contraction actually enters the cell through the exterior cell membrane during the action potential and membrane depolarization. The contraction and relaxation cycle of the myocyte are controlled by the flux of Ca^{2+} into and out of the SR into the cell cytoplasm.[6 , 59] When Ca^{2+} enters the cell cytoplasm, RyR2 channels open on the SR membrane and release Ca^{2+} from the intracellular SR stores into the cytoplasm. This phenomenon of calcium-induced calcium release results in a rapid increase in the intracellular Ca^{2} concentration, and initiates a rapid myosin and actin interaction. At the conclusion of cellular contraction, an SR-associated calcium ATPase adenosine triphosphatase pump returns the cytosolic Ca^{2+} into the SR. This SR associated calcium ATPase pump is regulated by phospholamban, cellular protein. Phosphorylation of phospholamban decreases its affinity for binding to the calcium pump; dissociation of the phosphorylated phospholamban increases the activity of the calcium ATPase pump. Î²-Adrenergic stimulation leads to phosphorylation of phospholamban. Phosphorylated phospholamban dissociates from the pump, the activity o

the pump increases, and the total SR calcium stores increase.[31, 32] Increased activity of the SR associated calcium pump increases the rate o relaxation (ie, lusitropy) and enhances contractility (ie, inotropy).

Cellular contraction occurs when myosin filaments interact with the actin-tropomyosin helix. A complex of troponin T, troponin I, and troponin C binds to the actin helix near the myosin binding site and act as regulators of the interaction. Troponin T actually binds the regulatory complex to th actin helix, troponin I prevents myosin from accessing its binding site on the actin helix, and troponin C acts as a calcium trigger to initiate contraction. When the intracellular Ca^{2+} concentration increases, 4 molecules of Ca^{2+} bind to troponin C and a conformational shift occurs in the troponin complex. Troponin I shifts and the myosin-binding site is exposed; myosin binds to the exposed site and myofibril contraction occurs (Fig. 23-3).[50, 51, 94, 95]

Calcium transport through the cellular membrane ion channels is critical for normal muscle function and contractility, for cell membrane conductance and electrical impulse generation, for cardiac muscle contraction and rhythm generation, and for maintenance of vascular smooth muscle tone. The physiologic response to calcium channel-blockin agents and to xenobiotics that interact with the Î±- or Î²-adrenergic receptors is mediated through changes in the intracellular calcium. Calcium channel blockers in current clinical use primarily block the L-type calcium channel, although their specificity differs for calcium channels on the vascular smooth muscle cells versus myocardial cells. This results in variable effects of different calcium channel blockers on the vascular tone and

peripheral vascular resistance, and on the contractility and electrical activity of the myocardial cells.

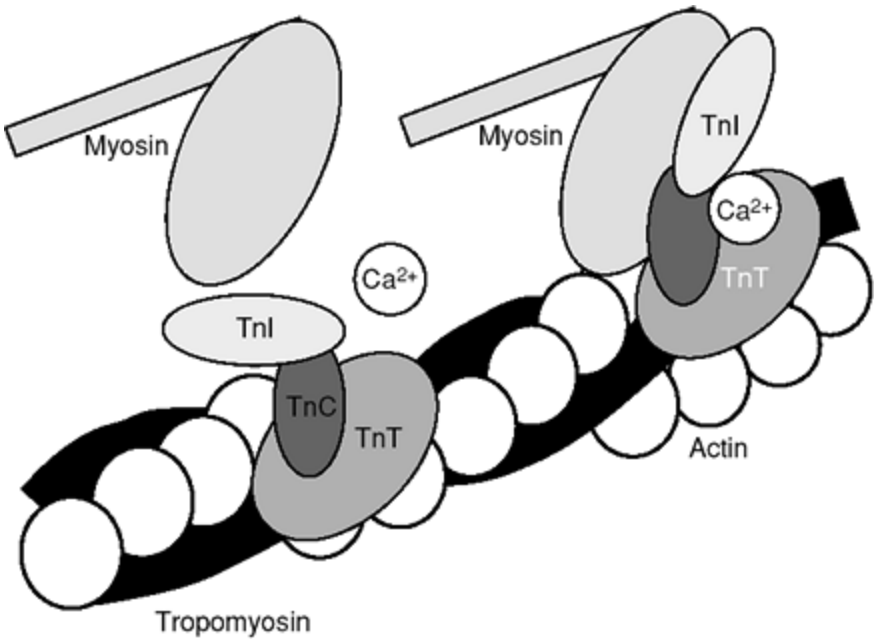

Figure 23-3. Troponin regulation of actin and myosin interaction. On the left, troponin I (TnI) blocks the binding site for myosin on the tropomyosin-actin helix. On the right, calcium binding to troponin C (TnC causes a conformational shift in the troponin molecules, and myosin is able to bind to the actin helix and initiate myofibril contraction. TnT is Troponin T.

Patients poisoned by calcium channel blockers have less Ca^{2+} entry into the cell during cardiac membrane depolarization. Administration of exogenous Ca^{2+} increases the concentration gradient across the cell membrane, enhances flow through available Ca^{2+} channels and restores the triggered response of the RyR2 channels to release Ca^{2+} from the sarcoplasmic reticulum (see Antidotes in Depth: Calcium). Because Î²-adrenergic antagonists have negative effects on Ca^{2+} handling by the SR similar effects are expected in the myocyte affected by these agents.

Cardiac Dysrhythmias and Conduction Abnormalities

Xenobiotics may produce adverse effects on the electrical activity of the

heart, often by acting directly on the myocardial cells. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate the toxicity, or can actually be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning may include nonspecific hemodynamic abnormalities an cardiac dysrhythmias. However, many xenobiotics directly or primarily affect cardiac rhythm or conduction, often through effects on the cardiac ion channels.

Mechanisms of Cardiac Conduction Abnormalities and Dysrhythmias

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. The myocyte ion channel composition and conduction characteristics vary regionally throughout the heart (eg, subendocardial cells have a longer action potential duration than do epicardial cells; this is called dispersion of repolarization and is normal). This is important to allow the heart to contract as a unit even though the impulse takes time to travel through the full thickness of the myocardial wall, from endocardium to epicardium Furthermore, xenobiotics that modify ion channels may alter the transmembrane potentials within myocytes and may result in the spontaneous generation of an abnormal rhythm.

Mechanisms of Dysrhythmia Initiation and Propagation

Abnormal cardiac rhythms, or dysrhythmias, can be commonly related to mechanisms: abnormal spontaneous depolarization (enhanced automaticity), afterdepolarization (triggered automaticity), and reentry. I normal myocardium, spontaneous phase 4 depolarization occurs most rapidly in the sinus node, the normal pacemaker for the heart. Speeding

slowing the rate of phase 4 depolarization of the pacemaker cell results i sinus tachycardia or sinus bradycardia, respectively. However, xenobiotic can also speed the depolarization of other myocardial cells that have pacemaker potential allowing them to overtake the sinus node as the heart's primary pacemaker. This mechanism, called increased automaticity, accounts for many of the dysrhythmias that occur with cardioactive steroid and Î²-adrenergic agonist poisoning.

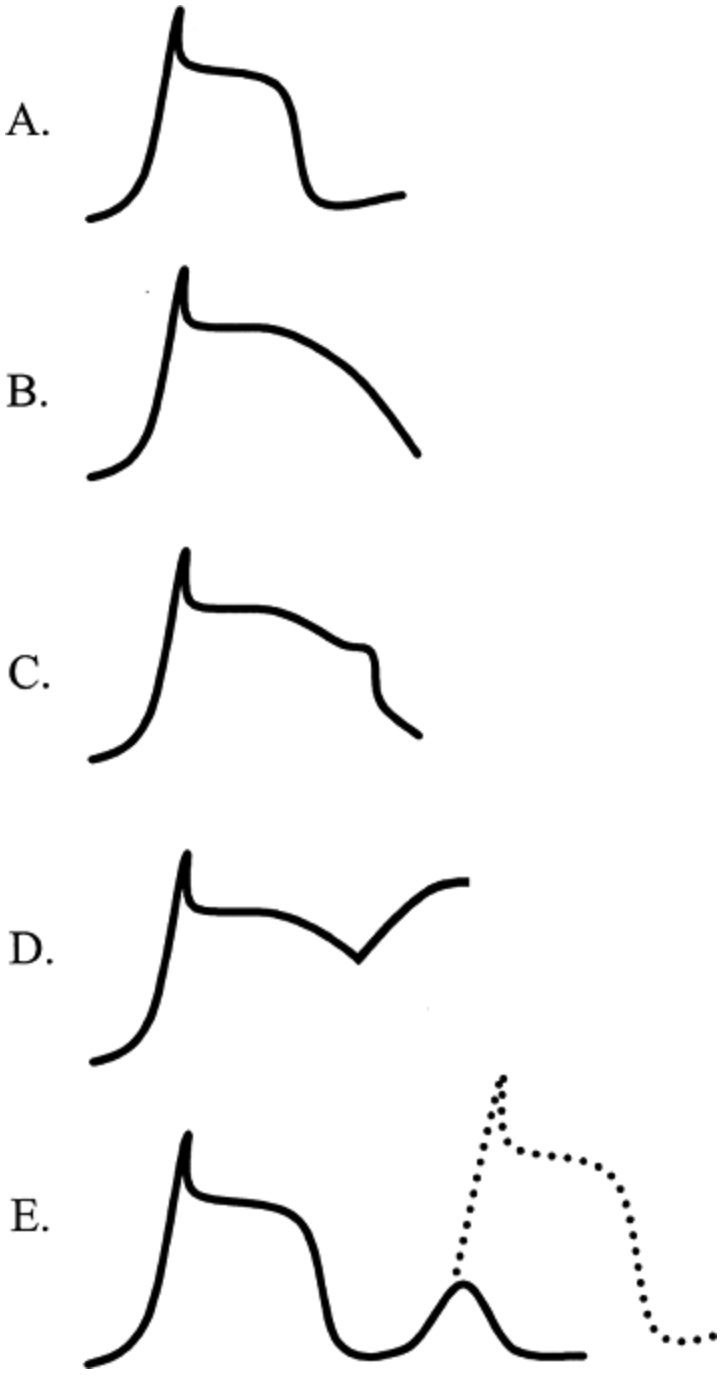

Figure 23-4. Afterdepolarization. A. The normal action potential. B. Prolonged duration action potential. C. Prolonged duration action potentia with an early afterdepolarization (EAD) occurring during the downslope o phase 3 of the action potential. D. Early afterdepolarization that reaches the depolarization threshold and initiates another depolarization, or a

triggered beat. E. Delayed afterdepolarization, which occurs after repolarization is complete.

Dysrhythmias can also result from spontaneous oscillations in the membrane potential, called afterdepolarizations, that occur during phase or 4 of the action potential. If the oscillations are of sufficient magnitude to reach the threshold potential, the fast sodium channels open and an action potential occurs (Fig. 23-4). These spontaneous oscillating depolarizations are mediated by depolarizing inward calcium currents, primarily through the L-type calcium channels. Early afterdepolarizations (EADs) occur during the plateau phase (phase 2) or during the downslope (phase 3) of the action potential. Oscillations in the membrane potential that occur after repolarization is complete, during phase 4, are called delayed afterdepolarizations (DADs). EADs most commonly occur in situations in which the action potential is prolonged, typically as a consequence of the blockade of I_{Kr} (such as by antidysrhythmic agents). EADs account for the â€œtrigger beatsâ€• that initiate episodes of torsades de pointes (TdP) discussed below. DADs occur primarily under conditions of increased intracellular Ca^{2+} , and account for many of the dysrhythmias that are associated with cardioactive steroid toxicity.[80]

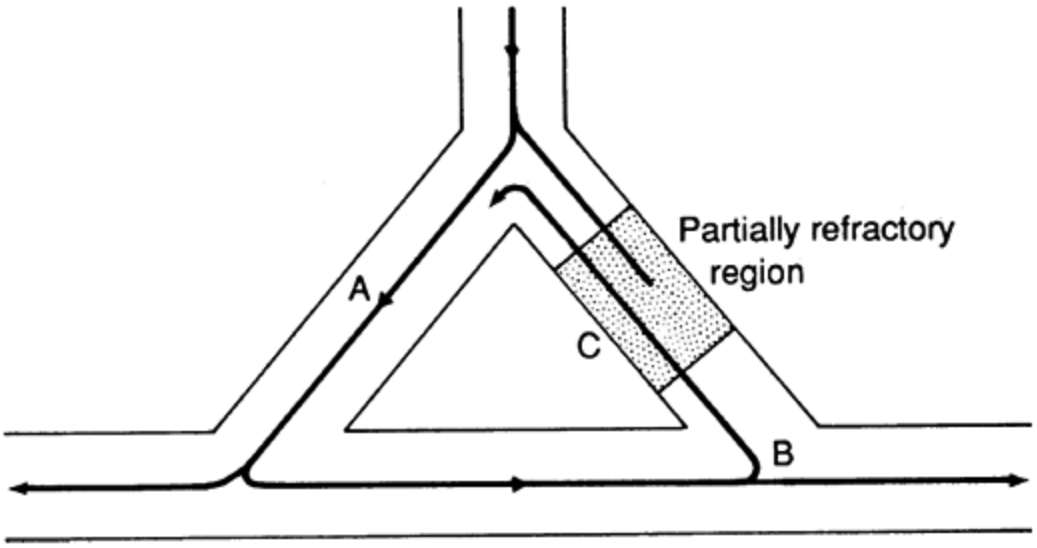

Figure 23-5. Mechanism of reentry dysrhythmias. An impulse traveling

down a conduction pathway reaches a branch point with one branch refractory (*C*). The impulse is conducted down branch *A* and spreads through the myocardium eventually to reach *B* , the distal end of the originally refractory branch. However, branch *C* is no longer refractory, and the impulse is conducted retrograde up through branch *C* , again to b conducted down branch *A* . The myocardium is depolarized during each loop around the circuit as the impulse spreads from the distal end of branch *A* to the rest of the heart.

Most afterdepolarizations propagate rapidly throughout the myocardium and generate ectopic beats. However, because the normal dispersion of repolarization is increased by certain xenobiotics, ectopic beats (eg, an atrial premature contraction or ventricular premature contraction) may propagate abnormally within the myocardium. Occasionally, because of th altered regional repolarization, an impulse may reach a branch point with a partial block (ie, relatively refractory) to conduction in one of the branches (Fig. 23-5). The impulse is carried through only one of the branches and then spreads through the myocardial cells. After a short delay, the impulse reaches the distal end of the previously blocked pathway. By this time, the region is no longer refractory and conducts th impulse in a retrograde fashion. The impulse may continue in a continuou loop circuit, depolarizing the heart with each passage; this process is called reentry. Reentry mechanisms appear to be responsible for the majority of the tachydysrhythmias attributable to poisoning.

Bradycardic Dysrhythmias

Bradycardia, heart block, and asystole are frequently the terminal events in patients with massive overdose. These dysrhythmias may occur as a result of direct effects on the myocardial system or of indirect metabolic effects. For instance, severe hyperkalemia (which may accompany any acidosis) results in a wide complex, sinusoidal bradycardic rhythm.

Many xenobiotics (Table 23-1) produce bradycardia through several

different mechanisms. The xenobiotic may affect the central or periphera nervous system, or may affect rhythm generation or conduction in the heart. Central nervous system-mediated bradycardia is probably the mos common xenobiotic-induced cause for mild sinus bradycardia. Xenobiotics that cause CNS sedation, such as the sedative-hypnotic agents, opioids, and Î±$_2$ -adrenergic receptor agonist (â€œcentrally actingâ€•) antihypertensive drugs, will usually decrease sympathetic outflow to the heart and produce a heart rate in the range of 40â€“60 beats/min.

The most profound bradycardia results from overdoses of xenobiotics tha have direct depressant effects on the cardiac

pacemaker. The ultimate manifestation of pacemaker and conduction failure is asystole. Examples of medications that in overdose can produce these effects include calcium channel blockers and Î²-adrenergic antagonists.

TABLE 23-2. Xenobiotics that Cause Conduction Abnormalities and/or Heart Block

Conduction Abnormalities and Atrioventricular Nodal Block

The cardiac toxicity of some xenobiotics results from their effects on the propagation of the electrical impulse through the conduction system of th heart. The ECG abnormalities produced by these agents may be a result c effects on the atrioventricular (AV) node, producing first-, second-, or third-degree (complete) heart block, or on the His-Purkinje system, producing intraventricular conduction delays such as bundle-branch block The effects of xenobiotics on myocardial conduction are often mediated through interactions with the sodium or potassium membrane channels. For example, xenobiotics that affect the fast inward I_{Na} currents (such as the type I antidysrhythmics and tricyclic antidepressants) prolong the action potential duration, slow ventricular myocyte depolarization, and slow intraventricular conduction. This produces widening of the QRS complex and prolongation of the QTc interval on the ECG (Chaps. 61 , 62 and 71). Table 23-2 lists some of the xenobiotics that cause conduction abnormalities. Many of the antidysrhythmic agents derive their clinical benefit from their ability to alter sodium and potassium channel function and slow conduction through the myocardium. Xenobiotics that depress phase 0 (the inward I_{Na} currents) produce slowing of conduction and

widening of the QRS complex. Xenobiotics that prolong depolarization and repolarization (phase 2 or phase 3 of the action potential) produce prolongation of the QTc interval on the ECG. The classes of the antidysrhythmic agents, their effects on the ion channels and on the action potential, and the resulting ECG abnormalities, are shown in Table 23-3 and discussed in detail in Chap. 61 .

Tachycardic Dysrhythmias

Both supraventricular and ventricular tachydysrhythmias can occur in poisoned patients (Table 23-4). Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic drugs, such as atropine, raise the heart rate to its innate rate by eliminating the inhibitory tonic vagal influence. However, more rapid rates require direct myocardial stimulatory effects, generally mediated by Î²-adrenergic agonism. For

example, catecholamine excess (eg, cocaine, psychomotor agitation, fever) may cause sinus tachycardia with rates faster than 150 beats/min. Ventricular dysrhythmias frequently accompany hypotension, hypoxia, acidemia, electrolyte abnormalities, and other metabolic derangements that may be present in poisoned patients or may be a direct effect of the xenobiotic (Table 23-4).

TABLE 23-4. Xenobiotics that Cause Ventricular and Supraventricular Tachydysrhythmias

Dysrhythmias Associated with a Prolonged QTc Interval: Torsades De Pointes

Prolongation of the QT interval corresponds to an increase in the duration of phase 2 or phase 3 of the action potential. Although there is agreement that the QT interval includes the entire period of cardiac activation and recovery, there is no universal standard accepted by experts for the measurement of the QT interval. The QT interval normally varies because of biologic diurnal effects and autonomic tone; technical issues with the environment or with processing and acquiring the ECG; and intra- and interobserver variability.[2,73,75] The QT interval corresponds to the duration of the ventricular action potential, and should be measured from the beginning of the QRS to the end of the T wave. However, variations in the speed of the paper,[28] T-wave morphology, irregular baseline, and the presence of U waves may make this determination difficult.[5] U waves are particularly important because they are thought to correspond to late repolarization of myocardial cells in the mid-myocardium, and are implicated in the initiation of cardiac dysrhythmias.[5] QT interval measurements from the computerized ECG algorithms are less accurate than careful manual determinations of the interval.[52] In August 2000, a

panel of experts convened to address these issues and suggested that the QT interval should be measured manually in one of the limb leads that best shows the end T wave; the QT interval should be measured and averaged over 3 to 5 beats; and large U waves should be included in the QT interval measurement if they merge into the T wave and obscure the end of the T wave.[5] However, a subsequent study of 334 healthcare practitioners found that only 60% of the physicians were able to correctly measure a sample QT interval on the survey, even though nearly all correctly indicated the measurement should be from the beginning of the QRS to the end of the T wave.[57]

The QT interval is normally prolonged at slower heart rates and shortens as the heart rate increases. This is especially important since many of the xenobiotics that affect the QT interval also affect the heart rate. A variety of correction formulas have been utilized in order to correct for the effects of heart rate on the QT interval. With a rate of 50–90 beats/min, the commonly used Bazett formula (QTc [msec] = QT [msec]/$\sqrt{\text{R-R interval}}$ (sec) is adequate for determining a rate corrected QT interval (QTc). In this heart rate range, 99% of men have a QTc <450 msec and 99% of women have a QTc <460 msec,[77] and a QTc interval >500 msec weakly correlates with an increased risk of developing ventricular dysrhythmias. However, at higher heart rates, a normal patient will have an inaccurately calculated "prolonged" QTc interval using this Bazett formula.[5,72] Studies suggest that medications such as bupropion[48] and quetiapine[10] prolong the QT interval when the "increase" in the QTc may be only a result of the increased heart rate. A variety of formulas and corrections are proposed to attempt to identify normal QT intervals on ECGs at higher heart rates,[8,24,45,66,67] including the Friderician formula (QTc = $\sqrt{\text{QT/R-R interval}}$) and the Framingham linear regression analysis (based on large population observation). None of these formulas, however, are validated clinically (Chap. 5).

Ventricular tachycardia, including TdP, is usually a reentrant-type rhythm that requires an initiating impulse that spreads through the myocardial tissue and a branch point with unequal refractory periods (Fig. 23-5). The presence of a prolonged QTc interval on the ECG may indicate the possible existence of conditions within the myocardium that favor occurrence of

reentry dysrhythmias, as discussed above. The long action potential duration resulting from prolongation in the duration of phase 2 or phase 3 increases the occurrence of EADs. These, in combination with an increase dispersion of repolarization, increase the risk for reentrant dysrhythmias, particularly TdP (Chap. 5).

Many xenobiotics may also interact with cardiac membrane ion channels and increase the risk of TdP. Most of these agents interact with the HERG encoded Î± subunit of the potassium channel to reduce the current through the I_{Kr} channel and prolong the action potential duration. The HERG Î± subunit of the channel is particularly susceptible to xenobiotic interactions because of the larger inner cavity with aromatic binding domains.[53 , 92 , 93 , 114] Acquired QTc interval prolongation and TdP from xenobiotics occur most often with class Ia and Ic antidysrhythmics, the cyclic antidepressants,

and the phenothiazines. Although the newer class Ic antidysrhythmics (such as encainide and flecainide) cause greater QTc interval prolongatio the class Ia agents (such as quinidine and procainamide) are responsible for more reported cases. This is probably a result of the relatively infrequent use of the class Ic antidysrhythmics (due, paradoxically, to concerns about the higher risk of prodysrhythmic effects). Class Ib agent such as lidocaine, have no significant effect on K^+ channels and the QTc interval, and do not cause TdP. Acquired QTc interval prolongation and Tc also commonly result from metabolic and electrolyte abnormalities, particularly hypocalcemia, hypomagnesemia, and hypokalemia (Chap. 61).

Decreased Cardiac Contractility and Congestive Heart Failure

Xenobiotics can reduce cardiac contractility with a resulting decrease in cardiac ejection fraction and cardiac output, a decrease in blood pressure and development of congestive heart failure (CHF). Cardiogenic pulmonar edema generally occurs as a result of the direct effects of the xenobiotic

on the contractility, or inotropy, of the heart, or through increases in the preload or afterload. Acute cardiogenic pulmonary edema, resulting from decreased cardiac output, occurs primarily in patients poisoned by a calcium channel blocker or Î²-adrenergic receptor antagonist. Other xenobiotics that can exert direct depressant effects on cardiac contractili include antihistamines, phenothiazines, antidysrhythmics, and local anesthetics. Many of these agents reduce contractility through sodium channel blockade, which, by slowing intraventricular conduction, reduces the ability of the heart to contract efficiently. Pulmonary edema may also result from the fluid overload accompanying ingestion of large quantities of sodium-containing xenobiotics (eg, sodium penicillin), the renal effects of medications such as nonsteroidal antiinflammatory drugs, or as a late consequence of xenobiotics that cause renal failure.

Other xenobiotics can exert chronic toxic effects on the myocardium, either directly, or indirectly through effects on blood pressure or cardiac vasculature, and result in the development of cardiomyopathy. Xenobiotic causing cardiomyopathy include anthracycline antineoplastic agents (dactinomycin, daunorubicin, idarubicin, and doxorubicin),[4 , 30 , 47 , 63] amphetamines,[46 , 121] antimony,[3] cobalt,[69 , 70 , 76] cocaine,[21 , 43] ethanol,[99 , 129] and syrup of ipecac.[98] In most cases, the exact mechanism of the toxicity is not known. However, free radical generation nitrous oxide formation, myocardial ischemia, mechanical overload, and persistent tachycardia are each implicated in the cellular toxicity of the various xenobiotics and development of cardiomyopathy.

Patients with acute xenobiotic-induced congestive heart failure or xenobiotic-induced cardiogenic shock should receive aggressive hemodynamic support. Acutely poisoned patients often have a completely reversible process. Every effort must be made to support the patient's vital functions until the poison can be eliminated or removed. If the patient is bradycardic, an electrical pacemaker may be indicated, althoug its usefulness may be limited by the reduced electrical sensitivity of the heart affected by certain xenobiotics, such as calcium channel blockers.[1 68 , 105 , 118] Patients may recover completely even after prolonged cardiopulmonary resuscitation (CPR),[1 , 56] extracorporeal membrane

oxygenation,[7 , 23 , 26 , 39 , 101] intraaortic balloon pump use,[33 , 42 , 56 , 96] or cardiopulmonary bypass.[42 , 118]

The Autonomic Nervous System and Hemodynamics

In addition to the voltage dependent ion channels, the cell membrane contains channels that open in response to receptor binding of neurotransmitters or neurohormones.[83 , 84 and 85] A large number of xenobiotics exert their effects via interactions with membrane receptors. These receptor-binding agents include such diverse xenobiotics as pertussis and cholera toxins,[17] Î³-aminobutyric acid (GABA),[60] nicotine,[18 , 19 , 25] calcium channel antagonists, and adrenergic agonists and antagonists.

The hemodynamic effects of many xenobiotics are mediated by changes i the autonomic nervous system. The autonomic nervous system is functionally divided into the sympathetic (ie, adrenergic) and parasympathetic (ie, cholinergic) systems. These two systems, which share certain common features, function semi-independently of each other. Through complex feedback, the two systems provide the balance needed for existence under changing external conditions.

The sympathetic nervous system is primarily responsible for the maintenance of arteriolar tone and cardiac function. Although the ganglionic neurotransmitter of the sympathetic nervous system is acetylcholine, norepinephrine is its primary postganglionic neurotransmitter (Fig. 23-6). On release into the synapse, norepinephrir

binds to the postsynaptic adrenergic receptors to elicit an effect by the postsynaptic cell.

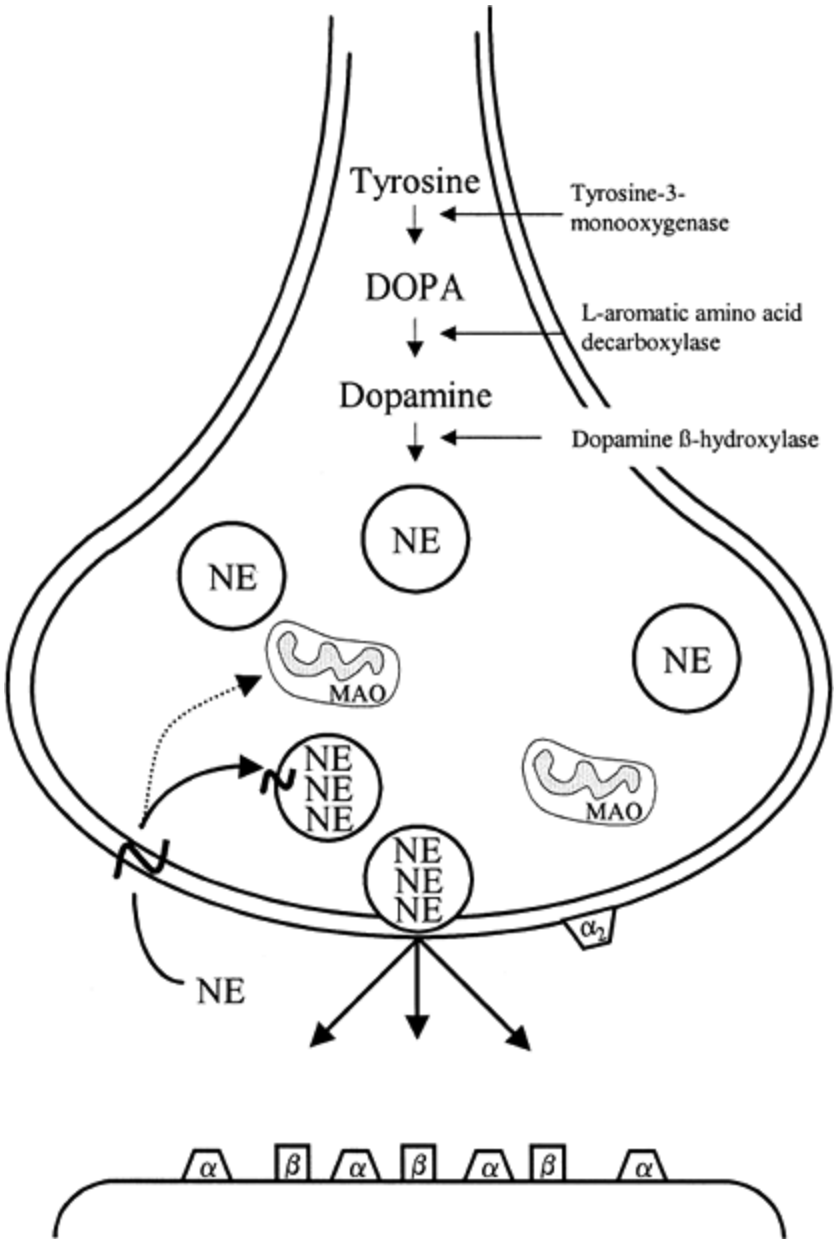

Figure 23-6. Shown is the synthesis in storage granules, release, reuptake, and degradation of norepinephrine (NE). NE is synthesized in storage vesicles in the nerve ending. These vesicles fuse with the neuron membrane in response to stimulation and release the NE into the synapti space. The NE binds postsynaptic adrenergic receptors, following which it either undergoes active reuptake into the proximal neuron or is metabolized. MAO = monoamine oxidase; N = reuptake mechanism.

Adrenergic Receptors

The existence of two types of adrenergic receptors, Î± and Î², was first proposed in 1948 to explain both the excitatory and the inhibitory effects of catecholamines on different smooth muscle tissue.[1] The Î± receptor was subsequently further subdivided into $Î±_1$ and $Î±_2$ when norepinephri and other Î±-adrenergic agonists were found to inhibit the release of additional norepinephrine from neurons into the synapse. These â€œautoregulatoryâ€• $Î±_2$ receptors are primarily located on the presynaptic neuronal membrane; however some $Î±_2$ -adrenergic receptor are found on the postsynaptic membrane. Activation of these postsynapti $Î±_2$ receptors in the cardiovascular control centers in the medulla and elsewhere in the central nervous system decreases sympathetic outflow from the brain. Therefore, $Î±_2$ -adrenergic agonists generally cause decreased peripheral vascular resistance, decreased heart rate, and decreased blood pressure (even though some blood vessels have $Î±_2$ -adrenergic receptors that mediate vasoconstriction). The $Î±_1$ -adrenergic receptors are located on postsynaptic cells outside the central nervous system, primarily on blood vessels, and mediate arteriole constriction. Th adrenergic receptors also interact with circulating catecholamines and other sympathomimetic agents. The effects that catecholamines produce vary based on the organ system. These diverse effects are caused by variations in the adrenergic receptors and to differences in the cellular responses to the receptor interactions.

The Î²-adrenergic receptors have been subclassified into 3 subtypes: $Î²_1$ $Î²_2$, and $Î²_3$ (Table 23-5). The most prevalent Î²-adrenergic subtype in the heart is $Î²_1$, although $Î²_2$ and $Î²_3$ receptors are also present.[15 , 27 , 35 , 104] Stimulation of the $Î²_1$ -adrenergic receptors increases heart rate, contractility, conduction velocity, and automaticity. The $Î²_2$ -adrenergic receptors are primarily responsible for relaxation of smooth muscle with resulting bronchodilation and arteriolar dilation. The $Î²_3$ receptors are located primarily on adipocytes where they play a role in lipolysis and thermogenesis.[27] $Î²_3$ -Adrenergic receptors in the heart may increase contractility,[119] but the bulk of evidence suggests that the $Î²_3$ receptors

are mediators of negative inotropy.[34 , 35 and 36 , 74] The Î²-adrenergic antagonists in current clinical use are ineffective at blocking $Î²_3$ -adrenoreceptors and may even act as agonists at these receptor sites.[106 107]

Type Location Function

TABLE 23-5. Types and Functions of the Î²-Adrenergic Receptor

Cellular Physiology of the Adrenergic Receptors

The effects of adrenergic agents on the cell are primarily mediated through a secondary messenger system of cyclic adenosine monophosphate (cAMP). The intracellular cAMP concentration is regulated by the membrane interaction of three components: the actual adrenergic receptor, a â€œG-proteinâ€• complex, and adenyl cyclase, the enzyme that synthesizes cAMP in the cell.[17 , 37 , 112 , 113] These receptors are described in detail in Chap. 14 .

The G protein serves as a â€œsignal transducerâ€• between the receptor molecule and the effector enzyme, adenyl cyclase. The G proteins consist of 3 subunits: Î±, Î², and Î³.[22 , 78 , 79] The Î± subunit of the G protein complex binds to the COOH-terminal tail and to the intracytoplasmic loop of the adrenergic receptor, as well as to the adenyl cyclase enzyme. The Î± subunit of the G protein complex exists in several isomeric forms, depending on their interactions with the adenyl cyclase enzyme. G_s proteins contain $Î±_s$ subunits that stimulate adenyl cyclase when â€œactivatedâ€• by adrenergic receptor interaction. The $Î±_i$ subunits of G_i proteins inhibit the activity of adenyl cyclase. $Î²_1$ - and $Î²_2$ -adrenergic receptors interact primarily with $Î²_s$ subunits in stimulatory G_s protein complexes. $Î²_2$ -Adrenergic receptors also interact with G_i proteins. The $Î±_2$ -adrenergic receptors interact with inhibitory G_i proteins. A third form G_q , interacts with the $Î±_1$ -adrenergic receptors, but does not interact directly with the adenyl cyclase. The G_q interacts with phospholipase C to mediate cell response to $Î±_1$ -adrenergic stimulation.

When not stimulated by the presence of a catecholamine, the receptor protein is bound to the Î² and Î²Î³ dimers of the G protein, and guanosine diphosphate (GDP) is bound to the Î± subunit. Catecholamine binding to the receptor causes a conformational change in the Î± subunit; GDP

dissociates and guanosine triphosphate (GTP) binds to the Î± subunit. Th Î± subunit (with GTP bound) then dissociates from the receptor and from the Î²Î³ dimer. This â€œactivatedâ€• Î± subunit can now interact with adenyl cyclase or other effector enzymes. Interaction of the $Î±_S$ subunit with adenyl cyclase increases the activity of the enzyme resulting in a rapid increase in the intracellular cAMP (Fig. 23-7).[17 , 22 , 62 , 78 , 97]

The cAMP acts as a secondary messenger in the cell. cAMP interacts with protein kinase A (PKA) and other cAMP-dependent protein kinases to increase their protein phosphorylating activity.[61] In the absence of cAMP, PKA is a tetramer of two regulatory and two catalytic subunits. cAMP binc to the regulatory subunits to release the active enzymatic units from the tetramer (Fig. 23-7). Protein kinases then transfer phosphate groups fro ATP to serine (as well as to threonine and tyrosine amino acid groups) on enzymes that are involved in intracellular regulation and activities. Phosphorylation may increase or decrease the activity of specific enzyme and specific protein kinases are highly selective in the proteins that they phosphorylate.[109 , 110]

PKA phosphorylates a variety of cellular proteins involved in calcium regulation, including the voltage-sensitive calcium channel, phospholamban, and troponin.[41 , 44 , 108] Phosphorylation of the

L-type calcium channel increases the entry of calcium ions during membrane depolarization.[87 , 88 , 127] Phosphorylation of phospholamban decreases its activity to inhibit the calcium ATPase pump on the SR. This decreased inhibition of the calcium ATPase pump increases the efficiency of Ca^{2+} storage in the SR, which enhances both cellular contractility,[6 , 3 , 32 , 127] as the Ca^{2+} is released into the cell cytosol, and the relaxation muscle fibers, as the Ca^{2+} is pumped back into the SR.[59]

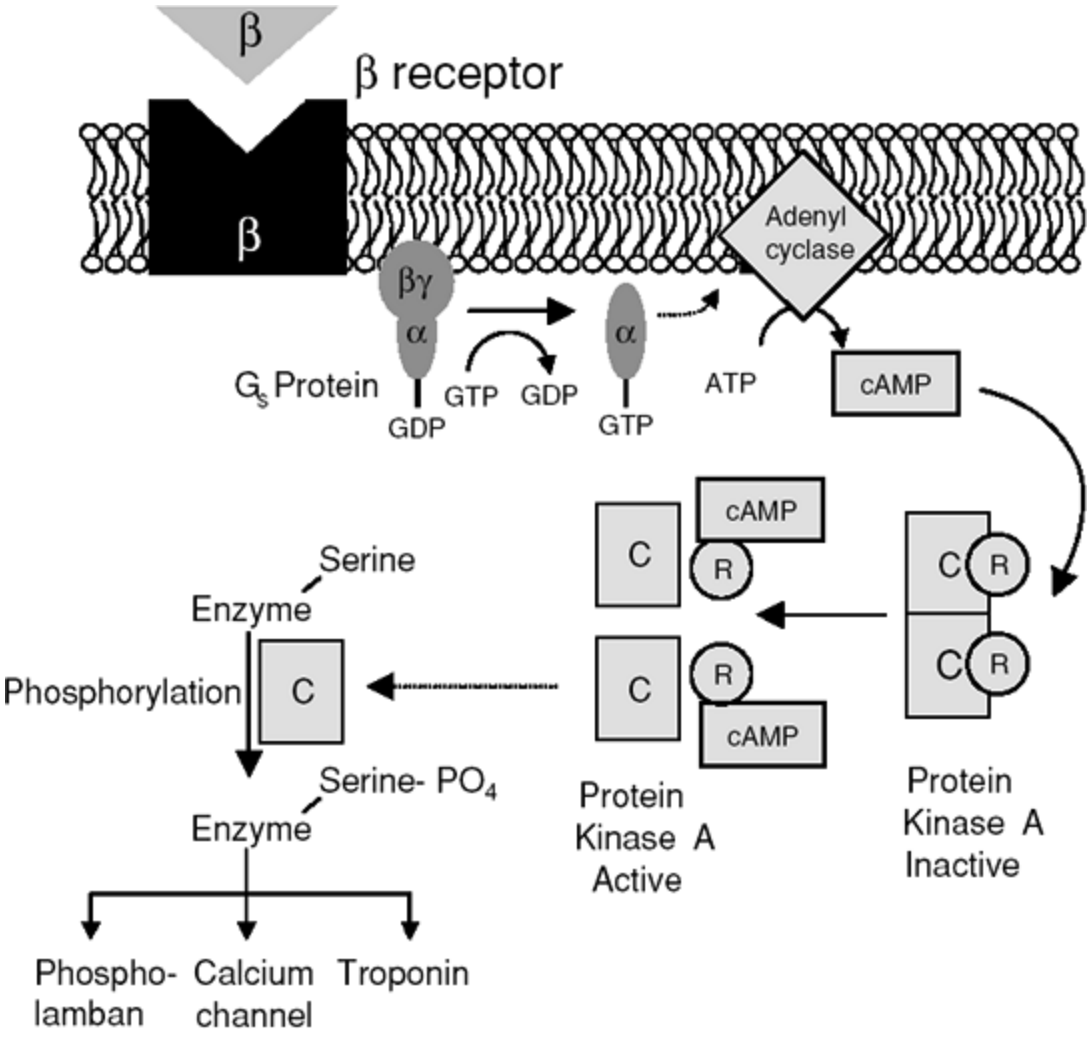

Figure 23-7. Binding of the Î² agonist to the Î² receptor causes the G_s protein to release bound GDP and bind GTP to activate the Î± subunit. Th activates adenyl cyclase to produce cAMP. The cAMP interacts with protei kinase A to activate the enzyme. Phosphorylation by protein kinase A changes the activity of various cellular proteins (see text).

Physiologic Effects of Adrenergic Receptors

The $Î²_1$, $Î²_2$, and $Î±_2$ adrenergic receptors all interact with G_s proteins and stimulate the adenyl cyclase enzyme. Differences in the resultant clinical effects are primarily related to the location and number of the different receptors in different tissues and to differences in the specificity

of the protein kinases activated by cAMP Table 23-5 shows the function and tissue distribution of the types of Î² receptors. Stimulation of the $Î²_1$ receptor results in increased heart rate and increased contractility. However, $Î²_2$ stimulation causes relaxation, as opposed to contraction, of smooth muscle. Because both Î²-adrenergic receptor subtypes interact with stimulatory G_s proteins, their clinical effects would appear to be paradoxical. However, there are two primary reasons for the different effect. First, PKA is not a single enzyme, but a group of related isoenzymes variably expressed in different tissues.[12, 49, 81] The actions and the substrates of the varied protein kinase isoenzymes may differ between $Î²_1$ - and $Î²_2$ -responsive tissues. Secondly, whereas $Î²_1$ stimulation results in cAMP-mediated effects throughout the cytoplasm, Î stimulation is compartmentalized within the cell. The effect of $Î²_2$ stimulation of G_s type receptors is localized phosphorylation of the L-type calcium channels, increasing their activity.[20, 54, 124, 125] $Î²_2$ receptors are also coupled to G_i -type receptors that inhibit adenyl cyclase and prevent the diffuse cytoplasmic increases in cAMP.[103, 104, 124] Additionally, $Î²_2$ -receptor stimulation does not result in phosphorylation phospholamban[54] or troponins.[20]

The $Î±_2$ -adrenergic receptor interacts with a G_i protein that has an inhibitory interaction with adenyl cyclase. Binding of $Î±_2$ -adrenergic agents to the receptor results in inhibition (not stimulation) of adenyl cyclase and to a decrease in the intracellular cAMP.

The $Î±_1$ -adrenergic receptors also are associated with G proteins. However, rather than being associated with G_s proteins and adenyl cyclase, the $Î±_1$ -adrenergic receptors are associated with G_q proteins th are linked to phospholipase C. Binding to the receptor activates the hydrolysis of phosphatidyl inositol 4,5-bisphosphate (PIP_2) to 1,2-diacylglycerol (DAG) and inositol triphosphate (IP_3).[40] The IP_3 , acting a an intracellular messenger, binds to receptors on the SR and initiates the release of calcium ion.[11] DAG activates protein kinase C, which phosphorylates slow calcium channels and other intracellular proteins, an increases the influx of calcium ion into the cell (Fig. 23-8).[41, 44, 87, 88, 102, 108, 111, 127]

Many xenobiotics and antidotal agents interact with G-protein membrane receptors and alter the intracellular cAMP or Ca^{2+} concentration. Î²-Adrenergic antagonist overdose results in decreased stimulation of adeny cyclase by G_S proteins, decreased production of cAMP, decreased activation of the cAMP-dependent kinases, and decreased calcium release (Chap. 59). Similarly, by different mechanisms, calcium channel-blocker overdose results in decreased cytoplasmic calcium concentration (Chap. 5).

Glucagon receptors, which are similar to the Î²-adrenergic receptors, are coupled to G_S proteins and stimulate adenyl cyclase activity.[9 , 29 , 38 , 58 , 117 , 126] Glucagon's activity to increase cAMP is further enhanced by its inhibitory activity on phosphodiesterase

(preventing cAMP breakdown).[71] Phosphodiesterase inhibitors, such as amrinone, milrinone, and enoximone, exert at least some of their inotrop activity by preventing the degradation of cAMP and enhancing calcium cycling.[59 , 64 , 115 , 120] In a canine model of propranolol poisoning, amrinone significantly increased inotropy, stroke volume, and cardiac output.[64]

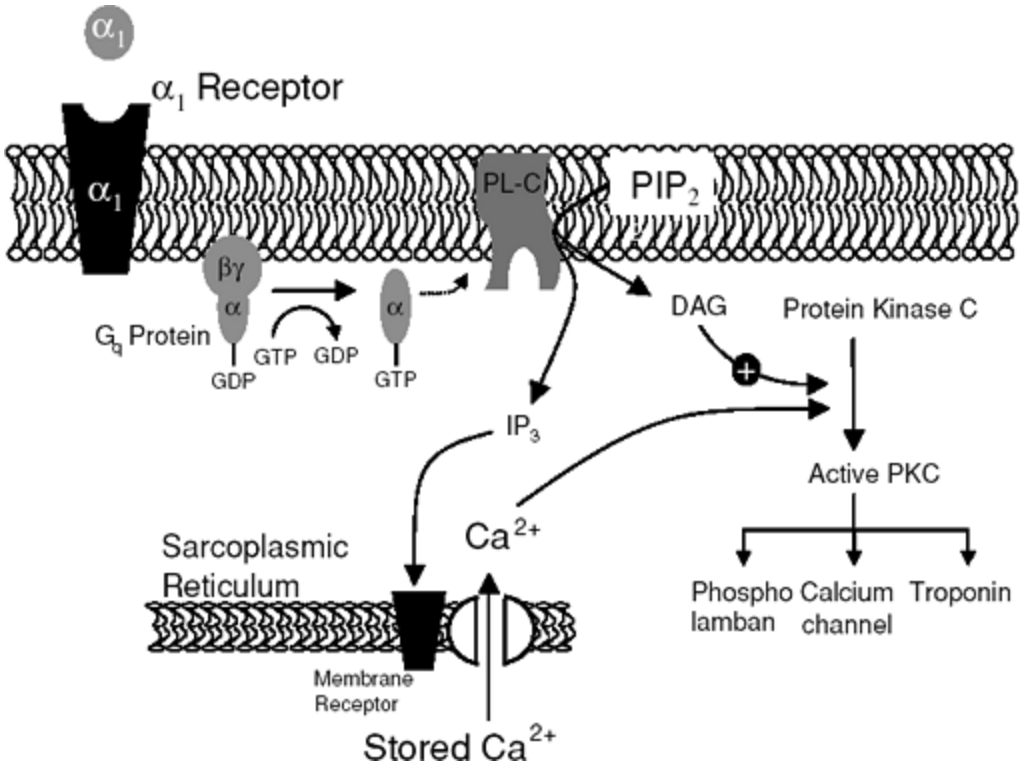

Figure 23-8. Binding of the Î± agonist to the Î±$_1$ receptor causes the G_q protein to release bound GDP and to bind GTP to activate the Î± subunit. This activates phospholipase C (PL-C) to catalyze the hydrolysis of phosphatidylinositol to 4,5-bisphosphate (PIP_2) to produce 1,2-diacylglycerol (DAG) and inositol triphosphate (IP_3). IP_3 interacts with a membrane receptor on the sarcoplasmic reticulum to enhance release of calcium from the cellular stores. The calcium and DAG interact with prote kinase C (PKC) to activate the enzyme. PKC phosphorylates and changes the activity of various cellular proteins (see text).

Hemodynamic effects of Xenobiotics

Xenobiotics that act directly on the cardiovascular or nervous system ma cause a characteristic alteration of blood pressure, heart rate (ie, chronotropy), and cardiac rhythm. Recognizing these patterns (toxic syndromes or â€œtoxidromesâ€•) and understanding their etiology allow for specific, rather than empiric, therapy.

Blood Pressure Abnormalities

Blood pressure is dependent upon normal cardiac and vascular function. The blood pressure (BP) is directly related to the heart rate (HR), the stroke volume (SV), and the systemic vascular resistance (SVR): BP = HR Ã— SV Ã— SVR. The systolic component of the blood pressure measurement is a reflection of the inotropic state of the myocardium, whereas the diastolic component reflects the vascular tone. It is important, as described below, to consider both components of the blood pressure, because the many compensatory mechanisms within the cardiovascular system produce recognizable patterns of blood pressure alteration.

Many xenobiotics affect blood pressure by modulation of the normal chemical interactions at the postganglionic sympathetic neurons. The interaction between these nerve endings and the receptors on vascular and cardiac smooth muscle largely determines the patient's blood pressure. Xenobiotics may initiate complex interactions at this postganglionic neuron (Table 23-6) that results in hypotension or hypertension.

Hypertension Caused by Xenobiotics

Hypertension may be the result of an increase in either inotropy or vascular resistance or both. For example, stimulation of the $\hat{I}\pm_1$ -adrenergic receptor causes hypertension through vasoconstriction, and stimulation of the $\hat{I}^2_1$ -receptor causes hypertension through enhanced myocardial contractility (Table 23-6).

Because of the functional overlap of most sympathomimetics, physical examination alone seldom identifies the specific causative agent in any toxic exposure. However, often a clinical constellation of signs and symptoms can be identified that is associated with this general class. For example, patients who ingest sympathomimetic amines such as cocaine or amphetamines typically have central nervous system stimulation. The presence of lethargy or coma in a patient suspected of a cocaine or

amphetamine overdose should suggest other possible diagnoses, includin mixed overdose, metabolic disorders, a postictal state, or central nervous system infection or hemorrhage.

The hemodynamic results of an overdose depend on the specific agent ingested and the relative action on the various types of Î²-adrenergic receptors (see Table 23-5). The pattern of blood pressure elevation is sometimes helpful in determining the specific class of sympathomimetic ingested. For example, nonselective Î²-adrenergic agonists (those that agonize at both $Î²_1$ and $Î²_2$) produce $Î²_1$ -mediated systolic hypertension (through inotropic effects) with $Î²_2$ -mediated vascular vasodilatation and diastolic hypotension. This results in a widened pulse pressure, which is the numerical difference between the systolic and diastolic pressures.

Hypertensive effects mediated by Î±-adrenergic receptor interaction

- Direct Î±-receptor agonists
  - Clonidine[a]
  - Epinephrine
  - Ergotamines
  - Methoxamine
  - Norepinephrine
  - Phenylephrine
  - Tetrahydrozoline
- Indirect-acting agonists
  - Amphetamines
  - Cocaine
  - Dexfenfluramine
  - Monoamine oxidase inhibitors
  - Phencyclidine
  - Yohimbine
- Direct- and indirect-acting agonists
  - Dopamine
  - Ephedrine
  - Metaraminol

Naphazoline
Oxymetazoline
Phenylpropanolamine
Pseudoephedrine

Hypertensive effects not mediated by Î±-adrenergic receptor interaction

Î²-Adrenergic receptor agonists[b]
Nonselective
Isoproterenol
Cholinergics[a]
Corticosteroids
Nicotine[a]
Vasopressin

[a] These may cause transient hypertension followed by hypotension.
[b] These can also cause hypotension.

TABLE 23-6. Xenobiotics that Commonly Cause Hypertension

$Î²_1$ -Adrenergic receptors cause increased inotropy and chronotropy, whereas $Î²_2$ -adrenergic receptors mediate vasodilation.[55] This suggests that, among Î²-adrenergic agonists, only those with a predominant $Î²_1$ -adrenergic effect cause hypertension. However, 10â€“50% of the heart's Î²-adrenergic receptors may be of the $Î²_2$ -adrenergic subtype.[13, 14, 16, 82, 128] In overdose, the relative specificity of the agents no longer is apparent, so even relatively selective $Î²_2$ -adrenergic agonists may cause increased inotropy and chronotropy. The resulting blood pressure depend on the relative physiologic balance between inotropy and vasodilation. Norepinephrine is primarily an $Î±_1$ - and Î²-adrenergic agonist and profound hypertension is the primary hemodynamic toxic effect. This relates to the effects of norepinephrine as both a positive inotrope ($Î²_1$), and a vasoconstrictor ($Î±_1$).

Hypotension Caused by Xenobiotics

An extremely large number of xenobiotics are reported to cause

hypotension. However, the hypotension often is not a direct action of the xenobiotic. Rather, the cause of hypotension is coexisting hypoxia, acidosis, anaphylaxis, volume depletion, or dysrhythmias. The terminal event in any patient with massive poisoning may be cardiovascular collapse and hypotension.

Typically, hypotension in adults is arbitrarily defined as a systolic blood pressure of less than 90 mm Hg. However, this is not an adequate clinical parameter. Young children and adults with a small body habitus may have a normal systolic pressure less than 90 mm Hg (Chap. 3). Patients with hypothermia have decreased metabolic demands, and a lower blood pressure may be considered â€œnormalâ€•

for these patients. Most importantly, patients with long-standing hypertension may have inadequate tissue perfusion even with systolic pressures greater than 90 mm Hg. The cerebral arterioles constrict or dilate to maintain a relatively constant cerebrovascular blood flow despite changes in the peripheral blood pressure. Chronically hypertensive patients lose this autoregulatory response as a consequence of atherosclerotic disease, arteriolar hypertrophy, or arteriolar smooth muscle constriction. These narrowed arterioles may require a higher peripheral blood pressure to properly perfuse the brain. Because the tolerable blood pressure shifts upward in chronically hypertensive patient they may manifest the clinical findings of hypotension at blood pressures in the â€œnormalâ€• range.

Hypotension is best clinically defined as a blood pressure that is inadequate to perfuse tissues. The clinical assessment of tissue perfusion is based on the vital signs, skin color, capillary refill, mental status, urine output and concentration, and acidâ€“base balance. However, if a xenobiotic directly affects one or more of these clinical parameters, the clinical assessment of volume and hemodynamic status may be difficult. Measurement of central venous pressure is beneficial in the early treatment of the sepsis syndrome,[89 , 90 and 91] and most likely would be beneficial in the treatment of other potentially hypotensive states, including that occurring in poisoned patients. Cardiac filling pressure,

cardiac output, systemic vascular resistance, and precise arterial pressures may be necessary in critically ill patients with severe poisoning

Poor tissue perfusion may result from hypovolemia, decreased peripheral vascular resistance, myocardial depression, or a dysrhythmia that reduce the cardiac output. A single xenobiotic may exert several effects on the hemodynamic system. Appropriate treatment of the hypotension requires an understanding of the pathophysiologic consequences of the xenobiotic and the resultant hemodynamic derangement.

A common etiology of hypotension in a poisoned patient is intravascular volume depletion. Intravascular volume may decrease due to gastrointestinal, urinary, or insensible losses, and fluid may redistribute from the intravascular space into the intracellular, interstitial, pleural, or peritoneal spaces. Xenobiotics can cause significant intravascular volume depletion through all of these mechanisms.

Hypotension may also be caused by xenobiotics that affect the venous tone. These xenobiotics increase venous capacitance, decrease the centra venous pressure, and result in a relative hypovolemia. The effects may b mediated via central effects on the sympathetic nervous system or direct effects on the peripheral vasculature. Sedative-hypnotics and central Î±$_2$ adrenergic agonists (eg, clonidine) decrease the central sympathetic outflow and may result in hypotension. Other xenobiotics directly block peripheral Î±$_1$ -adrenergic receptors or stimulate Î²$_2$ -adrenergic recepto on the blood vessels to produce vascular smooth muscle relaxation, venodilation, and hypotension. Tricyclic antidepressant agents, phenothiazines, theophylline, and cocaine may deplete catecholamines in the presynaptic nerve endings with resultant hypotension.

Assessment of Volume Status in the Poisoned Patient

Assessment of volume status may be particularly difficult in the poisoned patient because of functional alterations in the patient's autonomic nervous system and the pharmacologic effects of the xenobiotic. For

example, the usual signs of dehydration, such as dry mucous membranes dry skin, low blood pressure, tachycardia, narrowed pulse pressure, clouded sensorium, and decreased urine output, can be mimicked by a number of xenobiotics, including tricyclic antidepressants. Moreover, hypovolemic patients may present with diaphoresis, flushed skin, hypertension, bradycardia, or increased urine output after the exposure t a cholinergic agent such as an organic phosphorus compound. In most cases, clinical assessment of central venous pressures and neck vein distension[123] or the hemodynamic response to a fluid bolus can assist in the determination of

the patient's volume status. A central venous or pulmonary artery pressure catheter may be required in some critically ill patients.

Bradycardia
Î±2 -Adrenergic agonists
Î²-Adrenergic antagonists
Digoxin
Opioids
Calcium channel blockers
Plant toxins
Sedative-hypnotics
Cholinergics
  Aconitine
Vancomycin

	Characteristic ECG Abnormalities		
Heart Rate	No Change	Heart Block or Prolonged Intervals	Dysrhythmia

TABLE 23-7. Heart Rate and ECG Abnormalities of Xenobiotics that Cause Hypotension

Additional information about the adequacy of the patient's volume status may be obtained by orthostatic vital sign testing. Even with a 30% or greater volume loss, the supine blood pressure may remain normal in young, previously healthy patients. Normally, the cardiovascular system responds to sitting or standing with vasoconstriction and a slight increase in heart rate. Patients with hypovolemia are unable to maintain adequate intravascular pressure when upright and have either an exaggerated refle increase in heart rate or a drop in blood pressure (ie, orthostasis).

A variety of xenobiotics can produce orthostatic blood pressure changes (see Table 23-7).[65 , 122] Volume depletion is the most common cause of xenobiotic-induced orthostatic vital sign changes. However, xenobiotics may mimic orthostatic vital sign changes. For instance, Î±$_1$ -adrenergic antagonists may prevent an adequate vasoconstrictor response or may block the normal slight heart rate increase, and result in positive orthostatic vital sign testing. In these cases, cardiac output and blood pressure decrease when the patient is upright.

Identification of the specific xenobiotic causing hypotension requires the integration of a detailed history, complete physical examination, and laboratory studies. Often the identification of the specific xenobiotic responsible for hypotension is based on other physical findings associated with the xenobiotic or recognition of a specific toxic syndrome. Some toxins that produce hypotension also exert specific cardiac effects that ca help to identify them as the causative xenobiotic (Table 23-8). Various medications and xenobiotics can be separated into groups depending on their effects on the heart rate and possible effects on the ECG. The presence of cardiac conduction abnormalities or dysrhythmias could suggest a particular class or group of medications. Similarly, the absence of specific pulse or ECG changes may reduce the likelihood

of a particular xenobiotic as the cause for hypotension (although not completely eliminating the possibility). Although Table 23-7 lists common ECG manifestations associated with particular xenobiotics, individual xenobiotics in specific cases may demonstrate different heart rate or ECG findings.

Antianginals
- Î²-Adrenergic antagonists
- Calcium channel blockers
- Nitrates

Antidepressants
- Cyclic
- MAO inhibitors

Antihypertensives
- Angiotensin-converting enzyme inhibitors
- Angiotensin receptor antagonists
- Central $\hat{I}\pm_1$ -adrenergic agonists
  - Clonidine
  - Guanabenz
  - Guanfacine
  - Methyldopa

Antiparkinsons
- Bromocriptine
- L-Dopa
- Pergolide mesylate

Antipsychotics
- Butyrophenones
- Phenothiazines

CNS depressants
- Ethanol
- Opioids
- Sedative-hypnotics

Diuretics
- Loop diuretics
- Thiazides

Ganglionic blockers
Miscellaneous
Reserpine
Peripheral Î±-adrenergic antagonists
Phenoxybenzamine
Prazosin
Trimethaphan
Vasodilators
Hydralazine

TABLE 23-8. Xenobiotics that Cause Orthostatic Hypotension

History
New-onset, concomitant seizure
Gastrointestinal disturbances (colicky pain, nausea, vomiting, diarrhea)
Prior ingestion of medications (consider possibility that the container is mislabeled or misidentified)
Depression (even if patient denies ingestion)
Suspected myocardial ischemia in patient younger than 35 years old
Past medical history
Treatment with *any* cardiac medications (especially antidysrhythmics or digoxin)
History of psychiatric illness, asthma, or hypertension
History of drug use or abuse
Physical examination and vital signs
Heart rate
Sinus tachycardia with rate >130 beat/min
Sinus tachycardia without apparent identified cause
Sinus bradycardia
Respiratory rate
Any unexplained depression or elevation in rate
Temperature
Elevation especially if >106Â°F (>41.1Â°C)

- Hypothermia
- Dissociation between typically paired changes, for example:
  - Hypotension and bradycardia (tachycardia expected)
  - Fever and dry skin (diaphoresis expected)
  - Hypertension and tachycardia (reflex bradycardia anticipated)
  - Depressed mental status and tachypnea (decreased respirations common)
- Relatively rapid changes in vital signs
  - Initial hypertension becomes hypotension
  - Increasing sinus tachycardia or hypertension

General

- Alteration in consciousness, such as depressed mental status, confusion or agitation
- Findings usually not associated with cardiovascular diseases
  - Ataxia, bullae, dry mucous membranes, lacrimation, miosis or mydriasis nystagmus, unusual odor, flushed skin, salivation, tinnitus, tremor, visual disturbances
- Findings consistent with a toxic syndrome
  - Especially findings consistent with anticholinergics, sympathomimetics or sedative hypnotics

Laboratory tests

- Any unexpected or unexplained laboratory result, especially:
  - Metabolic acidosis
  - Respiratory alkalosis
  - Hypokalemia or hyperkalemia

TABLE 23-9. Clues that an Unanticipated Xenobiotic Might be the Cause of Hemodynamic Compromise or Dysrhythmia

Summary

Xenobiotics can interact with the heart or blood vessels to produce hypotension or hypertension, congestive heart failure, dysrhythmias (including bradycardias and tachycardias), or cardiac conduction delays.

These toxic effects often occur through interactions with specific receptor or with the ion channels in the cell membrane. Disruption of the normal cellular regulation of metabolic processes or of the cellular ionic status leads to the cardiovascular and hemodynamic compromise.

The occurrence of these abnormalities, individually or in combination, might suggest a particular xenobiotic or class of xenobiotics as the etiologic agent (toxic syndrome or â€œtoxidromeâ€•) and might dictate initial treatment. Often, however, significant abnormalities in vital signs must be corrected before the xenobiotic is identified. By understanding both the pharmacology of the xenobiotic and the physiology of the heart and vasculature, appropriate treatment can be delivered.

Definitive care of the poisoned patient with hemodynamic compromise or dysrhythmia begins with recognition that a xenobiotic may be present. Infectious, cardiovascular disease, and other metabolic disorders must always be considered; however, the toxic effects of xenobiotics must be included in the differential diagnosis. A variety of clinical clues, when present, should heighten the physician's suspicion that a xenobiotic effec may be responsible for the hemodynamic or dysrhythmic problem. Table 23-9 identifies some of these clues.

Chapter 24
Hematologic Principles

Marco L.A. Sivilotti

Blood is rightfully considered the vital fluid, as every organ system depends on the normal function of blood. Blood delivers oxygen and other essential substances throughout the body, removes waste products of metabolism, transports hormones from their origin to site of action, signals and defends against threatened infection, promotes healing via the inflammatory response and maintains the vascular integrity of the circulatory system. It also contains the central compartment of classical pharmacokinetics, and thereby comes into direct contact with virtually every toxin that acts on the organism.[155] The ease and frequency with which blood is assayed, its central role in functions vital to the organism, and the ability to analyze its characteristics, at first by light microscopy and more recently with molecular techniques, have enabled a detailed understanding of blood that has advanced the frontier of molecular medicine.

In addition to transporting xenobiotics throughout the body, blood and the blood-forming organs can at times be directly affected by these same xenobiotics. For example, decreased blood cell

production, increased blood cell destruction, alteration of hemoglobin, and impairment of coagulation can all result from exposure to a large variety of xenobiotics. The response in many cases depends on the nature and quantity of the xenobiotic, and the capacity of the system to respond to the insult. In other cases, no clear and predictable doseâ€“response relationship can be determined, especially when an interaction with the heterogeneous immune system is involved. These latter reactions are often termed idiosyncratic, reflecting an incomplete understanding of their causative mechanism. In general, such reactions can often be reclassified when advancing knowledge identifies the characteristics which render the individual vulnerable. For example, the observation of hemoglobinuria following primaquine administration to healthy, African American military recruits led to the recognition of the importance of glucose-6-phosphate dehydrogenase activity in protecting the erythrocyte from oxidative injury.

Hematopoiesis

Hematopoiesis is the development of the cellular elements of blood. The majority of the cells of the blood system may be classified as either lymphoid (B, T, and natural-killer lymphocytes) or myeloid (erythrocytes, megakaryocytes, granulocytes, and macrophages).[123] All of these cells are descended from a small common pool of totipotent cells called hematopoietic stem cells.[176] Indeed, the study of this process and its regulation has provided fundamental insight into embryogenesis, stem cell pluripotency, and complex cell-to-cell signaling and interaction.

Bone Marrow

Marrow spaces within bone begin to form in humans at about the 5th fetal month and become the sole site of granulocyte and megakaryocyte proliferation. Erythropoiesis moves from the liver to the marrow by the end of the last trimester. At birth, the red marrow

can be found in the fingers, toes, ribs, vertebrae, pelvis, long bones, and cranium. By adulthood, the same volume of hematopoietic marrow is located in the sternum, ribs, pelvis, and scapulae, and represents the normal site for blood cell formation. So-called extramedullary hematopoiesis in the liver and spleen may reemerge as a compensatory mechanism under severe stimulation.

The arterial blood supply of the bone marrow comes from nutrient arteries, which penetrate the outer cortex and form periosteal capillaries. Blood from these two systems mixes and enters the marrow sinus system, from which blood drains into the systemic circulation via emissary veins.[98]

In mammals, blood formation takes place in marrow spaces between the venous sinuses. The developing blood cells are closely and systematically related to the sinuses and must traverse the wall of the sinus before entering the general circulation.[123] The sinus wall is composed of a layer of endothelial cells, a thin basement membrane, and a layer of adventitial reticular cells that form the outer layer and the cell layer in closest approximation to the hematopoietic spaces.[97] A central arteriole runs along the hematopoietic spaces. Developing cell lines cluster into territories specific to their lineage. Granulopoietic cells are distributed along the walls of the central arteriole. Erythropoietic cells are distributed in a continuous network of cords around the sinus wall.[123] Megakaryocytes exist in close proximity to the surface of the sinus wall.[97] Erythrocytes are found closely associated with macrophages whose function may be to phagocytose the nuclear material extruded from red cells and megakaryocytes in the final stages of development.[98] Mature cells apparently enter the systemic circulation by passing through the cytoplasm of the endothelial cells.[185]

Progenitor cells must interact with a supportive microenvironment to sustain hematopoiesis. The hematopoietic stroma consists of macrophages, fibroblasts, adipocytes, and endothelial cells.[98] The extracellular matrix is composed of various fibrous proteins,

glycoproteins, and proteoglycans, which are produced by the stromal

cells and include collagen, fibronectin, laminin, hemonectin, thrombospondin, and proteoglycans.[97] Hematopoietic progenitor cells have receptors that bind to particular matrix molecules. The extracellular matrix provides a structural network to which the progenitors are anchored. As the cells approach maturity, they lose their surface receptors, presumptively allowing them to leave the hematopoietic space and enter the venous sinuses. Blood cell release depends upon the development of a pressure gradient that drives mature cells through channels in endothelial cell cytoplasm.[185] Pressure within the marrow is increased by erythropoietin and by granulocyte colony-stimulating factor (G-CSF).[74,75]

Stem Cells

A stem cell is capable of self-renewal as well as differentiating into a specific cell type. The pluripotent hematopoietic stem cell can therefore continuously replicate, while awaiting the appropriate signal to differentiate into either a myeloid stem cell (for myelo-, erythro-, mono-, or megakaryopoiesis) or a lymphoid stem cell (for lymphopoiesis of T, B, null, and natural-killer cells) (Fig. 24-1). The stem cell pool represents approximately 1 in 100,000 of the nucleated cells of the bone marrow, and the majority of these stem cells are usually quiescent. Nevertheless, these relatively few cells are directly responsible for the estimated 3 billion red cells, 2.5 billion platelets, and 1.5 billion granulocytes per kilogram of body weight produced each day. In response to hemolysis or infection, substantially larger numbers of blood cells can be produced.[123,125]

Hematopoietic stem cells are found in umbilical cord blood, bone marrow, and peripheral blood.[58] With subsequent division and maturation, these cells progressively display the antigenic, biochemical, and morphologic features characteristic of mature cells of the appropriate lineages, and lose their capacity for self-renewal.

Multiple steps are involved in the commitment of less-differentiated cells to more mature cell lines. The final steps in the maturation of erythrocytes alone, for example, involve extensive remodeling, the restructuring of cellular membranes, the accumulation of hemoglobin, and the loss of nuclei and organelles. In the case of granulocytes, granules containing proteolytic enzymes are formed in cell cytoplasm, and the nucleus condenses to form the multilobulated nucleus of the mature cell. Megakaryocyte cytoplasm demarcates into units that are eventually split off as platelets. This traditional hierarchical model has been challenged recently by the observation that hematopoietic stem cells can also differentiate into nonblood tissues, including tissues originating from the endo- and ectoderm, with profound implications for organ homeostasis and repair throughout the organism.[88,96]

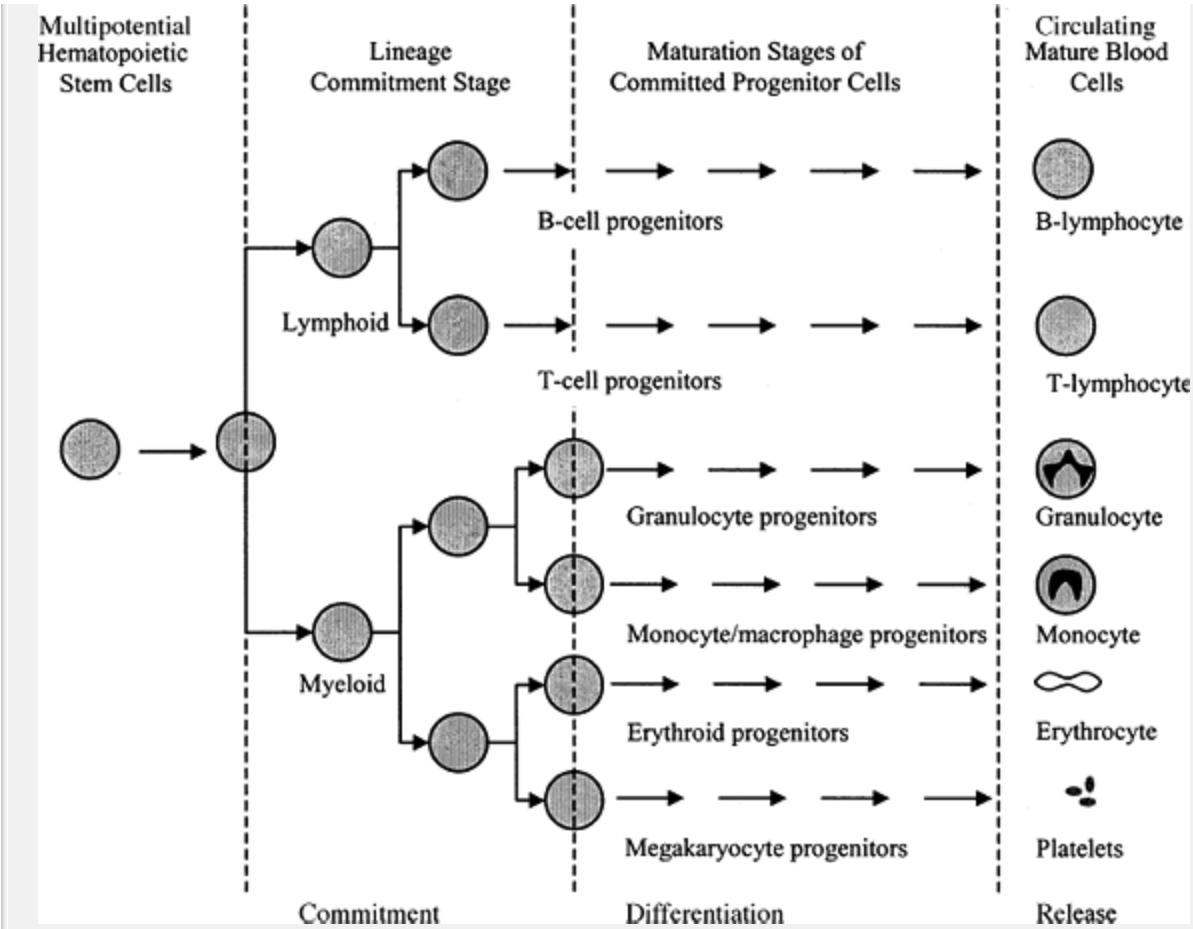

Figure 24-1. Principles of hematopoiesis. Commitment refers to the apparent inability of progenitor cells to generate hematopoietic stem cells. Following differentiation, the various mature blood cells are released into the circulation.

Cytokines

Cytokines are soluble mediators secreted by cells for cell-to-cell communication. Initially termed growth factors, it is now recognized that not all cytokines are growth factors. Cytokines promote or inhibit the differentiation, proliferation, and trafficking of blood cells and their precursors. Importantly, they can also inhibit apoptosis,

and their absence therefore results in the self-destruction of unwanted cells. They include growth factors or colony-stimulating factors (CSFs), interleukins, monokines, interferons, and chemokines. At baseline, these act in concert to maintain normal blood counts. In response to antigens or other stimuli, cytokines are released to combat perceived infection. Recombinant cytokines are being developed for therapeutic use in immunocompromised patients, transplant recipients, sepsis, and cancer. They have also been used in clinical toxicology for the treatment of colchicine and podophyllum toxicity.[37,64]

Growth factors are glycoproteins necessary for the differentiation and maturation of individual or multiple cell lines.[74,83,84,116] They fall into two families based on their target receptors. The ligands of the cytokine receptor family include growth hormone, interleukin-2 (IL-2), macrophage colony-stimulating factor-1 (CSF-1), granulocyte-macrophage colony-stimulating factor (GM-CSF), Î³-interferon, and granulocyte colony-stimulating factor (G-CSF), to name a few. The second group, the tyrosine kinase family, includes Kit ligand and insulinlike growth factor-I receptor (IGF-1R), a member of the insulin family. The complete development of all of the mature blood cells from stem cells or multilineage progenitors requires the action of growth factors, either alone or in combination, for successful differentiation and final maturation.

Cell Surface Antigens

With the use of monoclonal antibody technology, cell surface antigens can be identified and are used increasingly to characterize cell types. The cluster designation (CD) nomenclature is used, and more than 160 types have been classified.[192] For example, the CD34 antigen is a 115-kilodalton (kDa) highly glycosylated transmembrane protein that is selectively expressed by primitive multipotent hematopoietic stem cells shortly after activation, but is absent from mature T and B lymphocytes.[161] Cells expressing the CD34 antigen

can repopulate all hematopoietic cell lines, although more primitive pluripotent cells lacking this antigen have also been identified.[45] Combined with flow cytometry, the ability to subtype blood cells phenotypically has transformed the approach to the leukemias, autoimmune disease, transplantation medicine and thromboembolic disease.

Aplastic Anemia

Aplastic anemia is characterized by pancytopenia on peripheral smear, a hypocellular marrow, and delayed plasma iron clearance.

Severe aplastic anemia denotes a granulocyte count of less than 500 cells/mm^3, a platelet count of less than 20,000/mm^3, and a reticulocyte count of less than 1% after correction for anemia. Following acute insult and depletion of extracirculatory reserves, cell line counts fall at a rate inversely proportional to their life span: granulocytes (half-life 6â€“12 hours in the circulation) disappear within days, platelets (life span of 7â€“10 days) decline by half in about 5 days, erythrocytes (normal life span 120 days) take up to 2 months before being reduced to 50% of their baseline counts. Approximately 1000 new cases of aplastic anemia are diagnosed yearly in the United States. The incidence is much higher in Asia, especially in individuals between the ages of 10 and 40 years, presumably because of the greater prevalence of hepatitis. Aplastic anemia may be inborn (as in Fanconi anemia) or acquired. Specific etiologies of acquired aplastic anemia include certain xenobiotics (Table 24-1).[25,189] Although the vast majority of acquired cases are ascribed to medications, the pathogenesis in most of these cases is idiosyncratic, precluding a reliable predictive test.

Generally speaking, the mechanism is believed to involve the acquisition of intrinsic defects of the hematopoietic stem cells, and abnormal humoral and cellular immune control of hematopoiesis. Because approximately 10% of the pluripotent stem cells are active

at baseline, it can be assumed that well over 90% of these stem cells must be affected before pancytopenia develops.[190] Allogenic stem cell transplantation is used for patients with a suitably matched donor, usually identified in large registries. Otherwise, immunosuppressive therapy is needed to allow recovery of hematopoiesis.

Xenobiotic-Induced Immune-Mediated Causes of Aplastic Anemia

It is now believed that the majority of cases of aplastic anemia previously determined to be idiosyncratic are caused by immunologically mediated tissue specific destruction of CD34+ hematopoietic progenitor cells.[190,191] Following an exposure to an inciting antigen, T cells and cytokines act destructively on stem cells, reducing their numbers so that normal levels of circulating mature leukocytes, erythrocytes and platelets fall to dangerously low levels.[192] Toxicity may be mediated through intermediate metabolites that bind covalently to protein and DNA. These reactive metabolites are formed and degraded by complex metabolic pathways; genetic variation in the enzyme systems involved may contribute to the rarity of idiosyncratic drug reactions.[189] Human leukocyte antigen (HLA) DR2 is overrepresented among European and American patients with aplastic anemia. Clozapine-induced agranulocytosis is associated with the HLA B38, DR4, and DQ3 haplotypes, underlining a genetic predisposition to acquired aplastic anemia.[127]

TABLE 24-1. Xenobiotics Associated with Aplastic Anemia

Analgesics
Acetaminophen
Acetylsalicylic acid

- Diclofenac
- Dipyrone
- Indomethacin
- Phenylbutazone

Antibiotics

- Adriamycin[a]
- Azidothymidine
- Chloramphenicol
- Daunorubicin[a]
- Mefloquine
- Penicillin

Anticonvulsants

- Carbamazepine
- Felbamate

Antidysrhythmics

- Tocainide

Antihistamines

- Cimetidine

Antiplatelets

- Ticlopidine
- Chlorpromazine
- Clozapine

Antirheumatics

- Gold salts
- Methotrexate
- D-Penicillamine

Antithyroids

- Propylthiouracil

Diuretics

- Acetazolamide
- Metolazone

Occupational

- Arsenic[a]
- Benzene[a]

Cadmium
Copper
Pesticides
Antineoplastics[a]
Antimetabolites
Colchicine
Mustards
Vinblastine
Vincristine
Radiation[a]
[a] Denotes agents that predictably result in bone marrow aplasia following a sufficiently large exposure.

The peripheral blood and bone marrow of patients with aplastic anemia produces a soluble factor identified as Î³-interferon (INF-Î³) that inhibits hematopoiesis; normal lymphocytes can be stimulated to produce the same factor.[193] Both the blood and bone marrow of patients with aplastic anemia contain increased numbers of activated cytotoxic lymphocytes. The numbers and activity of activated cells decrease with immunosuppressive therapy.[92,137] The T cells of patients with aplastic anemia overproduce INF-Î³ and tumor necrosis factor (TNF).[179] Both cytokines are capable of suppressing proliferating early and late hematopoietic progenitor and stem cells.[157] In addition to the inhibition of the mitotic cycle, it is likely that the pathology includes the induction of programmed cell death through the induced expression (by TNF and INF-Î³) of the Fas receptor on CD34+ progenitor cells. Fas (CD95) is a receptor molecule that mediates signal transduction for apoptosis, or programmed cell death. Apoptosis is a morphologic pattern of genetically programmed cell death marked by cell shrinkage, condensation of chromatin, the formation of cytoplasmic blebs, and the fragmentation of the cell into membrane bound bodies that are

eliminated by phagocytosis. It is a physiologic mechanism for cell deletion in the regulation of cell populations. Fas is a member of the TNF receptor family. Engagement of the Fas receptor by another cell surface molecule triggers apoptosis in the Fas-expressing cell. The initial focus of immune attack may be limited. As more tissue is damaged, the exposure of previously hidden cellular antigens increases the range of immune targets in a process known as antigenic spread.[41] In normal individuals, Fas is rarely expressed on CD34+ cells. In patients with aplastic anemia, CD34+ bone marrow cells express Fas receptors to a much greater extent, resulting in anti-Fas antibody-mediated inhibition of hematopoiesis.[101,124] The genes for INF-Î³ and TNF are overexpressed in the marrow and blood cells of patients with aplastic anemia. The expression of Fas is also associated with infection by viruses implicated in marrow suppression such as the human immunodeficiency virus (HIV) and hepatitis C.[128] INF-Î³ expression is eliminated in patients successfully treated with immunosuppressive therapy, usually with antithymocyte globulin, cyclosporine, or cyclophosphamide. INF-Î³ again becomes detectable in those patients who have relapsed following therapy. It is not detectable in patients with Fanconi anemia.[128]

The Erythron

The erythron can be considered to be a single tissue, defined as the entire mass of erythroid cells beginning with the first committed progenitor cell and ending with the mature circulating

erythrocyte. This functional definition emphasizes the distributed nature yet integrated regulation of the erythron, both in health and disease. Homeostasis of the erythron is primarily maintained by the equilibrium between stimulation via the hormone erythropoietin, and apoptosis controlled by two receptors, Fas and FasL, expressed on the membranes of erythroid precursors. At the other extreme, erythrocytes are culled from the circulation at the end of their life span, primarily by the action of the spleen. Erythrocytes less able to

negotiate the narrow red pulp passages are phagocytosed by macrophages, thereby minimizing both entrapment in the capillary beds of the microvasculature, and spillage of intracellular contents into the intravascular circulation.

The primary function of the erythron is to transport molecular oxygen throughout the organism. To accomplish this, adequate numbers of circulating erythrocytes must be maintained. These erythrocytes must be able to preserve their structure and flexibility to circuit repeatedly through the microcirculation and to resist oxidant stress accumulated during their life span.[145] It is recognized that interactions between oxyhemoglobin and nitric oxide are also key to the modulation of vascular tone, potentially matching vasomotor tone to local tissue oxygen demands.[38,58,63,112,153]

Erythropoietin

Erythropoietin (EPO) is a glycoprotein hormone of molecular weight 34,000 daltons that is produced in the epithelial cells lining the peritubular capillaries in the normal kidney. Anemia and hypoxemia stimulate its synthesis.[1,2] EPO receptors are found in human erythroid cells, megakaryocytes, and fetal liver. EPO promotes erythroid differentiation, the mobilization of marrow progenitor cells, and the premature release of marrow reticulocytes.[1] The cell most sensitive to EPO is a cell between the erythroid colony-forming unit (CFU-E) and the proerythroblast.[2] In the absence of EPO, rapid DNA cleavage, in a pattern characteristic of apoptosis, results in erythroid cell death.

The Mature Erythrocyte

The mature erythrocyte (red blood cell) is a highly specialized cell, designed primarily for oxygen transport. Accordingly, it is densely packed with hemoglobin, which constitutes approximately 90% of the dry weight of the erythrocyte, or 30â€“35 g/dL. During maturation,

the erythrocyte loses its nucleus, mitochondria and other organelles, rendering it incapable of synthesizing new protein, replicating, or using the oxygen being transported for oxidative phosphorylation. Its metabolic repertoire is also severely limited, and largely restricted to a few pathways described below under Metabolism. In general, the enzymatic pathways are those required for optimizing oxygen and carbon dioxide exchange, transiting the microcirculation while maintaining cellular integrity and flexibility, and resisting oxidant stress especially on the iron and protein of the cell. The characteristic biconcave discocyte shape is dynamically maintained, allowing an excess of membrane surface to cell volume.[111] This shape both decreases intracellular diffusion distances to the extracellular membrane[95] and allows plastic deformation when squeezing through the microcirculation.[28,154] The shape is the net sum of elastic and electrostatic forces within the membrane, surface tension, and osmotic and hydrostatic pressures. The cell membrane contains globular proteins floating within the phospholipid bilayer. The major blood group antigens are carried on membrane ceramide glycolipids and proteins, particularly glycophorin A and the Rh proteins.[32] Membrane proteins generally serve to maintain the structure of the cell, to transport ions and other substances across the membrane, or to catalyze a limited number of specific chemical reactions for the cell.

Structural Proteins

The cell membrane is coupled to, and interacts dynamically with, the cytoskeleton, allowing changes in cell shape as well as tank treading or rotation of the membrane relative to the cytoplasm. This cytoskeleton consists of a hexagonal lattice of proteins, especially spectrin, actin, and protein 4.1, which interact with ankyrin and band 3 in the membrane to provide a strong but flexible structure to the membrane.[13,90,152] Other essential structural proteins include tropomyosin, tropomodulin, and adducin. Absence or abnormalities of these proteins can result in abnormal erythrocyte shapes such as

spherocytes and elliptocytes.

Transport Proteins

Many specialized transport proteins are embedded in the erythrocyte membrane. These include anion and cation transporters, glucose and urea transporters, and water channels.[172] The erythrocyte membrane is relatively impermeable to ion flux. Band 3 anion-exchange protein plays an important role in the chloride-bicarbonate exchanges that occur as the erythrocyte moves between the lung and tissues. Glucose, the sole source of energy of the erythrocyte, crosses the membrane by facilitated diffusion mediated by a transmembrane glucose transporter. Sodium-potassium adenosine triphosphatase (Na^+-K^+-ATPase) maintains the primary cation gradient by pumping sodium out of the erythrocyte in exchange for potassium.

Membrane-Associated Enzymes

At least 50 membrane-bound or -associated enzymes are known to exist in the human erythrocyte. Acetylcholinesterase is an externally oriented enzyme whose role in the function of the erythrocyte remains obscure.[173] Its function is inhibited by certain xenobiotics, most notably the organic phosphorus insecticides, and can be conveniently assayed as a marker for such exposures.

Metabolism

Without mitochondria and the ability to efficiently generate adenosine triphosphate (ATP) using molecular oxygen, the mature erythrocyte has a severely limited repertoire of intermediary metabolism compared to most mammalian cells. Without the ability to synthesize new enzymes, its metabolic capacity is also limited once its nucleus, ribosomes, and translational apparatus are lost. This capacity, in fact, declines over the lifetime of the cell because of declining enzyme function with time. Fortunately, the metabolic

demands of the erythrocyte are usually modest, but under conditions of stress this capacity can be overwhelmed, especially among senescent cells. The greatest expenditure of energy under physiologic conditions is for the maintenance of transmembrane gradients and for the contraction of cytoskeletal elements. However, oxidant stress can put severe strain on the metabolic reserves of the erythrocyte, and lead ultimately to the destruction of the cell, a process termed hemolysis.

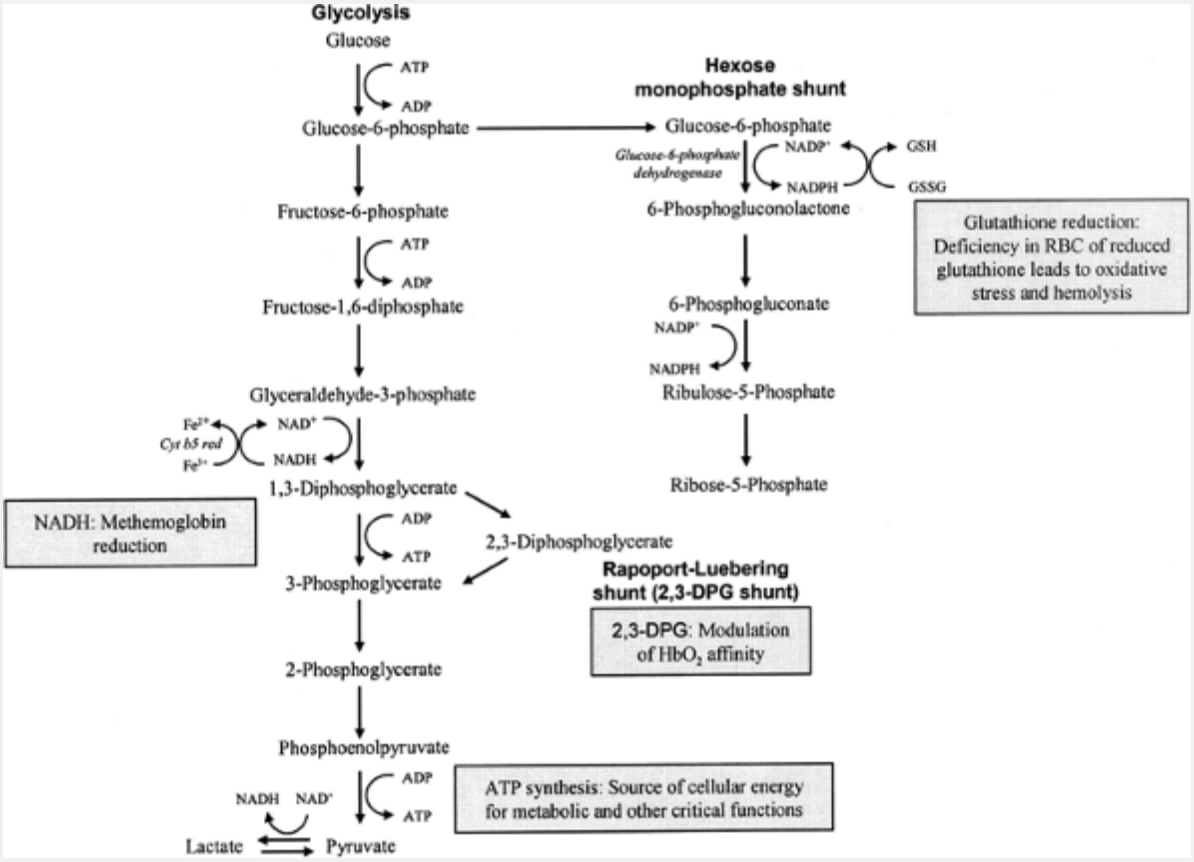

Figure 24-2. Metabolic pathways of the erythrocyte. The main metabolic pathways available to the mature erythrocyte are shown (rectangles). Glucose is imported into the cell, while pyruvate, lactate, and oxidized glutathione (GSSG) are exported. 2,3-DPG = 2,3-Diphosphoglycerate; ADP = adenosine

diphosphate; ATP = adenosine triphosphate; cyt b5 red = cytochrome b5 reductase; G6PD = glucose-6-phosphate dehydrogenase; GSH = reduced glutathione; Hb = hemoglobin; NADH = reduced form of nicotinamide adenine dinucleotide (NAD^+); NADPH = reduced form of nicotinamide adenine dinucleotide phosphate ($NADP^+$); RBC = red blood cell (erythrocyte).

Figure 24-2 illustrates the main metabolic pathways and their purpose. The Embden-Meyerhof glycolysis is the only source of ATP for the erythrocyte, and accounts for approximately 90% of the glucose imported by the cell. The reduced nicotinamide adenine dinucleotide (NADH) generated during glycolysis, which would ordinarily be used for oxidative phosphorylation in cells containing mitochondria, is directed toward the reduction of either methemoglobin to hemoglobin by cytochrome b5 reductase, or of pyruvate to lactate. Both pyruvate and lactate are exported from the cell. During glycolysis, metabolism can be diverted into the Rapoport-Luebering shunt, generating 2,3-bisphosphoglycerate (2,3-BPG, formerly known as 2,3-diphosphoglycerate or 2,3-DPG) in lieu of ATP. 2,3-BPG binds to deoxyhemoglobin to modulate oxygen affinity and allow unloading of oxygen at the capillaries. In response to anemia, altitude, or changes in cellular pH, the activity of the shunt increases, thereby favoring synthesis of 2,3-BPG and increasing oxygen delivery considerably.[33,107] Reduced levels of 2,3-BPG in stored blood are believed to result in impaired oxygen delivery for approximately 12 hours following massive transfusion.[177]

As an alternative to glycolysis, glucose can be directed toward the hexose monophosphate shunt during times of oxidant stress. This pathway results in the generation of reduced nicotinamide adenine dinucleotide phosphate (NADPH), which the erythrocyte uses to maintain reduced glutathione which, in turn, inactivates oxidants and

protects the sulfhydryl groups of hemoglobin and other proteins. The initial, rate-limiting step of this pathway is controlled by glucose-6-phosphate dehydrogenase (G6PD). Accordingly, cells deficient in this enzyme are less able to maintain glutathione in a reduced state, and are vulnerable to irreversible damage under oxidant stress. The consequences of this deficiency are discussed in greater detail below under Glucose-6-Phosphate Dehydrogenase Deficiencies.

The erythrocyte also contains enzymes to synthesize glutathione (Î³-glutamyl-cysteine synthetase and glutathione synthetase), to convert CO_2 to bicarbonate ion (carbonic anhydrase I), to remove

pyrimidines resulting from the degradation of RNA (pyrimidine 5â€²-nucleotidase), to protect against free radicals (catalase, superoxide dismutase, glutathione peroxidase), and to conjugate glutathione to electrophiles (Ï•-*S*-transferase).

Hemoglobin

Hemoglobin, the major constituent of the cytoplasm of the erythrocyte, is a conjugated protein with a molecular weight of 64,500 daltons. One molecule is composed of 4 protein or globin chains, each attached to a prosthetic group called heme. Heme contains an iron molecule complexed at the center of a porphyrin ring. The globin chains are held together by noncovalent electrostatic attraction into a tetrahedral array. Hemoglobin is so efficient at binding and carrying oxygen that it enables blood to transport 100 times as much oxygen as could be carried by plasma alone (Chap. 22). In addition, the capacity of hemoglobin to modulate oxygen binding under different conditions allows adaptation to a wide variety of environments and demands. Three complex and integrated pathways are required for the formation of hemoglobin: globin synthesis, protoporphyrin synthesis, and iron metabolism.

Globin Synthesis

The protein chains of hemoglobin are produced with information from two different genetic loci. The Î±-globin gene cluster spans 30 kb on the short arm of chromosome 16, and codes for 2 identical adult Î±-chain genes, as well as the Î¶-chain, an embryonic globulin. The Î² cluster is 50 kb on chromosome 11, and codes for the two adult globins Î² and Î´, as well as two nearly identical Î³ chains expressed in the fetus and an embryonic globulin Îµ. The expression of genes in each family changes during embryonic, fetal, neonatal, and adult development. Until 8 weeks of intrauterine life, Îµ, Î¶, Î³, and Î± chains are produced and assembled in various combinations in yolk sac-derived erythrocytes. With the shift in erythropoiesis from yolk sac to fetal liver and spleen, embryonic hemoglobin is no longer detectable, and the Î± and Î³ globin chains are paired into fetal hemoglobin (HbF = $Î±_2Î³_2$). Erythrocytes containing HbF have a higher O_2 affinity than does adult hemoglobin, which is important for oxygen transfer across the placenta into the relatively hypoxic uterine environment. Beginning shortly before birth, expression shifts to the Î± and Î² globins, which constitute the predominant adult hemoglobin termed hemoglobin A ($Î±_2Î²_2$). Approximately 2.5% of normal adult hemoglobin is in the form of hemoglobin A_2 ($Î±_2Î´_2$).

The rate of globin synthesis is increased in the presence of heme, and inhibited in its absence.[110] As the globin chains are released from the ribosomes, they spontaneously assemble into Î±Î² dimers, and then into $Î±_2Î²_2$ tetramers. The thalassemias, a group of inherited disorders, result from defective synthesis of one or more of the globin chains. Clinically this results in a hypochromic, microcytic anemia.[60,110]

Heme Synthesis

Heme is the iron complex of protoporphyrin IX. Protoporphyrin IX is a tetramer composed of four porphyrin rings joined in a closed, flat-ring structure. The IX designation refers to the order in which it was synthesized in the laboratory by Hans Fischer. Of the 15 possible

isomers, only protoporphyrin IX occurs in living organisms. Technically, only iron complexes with the iron in the Fe^{2+} state can be called heme, but the term is commonly used to refer to the prosthetic group of metalloproteins such as peroxidase and cytochrome c, whether the iron is in the Fe^{2+} or Fe^{3+} state. The terms â€œhemiglobinâ€• and â€œferrihemoglobinâ€• are synonymous with methemoglobin but rarely used. All animal cells can synthesize heme, with the notable exception of mature erythrocytes.[138] Hemoproteins are involved in a multitude of biologic functions, including oxygen binding (hemoglobin, myoglobin), oxygen metabolism (oxidases, peroxidases, catalases, and hydroxylases), and electron transport (cytochromes).[22,139] Erythroid cells synthesize 85% of total body heme, with the liver synthesizing most of the balance. Hemoglobin is the most abundant hemoprotein, containing 70% of total body iron.[138]

The first step in the synthesis of heme takes place in the mitochondrion and is the condensation of glycine- and succinyl-coenzyme A (CoA) to form Î´-aminolevulinic acid (Î´-ALA) (see Fig. 24-3).[22,110] The formation of Î´-ALA is catalyzed by aminolevulinic acid synthase (ALAS). It is possible that mammals may also synthesize ALA as do plants, namely via the transamination of Î±-ketoglutaric acid, using the mitochondrial enzyme alanine-dioxovalerate aminotransferase. Of the two isoforms of ALAS known to exist, erythroid cells contain the ALAS 2 isoform which resides on the X chromosome. Comparatively more is known about ALAS 1 (chromosome 3), which is derived from hepatic tissue. ALAS 1 activity is induced by many factors, and strongly inhibited by heme in a classical negative feedback fashion.[138] Pyridoxal phosphate (active vitamin B_6) serves as a cofactor to both isoforms of ALAS. The clinical consequences of pyridoxine deficiency may include a hypochromic, microcytic anemia, iron overload, and neurologic impairment. Xenobiotics that increase the rate of synthesis of Î´-ALA may precipitate an inducible porphyric crisis.[40,139] This may occur in hepatocytes through drug-mediated induction in the rate of

transcription of the ALAS 1 gene.[110] The

result is an accumulation of porphyrins, clinically expressed as abdominal pain and neuropsychiatric symptoms.

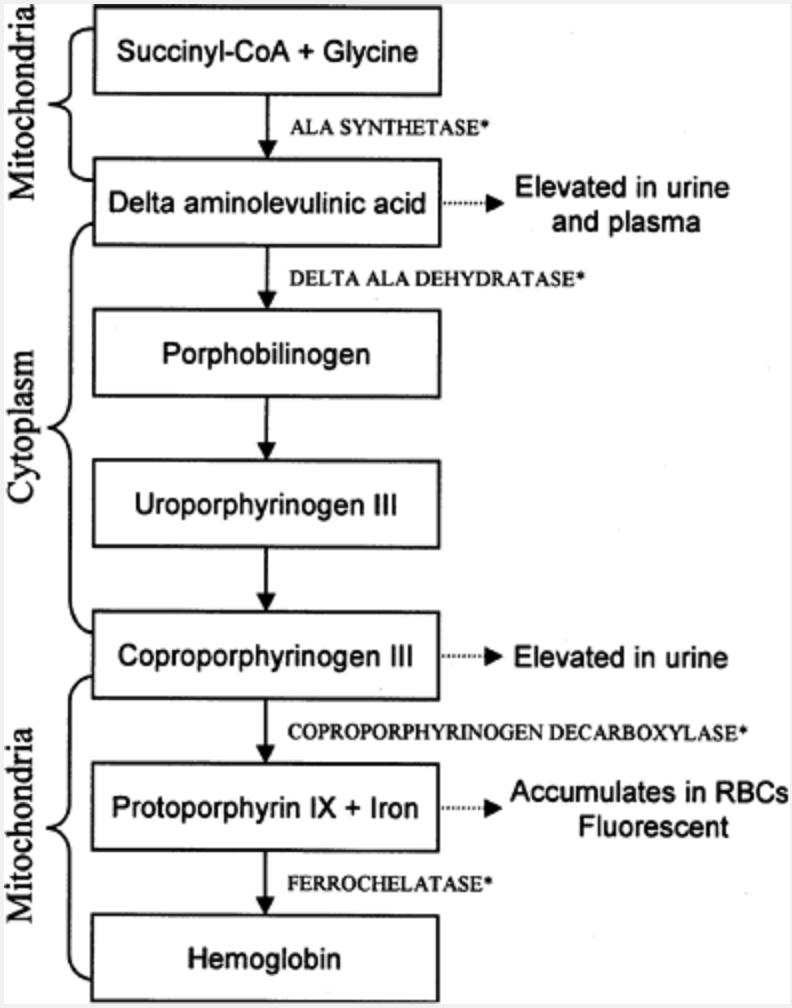

Figure 24-3. The heme synthesis pathway. The enzymatic steps inhibited by lead are marked with an asterisk (*) RBCs = red blood cells.

The next step in the synthesis of hemoglobin is the formation of the

monopyrrole porphobilinogen via the condensation of 2 molecules of ALA. This reaction is catalyzed by ALA dehydratase, and is inhibited by lead (Fig. 24-3). Porphobilinogen is excreted in large quantities by patients with acute intermittent porphyria, coloring the urine a deep red wine color.[22]

The subsequent steps in heme synthesis involve the condensation of 4 molecules of porphobilinogen into a ring, which is transported back into the mitochondrion by an unknown mechanism. The final step is the insertion of iron into protoporphyrin IX, a reaction that is catalyzed by ferrochelatase to form heme. Given that ALAS 2 is constitutively expressed at such high levels in erythroid precursors, this last reaction is the likely site of feedback inhibition of heme and of heme synthesis control in immature erythrocytes.[22,138] Most steps in the heme biosynthetic pathway are inhibited by lead (Fig. 24-3; Chap. 91). ALA dehydratase is the most sensitive, followed by ferrochelatase, coproporphyrinogen oxidase, and porphobilinogen (PBG) deaminase. As a consequence, urinary ALA is greatly increased.

Iron Metabolism

Unless appropriately chelated, free iron not bound by transport or storage proteins can generate harmful oxygen free radicals that damage cellular structures and metabolism (Chaps. 12 and 40).[140] For this reason, it is imperative to bind iron in the circulation to the transfer protein, transferrin, and to store iron in the tissues using ferritin. Although each molecule of transferrin can bind two iron atoms, ferritin has a large internal cavity, approximately 80 Ã… in diameter, that can hold up to 4500 iron atoms per molecule. The amount of iron transported through plasma depends on total-body iron stores and the rate of erythropoiesis. Only about one-third of the iron-binding sites of circulating transferrin are normally saturated, as demonstrated by the usual serum iron content of 60â€“170 Âµg/dL (10â€“30 Âµmol/L) as compared to the total iron-

binding capacity of 280â€“390 Âµg/dL (50â€“70 Âµmol/L). It is likely that transferrin bound iron is a regulator of heme synthesis.[2,138] The expression of ALAS 2 in human erythroid cells is limited by the availability of iron.[138,140]

Only transferrin can directly supply iron for hemoglobin synthesis.[138] The ironâ€“transferrin complex binds to transferrin receptors on the surface of developing erythroid cells in bone marrow. Iron in the erythroid cell is used for hemoglobin synthesis or is stored in the form of ferritin. Lead limits the delivery of iron to ferrochelatase, contributing to the anemia of lead poisoning. In its place, zinc is inserted into protoporphyrin, resulting in the accumulation of zinc protoporphyrin.

The senescent erythrocyte is usually culled from the circulation by splenic macrophages. Heme is degraded by heme oxygenase to carbon monoxide and biliverdin, and the iron is extracted from hemoglobin.[140] Some iron may remain in macrophages in the form of ferritin or hemosiderin. Most is delivered back to the plasma where it is again bound to transferrin.

Oxygen-Carbon Dioxide Exchange

The evolutionary transition of organisms from anaerobic to aerobic life allowed the liberation of 18 times more energy from glucose. Vertebrates have developed two important systems to overcome the relatively small quantities of oxygen dissolved in aqueous solutions under atmospheric conditions: the circulatory system and hemoglobin. The circulatory system allows delivery of oxygen and removal of carbon dioxide throughout the organism. Hemoglobin also plays an essential role in the transport and exchange of both gases.[68] Moreover, the interactions between these gases and hemoglobin are directly linked in a remarkable story of molecular evolution. Understanding these interactions has allowed fundamental insight into protein conformation and the importance of allosteric interactions between molecules.

The binding of oxygen to each of the 4 iron molecules in heme results in conformational changes that affect binding of oxygen at the remaining sites. This phenomenon is known as cooperativity, and is a fundamental property to allow both the transport of relatively large quantities of oxygen and the unloading of most of this oxygen at tissue sites. Cooperativity results from the intramolecular interactions of the tetrameric hemoglobin, and is expressed in the sigmoidal shape of the oxyhemoglobin dissociation curve (Chap. 22). Conversely, the monomeric myoglobin has a hyperbolic oxygen binding curve. The partial pressure of oxygen at which 50% of the oxygen bindings sites of hemoglobin are occupied is about 26 mm Hg, in contrast with about 1 mm Hg for myoglobin. Moreover, hemoglobin is nearly 100% saturated at partial oxygen pressures of about 100 mm Hg in the pulmonary capillaries, transporting 1.34 mL of oxygen per gram of hemoglobin A. About one-third of this oxygen can be unloaded under normal conditions at tissue capillaries with partial oxygen pressures around 35 mm Hg. This proportion rises during exercise and sepsis, and with poisons that uncouple oxidative phosphorylation. Elite athletes can extract up to 80% of the available oxygen under conditions of maximal aerobic effort.

This oxygen reserve, however, is only one of the reasons for the large quantity of hemoglobin in circulation. The ability of hemoglobin to buffer the acid equivalent of CO_2 in solution is equally vital to respiratory physiology, as it allows the removal of large quantities of CO_2 from metabolically active tissues with minimal changes in blood pH. To put things in perspective, the typical adult male has approximately 75 mL/kg of blood containing 15 g/100 mL of hemoglobin, or nearly 1 kg of hemoglobin. His 0.3-kg heart must also pump this entire mass of hemoglobin every minute at rest, a substantial work expenditure. This inefficiency is partly explained by the observation that hemoglobin is by far the largest buffer in circulation, accounting for nearly 7 times the buffer capacity of the serum proteins combined (28 vs. 4 mEq H^+/L of whole blood). For every 1 mol of oxygen unloaded in the tissue, about 0.5 mol of H^+ is

loaded onto hemoglobin.

The linked interaction between oxygen and carbon dioxide transport can be first considered from the perspective of oxygen binding to hemoglobin. The affinity of oxygen for hemoglobin is directly affected by pH, which is a function of the CO_2 content of the blood. The oxyhemoglobin dissociation curve shifts to the left in lungs, where the level of carbon dioxide, and thus carbonic acid, are kept relatively low as a result of ventilation, an effect that promotes oxygen binding. The curve shifts to the right in tissues where cellular respiration increases CO_2 concentrations. This phenomenon, known as the *Bohr effect*, promotes the uptake of oxygen in the lungs and the release of oxygen at tissue sites.

From the perspective of carbon dioxide, while it does not bind directly to hemoglobin, hemoglobin plays an essential role in its transport nevertheless. Carbon dioxide dissolves into serum, and is slowly hydrated to carbonic acid which dissociates to H+ and HCO_3^- (pK_a 6.35). The hydration reaction is accelerated from

about 40 seconds to 10 msec by the abundant enzyme carbonic anhydrase, which is located within the erythrocyte. Most carbon dioxide collected at the tissues diffuses into erythrocytes where it becomes H^+ and HCO_3^-. This HCO_3^- is then rapidly transported back to the serum in exchange for chloride ion via the band 3 anion exchange transporter located in the erythrocyte membrane, thereby shifting serum Cl^- into the erythrocyte (the *chloride shift*).[172] The hydrogen ion is accepted by hemoglobin, largely at the imidazole ring of histidine residues which have a pK_a of about 7.0. A small amount of CO_2 reacts directly with the amino terminal of the globin chains to form carbamino residues ($HbNHCOO^-$). Thus, most of the transported carbon dioxide is transformed by the erythrocyte into bicarbonate ion that is returned to the serum, and hydrogen ion that is buffered by hemoglobin. Each liter of venous blood typically carries 0.8 mEq dissolved CO_2 and 16 mEq HCO_3^- in the serum, and 0.4 mEq dissolved CO_2, 4.6 mEq HCO_3^-, and 1.2 mEq $HbNHCOO^-$ in the

erythrocyte (a total of 23 mEq CO_2, equivalent to 510 mL CO_2/L blood). Whereas two-thirds of the total CO_2 content appears to be carried in the serum, essentially all of the serum bicarbonate is originally generated within erythrocytes. In the capillaries of the lungs, the reverse reactions occur to eliminate CO_2. Because deoxyhemoglobin is better able to buffer hydrogen ions, the release of oxygen from hemoglobin at the tissues facilitates the uptake of carbon dioxide into venous blood. This effect is known as the Haldane effect. In fact, 1 L of venous blood at 70% oxygen saturation can transport an additional 20 mL of CO_2 compared to arterial blood. Both the Bohr and Haldane effects can have important consequences, either at the extremes of acidâ€“base perturbations or because of interference with oxygen metabolism, as can occur in a number of poisonings.

Abnormal Hemoglobins

Several alterations of the hemoglobin molecule are encountered in clinical toxicology. A detailed understanding of their molecular basis, clinical manifestations, and effects on gas exchange are essential. Unfortunately, the nomenclature can be ambiguous and overlap with distinct clinical entities such as oxidant injury and hemolysis. Therefore, although a detailed discussion of these abnormal hemoglobins appears elsewhere (Chaps. 120 and 122), an overview of the subject is presented here. It is helpful to recall that the iron atom has 6 binding positions. Four of these positions are attached in a single plane to the protoporphyrin ring to form heme. The remaining 2 binding positions lie on opposite sides of this plane. Iron is ordinarily bonded on one side to the F8 proximal histidine residue of the globin chain. The remaining site is available for binding molecular oxygen, but can also bind carbon monoxide, nitric oxide, cyanide, hydroxide ion, or water. The E7 distal histidine residue facilitates the binding of oxygen, while stearically hindering carbon monoxide binding.

Methemoglobin

Methemoglobin (ferrihemoglobin or hemiglobin) is the oxidized form of deoxyhemoglobin in which at least 1 heme iron is in the oxidized (Fe^{3+}) valence state. A number of valency hybrids can occur depending on the number of ferric versus ferrous heme units within the tetramer. Methemoglobin therefore represents oxidation (loss of electrons) of hemoglobin molecule at the iron atom. It occurs spontaneously as a consequence of interactions between the iron and oxygen. Normally, in deoxygenated hemoglobin, the heme iron is in the ferrous (Fe^{2+}) valence state. In this state, there are 6 electrons in the outer shell, 4 of which are unpaired. When oxygen is bound, one of these electrons is partially transferred to it and the iron is reversibly oxidized. When O_2 is released, the electron is usually transferred back to heme iron, yielding the normal reduced state. Sometimes, the electron remains with the O_2 yielding a superoxide anion radical O_2^- rather than molecular oxygen. In this case, heme iron is left in the Fe^{3+}, or oxidized, state and is unable to release another electron to bind oxygen. This oxidation is primarily reversed via the action of cytochrome b5 reductase, also known as NADH methemoglobin reductase, which uses the electron carrier NADH regenerated by glycolysis (Chap. 13).[70,106] Minor pathways are also involved in methemoglobin reduction, including NADPH methemoglobin reductase, which normally reduces only approximately 5% of the methemoglobin, and vitamin C, a nonenzymatic reducing agent. The activity of NADPH methemoglobin reductase may be significantly accelerated by the presence of the electron donor methylene blue (see Antidotes in Depth: Methylene Blue and Chap. 122) or riboflavin.[81] Equilibrium is maintained with methemoglobin concentrations of 1% of total hemoglobin. Many xenobiotics are capable of increasing the rate of methemoglobin formation as much as 1000-fold. Nitrites, nitrates, chlorates, and quinones are capable of directly oxidizing hemoglobin.[23] Certain individuals may be especially vulnerable because of deficient methemoglobin reduction.[35] The fetus and neonate are more

susceptible to methemoglobinemia than the adult, as HbF is more susceptible to oxidation of the heme iron than adult hemoglobin. The newborn also has a limited capacity to reduce methemoglobin, because levels of cytochrome b5 reductase only reach adult levels around 6 months of age.

Carboxyhemoglobin

Carbon monoxide (CO) can reversibly bind to heme iron in lieu of molecular oxygen. The affinity of CO for hemoglobin is 200â€“300 times that of oxygen, despite the stearic hindrance of the E7 distal histidine. The presence of CO thereby precludes the binding of oxygen. In addition, CO binding within any one heme subunit degrades the cooperative binding of oxygen at the remaining heme groups of the same hemoglobin molecule. The oxyhemoglobin dissociation curve is therefore shifted to the left, reflecting the fact that oxygen is more tightly bound by hemoglobin and less able to be unloaded to the tissues. In addition, CO binds to the heme group of myoglobin and the cytochromes, interfering with cellular respiration, exacerbating the clinical symptoms of hypoxia (Chap. 120).[61]

Sulfhemoglobin

Sulfhemoglobin is a bright green molecule in which the hydrosulfide anion HS^- irreversibly binds to ferrous hemoglobin. The sulfur atom is probably attached to a Î² carbon in the porphyrin ring, and not at the normal oxygen-binding site.[118] It has a spectrophotometric absorption band at approximately 618 nm,[15] is ineffective in oxygen transport, and clinically produces cyanosis. The oxygen affinity of sulfhemoglobin is approximately 100 times less than that of oxyhemoglobin, shifting the oxyhemoglobin dissociation curve to the right, in favor of O_2 unbinding. Thus, the symptoms of hypoxia are not as severe with sulfhemoglobinemia as with carboxy- or methemoglobinemia.[132]

Oxidation of the Globin Chain

Oxidation can also occur at the amino acid side chains of the globin protein. In particular, sulfhydryl groups can oxidize to form disulfide links between cysteine residues, which leads to the unfolding of the protein chain, exposure of other side chains and further oxidation. When these

disulfide links join adjacent hemoglobin molecules, they cause the precipitation of the concentrated hemoglobin molecules out of solution. Covalent links can also form between hemoglobin and other cytoskeletal and membrane proteins.[31] Eventually, aggregates of denatured and insoluble protein are visible on light microscopy as Heinz bodies. The distortion of the cellular architecture, and the loss of fluidity in particular, is a signal to reticuloendothelial macrophages to excise sections of erythrocyte membrane (â€œbite cellsâ€•) or to remove the entire erythrocyte from the circulation (â€œhemolysisâ€•; see Hemolysis below). To guard against these oxidation reactions, the erythrocyte maintains a pool of reduced glutathione via the actions of the NADPH generated in the hexose monophosphate shunt (assuming adequate G6PD activity to initiate this pathway). This glutathione transfers electrons to break open disulfide links and to preserve sulfhydryl groups in their reduced state.

Hemolysis

Hemolysis is merely the acceleration of the normal process by which senescent or compromised erythrocytes are removed from the circulation.[162] The normal life span of a circulating erythrocyte is approximately 120 days, and any reduction in this life span represents some degree of hemolysis. If sufficiently rapid, hemolysis can overwhelm the regenerative capacity of the erythron, resulting in anemia. Intravascular hemolysis occurs when the rate of hemolysis exceeds the capacity of the reticuloendothelial macrophages to

remove damaged erythrocytes, and free hemoglobin and other intracellular contents of the erythrocyte appear in the circulation. Reticulocytosis, polychromasia, unconjugated hyperbilirubinemia, increased serum lactate dehydrogenase, and decreased serum haptoglobin are characteristic of hemolysis. Hemoglobinemia, hemoglobinuria, and hemosiderinuria can occur with intravascular hemolysis. Specialized tests to measure hemolysis include shortened erythrocyte survival, increased endogenous carbon monoxide generation from heme oxygenase,[170] and increased fecal urobilinogen.

Table 24-2 presents a brief classification of acquired causes of hemolysis relevant to toxicology. Oxidant injury following xenobiotic exposure is one of the triggers of hemolysis, as it may cause irreversible changes in the erythrocyte. Xenobiotics can also interact with the immune system to cause hemolysis. Finally, erythrocytes deficient in G6PD by virtue of cell age or enzyme mutations are particularly vulnerable to hemolysis following oxidant stress due to limited capacity to generate NADPH and reduced glutathione.

TABLE 24-2. Xenobiotics Causing Acquired Hemolysis

Immune-mediated
  Type I: Drug-red cell complex; IgG triggers complement
  Type II: Immune complex mediated; IgM triggers complement
  Type III: True autoimmune response to red cell membrane
Nonimmune-mediated
  Oxidants (see Table 24-3)

Nonimmune-Mediated Causes of Xenobiotic-Induced Hemolysis

A number of xenobiotics or their reactive metabolites can cause hemolysis via oxidant injury; Table 24-3 provides a partial list. A Heinz-body hemolytic anemia can result, which typically resolves within a few weeks of drug discontinuation. Some xenobiotics cause hemolysis in the absence of overt oxidant injury (Table 24-2). Copper sulfate hemolysis is described in Chap. 90, and the delayed hemolysis following exposure to arsine or stibine are described below.

Arsine

Arsine is a colorless, odorless, nonirritating gas that is 2.5 times denser than air (Chap. 85). It is produced by the action of water on a metallic arsenide, as can occur during the processing of crude metal ores. It is also widely used as a dopant in the semiconductor industry, and less frequently for galvanizing, soldering, etching, and lead plating. Clinical signs and symptoms appear after a latent period of up to 24 hours after exposure to concentrations above 30 ppm, and may include headache, malaise, dyspnea, abdominal pain with nausea and vomiting, hepatomegaly, hemolysis with hemoglobinuric renal failure, and death.[30,49,77,86,136] Delayed effects include bone marrow suppression, desquamation, and peripheral neuropathy. The mechanism of hemolysis is believed to involve the fixation of arsine by sulfhydryl groups of hemoglobin and other essential proteins.[59,187] Interestingly, hemolysis is prevented in vitro by conversion to carboxy- or methemoglobin.[65] Impairment of membrane proteins including Na^+-K^+-ATPase is another potential mechanism for arsine-induced hemolysis.[143] Chronic exposure to low levels of arsine can produce clinically significant disease.[30] The treatment of choice is cessation of exposure and supportive care. In extreme cases, exchange transfusion can be used, in part to reduce

the body burden of arsenic. Stibine likely causes hemolysis via similar mechanisms.

Immune-Mediated Hemolytic Anemia

The immune-mediated hemolytic anemias occur when ingested xenobiotics trigger an antigen antibody reaction (see Table 24-2).[134] In general, drug molecules are too small to be sensitizing agents. Antigenicity is acquired following the binding of molecules to carrier proteins in blood. The particulars of the xenobiotic-carrier immune activation sequence form the basis for the classification of this group of hemolytic anemias.[158,159]

The first class of reaction (hapten model) occurs when the xenobiotic acts as a hapten and binds to cell membrane glycoproteins on the surface of the erythrocyte. This results in the formation of a neoantigen, against which IgG develop, and subsequent removal of the erythrocyte by splenic macrophages. The prototype of this reaction is the hemolytic anemia observed following high-dose penicillin therapy.[50] Historically, approximately 3% of patients treated with megadose penicillin over weeks for infectious endocarditis developed a positive direct Coombs test, demonstrating the erythrocytes were coated with IgG or complement. The positive direct Coombs test is a necessary, but insufficient, condition for the hemolytic reaction. Discontinuation of the xenobiotic results in cessation of hemolysis, because its presence is needed for antibody binding.

The second class of reaction (immune complex) occurs with drugs that have a low affinity for cellular membrane glycoproteins. Examples are quinine, quinidine, and newer-generation cephalosporins, such as cefotetan, cefotaxime, and ceftriaxone. Small doses of xenobiotics result in hemolysis, and erythrocyte injury is primarily mediated by complement. Complexes of drug and IgM are implicated as the complement trigger in this second process.

The third class of reaction (true autoimmune) occurs when the xenobiotic alters the natural suppressor system, allowing the formation of antibody to cellular components. This is a true autoantibody reaction directed against erythrocyte surface antigen.[9] The classic example is Î±-methyldopa, but chlorpromazine, cladribine, cyclosporine, fludarabine, levodopa, and procainamide can also trigger autoimmune hemolysis.[93,121,148] An indirect Coombs test that is positive in the absence of drug demonstrates the presence of IgG autoantibodies in the patient's serum when incubated with normal erythrocytes. The severity of hemolysis is variable, but can continue for weeks to months despite removal of the inciting agent.

Glucose-6-Phosphate Dehydrogenase Deficiencies

G6PD is the enzyme that catalyzes the first step of the hexose monophosphate shunt: the conversion of glucose-6-phosphate to phosphogluconolactone. In the process, $NADP^+$ is reduced to NADPH, which the erythrocyte uses to maintain a supply of reduced glutathione and to defend against oxidation. It follows that erythrocytes deficient in G6PD activity are less able to resist oxidant attack and, in particular, to maintain sulfhydryl groups of hemoglobin in their reduced state, resulting in hemolysis. It is important to recognize that the term G6PD deficiency encompasses a wide range of differences in enzyme activities among individuals. These differences may result from decreased enzyme synthesis, altered catalytic activity, or reduced stability of the enzyme. Approximately 7.5% of the world population is affected to some degree, with more than 400 variants having been identified. Most cases involve relatively mild deficiency and minimal morbidity.[17,29,108] Ethnic populations from tropical and subtropical countries (the so-called malaria belt) have a much higher prevalence of G6PD deficiency, possibly because that phenotype protects against malaria.[122]

The gene that encodes for G6PD resides near the end of the long arm

of the X-chromosome. Most mutations consist of a single amino acid substitution, as complete absence of this enzyme is lethal. Although males hemizygous for a deficient gene are more severely affected, females randomly inactivate one X-chromosome during cellular differentiation according to the Lyon hypothesis. Thus, female carriers heterozygous for a deficient G6PD gene have a mosaic of erythrocytes, some proportion of which express the deficient gene during maturation. Accordingly, approximately 10% of carrier females may be nearly as severely affected as a male hemizygous for the same deficient gene. Because of the high gene frequency in certain ethnic groups, another approximately 10% of females may be homozygous for the deficient gene.

Normal G6PD has a half-life of about 60 days. Because the erythrocyte cannot synthesize new protein, the activity of G6PD normally declines by approximately 75% over its 120-day life span. Consequently, even in unaffected individuals, susceptibility to oxidant stress varies based on the age mix of circulating erythrocytes. In all cases, older erythrocytes are less likely to recover following exposure to an oxidant and will hemolyze first. Moreover, after an episode of hemolysis following acute exposure to an oxidant stress, the higher G6PD activity of surviving erythrocytes will confer some resistance against further hemolysis in most individuals with relatively mild deficiency, even if the offending xenobiotic is continued. In fact, phenotypic testing for G6PD deficiency is best done 2 to 3 months after a hemolytic crisis, after the reticulocyte count has normalized.

The World Health Organization classification of G6PD is based on the degree of enzyme deficiency and severity of hemolysis.[19] Both classes I and II patients are severely deficient, with less than 10% of normal G6PD activity. Class I individuals are prone to chronic hemolytic anemia, whereas class II patients experience intermittent hemolytic crises. Class III patients have only moderate (10â€“60%) enzyme deficiency, and experience self-limiting hemolysis in response to certain drugs and infections. Approximately 11% of

African Americans have a class III deficiency, traditionally termed type A^-, and experience a decline of no more than 30% of the red blood cell mass during any single hemolytic episode. Another 20% of African Americans have type A^+ G6PD enzyme, which is functionally normal, and therefore of no consequence despite a 1-base substitution compared to wild-type B of G6PD. The Mediterranean type found in Sardinia, Corsica, Greece, the Middle East, and India is a class II deficiency, and hemolysis can occur spontaneously or in response to ingestion of Î²-glycosides found in *Vicia fava* beans.

The most common clinical presentation of previously unrecognized G6PD deficiency is the acute hemolytic crisis. Typically, hemolysis begins 1 to 4 days following the exposure to an offending xenobiotic (Table 24-4). Infections such as pneumonia, viral

hepatitis, and *Salmonella* also frequently cause hemolysis. Jaundice, pallor, and dark urine may occur with abdominal and back pain. A decrease in the concentration of hemoglobin occurs. The peripheral smear demonstrates cell fragments and cells that have had Heinz bodies excised. Bone marrow stimulation results in a reticulocytosis by day 5 and an increased erythrocyte mass. In general, a normal bone marrow can compensate for ongoing hemolysis, and can return the hemoglobin concentration to normal. Most crises are self-limiting because of the higher G6PD activity of younger erythrocytes. Historically, the anemia observed when primaquine was administered to type A^- military recruits for malaria prophylaxis resolved within 3 to 6 weeks in most cases.[18] Some xenobiotics, including acetaminophen, vitamin C, and sulfisoxazole, are safe at therapeutic doses but can cause hemolysis in G6PD-deficient patients following overdose.[161,164,188]

TABLE 24-4. Xenobiotics That Can Cause Hemolysis in Patients with Class I, II, or III G6PD Deficiency

Doxorubicin	Phenylhydrazine
Furazolidone	Primaquine
Isobutyl nitrite	Sulfacetamide
Methylene blue	Sulfamethoxazole
Nalidixic acid	Sulfanilamide
Naphthalene	Sulfapyridine
Nitrofurantoin	Toluidine blue
Phenazopyridine	Trinitrotoluene

Adapted from Beutler E: Glucose-6-phosphate dehydrogenase deficiency. N Engl J Med 1991;324:169â€“174, and Beutler E: G6PD deficiency. Blood 1994;84:3613â€“3636.

Other presentations of more severe variants of G6PD include neonatal jaundice and kernicterus, chronic hemolysis with splenomegaly and black pigment gallstones, megaloblastic crisis caused by folate deficiency, and aplastic crisis after parvovirus B19 infection.

Megaloblastic Anemia

Vitamin B_{12} and folate are essential for DNA synthesis. They serve as cofactors in the methylation of deoxyuridine monophosphate to deoxythymidine monophosphate. A deficiency of B_{12} or folate may result from nutritional factors, or the use of the folate antagonists methotrexate, pyrimethamine, proguanil, and trimethoprim-sulfamethoxazole. Vitamin B_{12} metabolism can be affected by chronic exposure to nitrous oxide, biguanides, colchicine, and neomycin. Purine analogs (eg, azathioprine, 6-mercaptopurine, 6-thioguanine, acyclovir) and pyrimidine analogs (eg, 5-fluorouracil, 5-azacitidine, and zidovudine) can also disrupt nucleic acid synthesis. Typically, the result is a megaloblastic anemia, with characteristic nuclear-cytoplasmic asynchrony in erythrocyte precursors in the marrow and ineffective erythropoiesis.[141] Chronic ethanol abuse can result in a macrocytic anemia, with increased size of circulating erythrocytes.

Pure Red Cell Aplasia

Pure red cell aplasia is an uncommon condition in which erythrocyte precursors are absent from an otherwise normal bone marrow. It results in a normocytic anemia with inappropriately low reticulocyte count. The other blood cell lines are unaffected, unlike aplastic anemia. Drugs cause less than 5% of cases of this uncommon condition, having been implicated in fewer than 100 human reports.[175] Applying the Naranjo scale of causality to these reports, only phenytoin, azathioprine, and isoniazid meet the threshold of definite causality; chlorpropamide and valproic acid can only be considered as possible causes.[175] Most other xenobiotics are cited only in single case reports, and drug rechallenge was not used, making the association uncertain.

Erythrocytosis

Erythrocytosis denotes an increase in the red cell mass, either in

absolute terms or relative to a reduced plasma volume. An increasingly recognized cause of drug-induced absolute erythrocytosis is the abuse of recombinant human erythropoietin by athletes to enhance aerobic capacity.[27,52,57,168] Autologous blood transfusions (doping) are also used in this population, and both can cause dangerous increases in blood viscosity. Cobalt can cause a secondary erythrocytosis by inhibiting oxidative phosphorylation (histotoxic anoxia), and once was considered for the treatment of chronic anemia.[43]

The Leukon

The leukon represents all leukocytes (white blood cells), including precursor cells, cells in the circulation, and the large number of extravascular cells, which include the granulocytes (neutrophils, eosinophils, and basophils), lymphocytes, and monocytes. Neutrophils (polymorphonuclear leukocytes) are highly specialized mediators of the inflammatory response, and are a primary focus of concern regarding hematologic toxicity of xenobiotics. B and T lymphocytes are involved in antibody production and cell-mediated immunity. Monocytes migrate out of the vascular compartment to become tissue macrophages and to regulate immune system function.

Neutrophils provide the primary defense against the invasion of bacterial and fungal pathogens. They emerge from the bone marrow with the biochemical and metabolic machinery needed for the efficient killing of microorganisms. Neutrophils are activated when circulating cells detect low levels of chemokines released from sites of inflammation.[102] On activation by invading organisms, they undergo conformational and biochemical changes that transform them from resting cells into powerful host defenders.[109] These changes allow rolling along the endothelial lining of postcapillary venules, migration toward the site of inflammation, adherence to the endothelium, migration through the endothelium to tissue sites,

ingestion, killing, and digestion of the inciting agent.[109]

Neutrophils migrate to sites of infection along gradients of chemoattractant mediators. An acute inflammatory stimulus leads to the accumulation of neutrophils along the endothelium of postcapillary venules.[26] The major molecules involved in this process fall into a few basic superfamilies: the selectins and their mucin ligands, the integrins and their extracellular matrix, or immunoglobulin superfamily ligands. Loose adhesions between neutrophils and endothelium are made and broken, resulting in the slow movement of leukocytes along endothelium and a more intense exposure of neutrophils to activating factors. Chemotaxis requires responses involving actin polymerizationâ€“depolymerization adhesion events mediated by integrins and involving microfilamentâ€“membrane interactions.[21] Colchicine depolymerizes microfilaments, causing the dissolution of the fibrillar microtubules in granulocytes and other motile cells, impairing cellular function.

Opsonized particles, immune complexes, and chemotactic factors activate neutrophils in tissues by binding to cell surface receptors.[166] The neutrophil makes tight contact with its target, and the plasma membrane surrounds the organism completely enclosing it. Phagocytosing neutrophils undergo a burst of oxygen consumption caused by an NADPH oxidase complex that assembles at the phagosomal membrane. Electrons are transferred from cytoplasmic NADPH to oxygen on the phagosomal side of the membrane, generating superoxide, hydrogen peroxide, hydroxyl radical, singlet oxygen, hypochlorous acid, chloramines, nitric oxide, and peroxynitrite.[62] Cytoplasmic granules within the neutrophil fuse with the phagosome and empty their contents into it. There are at least 4 different classes of granules.[62] The components of these granules include myeloperoxidase (MPO), elastase, lipases, metalloproteinases, and a pool of CD11b/CD18 proteins,

which must be rapidly mobilized upon neutrophil activation for adhesion and migration.[144] Finally, the phagocytized organism is

digested and eliminated by the neutrophil. Overstimulation of this complex and highly regulated system can at times become deleterious, as is postulated to occur with reperfusion injury or carbon monoxide poisoning, to cite two examples.[174,182]

Neutropenia and Agranulocytosis

Neutropenia is a reduction in circulating neutrophils at least 2 standard deviations below the age norm. Severe neutropenia is termed *agranulocytosis*, and is generally defined to be an absolute neutrophil count of less than 0.5 Ã— 10^9/L. Neutropenia can result from decreased production, increased destruction or retention of neutrophils in the various storage pools. Their high rate of turnover renders neutrophils vulnerable to any xenobiotic that inhibits cellular reproduction. As such, the various antineoplastic xenobiotics including antimetabolites, alkylating agents and antimitotics will predictably cause neutropenia. This predictable, dose-dependent reaction serves as an important dose-limiting adverse effect of therapy. On the other hand, a number of xenobiotics are implicated in idiosyncratic neutropenia. Table 24-5 provides an abbreviated list.[171]

Eosinophilia

Eosinophilia is arbitrarily classified as mild (absolute eosinophil counts of 0.35â€“1.5 Ã— 10^9/L), moderate (1.5â€“5 Ã— 10^9/L) or severe (>5 Ã— 10^9/L). Allergic or inflammatory reactions, infections with parasites, and certain malignancies, such as lymphoma, are the most common causes of eosinophilia.[150] Two unusual toxicologic outbreaks were characterized by eosinophilia. The first outbreak, named the toxic oil syndrome, took place in central Spain in 1981, when industrial-use rapeseed oil denatured with 2% aniline was fraudulently sold as olive oil by door-to-door salesmen.[53] The ingestion of this oil resulted in the acute onset of cough, fever, and pulmonary infiltrates, followed by severe myalgia, neuropathy, and

eosinophilia. The precise causative agent remains uncertain, but may include fatty acid esters of 3-(*N*-phenylamino)-1,2-propanediol.[53] The second outbreak, called the eosinophilia-myalgia syndrome, occurred during 1988 and 1989 in users of L-tryptophan supplements traced back to a single wholesaler in Japan.[5] The causative contaminant has not been identified, but is believed to have been present in only trace quantities in the L-tryptophan purified from microbial culture. Both syndromes appear to be mediated by immunologic mechanisms.

Leukemia

The leukemias represent the malignant, unregulated proliferation of hematopoietic cells. Although monoclonal in origin, they affect all cell lines derived from the progenitor cell. Acute myeloid leukemia (AML) and the myelodysplastic syndromes are the most common leukemias associated with xenobiotics. The long-recognized association between AML and occupational benzene exposure, radiation, or treatment with alkylating antineoplastic agents has helped to advance understanding of the molecular mechanisms underlying leukemogenesis.[14] The necessary events are believed to involve several sequential genetic and epigenetic alterations, as evidenced by a distinct pattern of chromosomal deletions preceding the development of AML.[72,73] Other recognized xenobiotics that can cause leukemia include topoisomerase II inhibitors, 1,3-butanediol, styrol, ethylene oxide, and vinyl chloride.[82] In many cases, the latency period between exposure and illness is prolonged. For example, leukemia linked to benzene is preceded by several months of anemia, neutropenia, and thrombocytopenia. Benzene or other petroleum products are not believed to cause multiple myeloma.[14]

TABLE 24-5. Selected Causes of Idiosyncratic Drug-Induced Agranulocytosis

- Anticonvulsants
  - Carbamazepine
  - Phenytoin

- Hydrochlorothiazide

Hypoglycemics
- Chlorpropamide
- Tolbutamide

Sedative-hypnotics
- Barbiturates
- Flurazepam

Hemostasis

In the absence of pathology, blood remains in a liquid, flowing form with cells in suspension. In response to injury, the processes of coagulation and thrombosis are triggered. The result, including clot formation, retraction, and dissolution involves an interaction between the vessel endothelium, soluble constituents of the coagulation system, and receptors and intracellular proteins contained on the surface of and within platelets. Platelet function is influenced by the physical properties of flowing blood, as well as by the chemical constituents within it. Platelets respond to signals within their immediate environment and from injured components of the distant microcirculation. A dynamic balance must be maintained between coagulation and fibrinolysis to maintain the integrity of the circulatory system (Fig. 24-4).

Coagulation

Two basic pathways are involved in the initiation of coagulation. Activation of the intrinsic system occurs when blood is exposed to tissue factor in damaged blood vessels or on the surface of activated leukocytes. Tissue factor binds factor VIIa, forming the intrinsic

tenase complex, which activates factors IX and X. Factor IXa binds to the surface of activated platelets together with VIIIa and calcium, forming the extrinsic tenase complex. Factor X, which is activated by extrinsic and intrinsic tenase, binds to factor Va on the surface of activated platelets, forming the prothrombinase complex. The prothrombinase complex activates prothrombin, which results in the generation of thrombin activity. Thrombin

activates platelets, promotes its own generation by activation factors V, VIII, and XI, and converts fibrinogen to fibrin (Chap. 57).[66]

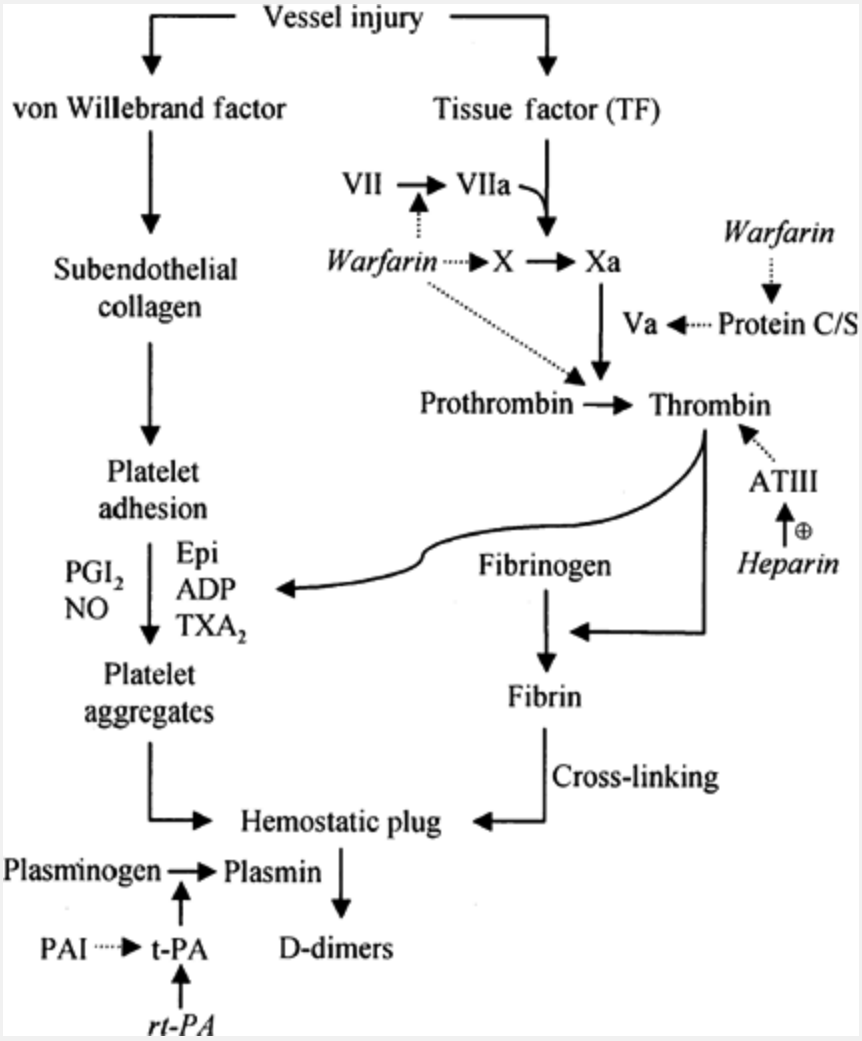

Figure 24-4. The relationships between thrombosis, coagulation, and fibrinolysis. Although these pathways are shown independently, they are intricately linked as outlined in the text. Dotted lines indicate inhibition; drugs are shown in italics. ATIII = antithrombin III; PAI = plasminogen activator inhibitor; t-PA = tissue plasminogen activator; rt-PA = recombinant t-PA; [circled plus] = activation of catalytic activity.

Fibrinolysis

The coagulation system is opposed by three major inhibitory systems. As with the coagulation cascade, components of the fibrinolytic system circulate as zymogens, activators, inhibitors, and cofactors.[46] Plasminogen can be activated to plasmin by an intrinsic pathway involving factor XII, prekallikrein, and high-molecular-weight kininogen. This produces the degradation products and fibrin monomers that are found in disseminated intravascular coagulation. The extrinsic pathway involves the release of tissue plasminogen activator (t-PA) from tissues and urokinase plasminogen activator (u-PA) from secretions.[46] Once activated, plasmin can degrade fibrinogen, fibrin, and coagulation factors V and VIII. The degradation of cross-linked fibrin strands results in the formation of D-dimers.

Several inhibitors oppose the fibrinolytic system, including Î±$_2$-antiplasmin, Î±$_2$-macroglobulin, both of which oppose plasmin activity, and plasminogen activator inhibitor (PAI) types 1 and 2, which oppose t-PA. PAI-1 and -2 are opposed by activated protein C and protein S. Activated protein C is activated by thrombin. Congenital deficiencies of proteins C and S may result in pathologic venous thrombosis. Decreased fibrinolytic activity may result from decreased synthesis, release of t-PA, or from an elevation of the PAI-1 level. Both conditions have been observed postoperatively, with the use of oral contraceptives, in the third trimester of pregnancy,

and in obesity. The activity of Î±$_2$-antiplasmin and Î±$_2$-macroglobulin are increased in pulmonary fibrosis, malignancy, infection, and myocardial infarction, and in thromboembolic disease.[46]

Platelets

In the resting state, platelets maintain a discoid shape. The platelet membrane is a typical trilaminal membrane with glycoproteins, glycolipids, and cholesterol embedded in a phospholipid bilayer. The plasma membrane is in direct continuity with a series of channels, the surface-connected canalicular system (SCCS), which is sometimes referred to as the open canalicular system. The SCCS provides a route of entry and exit for various molecules, a storage pool for platelet glycoproteins, and an internal reservoir of membrane that may be recruited to increase platelet surface area.[129] This facilitates platelet spreading and pseudopod formation during the process of cell adhesion.

The glycocalyx, or outer coat, is heavily invested with glycoproteins that serve as receptors for a wide variety of stimuli. The Î²$_1$-integrin family includes receptors that mediate interactions between cells and mediators in the extracellular matrix, including collagen, laminin, and fibronectin.[163] The Î²$_2$-integrin receptors are present in inflammatory cells and platelets and are important in immune activation. The Î²$_3$-integrin receptors (also known as cytoadhesins) include the glycoprotein (GP) IIb-IIIa fibrinogen receptor, as well as vitronectin.[66] Vitronectin has binding sites for other integrins, collagen, heparin, and components of complement. All of the integrins are active in the process of platelet adhesion to surfaces. Platelet aggregation is mediated by the GP IIb-IIIa receptors.[66]

The submembrane region contains actin filaments that stabilize the platelets' discoid shape and are involved in the formation and stabilization of pseudopods. They also generate the force needed for the movement of receptor-ligand complexes from the outer plasma membrane to the SCCS. These mobile receptors are important in the

spreading of platelets on surfaces, and for binding fibrin strands and other platelets. Platelet cytoplasm contains three types of membrane bound secretory granules.[66] The Î± granules contain Î²-thromboglobulin, which mediates inflammation, binds and inactivates heparin, and blocks the endothelial release of prostacyclin. In addition, platelet factor-4, which inactivates heparin, and fibrinogen are contained within the Î± granules. Dense granules store adenine nucleotides, serotonin, and calcium, which are secreted during the release reaction. Platelet lysosomes contain hydrolytic enzymes. Stimulation by platelet agonists causes the granules to fuse with the channels of the SCCS, driving the contents out of the platelets and into the surrounding media.

Platelet Adhesion

In the vessel wall, collagen, von Willebrand factor (vWF), and fibronectin are the adhesive proteins that play the most prominent role in the adhesion of platelets to vascular subendothelium.[163] On the exposure of collagen (eg, following a laceration or the rupture of an atherosclerotic plaque), platelet adhesion is triggered. Under conditions of high shear (flowing blood), platelet adhesion is mediated by the binding of GP Ib-IX receptors on platelet membranes to vWF in the vascular subendothelium.[66,163] Following adherence of platelets to subendothelial vWF, a conformational change in GP IIb-IIIa on platelet membrane occurs, activating this receptor complex to ligate vWF and fibrinogen. The result is the amplification of platelet adhesion and aggregation. An important interaction occurs between thrombosis and inflammation. Platelet-activating factor is synthesized and coexpressed with P-selectin on

the surface of the endothelium in response to mediators such as histamine or thrombin. Platelet-activating factor interacts with a receptor on the surface of neutrophils that activates the CD11/CD18 adhesion complex, and results in adhesion of neutrophils to endothelium and to platelets. This results in the synthesis of

leukotrienes and other mediators of inflammation.

Platelet Activation

Thrombin, collagen, and epinephrine can activate platelets. In response to thrombin, Î± granules fuse with each other and with elements of the SCCS to form secretory vesicles.[129] These vesicles are believed to fuse with the surface membrane, releasing their contents into the surrounding medium. The membranes of the secretory granules become incorporated into the platelet surface membrane.

Platelet Aggregation

Following activation, GP IIb-IIIa is expressed in active form on platelet surface. This receptor binds exogenous calcium and fibrinogen. GP IIb-IIIa ligates fibrinogen along with fibronectin, vitronectin, and vWF, resulting in the binding of platelets to other platelets, and ultimately the formation of the platelet plug. Collagen-induced platelet aggregation is mediated by adenosine diphosphate (ADP) and thromboxane A_2. ADP binds to the metabotropic purine receptors P2Y1 and P2Y12, leading to transient and sustained aggregation, respectively.[51] Thromboxane A_2 is formed from arachidonic acid by the action of cyclooxygenase (COX) 1. It is a potent vasoconstrictor and inducer of platelet aggregation and release reactions.[66] Platelets participate in triggering the coagulation cascade by binding coagulation factors II, VII, IX, and X to membrane phospholipid, a calcium-dependent process.

Xenobiotic-Induced Defects in Coagulation

Warfarin

The recognition of a hemorrhagic disease in cattle in the 1920s and

the isolation of the causative agent dicoumarol from spoiled sweet clover in the 1940s resulted in the development of the warfarin-type anticoagulants (Chap. 57). This group of anticoagulants indirectly inhibits hepatic synthesis of coagulation factors II, VII, IX, X, and proteins C and S.[135] Hepatic Î³-carboxylation of glutamic acid residues by vitamin K-dependent carboxylase results in the formation of the vitamin K-dependent clotting factors. Vitamin K must be available in its reduced form, vitamin K quinol, to effectively catalyze this reaction. The carboxylation reaction oxidizes vitamin K quinol to vitamin $K_{2,3}$ epoxide, which must be reduced to vitamin K by reductase enzymes. The warfarin anticoagulants inhibit the reductase that is responsible for the regeneration of vitamin K quinone from vitamin K epoxide, impairing the synthesis of the vitamin K-dependent proteins.[85,165]

Heparin

Heparin is a highly sulfated glycosaminoglycan that is normally present in tissues. Commercial unfractionated heparin is either bovine or porcine in origin, and consists of a mixture of polysaccharides with molecular weights ranging from 4000â€“30,000 daltons. It is used extensively for the prophylaxis and treatment of venous thrombosis and thromboembolism. It is ineffective orally because it cannot cross membranes. This same property makes it safe for use during pregnancy because heparin cannot cross the placenta.[151] The anticoagulant activity of heparin is through its catalytic activation of antithrombin III. Antithrombin III is a serine protease that inactivates thrombin and factor X.[119]

Adapted from Fareed J, Hoppensteadt DZ, Jeske WP, et al: Acquired defects of fibrinolysis associated with thrombosis. Semin Thromb Hemost 1999;25:367â€“374.

The low-molecular-weight heparins (LMWHs) have a mean molecular weight of 4000â€“6000 Da.[66] The pharmacokinetics and bioavailability of the LMWHs are more predictable, eliminating the need for close monitoring. They exhibit lower protein binding and a longer half-life, making them more convenient to use.[119]

Xenobiotic-Induced Defects in Fibrinolysis

Table 24-6 lists xenobiotics associated with an acquired defect of fibrinolysis. The antitumor agents may result in a reduction in serine protease inhibitors such as antithrombin. L-Asparaginase is associated with a reduction in circulating t-PA levels. Methotrexate can damage vascular endothelium, which may trigger thrombosis (Chap. 52).[46] Hemostatic drugs used therapeutically include the

synthetic lysine derivatives aminocaproic acid and tranexamic acid, which bind reversibly to plasminogen; the bovine protease inhibitor aprotinin, which inhibits kallikrein; the vasopressin analog desmopressin, which increases plasma concentrations of factor VIII and vWF; and conjugated estrogens, which normalize bleeding times in uremia.[105]

Antiplatelet Agents

Aspirin

Aspirin inhibits COX by the irreversible acetylation of a serine residue at the active site of the enzyme. Aspirin inhibition of the COX-1 isoform of this enzyme is 100â€“150 times more potent than its inhibition of the COX-2 isoform. The inhibition of COX-1 results in the irreversible inhibition of thromboxane A_2 formation. Because platelet activation by other mechanisms, such as thrombin, remain intact, thrombosis can develop despite aspirin therapy (Chap. 35).[156]

Selective COX-2 Inhibitors

Platelets express primarily COX-1 and use it to produce mostly thromboxane A_2, which leads to platelet aggregation and vasoconstriction. Endothelial cells express COX-2 and use it to produce prostaglandin I_2, an inhibitor of platelet aggregation and a vasodilator. Whereas aspirin and traditional (nonselective) nonsteroidal antiinflammatory medications inhibit the production of thromboxane A_2 and prostaglandin I_2 at both sites, the selective COX-2 inhibitors do not affect platelet-derived thromboxane A_2, perhaps accounting for the increase in cardiovascular events associated with long-term use of some of these xenobiotics.[34,79,89,104,167,180]

GP IIb-IIIa Antagonists

The GP IIb-IIIa antagonist abciximab is a chimeric human-murine monoclonal antibody that binds the GP IIb-IIIa receptor of platelets and megakaryocytes. Two synthetic GP IIb-IIIa receptor antagonists have been developed: eptifibatide and tirofiban. These agents are used primarily in patients undergoing

percutaneous coronary interventions.[66] Reversible thrombocytopenia can occur within hours of initiation of these xenobiotics.

Thienopyridines

The prodrugs clopidogrel and ticlopidine antagonize ADP-mediated platelet aggregation by noncompetitive inhibition of ADP binding to the P2Y12 receptor.[133,142] Both prodrugs are associated with thrombotic thrombocytopenic purpura, as well as neutropenia and aplastic anemia.[11,12,130,131,142] Thrombotic thrombocytopenic purpura is characterized by microangiopathic hemolytic anemia, severe thrombocytopenia, and fluctuating neurologic abnormalities.[117] The hallmark is the presence of platelet aggregates throughout the microvasculature, without fibrin clot, and therefore involves a derangement of platelet aggregation. It is believed that drug-induced autoantibodies inactivate a metalloprotein ADAMTS13, thereby blocking its ability to depolymerize large multimers of vWF and leading to platelet clumping.[6,7,11,181]

Dipyridamole

The pyrimidopyrimidine derivative dipyridamole inhibits cyclic nucleotide phosphodiesterase in platelets, resulting in the accumulation of cyclic adenosine monophosphate and perhaps cyclic guanine monophosphate.

Xenobiotic-Induced Thrombocytopenia

Multiple drugs are reported to cause thrombocytopenia, generally

mediated via the formation of drug-dependent antiplatelet antibodies. Drug-induced platelet antibodies are estimated to occur in 1 in 100,000 drug exposures. Reversible drug binding to platelet epitopes such as GP Ib-IX, GP IIb-IIIa, and plateletâ€“endothelial cell adhesion molecule-1, lead to a structural change that can form or expose a neoepitope target for antibody formation.[6,147] The presence of the drug is required for antibody binding and increased platelet destruction, but there is no covalent bond (as occurs in the hapten model of penicillin binding to the erythrocyte membrane).

Thrombocytopenia can also occur as a result of heparin-induced thrombocytopenia (discussed in Chap. 57), bone marrow toxicity, and thrombotic thrombocytopenic purpura. After excluding these conditions and nontherapeutic exposures, a systematic literature search updated annually lists more than 1000 cases reported in English involving more than 150 xenobiotics.[186] Table 24-7 lists the xenobiotics appearing in multiple cases satisfying criteria for probable to definite causality including drug rechallenge. Nevertheless, a common clinical problem is to distinguish drug-induced thrombocytopenia from idiopathic thrombocytopenic purpura in a patient on multiple medications who develops thrombocytopenia. In the absence of validated laboratory assays for drug-dependent platelet antibodies other than heparin, diagnosis still depends on the clinical course following drug discontinuation and perhaps rechallenge. Large databases exist to provide some guidance regarding past reported experience.[54,146,186]

In patients administered the sensitizing agent de novo, at least 7 days are typically required for the development of the immune response. During rechallenge, thrombocytopenia can develop within 12 hours. Interestingly, the unique ability of GP IIa/IIIb inhibitors such as abciximab to cause thrombocytopenia within hours of first use suggests the presence of preformed antibodies directed against platelet epitopes, perhaps accounting for ex vivo clumping of platelets observed in approximately 0.2% of normal patients having routine automated blood counts.[147] Clinically, fever, chills, pruritus,

and lethargy may occur. The onset of bleeding may be abrupt. Hemorrhagic vesicles may be seen in the oral mucosa.[44] Life-threatening hemorrhage may develop. Laboratory investigations will demonstrate an absence of platelets on peripheral smear, prolongation of the bleeding time, deficient clot retraction, and an abnormal prothrombin consumption test. Bone marrow aspiration will demonstrate normal or increased numbers of megakaryocytes and immature forms. Treatment includes the transfusion of blood products, glucocorticoids, and the withdrawal of the offending agent.

TABLE 24-7. Xenobiotics Reported to Cause Thrombocytopenia as a Result of Antiplatelet Antibodies[a]

Abciximab
Acetaminophen
Aminoglutethimide
Aminosalicylic acid
Amiodarone
Amphotericin B
Carbamazepine
Cimetidine
Danazol
Diclofenac
Digoxin
Eptifibatide
Gold
Heparin
Indinavir
Levamisole
Meclofenamic acid
Methyldopa
Nalidixic acid
Oxprenolol

Procainamide
Quinidine
Quinine
Rifampin
Tirofiban
Trimethoprim-sulfamethoxazole
Vancomycin

[a] Xenobiotics reported in at least 2 cases to have definitely caused immune thrombocytopenia, or in at least 5 cases to have probably caused immune thrombocytopenia following therapeutic use.

Heparin-Induced Thrombocytopenia

An immune response to heparin, manifested clinically by the development of thrombocytopenia and, at times, venous thrombosis, is now recognized to result from antibodies to a complex of heparin and platelet factor 4. The heparinâ€“platelet factor 4 antibody complex can directly activate platelets, and is believed to be the mechanism for the paradoxical thrombosis associated with this condition. Indeed, although bleeding is uncommon, the thrombotic complications that develop in approximately 20% of patients with heparin-induced thrombocytopenia are associated with a mortality rate of up to 30% (Chap. 57).[4]

Summary

The mechanisms of toxic injury to the blood are extremely varied and complex. The response to injury may be idiosyncratic, as in many xenobiotic-related causes of agranulocytosis and aplastic anemia, or predictable, as in the case of significant exposures to ionizing radiation or to benzene. Injury may depend on the presence of certain host factors, such as G6PD deficiency. Xenobiotics may directly injure mature cells or the stem cell pool, thus prohibiting the development of mature cells. Toxicity may result from the amplification of a potentially therapeutic intervention, such as occurs with many chemotherapeutic agents and anticoagulants. Finally, a common theme in hematologic toxicity is the perturbation of homeostatic equilibria that exist between cell proliferation and apoptosis, between immune activation and suppression, or between thrombophilia and thrombolysis. It is therefore important to be aware of these complex pathways in order to better understand, diagnose, and treat toxic injury to the blood.

Chapter 25
Gastrointestinal Principles

Donald P. Kotler

Neal E. Flomenbaum

The gastrointestinal (GI) mucosa, like other mucous membranes, occupies a discrete anatomic niche: the interface between a sterile internal environment and a contaminated external, or luminal environment. Humans are continuously in contact with potential xenobiotics, and the GI mucosa forms part of the initial line of defense. Despite this important responsibility, the GI mucosa lacks a strong physical barrier, with the interface between the internal and external environments being the apical cell membranes of epithelial cells. The reason for this seemingly paradoxical situation is that epithelial cells require intimate contact with the luminal environment in order to carry out their primary functionâ€”the absorption of nutrients, ions, and water. The need for such intimate contact with the external environment makes the GI tract inherently vulnerable. The task of mucosal defense is confounded by a large surface area, which is an adaptation that maximizes absorptive capacity.

The GI tract may be exposed to a wide variety of potentially toxic xenobiotics, including those with diffuse, nonspecific pathogenic effects, such as caustic agents and ionizing radiation, as well as highly specific xenobiotics and microbial pathogens. The GI tract also is vulnerable to the physical effects of foreign bodies, unlike the situation in most other organ systems. The GI tract, including the liver and pancreas, may be targeted specifically by xenobiotics. Alternatively, the gut may play a permissive role by absorbing xenobiotics with systemic toxicity.

Antimicrobial defense in the GI tract is complicated and involves both nonspecific and specific processes. The nonspecific processes include antiinfective and other factors in saliva and other endogenous secretions, gastric acid, the mucus layer overlying the epithelial surface, intestinal motility, and the endogenous flora. In addition, specific molecular pumps, as well as biotransforming enzymes within the epithelial cell, may modify potentially toxic xenobiotics. The mucosal immune system of the GI tract is the largest lymphoid compartment in the body.[15] Antimicrobial defenses include both innate and adaptive immunity. Innate immunity is an antimicrobial defense system that is based on the recognition of nonspecific, nonâ€“self antigens and is mediated through such nonspecific processes as complement activation. In contrast, adaptive immunity is based on the recognition of specific epitopes, and the responses are directed specifically at the invading microbe.

This chapter discusses the role of the GI tract as it relates to toxicology. Anatomic, physiologic, and microbiologic principles are discussed, including the role of the GI tract in the metabolism of xenobiotics. Although the liver is the body's major metabolic organ, the intestines also contribute significantly. Examples of specific GI toxicities and their clinical GI manifestations are discussed.

Anatomic Principles

The luminal GI tract can be divided into 5 distinct structures and luminal environments: oral cavity and hypopharynx; esophagus; stomach; small intestine; and colon. These environments differ in luminal pH, specific epithelial cell receptors, and endogenous flora. The transitional areas between these distinct organs have specialized epithelia and muscular sphincters, with specific functions and vulnerabilities. Knowledge of the anatomy of the transitional areas is particularly important to the localization and management of foreign bodies. The functions of the pancreas and liver are closely integrated with those of the luminal organs, although they are not within the nutrient stream. The liver and its metabolic functions are discussed extensively in Chaps. 13 and 26; the pancreas is discussed below.

The organs of the GI tract are composed of 5 layers: the epithelium, lamina propria, submucosa, muscle layers (circular and longitudinal), and serosa, the latter only in intraperitoneal organs. Some authors combine the epithelial layer, the lamina propria, and the muscularis mucosa into a single compartment, the mucosa. Neural tissue is found diffusely in the intestine, and organized into a neural plexus in the submucosa and between the muscle layers. Immunocompetent cells also are located in all of the layers, with the subpopulations in the epithelium and lamina propria being the best studied.

The major structural adaptations of the intestine are designed to increase the surface area available for absorption. These adaptations include mucosal folds; the so-called valves of Kerckring, which triple surface area; villus formation, which also increases the surface area by a factor of 10; and microvilli on the apical surface of epithelial cells, which increase surface area by a factor of 20. Because of all these anatomic adaptations, the surface area of the intestine is 600-fold greater than that of a simple tube.[103] To provide the cells to cover the surface, cell

proliferation is continuous in the intestinal crypts. Intestinal epithelium is one of the most rapidly proliferating cell compartments in the body, which makes it vulnerable to xenobiotics that affect the cell cycle.

The most specialized cell type in the intestine is the epithelial cell. There is a polarity, distinct to epithelia, in which one side of

the cell (basal) faces â€œselfâ€• while the other side (apical) faces â€œnonâ€“self.â€• To adapt to these different environments and to facilitate the different functions, the apical and basal membranes of the epithelial cell contain different receptors and other surface molecules. The basal layer of the epithelial cell faces the lamina propria and the lamina propria mononuclear cells. In addition to its role as an absorptive organ, the epithelial cell also functions as part of mucosal immune defense, as it communicates with lamina propria cells, both in heralding the presence of microbial pathogens and in downregulating the immune system in the presence of nonpathogenic or probiotic microbes.

An elaborate system has evolved to protect the GI tract from pathogens, which is part of a common mucosal immune system.[94] Mucosal immunity can be divided into an afferent limb, which recognizes a pathogen and induces the proliferation and differentiation of immunocompetent cells, and an efferent limb, which coordinates and effects the immune response. The afferent and efferent limbs of the mucosal immune system are anatomically separate, but intermingled. The afferent system includes discrete lymphoid follicles, which are overlaid by a follicle-associated epithelium, including microfold, or M cells, that promote transit of particulate and soluble antigens to antigen-presenting cells.[69] Once sensitized, immune cells undergo a complicated process of clonal expansion and differentiation, which occurs in mucosal and mesenteric lymphoid follicles, as well as in extraintestinal sites. Immunocompetent cells then return to the intestine and other

mucous membranes, and are scattered diffusely within the epithelial and lamina propria compartments.

The function of the muscle layers is integrated with the enteric nervous system to provide for a coordinated movement of luminal contents through the GI tract so as to maximize absorption and minimize bacterial growth. One level of integration provides for an aborad flow of chyme, which requires a coordinated sequence of muscular contractions and relaxations and leads to segmenting and to peristaltic movements. For unidirectional flow to occur, the intestine distal to the contraction of circular muscle must decrease its muscular tone and increase compliance, while the intestine proximal to the contraction must increase muscle tone and decrease compliance. Furthermore, this gradient of muscular tone and compliance must, itself, move down the intestine. This level of neural control is maintained within the intestine, using a variety of neurotransmitters. The various neural circuits also can be affected by external stimuli originating in the central nervous system, or via xenobiotics. Destruction of the neural circuits at the level of the intestine abolishes neuromuscular coordination and leads to stasis, which presents clinically as pseudoobstruction, that is, absence of propulsion of a meal in the absence of an organic, obstructing lesion.

A second level of neural integration relates to the overall speed of intestinal transit. Digestion and absorption are time-dependent processes and optimal absorption requires adjustment of the luminal environment through secretion of ions and water, to accommodate meals that vary considerably in nutrient composition and density. Osmoreceptors and chemoreceptors in the GI tract fine-tune the digestive and absorptive process by regulating transit and secretion, using a variety of neurocrine, paracrine, and endocrine mechanisms, allowing optimum absorption under a variety of circumstances. For example, hyperosmolar solutions empty more slowly from the stomach than isosmolar solutions.[65] Interference with this integrated response may lead to stasis and

bacterial overgrowth, or rapid transit with decreased absorption and the development of diarrhea. A large number of mediators affect motility, including common neurotransmitters, such as acetylcholine and norepinephrine as well as peptidergic nerves, hormones, cytokines, inflammatory compounds, and others; typically, multiple agents affect motility. In general, parasympathetic impulses promote motility, whereas sympathetic impulses inhibit motility. Other transmitters, such as serotonin, promote transit while others, such as dopamine and enkephalins, slow transit.

The luminal contents also can be considered an anatomic structure, especially the endogenous flora. There are two subcompartments of endogenous flora. Microbes within the bulk luminal contents play a relative small role in the body's economy, except for possible biotransforming functions. Organisms, predominantly anaerobes, also bind to specific receptors in the mucus layer overlying the epithelial cells and may play a more important, but perhaps a poorly understood role, including effects on epithelial cell gene expression. The importance of the endogenous flora is best illustrated by the result of their unintentional eradication during antibiotic therapy, when the pathogenic or toxigenic bacteria that replace them cause functional alterations and clinical symptoms.[7] Differences in the luminal environment in young infants, compared to adults, underlie the endogenous production of botulinum toxin, with the clinical consequence being infant botulism.[18]

Physiologic Principles

Intestinal Absorption

The microenvironment between the bulk luminal contents and the epithelial cells has special properties. An â€œunstirred layerâ€• is characteristic of all tubular structures through which fluids flow.[92]

Whereas the bulk luminal contents move through the GI tract with a velocity that is dependent primarily upon muscle activity, water molecules immediately adjacent to the epithelial cell membrane do not move at all, and water molecules slightly more distant from the epithelial cell may move with a velocity below that of the bulk luminal contents. The unstirred layer has an estimated thickness of about 35 microns, as compared to the (approximately) 5-cm diameter of the small intestine.[57] Although this layer presents little impediment to the diffusion of water-soluble materials, it poses a more substantial problem to the diffusion of lipid-soluble materials. In the stomach, secretion of bicarbonate into the unstirred layer below a mucus layer protects the epithelial cells from gastric acid (pH [congruent] 1).[28] The chemical composition of the unstirred layer also may differ from that of the bulk luminal contents, resulting in a pH immediately adjacent to the epithelial cell that is lower than the pH of the bulk luminal contents. Based on the absorption rates of weak acids, an acidic microenvironment is hypothesized to face the small intestinal epithelium.[85]

The major barrier to the penetration of xenobiotics and microbes is the GI epithelium, a single-cell-thick membrane.[24] The cell membrane is a lipid bilayer that contains proteins, which act as aqueous pores through which certain materials can pass, based on size or molecular structure, providing the basis for semipermeability. The membrane is not continuous as it consists of epithelial cells. However, the epithelial cells are attached to one another by structures known as tight junctions, which are located on the lateral surfaces of the cells, near their apical membranes. The tight junctions have a gap of about 8 Ã…, which allows passage only of water, ions, and low-molecular-weight materials.

Of all the functions of the intestine, the absorption of nutrients, ions, and water is the most important for survival. Nutrient

absorption is a function of the small intestine, while the colon contributes to the absorption of ions and water, and salvages

some malabsorbed carbohydrates. The role of the other GI organs is to prepare food for absorption and to deliver it to the absorptive surface at a rate promoting optimal absorption. For example, the major digestive functions of the oral cavity are to initiate the mechanical and enzymatic breakdown of foods into a form that is optimal for absorption. This process is continued in the stomach, where the gastric antrum further grind foods to particle sizes less than 0.2 mm, in addition to continuing protein digestion.[66] Gastric emptying rates vary in accordance with the chemical and physical characteristics of the meal, and in a manner that optimizes nutrient absorption. Bicarbonate in bile and pancreatic juice neutralize gastric acid. In addition, pancreatic secretions continue the digestive process and yield small molecules that are capable of being hydrolyzed and transported by the intestinal mucosa, while bile salts and lecithin form micelles that maintain products of lipid digestion in solution (emulsion) so that absorption can occur. Ingested food also is diluted with endogenous secretions in order to optimize nutrient absorption. In addition to absorbing ions and water, the colon converts indigestible and unabsorbed materials plus bacteria to solid feces, which are stored and then eliminated.

Multiple factors affect absorption from the intestine, transport from the lumen into the body may occur via transcellular or intercellular routes; absorption may occur by passive or active (energy-using) processes. Passive diffusion through the luminal membrane is directly related to the surface area of the membrane, to the concentration or concentration difference on the two sides of the membrane, to the degree of lipid solubility, and to a diffusion constant that varies with each chemical; passive diffusion is *inversely* related to diffusion distance. Written as an equation, these factors would appear as:

Flux = (Diffusion Constant)(Surface Area)(Concentration Difference)/Diffusion Difference

The diffusion constant, and thus the flux rate, is related to

molecular size. This relationship establishes the principles for clinical permeability tests performed clinically, such as the lactulose-mannitol permeability test, which compares the relative absorption rates of nonmetabolizable monosaccharides and disaccharides.[48] Transcellular transport of many nutrients, ions, and xenobioticsâ€”both uptake at the lumen and excretion at the basolateral membranesâ€”occur via carrier-mediated mechanisms.[1] These transport processes are subject to multiple controls allowing positive and negative adaptations to optimize absorption and limit toxicity, as described for such diverse nutrients as glucose and iron.[67 , 78] Net absorption is a combination of active and passive processes, plus secretion in some situations. The same transport processes may be used both by essential and toxic materials. For example, the absorption of both lead and calcium are increased by vitamin D.[31] The chemotherapeutic agent 5-fluorouracil, and the nucleoside reverse transcriptase inhibitor zidovudine, are absorbed by the same transport process used for the absorption of naturally occurring pyrimidines.

The pH of the luminal contents is important in modulating the absorption of acids and bases. Many xenobiotics are either weak acids or weak bases and the effect of ambient pH is to affect water versus lipid solubility. For example, acids are ionized at basic pH, but nonionized at acid pH.

In contrast, bases are nonionized at basic pH and ionized at acid pH. In general, ionized molecules are more water soluble, whereas nonionized molecules are more lipid soluble. Because the total area of membrane lipid is much greater than that of the membrane's aqueous pores, nonionized xenobiotics typically are absorbed more rapidly than ionized xenobiotics. Thus, one would expect weak acids to be better absorbed in the stomach and weak bases to be better absorbed in the small intestine. This may not always be the case, because surface area is much greater in the intestine than in the stomach.

Salicylate toxicity to the gastric mucosa is a classic example of pH-dependent absorption.[81] Acetyl salicylate (aspirin) is a water-soluble salt of the weak acid salicylic acid, which is poorly soluble in water. At gastric pH, aspirin is converted to the nonionized salicylic acid, which facilitates its uptake through the luminal membrane of the gastric epithelial cell. Once intracellular, the acid dissociates, leading to elevated intracellular concentrations of water-soluble salicylate, which is toxic to the cell.

The pH in the small intestine and colon are higher than in the stomach, which would be expected to favor the uptake of weak bases. However, there is evidence that the pH at the epithelial microenvironment in the intestine is lower than the pH of the bulk luminal contents as a result of the active secretion of an acidic compound; the lower pH at the cell surface facilitates the absorption of weak acids in the small intestine.[85] The actual relationship between nonionized and ionized compounds and pH is specific for each xenobiotic and is related to its ionization constant (pK_a), which is the pH at which 50% of the compound is ionized.

Variation in the diffusion of chemicals across the intestinal membrane also may be important in elimination. For example, acidification of colonic contents may occur as a result of lactulose therapy for hepatic encephalopathy, via production of lactic acid and other short-chain fatty acids in the colon which trap ammonia as NH_4^+ and promote its fecal excretion.[19] Such a process also might affect the ability of multiple doses of activated charcoal to promote elimination of already absorbed xenobiotics.[10]

Other luminal factors affecting absorption include particle size, which is relevant for the ingestion of mercury and other heavy metals. Intestinal transit time can also theoretically modify the absorption of potential xenobiotics, although evidence of efficacy in overdoses is lacking. With respect to the absorption of medications, different types of drug formulations, such as timed release via enteric coating, slowly dissolving matrices, dissolution

control via osmotic pumps, ion exchange resins, pH-sensitive mechanisms, or other mechanisms, can limit bioavailability. In the case of analgesics and other medications with potent CNS effects, the potential for unintentional overdose may be diminished by these formulations, although external manipulation of the product, such as crushing time-release beads prior to ingestion, may circumvent the pharmaceutical design.[71] Stimulation of intestinal transit using magnesium salts or other cathartics is an outdated approach to manipulating transit time in attempting to decrease the absorption of xenobiotics. However, apart from the paucity of any reliable data demonstrating beneficial effects, adverse effects on fluid and electrolyte balance were often problematic. The use of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) in toxicologic management may be thought of as the modern therapeutic approach to decrease transit time of harmful xenobiotics without interfering with fluid and electrolyte balance. Unfortunately, with the possible exception of its use to ameliorate the effects of intentional or unintentional overdoses with iron tablets, the scientific evidence to substantiate the beneficial effects of WBI is limited. Anticholinergic and other antidiarrheal agents may exacerbate microbial or other luminal xenobiotics by

increasing contact time and absorption, and by preventing the innate response of flushing away noxious material. In fact, the Infectious Disease Society of America guidelines on the management of acute diarrhea strongly recommend avoiding the use of antimotility agents in the management of acute diarrhea.

Xenobiotic Metabolism

Although the liver is usually identified as the site of xenobiotic metabolism, similar functions also are found in the luminal GI tract. The stomach has long been known to contain alcohol dehydrogenase activity. Biotransformation is a property both of

luminal bacteria and enterocytes. The consequences of metabolism differ for diverse xenobiotics. Metabolism by the intestine affects the amount of orally administered xenobiotic that enters the body and contributes to the first-pass effect, or presystemic disposition. Variations in intestinal metabolism also may influence the pharmacokinetics of a xenobiotic. Metabolism can result in detoxification or the production of xenobiotics, and the rate of metabolism affects the exposure to xenobiotics by the body as a whole and the epithelial cell.

Intestinal epithelial cells metabolize xenobiotics by multiple types of reactions such as hydroxylation, sulfation, acetylation, and glucuronidation. Intestinal epithelial cells contain many of the same metabolic enzymes as the liver. In addition, epithelial cells contain export pumps, as do hepatocytes and other cells.[101] The responsible agent, P-glycoprotein, is related to the cystic fibrosis transmembrane regulator.[98] P-glycoprotein is involved in chloride secretion and the regulation of cell volume, and is encoded by the multidrug-resistance gene. Its function in the enterocyte likely is the secretion of unmetabolized and metabolized xenobiotic agents directly into the intestinal lumen.

Intestinal epithelial cells contain many metabolic enzymes, with variable specificities. Clinical studies have been performed using pharmacologic â€œcocktailsâ€• of probe substrates, whose metabolic disposal is well understood. For example, the clearance of caffeine, administered orally, is mediated by cytochrome CYP1A2, whereas the clearance of midazolam is mediated by CYP3A. Providing both xenobiotics would allow understanding of the relative metabolic rates of these two enzymes in a given subject. To further determine the relative contributions of intestine and liver in drug metabolism, the relative clearance rates after oral and intravenous administration can be compared. A greater or lesser clearance after oral administration is evidence of metabolic induction and inhibition, respectively.

There is wide variation in the rates of metabolism of xenobiotics between individuals. Demographic variables, such as age and sex,[43] and inherited variables, such as specific polymorphisms, are demonstrated. Metabolism of individual xenobiotics may be affected by foods, herbal products, and other xenobiotics. For example, clinical observations associated the intake of grapefruit juice and Brussels sprouts with xenobiotic toxicity or ineffectiveness. Formal studies then demonstrated the effects of these foods on the pharmacokinetics of certain xenobiotics.[6, 73] Grapefruit juice inhibits intestinal CYP3A and other enzymes, including the P-glycoprotein transporter, which, following ingestion, may lead to exaggerated pharmacologic effects from medications such as calcium channel blockers and statins.[25, 80] One compound in grapefruit juice, 6,7-dihydroxybergamottin, not only directly inhibits CYP3A but also promotes its degradation.[60] The same pharmacokinetic effects were not observed when the some medications were administered intravenously, implying that the effect may be limited to drug metabolism during its transport across the intestinal epithelium, rather than in the liver. This interaction is especially problematic when the grapefruit juice is taken intermittently rather than consistently, as the pattern may be erratic and may consequently go unnoticed.

Many interactions between allopathic medications and herbal products also have been described. For example, observational studies demonstrated that plasma levels of indinavir, digoxin, and other drugs are lowered by concomitant long-term use of St. John's wort.[47, 75] The FDA has further reported interactions between St. John's wort and a wide variety of medications, including oral contraceptives, selective serotonin reuptake inhibitors, HIV protease inhibitors, cyclosporine, and sildenafil.[17] St. John's wort is associated with breakthrough menstrual bleeding and pregnancies occurring in women using oral contraceptives.[83]

The interactions of St. John's wort and the intestine are complex, as the xenobiotic has been found to inhibit intestinal CYP3A4 over

the short-term and to induce intestinal CYP3A and P-glycoprotein over the long-term. Thus, the actual effect of St. John's wort on a drug metabolized by CYP3A4 and/or P-glycoprotein will differ when the drug is initiated, when it is continued, and when it is stopped. Echinacea also affects drug-metabolizing enzymes, specifically inhibiting CYP3A4, CYP2C9, and CYP1A2, and inducing CYP3A activities, leading to reported interactions with theophylline, phenytoin, and cyclosporine.[37]

Drugâ€“drug interactions also may affect the intestine. The interactions may include inhibition or induction. A prominent example is rifampin, which induces CYP3A4 enzymes and P-glycoprotein in both the intestine and liver.[82] Both activities would lead to enhanced drug disposition and decreased effectiveness. Rifampin exerts these effects binding to and activating the pregnane X receptor nuclear transcription factor, and promoting transcription of relevant mRNA in the intestinal epithelium and liver.[35] On the other hand, ketoconazole inhibits P-glycoprotein transporter, which could lead to higher concentrations than expected of administered drug.

Biotransformation and Carcinogenesis

The processes of biotransformation in the intestine are relevant to colonic carcinogenesis. For example, environmental factors, such as diet and tobacco use increase the risk of developing adenomatous polyps or colorectal cancer.[68 , 90] Uridine diphosphate glucuronosyltransferase (UDPGT) catalyzes the conjugation of numerous xenobiotics with uridine diphosphate glucuronic acid. Colonic epithelial cells express several UDPGT isoforms, which may be involved in the detoxification of colorectal carcinogens.[91] Glucuronidation is a critical detoxification pathway for the two major classes of tobacco smoke carcinogens, as well as heterocyclic amines, which are mutagenic compounds that are abundant in tobacco smoke and in fried and broiled meats. It is

possible that other environmental xenobiotics could have similar effects over a period of years. The activities of these detoxifying enzymes vary greatly in different individuals.[89] These differences lead to variable rates of disappearance of the potential carcinogen and, in combination with dose of carcinogen and other factors, could influence the development of carcinoma in an individual.

Microbiologic Considerations

The endogenous flora in the GI tract includes more than 400 different species of bacteria. The number of bacterial â€œcellsâ€• in the intestinal lumen is greater than the total number of host cells, the mass of bacteria is more metabolically active than the liver, and the bacteria have a greater diversity in genetic material than the host. The

concentration of luminal bacteria varies by site, from lowest in the proximal small bowel to highest in the colon. Endogenous bacteria occupy unique niches related to host physiology, environmental pressures, and microbial interactions, which result in long-term stability.[41] There is considerable variation in the composition of the endogenous flora between individuals. The flora may be altered by various insults but returns to baseline once the insults are removed. The endogenous flora affects enterocyte and lamina propria mononuclear cell functions. This is best shown in studies of germ-free animals that are colonized with a single species of bacteria. The intestinal microflora also modifies the intestinal and systemic responses to intestinal injury, as demonstrated by the mild nature of graft-versus-host disease in germ-free animals.[8]

The endogenous flora has multiple metabolic functions. A primary function in the colon is the salvage of malabsorbed carbohydrates by fermentation and production of short-chain fatty acids, which is a preferred substrate for colonic epithelial cells. Hydrolysis of urea occurs following its passive diffusion into the intestinal lumen,

producing NH_3 and a carbon skeleton. Elevated levels of nitrogenous compounds, including ammonia, may result from increased dietary load, or from gastrointestinal hemorrhage, by decreased excretion caused by renal failure, or by decreased clearance, such as occurs in end-stage liver disease with hepatic encephalopathy. Bacterial fermentation of the nonabsorbable disaccharide lactulose in the colonic lumen leads to the production of lactic acid and other short-chain fatty acids, which decrease intraluminal pH and trap nitrogen in the lumen as NH_4^+, conditions that are useful in treating patients with hepatic encephalopathy.[19]

Bacterial metabolism also may affect the disposition of intraluminal compounds. Bacterial metabolism of digoxin contributes to its steady-state concentrations in the body, and antibiotic treatment may reduce or eradicate the intestinal flora, affecting the steady state and predisposing to digoxin toxicity.[20] Bacterial contribution to vitamin K metabolism also is demonstrated by changes in the prothrombin time, necessitating adjustments in the therapeutic doses of warfarin after antibiotic therapy. Bacterial metabolism also affects the composition and concentration of various bile acids and steroid hormones. Bacterial enzymes have been incorporated into treatment strategies, for example, as in the treatment of ulcerative colitis. The first effective drug treatment for this disease was developed by linking 5-aminosalicylic acid, an antiinflammatory agent, to sulfapyridine, thus making it nonabsorbable in the small intestine. This medication only becomes active when bacterial azoreductases in the terminal ileum and colon break the azo bonds, making the products absorbable in the colon at the site of inflammation.[86]

There is considerable evidence that the endogenous flora also might affect carcinogenesis in the intestinal lumen. Because many lipophilic xenobiotics are excreted from the liver after conjugation with glucuronic acid, bacterial Î²-glucuronidases might lead to reabsorption and recirculation of these compounds. In addition,

bacterial Î²-glucosidases may activate carcinogens. For example, germ-free animals do not develop tumors when fed cycasin, but in nonâ€“germ-free animals bacterial metabolism produces methazoxymethanol, a known carcinogen found in the colon.[55] Consumption of a high-beef diet leads to increased fecal bile acid excretion and changes in colonic bacterial metabolism,[39] which may convert a bile salt, chenodeoxycholic acid, into a carcinogen. Bacterial sulfatases also are capable of converting dietary cyclamate to cycloheximine, which is a bladder carcinogen.[13]

The term *probiotics* connotes live, nonpathogenic bacteria and fungi that are part of the normal flora, and which can be used as prophylactic or therapeutic agents. These bacteria compete for and displace pathogenic bacteria from ecologic niches, they directly modulate intestinal immune function, and they exert a trophic effect on the gut. They are being studied to decrease traveler's diarrhea, suppress recurrent *Clostridium difficile* toxin-associated diarrhea, and to reduce the inflammation in ileal pouches after colectomy in patients with ulcerative colitis, among other uses.[14]

An Anatomic Approach to Xenobiotics and the Gastrointestinal Tract

An anatomic approach to the effects of xenobiotics on the lips, mouth, and oropharynx (Table 25-1), the esophagus (Table 25-2),

the stomach (Table 25-3), and the small and large intestines (Table 25-4) is offered in brief in these tables.

TABLE 25-2. Xenobiotics that Affect the Esophagus

The Pancreas and Pancreatic Disease

The pancreas lies in the retroperitoneum, in a transverse fashion, between the second portion of the duodenum and the spleen. The gland serves both exocrine and endocrine functions, with the secretion of pancreatic juice and enzymes as exocrine functions,

and the secretion of insulin, glucagon, and other hormones as endocrine functions. The pancreatic acini contain cells producing digestive enzymes, which flow to the duodenum through the pancreatic ducts. Endocrine cells are found in the islets of Langerhans, which are found diffusely throughout the pancreas.

Pancreatic exocrine function responds to neural, hormonal, and luminal stimuli. The strongest stimulus is the presence of partially digested food in the duodenum, which leads to the release of cholecystokinin and subsequent stimulation of pancreatic secretion and fluid flow, among other effects. Pancreatic exocrine function is inhibited by hormones derived from the distal intestine. Pancreatic enzyme activities are further regulated by the secretion of inactive precursors, which require activation in the intestinal lumen. This is accomplished by the action of trypsin, after the activation of trypsinogen by enterokinase in the duodenum. In fact, amylase and lipase are the only pancreatic enzymes to be secreted in an active form.

TABLE 25-4. Xenobiotics that Affect the Small and Large Intestines

Pancreatitis connotes tissue damage and inflammation. Pancreatitis can be categorized clinically as acute or chronic, based upon course and mild or severe, based upon organ function, systemic effect, complications, and recovery time. Pancreatitis also can be categorized pathologically as interstitial or hemorrhagic. Interstitial pancreatitis features edema and inflammation histologically, plus acinar cell necrosis. In contrast, hemorrhagic pancreatitis features more widespread necrosis and widespread tissue hemorrhage and vascular thrombosis.

Pathogenically, acute pancreatitis usually involves premature activation of pancreatic enzymes in the acinus. Pathogenic mechanisms include both pancreatic hypersecretion and inhibition of secretion. The activity of the pancreatic proteases and other digestive enzymes is opposed by circulating protease inhibitors, $\hat{I}\pm_2$ -macroglobulin, $\hat{I}\pm_1$ -antitrypsin, and others. These latter proteins are acute-phase reactants and are released in response to tissue damage. They act to localize the damage, limit its severity, and prepare for tissue repair, but they respond to the development of pancreatitis and do not play a preventive role.

Although there are multiple etiologies underlying acute pancreatitis, alcohol, and gallstones are the most important. The specific effects of alcohol are uncertain, but may include hypersecretion, sphincter of Oddi spasm, and hypertriglyceridemia.[36] The delivery of ethanol to the pancreatic interstitium and ductal space results in premature release of free fatty acids, hypertriglyceridemia, and subsequent epithelial damage.

Evidence of chronic pancreatitis occurs in the majority, but not all

alcoholic patients with pancreatitis. In contrast, the effect of gallstones in promoting pancreatitis is likely to be physical in nature, that is, an impacted gallstone directly blocks the pancreatic duct. Recent evidence suggests that excess free radicals may exacerbate pancreatitis from many causes.

Xenobiotic-induced pancreatitis is a broad topic with multiple agents, whose association with disease can be listed as definite, likely, or possible (Table 25-5). The pathogenic mechanism varies with the specific xenobiotic, although some xenobiotics, such as the nucleoside reverse transcriptase 2â€²,3â€²-dideoxyinosine, may promote pancreatitis as a result of mitochondrial toxicity.[84] Multiple mechanisms account for xenobiotic-induced pancreatitis. Overstimulation is recognized with exposure to cholinesterase inhibitors, such as parathion[56] or scorpion venom;[76] vasospasm, secondary to ergot alkaloids, is also reported.[23] Acute exposure to excessive amounts of dioxin led to acute pancreatitis in an assassination attempt during the 2004 presidential campaign in the Ukraine.[49] Of more widespread concern, environmental exposures to dioxins are known to produce pancreatic disease with ultrastructural studies demonstrating evidence of mitochondrial damage.[70 , 79]

Direct Toxicity to the GI Tract

There are several important categories of xenobiotics that are directly toxic to the GI tract. Among them are â€œtraditional agentsâ€• such as caustics, ethanol, and other alcohols. In recent years, the potential damage of biologic, chemical, or radiologic weapons to the body in general, and to the GI tract in particular, has become a great concern. Among the biologic agents considered to be potential weapons, botulism, ricin, and staphylococcal enterotoxin B are of particular concern to the GI tract. Exposure to ionizing radiation affects the GI tract to a greater extent than most other areas of the body because of the

rapid cell turnover in the GI tract.

Caustics

Caustics are a commonly available, serious source of direct toxicity to the upper GI tract. Alkaline caustics such as sodium hydroxide (NaOH), the main ingredient in lye, drain cleaners, and oven cleaners, produce liquefactive destruction of the mucosa that may involve all layers of the esophagus and stomach. In contrast, hydrogen ions desiccate epithelial cells and denature proteins, producing an eschar and resulting in what is histologically referred to as coagulation necrosis. In some series, both the gastric and esophageal mucosae are equally affected by acids,[105] while in others, the esophagus is spared and the stomach is severely injured.[38] Although the esophageal lining is well equipped to withstand the effects of brief exposure to pH 1, which is the same concentration of hydrochloric acid as is present in gastric acid, much higher concentrations can be obtained commercially, and the risk of acid damage to the esophagus is most likely related to concentration.

Perhaps as a result of the coagulation necrosis produced by acids in that location, the acid damage to the esophagus may not be as great

as the damage caused there by strong alkalis. However, in marked contrast, the damage to the stomach and the resultant systemic effects of acid ingestion may be devastating. Because of its tendency to perforate the stomach, acid ingestion may result in widespread damage to other abdominal organs including the spleen, pancreas, and biliary tract.[104] Late effects of acid ingestions include esophageal pseudodiverticula, gastric atony, decreased acid secretion, and gastric outlet obstruction.[53] Both acid and alkali ingestions are linked to the subsequent development of squamous cell carcinoma of the esophagus and

stomach, particularly at the gastroesophageal junction.[45]

Exocrine Pancreas	Endocrine (Islets of Langerhans) Pancreas

TABLE 25-5. Xenobiotics Associated with Pancreatitis

Endoscopy cannot provide information about the depth of injury and is best at determining whether there is little or no injury. The most serious toxicity is full-thickness ulceration, with esophageal perforation and the development of mediastinitis. When perforation does not occur, healing is characterized by dense scarring, despite steroid or other therapies,[42, 77] with strictures that can be so irregular and severe as to require surgical intervention to allow food intake (see Fig. 6-22).

For the clinical presentation and treatment of caustic acid and alkali injuries, see Chap. 100 .

Biologics

Botulism is an old disease whose presentation has evolved.[18] Classically a food-borne disease, it also became recognized as a complication of wounds, and is recognized to occur in infants. In addition, the potential use of botulinum toxin as a weapon has been emphasized. In fact, the toxin has been applied both therapeutically and cosmetically.

The toxin is a product of the anaerobic Gram-positive bacterium *Clostridium botulinum* . In food-borne botulism, the toxin is ingested, whereas in young infants, poorly formed normal flora and other products fail to inhibit the organism's growth. For this reason, in situ production of toxin may occur and lead to neurologic impairment. Rarely, a similar complication may occur in an adult.

Ricin is extracted from the seeds of the castor bean, whose

ingestion can be lethal. The toxin is protein in nature and is largely degraded in the GI tract, so that toxicity is 1/100 that of a dose administered parenterally. Ricin and the related compound abrin are dimers. One chain inhibits protein synthesis via an enzymatic effect on the 60 S ribosome subunit. The other chain is a lectin and acts as an agglutinin after being taken up by cells. Clinically, ricin produces a severe inflammatory response resembling, in an experimental mouse model, the hemolytic uremic syndrome.[54] Because of its protein composition, protective vaccination is possible and is being investigated.

Staphylococcal enterotoxins are exoproteins produced by *Staphylococcus aureus* . Exposure to these toxins produces a wide range of GI effects, ranging from mild upset to lethal toxic shock. There are multiple types of staphylococcal enterotoxins. Staphylococcal enterotoxin B may produce typical food poisoning, with 12â€“24 hours of fever, vomiting, diarrhea, and more prolonged anorexia. In addition, the enterotoxin may act as a superantigen and bind directly to major histocompatibility complex class II and T-cell receptors in large numbers of T lymphocytes, leading to massive stimulation and release of huge amounts of proinflammatory cytokines, presenting clinically as toxic shock. The toxin has the ability to bind to a receptor on the apical surface of the intestinal epithelial cell, to be transcytosed intact, and to gain access to the systemic circulation. In experimental animals, lymphoid hyperplasia developed after lethal exposure to the toxin, which is consistent with widespread immune activation.[99] In addition to lymphoid effects, direct toxicity on pulmonary and renal endothelium can be demonstrated. Clinically, a biphasic response occurred, with an early GI syndrome and a later systemic shock syndrome and renal failure.

Radiation

The GI tract is a major site of acute and chronic radiation injury

related either to environmental contamination or to radiation applied for medical use. Radiation damage to normal tissues occurs

by the same mechanisms as the damage intended for a targeted neoplasm.[26] Electrons ejected by high-energy photons as they pass through the body (Compton effect) damage DNA directly or through the generation of free radicals.[59] The result is abnormal cross-linking of the DNA strands (guanineâ€“guanine bonds), which must be excised and repaired, as they interfere with DNA replication and subsequent cell mitosis. The degree of damage is related to the dose of radiation as well as factors intrinsic to individual cells and tissues, such as degree of oxygenation, the cell cycle of the individual cells, and others.[27] As damage from radiation and other agents is a normal phenomenon, the cell has the machinery to repair damaged DNA. Excess radiation injury overwhelms the reparative processes and leads to programmed cell death (apoptosis). Individual variation in the efficiency of the DNA repair processes also may influence the fate of radiation injury, especially the buildup of mutations leading to enhanced carcinogenesis.[46] Such a process underlies the pathogenic mechanism in several familial cancer syndromes (Chap. 128).[62]

The pathology of radiation injury is related to its effect on DNA and subsequent inhibition of cell replication. The vulnerability to radiation-induced damage is related to cell proliferation rate. As stated above, the intestine is one of the most rapidly proliferating organs of the body. Damage is greatest with alpha particles intermediate with beta particles and least with gamma irradiation. However, gamma radiation may penetrate and produce deep injury. Radiation injury can occur to the whole body or may be localized, and can be divided into acute and chronic forms, with the chronic form subdivided into chronic damage and secondary carcinogenesis of either epithelial or stromal origin.

Clinically, acute response to radiation exposure is comprised of

nausea, vomiting, cramps, diarrhea, and dehydration, and may have a neurogenic origin.[50] If there has been significant environmental exposure, or the patient has received total-body irradiation sufficient to ablate the bone marrow, this phase is followed within a few days by diffuse destruction of many cell types in the intestine, including lymphocytes, epithelial cells, and vascular endothelial cells. Damage to the intestinal epithelium is enhanced because of its rapid turnover rate under normal situations. The injury persists at higher doses of radiation, leading to diffuse enteropathy, fluid and protein losses through the GI tract, and Gram-negative bacterial and candidal sepsis of presumed enteric source. Healing is associated with neovascularization and dense fibrogenesis, which promotes stricture formation.

The clinical manifestations of radiation injury in the GI tract are dependent on the specific part of the tract involved.[52] Acute and chronic injury to the esophagus leads to dysphagia from ulcers and edema acutely, and from stricture chronically. Rarely, the injury leads to fistulization. The stomach is relatively radioresistant, although affected in cases of high radiation exposure. In contrast, the small intestine is relatively radiosensitive.[95] Radiation injury is very common clinically, and is usually reversible. Although the colon is thought to be relatively radioresistant, it is frequently involved in cases of pelvic irradiation. The situation is worse in segments fixed in the retroperitoneal space, like the rectum, or in segments immobilized by previous surgery.

Acute injury is related to epithelial cell injury and is usually reversed within 2 weeks. In contrast, chronic radiation injury is a progressive process with an initiation within a few years of radiation but progressive damage for decades.[32] Progressive disease may occur even after resection of severely damaged segments and preservation of â€œhealthyâ€• intestine.[63]

Ethanol

Many studies have documented a wide range of GI toxicity in experimental models of alcohol excess and in people who consume large quantities of ethanol (Table 25-6). The toxicities of alcohols other than ethanol, such as methanol and isopropanol, are generally systemic rather than intestinal, but hemorrhagic gastritis or other effects may occur. The major gastrointestinal toxicity of ethanol occurs in the stomach. Alcohol-induced lesions tend to occur after acute ingestions of 8% or higher concentrations in total volume of intake, and alcohol-associated erosive gastritis (sometimes with the concomitant use of aspirin and/or NSAIDs) may be responsible for a majority of cases of upper GI hemorrhage.[22] As commonly used, the term *alcoholic gastritis* describes the gastric erosions and subepithelial hemorrhages, with or without inflammatory cell infiltrates, seen endoscopically in alcoholics.

Alcohol stimulates the secretion of gastric acid and reduces the transmucosal potential difference, allowing back diffusion of hydrogen ions and increased mucosal permeability.[34] Microscopically, alcohol-induced lesions initially alter cell cytoplasm and nuclei, which is followed by widening of intercellular spaces, focal separation of tight junctions, and disruption of apical membranes.

Most studies of small intestinal mucosa show only minimal light microscopic changes induced by alcohol. However, many people who drink large amounts of ethanol, acutely or chronically, note alterations in bowel habits. On investigation, a number of abnormalities in the GI tract are found, including rapid intestinal transit, decreased intestinal disaccharidase activity, decreased bile secretion as a consequence of alcoholic liver disease, and decreased

pancreatic exocrine secretion as a consequence of chronic

pancreatitis. Markedly decreased absorption of fluid and electrolytes together with ileal and colonic fluid malabsorption has been documented in clinically ill subjects, although the role played specifically by alcohol is uncertain.

TABLE 25-6. Gastrointestinal Effects of Ethanol

Other gastrointestinal lesions that occur with consumption of large quantities of alcohol include reflux esophagitis associated with reduced lower esophageal sphincter pressure, GI hemorrhage associated with mucosal tears at the gastroesophageal junction (Mallory-Weiss syndrome), and esophageal perforation associated with vomiting (Boerhaave syndrome), as well as acute and chronic pancreatitis, hepatitis, and cirrhosis. In a Scandinavian study of 591 first episodes of acute alcoholic pancreatitis, 260 (46%) of the 562 patients who survived the episode developed recurrent disease. The overwhelming majority of patients were men (503) and 80% of the first relapses occurred within 4 years.[74]

Iatrogenic Diseases

Foreign Bodies

For obvious reasons, the esophagus is the site of most foreign bodies, which may be found in the cervical esophagus, at the level of the aortic notch, just above the gastroesophageal junction, or just proximal to an esophageal narrowing.[16] Food impaction is a foreign body composed of ingested food and is often found in the presence of some esophageal narrowing. The likelihood that a foreign object will lodge in the esophagus is related to its size and shape. The major symptoms related to foreign objects in the upper GI tract are pain, bleeding, perforation, or obstruction. The general rule is that nonoperative means can be employed for up to 12 hours, after which time surgery should be considered, as the chances of tissue necrosis and perforation increase after this time.[12]

Foreign bodies also are commonly found in the stomach. Many small foreign bodies will pass through the stomach and the rest of the GI tract without problems, although objects greater than 5 cm in the largest diameter or 2 cm in the smallest diameter may not be able to traverse the duodenum and must be removed

endoscopically[33] or surgically.

Once in the small intestine, the narrowest area and a site for obstruction is the ileocecal valve, whose maximal opening is about 2.5 cm. Probably the most common type of â€œforeignâ€• body to become impacted at the ileocecal valve is a large gallstone, which gives rise to â€œgallstone ileus.â€•

Foreign objects in the rectum usually are introduced retrograde and may be low-lying in the rectum, or high-lying, above the rectosigmoid junction.[51] Low-lying foreign objects usually can be removed transanally. For more proximally placed objects, the same 12-hour rule can be followed, after which time surgical intervention may be considered.

Gastrointestinal Therapies

A variety of techniques have been applied to the GI tract over the years to minimize local or systemic damage related to xenobiotics, including the induction of vomiting with ipecac,[40,88,97,100] the use of activated charcoal,[2,10,58] prokinetic agents, WBI[4] and luminal acidification.[19] The literature is large but varied, with a relative lack of randomized, controlled studies and great variability in the clinical material available for treatment and for study.[102] It may be difficult to distinguish complications from the poisoning from those related to therapy, for example, aspiration pneumonitis (Table 25-7).[44]

There is little evidence that cathartic use alters the outcomes of activated charcoal therapy,[64] and repeated use of cathartics may have its own toxicities. WBI with a balanced polyethylene glycol and electrolyte solution, decreases the effectiveness of activated charcoal in both in vitro and in vivo studies.

The application of multiple doses of activated charcoal has two rationales: (a) to prevent absorption of xenobiotics, and (b) to speed the elimination of xenobiotics that have already been

absorbed.[3, 29]

Many agents promote intestinal evacuation, and are referred to as laxatives, cathartics, purgatives, promotility agents, and evacuants. These descriptions connote varying degrees of activity. Laxatives and cathartics act within the intestinal lumen, while promotility agents are systemic drugs that have effects on neuromuscular activity. Evacuants typically are used to prepare the colon for diagnostic or therapeutic procedures, but also are used in the case of toxic ingestion. In the past, saline cathartics, such as magnesium salts, and hyperosmolar agents, such as nonabsorbable sugars,

often were used, but there were problems with fluid and electrolyte balances. Currently, bowel evacuation is typically performed using a solution of polyethylene glycol (PEG) with added electrolytes. The PEG is minimally absorbed, and increases the amount of intraluminal water by osmotic means, while the added electrolytes minimize solute fluxes into or out of the intestine. This treatment is ideal for ingestion of sustained-release or enteric-coated drugs, drug packets used for illicit smuggling,[87] and for xenobiotics that are slowly absorbed, like iron and lead.[4]

Orogastric lavage
Emesis
Esophageal tears or perforation (Mallory-Weiss or Boerhaave syndromes)
Gastric perforation
Hemorrhage
Activated charcoal
Constipation
Diarrhea
Intestinal obstruction or pseudo-obstruction (especially after repetitive doses in the setting of dehydration or prior bowel adhesions)

Procedure	Adverse Effect
	Vomiting and aspiration
Cathartics	
	Abdominal cramping (sorbitol)
	Diarrhea and frequent watery stools (sorbitol)
	Electrolyte imbalance: increased Mg^{2+}, decreased K^{+} and Na^{+} (also increased PO_4^{3-} and decreased Ca^{2+} and K^{+} from phosphate enemas)
	Nausea and vomiting
	Rectal prolapse
	Volume depletion and consequent metabolic alkalosis
Emesis with syrup of ipecac	
	Delayed emesis after loss of gag reflex
	Diarrhea
	Electrolyte imbalance with chronic use
	Esophageal (Mallory-Weiss) tears
	Gastric rupture or herniation
	Intractable vomiting and aspiration
Whole-bowel irrigation	
	Bloating
	Colonic perforation (in the presence of severe diverticulitis)
	Rectal itching (from excessive wiping)
	Vomiting, especially with rapid administration

TABLE 25-7. Gastrointestinal Complications of Gastric Decontamination Measures

Saline cathartics, such as magnesium salts, are poorly absorbed, and increase intraluminal osmolality, leading to a flux of water into the intestine, dependent upon the permeability characteristics of the small intestine. Intraluminal magnesium also stimulates the release of cholecystokinin. Among other effects, cholecystokinin stimulates gallbladder emptying and biliary pancreatic flow, as well

as intestinal motor activity.[11]

Hyperosmotic laxatives include sorbitol (D-Glucitol) and lactulose (Cephulac). Milk is an effective hyperosmotic laxative in people who are lactase deficient, as is any nonabsorbable sugar. By remaining in the lumen, the sugar prevents isosmolar water absorption in the duodenum and jejunum, where carbohydrate and water absorption is maximal. Thus, a larger-than-normal amount of fluid, electrolytes, and solute (sugar) enters the colon. Once in the colon, bacteria ferment the sugars, producing 2-, 3-, and 4-carbon compounds that further increase luminal osmolality, as well as hydrogen gas, leading to the production of flatus. Motility also is affected, leading to the symptom of cramping. PEG is a nonabsorbable, nonmetabolizable sugar in polymeric form, that exerts similar osmotic effects as the laxatives mentioned above. However, the PEG is inert, so that it is not metabolized. In addition, the electrolyte composition is balanced so that significant ion or water fluxes do not occur, and symptoms typically are minor. Many studies document its safety and efficacy.[93, 96]

Cathartics have long been recommended for basic poison management but there is little evidence of clinical effectiveness. Bowel evacuation with PEG solutions is currently recommended to speed the elimination of poorly absorbed xenobiotics or sustained-release medications, although evidence, once again, is limited. It is unlikely that evidence will ever be developed to support the efficacy of PEG-ELS based on large, randomized clinical trials; in its absence, reliance on case series and volunteer studies will continue. In one study using orally administered radiopaque markers, administration of PEG solution 30 minutes later did not lead to clearance. Abdominal radiographs taken after the administration of the PEG showed that, in 8 of 10 subjects, some radiopaque markers remained in the right colon, whereas the markers were present throughout the intestine in the other 2 subjects.[61] Thus, some care in the clinical application of this technique in a variety of circumstances is warranted, especially in

the follow up of treatment in cases where the offending agent can be detected, such as iron tablets and drug packets (see Figs. 6-8 , 40-1 , and 40-2).

Alterations in fluid and electrolyte balance are the major potential adverse effects of cathartics and other agents, especially when used repetitively. Nausea, vomiting, and cramping are most common, while other problems, such as rectal prolapse, have been reported. Morbidity may be higher in the elderly[9] and in young infants. Antiemetics may be used, if needed.

While antiemetic therapies are not usually considered in discussions of toxicology, they may play a role in the management of symptoms related to toxic agents. A number of antiemetic agents with differing mechanisms of activity have been developed. Phenothiazines and butyrophenones prevent nausea and vomiting via central nervous system dopamine antagonism. Metoclopramide is a substituted benzamide and procainamide derivative with a variety of central and peripheral effects, predominantly dopamine antagonism, but also 5-hydroxytryptamine type 3 (5-HT_3) receptor antagonism and cholinomimetic effects. Domperidone is a benzimidazole derivative that blocks peripheral dopamine receptors and is thought not to cross the bloodâ€“brain barrier, although it does affect the circumventricular areas where the barrier is incomplete, such as the area postrema. It is not approved for any specific indication by the FDA, but is available in many other countries. Anticholinergics, such as transdermally administered scopolamine, are not antiemetics, but decrease the sensation of nausea, especially related to motion sickness. Based on studies that show that nausea and vomiting may be mediated via 5-HT_3 receptors,[30] particularly in the area postrema, a number of inhibitors have been developed and are in wide clinical use.

Summary

The GI tract is vulnerable to a wide variety of pathogenic agents

with diverse physical, chemical, and biologic forms. Understanding the effects of such xenobiotics on the intestine and the body requires an understanding of the normal anatomy and physiology of the intestine. Except when injured or perforated by agents such as caustics, ionizing radiation, and alcohol, or obstructed by drug-containing packets or batteries, the GI tract is typically not regarded as a significant site of drug toxicity. Nevertheless, because of both its potential as a site of severe local or systemic effects and the role that GI signs and symptoms play in various diagnostic toxic syndromes, the GI tract is an important consideration in almost any toxicologic emergency.

Chapter 26
Hepatic Principles

Kathleen A. Delaney

The liver plays an essential role in the maintenance of physiologic homeo include the synthesis, storage, and breakdown of glycogen; the metabolis synthesis of albumin, clotting factors, and other important proteins; synth acids necessary for the absorption of lipids and fat-soluble vitamins; the cholesterol; the excretion of metals, most importantly iron, copper, zinc, mercury, and aluminum; and the detoxification of products of metabolism and ammonia.[28, 62, 129] Generalized disruption of these important functi familiar manifestations of liver failure: hyperbilirubinemia, coagulopathy, hyperammonemia, and hypoglycemia.[40, 74] Disturbances of more specific accumulation of fat, toxic metals, hypercholesterolemia, and fat-soluble deficiencies.[20]

The liver is also the primary site of biotransformation and detoxification contains the highest concentration of enzymes involved in phase I oxida reactions.[46] Its interposition between the gut and systemic circulation ma recipient of xenobiotics absorbed from the gastrointestinal tract into the also receives blood from the systemic circulation and participates in the elimination of xenobiotics that reach the bloodstream through other route

or cutaneous absorption. Many detoxified xenobiotics are excreted in the the biliary tract provides a second essential route for the elimination of and products of metabolism.[20 , 28]

Many xenobiotics are lipophilic, inert substances requiring chemical activa sufficiently soluble to be eliminated. This is accomplished by conjugation products of phase I biotransformation with molecules such as glucuronide or biliary excretion. Although phase I activation followed by phase II cor results in detoxification of these xenobiotics, it occasionally leads to the xenobiotics with increased toxicity, which is often manifest at the site of [83] Because of its location at the end of the portal system and its substan biotransformation enzymes, the liver is especially vulnerable to toxic inju for a more in-depth discussion of the biotransformation reactions.)

Morphology and Function of the Liver

Approximately 75% of the blood supply to the liver is derived from the p drains the alimentary tract, spleen, and pancreas. This blood is enriched other absorbed xenobiotics and is poor in oxygen. The remainder of the l comes from the hepatic artery, which delivers well-oxygenated blood from circulation.[20 , 129] Blood from the hepatic artery and portal vein mixes in coming in close contact with cords of hepatocytes before it exits through wall of the vein. Oxygen content diminishes several fold as blood flows fr to the central vein, affecting the localization of oxygen-dependent mecha [, 16] The sinusoidal lining formed by endothelial cells is thin and fenestrat of fluid, chylomicrons, and proteins across the space of Disse, an extrasi with microvilli.[20] Macrophages (Kupffer cells) within the sinusoids scaven materials and cell debris. When immunologically activated by xenobiotics, contribute to the generation of oxygen free radicals and may also particip production of autoimmune injury to hepatocytes.[33] Ito cells found betwee cells and hepatocytes are a primary site for the storage of fat and vitamin

Bile acids, organic anions, bilirubin, phospholipids, xenobiotics, and other in bile are actively transported across the hepatocyte plasma membrane i canaliculi at sites that have specificity for acids, bases, and neutral comp junctions separate the contents of the bile canaliculi from the sinusoids a

maintaining a rigid and functionally necessary compartmentalization. Bile

adenosine triphosphate (ATP)-dependent bile salt carrier in the canalicular
canalicular membrane transport site driven by the membrane voltage po
Glucuronidated xenobiotics are substrates for the bile acid transport syste
secreted into bile. Xenobiotics with molecular weights greater than 350 d
preferentially secreted into bile. Like the transport and concentration of
sinusoids and hepatocytes, the flow of bile through the canaliculi is an ac
facilitated by ATP-dependent contractions of actin filaments that encircle
[139] Xenobiotics induce cholestasis by targeting specific mechanisms of bil
flow.[67]

The enterohepatic circulation of bile acids and some vitamins plays a cruc
conservation. Unfortunately, this physiologically important process impede
elimination of some xenobiotics by reabsorbing and returning them back
circulation, prolonging their half lives and toxicity. Xenobiotics that are n
intestinal pH and that have low

molecular weights, such as methyl mercury, phencyclidine, and nortriptyli
to be reabsorbed.[28 , 114]

Two basic pathologic concepts are used to describe the appearance and f
a structural one represented by the hepatic lobule, and a functional one
acinus. The basic morphologic unit of the liver characterized by light micr
hepatic lobule, a hexagon with the central vein at the center and the port
angles. Cords of hepatocytes are oriented radially around the hepatic veir
â€œmetabolic lobuleâ€• is a functional unit of the liver. Located betweer
it is bisected by terminal branches of the hepatic artery and portal vein t
bases of the acini toward hepatic venules at the apices. The acinus is sul
metabolically distinct zones. Zone 1 lies near the portal triad, zone 3 nea
and zone 2 is intermediate. Figure 26-1 illustrates the relationship of the
functional concepts of the liver. The different metabolic functions of these
cellular location of biotransformation reactions affect the anatomic distribu
produced by xenobiotics. There is useful correlation between these anato
conceptualizations of the liver. Hepatocellular injury that occurs near the
periportal necrosis. This term describes injury in zone 1.[20] The terms *cen*

necrosis refer to injury that surrounds the central vein. Figure 26-2 show necrosis caused by exposure to bromobenzene.

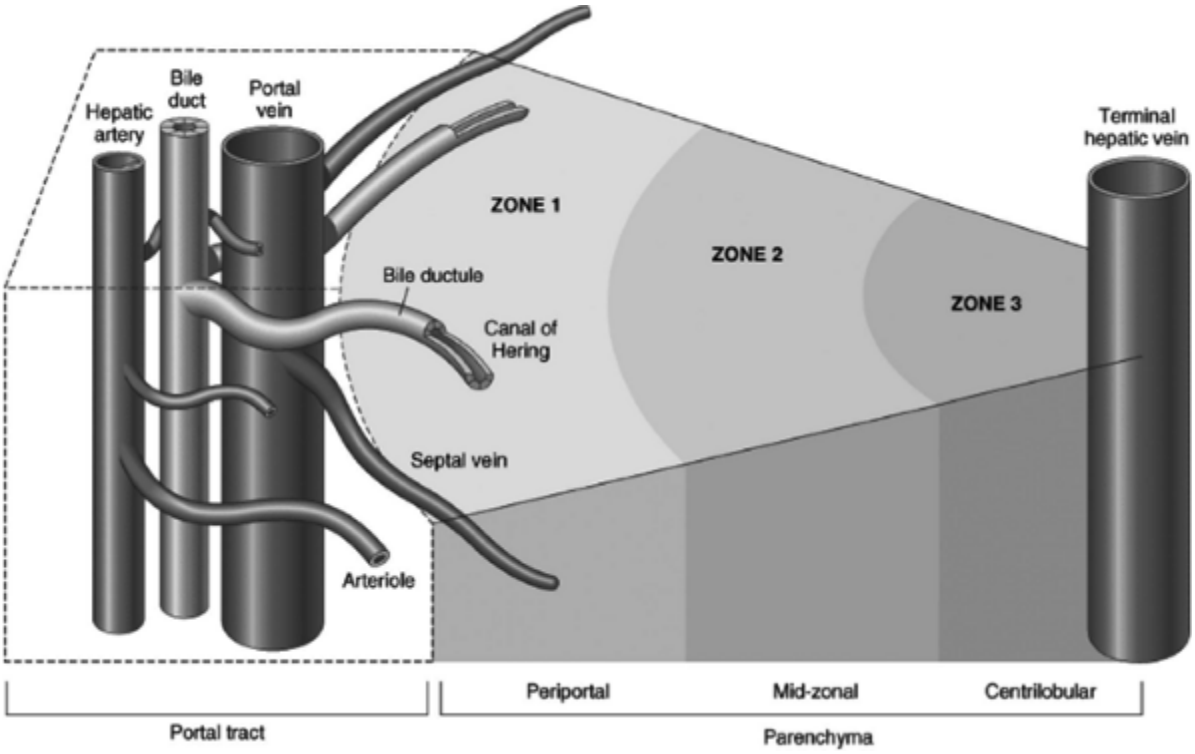

Figure 26-1. The acinus is defined by three functional zones. Specific co zone to the biotransformation of xenobiotics reflect the declining oxygen c it flows along sinusoids from the oxygen-rich portal area to the central h Hepatocytes that form the parenchyma of these three zones also have er metabolic functions that are specific to each of the three zones. The hepa shown) is a structural concept, a hexagon with the central vein at the cer portal areas that contain branches of the hepatic artery, bile duct, and po hepatocytes that is confined to zone 3 is called â€œcentrilobularâ€• beca of the lobule, zone 3 encircles the central vein, which is the center of the *(Adapted with permission from Crawford JM: The liver and the biliary trac Fausto N, Abbas A, eds: Robbins and Cotran's Pathologic Basis of Disease, Philadelphia, Elsevier, 2004,* Fig. 18.1 *, p. 879.)*

Factors Affecting the Localization of Hepat

Metabolic characteristics of the three zones of the acinus have important anatomic distribution of toxic liver injury. Zone 1, which begins in the pe closest to the vascular supply and has a 2-fold higher oxygen content tha Predictably, hepatic injury that results from the metabolic production of predominates in zone 1.[7] The tendency for centrilobular or zone 3 accumu patients with alcoholic steatosis is attributed to the effect of relative hypo vein area on the oxidation potential of the hepatocyte.[80] The availability detoxification and the localization of enzymes involved in biotransformatio site of injury. Zone 1 has a higher concentration of glutathione, whereas capacity for glucuronidation and sulfation.[134] Zone 3 has higher levels of dehydrogenase, which may lead to increased production of toxic acetaldeh centrilobular sites.[80 , 84] Zone 3 also has high levels of cytochrome oxid (CYP) 2E1, which converts acetaminophen, nitrosamines, benzene, and CCl_4) to reactive intermediates that may cause centrilobular injury. In proliferation of the smooth endoplasmic reticulum in the centrilobular are increased activity of CYP2E1.

This increases the risk of liver injury in alcoholic patients exposed to xen metabolized by CYP2E1 (Table 26-1).[48 , 81 , 99]

the necrotic area. *(Reprinted with permission from Hetu C, Dumont A, Joly chronic ethanol administration on bromobenzene liver toxicity in the rat. 1983;676:166.)*

The behavior of free radicals produced by the metabolism of CCl_4 has be studied in the laboratory. The following steps are proposed to explain the hepatic injury by CCl_4 . The trichloromethyl free radical ($Â·CCl_3$) is gene CYP2E1 in a reduced form of nicotinamide adenine dinucleotide (NADPH) reaction.[2 , 81] This occurs primarily in zone 3, which has the higher conc activity. It can form covalent bonds with cellular proteins, cause lipid pe spontaneously react with oxygen to form the more highly reactive trichlo radical (CCl_3 OOÂ·).[2 , 33] Low oxygen tension in zone 3 limits synthesis o whereas high oxygen tension in zone 1 fosters its formation. The highly that predominates in zone 1 is rapidly detoxified by glutathione; however $Â·CCl_3$ that predominates in zone 3 is not. Therefore, zone 3 incurs the g injury. Hyperbaric oxygen increases the oxygen tension throughout the li liver injury caused by exposure to CCl_4 , possibly by increasing the forma zone 3, which is then efficiently detoxified by glutathione.[16]

TABLE 26-1. Metabolic Zones of the Liver

The observed effects of isoniazid (an inhibitor of the enzyme CYP2E1) an intake (an inducer of the CYP2E1 gene) on injury in cell cultures from the centrilobular areas exposed to CCl_4 support the association of CCl_4 injury of CYP2E1 activity. Acute exposure to isoniazid significantly decreases th with exposure of cultured zone 3 cells to CCl_4 , whereas chronic treatmer significantly enhances it (see Table 26-1).[81]

Factors that affect the Development of He

Xenobiotics that produce liver damage in all humans in a predictable and manner, such as acetaminophen, CCl_4 , and yellow phosphorous, are call hepatotoxins. Those that cause liver damage in a small number of individ effect is not apparently dose dependent or predictable are called *idiosync* Some cause hepatotoxicity very rarely, whereas others produce it commo hepatotoxins fall into the category of idiosyncratic xenobiotics.[75 , 83] The agent halothane is both an intrinsic and an idiosyncratic hepatotoxin. A m hepatitis occurs in as many as 20% of patients exposed to halothane.[32] T halothane hepatitis, which can be reliably induced in animals, is likely cau toxicity.[117] A more severe idiosyncratic form appears to be caused by an response induced by halothane that targets liver proteins.[13 , 127 , 135]

Sporadic unpredicted hepatotoxicity is not really idiosyncratic, but more lik the combined effects of genetic and other factors that result in the overp decreased clearance of toxic metabolites. Idiosyncratic toxicity is related variability in the capacity to metabolize a specific xenobiotic and would b than â€œidiosyncratic,â€• if the exposed individual's metabolic capabilitie prospectively defined (Chap. 13). An individual's susceptibility to a hepa numerous factors, including the activity of biotransformation enzymes, th substrates, and the immune competence of the individual. In turn, these

sex, diet, underlying diseases, concurrent exposure to other xenobiotics, The susceptibility to toxic effects of a drug may be determined by inherit enzymes. Many enzymes involved in biotransformation show genetic poly example, approximately 8% of whites are deficient in CYP2D6 (formally hydroxylase), which is responsible for the metabolism of a number of dru debrisoquine (an antihypertensive first identified as the substrate of this antidepressants and antidysrhythmics, some opioids, and phenformin.[75] F antianginal agent marketed in Europe in the 1980s, caused severe liver d peripheral neuropathy in persons with a demonstrated inability to metab The congenital disorder that results in Gilbert syndrome is characterized glucuronyltransferase. These patients demonstrate decreased glucuronidat bioactivation of acetaminophen during chronic therapeutic dosing, sugges risk of hepatic injury following ingestions of acetaminophen.[25]

Effects of Other Xenobiotics on Enzyme Fu

Changes in the activities of biotransformation enzymes that result in incr hepatotoxic metabolites increase susceptibility to hepatic injury. Induction gene by the chronic ingestion of ethanol results in a 5- to 10-fold increas activity.[23, 80] Chronic administration of isoniazid (INH) to slow acetylato CYP2E1 activity.[145] Anecdotal observations in humans suggest the possib toxicity caused by solvents such as CCl_4, dimethylformamide, and bromo exacerbated by the chronic ingestion of ethanol.[6, 107] Currently, no data contention that using ethanol increases the clinical risk of acetaminophe [103, 121, 148]

The major studies that describe these xenobiotic interactions were done animals.[48] Bromobenzene is a xenobiotic whose metabolism and hepatoto that of acetaminophen. When administered to rats chronically exposed to of hepatotoxicity occurs more rapidly in study animals, with only a small extent of hepatic necrosis. The dose of bromobenzene required for hepatic not altered by pretreatment with ethanol.[48] Conversely, chronic administr phenobarbital to rats results in a very significant increase in the hepatotc bromobenzene.[109] In other rat studies, prior administration of CYP inhibit

cimetidine may protect against acetaminophen-induced hepatic necrosis.[1] hepatocytes of ethanol-treated rats show increased in vitro susceptibility effects of CCl_4 .[81]

Some xenobiotic combinations increase the possibility of hepatotoxic reac xenobiotic alters the metabolism of the other, leading to the production This is the case with combinations of rifampin and isoniazid; amoxicillin a and trimethoprim and sulfamethoxazole.[3 , 55 , 72 , 102 , 106]

Hypersensitivity

Immune-mediated liver injury is an idiosyncratic and host-dependent hy response to exposure to xenobiotic.[83] It is differentiated from liver injury autoimmune disorders by the absence of self-perpetuation, that is, the n exposure to the xenobiotic to perpetuate the injury.[83] Hypersensitivity rea forms of liver injury that include hepatitis, cholestasis, and mixed disorde hypersensitivity reactions that typically present with hepatitis include ha trimethoprim-sulfamethoxazole, anticonvulsants, and allopurinol.[3 , 4 , 86] present with cholestatic signs and symptoms (pruritus, jaundice, insignifi aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) i chlorpromazine, erythromycin, penicillins, rifampin, and sulfonamides.[27] injury typically begin 1â€“8 weeks following the initiation of the drug, alt begin as late as 20 weeks for drugs such as INH or dantrolene.[37] The ons associated with the oxypenicillins may occur up to 2 weeks after the drug all cases, the onset is earlier when the patient is rechallenged with the d eosinophilia, atypical lymphocytosis, fever, and rash are common clinical hypersensitivity, their absence does not exclude the diagnosis of drug as injury.[63 , 64 , 83 , 86]

How the immune response ultimately leads to cell injury is not well defin the hepatocyte may be mediated by complement- or antibody-directed lys mediated cytotoxicity; or by an inflammatory response induced by immun complement.[10 , 14 , 59 , 61 , 92 , 118] The covalent binding of a reactive e metabolite with a hepatocellular protein resulting in the formation of a ne defined first step in the development of xenobiotic-related autoimmune li covalent binding creates an â€œadductâ€• that is perceived as foreign b

system and induces an immune response. In cases where the metabolite the electrophilic attack is directed against the CYP enzyme at the site of metabolite.[13 , 77 , 83] Adducts and associated autoantibodies have been acetaminophen,[18] minocycline,[10] halothane,[13 , 127] dihydralazine,[14] phen germander.[71] The most severe form of idiosyncratic halothane liver injury fulminant hepatic failure associated with formation of adducts of its trifl (TFA) metabolite with numerous hepatoproteins.[9 , 135] TFA binds and for hepatic enzymes that include pyruvate dehydrogenase.[31 , 59 , 127] It also CYP2E1, the enzyme that metabolizes halothane to TFA. Studies demons against the CYP2E1 enzyme (Chap. 65).[13 , 59 , 118 , 135] Autoantibodies against CYP enzymes have also been demonstrated for dihydralazine,[14] a trifluoroacetyl protein adduct similar to that associated with halothane he in workers who developed hepatic necrosis following exposure to hydro Whether autoantibodies stimulated by the xenobiotic-protein adducts are of cell injury is not clear.

Early reports of lymphocyte sensitization in cases of xenobiotic-mediated suggested that cell-mediated immunity may play a role.[137] Cell-mediated cytotoxicity is implicated in the idiosyncratic type of halothane hepatitis.[3] autoimmune mechanisms are suspected in an increasing number of mode xenobiotic-mediated liver injury. Polymorphonucleocyte activation appears factor in one experimental rat model, where exposure to Î±-naphthyl-isc causes acute cholangitis associated with polymorphonucleocyte (PMN) infi exposure to ANIT stimulates the release of cytotoxic lysosomal enzymes a radicals by activated PMNs.[92] In addition, antibodies directed against cir decrease the extent of liver damage caused by ANIT.[22] Natural killer T ce ubiquitous in the liver, and their possible role in facilitation of cell-media injury is currently being investigated in other models.[21 , 45]

Availability of Substrates

The availability of substrates for detoxification may significantly affect th hepatic injury. The metabolism of acetaminophen illustrates the effect of concentration on the delicate balance between detoxification and the pro metabolites. In healthy adults taking therapeutic amounts of acetaminop

Morphologic and Biochemical Manifestations Injury

The liver responds to injury in a limited number of ways. Cells may swell
degeneration) and accumulate fat (steatosis) or biliary material. They ma
or undergo the slower process of apoptosis, forming shrunken, nonfunct
bodies. Necrosis may be focal or bridging, linking the periportal or centri
or pan acinar; or it may be massive. An inflammatory cell response may
necrosis.[20 , 75] Injury to the bile ducts results in cholestasis. Vascular in
obstruction to venous or arterial flow. The variety and spectrum of injury
azathioprine illustrates the difficulty in categorizing and characterizing all
causes of xenobiotic hepatic injury. This single agent is associated with m
including asymptomatic aminotransferase elevations, simple cholestasis, h
injury, and vascular injury.[37] All of these manifestations of toxic injury a
Table 26-2 lists characteristic morphologies of hepatic injury and associa

Acute Hepatocellular Necrosis

Acute necrosis of a hepatocyte disrupts all aspects of its function. Because

TABLE 26-2. Morphology of Liver Injury by Common Xenobiotics

Acetaminophen is a common cause of acute hepatic injury, as are herbal risks are increasingly recognized.[1,34,51,52,71,97] Many halogenated include carbon tetrachloride, bromobenzene, monochlorobenzene, hydr and halothane also produce hepatocellular necrosis.[6,48,49] A recent stu 11,000 patients exposed to isoniazid during preventive treatment showed injury occurred in 0.10% of those starting treatment, and in 0.15% of th treatment.[93,94,101] Risk factors for the development of hepatotoxicity are female sex, increasing age, coadministration with rifampin, and alcol discussed extensively in Chap. 55 . The thiazolidinedione agents troglitaz rosiglitazone, marketed for the treatment of type 2 diabetes, are associat hepatocellular necrosis.[5,44] The much higher incidence of liver injury at troglitazone led to its withdrawal from the market in March 2000.[78] Table the pharmacologic and toxic xenobiotics that have been reported to caus

Steatosis

Steatosis is the abnormal accumulation of fat in hepatocytes. It occurs in metabolic conditions that include responses to xenobiotics. Two forms of described: macrovesicular steatosis, in which the nucleus is displaced by intracellular fat, and microvesicular steatosis, which is characterized by fa not displace the nucleus. The intracellular fat accumulation reflects abnc metabolism and may occur as a result of any one or more of the followin impaired synthesis of lipoproteins; increased mobilization of peripheral a increased uptake of circulating lipids; increased triglyceride production; d triglycerides to lipoprotein; decreased release of very-low-density lipoprot hepatocytes; and decreased Î²-oxidation of fatty acids.[80] Steatosis is a c usually well tolerated by hepatocytes and is reversible following withdraw

When associated with hepatocellular injury by xenobiotics, it signals the underlying metabolic dysfunction that may lead to cell injury and death. associated with macrovesicular steatosis include ethanol and amiodarone. the uptake of fatty acids into hepatocytes and decreases lipoprotein secr the increased ratio of the reduced form of nicotinamide adenine dinucleoti oxidized form of nicotinamide adenine dinucleotide (NAD^+), associated w metabolism of ethanol, decreases oxidation of fatty acids and promotes f The initial pathologic lesion that occurs in alcoholic liver disease is reve steatosis. Mallory bodies, eosinophilic cytoplasmic deposits of keratin fila degenerating hepatocytes, are also common microscopic findings in alcoh Amiodarone is concentrated in the liver and may account for up to 1% of during chronic therapy.[37] Amiodarone hepatic toxicity resembles that of with steatosis, Mallory bodies, and potential for progression to cirrhosis. intralysosomal phospholipid inclusion bodies were found in all cases in one be specific for amiodarone toxicity.[112] Figure 26-3 shows macrovesicular Mallory bodies caused by administration of amiodarone.

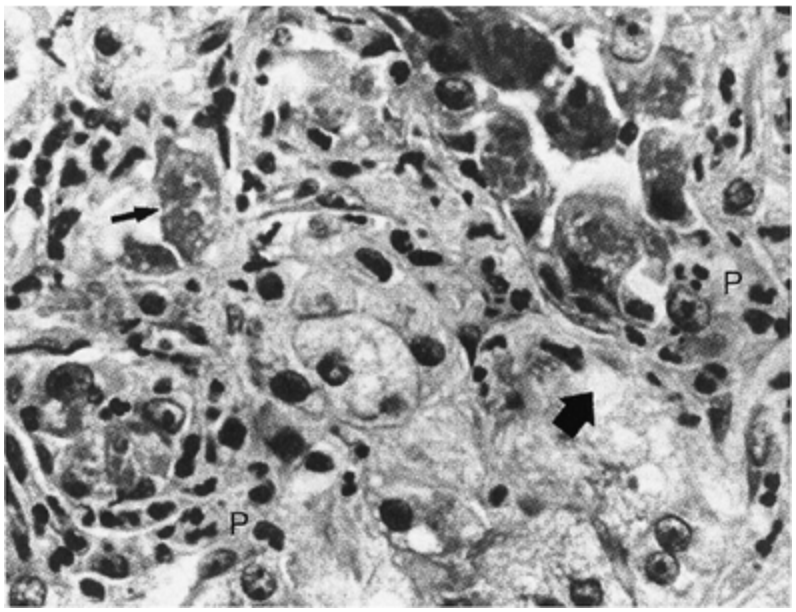

Figure 26-3. Macrovesicular steatosis associated with administration of *small arrow* indicates the presence of Mallory bodies. The *large arrow* poi intracellular fat. (Note that the nuclei are displaced.) Polymorphonuclear also present. *(Reprinted with permission from Lee WM: Drug-induced hep*

Med 1995;333:1118.)

Microvesicular steatosis is attributed to impairment of ATP-dependent Î²-
acids within hepatocyte mitochondria and is a sign of failure of hepatic r
oxidative phosphorylation.[42 , 90 , 119 , 122] It is associated with a much n
hepatocellular dysfunction. High doses of tetracycline produce microvesic
associated with moderate elevations of aminotransferases, markedly pro
time, and progression to fulminant hepatic failure.[122] Recently, microvesic
been reported in patients taking nucleoside analogs (zidovudine, zalcitabi
for the treatment of HIV infection.[119 , 131] This is attributed to disruption
DNA synthesis.[19] The nucleoside analog fialuridine caused severe hepatot
deaths during a study of its use in the treatment of chronic hepatitis B i
examinations of liver specimens showed marked accumulation of fat with
structural injury. In these cases, severe acidosis with minimal elevation
enzymes and bilirubin, and failure of hepatic synthetic function suggested
the mitochondria. Mitochondria examined under the electron microscope
abnormal.[90] Microvesicular steatosis attributed to mitochondrial failure was
case of *Bacillus cereus* food poisoning, where high levels of the bacterial
cereulide were found in the bile and liver. In this case, microvesicular ste
associated with extensive hepatocellular necrosis.[85] In all cases, lactic ac
biochemical manifestation of impaired energy production.[42 , 119] In additi
other xenobiotics associated with mitochondrial failure are hypoglycin, the
vomiting sickness, aflatoxin, and margosa oil.[119] Figure 26-4 demonstrat
steatosis in a patient with fialuridine hepatotoxicity.

Sodium valproate causes mild elevations of aminotransferases in approxin
patients, usually during the first few months of therapy. The earliest patl
signals progression of liver injury is microvesicular steatosis, which occurs
necrosis. A small percentage of patients progress to

fulminant hepatic failure characterized by centrilobular necrosis.[146] The i
hepatocellular injury is highest in children, approaching 1 in 800 children
years.[104] Carnitine is an amino acid that has an essential role in the tran
into the mitochondria and their subsequent Î²-oxidation. An association b
carnitine and the development of hyperammonemia is observed in childre

valproic acid.[104 , 136] It is not yet known whether valproic acid causes c that results in hepatic injury, or whether patients with preexisting metab in carnitine deficiency are at greater risk of hepatic injury. A retrospective patients showed a significant decrease in the mortality rate in patients w acidâ€“induced hyperammonemia treated with carnitine.[11]

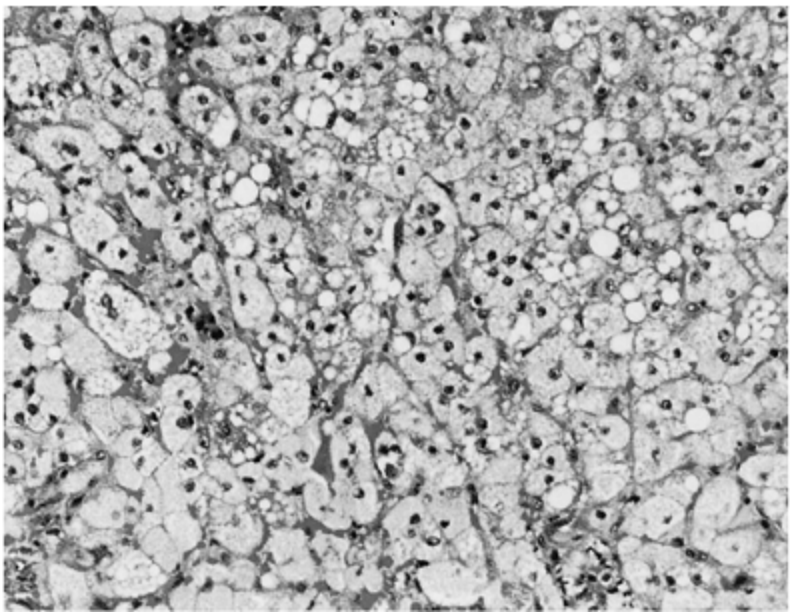

Figure 26-4. This figure shows severe microvesicular steatosis in a patie fialuridine. Note the central location of the nuclei. *(Reprinted with permis R, Fried MW, Sallie R, et al: Hepatic failure and lactic acidosis due to fial investigational nucleoside analogue for chronic hepatitis B. N Engl J Med*

Steatosis is also observed following exposure to the industrial solvent d The mechanism of hepatotoxicity in humans is unknown. Liver biopsies in illness show focal hepatocellular necrosis and microvesicular steatosis. M symptomatic exposures result in significant macrovesicular steatosis with aminotransferase elevations.[107 , 108]

Cholestasis

Cholestasis results from a number of toxic mechanisms. It may occur with associated hepatitis. The development of jaundice following hepatic necros

manifestation of general failure of liver function. More specific mechanism postulated to result in cholestasis include (a) impairment of the integrity junctions that functionally isolate the canaliculus from the hepatocyte and failure of transport of bile components across the hepatocytes; (c) blocka membrane active transport sites; (d) decreased membrane fluidity resulti transport; and (e) decreased canalicular contractility resulting in decrease 5).[67]

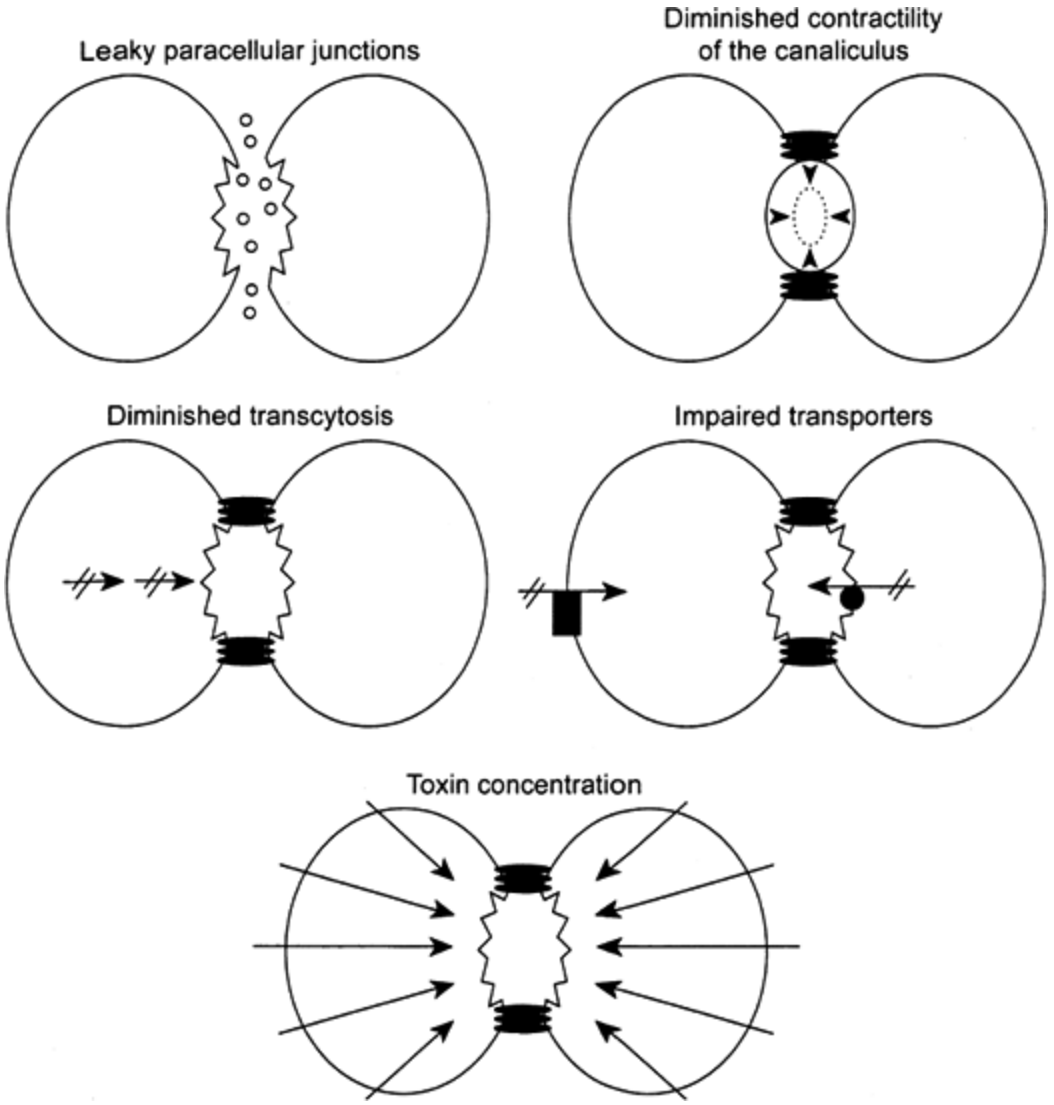

Figure 26-5. Potential mechanisms of xenobiotic-induced cholestasis. *(Re permission from Moslen MT: Toxic responses of the liver. In: Klaassen CD Doull's Toxicology, The Basic Science of Poisons. New York, McGraw-Hill,*

Estrogens cause intrahepatic cholestasis by altering the composition of th and inhibiting the rate of secretion of bile into the canaliculi.[67 , 78] Rifamp uptake of bilirubin into hepatocytes. Methyltestosterone and C-17 alkylat impair the secretion of bilirubin into canaliculi.[78] Exposure to chlorpromaz with cholestasis and periductal inflammation. This may be caused by inhib adenosine triphosphatase (ATPase), which results in decreased canalicula [116] Cyclosporine inhibits sodium-dependent uptake of bile salts across th membrane, and blocks ATP-dependent bile salt transport across the cana Floxacillin causes cholestasis with minimal inflammation or evidence of l injury.[137] Exposure of rats to ANIT causes a specific injury localized to tl that separate the hepatocyte from the canaliculi. This results in reflux of the sinusoidal space and increased access of sinusoidal molecules to the

Venoocclusive Disease

Hepatic venoocclusive disease is caused by toxic injury to the endotheliur venules that results in intimal thickening, edema, and nonthrombotic obs sublobular hepatic veins may also become edematous and fibrosed. There sinusoidal dilation in the centrilobular areas associated with liver cell atro The injury is caused by an activated pyrrole derivative produced by the c system.[87 , 142] The gross pathologic appearance is that of a â€œnutmegâ Massive hepatic congestion and ascites ensue.[69 , 111] Hepatic venoocclusiv fatal in

15â€“20% of cases. It is also associated with exposure to pyrrolizidine al many plant species, and with the use of cytotoxic drugs, especially in pa bone marrow transplantation. A rapidly progressive form may follow high cyclophosphamide.[89] Hepatic venoocclusive disease is also associated wit comfrey tea (*Symphytum* species),[140 , 144] and other pyrrolizidine alkalo preparations that include *Heliotrope,* *Senecio* , and *Crotalaria* species.[69] I epidemic proportions, in South Africa after the ingestion of flour contami (*Senecio*); in Jamaica after the ingestion of â€œbush teasâ€• (*Crotalari* India and Afghanistan when food was contaminated with *Heliotropium* *la* *Crotalaria* .[15 , 95 , 124 , 132]

Peliosis Hepatis

Peliosis hepatis is characterized by large blood-filled cavities associated dilation (Chap. 44). It is most frequently associated with the use of and Although most patients are asymptomatic, occasionally the dilated sinuso cause hemoperitoneum.[8]

Chronic Hepatitis

A form of hepatitis that clinically resembles autoimmune hepatitis occurs administration of some drugs such as methyldopa, nitrofurantoin, propy dantrolene, and diclofenac.[4 , 60 , 88 , 110 , 115 , 123 , 130] Many of these c with positive antinuclear antibody (ANA), smooth muscle antibody (SMA), hyperglobulinemia. Jaundice is prominent and hepatocellular enzymes are fold. Liver biopsy commonly reveals intrahepatic cholestasis, as well as inflammation.[37 , 83]

Granulomatous hepatitis is associated with infiltration of the hepatic pare granulomata. As many as 60 drugs are associated with this disorder. Fev symptoms are common, 25% have splenomegaly. Liver enzymes are mix variable degrees of cholestasis and hepatocellular injury. Eosinophilia occu extrahepatic manifestation of drug hypersensitivity. Continued exposure m severe form of liver disease. Small vessel vasculitis, which may involve th kidney, is a disturbing sign associated with increased mortality.[37 , 75 , 9 lists some of the xenobiotics that have been implicated in this disorder.

Cirrhosis

Cirrhosis, which results in irreversible hepatic dysfunction and portal hyp by progressive fibrosis and scarring of the liver. Fibrosis is related to inc collagen. In alcoholic cirrhosis, â€œactivatedâ€• lipocytes in the centrilob play a major role in the production of septal and perivenular collagen tha collagen deposition in the space of Disse. Acetaldehyde also stimulates c lipocytes, as do other aldehydes that are products of lipid peroxidation.[80 generally precedes cirrhosis, although cirrhosis may develop in its absen

ingestion of excessive amounts of vitamin A (25,000 U/d for 6 years or 1 years) results in cirrhosis. An increase in the fat content of the sinusoidal increasing degrees of collagen formation are characteristic lesions that oc A toxicity (Chap. 41). Portal hypertension may be early and striking.[43] Li methyldopa and methotrexate also cause a slow progressive development minimal clinical symptoms.[76 , 141] Methotrexate-induced hepatic fibrosis is Risk factors include associated alcohol intake and preexisting liver diseas has largely eliminated the risk of the development of cirrhosis in patients methotrexate.[58 , 141]

Hepatic Tumors

There is persuasive evidence that the use of oral contraceptive steroids ir hepatic adenomas.[29 , 63] There is also evidence that oral contraceptives risk of hepatocellular carcinoma; however, the number of cases associate therapy is low.[53 , 70] Anabolic steroids are rarely associated with the dev benign and malignant hepatic tumors.[17 , 38 , 56] Angiosarcoma is strongly exposure to vinyl chloride, in addition to arsenic, thorium dioxide, and s [37]

Hepatic Injury Associated with Plants and

In addition to the venoocclusive disease associated with pyrrolizidine alk above, herbal remedies are increasingly recognized as a cause of acute Numerous plants or plant products are known or suspected to cause hepa and 114).[1 , 30 , 34 , 51 , 52 , 71 , 97 , 120]

Clinical Presentations

Two general types of clinical patterns occur with hepatic toxins: a chroni progression of injury that may elude diagnosis, and a more acute, somet progression of injury that is temporally related to exposure to the xenob

Chronic injury is associated with an initially asymptomatic or minimally s state, with mildly abnormal liver chemistries and slow progression to clin dysfunction or cirrhosis.[37 , 75 , 137] Over a period of time ranging from m

jaundice, coagulopathy, encephalopathy, hepatomegaly, or signs of cirrhos angiomata, ascites, caput medusa, and gynecomastia may be evident. Ar to cirrhosis with minimal symptoms occurs in some patients with chronic A, methotrexate, ethanol, amiodarone, and methyldopa.[43 , 75 , 80 , 84] Ch manifested primarily by jaundice and pruritus.

Symptoms of acute liver injury include fever, anorexia, nausea, vomiting, include coagulopathy, jaundice, percussion tenderness in the right upper encephalopathy. Rapid development of portal hypertension, ascites, and c onset of some cases of venoocclusive disease.[69] Patients with acute, large carbon tetrachloride, yellow phosphorus, acetaminophen, and cyclopept mushrooms present first with gastrointestinal symptoms. This is followed b being (1â€“3 days), and then signs of acute hepatic and renal failure, wi and nausea, followed by profound jaundice, hemorrhage, ascites, hepatic and death.[74 , 113] Patients with significant acute occupational exposure

present with abdominal pain, anorexia, and disulfiram-type reactions.[108]

May have decerebrate posturing; Cheyne-Stokes respirations; pupils are the oculocephalic reflex is intact; may have signs of intracranial pressure

Clinical Stage	Mental Status	Neuromotor Function

TABLE 26-3. Stages of Hepatic Encephalopathy

Fulminant hepatic failure (FHF) is defined as liver injury that progresses within 8 weeks of the onset of illness in a patient without preexisting live Complications from FHF include encephalopathy, cerebral edema, coagulo dysfunction, hypoglycemia, hypotension, acute lung injury, sepsis, and de a patient may progress from health to death in as little as 2â€“10 days.[74] 3 shows the clinical progression of liver failure as hepatic encephalopathy prognosis of FHF is related to the time that passes between the onset of onset of encephalopathy. Perhaps surprisingly, a better prognosis is asso (2â€“4 weeks) jaundice-to-encephalopathy intervals.[113] Most cases of fu failure are caused by xenobiotics or viral hepatitis. Fulminant hepatic failu associated with extensive necrosis, although it may occur in the absence necrosis, as occurs in exposures to xenobiotics that injure mitochondria, analogues and *Bacillus cereus* toxin.[85, 90, 131] Some xenobiotics that ar fulminant necrosis are clove oil, bromfenac, amanitin cyclopeptides, ace tetracycline, phosphorus, halogenated hydrocarbons, INH, methyldopa, an [41, 74, 96]

The Evaluation of the Patient with Liver Di

The history is critical in establishing the diagnosis of the patient with live medication history should include careful investigation of nonprescription acetaminophen and the possible use of herbal therapies. Nearly all chron medications should be suspect. An occupational history may indicate expo chloride (plastics industry), dimethylformamide (leather industry), or oth solvents. Table 26-4 lists some of the occupational exposures that result Alcohol abuse is a common cause of acute hepatitis and the most commo in this country.[80, 84] A history of male homosexual contacts, healthcare intravenous drug use indicates the possibility of hepatitis B, whereas rece underdeveloped country suggests the possibility of hepatitis A. In patient

pain, the possibility of cholelithiasis should be considered.

Clinical Laboratory

Aminotransferases

Laboratory tests are helpful and certain patterns may be suggestive of s (Table 26-5). Elevation of hepatocellular enzymes, especially the AST an hepatocellular injury, and within a given clinical context, has useful diag Aminotransferases may be increased up to 500 times normal when hepati extensive, such as in severe acute viral or toxic hepatitis.[74] The degree c always reflect the severity of injury as concentrations may decline as ful progresses. Only moderately elevated, or occasionally normal aminotran concentrations occur in some patients with hepatic failure caused by mit cirrhosis, or venoocclusive disease.[43 , 69 , 146] Processes associated with cholestasis in the absence of hepatitis also may not lead to significant a elevation.[98 , 106 , 147] Patients with acute liver injury caused by dimethy demonstrated

aminotransferase concentrations 2â€“30 times normal, and ALT greater th and alkaline phosphatase concentrations were often normal.[108] In alcohol contrast to other forms of hepatitis, the AST concentration is typically two greater than the ALT. This is attributed to impairment of ALT synthesis b 5â€²-phosphate deficiency in alcoholics. Elevation of either of these enzyn is inconsistent with injury caused by ethanol.[129] During acute extrahepatic biliary tract, the AST or ALT may be as high as 1000 IU/L, indicating infla reflux of bile acids into the biliary tree.[129] The measurement of Î³-glutar (GGTP) is not very useful as it is present throughout the liver and its elev nonspecific.[129]

Disorder	Alkaline Phosphatase	AST, ALT	Albumin	Prothrombin Time	Bilirubin

TABLE 26-5. Laboratory Tests that Evaluate the Liver

Alkaline Phosphatase

In patients with cholestasis, bile acids stimulate the synthesis of alkaline hepatocytes and biliary epithelium in response to a number of pathologic liver. Elevations of the alkaline phosphatase as high as 10-fold may occu liver diseases, but are most commonly associated with extrahepatic obst Although the alkaline phosphatase may be normal or elevated only minin injury, it is unusual for obstruction to occur without some elevation of th phosphatase. Elevations of alkaline phosphatase and GGTP parallel each o the biliary tract.[129]

Bilirubin

Elevation of conjugated, or direct, bilirubin implies impairment of secretio elevation of unconjugated, or indirect, bilirubin implies impairment of co Unconjugated hyperbilirubinemia also occurs during hemolysis and in rare conjugation such as Gilbert or Crigler-Najjar syndromes. Except in cases unconjugated hyperbilirubinemia, the fractionation of bilirubin in the case disorders does not have any important diagnostic utility, and will not dis parenchymal disorders of the liver from intrinsic or extrinsic cholestatsis. bilirubin in the urine implies elevation of conjugated (direct) bilirubin and for laboratory fractionation.

Urobilinogen is produced by the bacterial metabolism of bilirubin in the bo absorbed and excreted in the urine. Its presence in the urine indicates th of bilirubin in bile, while its absence is associated with complete biliary o result of more modern methods of detection of complete obstruction of th test is mainly of historical interest.

Serum Albumin

Quantitatively, albumin is the most important protein that is made in the of up to 20 days, the albumin is usually normal in the previously healthy liver injury. In the absence of other disorders that affect albumin, such a syndrome, protein-losing enteropathy, or starvation, a low serum albumin for the severity of chronic liver disease.[129]

Coagulation Factors

Impairment of coagulation is a marker of the severity of hepatic dysfuncti and chronic liver disease. Unlike the case with serum albumin, with its ha the onset of coagulopathy as a consequence of impaired synthesis of the K-dependent clotting factors II, VII, IX, and X is rapid. Very acute chang reflect the concentration of factor VII, which has the shortest half life.[57] coagulation pathway, as measured by the prothrombin time (PT) or the normalized ratio (INR), is affected by reductions in factors II, VII, and X. or PT in acute hepatitis is associated with a higher risk of fulminant hepa In addition to failure of hepatic synthesis, inadequate levels of factors II, also result from ingestion of warfarin anticoagulants or malabsorption of v).[24]

International Normalized Ratio or Prothrombin

Because different thromboplastin reagents give different PT values on the INR was developed to normalize PT measurements in patients treated wi comparisons of therapeutic outcomes across different care settings and a The INR uses the ISI (International Sensitivity Index) that is derived from patients on stable anticoagulant therapy. It normalizes the responsiveness thromboplastin reagent in comparison to a WHO reference standard that i of 1.0.[66] There is little controversy regarding the value of the INR when c ratio for measuring the extent of warfarin-induced anticoagulation. Becau deficiencies in patients with liver disease are different from those in patie there is considerable

controversy regarding which measurement is best for patients with liver Although comparison of factor levels in warfarin-treated patients with tho showed no difference in factor VII, there are significant differences in fact fibrinogen. Comparison of the PT with INR in the evaluation of test result thromboplastin reagents showed consistency among the control groups c patients, but no consistency among PT or INR measurements using the s reagents in patients with liver disease.[66] Because of a failure to demonst liver specialists who have expressed an opinion support the continued use

describe the degree of liver injury, bemoaning the availability of a single that would help predict operative risk.[24, 26, 66] In patients with liver dis implies a normalized correlation that does not exist and is therefore pot The implication for toxicologists is that caution should be exercised in rely published INR values that purportedly predict the severity of illness in pa liver failure.

Ammonia

Severe generalized impairment of hepatic function leads to a rise in the concentration as a result of impairment of detoxification of ammonia pro catabolism of proteins. The absolute level of elevation is not clearly asso status alteration.[129] Elevations of serum ammonia concentrations occur in patients with hepatic encephalopathy, suggesting that ammonia may be a a primary cause of CNS dysfunction.[40]

Some patients treated with valproic acid have developed alterations in m associated with elevated ammonia levels, sometimes in the absence of o indicators of hepatic injury, and without demonstrable toxic levels of valp attributed to selective impairment of urea cycle enzymes ornithine transc carbamyl phosphate synthetase by pentanoic acid metabolites (Chap. 47

Other

Serologic studies for the presence of markers of hepatitis A, B, and C sho routinely in patients with hepatitis.

In the patient with severe liver injury, hypoglycemia is a major concern b impairment of glycogen storage and gluconeogenesis. Hyperglycemia also of the liver's inability to handle a large glucose load. The arterial blood-g commonly shows a respiratory alkalosis. Severe lactic acidosis occurs in failure caused by mitochondrial injury. Measurements of serum lactate co useful in identifying the cause of acidosis in a patient with suspected toxi [119]

The CT and MRI scans are useful tests for evaluation of parenchymal dise ultrasound examination reliably demonstrates dilation of the extrahepatic

biopsy may be helpful but is not specifically diagnostic of xenobiotic-indu

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a severe, but potentially fully reversible, liver failure, even in cases of deep coma.[39, 40] Table 26-3 describes, in stages of acute HE. Ammonia levels are elevated in patients with nitrogen elevated in nonnitrogenous HE. Conditions associated with nonnitrogenous hypoglycemia, hypoxia, anemia, and exposure to sedative hypnotic agent is precipitated by processes that elevate CNS ammonia concentrations, su alkalosis, increased muscle wasting, volume depletion, azotemia, or gas bleeding.[40] Alkalosis and hypokalemia facilitate conversion of NH_4^+ to NI more easily across the bloodâ€“brain barrier. The clinical improvement in lowering of serum ammonia levels, continues to be accepted as evidence of ammonia in the pathogenesis of HE.[39] The demonstration that ammonia many cases suggests that it may be an epiphenomenon, or marker, for o endogenous toxins. There is evidence that liver failure is associated with substances that stimulate central benzodiazepine receptors, leading to in transmission. Although it is clear that sedatives that depress Î³-aminobut transmission can make encephalopathy worse, studies of the use of fluma of encephalopathy show conflicting results. There does seem to be a sig improvement in some patients who already have a highly favorable progr is no clear evidence that all patients will benefit from flumazenil, some i benefit for a short time. Certainly, the administration of benzodiazepines The pathophysiologic processes discussed above are not mutually exclusive HE is likely multifactorial.

Management

In many cases, toxic liver injury resolves with simple withdrawal of the In cases of severe injury, significant improvement in survival is associate supportive care in an intensive care environment.[74] Early referral to a tr patients with evidence of severe or rapidly progressive toxic injury is inc of indications for the use of *N* -acetylcysteine and discussion of indication transplantation, see Antidotes in Depth: *N* -Acetylcysteine and Chap. 34

Summary

The primary role of the liver in the biotransformation of xenobiotics resul risk of hepatotoxicity. The spectrum of liver injury includes combinations steatosis, and hepatocellular necrosis. Injury may be a result of cellular autoimmune mechanisms; free radical initiation of lipid peroxidation; mi formation of adducts with critical cellular enzymes; and other, less-well- Disturbances in intracellular calcium concentrations may play a role in th hepatocellular injury, although the common â€œfinal pathwayâ€• role of into question. Xenobiotic-induced liver injury can be dose-dependent and idiosyncratic and unpredictable. Idiosyncratic injury is affected by host c include genetic makeup, concomitant or previous exposure to drugs and t underlying condition of the liver.

Chapter 27
Renal Principles

Donald A. Feinfeld

Vincent L. Anthony

Overview of Renal Function

Anatomic Considerations

The kidneys lie in the paravertebral grooves at the level of the T12-L3 ve while the lateral margins are convex, giving the organ a bean-shaped ap 10â€“12 cm in length, 5â€“7.5 cm in width, and 2.5â€“3.0 cm in thicknes 125â€“170 g; in the adult female, each kidney weighs 115â€“155 g.

At its concave surface is the hilum, through which the renal artery, vein, lymphatics pass. On the convex surface, the kidney is surrounded by a fil capsule with a fibroareolar capsule (called the *renal fascia*), which offers place.

The arterial supply begins with the renal artery, which is a direct branch artery subdivides into branches supplying the 5 major segments of each segment, the anteroinferior segment, the posterior segment, and the infe within each segment to become lobar arteries. In turn, these vessels give

sharply branching interlobular arteries, which directly supply the glomeru

The cut surface of the kidney reveals a pale outer rim and a dark inner r medulla, respectively. The cortex is 1 cm thick and surrounds the base o consists of between 8 and 18 cone-shaped areas called *medullary pyrami* containing the ends of the collecting ducts. Urine empties from these duct and, subsequently, into the urinary bladder.

The kidneys maintain the constancy of the extracellular fluid by creating free of cells and larger macromolecules, and then processing that filtrate, the rest escape as urine. Every 24 hours, an adult's kidneys filter about 1 25â€“60 L), and 25,000 mEq of sodium (total body Na^+ is 1200â€“2800 kidneys regulate these two substances independent of each other, depend 1% of the filtered water and 0.5â€“1% of the filtered Na^+ are excreted.

Renal function begins with filtration at the glomerulus, a highly permeabl arterioles in series. The relative constriction or dilation of these vessels (GFR). Under normal circumstances, approximately 20% of the plasma wa actually goes through the filter, carrying with it electrolytes, small metab and urea, and leaving behind the blood cells and nearly all the larger pr filtrate then enters a series of tubules that reabsorb most of it and secre and bases, into the urinary space. The proximal tubule performs bulk r of the filtrate. Distal to the proximal tubule are the loop of Henle, which urine, and the distal nephron, which does the fine-tuning in the balance Reabsorption of sodium is controlled proximally by hydrostatic and oncoti distally by hormones such as aldosterone. Control of water reclamation de of the loop of Henle, which absorbs solute without water. This produces a makes the medullary interstitium hypertonic. Final regulation of water rea antidiuretic hormone (ADH), which opens water-reabsorbing channels (aqu nephron segments (collecting ducts). The kidneys also regulate balance fo are influenced by the effect of aldosterone on the distal nephron), and ca influenced by the blood level of parathormone).

Injury to either the glomeruli or the tubules can lead to renal dysfunction filtration. As the kidneys fail, serum levels of the marker substances urea relationship between these levels and the level of GFR is hyperbolic, not l levels of these substances denotes a large decrease in renal function. By

creatinine exceeds the upper limit of normal, GFR is already reduced by r

Many xenobiotics cause or aggravate renal dysfunction. The kidneys are reasons;[141] (a) They receive 20â€“25% of cardiac output yet make up les metabolically active, and thus vulnerable to xenobiotics that disrupt meta

remove water from the filtrate and may build up a high concentration of interstitium are susceptible to attack by the immune system. Many factors individual's reaction to a particular nephrotoxin.[12] The clinician should be alter them to minimize the adverse effect after a toxic exposure.

Functional Toxic Renal Disorders

Although most toxic renal injury results in decreased renal function, there balance despite normal GFR in anatomically normal kidneys: renal tubula secretion of antidiuretic hormone, and nephrogenic diabetes insipidus.

Renal tubular acidosis (RTA) is a loss of ability to reclaim the filtered bic to generate new bicarbonate to replace that lost in buffering the daily acid nonanion-gap metabolic acidosis, usually accompanied by hypokalemia.

The primary defect in distal RTA involves the decreased secretion of hydr distal tubule. This most often denotes a defect in the H^+ -translocating a luminal surface of these cells. Less frequently occurring mechanisms inc exchanger, which is responsible for returning bicarbonate generated within given the voltage dependence of hydrogen secretion, if there is a decreas charge, there will be a decrease in this secretion. Most of this voltage is d on the peritubular capillary side of the adjacent cell. (*Note:* Cells adjacen cells and primarily control K^+ secretion.) As this pump malfunctions, less a decreased gradient from the lumen to the cell. Thus, the lumen becom transmembrane potential.

The primary defect in proximal RTA is incompletely understood. Normally, membrane, the Na^+ -K^+ -ATPase in the basolateral membrane, and the e systems necessary for proximal tubular bicarbonate reabsorption. It is pro become disordered and thereby diminish the resorptive capacity of the pr part of the *Fanconi syndrome* , a generalized failure of proximal tubular

renal glycosuria, and hyperphosphaturia).

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) occ fall in plasma osmolality, which normally inhibits ADH secretion. ADH prir increased water reabsorption by increasing the aquaporin channels in this altered physiology: there may be altered secretion of ADH, a resetting of secretion), or the inability to decrease ADH secretion in the face of a wat serves to augment normal free water retention, which subsequently leads concentrated urine (as reflected in a relative increase in urine osmolality) Although this most often occurs as a complication of intracranial lesions o in a diseased lung, many xenobiotics (eg, chlorpropamide, antidepressant methylenedioxymethamphetamine [MDMA or Ecstasy]) can also cause ina

Nephrogenic diabetes insipidus (NDI) is the reverse of SIADH. It denotes stimulation despite severe losses of body water. There are many causes c disease states. Several xenobiotics also cause NDI. Lithium, demeclocycl are noted drugs that can cause this syndrome (Chap. 17). Of these, our described, although the exact mechanism has not been elucidated. After through the sodium channel, it interferes with ADH-mediated water trans channels.

Major Toxic Syndromes of the Kidney

Most nephrotoxicity involves histologic renal injury. Although xenobiotics ca), there are three major syndromes of toxic renal injury: (a) chronic rena especially, (c) acute renal failure (Table 27-1). For purposes of continuit Because nephrotoxins usually affect the tubules, the most metabolically a nephrotoxicity involves either acute or chronic tubular injury, although gl xenobiotics. These processes are not mutually exclusive, and toxic nephrop the nephron (eg, nonsteroidal antiinflammatory drug [NSAID]-induced acu

Chronic renal failure refers to any disease process that causes progressive months to years. There is usually a gradual rise in BUN and serum crea falls; often there are no symptoms other than nocturia (indicating loss o

The most common lesion of nephrotoxic chronic renal failure is chronic in destruction of tubules over a prolonged period,[74] with tubular atrophy,

fibrosis, and a variable cellular infiltrate (Fig. 27-2), sometimes accomp

hyperkalemia early in the disease course.[70] Injury to erythropoietin-secre
anemia.

Chronic Renal Failure (slowly increasing azotemia)
- Chronic interstitial nephritis
- Papillary necrosis
- Chronic glomerulosclerosis

Nephrotic Syndrome (proteinuria, hypoalbuminemia, edema)
- Minimal glomerular change
- Membranous nephropathy
- Focal segmental glomerulosclerosis

Acute Renal Failure (rapidly increasing azotemia)
- Acute prerenal failure
- Acute urinary obstruction
- Acute tubular necrosis
- Acute interstitial nephritis
- Acute vasculitis

TABLE 27-1. Major Nephrotoxic Syndromes

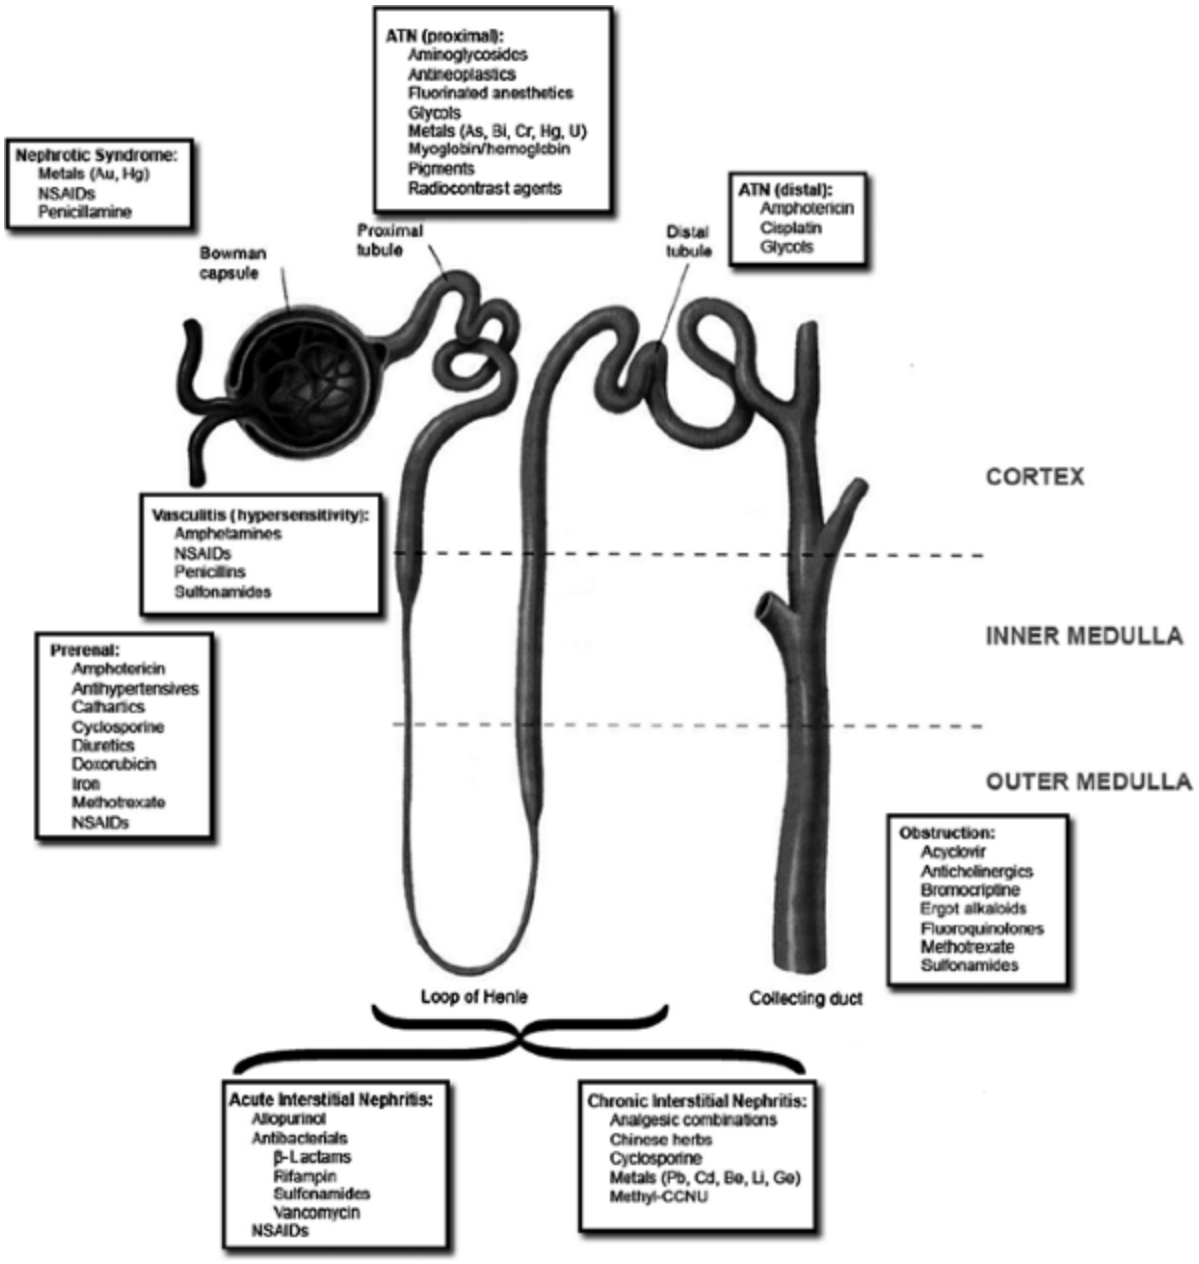

Figure 27-1. Schematic showing the major nephrotoxic processes and the affect. ATN = acute tubular necrosis. *(Courtesy of the National Institutes*

Nephrotic syndrome is characterized by massive proteinuria (>3 g/d in and the edema that usually prompts the patient to seek medical attentio findings are not completely understood, the underlying event is injury to macromolecules from passing from the capillary lumen into the urinary s

excretion as a result of renal tubular catabolism of filtered protein. The

of the extracellular space and edema. The glomerular lesion may progress continues. Xenobiotics induce nephrotic syndrome (Table 27-2) in 2 way the blood, which leads to antigenâ€“antibody complex formation after the complexes subsequently deposit in the glomerular basement membrane, t Fig. 27-3). Second, they can upset the immunoregulatory balance (eg, N hypersensitivity vasculitis.

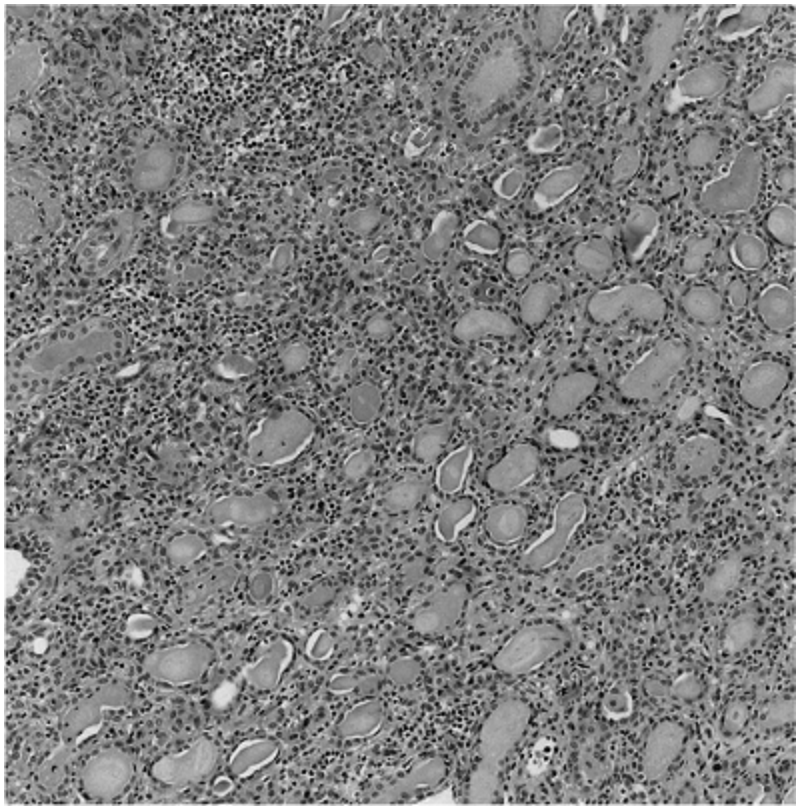

Figure 27-2. Chronic interstitial nephritis (secondary to NSAIDs). Inters tubular atrophy (H&E Ã— 225). *(Courtesy of Dr. Rabia Mir.)*

Acute renal failure is defined as any abrupt decline in renal function that metabolic balance. The 3 main categories of acute renal failure are prere

Prerenal failure involves impaired renal perfusion, which can occur with failure. Hence, toxic events that cause bleeding (overdose of anticoagula

or emetics), cardiac dysfunction (Î²-adrenergic antagonists), or hypotensio failure.[66]

One important cause of prerenal failure is the extreme renal hypoperfusic syndrome. This syndrome is characterized by impaired renal function and associated with severe chronic or acute hepatic failure. Many neurohumora systemic hemodynamic changes that occur in the syndrome. Specifically, greatly increased in hepatorenal syndrome. Angiotensin, norepinephrine, all contribute to the extreme cortical vasoconstriction. Furthermore, splar increases in endotoxin, nitrate, nitrite, and glucagon, all decrease mean renal blood flow. That this renal insufficiency is prerenal is best illustrated patient with hepatorenal syndrome is transplanted into a uremic patient, t normal.

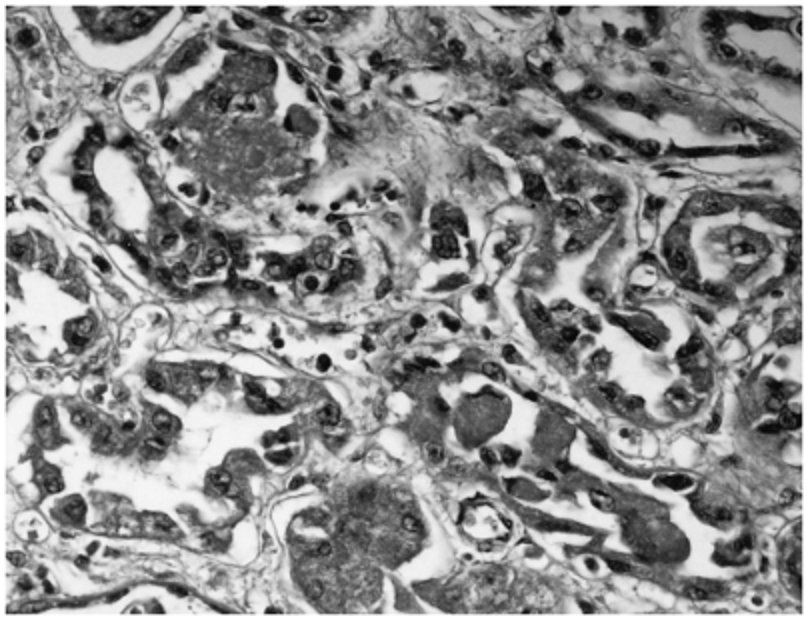

Figure 27-4. Acute tubular necrosis (secondary to mercury). Proximal tu associated with interstitial edema (H&E Ã— 450). *(Courtesy of Dr. Rabia*

Pigmenturia refers to either myoglobinuria from rhabdomyolysis (skeletal massive hemolysis.[59] Either pigment may cause tubular injury and necros [166] Myoglobinuria follows necrosis of striated muscle. Alcohol can be dire Î²-hydroxy-Î²-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors Xenobiotics that produce hypokalemia (eg, diuretics and laxatives) or pr cause muscle necrosis on this basis. Most often, poisoning leads to musc prolonged unconsciousness (opioids and sedative-hypnotics), excessive mu seizures (alcohol withdrawal, theophylline).[82] Pigmenturic acute renal fail carbon monoxide, copper sulfate, and zinc phosphate.[35 , 124 , 139]

Myoglobin is normally excreted without causing toxicity. A study of patien concentration of myoglobin in the urine may affect the development of re

tubular lumen because of renal hypoperfusion and high water absorption, environment as H^+ is secreted, releasing tubulotoxic hematin.[59] This toxi production of oxygen free radicals.

Myoglobinuric renal failure is diagnosed when acute renal failure occurs fo simultaneous elevation of concentration of serum muscle enzymes such as urine orthotolidine test, with no erythrocytes in the sediment, and urine because primary renal failure may itself cause detectable myoglobinuria th myoglobin in the urine does not prove the diagnosis.

Myoglobinuric renal failure can be prevented by early volume expansion if Alkalinizing the urine may prevent dissociation of myoglobin and minimiz rhabdomyolysis can lead to severe hypocalcemia from the release of large Alkalemia in this setting can cause tetany or seizures, worsening muscle must be weighed against the benefit.

Hemoglobinuria follows hemolysis, which can be caused by a number of venoms, cresol, phenol, aniline, arsine, naphthalene, and methylene chlo (hydralazine, quinine) can also cause hemolysis.[59] The pathophysiology o of myoglobinuria. The pigment deposits in the tubules and dissociates, ca and acidosis precipitate this disorder, so volume expansion and alkalinizat

Although there is controversy as to how a tubular lesion leads to glomeru obstruction, back-leak of filtrate across injured epithelium, renal hypoper surface combine to impair glomerular filtration.[215] Recent evidence sugge perhaps caused by an imbalance in the production of vasoconstrictors suc nitric oxide, is important in prolonging the renal dysfunction after the tu

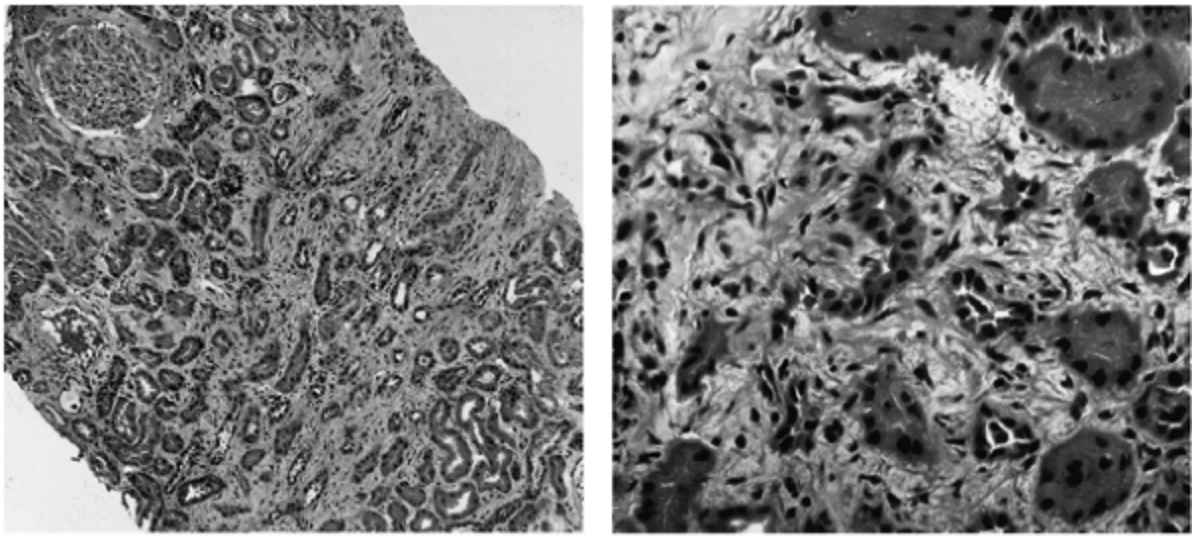
TABLE 27-4. Xenobiotics that Cause Acute Interstitial Nephritis

Clinically, acute tubular necrosis presents as a rapid deterioration of rena Muddy brown casts or renal tubular cells may be seen in the urinary sed unusual. Disorders of metabolic balance, such as hyperkalemia and metal tubular sodium reabsorption is decreased, the fall in glomerular filtration balance, as renal output of these substances is fixed.[147]

Acute interstitial nephritis (Table 27-4) is clinically similar to acute tubu renal biopsy, which shows a cellular infiltrate separating tubular structure nephritis is caused by hypersensitivity.[219] In many cases, the renal failu systemic allergy such as fever, rash, or eosinophilia. Finding eosinophils i However, approximately 25% of patients with xenobiotic-induced interstiti Unlike those with tubular necrosis, most patients with acute interstitial r particularly eosinophiluria.[12] Secondary fever at the onset of azotemia is present. The lesion usually improves once the xenobiotic is removed. Co many physicians use this treatment only if the renal failure does not imp stopped.



A B

Figure 27-5. Acute interstitial nephritis (secondary to rifampin). Interstit cell, and eosinophil infiltration occurs without fibrosis. Tubular epithelium changes and mononuclear cell infiltration (tubulitis) (A , H&E Ã— 112; B

Differential Diagnosis of Acute Renal Failu

Patients who present with acutely deteriorating renal function often repre are there 3 major etiologic categories, but each category has several subc present. For example, a patient with an opioid overdose may have neuro muscle necrosis causing myoglobinuric renal failure (intrinsic renal) and Because renal, prerenal, and postrenal processes are not mutually exclus three should always be considered, even when one appears to be the mo

Prerenal failure (renal hypoperfusion) initiates a sequence of events leadir is released, causing production of angiotensin, which both enhances prox stimulates adrenal aldosterone release, thus increasing distal sodium rea accompanied by low urinary sodium excretion (Table 27-5). Release of retention. Unresolving renal hypoperfusion may cause tubular necrosis.

Xenobiotics may decrease renal blood flow without necessarily causing int cathartics can decrease blood volume and antihypertensive agents can e

reduce blood pressure. Some xenobiotics (eg, cyclosporine, amphotericin

vasoconstriction. NSAIDs lower filtration rate by inhibiting production of arteriole. Finally, cardiotoxins, such as doxorubicin, can cause severe hea hypersensitivity vasculitis (Fig. 27-1).

Acute

To differentiate prerenal failure from acute tubular necrosis:

1. BUN-to-creatinine ratio; usually >20:1 in prerenal failure
2. Urine Na^+ usually <20 mEq/L in prerenal failure; usually >40 mEq/L in acute tubular necrosis
3. Fractional Na^+ excretion (FE_{Na}) is most reliable test:[12,13]

$$FE_{Na} = \frac{\text{Urine [Na]/Plasma [Na}^+\text{]}}{\text{Urine [Creatinine]/Plasma [Creatinine]}} \times 100$$

FE_{Na} <1% (ie, normal) in prerenal failure, if the patient has not received diuretics or large infusions of sodium, which increase Na^+ excretion despite normal tubular function. In tubular necrosis or interstitial nephritis, renal Na^+ absorption is decreased, and FE_{Na} >1%. This is useful except in pigmenturic or iodinated radiocontrast-associated renal failure, when the test is of no benefit.

Chronic

Creatinine clearance (C_{cr}) = U × V/P (normal range 90–130 mL/min), where U is urine creatinine concentration, V is urine flow in mL/min, and P is plasma creatinine concentration. Urine collection must be complete (not necessarily 24 hours), and U and P must be in the same units.

In steady states, C_{cr} can be approximated by estimating a patient's 24-hour creatinine output (~12 mg/kg of body weight in females; ~15 mg/kg of body weight in males), dividing the estimated 24-hour creatinine by the plasma creatinine concentration, and multiplying the result by 0.07 to convert to mL/min; or from the Cockroft-Gault equation:[44a]

$$C_{cr} = \frac{(140 - \text{age}) \times \text{ideal body weight (kg)}}{72 \times \text{serum creatinine}} (\times 0.85 \text{ for women})$$

TABLE 27-5. Tests of Renal Fu

Urinary tract obstruction should always be considered when the kidneys leads to anuria, partial obstruction, which is more common, is usually as Continued production of urine in the presence of obstruction leads to dist

blockage. Calyceal dilatation is common. Obstruction of the bladder outlet

Obstruction may be caused by xenobiotics (Table 27-6).[74] Most do so by anticholinergic action (atropine, tricyclic antidepressants). Rarely, certain cause retroperitoneal fibrosis and ureteral constriction. Finally, a few xen obstruction. Sometimes the xenobiotic itself forms precipitates (sulfonam excretion of a precipitating chemical such as oxalate (ethylene glycol an

Patient Evaluation

Evaluation of a patient with suspected toxic renal injury should include ex response to xenobiotics is affected by previous renal function, renal blood obstruction that can exert back-pressure on the nephrons, all of which m

History

A past history of renal disease or conditions that can affect the kidney disease) should be noted. Flank pain, hematuria, or any abnormal pattern patient's intravascular volume status affects renal perfusion. Thus, a histo plasma volume such as vomiting or diarrhea is important. Prior cancer ch methyl-CCNU (methyl-1-[2-chloroethyl]-3-cyclohexyl-1-nitrosourea) should b evaluated for potential renal effects, both those with direct and indirect alcohol and drugs of abuse should be explored. A careful occupational his are crucial, with emphasis on exposure to nephrotoxic xenobiotics.

Physical Examination

The patient's hemodynamic status should be carefully assessed. Postural c either engorgement or decreased filling of the neck veins, give important The skin should be examined for lesions. Pupillary abnormalities may sug reveal evidence of chronic hypertension or diabetes. All aspects of cardia or absence of edema. Injuries or scars in the suprapubic area or evidenc may suggest obstruction, as may a palpable or percussible bladder.

Laboratory Evaluation

Nephrotoxic injury is not always apparent clinically, so the laboratory is function may be suspected if urine output decreases, but oliguria is not renal function is glomerular filtration. Because urea and creatinine are lar these substances are used as markers of renal function. However, the blo production and excretion. Azotemiaâ€”elevation of BUN or creatinineâ€”is However, BUN or creatinine in the normal

range does not exclude a substantial degree of renal impairment because relationship between these parameters and GFR. In addition, decreased p or creatinine (amputation, muscle wasting) may result in a normal value f significant renal impairment. Conversely, decreased renal perfusion (prere disproportionate rise in BUN as compared to the rise in creatinine, becaus and water, whose reabsorption is increased when the kidneys are underp is suggestive of prerenal failure (Table 27-5). Because many nephrotoxi acute renal failure (urine volume >400 mL/d), progressive azotemia witho drug-related cause. Tubular injury, especially in lead poisoning and myo decreased tubular secretion of uric acid.

TABLE 27-7. Nephrotoxic Effects of Metals

Certain xenobiotics alter measured levels of urea and creatinine in the ab most obvious is exogenous creatine taken to build muscle mass. Cefoxitir the same frequency as the creatinine reaction product, thus artifactually a component of rocket model fuel, produces extreme elevation of creatini

renal creatinine secretion, such as cimetidine and trimethoprim, may also raised independently of renal function by tetracycline or corticosteroids,

In patients with chronic renal insufficiency or failure, it is necessary to as the patient properly. Clearance measurements are generally used to dete common is endogenous creatinine clearance (see Table 27-5).

Determining creatinine clearance in acute renal failure is not helpful, as tl state. Changing GFR during a clearance time period distorts the resulting between changes in kidney function and changes in BUN or creatinine cor renal failure should be treated as if glomerular filtration were <10 mL/mi random sample of urine may be sent promptly to the laboratory for sodi

fractional sodium excretion, which may help differentiate prerenal azotem

Solvents

- Carbon tetrachloride[143,166,206,209]
  - Hepatic failure leading to hepatorenal syndrome
  - Occasional acute nephrotoxic renal failure
- Tetrachloroethylene[199]
  - Hepatic failure leading to hepatorenal syndrome
  - Occasional acute nephrotoxic renal failure
- Trichloroethylene[15]
  - Acute tubular necrosis
- Toluene[184]
  - Hippuric acidosis

Glycols

- Ethylene glycol[37,171]
  - Metabolized to glycolic acid (metabolic acidosis)
  - Further metabolized to oxalic acid (acute tubular necrosis)
- Diethylene glycol[96,166]
  - Direct tubular toxin (acute tubular necrosis)
  - Hyperoxaluria may add to renal injury
- Propylene glycol[121]
  - May cause hemolysis and hemoglobinuric renal failure

TABLE 27-8. Nephrotoxic Hydrocarbons and Their Mechanisms of

Acute tubular necrosis
- Aminoglycosides[28,54,169,191,204]

TABLE 27-14. Nephrotoxicity of â€œAlternativeâ€• Medical Trea

Further evaluation of the patient with acute renal failure should include te number of substances (see Table 27-6). Renal ultrasonography should b Postvoiding residual urine volume may be measured as appropriate by cat 75â€“100 mL, one should suspect bladder dysfunction or obstruction.

Nephrotoxic complications of specific xenobiotics are found in Tables 27-7 13 and 27-14 .

Summary

The kidneys are exposed to exogenous or endogenous xenobiotics in thei xenobiotics entering the bloodstream. The environment, the workplace, a medications, all represent potential sources of nephrotoxicity. Consequentl and observation, to what xenobiotics a patient may have been exposed an kidneys. It is equally crucial to work the other way when a patient prese medications, both conventional and â€œalternative,â€• all xenobiotic exp adversely affect the kidneys.

Chapter 28
Genitourinary Principles

Jason Chu

The genitourinary system encompasses two major organ systems: the reproductive and the urinary. Successful reproduction requires interaction between two sexually mature individuals. Xenobiotic exposures to either individual can have an adverse impact on fertility, which is the successful production of children, and fecundity, which is an individual's or a couple's capacity to produce children. However, the role of occupational and environmental exposures in the development of infertility is difficult to define.[11 , 49 , 120 , 125] Well-designed and conclusive epidemiologic studies are difficult to accomplish because of the following factors: laboratory tests used to evaluate fertility are relatively unreliable; clinical end points are unclear; xenobiotic exposure is difficult to monitor; and indicators of biologic effects are imprecise. The negative impact on fertility as an adverse effect of xenobiotics is often ignored, but the evaluation of infertility is incomplete without a thorough drug and occupational history. Differences in the toxicity of xenobiotics in individuals may be sex- and/or age-related. Xenobiotic-related, primary infertility may be

the result of effects on the hypothalamicâ€“pituitaryâ€“gonadal axis or of a direct toxic effect on the gonads.[105] Fertility is also affected by exposures that cause abnormal sexual performance. Table 28-1 lists xenobiotics associated with infertility.

Aphrodisiacs are used to heighten sexual desire and to counteract sexual dysfunction. Historically, humans have continued to search for the perfect aphrodisiac. Efficacy is variable, and toxic consequences occur commonly. Various treatments have been evaluated for male sexual dysfunction, but the perfect remedy remains a mystery.

Whereas many people search for a cure for impotence or infertility, many others explore drugs and plants that can be used as contraceptives and abortifacients. Routes of administration vary from oral to parenteral to intravaginal. Toxicity results not only in the termination of pregnancy but also from the systemic effects of the various xenobiotics.

This chapter examines all of these issues, as well as the impact of xenobiotics on the urinary system, specifically, urinary retention and incontinence and abnormalities detected in urine specimens. Renal (Chap. 27), teratogenic, and carcinogenic (Chap. 30) principles are discussed in further detail elsewhere in this text.

Male Fertility

The male reproductive system is comprised of the male gonads and the endocrine organs that provide the hormonal controls. Disruption of normal function at any part of the system affects fertility. There are a multitude of xenobiotics that adversely affect spermatogenesis and sexual function.

Spermatogenesis

Central to the male reproductive system is the process of spermatogenesis, which occurs in the testes. The bulk of the

testes consist of seminiferous tubules with germinal spermatogonia and Sertoli cells. The remainder of the gonadal tissue is comprised of the interstitium containing blood vessels, lymphatics, supporting cells, and Leydig cells. Spermatogenesis begins with the maturation and differentiation of the germinal spermatogonia. The process is controlled by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus, which stimulates the pituitary to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates the development of Sertoli cells in the testes, which are responsible for the maturation of spermatids to spermatozoa. LH promotes production of testosterone by Leydig cells. Testosterone levels must be maintained to ensure the formation of spermatids.[27] Both FSH and testosterone are required for initiation of spermatogenesis, but testosterone alone is sufficient to maintain the process.

Testicular Xenobiotics

Xenobiotics can affect any part of the male reproductive tract, but, invariably, the end result is decreased sperm production, defined as oligospermia, or absent sperm production, azoospermia. Spermatogenesis is an ongoing process throughout life (as compared to oogenesis in women) and can be inhibited by decreases in FSH and/or LH or Sertoli cell toxicity. Spermatogenic capacity is evaluated by semen analysis, including sperm count, motility, sperm morphology, and penetrating ability. Normal sperm count is above 40 million sperm/mL of semen, and a count below 20 million sperm/mL of semen is indicative of infertility.[27] Decreased motility (asthenospermia) below 40% of normal or abnormal morphology (teratospermia) of more than 40% of the total number of sperm also indicates infertility.[27, 140]

Antineoplastics

Oligospermia and azoospermia are reported with cyclophosphamide, chlorambucil, and methotrexate when used as single agents.[27 , 138] Combination therapies with procarbazine, vinca alkaloids, or any of the above agents also decrease sperm production and fertility with variable recovery rates.[27]

Xenobiotic Effects	Xenobiotic Effects

TABLE 28-1. Xenobiotics Associated with Infertility

Hormonals

Diethylstilbestrol exposure in utero can lead to testicular hypoplasia in men, but may not lead to infertility or sexual dysfunction.[27, 160] Work-related exposure to estrogens and

progestins in the oral contraceptive industry may result in decreased libido, impotence, and gynecomastia caused by hyperestrogenism.[140] Anabolic steroid use can result in decreased libido, azoospermia, and decreased testicular size.

Radiation Therapy

Treatment of neoplasms with ionizing radiation leads to dose-dependent oligospermia and azoospermia. Time to recovery is dependent on dose and duration of exposure.[7]

Occupational Exposures

1,2-Dibromo-3-Chloropropane

A soil fumigant used in agriculture to control nematodes, 1,2-dibromo-3-chloropropane (DBCP) provides the clearest example of occupational exposure resulting in testicular toxicity and human reproductive dysfunction. In one small series, 7 of 10 patients who were exposed to DBCP had decreased or absent spermatogenic activity on testicular biopsy. This correlated with duration of exposure and was most consistently observed after inhalation exposure. A selective decrease or loss of spermatogenic activity was observed without any other consistent testicular defect, and all stages of differentiation were affected. In the most severe cases, the seminiferous tubules were devoid of germ cells.[17]

The mechanism of toxicity of DBCP is unknown but may be the result of transformation of the parent compound to an alkylating agent. Testosterone levels remain normal, although testicular size is decreased. After removal from exposure, improvement in sperm counts occurred in most oligospermic men, but those who had developed azoospermia showed no recovery of spermatogenic function.[159]

Lead

Painters and artisans are commonly exposed to inorganic lead, which is also a hazard in the smelting and battery industries.[89] Lead is a proven spermicide, and lead exposure is associated with decreased libido, asthenospermia, oligospermia, teratospermia, and testicular atrophy. An increase in the frequency of stillbirths and spontaneous abortions results when the male partner is a lead worker.[162] Lead levels of 35â€“50 Âµg/dL are associated with direct spermatogenic toxicity. Indirect effects result from the inhibition of general metabolic processes by lead (Chaps. 91).[162]

Glycol Ethers

Glycol ethers are used as fuel, deicers, and as components in paints, varnishes, thinners, and printing inks. Animal studies with methoxymethanol and ethoxyethanol show oligospermia, azoospermia, and testicular atrophy. One study documents decreased sperm counts in human workers exposed to ethylene glycol ether.[124]

Male Sexual Dysfunction

Sexual dysfunction can be a result of decreased libido (sexual desire), impotence, diminished ejaculation, and erectile dysfunction. Libido can be decreased by xenobiotics that block dopaminergic pathways or testosterone production, or by xenobiotics that produce dysphoria. Xenobiotics that affect spinal reflexes can cause diminished ejaculation and erectile dysfunction.[161]

Approximately 30 million men in the United States suffer from erectile dysfunction, with an increased prevalence in older men.[70] Erectile dysfunction, as defined by the National Institutes of Health (NIH), is the inability to achieve and/or maintain an erection for a period of time that is long enough to permit satisfactory sexual

intercourse[116] and can be divided into the following classifications: psychogenic, vasculogenic, neurologic, endocrinologic,

and xenobiotic-induced. Xenobiotic-induced erectile dysfunction is associated with the following categories of xenobiotics: antidepressants; antipsychotics; centrally and peripherally acting antihypertensives; CNS depressants; anticholinergics; exogenous hormones; antibiotics; and chemotherapeutic agents.[97, 139, 161] Treatment of this disorder is varied and includes vacuum-constriction devices, penile prostheses, vascular surgery, and medications (intracavernosal, transdermal, and oral agents).

The following section contains a discussion of the physiology of erection followed by a discussion of agents that cause sexual dysfunction in men, agents that are used to treat erectile dysfunction, and priapism.

Physiology of Erection

Normal penile erection is a result of both neural and vascular effects leading to smooth muscle relaxation and increased blood flow into the corpora cavernosa sinusoids of the penis. Psychogenic neural stimulation arising from the cerebral cortex is mediated through the thoracolumbar sympathetic and sacral parasympathetic tracts. In animals, dopamine and nitric oxide play a role in erection.[111] Reflex stimulation can also occur from the sacral spinal cord. The afferent limb of the reflex arc is supplied by the pudendal nerves and the efferent limb by the nervi erigentes (pelvic splanchnic nerves).

The internal pudendal arteries supply blood to the penis via 4 branches. Blood outflow is via multiple emissary veins draining into the dorsal vein of the penis and plexus of Santorini. Within the penis, the corpora cavernosa share vascular supply and drainage as a result of extensive arteriolar, arteriovenous, and sinusoidal anastomoses.[166] When penile blood flow is above

20â€“50 mL/min, erection occurs. Maintenance of tumescence occurs with flow rates of 12 mL/min. The tunica albuginea limits the absolute size of erection.

Penile erection depends on corpus cavernosal smooth muscle relaxation to allow increased blood flow and involves parasympathetic dominance, either by stimulation of parasympathetic receptors or inhibition of the sympathetic axis. Both cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP) pathways mediate smooth muscle relaxation. Cholinergic nerves release acetylcholine, which stimulates endothelial cells via M_3 receptors to produce nitric oxide and prostaglandin E_2 (PGE_2). Prostaglandin E_2 and nerves containing vasoactive intestinal peptide (VIP) and calcitonin gene-related peptide (CGRP) increase cellular cAMP to potentiate smooth muscle relaxation. Nonadrenergic-noncholinergic nerves and endothelial cells produce nitric oxide, which activates guanylate cyclase conversion of guanosine triphosphate (GTP) to cGMP. Increasing levels of cGMP act as a second messenger, mediating arteriolar and trabecular smooth muscle relaxation to enable increased cavernosal blood flow and penile erection.[111]

In the flaccid state, sympathetic efferent nerves maintain helicine-resistant arteriole constriction primarily through norepinephrine-induced Î±-adrenergic agonism. Î±-Adrenergic receptor agonism in the erectile tissues decreases cAMP to produce flaccidity, whereas Î±-adrenergic antagonism can result in pathologic erection (priapism) as a consequence of parasympathetic dominance.[166] Other vasoconstrictors, such as endothelin, prostaglandin F_{2a} , and thromboxane A_2 play a role in maintaining corpus cavernosal smooth muscle tone in contraction, which results in a flaccid state.[111]

Antihypertensives

Erectile dysfunction is reported as an adverse effect with all

antihypertensives and may be caused, in part, by a decrease in hypogastric artery pressure, which impairs blood flow to the pelvis.[159] Methyldopa and clonidine both are centrally acting Î±$_2$-adrenergic agonists that inhibit sympathetic outflow from the brain. Sexual dysfunction is reported in 26% of patients taking methyldopa and in 24% of those patients receiving clonidine.[16, 114] Erectile dysfunction associated with thiazide diuretics may be related to decreased vascular resistance, diverting blood from the penis.[29] Spironolactone acts as an antiandrogen by inhibiting the binding of dihydrotestosterone to its receptors. Impotence related to use of Î²-adrenergic antagonists is well documented[1, 77, 156] and may be caused by unopposed Î±-mediated vasoconstriction resulting in reduced penile blood flow.

Ethanol

Ethanol is directly toxic to Leydig cells

Chronic alcohol abuse causes decreased libido, erectile dysfunction, and testicular atrophy. In alcoholics, liver disease contributes to sexual dysfunction because of decreased testosterone and increased estrogen production. Alcoholics also can have autonomic neuropathies affecting penile nerves and subsequent erection. Alcoholics suffer more erectile dysfunction than do episodic drinkers.[158]

Psychotropics

Individuals who take psychotropics therapeutically have varying levels of sexual dysfunction related to both their underlying disease and their medications. All psychotropic agents are associated with sexual dysfunction to some degree. Monoamine oxidase inhibitors (MAOIs), cyclic antidepressants, antipsychotics, and selective serotonin reuptake inhibitors (SSRIs) are associated with decreased libido and erectile dysfunction in men.[39]

Thioridazine is associated with significantly lower LH and testosterone levels in men compared to other antipsychotics.[27] Table 28-2 lists other xenobiotics associated with sexual dysfunction.

Xenobiotics Used in the Treatment of Erectile Dysfunction

Intracavernosal Use

The three most common intracavernosal agents used for erectile dysfunction are papaverine, prostaglandin E_1 , and phentolamine. Papaverine is a benzylisoquinoline alkaloid derived from the poppy plant *Papaver somniferum* . It exerts its effects through nonselective inhibition of phosphodiesterase, leading to increased cAMP and cGMP levels and to subsequent cavernosal vasodilation. Papaverine was used for the treatment of cardiac and cerebral ischemia, but had limited efficacy. Presently, it is used as intracavernosal therapy for erectile dysfunction either alone or in conjunction with phentolamine. Systemic side effects include dizziness, nausea, vomiting, hepatotoxicity, lactic acidosis with oral administration, and cardiac dysrhythmias with intravenous use.

Intracavernosal administration is associated with penile fibrosis which is usually a dose-related phenomenon, although fibrosis can also occur with limited use.[43] More concerning is the development of priapism with papaverine use.

Anabolic steroids
Cyclic antidepressants
Anticholinergics[a]
Ethanol
Anticonvulsants

Lead
Antiestrogens
Lithium
Î±-Adrenergic antagonists
Monamine oxidase inhibitors[a]
Î²-Adrenergic antagonists[a]
Opioids (high dose)
Benzodiazepines
Oral contraceptives
Calcium channel blockers
Phenothiazines
Diuretics
Selective serotonin reuptake inhibitors
Cimetidine
Spironolactone

[a] Associated with erectile dysfunction.

TABLE 28-2. Xenobiotics Associated with Sexual Dysfunction (Particularly Diminished Libido and Impotence)

Prostaglandin E_1 (alprostadil) is a nonspecific agonist of prostaglandin receptors resulting in increased levels of intracavernosal cAMP, cavernosal smooth muscle relaxation, and penile erection. It is effective via intracavernosal administration as a single agent. Other preparations include an intraurethral preparation, which is less efficacious, and a topical gel formulation.[71] Penile fibrosis can occur, but the incidence is lower than with papaverine. Other adverse effects include penile pain, secondary to its effects as a nonspecific prostaglandin receptor agonist, and priapism.

Phentolamine is a competitive Î±-adrenergic antagonist at $Î±_1$ and $Î±_2$ receptors. It effects erection by inhibiting the normal resting adrenergic tone in cavernosal smooth muscle, thus allowing

increased arterial blood flow and erection. Intracavernosal use can cause systemic hypotension, reflex tachycardia, nasal congestion, and gastrointestinal upset. Penile fibrosis and priapism are also reported.

Oral Use

Phosphodiesterase 5 Inhibitors

Since the development of the phosphodiesterase 5 inhibitors, oral therapy has replaced intracavernosal injections as the mainstay for treatment of erectile dysfunction. Sildenafil was the first agent developed, followed by vardenafil and tadalafil. These medications have similar mechanisms of action but differ in their pharmacokinetics. Phosphodiesterase 5 inhibitors increase nitric oxide-induced cGMP concentrations by preventing phosphodiesterase breakdown of cGMP, enhancing nitric oxide-induced vasodilation to promote penile vascular relaxation and erection.[21]

After oral administration, sildenafil is rapidly absorbed, with a bioavailability of 40% and a median peak plasma concentration of 60 minutes. Its mean volume of distribution is 105 L, and its elimination half-life is 3â€“5 hours. Metabolism is primarily by the cytochrome P450 (CYP) 3A4 pathway, with some minor metabolic activity via the CYP2C9 pathway. Plasma concentrations of sildenafil are increased in patients older than age 65 years, as well as in patients with hepatic dysfunction or severe renal dysfunction (creatinine clearance <30 mL/min), and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).[35]

Vardenafil has more selective inhibition of phosphodiesterase 5 enzymes and less inhibition of phosphodiesterase 6 enzymes compared to sildenafil. After oral administration, it has a 14% bioavailability, a volume of distribution of 208 L, a median peak

plasma concentration of 60 minutes, and an elimination half-life of 4â€“5 hours. The CYP3A4 pathway is the primary hepatic metabolic pathway with minor contributions from CYP3A5 and CYP2C9 enzymes.[14, 18] The primary metabolite, M1, has phosphodiesterase 5 inhibitory activity but is 4 times less potent than vardenafil.[18] As with sildenafil, vardenafil levels are increased in patients older than age 65 years, and in patients with hepatic dysfunction or severe renal dysfunction (creatinine clearance <30 mL/min), and when used with CYP3A4 inhibitors (macrolide antibiotics, cimetidine, antifungal agents, protease inhibitors).[83]

Tadalafil has a median peak plasma concentration of 2 hours and a mean elimination half-life of 17.5 hours. It is predominantly metabolized by CYP3A4 enzymes. Unlike sildenafil and vardenafil, plasma levels are not affected by age, hepatic dysfunction, renal dysfunction or CYP3A4 inhibitors. However, the FDA has issued recommendations to decrease the dosage of all phosphodiesterase 5 inhibitors if used in conjunction with atazanavir.[8]

The most common adverse effects of the phosphodiesterase 5 inhibitors are headache, flushing, dyspepsia, and rhinitis, which are related to phosphodiesterase 5 inhibitory effects on extracavernosal tissue.[70] Blurred vision, increased light perception and transient blue-greenâ€“tinged vision are also reported and are related to the weak phosphodiesterase 6 inhibition of sildenafil in the retina.[70] Vardenafil is associated with infrequent abnormal vision, such as haziness, but not color vision.[72] Blurred or color vision is not reported with tadalafil.

More serious adverse effects of sildenafil include myocardial infarction, when used alone or with nitrates, hypertrophic subaortic stenosis obstruction, priapism, and optic ischemia.[6, 55, 82, 142, 145] Tadalafil use is associated with anterior ischemic optic neuropathy.[19]

When taken alone, the vasodilatory effects of phosphodiesterase 5

inhibitors cause a modest decrease in systemic blood pressure. However, because of their mechanism of action via cGMP inhibition and vascular vasodilation, phosphodiesterase 5 inhibitors can have synergistic interactions with the vasodilatory effects of nitrates resulting in profound hypotension.[21 , 84] A study of healthy male volunteers taking sildenafil demonstrated significantly less tolerance to a glyceryl trinitrate infusion as compared to placebo.[157] Because of this interaction, patients with acute myocardial ischemic syndromes who are using phosphodiesterase 5 inhibitors should avoid taking organic nitrates.[35] Î±-Antagonists are also contraindicated for concurrent use with phosphodiesterase 5 inhibitors because of increased hypotensive effects.[84] Hypotension occurred in patients using vardenafil with terazosin and tamsulosin,[84] and in patients using tadalafil with doxazosin.[85] However, patients using tadalafil with tamsulosin did not develop hypotension.[85]

Yohimbine

Yohimbine, an indole alkylamine alkaloid from the West African yohimbe tree (*Corynanthe yohimbe*), is an $Î±_2$ -adrenergic antagonist with cholinergic activity used to treat erectile dysfunction and postural hypotension associated with anticholinergic drugs.[94] It is structurally similar to reserpine. Other names for yohimbine include Aphrodyne, corynine, hydroergotocin, quebrachine, and the street name â€œyo-yo.â€•[95] Its use in the treatment of impotence is based on the theory that erection is linked to cholinergic stimulation and $Î±_2$ -antagonism, resulting in an increase inflow and decrease outflow of blood to the penis. Although the agent Aphrodex, which contained 5 mg of yohimbine, 5 mg of methyltestosterone, and 5 mg of strychnine, improved performance in males with erectile failure,[101] its distribution was halted in 1973 because of safety concerns.[136]

Yohimbine can be obtained by prescription, but extracts are also available in â€œhealth foodâ€• products marketed as â€œvitalizing agents for men and women.â€•[47] Yohimbine can also be extracted from the Rauwolfia root.[60] The â€œtherapeuticâ€• dose is 2â€“6 mg 3 times daily. The drug is rapidly absorbed, with peak serum levels occurring in 45â€“60 minutes. The half-life is 36 minutes, and clearance is by hepatic metabolism without renal excretion.[121] Maximum pharmacologic effects occur 1â€“2 hours after ingestion, and effects persist for 3â€“4 hours.[95]

Because the erectile process involves various neurotransmitters, a single agent would be expected to only have a partial effect. In a double-blind study of 100 males with erectile failure treated with 18 mg/d of yohimbine, 42.6% of the treatment group and 27.6% of the placebo group reported some improvement in erectile function,

which was not statistically significant.[110] Another study that compared a higher dose of yohimbine and placebo in 82 males showed a statistically significant improvement with treatment.[148]

Adverse effects can occur with relatively low doses of yohimbine. Tachycardia, hypertension, mydriasis, diaphoresis, lacrimation, salivation, nausea, vomiting, and flushing can occur following intravenous administration.[78] In patients with bipolar disorder,[131] 10 mg of yohimbine can elicit manic symptoms and 15 mg/d is associated with bronchospasm[88] and a lupuslike syndrome.[137] A 16-year-old girl who ingested 250 mg of yohimbine powder, purchased for its purported aphrodisiac activity, developed an acute dissociative reaction with weakness, paresthesias, headache, nausea, palpitations, and chest pain. She also developed tachycardia, tachypnea, diaphoresis, tremors, and a rash. Her symptoms resolved without treatment after 36 hours.[95] Another report describes a 62-year-old man who ingested 200 mg of yohimbine and developed tachycardia, hypertension, and a brief

period of anxiety that resolved without treatment.[60] Symptomatic patients who ingest yohimbine should receive activated charcoal and should be observed until asymptomatic. Clonidine has been recommended for treatment of yohimbine's central and peripheral effects.[95] Î²-Adrenergic antagonists may attenuate some of the peripheral toxicity, but may also result in unopposed Î±$_1$ -adrenergic activity and worsening of hypertension, and should be avoided. Benzodiazepine administration may be sufficient for the treatment of agitation and sympathomimetic effects related to yohimbine.

Apomorphine

Sublingual apomorphine effects erection through activation of central dopaminergic pathways, most likely D_2 receptors in the paraventricular nucleus of the hypothalamus.[76] It reaches maximum plasma concentrations within 40â€“60 minutes after sublingual administration and is metabolized hepatically with a half-life of 2â€“3 hours.[5] Common adverse effects are nausea, headache, dizziness, and syncope. Unlike the phosphodiesterase 5 inhibitors, apomorphine is not associated with hypotension when used with antihypertensive medications, such as nitrates.

Priapism

Priapism is defined as a prolonged involuntary erection that is painful, unassociated with sexual stimulation, and can result in impotence. It most commonly occurs during the third and fourth decades of life and is caused by inflow of blood to the penis in excess of outflow. The corpora cavernosa become firm and the corpus spongiosum becomes flaccid. Intracavernosal pressures can exceed arterial systolic pressure, resulting in cell death. Priapism can occur from an imbalance in neural stimuli, interference with venous outflow, or as a result of xenobiotic-induced inhibition of penile detumescence. Î±-Adrenergic antagonist agents prevent

constriction of blood vessels supplying erectile tissue, resulting in priapism.[166] One of 10,000 patients taking trazodone develop priapism, which is thought to be related to its Î±-adrenergic antagonist effects.[136] A common cause of priapism is iatrogenic, resulting from the injection of papaverine for the treatment of impotence.[149] Other xenobiotics associated with xenobiotic-induced priapism include prazosin, labetalol, guanethidine, hydralazine, phenothiazines, and, rarely, androgens, anticoagulants, ethanol, marijuana, and cantharidin (Table 28-3).[81 , 149 , 166]

The goal in the treatment of priapism is detumescence with retention of potency. Initial therapy includes sedation with benzodiazepines, analgesia with opioids, ice packs, and early urologic consultation. Oral terbutaline (5â€“10 mg) is effective for prostaglandin E_1 -induced priapism and may be effective for other xenobiotic-induced priapism.[96 , 132] Aspiration and normal saline irrigation of the corpora cavernosa may be effective. If priapism occurs secondary to Î±-adrenergic antagonism, an Î±-adrenergic agonist (0.02 mg norepinephrine or 0.2 mg phenylephrine) diluted with 0.9% sodium chloride solution to 10 mL volume can be instilled by placing a 19-gauge butterfly needle into the corpora cavernosa. If the above measures fail, operative venous shunt placement may be required.[149 , 166]

TABLE 28-3. Xenobiotics Associated with Priapism

Female Fertility

The female reproductive system consists of the female gonadal organs and the respective hormonal system. Fertility encompasses the reproductive system, the process of oocyte fertilization, and gestation. Female infertility may result from changes in hormone levels, direct toxicity to the ovum, interference with the transport of the ovum, or inhibition of implantation of the ovum in the uterus. Women usually notice reproductive abnormalities more quickly than men, because menses may be affected, although infertility may occur while normal menses persist. Evaluation of female fertility is more difficult owing to the complexity of the systems involved and the inaccessibility of the female germ cell, but it is feasible and involves investigations of the anatomy and hormonal levels. The following is a discussion of oogenesis, xenobiotics that disrupt oogenesis, and xenobiotics that affect early embryo gestation.

Oogenesis

In contrast to men, women have a limited number of reproductive cells (ovarian follicles). Follicles are most numerous while the fetus is in utero, with the number decreasing to approximately 2

million at birth. By the time a woman reaches puberty, the majority of follicles have degenerated, leaving 300,000â€“400,000 ova, of which only about 400 will eventually produce mature ova during a woman's reproductive years. In contrast, men produce millions of spermatozoa a day. The process of oogenesis requires secretion of GnRH from the hypothalamus, resulting in production of LH and FSH from the pituitary, which are required for ovarian follicle maturation.[27] FSH induces early maturation by stimulating granulosa and thecal cell proliferation and estrogen production. LH is required for ovulation and for the formation of the corpus luteum. The corpus luteum continues estrogen production and produces progesterone, which stimulates the uterus to develop an endometrium receptive to any fertilized ovum. Successful ovulation requires not only hormone secretion but appropriate cyclic secretion as well.

Xenobiotics That Decrease Female Fertility

Antineoplastics

Alkylating agents are well described as causing oocyte destruction and disruption of the hypothalamicâ€“pituitaryâ€“ovarian axis in women. Ovarian failure with menstrual cycle disruptions and amenorrhea are reported with cyclophosphamide and busulphan as single agents.[27 , 155] Combination therapies with alkylating agents and vinca alkaloids are also reported to cause menstrual irregularities.

Hormonals

Exposure to diethylstilbestrol in utero rarely can lead to cervical and vaginal abnormalities in women.[27] Oral contraceptives can

rarely produce persistent infertility in women, following their discontinuation particularly in those women who are nulliparous. Prolonged infertility is more common with the use of the combined preparations as opposed to the use of sequential estrogen/progesterone contraceptives.[27] Medroxyprogesterone acetate depot administration is associated with transient ovulatory dysfunction of variable duration after cessation of therapy. These xenobiotics may affect the hypothalamicâ€“pituitary axis, gonadotropin release, or end-organ sensitivity to hormonal stimulation.

Psychotropics

As in men, all psychotropic agents can cause sexual dysfunction. MAOIs and tricyclic antidepressants are associated with the highest rates of sexual dysfunction, followed by antipsychotics and SSRIs.[39] These drug classes decrease libido and cause orgasmic dysfunction. Bupropion and nefazodone have the lowest rates of sexual dysfunction and are used to reverse SSRI-induced sexual dysfunction.[38 , 165] One study reported amenorrhea in 50% of women on thioridazine with return of menstruation 6 months after discontinuation.

Environmentals

Chlorinated hydrocarbons are a large group of chemicals that include polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT), pentachlorophenol, and hexachlorocyclohexane. PCBs were widely used prior to the 1970s and often released into the environment, where they continue to exist and contaminate the food chain. Studies of the effect of PCBs on fertility are mixed. Some studies show no association with PCB exposure, whereas others show increased levels of PCBs in women with endometriosis. The same study showed increased levels of hexachlorocyclohexane and pentachlorophenol in women with

miscarriages and decreased conception rates with increasing DDT levels.[124]

Female Sexual Dysfunction

The National Health and Social Life Survey found that 43% of women in the United States (compared to 31% of men) reported having sexual dysfunction.[90] In 1999, a consensus panel of the American Foundation for Urologic Disease revised the classification of female sexual dysfunction into the following 4 categories: (a) sexual desire disorders, which include hypoactive sexual desire disorder and sexual aversion disorder; (b) sexual arousal disorder; (c) orgasmic disorder; and (d) sexual pain disorders, which include dyspareunia, vaginismus, and noncoital sexual pain disorder.[12] The organic etiologies of female sexual dysfunction parallel those of male sexual and erectile dysfunction: vasculogenic, neurogenic, musculogenic, psychogenic, endocrinologic, and xenobiotic-induced causes. The xenobiotics implicated in female sexual dysfunction are similar to the xenobiotics that decrease female fertility, with antihypertensives, antidepressants, and antipsychotics as the most frequent causes.[56]

Treatment for xenobiotic-induced female sexual dysfunction includes decreasing medication dosages, switching to alternate medications with less adverse effects on sexual function (ie, bupropion and nefazodone), temporary cessation of the medication (drug holiday), or adding another medication to stimulate sexual function. Bupropion alone was as effective as fluoxetine for the treatment of depression but with less sexual dysfunction,[41] and when used in conjunction with SSRIs, bupropion improved sexual function compared to SSRIs alone.[38] Sildenafil was successful for treating spinal cord-induced[144] and antidepressant-induced sexual dysfunction;[118] however, larger trials had mixed results with sildenafil for sexual arousal disorder.[13, 31] Sublingual apomorphine improved sexual function in women with hypoactive

sexual disorder.[30]

Most medical therapy for female sexual dysfunction is centered on hormonal agents, both estrogen and androgen supplementation. Estrogen replacement therapy is available in oral, dermal, vaginal ring, and topical cream formulations, either alone or in combination with progesterone.[154] Estrogen therapy is associated with a higher incidence of coronary disease, breast cancer, stroke, and venous thromboembolism. Androgen therapy includes testosterone, which is available in oral, dermal, and topical preparations, and dehydroepiandrosterone.[141] Adverse effects are weight gain, increased cholesterol, and androgenization.

Abortifacients

An abortifacient is defined as an agent that affects early embryonic gestation to induce abortion. These substances may act by flushing the zygote from the fallopian tube, blocking the uterine horn, inhibiting implantation, inducing fetal resorption, or by producing oxytocin-like activity that results in uterine irritation and contraction. Abortifacients may also indirectly affect pregnancy by altering hormonal levels through placental inhibition of human chorionic gonadotropin (hCG) or progesterone production, or through interference with progesterone receptors. In a US poison center study, 5 of 43 pregnant women who intentionally overdosed used known abortifacients, including quinine, misoprostol, methylergonovine, and oral contraceptives. Four of these patients developed vaginal bleeding and cramping, but no short-term (1â€“3 days) fetal demise was reported.[127] The use of abortifacients is more common in underdeveloped countries and by people without access to safer methods for termination or prevention of pregnancy.

Misoprostol is a synthetic prostaglandin E_1 methyl analog indicated for the prevention of gastric ulcers caused by nonsteroidal antiinflammatory drugs. It was approved for marketing in Brazil in

1985 and in the United States in 1988. The abortifacient properties of prostaglandins are well established,[100] and misoprostol can produce uterine contractions, uterine bleeding, and expulsion of the products of conception.[133] Common adverse effects are nausea, vomiting, diarrhea, abdominal pain, chills, shivering, and fever. In one case, overdose with 6000 Âµg of misoprostol resulted in abortion, hyperthermia, rhabdomyolysis, hypoxemia, and a metabolic acidosis.[67] Cases of congenital abnormalities such as scalp and skull defects, cranial nerve palsies, and limb defects such as talipes equinovarus are reported when misoprostol did not terminate pregnancy.[36] This drug has been extensively misused in Brazil to induce abortion.[40 , 44 , 126] In 1991, an estimated 10% of mothers giving birth at public hospitals in Rio de Janeiro were exposed to misoprostol.[44 , 126] The rate of successful pregnancy termination with this drug is 11â€“50%, and abortion can occur after amounts just above the recommended therapeutic dose.[86 , 133]

Xenobiotic Source	Country of Origin or Use	Miscellaneous/Toxicity

TABLE 28-4. Xenobiotics Used as Abortifacients

Mifepristone, or RU-486, an antiprogesterone used in Europe and the United States, is an effective abortifacient, especially when used in conjunction with a prostaglandin.[128, 135] RU-486 is a steroid compound with a 5-fold greater affinity for progesterone

receptors than progesterone. Upon complexing with these receptors, it causes downregulation of progesterone-dependent genes, decidual necrosis, cervical dilation, and consequent expulsion of the products of conception.[36] The sensitivity of the uterus to prostaglandins is also increased.[15] Adverse effects include excessive blood loss and fatigue, gynecomastia, alopecia, nausea, vomiting, and abdominal pain.[62, 73] Data on toxicity in overdose are not known.

Methotrexate is a folic acid analog that is used in conjunction with a prostaglandin in medical terminations of pregnancy. It competitively inhibits dihydrofolate reductase and decreases nucleic acid synthesis, which is necessary in rapidly dividing cells such as trophoblasts. Common adverse effects are nausea, vomiting, diarrhea, fever, and chills.[36] Large doses or decreased clearance of methotrexate can lead to clinical toxicity, which includes stomatitis and esophagitis, renal failure, and myelosuppression, and can be ameliorated with folinic acid administration. (See Chap. 52 for a more in-depth discussion of methotrexate toxicity and Antidotes in Depth: Folic Acid and Leucovorin [Folinic Acid].)

Many abortifacients are derived from plants and their extracts (Table 28-4). Not only are these agents toxic to the mother, but because many are ineffective in producing abortion, possible teratogenicity is a concern. Trichosanthin is an abortifacient protein extracted from the root of *Trichosanthes kirilowii*, a Chinese medicinal plant. The root is powdered and is used as a folk remedy to induce menstrual bleeding and to expel the fetus.[151] The active ingredient, trichosanthin, has abortifacient activity in animals and in humans when injected or applied intravaginally.[151] The mechanism is unknown, but may be related to inhibition of protein synthesis by preventing the incorporation of leucine.[151] Trichosanthin injures trophoblasts, and it may also inhibit hCG and progesterone production by the placenta.[151] Hypersensitivity occurs in some patients, limiting its clinical

usefulness.

Pennyroyal oil is a volatile oil extracted from the leaves of *Mentha pulegium* and *Hedeoma pulegioides* and contains the ketone pulegone (Chap. 43). Preparations also include a tablet, tea, essence of pennyroyal, and leaves. There are several reports of its use as an emmenagogue and illicit abortifacient. Pulegone depletes glutathione stores in the liver and is a direct hepatotoxin. The epoxide metabolite menthofuran may also contribute to hepatotoxicity. Fulminant hepatic failure can occur after ingestion of 2 ounces of pennyroyal oil.[3 , 10] Renal failure is also described (Chap. 42).[147] *N* -acetylcysteine has been successfully used to prevent pulegone-induced hepatotoxicity.[28]

Because of its oxytocic action, the cinchona alkaloid quinine has been used intravenously to induce labor in cases of fetal death.[113] It has also been used as an illicit abortifacient.[163 , 164] Because it is ineffective when ingested orally for this purpose, it may be taken in repeated doses leading to toxicity (Chap. 56).

Black cohosh root (*Cimicifuga racemosa*) extract is an herbal preparation used to induce abortion and primarily results in gastrointestinal toxicity after ingestion. Blue cohosh (*Caulophyllum thalictroides*) is also used and contains methylcytosine, which causes toxicities similar to nicotineâ€”nausea, vomiting, muscle paralysis, seizures, tachycardia, and hypotension.

Toxicity of Aphrodisiacs

Aphrodisiacs are defined as xenobiotics that heighten sexual desire, pleasure, and/or performance, and include xenobiotics from the plant, animal, and mineral kingdoms.[45] The search for an effective aphrodisiac has been ongoing for thousands of years. Ancient fertility cults used *Datura* , belladonna, and henbane as aphrodisiacs. Yohimbine has been used by African cultures to enhance sexual prowess, and mandrake was used in medieval

xenobiotics recommended include oysters, vitamin E, and ginseng. Because there are no measurable objective parameters, research in this area is lacking. Most published studies evaluating aphrodisiacs have been conducted in male rodents, and little information is available regarding humans.

Dopamine, nitric oxide, oxytocin, and adrenocorticotropic hormone (ACTH) all facilitate sexual behavior. Dopamine stimulates the forebrain and midbrain and leads to an increase in sexual response and arousal. In animals, dopamine agonists, such as apomorphine and quinpirole, have proerectile effects through stimulation of dopamine pathways, increasing nitric oxide in the paraventricular nucleus in the hypothalamus, and releasing oxytocin.[111] Other preparations tested for the treatment of impotence include bromocriptine,[2 , 20] glyceryl trinitrate,[112] zinc,[4] oxytocin,[93] and LH.[92] Endogenous opioids, Î³-aminobutyric acid (GABA), and norepinephrine are associated with decreased sexual behavior. Serotonin is generally inhibitory to sexual function, but the effects are dependent on the receptor subclass. 5-Hydroxytryptamine (5-HT)$_{1A}$ receptor stimulation inhibits erection, but facilitates ejaculation in rats, whereas 5-HT$_{2C}$ receptors facilitate male sexual behavior.[111] Various serotonergic drugs, including trazodone, nefazodone, bupropion, and clomipramine, are reported to improve sexual dysfunction.[136 , 165]

Lead

Some â€œaphrodisiacsâ€• in Asian countries contain lead and are associated with toxicity. In a British report, a 50-year-old man from Pakistan presented with anorexia, abdominal pain, and anemia with basophilic stippling. His whole-blood lead concentration was 96 Âµg/dL. He reported ingestion of a yellow-white powder provided to him by a traditional Asian practitioner

for the treatment of impotence, which contained 84% elemental lead by weight.[51] A 24-year-old man from Bangladesh presented to a London hospital with similar complaints and had a whole-blood lead concentration of 102 Âµg/dL after chronic ingestion of an aphrodisiac containing 46% lead.[23] Traditionally, aphrodisiacs from the Indian subcontinent contain silver and/or gold, but occasionally lead is substituted. The indications for chelation therapy are the same as in other cases of lead poisoning (Chap. 91).

Topical Agents

Spanish Fly

Spanish fly is cantharidin derived from crushed blister beetles (*Cantharis vesicatoria*) and is used to enhance sexual potency.[81] A 1% topical solution available for use in wart removal is also marketed in adult sex shops and by mail order as an aphrodisiac. Adverse effects are a consequence of the vesicant properties of the agent, and gastrointestinal, dermatologic, genitourinary, renal, cardiac, pulmonary, neurologic, and hematologic effects are all described (Chap. 115).

Following absorption, ingested cantharidin is bound to albumin and excreted by the kidney.[130] Symptoms generally occur 2â€“6 hours after ingestion. Gastrointestinal and genitourinary signs include dysuria, oral pain, dysphagia, nausea, hematemesis, and hematuria. Blistering of mucous membranes also occurs, and patients commonly develop hemorrhagic mucositis of the mouth, esophagus, and stomach. Fatal gastrointestinal hemorrhage has been reported, and the lethal dose varies from 10â€“80 mg in adults.[115 , 130] Blister formation in the urinary tract, tubular necrosis, and glomerular damage all result in gross hematuria, which can continue for 2 weeks after ingestion. Proteinuria is common, and death from acute tubular necrosis and renal failure

can occur.[150] Dermal exposure can result in blistering, ulceration, and systemic toxicity. Hemorrhage occurs in the ureters, bladder, and urethra, and hemorrhagic bullae may be noted in the bladder. Priapism, ovarian engorgement, and vaginal bleeding can also occur.[119] Sinus tachycardia is the most common cardiac manifestation of toxicity, but pericardial and subendocardial hemorrhage are also described. Patients may also develop dysrhythmias, ST-segment elevation, and T-wave changes.[119] Pulmonary effects are rare and include acute lung injury and bronchial hemorrhage. Disseminated intravascular coagulation occurs and may be caused by vesicant-related vascular injury. Neurologic symptoms are rare. No specific antidote is available and treatment is supportive. Cantharidin exposure should be considered in the differential diagnosis of unexplained hematuria or gastrointestinal hemorrhage.

Bufotoxin

â€œStone,â€• â€œlove stone,â€• â€œblack stone,â€• and â€œrock hardâ€• all refer to topical aphrodisiac preparations made from dried toad venom that contains bufalin, cinobufalin, cinobufagin, and other cardioactive steroids in the bufadienolide class. A 90-year-old man presented with bradycardia and a history of syncope after ingesting Yixin Wan, a nonprescription Chinese medication containing toad venom, ginseng, pearl, and musk.[87] Chan Su is a traditional Chinese medication produced from the venom of *Bufo bufo gargarizans* , which contains several cardioactive steroids, a topical anesthetic, and bufotenine.[24] Kyushin is another popular Asian traditional medication that contains dried toad venom. The cardioactive steroids have a similar structure and action to digoxin. Digoxin immunoassay may be positive after exposure to these agents, although the level may not correlate with toxicity. Four deaths were reported between 1993 and 1995 following ingestion of these topical aphrodisiacs. The patients presented with bradycardia and measurable digoxin

levels. Hyperkalemia also occurred. One patient was successfully treated with digoxin-specific Fab fragments.[25,26] An animal study evaluating the usefulness of digoxin-specific fragments in mice intoxicated with Chan Su demonstrated survival in 8 of 15 mice treated with digoxin-specific Fab, as compared with no survivors in the control group.[25] Digoxin-specific Fab (at least 10 vials) should be administered to any patient with a suspected cardioactive steroid overdose with hyperkalemia and/or dysrhythmia (see Chap. 62 and Antidotes in Depth: Digoxin-Specific Antibody Fragments [Fab]).

Inhaled Agents

Nitrites

Alkyl (amyl, butyl, and isobutyl) nitrites are aliphatic esters of nitrous acid and are yellow, highly volatile, sweet-smelling liquids administered by inhalation. Glass capsules typically contain 0.3 mL and are enclosed in a gauze jacket of woven absorbent covering that can be crushed and held to the nostrils. The capsules are called â€œpoppersâ€• because of the sound that is produced when they are broken.[75,99] The vasodilatory effects produced by inhalation of amyl nitrite were first described in 1859, and amyl nitrite was first used for the treatment of angina in 1867. Amyl nitrite was originally marketed as a prescription drug in 1937, but the FDA removed the requirement for a prescription in 1960. After 1960, nitrates replaced nitrites in the treatment of angina. Because abuse of inhaled nitrites became widespread in the 1960s, particularly by healthy young males, the FDA reinstated the prescription requirement for amyl nitrite in 1968.[75] Since 1968, isobutyl and butyl nitrite have been legally marketed as â€œroom deodorizersâ€• in bottles containing 10â€“30 mL.[66]

Amyl nitrite and other alkyl nitrites are especially popular

aphrodisiacs among men who have sex with other men. They are inhaled during foreplay to obtain a â€œhighâ€• and to produce anal sphincter relaxation, or just before orgasm to heighten and prolong the climax.[57] Butyl nitrite was popular among teens seeking a â€œhigh,â€• but the prevalence of usage among high school seniors decreased from 11.1% in 1979 to 1.6% in 2003.[80]

Nitrites are absorbed via the skin, lungs, mucus membranes, and the gastrointestinal tract. They are metabolized in the liver and excreted, partially unchanged, in the urine.[99] In mice, butyl nitrite undergoes rapid hydrolysis to nitrite ion and butyl alcohol. The half-life is 2â€“3 seconds, and metabolism is by first-order kinetics.[75] The relaxation of vascular smooth muscle results in potent vasodilation and hypotension. Blood pressure can decrease significantly within 30 seconds of inhalation. Inhalation of as little as 5 drops can result in hypotension and reflex tachycardia.[99] Cardiovascular collapse can occur, especially if nitrites are injected intravenously. Vasodilation of cerebral blood vessels results in increased intracranial pressure, and cerebral aneurysm rupture has been reported after amyl nitrite inhalation.[117]

A feeling of warmth and palpitations are frequently described after nitrite inhalation.[75] Headache, nausea, and syncope are also common. Nitrite use can be dangerous in patients with glaucoma due to a transient increase in intraocular pressure.[57] Nitrites can also cause methemoglobinemia (Chap. 122) which can be successfully treated with methylene blue.[53] Hemolytic anemia is also reported,[22 , 99] and is probably a result of the oxidizing effects of nitrites on hemoglobin. â€œPopper dermatitisâ€• is a characteristic rash that can be noted around the nose, lips, face, penis, and scrotum, and presents as erythematous, edematous, and crusted lesions.[57 , 98 , 99] It can have an appearance similar to that of impetigo and seborrheic dermatitis. The rash usually clears within 10 days, but reappears with repeat nitrite inhalation.[57] A generalized allergic dermatitis can also occur.[46]

The carcinogenic and immunosuppressive effects of amyl nitrite are not adequately tested in animals, although it is mutagenic with the Ames test.[54] There are some data to suggest that nitrites may be immunosuppressive in the setting of repeated viral antigenic stimulation.[66] It is postulated that this may contribute to the high frequency of Kaposi sarcoma in men who have sex with other men. In one study, amyl nitrite was the only xenobiotic that 100% of patients with Kaposi sarcoma reported using.[103] Concern for carcinogenicity associated with amyl nitrite has resulted in a recent decline in its use among men who have sex with other men.

Urinary System

The urinary system is composed of the kidneys, ureters, bladder, and urethra. Many xenobiotics are concentrated by the kidneys and eliminated in the urine. The effect of xenobiotics on the bladder and urine is discussed below. See Chap. 27 for further discussion on xenobiotics affecting the kidneys.

Bladder Anatomy and Physiology

The bladder is a hollow, muscular reservoir composed of two parts, the body and the neck, which, in adults, normally stores 350â€“450 mL of urine. A smooth muscle, the detrusor muscle, makes up the bulk of the body and contracts during urination. Urine from the ureters enters the bladder at the uppermost part of the trigone, an area in the posterior wall of the bladder, and leaves via the neck and the posterior urethra. Surrounding the neck and posterior urethra is smooth muscle interlaced with elastic tissue to form the internal sphincter. Sympathetic innervation from S2 to S4 of the sacral spinal cord to the internal sphincter maintains smooth muscle contraction. Distal to the internal sphincter is an area with voluntary skeletal muscle that forms the external sphincter.

The nerve supply and neurophysiology of urination involves interplay by the sympathetic and parasympathetic nervous systems (S2 to S4). Figure 28-1 illustrates the physiology of micturition. Norepinephrine is released by sympathetic postganglionic fibers. Î±-Adrenergic receptors predominate in the internal sphincter and the bladder neck, whereas Î²-adrenergic receptors supply the bladder wall. Stimulation of Î±- and Î²-adrenergic receptors results in internal sphincter contraction, increased bladder outlet resistance, and bladder filling, leading to urinary retention.[42] Parasympathetic pre- and postganglionic fibers release acetylcholine to M_2 and M_3 muscarinic receptors in the detrusor muscle. Stimulation of M_3 muscarinic receptors is responsible for detrusor muscle contraction and bladder emptying.[34] Conversely, anticholinergic drugs prevent bladder emptying and result in urinary retention.[32,33,37,59,65,109]

Urinary Abnormalities

Urinary incontinence is common as age increases and bladder size decreases, resulting in more frequent emptying. Early detrusor contraction, even with low bladder volumes, occurs more commonly in the elderly, causing a sense of urgency. There are many etiologies for urinary incontinence, including various xenobiotic exposures (Table 28-5). General or regional anesthesia, bladder instrumentation, and xenobiotics may produce bladder atony leading to incontinence.[37] Functional incontinence can also result from use of any xenobiotic that causes impaired cognition or decreased mobility, which is exemplified by the sedative-hypnotics and the opioids.[37] Pharmacologic agents used in the treatment of urinary incontinence

include the anticholinergics (tolterodine, oxybutynin, trospium chloride), imipramine, botulinum toxin A, and duloxetine. Duloxetine is a serotonin and norepinephrine reuptake inhibitor that acts centrally at the sacral cord pudendal motor nucleus to

stimulate urethral rhabdosphincter contraction.[50]

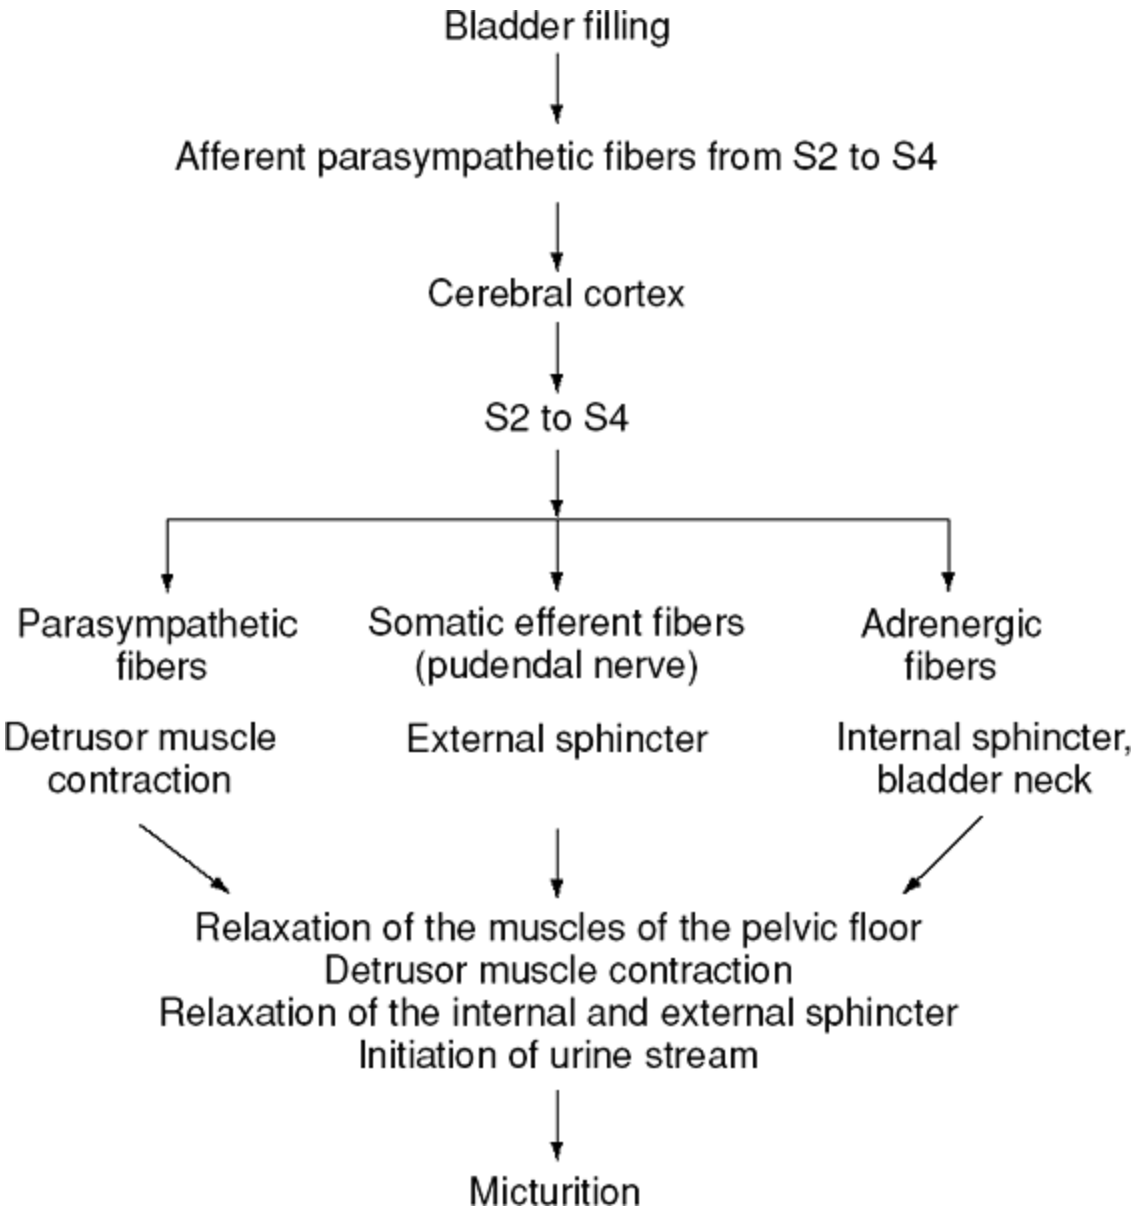

Figure 28-1. A schematic description of the physiology of micturition.

Î±-Adrenergic agonists
Increase internal sphincter tone; retention
Î±-Adrenergic antagonists

Decrease internal sphincter tone
Anticholinergics
Impair detrusor contraction; retention
Calcium channel blockers
Decrease detrusor contraction
Diuretics
Overflow (volume increase)
Opioids
Impair detrusor contraction; retention
Sedatives-hypnotics
Decrease sensorium; retention

Drug Action

TABLE 28-5. Xenobiotics that Cause Incontinence and Retention

Urinary retention can be obstructive, neurogenic, psychogenic, or pharmacologic in origin. Xenobiotics associated with urinary retention include sympathomimetics, anticholinergics, antidysrhythmics (quinidine, procainamide, disopyramide), antidepressants, antipsychotics, hormonal agents (progesterone, estrogen, testosterone), and muscle relaxants.[37, 59] In men older than age 50 years, benign prostatic hyperplasia is the most common cause of bladder outlet obstruction, leading to decreased urinary output and urinary retention. Treatment of benign prostatic hyperplasia consists of 5Î±-reductase inhibitors and Î±-adrenergic antagonists. 5Î±-Reductase inhibitors (finasteride, dutasteride) block the conversion of testosterone to dihydrotestosterone in order to decrease prostate volume.[106] The Î±-adrenergic antagonists (doxazosin, terazosin, alfuzosin,

tamsulosin) decrease urethral Î±-adrenergic contraction.[61]

Abnormalities in Urinalysis

Abnormalities of the urinalysis are often useful in identifying xenobiotic exposures. Color change or the presence of crystals may aid in diagnosis. The urinalysis in patients who ingest ethylene glycol often (but not always) reveals calcium oxalate or hippurate crystals. Calcium oxalate crystals are monohydrates (prism- or needlelike) or dihydrates (envelope-shaped). Hippurate crystals are needle shaped.[122] Crystalluria is present in 50% of cases of ethylene glycol poisoning (see Fig. 103-5). Hexagonal crystals are noted after massive primidone poisoning and result from precipitation of primidone in the urine.[152] Crystalluria is also described after therapeutic doses of salicylate, phenacetin, sulfonamide, and quinolones. After large ingestions, crystals can be seen with methotrexate, amoxicillin, cephalexin, ampicillin, and indinavir. Urine color is dependent on several factors, the xenobiotic, the pH, concentration, natural pigments, and length of time exposed to air.[69] Dilute urine secondary to diuretic use, diabetes mellitus, diabetes insipidus, or overhydration can appear colorless, whereas concentrated urine is usually orange. The presence of fluorescein, detected by illumination of the urine with a Wood lamp, suggests ethylene glycol (commercial antifreeze) ingestion, but this diagnostic test has poor sensitivity and specificity.[153] In a group of nonpoisoned children, all their urine samples had fluorescence when examined with a fluorometer, whereas physicians had a 61% sensitivity in detecting fluorescence in the same urine samples with a Wood lamp.[123] Table 28-6 notes other causes of colored urine.

TABLE 28-6. Xenobiotics that Cause Colored Urine

There are multiple causes of hematuria.[102] It can be a result of xenobiotic interstitial nephritis, a condition distinguished by fever, rash, eosinophiluria, azotemia, and oliguria.[48] Hemorrhagic cystitis is a more frequent cause of hematuria and is associated with a number of xenobiotics. The clinical presentation of hemorrhagic cystitis includes hematuria, dysuria, and urinary frequency. Criteria for the diagnosis of hemorrhagic cystitis include a history of gross hematuria, laboratory findings of gross hematuria (>5 red blood cells [RBC]/high-power field [HPF]), platelet count >50,000/mm,[4] and a negative urine culture.[134] When in doubt, the diagnosis may be confirmed by cystoscopy, which reveals an inflamed, hyperemic, and sometimes ulcerated bladder mucosa.

Cyclophosphamide-related hemorrhagic cystitis was first described in 1959,[108] and is the best-documented type of drug-induced hemorrhagic cystitis.[63] As many as 46% of patients

receiving cyclophosphamide develop hemorrhagic cystitis.[52, 79, 86, 91] Acrolein, the causative agent, is a metabolite of cyclophosphamide that damages the urothelium when excreted. There is no sex or age predilection, and symptoms can occur months after exposure. Hemorrhagic cystitis is described after oral doses exceeding 100 g and after a single intravenous dose of cyclophosphamide.[146] Sloughing of the bladder mucosa occurs, and 5% of patients die from intractable hemorrhage.[74, 129] Patients at highest risk are those who are volume depleted, receive cyclophosphamide intravenously, or have previous or concomitant exposure to busulfan or radiotherapy.[108] Treatment with cyclophosphamide is also associated with a dose-related increase (9- to 45-fold) in the risk of subsequent bladder cancer (Chap. 52).[127, 146]

Prophylaxis against cyclophosphamide-induced hemorrhagic cystitis includes bladder catheterization and drainage, bladder irrigation, hydration, forced diuresis, and administration of oral sodium 2-mercaptoethane sulfonate (MESNA).[108] MESNA binds to acrolein in the urine to form an inert, nontoxic thioester, reducing the incidence of hemorrhagic cystitis by 85%.[146] Bladder irrigation with alum, silver nitrate, prostaglandins, and formalin[9] has also been used to treat cyclophosphamide-induced hemorrhagic cystitis.[108] In an animal model, pretreatment with hyperbaric oxygen reduces the incidence of hemorrhagic cystitis.[74] In severe cases, hypogastric artery ligation and/or cystectomy may be required to control bleeding.[74]

An outbreak of hemorrhagic cystitis occurred in workers in a packaging plant after exposure to chlordimeform, a formamidine insecticide used to control mites and insects on cotton. Nine workers developed abdominal pain, dysuria, urgency, and hematuria, with biopsy-proven hemorrhagic cystitis.[58] Eight young adults developed painful hematuria after consuming â€œbootlegâ€• methaqualone. The cause was orthotoluidine, a compound used in the synthesis of methaqualone, and the

symptoms occurred within 6 hours of ingestion.[68] Cases of hemorrhagic cystitis are also described with ticarcillin,[104] nafcillin, penicillin G, carbenicillin, piperacillin, isoniazid, indomethacin, tiaprofenic acid, and busulphan.[64 , 107 , 143]

Summary

Toxicologic evaluation of the reproductive system is challenging because reproduction is an intermittent phenomenon. Adverse effects from xenobiotic exposures to both the male and female reproductive systems may not be noticed until fertility is desired. Toxicants can affect the hormonal controls or the organs of gametogenesis. Sexual dysfunction, whether psychogenic or xenobiotic-induced, negatively impacts fertility. Agents used to treat sexual dysfunction, such as aphrodisiacs, can have adverse systemic effects. Adverse effects on the genitourinary tract are often overlooked when evaluating the toxicologic potential of various xenobiotics. Few physical findings, laboratory tests, or ancillary studies aid in diagnosis. A thorough history including past and present medications, illicit drug use, occupational and environmental exposures, and the use of herbal or alternative therapies is mandatory in the evaluation of patients with genitourinary complaints.

Chapter 29
Dermatologic Principles

Dina Began

The skin shields internal organs from harmful xenobiotics in the environment and maintains internal organ integrity. The adult skin covers an average surface area of 2 m^2 .[10] Despite its outwardly simple structure and function, the skin is extraordinarily complex. When a xenobiotic exposure occurs, whether it is ingested, injected, or inhaled from an external source, the skin can express its effects. The basic principles of an adverse cutaneous reaction can be used to make relevant predictions, such as the physical and chemical properties of the xenobiotic and whether the effect of a response will be local or systemic. The clinician must obtain essential information as to the dose, timing, route, and location of exposure. Dermal exposures account for <10% of the cases and for approximately 1% of the fatalities reported to the American Association of Poison Control Centers (AAPCC) (Chap. 130). Dermatitis is among the most common occupational disorders. Where on the skin a xenobiotic acts histologically determines the morphology, the severity of the reaction pattern, and the overall clinical findings (Table 29-1). It should be noted, however, that

different xenobiotics may produce clinically similar skin changes and conversely that many xenobiotics may produce diverse dermal lesions.

Skin Anatomy and Physiology

The skin has three main anatomic components: the epidermis, the dermis, and the subcutis or hypodermis. The primary physiologic role of the epidermis, the most external layer of the skin, is to maintain water homeostasis and to establish immunologic surveillance. It is composed of five layers: the horny, transitional, granular, spinous, and basal layers (Fig. 29-1). The thin stratum corneum, or horny layer, is predominantly responsible for the protective function of the skin. Disruption or inadequate formation of the stratum corneum leads to a breakdown of this barrier function and many disease processes. The cells of the stratum corneum serve as a buffer to acidic and alkaline substances. Barrier function is also partly maintained by the granular layer. In this layer, there are Odland bodies, also known as membrane-coating granules, lamellar granules, and keratinosomes. The contents of these organelles provide a barrier to water loss while mediating stratum corneum cell cohesion.[12]

The stratum corneum is covered by a surface film composed of sebum emulsified with sweat and breakdown products from the horny layer.[1] The surface film functions as an external barrier to protect the entry of bacteria, virus, and fungi. The role of the surface film, however, is limited with regard to percutaneous absorption.[22] The major barrier molecules to percutaneous absorption in the skin are lipids called *ceramides* . Diseases characterized by dry skin, such as eczema, atopic dermatitis and psoriasis, are caused by decreased levels of ceramide in the stratum corneum which also allows increased xenobiotic penetration because of barrier degradation.[11] Similarly, hydrocarbon solvents, such as gasoline or methanol, or

detergents, commonly produce a â€œdefatting dermatitisâ€• by keratolysis or the dissolution of these surface lipids.

The degree of barrier function of the epidermis varies with its thickness as well. Differences in thickness are observed on different regions of the body. The epidermis varies from 1.5 mm on the glabrous surfaces (palms and soles) to 0.1 mm on the eyelids. The cells of the basal layer control the renewal of the epidermis. The basal layer contains stem cells and transient amplifying cells, which are the proliferative cells resulting in new epidermal formation that occurs every 59â€“75 days. As the basal cells migrate toward the skin surface they flatten, lose their nuclei, develop keratohyalin granules, and eventually develop into the horny layer. Patients with primary cutaneous diseases, such as psoriasis, have a significantly shortened epidermal renewal or turnover time resulting in a thicker epidermis (hyperkeratosis) and potentially less direct penetration of xenobiotics.[2] The basal layer is adjacent to the basement membrane zone and is also populated by melanocytes and Langerhans cells. Melanocytes contain melanin, which is the major chromophore in the skin that is responsible for absorbing ultraviolet and other light energies. They are also primarily responsible for skin pigmentation. The Langerhans cells are bone marrowâ€“derived cells with a primary role in immunosurveillance, including primary contact sensitization. Langerhans cells function in the recognition, uptake, processing, and presentation of antigens to previously sensitized T lymphocytes. Langerhans cells may also carry antigens via dermal lymphatics to regional lymph nodes.

The basement membrane zone, which consists of three layersâ€”the lamina lucida, the lamina densa, and the sublamina densaâ€”separates the epidermis from the dermis. It provides a site of attachment for keratinocytes and permits epidermalâ€“dermal interaction.

The dermis is deep to the epidermis and contains the adnexal

structures, blood vessels, and nerves. The dermis provides structural integrity as well as containing many important appendageal structures. The structural support is provided by both collagen and elastin fibers embedded in glycosaminoglycans, such as chondroitin A and hyaluronic acid. Mature dermis is predominantly composed of type I collagen. This collagen accounts for 70% of

the dry weight of the skin, whereas elastic fibers are equivalent to only 1â€“2% of the skin's dry weight. Several important cells, including fibroblasts and mast cells, are present in the dermis. Traversing the dermis are venules, capillaries, arterioles, nerves, and glandular structures.

Primary Cutaneous Lesions

Bulla: a circumscribed collection of free fluid more than 0.5 cm in diameter

Comedone: open and closed dilated pores (black heads and white heads)

Macule: a circumscribed flat variation of color that may be brown, blue, yellow, red, or hypopigmented (no thickness)

Nodule: a circumscribed elevation of â‰¥0.5 cm in diameter

Papule: an elevation of <0.5 cm in diameter

Plaque: a circumscribed elevation of more than 0.5 cm in diameter

Pustule: a circumscribed collection of leukocytes and free fluid that vary in size

Tumor: an elevation of greater than 0.5 cm in diameter

Vesicle: a circumscribed collection of free fluid up to 0.5 cm in diameter

Wheal: a firm edematous plaque resulting from infiltration of the dermis with fluid

Secondary Cutaneous Lesions

Erosion: a loss of the epidermis up to the full thickness of the epidermis but not through the basement membrane

Hypertrophy: a thickening of the skin

Lichenification: a secondary process with noted accentuation of skin surface markings

Scale: flaking that is separate from the original surface of a lesion

Scar: a thickened, often discolored, surface

Ulcer: a loss of full-thickness epidermis and papillary dermis, reticular dermis, or subcutis

TABLE 29-1. Dermatologic Diagnostic Descriptions of Lesions of the Skin

The arteriovenous framework of the skin consists of a deep plexus in the region of the subcutaneous dermal junction. From this deep plexus, smaller arterioles transverse upward to the junction of the reticular and papillary dermis, where they form the superficial plexus. Capillary-venules form superficial vascular loops that ascend into and descend from the dermal papillae. These communicating blood vessels provide channels in which xenobiotics exposed to the skin can be transported internally. In addition, they transport internally absorbed xenobiotics to the skin. These vessels also allow the cells of the immune system to be transported to the skin.

Parallel to the vasculature are cutaneous nerves, which serve the dual function of receiving sensory input and carrying sympathetically mediated autonomic stimuli that induce piloerection and sweating.[15]

The apocrine glands consist of secretory coils and intradermal ducts ending in the follicular canal. The secretory coil is located in the subcutis and consists of a large lumen surrounded by columnar to cuboidal cells with eosinophilic cytoplasm.[15] Apocrine glands, which are located in select areas of the body such as the axilla, produce secretions that are rendered odoriferous by cutaneous

bacterial flora.

The eccrine glands, in contrast, produce an isotonic to hypertonic secretion that is modified by the ducts and emerges on the skin surface as sweat. The eccrine unit consists of a secretory gland as well as intradermal and intraepidermal ducts. The coiled secretory gland is located in the area of the deep dermis and subcutis. Xenobiotics can be concentrated in the sweat with increased skin reactions at the sites of sweat secretion. Certain antineoplastic agents, such as cytarabine or bleomycin, directly damage the eccrine sweat glands, resulting in anhidrosis.

Sebaceous glands also reside in the dermis. They produce an oily, lipid-rich secretion that functions as an emollient for the hair and skin. The glands can be reservoirs of noxious environmental xenobiotics. Pilosebaceous follicles, which are present all over the body, consist of a hair shaft, hair follicle, sebaceous gland, sensory end organ, and erector pili. Certain halogenated aromatic chemicals, such as polychlorinated biphenyls (PCBs), dioxin, and 2,4-dichlorophenoxyacetic acid, are excreted in the sebum and cause hyperkeratosis of the follicular canal. This produces a syndrome, chloracne, that looks like acne vulgaris because of plugging of the ducts. Similar syndromes may result from exposure to brominated and iodinated compounds, known as bromoderma and ioderma, respectively.[34]

The hair follicle is divided into three portions. The lower portion of the hair follicle contains the bulb with matrix cells. These matrix cells are mitotically active with a rapid metabolic rate and often are the target of cytotoxic xenobiotics. The rate of growth and the type of hair are unique for different body sites. Hair growth proceeds through three distinct phases: the active prolonged growth phase (anagen phase) during which matrix cell mitotic activity is high; a short involutional phase (catagen phase); and a resting phase (telogen phase).[15] Understanding the phases and biochemical structure of hair growth is important because hair

growth can be used to identify clues regarding the timing and mechanism of a xenobiotic's action. For example, thallium toxicity results in alopecia 1â€“4 weeks after exposure. Within 4 days of exposure, a characteristic bandlike dark pigmentation is seen in the hair root. A hair mount observed using light microscopy will demonstrate tapered or bayonet anagen hair with black pigmentation at the base. (See ILTHALLIUM1 in the Image Library at http://www.goldfrankstoxicology.com) Seeing this anagen effect can reveal the timing of exposure. This effect is likely related to the structural similarity of thallium and potassium, allowing thallium to alter a number of potassium-mediated processes, including ligand formation with protein sulfhydryl groups which are present in human hair (Chap. 96).

The nail, which is often considered analogous to the hair, is also a continuously growing structure. Fingernails grow at average of 0.1 mm/d and toenails grow at about one-third that rate. The mitotically active cells of the nail matrix are subject to both traumatic and xenobiotic injury that affects the appearance and growth of the nail plate. Because nail growth is consistent, location of an abnormality in the plate can predict the timing of exposure, such as Mees lines (see ILMEESLINES in the Image Library).

Topical Toxicity

Exposure to any one of a myriad of industrial and environmental xenobiotics can result in skin â€œburns.â€• Although the majority of these xenobiotics injure the skin through chemical reactivity rather than thermal damage, the clinical appearances of the two are often identical. Injurious xenobiotics may act as oxidizing or reducing agents, corrosives, protoplasmic poisons, desiccants, or vesicants. Often an injury may initially appear to be mild or superficial with only faint erythema, blanching, or discoloration of the skin. Over the subsequent 24â€“36 hours there may be

progression to extensive necrosis of the skin and its underlying tissues.

Acids are water soluble and readily penetrate into the subcutaneous tissue. The damaged tissue coagulates and forms a thick

leathery eschar that limits the spread of the agent. The histopathologic finding following acid injury is termed *coagulative necrosis* . Alkali exposures characteristically produce a liquefactive necrosis, which allows continued penetration of the corrosive xenobiotic; consequently, dermal injury following alkali exposure is typically more severe than after an acid exposure of an equivalent magnitude.[8]

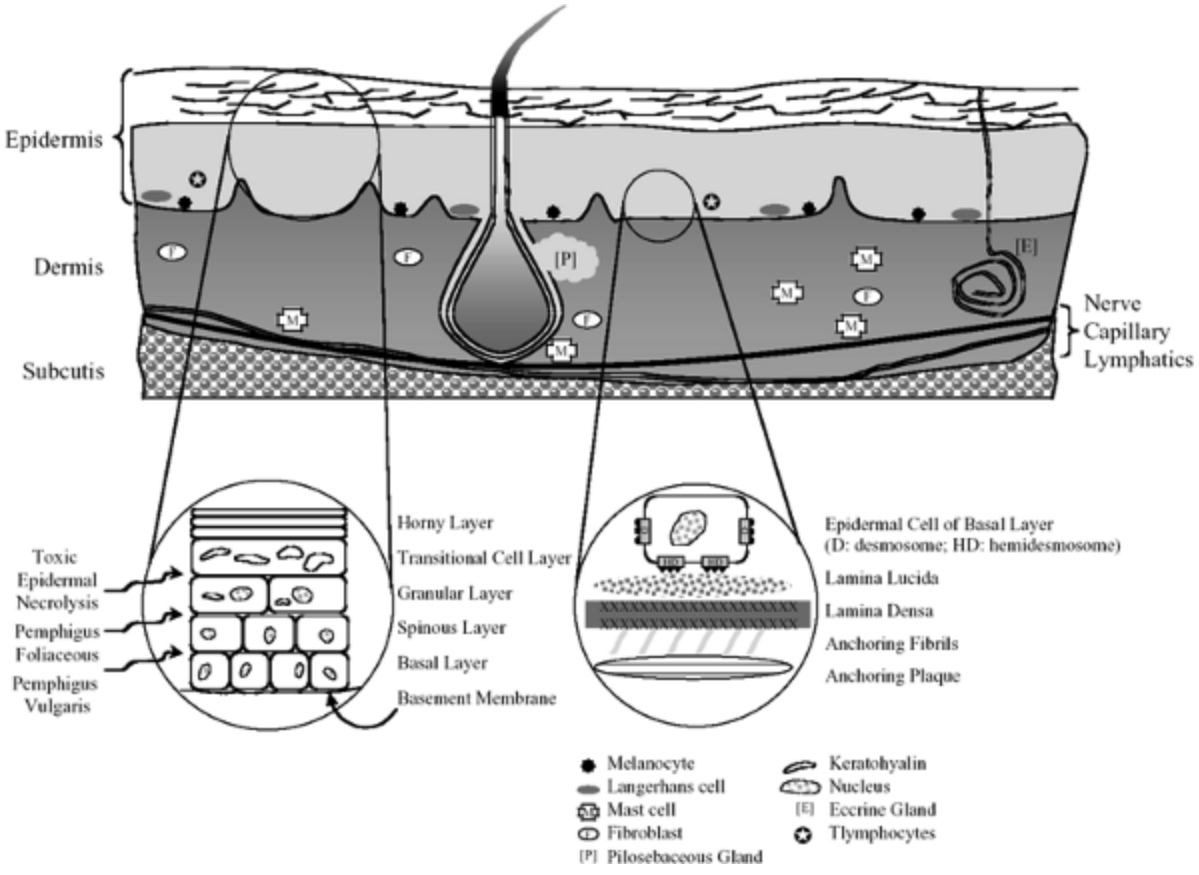

Figure 29-1. Skin histology and pathology. Intraepidermal cleavage sites in various drug-induced blistering diseases. In

pemphigus foliaceous, the cleavage is below or within the granular layer, whereas in pemphigus vulgaris, it is suprabasilar. This accounts for the differing types of blisters found in the two diseases.

Thermal damage can also be the result of a toxicologic exposure. For example, the exothermic reaction generated by the wetting of elemental phosphorus or sodium may result in a thermal burn. In these circumstances, the products of reactivityâ€”phosphoric acid and sodium hydroxideâ€”may produce secondary chemical injury. Alternatively, skin exposure to a rapidly expanding gas, such as nitrous oxide from a whipped cream cartridge or compressed liquefied nitrogen, or to frozen substances, such as dry ice, can produce a freezing injury, or frostbite.

Hydrocarbon-based solvents are typically liquids that are capable of dissolving nonâ€“water-soluble solutes.[8]

Absorption

In addition to producing topical injuries, many xenobiotics undergo percutaneous absorption by passive diffusion. Lipid solubility is the most important factor determining dermal absorption, although concentration, duration of exposure, molecular weight, and specific skin characteristics are also important determinants. Thus, although metal ions such as Hg^{+} have limited skin penetration, the addition of a methyl group, to form methylmercury, increases its lipophilicity and its systemic absorption. Dimethylmercury, formed by the addition of another methyl group, may produce life-threatening systemic effects with a minute amount applied to the skin (Chap. 92). Of importance is that the nonionized component of the weakly acidic hydrofluoric (HF) acid is able to penetrate deeply through the skin and even bone. The proton (H^{+}) and fluoride ion (F^{-}) are unable to penetrate the skin lipids because of their charged nature; however, once in the dermis, the HF acid

may ionize and cause both acid-induced tissue necrosis and fluoride-induced toxicity (Chap. 101).[5]

The vehicle of a xenobiotic may also influence absorption; indeed, transdermal drug-delivery systems are based on their ability to alter the skin partition coefficient through the use of an optimized vehicle. Similarly, through localized dermal occlusion, transdermal systems hydrate the skin and raise its temperature to increase the permeability. Despite these techniques to enhance drug delivery, transdermal systems still require that large amounts of drug be present externally to maximize the transcutaneous gradient.[31] Typically, much of the drug remains in the patch when it is discarded.

Percutaneous absorption may produce systemic, even life-threatening, toxicity. Morbidity and mortality are reported with the topical application of podophyllin, camphor, phenol, organic phosphorus insecticides, ethanol, organochlorines, nitrates, or salicylic acid. Children are particularly at risk for toxicities from percutaneous absorption because their skin is more penetrable than an adult's and specific anatomic sites, such as the face, often represent larger percentage of body surface areas than in the adult.[30] Furthermore, there is enhanced absorption on anatomic parts of the body with thinner skin, such as the mucous membranes, eyelids, and intertriginous areas (axillae, groin, inframammary, and intergluteal). Under certain circumstances, the stratum corneum may serve a depot function leading to continued systemic exposure despite apparent removal of the xenobiotic.[16]

Principles of Dermal Decontamination

On contact with xenobiotics, the skin should be thoroughly cleansed to prevent direct effects and systemic absorption. In general, a copious amount of water is the decontamination agent of choice for skin irrigation. Soap should be used when adherent

xenobiotics are involved. Following exposures to airborne xenobiotics, the mouth, nasal cavities, eyes, and ear canals should also be irrigated with appropriate solutions such as water or 0.9% NaCl. For nonambulatory patients, the decontamination process may need to be conducted using special collection stretchers if available.[7]

There are only a few situations in which water should not be used for skin decontamination. This includes contamination involving the reactive metallic forms of the alkali metals, sodium, potassium, lithium, cesium, and rubidium, which react with water to form strong bases. The dusts of pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium will ignite or explode in contact with water. Thus, following exposure to these metals, any residual metal should be removed mechanically with forceps, gauze, or towels and stored in mineral oil. Phenol has a tendency to thicken and become difficult to remove following exposure to water. Suggestions for phenol decontamination include high-flow water or low-molecular-weight polyethylene glycol solution. Lime, or CaO, also thickens and forms $Ca(OH)_2$ following wetting.[7, 9]

Dermatologic Signs of Systemic Diseases

Cyanosis

Normal cutaneous and mucosal pigmentation is caused by several factors, one of which is the visualization of the capillary beds through the translucent dermis and epidermis. Cyanosis manifests as a blue or violaceous appearance of the skin and mucous membranes. It occurs when the light-absorbing characteristics of hemoglobin are altered either through hypoxia or by oxidation of its iron moiety to the ferric state to form methemoglobin (Chap.

122). The presence of the more deeply colored hemoglobin moiety within the dermal plexus results in cyanosis that is most pronounced on the skin surfaces with the least overlying tissue, such as the mucous membranes or fingernails.

Jaundice

Jaundice is typically a sign of hepatocellular failure or hemolysis and is caused by hyperbilirubinemia, a condition in which this yellow pigment deposits in the subcutaneous fat. A yellow discoloration of the skin can also occur in patients with hypercarotenemia, caused by an excessive consumption of either carrots or the vitamin A precursor carotene. True hyperbilirubinemia is differentiated from hypercarotenemia by the presence of scleral icterus in patients with the former which is absent in the latter. In addition, the cutaneous discoloration seen in hypercarotenemia can be removed by wiping the skin with an alcohol swab. Lycopenemia, a similar entity to carotenemia, is caused by the excessive consumption of tomatoes. Also, topical exposure to dinitrophenol or picric acid, stains from cigarette use, or inhalation of lycopene produces localized yellow discoloration of the skin.

Urticarial Drug Reactions

Urticarial drug reactions are characterized by transient, pruritic, edematous, pink papules, or wheals that arise in the dermis, which blanch on palpation and are frequently associated with central clearing. This reaction pattern is representative of a type I, or IgE-dependent, immune reaction and commonly occurs as part of clinical anaphylaxis. Widespread urticaria may occur following systemic absorption of an allergen or following a minimal localized exposure in patients highly sensitized to the allergen. Following limited exposure, a localized form of urticaria also may occur. Regardless of the specific clinical presentation, this reaction occurs

when immunologic recognition occurs between IgE molecules and a putative antigen triggering the immediate degranulation of mast cells, which are distributed along the dermal blood vessels, nerves, and appendages. The release of histamine, complements C3a and C5a, and other vasoactive mediators result in leakage of fluid from dermal capillaries as their endothelial cells contract. This produces the characteristic urticarial lesions described above. Activation of the nearby sensory neurons produces pruritus. Nonimmunologically mediated mast cell degranulation producing an identical urticarial syndrome may also occur, following exposure to various xenobiotics, including jellyfish or benzoic acid.

Pruritus is a common manifestation of urticarial reactions, but it may also be of nonimmunologic origin. Patients with hepatocellular disease frequently suffer from pruritus, which is mediated by the release of bile acids. In addition, in patients with chronic liver disease and obstructive jaundice, pruritus can be caused by central mechanisms, as suggested by elevated central nervous system (CNS) opioid peptide concentrations. Pruritus can also be caused by topical exposure to the urticating hairs of Tarantula spiders, spines of the stinging nettle plant (*Urtica* sp), or certain xenobiotics such as capsaicin.[14]

Xenobiotics also can evoke a type III immune reaction that causes mast cells to degranulate. The cellular inflammatory response to released chemotactic factors leads to increased vascular permeability.

Flushing

Vasodilation of the dermal arterioles leads to flushing. Flushing can occur following autonomically mediated vasodilation, as occurs with stress, anger, or exposure to heat, or it can be chemically induced by vasoactive xenobiotics. Those xenobiotics that cause histamine release through a type I hypersensitivity reaction are the most frequent cause of xenobiotic-induced flush. Histamine

poisoning itself, most frequently caused by the consumption of scombrotoxic fish, can cause flushing. Flushing after the consumption of ethanol is common in patients of Asian descent and is similar to that following ethanol consumption in patients exposed to disulfiram or similar agents (Chap. 77). The inability to efficiently metabolize acetaldehyde, the initial metabolite of ethanol, and its

increased production, results in the characteristic syndrome of vomiting, headache, and flushing. Niacin causes flushing through an arachidonic acidâ€“mediated pathway that may be inhibited by preingesting aspirin.[32] Vancomycin causes a transient bright red flushing that is mediated by histamine. It occurs during and immediately after rapid infusion, and is termed â€œred man syndrome.â€•

Skin Moisture

Xenobiotic-induced diaphoresis may be part of a physiologic response to heat generation or may be pharmacologically mediated following sympathomimetic xenobiotic use. The eccrine sweat glands are responsible for sweat production, and they are uniquely innervated by acetylcholine-containing neurons within the sympathetic nervous system. Because the postsynaptic receptor on the eccrine glands is muscarinic, most muscarinic agonists are capable of stimulating sweat production. The latter most commonly occurs following exposure to cholinesterase-inhibiting insecticides, such as organic phosphorus compounds, but it may also occur with direct-acting muscarinic agonists such as pilocarpine. Alternatively, antimuscarinic agents, such as atropine or diphenhydramine, reduce sweating and produce dry skin.

Metallic Pigmentations

Pigmentary changes can result from the deposition of fine metallic

particles. These particles can be ingested and carried to the skin by the blood, or may permeate the skin from topical applications. Argyria, a slate-colored pigmentation of the skin resulting from the systemic deposition of silver particles in the skin, can be localized or widespread. The discoloration tends to be most prominent in areas exposed to sunlight, probably secondary to the fact that silver stimulates melanocyte proliferation. (See ILARGYRIA1 in the Image Library.) Histologically, fine black granules are found in the basement membrane zone of the sweat glands, blood vessel walls, the dermoepidermal junction, and along the erector pili muscles (Chap. 95). Gold, which is used parenterally in the treatment of rheumatoid arthritis, can cause a blue or slate-gray pigmentation known as chrysiasis. The pigmentation is also accentuated in light-exposed areas but, unlike in argyria, sun-protected areas do not histologically demonstrate gold. Also, melanin is not increased in the areas of hyperpigmentation. The hyperpigmentation is probably secondary to the gold itself, but the cause of its distribution pattern remains unknown. Histologically, the gold is distributed in a perivascular pattern in the dermis with granules accentuated at the basement membrane zone of sweat glands.

Bismuth produces a characteristic oral finding of the metallic deposition in the gums known as bismuth lines. (See ILBISMUTH1 in the Image Library.) Arsenic, which is found in certain pesticides and in contaminated well water, causes cutaneous hyperpigmentation with areas of scattered hypopigmentation. Chronic lead poisoning can produce a characteristic â€œlead hueâ€• with pallor. Lead also deposits in the gums, causing the characteristic â€œlead line.â€• Iron can cause staining of the skin, resulting in pigmentation similar to that seen in tattoos.[13]

Specific Syndromes

The ability to describe lesions accurately is an important skill, as is the ability to recognize specific patterns. Such abilities help

clinicians in their approach to the patient with a rash. Several cutaneous reaction patterns account for the majority of clinical presentations occurring in patients with xenobiotic-induced dermatotoxicity (Table 29-2).

Toxic Epidermal Necrolysis and Related Syndromes

Toxic epidermal necrolysis (TEN) is a rare, life-threatening dermatologic emergency. Its incidence is estimated at 0.4â€“1.2 cases per 1 million population, and medications are causally implicated in 80â€“95% of the cases. The cutaneous reaction pattern is characterized by tenderness and erythema of the skin and mucosa, followed by extensive cutaneous and mucosal exfoliation.[28]

Classically, the eruption occurs within days of the exposure to the implicated substance and is preceded by malaise, headache, fever, myalgias, arthralgias, nausea, vomiting, diarrhea, chest pain, or cough. Initially, a macular erythema develops that subsequently becomes raised and morbilliform (â€œmeasles likeâ€•). The face, neck, and central trunk are usually the initial areas affected. The disease generally progresses to involve the extremities and the remainder of the body. Individual lesions are reminiscent of target lesions because of their dusky centers. The entire thickness of the epidermis, including the nails, becomes necrotic and may slough off. The mucosal surfaces of the lips, oropharynx, conjunctiva, vagina, urethra, and anus may show erythema and sloughing. A Nikolsky sign, consisting of sloughing of the epidermis when direct pressure is exerted on the skin lesion, may occur.[3] Although suggestive, the Nikolsky sign is not pathognomonic of TEN and occurs in a variety of other dermatoses, including pemphigus vulgaris. If the diagnosis is suspected, a biopsy should be performed and treatment initiated immediately. The histopathology typically shows partial- or full-thickness epidermal necrosis, with

subepidermal bullae with a sparse infiltrate, and vacuolization with numerous dyskeratotic keratinocytes along the dermoepidermal junction adjacent to the necrotic epidermis. Removal of the inciting agent and transfer to a burn center for sterile wound care are widely accepted initial management strategies. Although glucocorticoids are not generally recommended, there is emerging support for the use of immunosuppressive or immunomodulatory agents, such as intravenous immunoglobulins, cyclophosphamide, and cyclosporine. Reported mortality is as high as 30%, particularly in patients with gastrointestinal and tracheobronchial involvement.[28]

TEN is often considered to be the most severe manifestation of the spectrum of syndromes represented by erythema multiforme. Erythema multiforme is characterized by target-shaped, erythematous macules and patches on the palms and soles, as well as the trunk and extremities. The Nikolsky sign is absent. The etiology of recurrent erythema multiforme minor appears to be predominantly associated with recurrent herpes simplex virus infections. Contact sensitization to sulfonamides, phenytoin, antihistamines, many antibiotics, dinitrochlorobenzene (DNCB), diphenylcyclopropenone (DPCP), isopropyl-*p* -phenylenediamine (IPPD), rosewood, and urushiol can elicit erythema multiforme. The Stevens-Johnson syndrome is similarly considered to be an overlap reaction with erythema multiforme major when greater than 30% of body surface area is involved.

Blistering Reactions

Xenobiotic-related cutaneous blistering reactions may be clinically indistinguishable from autoimmune blistering reactions, such as pemphigus vulgaris or bullous pemphigoid. Certain topically

applied xenobiotics cause blistering by disrupting the anchoring filaments of basal cell desmosomes at the dermalâ€“epidermal

junction. In high concentrations, this can lead to necrosis of both skin and mucous membranes. Other xenobiotics cause a similar reaction pattern mediated by the production of antibody directed against the cells at the dermalâ€“epidermal junction.

TABLE 29-2. Xenobiotics Commonly Associated with Various Cutaneous Reaction Patterns

A number of medications, many of which contain a â€œthiol groupâ€• such as penicillamine and captopril, can induce either

pemphigus foliaceous, a superficial blistering disorder in which the blister is at the level of the stratum corneum, or pemphigus vulgaris, in which blistering occurs at the suprabasilar level (Fig. 29-1). Other xenobiotics produce the tense bullae that resemble bullous pemphigoid. Immunofluorescence studies might show epidermal intracellular immunoglobulin deposits at the dermalâ€“epidermal junction. Treatment options include immunosuppressive agents. The reaction may persist for up to 6 months after the offending agent is withdrawn.

â€œComa bullaeâ€• are flaccid bullae that occur occasionally in patients with sedative-hypnotic overdoses, particularly phenobarbital, or carbon monoxide poisoning. (See ILBARBBLISTERS in the Image Library.) Although these blisters are thought to result from pressure-induced epidermal necrosis, they occasionally occur in nonâ€“pressure-dependent areas, suggesting a systemic mechanism. An intraepidermal or subepidermal blister may occur. There is accompanying eccrine duct and gland necrosis.

Bullous Drug Eruptions

Multiple, large, ill-defined, dull, purplish-livid patches sometimes accompanied by large flaccid blisters characterize these eruptions. Typical locations include acral extremities, genitals, and intertriginous sites, and the process may be confused with TEN if widely confluent. However, bullous drug eruptions spare the patient's mucous membranes. This reaction pattern is generally not life-threatening. Bullous fixed-drug reactions result from the ingestion of a variety of medications such as angiotensin-converting enzyme inhibitors and a variety of antibiotics.

Drug-Induced Hypersensitivity Syndrome

The skin may be involved with systemic drug-induced immunologic diseases. The hypersensitivity syndromes are characterized by erythroderma and facial and periorbital edema, and are typically accompanied by high fever, elevated hepatic aminotransferases, lymphadenopathy, and peripheral eosinophilia. The syndrome typically occurs 2â€“7 weeks after starting therapy with an anticonvulsant (Chap. 47) or a sulfa-based drug. (See ILANTICONVULSANTS in the Image Library.) Management of this syndrome is supportive following elimination of the offending substance.[20 , 33]

Exfoliative Erythrodermas

Exfoliative erythrodermic eruptions can result from any xenobiotic and is characterized by widespread erythema and scale with the potential for multisystem organ failure. The process may persist for months. Such patients with exfoliative erythrodermas require aggressive fluid and electrolyte repletion and nutritional support. Boric acid toxicity causes a bright red eruption (â€œlobster skinâ€•), followed usually within 1â€“3 days by a generalized exfoliation. The mechanism of toxicity is unknown.

Vasculitis

Hypersensitivity vasculitis is characterized by purpuric, nonblanching macules that usually become raised and palpable. The purpura tends to occur predominantly on gravity-dependent areas, including the lower extremities, feet, and buttocks. Sometimes the reaction pattern can have edematous purpuric wheals (urticarial vasculitis), hemorrhagic bullae, or ulcerations. The underlying cytopathology consistently shows a leukocytoclastic vasculitis, which is characterized by fibrin deposition in the vessel walls and a perivascular infiltrate with intact and fragmented neutrophils which appear as black dots, known as nuclear dust, visible only by electron microscopy. This reaction pattern may be limited to the skin, or may be more serious and involve other organ systems, particularly the kidneys, joints, liver, lungs, and brain. The purpura results from circulating immune complexes, which form as a result of a hypersensitivity to a xenobiotic.

Purpura

Purpura is the multifocal extravasation of blood into the skin or mucous membranes. Ecchymoses are, therefore, considered to be purpuric lesions. Cytotoxic agents that either diffusely suppress the bone marrow, or specifically depress platelet counts below $30{,}000/mm^3$, predispose to intradermal hemorrhage, resulting in petechiae or purpuric macules. Xenobiotics that interfere with platelet aggregation, such as, aspirin, clopidogrel, ticlopidine, and valproic acid, may cause purpura. Anticoagulants, such as heparin and coumarin, may also result in purpura (Chaps. 24 and 57).

Coumarin Necrosis

Skin necrosis from coumarin may occur from day 3 to day 10 after the initiation of treatment. The necrosis is secondary to thrombus formation in vessels of the dermis and subcutaneous fat. There

may be blisters, ecchymosis, ulcers, and massive subcutaneous necrosis, usually in areas of abundant subcutaneous fat, such as the breasts, buttocks, abdomen, thighs, and calves. It may be associated with protein C or S deficiency and anticardiolipin antibody syndrome, as well as Leiden V factor mutations.[21]

Contact Dermatitis

When a xenobiotic contacts the skin, it can result in either an allergic contact dermatitis or an irritant dermatitis. Contact dermatitis is characterized by inflammation of the skin with spongiosis (intercellular edema) of the epidermis that results from the interaction of a xenobiotic with the skin. Erythema, induration, pruritus, or blistering may be noted on areas in direct contact with the xenobiotic, while the remaining areas are spared.

Allergic contact dermatitis fits into the classic delayed hypersensitivity, or type IV, immunologic reaction. The development of this reaction requires prior sensitization to an allergen, which, in most cases, acts as a hapten by binding with an endogenous molecule that is then presented to an appropriate immunologic T cell. Upon reexposure, the hapten diffuses to the Langerhans cell, is chemically altered, bound to an HLA-DR, and the complex is expressed on the Langerhans cell surface. This complex interacts with primed T cells either in the skin or lymph nodes, causing the Langerhans cells to make interleukin-1 and the activated T cells to make interleukin-2 and interferon-Î³. This subsequently activates the keratinocytes to produce cytokines and eicosanoids that activate mast cells and macrophages, leading to an inflammatory response (Fig. 29-2).[17 , 18]

Many allergens are associated with contact dermatitis; a complete list is beyond the scope of this chapter. Among the most common sensitizers are urushiol (poison ivy) (see ILPOISONIVY in the Image Library), sesquiterpene lactone (ragweed), and tuliposide A (tulip bulbs). Metals, particularly nickel, are commonly implicated

in contact dermatitis. Several industrial chemicals, such as the thiurams (rubber) and urea formaldehyde resins (plastics), account for the majority of occupational contact dermatitis.

Medications, particularly topical medications such as neomycin, commonly cause contact dermatitis.

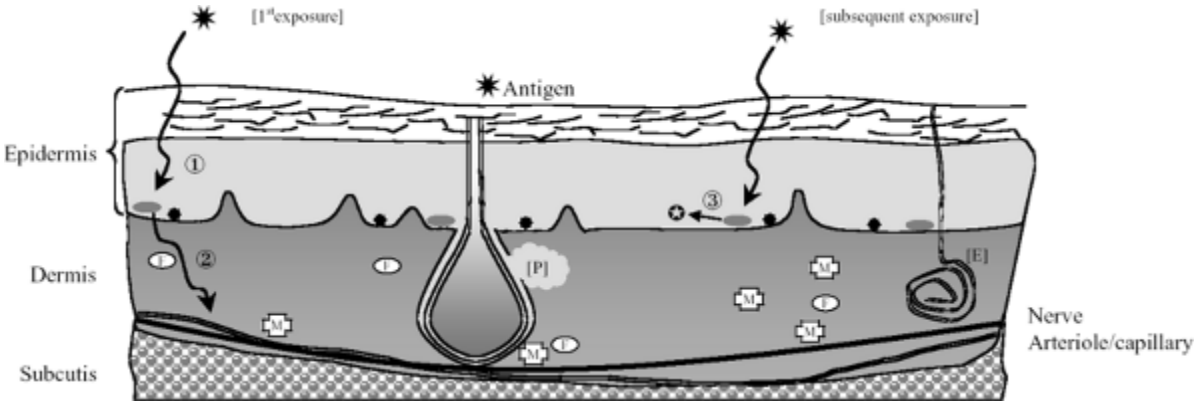

Figure 29-2. Contact dermatitis. (1) Causative chemical, typically a hapten of <500 daltons, diffuses through stratum corneum and binds to receptor on Langerhans cell. (2) The antigen is processed with HLA-DR receptor site, presented to T-helper lymphocytes, and carried through the lymphatics to regional lymph nodes. There it undergoes the sensitization phase by producing memory, effector, and suppressor T lymphocytes. (3) On reexposure to the same, or to a cross-reactive antigen, the Langerhans cell represents the antigen to T lymphocytes, which are now sensitized. This initiates an inflammatory process that appears as indurated, scaly patches. (See Figure 29-1 for symbol legend.)

Irritant dermatitis, while clinically indistinguishable, results from direct damage to the skin and does not require prior antigen sensitization. Still, the inflammatory response to the initial mild insult is the cause of the majority of the damage. Irritant xenobiotics include acids, bases, solvents, and detergents, many of which, in their concentrated form or following prolonged

exposure, can cause direct cellular injury. The specific site of damage varies with the chemical nature of the xenobiotic. Many xenobiotics can affect the lipid membrane of the keratinocyte, whereas others can diffuse through the membrane, injuring the lysosomes, mitochondria, or nuclear components. When the cell membrane is injured, phospholipases are activated and affect the release of arachidonic acid and the synthesis of eicosanoids. The second-messenger system is then activated, leading to the expression of genes and the synthesis of various cell surface molecules and cytokines. Interleukin-1 is secreted, which can activate T cells directly and indirectly by stimulation of granulocyte-macrophage colony-stimulating factor (GM-CSF) production.

Photosensitivity Reactions

Photosensitivity drug reactions are adverse reactions to nonionizing radiation, particularly to ultraviolet A (320â€“400 nm) and less often to ultraviolet B (280â€“320 nm). There are five types of acute photosensitivity reactions: polymorphous light eruption, subacute cutaneous lupus erythematosus, drug-induced phototoxicity, solar urticaria, and photoallergy.[19] There are generally two types of reaction patterns: phototoxic and photoallergic. Phototoxic drug reactions occur within 24 hours of the first dose and are dose-related. The clinical findings include erythema and edema in a light-exposed distribution, and resemble an exaggerated sunburn that can last for days to weeks. Photoallergic reactions occur less commonly, may occur following even small exposures, and are characterized by lichenoid papules or eczematous changes on exposed areas. Photoallergic reactions can be diagnosed by the use of patch tests. Both phototoxic and photoallergic reactions are managed with symptomatic therapy, including topical or, if needed, systemic corticosteroids. The patient should be advised to avoid sun exposure or wear a sunscreen that blocks both ultraviolet A and ultraviolet B with a

sun protection factor (SPF) of 15 or greater and is *para* -aminobenzoic acid (PABA) free.

Scleroderma-like Reactions

A number of environmental chemicals are associated with a localized or diffuse scleroderma-like reactions. Sclerodermatous changes refer to a tightened indurated surface change of the skin. These typically occur on the face, hands, forearms, and trunk. This may be accompanied by facial telangiectasias and Raynaud syndrome. Raynaud syndrome consists of skin color changes of white, red, and blue, accompanied by intense pain with exposure to cold, and can cause acral ulcerations, if untreated. The fibrotic process usually does not remit with removal of the external stimulus. The association of scleroderma-like reactions with polyvinyl chloride manufacture is likely related to exposure to vinyl chloride monomer. (See ILVINYLCHLORIDE in the Image Library.) Similar reports of this syndrome are associated with exposure to trichloroethylene and perchloroethylene, which are structurally similar to vinyl chloride.

Widespread cutaneous sclerosis, in patients exposed to imported rapeseed oil mixed with an aniline denaturant, occurred in Spain and became known as the â€œtoxic oil syndrome.â€• A similar syndrome, following ingestion of impure L-tryptophan as a dietary supplement, resulted in the eosinophilia-myalgia syndrome, which is characterized by myalgia, edema, arthralgias, alopecia, urticaria, mucinous yellow papules, and erythematous plaques.[6 , 24]

Hair

Xenobiotics that produce anagen effluvium, hair loss of those hairs in the anagen stage of the cycle, produce rapid hair loss, whereas those causing telogen effluvium might not produce hair loss for

weeks. Anagen toxicity is the most common mechanism and

occurs with chemotherapeutics and thallium exposures.[26] Many antineoplastic drugs reduce the mitotic activity of the rapidly dividing hair matrix cells, leading to the formation of a thin shaft that breaks easily. Thallium, a toxin classically associated with hair loss, causes alopecia by two mechanisms. Thallium distributes intracellularly, like potassium, inhibiting mitochondrial oxidative phosphorylation, thereby disrupting protein synthesis. In addition, by binding sulfhydryl groups, thallium also inhibits the normal incorporation of cysteine into keratin. Selenium may produce alopecia by similar mechanisms. Soluble barium salts, such as barium sulfide, are applied topically as a depilatory to produce localized hair loss. The mechanism of hair loss is undefined.

Nails

Nail findings may serve as important clues to xenobiotic exposures that have occurred recently or in the remote past. Matrix keratinization leads to the formation of the nail plate. This keratinization is programmed and occurs uniformly in a scheduled pattern. The observed changes in nails, such as Mees lines and Beau lines, can be used to predict the timing of a toxic exposure because of the reliability of rate of growth of the nails. Arsenic poisonings can accurately be dated by the position of growth of the Mees line, as nails grow approximately at an average rate of 0.1 mm/d. Thallium also causes Mees lines.[23] It should be noted that many xenobiotics, including radiation and chemotherapeutic agents, as well as starvation, cause these lines; they are nonspecific findings.

Summary

The integument is constantly exposed to xenobiotics. Whether the exposure occurs via ingestion, airborne, or topical routes, reactive

dermatoses may ensue. Prompt attention and diagnosis is imperative in treating such exposures. The skin, hair, and nails may provide invaluable clues as to the route and nature of the xenobiotic agent. With a careful history, clinical examination, and appropriate biopsy, the etiology and nature of the reaction can be ascertained and treated in a timely and an effective manner.

Chapter 30
Reproductive and Perinatal Principle

Jeffrey S. Fine

Reproductive and perinatal principles in toxicology derive from many area basic science and are applied to many aspects of clinical practice. This cl reviews several principles of reproductive medicine that have implications toxicology: the physiology of pregnancy and placental xenobiotic transfer, effects of xenobiotics on the developing fetus and the neonate, and the management of overdose in the pregnant woman.

One of the most dramatic effects of exposure to a xenobiotic during preg the birth of a child with congenital malformations. Teratology, the study defects, has principally been concerned with the study of physical malfor A broader view of teratology includes â€œdevelopmentalâ€• teratogensâ€”agents that induce structural malformations, metabolic or physiologic dysfunction, or psychological or behavioral alterations or defic the offspring, either at or after birth.[216] Only 4â€“6% of birth defects are related to known pharmaceuticals or occupational and environmental exposures.[31 , 216]

Reproductive effects of xenobiotics may occur before conception. Female cells are formed in utero; adverse effects from xenobiotic exposure can

theoretically occur from the time of a woman's own intrauterine developm the end of her reproductive years. An example of a xenobiotic that had b teratogenic and reproductive effects is diethylstilbestrol (DES), which cau vaginal and/or cervical adenocarcinoma in some women who had been ex to DES in utero and also had effects on fertility and pregnancy outcome.[1]

Men generally receive less attention with respect to reproductive risks. M gametes are formed after puberty; only from that time on are they susce to xenobiotic injury. An example of a toxin affecting male reproduction is dibromochloropropane, which reduces spermatogenesis and, consequentl fertility. In general, much less is known about the paternal contribution t teratogenesis.[266]

Occupational exposures to xenobiotics are potentially important but often defined. In 2004, it was estimated that there were 41 million women of reproductive age in the workforce.[181] Although approximately 90,000 ch are used commercially in the United States, only a few thousand industria pharmaceutic agents have been specifically evaluated for reproductive to Many xenobiotics have teratogenic effects when tested in animal models, relatively few well-defined human teratogens have been identified (Table).[224] Thus, most tested xenobiotics do not appear to pre-sent a human teratogenic risk, but most xenobiotics have not been tested. Some of the presumed safe xenobiotics may have other reproductive, nonteratogenic toxicities. Several excellent reviews and online resources are available.[79 216 , 224]

Another type of xenobiotic exposure for a pregnant woman is the intentio overdose. Although a xenobiotic taken in overdose may have direct toxici the fetus, fetal toxicity frequently results from maternal pulmonary and/o hemodynamic compromise, such as hypoxia or shock, further emphasizing critical nature of the maternalâ€“fetal dyad.

Xenobiotic exposures before and during pregnancy can have effects thro gestation and may extend into and beyond the newborn period. In additio effects of medication administration in the perinatal period, and the speci of delivering xenobiotics to an infant via the breast milk, deserve special consideration.

Physiologic Changes During Pregnancy tha affect Drug Distribution

Many physical and physiologic changes that occur during pregnancy affec absorption and distribution of xenobiotics in the pregnant woman and consequently affect the amount of xenobiotics delivered to the fetus.[103] ,

During pregnancy there is delayed gastric emptying, decreased gastroint (GI) motility, and increased transit time through the GI tract. These char result in delayed but more complete GI absorption of xenobiotics and, consequently, lower peak plasma concentrations. Because blood flow to th and mucous membranes is increased, absorption from dermal exposure m increased. Similarly, absorption of inhaled xenobiotics may be increased of increased tidal volume and decreased residual lung volume.

Amiodarone

Transient neonatal hypothyroidism, with or without goiter; hyperthyroidis Amiodarone contains 39% iodine by weight. Small to moderate risk from weeks to term for thyroid dysfunction.

Androgens (eg, methylsteroidtestosterone, danazol)

Virilization of the female external genitalia: clitoromegaly, labioscrotal fu Effects are dose dependent. Stimulates growth of sex-steroid, receptorâ€“containing tissue.

Effects are dose dependent. Stimulates growth of sex-steroidtestosterone receptorâ€“containing tissue.

Growth retardation, cleft palate, microphthalmia, hypoplastic ovaries, clo corneas, renal agenesis, malformations of digits, cardiac defects, other anomalies

A 10â€“50% malformation rate, depending on the agent. Cyclophospham induced damage requires cytochrome P450 oxidation.

Aminopterin, methotrexate (amethopterin)

Hydro/microcephaly; meningoencephalocele; anencephaly; abnormal cra ossification; cerebral hypoplasia; growth retardation; eye, ear, and nose malformations; cleft palate; malformed extremities/fingers; reduction in

derivatives of first branchial arch; developmental delay[254]

These folate antagonists inhibit dihydrofolate reductase. High rate of malformations. Methotrexate is used to terminate ectopic pregnancies.

Angiotensin-converting enzyme inhibitors

Fetal/neonatal death, prematurity, oligohydramnios, neonatal anuria, IUG secondary skull hypoplasia, limb contractures, pulmonary hypoplasia

Does not interfere with organogenesis. Significant risk of effects related t chronic fetal hypotension during second/third trimester. If used during ea pregnancy, can be switched during first trimester.[31]

Carbamazepine

Upslanting palpebral fissures, epicanthal folds, short nose with long philt fingernail hypoplasia, anticondevelopmental delay, NTD[110]

Risk unquantified, but may be significant for minor anomalies. Risk is inc in setting of therapy with multiple anticon-vulsants, particularly valproic Mechanism may involve an epoxide intermediate. A 1% risk for NTD. Hig folate, although unproven, is recommended to try to prevent NTD. Increa of perinatal/neonatal bleeding related to deficiency of vitamin K-depende clotting factors, requires vitamin K prophylaxis and therapy.

Carbon monoxide

Cerebral atrophy, mental retardation, microcephaly, convulsions, spastic disorders, intrauterine/death

With severe maternal poisoning, high risk for neurologic sequelae; no inc risk in mild exposures.

Cocaine

IUGR, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomenon (limb amputation, cerebral infarction, visceral/urinary tract abnormalities)

Vascular disruptive effects because of decreased uterine blood flow and f vascular effects from first trimester through the end of pregnancy. Risk f major disruptive effects is low.

Corticosteroids

Cleft palate, decreased birth weight (up to 9%) and head circumference (4%)

Low risk. Most information related to prednisone or methylprednisolone.

Coumadin	
Fetal warfarin syndrome: nasal hypoplasia, chondrodysplasia punctata, brachydactyly, skull defects, abnormal ears, malformed eyes, CNS malformations, microcephaly, hydrocephalus, skeletal deformities, menta retardation, spasticity	
A 10%â€“25% risk of malformation for first-trimester exposure, 3% risk hemorrhage, 8% risk of stillbirth. Bleeding is an unlikely explanation for produced in the first trimester. CNS defects may occur during second/thi trimesters and may be related to bleeding.[108] ,[253]	
Diazepam	
Cleft palate, other anomalies	
Controversial association, probably low risk.[32] ,[62] ,[79] Risk may extend to benzodiazepines. Also risk for neonatal sedation or withdrawal following maternal use near delivery.	
Diethylstilbestrol (DES)	
Female offspring: vaginal adenosis, clear cell carcinoma, irregular mense reduced pregnancy rates, increased rate of preterm deliveries, increased perinatal mortality and spontaneous abortion	
Male offspring: epididymal cysts, cryptorchidism, hypogonadism, diminish spermatogenesis	
A synthetic nonsteroidal estrogen that stimulates estrogen-receptorâ€“c tissue and may cause misplaced genital tissue with propensity to develop	
A 40â€“70% risk of morphologic changes in vaginal epithelium. Risk of carcinoma approximately 1/1000 for exposure before the 18th week. Mos patients exposed to DES in utero can conceive and deliver normal childre	
Ethanol	
Fetal alcohol syndrome (FAS): pre-/postnatal growth retardation, mental retardation, fine motor dysfunction, hyperactivity, microcephaly, maxillar hypoplasia, short palpebral fissures, hypoplastic philtrum, thinned upper joint, digit anomalies	
FAS in 4% of offspring of alcoholic women consuming ethanol above 2 g/l oz/d) over the first trimester. There may be a threshold for effects, but a dose has not been identified. Can see partial expression or other congeni anomalies (see text). Other effects: increased incidence of spontaneous	

abortion, premature delivery, and stillbirth; neonatal withdrawal.

Fluconazole

Brachycephaly, abnormal facies, abnormal calvarial development, cleft p femoral bowing, thin ribs and long bones, arthrogryposis, and congenital disease

Risk related to high dose (400â€“800 mg/d), chronic, parenteral use. Sin 150-mg oral dose probably safe.

Indomethacin

Premature closure of the ductus arteriosus; in premature infants, oligohydramnios, anuria, intestinal ischemia

NSAIDs generally labeled as category B. However, there is concern when after 34 weeks' gestation and for more than 48 hours and/or immediately to delivery. Risk may extend to other NSAIDs.

Iodine and iodinecontaining products

Thyroid hypoplasia after the 8th week of development

High doses of radioiodine isotopes can additionally produce cell death and mitotic delay. Tissue and organ-specific damage is dependent on the spe radioisotope, dose, distribution, metabolism, and localization.

Lead

Lithium carbonate

Lower scores on developmental tests

Ebstein anomaly

Higher risk when maternal lead is >10 g/dL. Low risk.

Methimazole

Aplasia cutis, skull hypoplasia, dystrophic nails, nipple abnormalities, hyp hyperthyroidism

Small risk of anomalies or goiter with first-trimester exposure. Hypothyr risk after 10 weeks' gestation.

Methylmercury, mercuric sulfide

Normal appearance at birth; cerebral palsyâ€“like syndrome after several months; microcephaly, mental retardation, cerebellar symptoms, eye/der anomalies

Inhibits enzymes, particularly those with sulfhydryl groups. Of 220 babies following the Minamata Bay exposure, 13 had severe disease. Mothers of

affected babies ingested 9â€“27 ppm mercury; greater risk with ingestion 6â€“8 months' gestation. In acute poisoning, the fetus is 4â€“10 times m sensitive than an adult. Pathologically, there is atrophy and hypoplasia of brain cortex and abnormalities in cytoarchitecture.[93] ,[259]

Methylene blue (intraamniotic injection)

Intestinal atresia, hemolytic anemia, neonatal jaundice

This xenobiotic was used to identify a twin.

Misoprostol

Vascular disruptive phenomena (eg, limb reduction defects); Moebius syn (paralysis of 6th and 7th facial nerves)

Synthetic prostaglandin E1 analog. Effects mostly observed in women aft unsuccessful attempts to induce abortion.

Oxazolidine-2,4-diones (trimethadione, paramethadione)

Fetal trimethadione syndrome: V-shaped eyebrows, low-set ears with an folded helix, high-arched palate, irregular teeth, CNS anomalies, severe developmental delay, cardiovascular, genitourinary, and other anomalies

An 83% risk of at least one major malformation with any exposure; 32% Characteristic facial features are associated with chronic exposure.

Penicillamine

Cutis laxa, hyperflexibility of joints

Copper chelatorâ€”copper deficiency inhibits collagen synthesis/ maturatio case reports; low risk.

Phenytoin

Fetal hydantoin syndrome: microcephaly, mental retardation, cleft lip/pa hypoplastic nails/phalanges, characteristic facesâ€”low nasal bridge, inn epicanthal folds, ptosis, strabismus, hypertelorism, low-set ears, wide m

Phenytoin has a direct effect on cell membranes and on folate and vitamin metabolism. May reduce the availability of retinoic acid derivatives or alte genetic expression of retinoic acid.

Epoxide intermediate may play a role in teratogenesis. Effects seen with exposure. A 5â€“10% risk of typical syndrome, 30% risk of partial syndr

Risks confounded by those associated with epilepsy itself and use of othe anticonvulsants. Increased risk of perinatal and neonatal bleeding related deficiency of vitamin K-dependent clotting factors requires vitamin K pro

and therapy. Possible increased risk of developing tumors, in particular, neuroblastoma, although absolute risk is very low.

Polychlorinated biphenyls

Cola-colored children; pigmentation of gums, nails, and groin; hypoplasti deformed nails; IUGR; abnormal skull calcifications

Cytotoxic agent. Body residue can affect subsequent offspring for up to 4 after exposure. Most cases followed high consumption of PCB-contaminate oil; 4â€“20% of offspring were affected.

Progestins (eg, ethisterone, norethindrone)

Masculinization of female external genitalia

Progestogens are converted into androgens or may have weak androgenic activity. Stimulates or interferes with sex-steroid receptors. Effects occur after exposure to high doses of some testosterone-derived progestins and be at the rate of 1% of those exposed. Oral contraceptives containing the agents are not thought to present teratogenic risk, despite their category designation.

Quinine Radiation, ionizing

Hypoplasia of 8th nerve, deafness, abortion Microcephaly, mental retarda eye anomalies, growth retardation, visceral malformations

Effects related to high doses used as abortifacients.

Significant doses of radiation from diagnostic or therapeutic sources prod death and mitotic delay. There is no measurable risk with X-ray exposures rads or less at any stage of pregnancy.[22] ,[30]

Retinoids (isotretinoin, etretinate, high-dose vitamin A)

Spontaneous abortions; micro-/hydrocephalus; deformities of cranium, e face, heart, limbs, liver

Retinoids can cause direct cytotoxicity and alter apoptosis. Neural crest c particularly sensitive. For isotretinoin, 38% risk of malformations; 80% a malformations. Effects are associated with vitamin A doses of 25,000â€“ U/d. Exposures below 10,000 U/d present no risk to fetus. Topical retinoi not considered a reproductive risk.[239]

Smoking

Placental lesions, IUGR, increased perinatal mortality, increased risk of SIDS77,129,227,[260]

Effects related to a combination of vasoconstriction (nicotine effect), hyp secondary to hypoperfusion, CO, and CN, and altered development of ne and neural pathways.212,[230]

Streptomycin

Hearing loss

Rare reports. A low-risk phenomenon that could be associated with long- maternal therapy during pregnancy.

Tetracycline

Yellow, gray-brown, or brown staining of deciduous teeth, hypoplastic toc enamel

Effects seen after 4 months of gestation, because tetracyclines must inte with calcified tissue. Effects occur in 50% of fetuses exposed to tetracycli in 12.5% of fetuses exposed to oxytetracycline.

Thalidomide

Limb phocomelia, amelia, hypoplasia, congenital heart defects, renal malformations, cryptorchidism, abducens paralysis, deafness, microtia, a Approximately 20% risk for exposure during days 34â€“50 of gestation.

Trimethoprim

NTD, oral clefts, hypospadias, and cardiovascular defects

Approximately 1% risk of NTD for first-trimester exposure. Mechanism is acid inhibition.

Valproic acid

Lumbosacral spina bifida with meningomyelocele; CNS defects, microcepl cardiac defects; narrow face with high forehead, epicanthal folds, broad, nasal bridge with short nose, long philtrum with a thin vermilion border; thin fingers and toes

Risk for spina bifida is approximately 1%, but the risk for dysmorphic fac be greater. The mechanism of teratogenicity is unknown. Possible explar include interference with glutathione, folate, or zinc metabolism, or regul intracellular pH. Risk is confounded by those risks associated with epileps or use of other agents.

Vitamin D

Possible association with supravalvular aortic stenosis, elfin facies, and r retardation

Large doses of vitamin D may disrupt cellular calcium regulation. Genetic susceptibility may play a role.

IUGR = intrauterine growth retardation; NSAID = nonsteroidal antiinflam drug; NTD = neural tube defect.

Xenobiotic	Reported Effects	Comments

TABLE 30-1. Known and Possible Human Teratogens

P.466

P.467

P.468

An increased free xenobiotic concentration in the pregnant woman can be by several factors, including decreased plasma albumin, increased bindin competition, and decreased hepatic biotransformation, during the later st pregnancy. Fat stores increase during the early stages of pregnancy; free acids are released during the later stages and, with them, xenobiotics tha have accumulated in the lipid compartment. The increased concentration fatty acids can compete with circulating free xenobiotic for binding sites albumin.

Other factors may lead to decreased free xenobiotic concentrations. Early pregnancy, increased fat stores, as well as the increased plasma and extracellular fluid volume, lead to a greater volume of distribution. Incre renal blood flow and glomerular filtration may result in increased renal elimination.

Cardiac output increases throughout pregnancy, with the placenta receivir

gradually increasing proportion of total blood volume. Xenobiotic delivery placenta may therefore increase over the course of pregnancy.

These processes interact dynamically, and it is difficult to predict their ne effect. The concentrations of many xenobiotics, such as lithium, gentamic carbamazepine, decrease during pregnancy, even if the administered dose changed.[143]

Although this is not specifically related to the physiologic changes occurr during pregnancy, the fetus may be exposed to xenobiotics that accumula adipose tissue before pregnancy. For example, typical retinoid malformat were seen in a baby born to a woman whose pregnancy began 1 year afte discontinued use of the xenobiotic etretinate (retinoic acid).[130]

Xenobiotic Exposure in Pregnant Women

Exposure to xenobiotics during pregnancy is common. Between 30 and 80 pregnant women take xenobiotics sometime during pregnancyâ€”primarily analgesics, antipyretics, antimicrobials, and antiemetics, as well as vitam caffeine, ethanol, and nicotine.[25 , 37 , 49 , 56 , 158 , 207 , 208] Some pregn women use medications to treat chronic disease; others use medications unknowingly, prior to the recognition that they are pregnant.

Pharmaceutical manufacturers are required by law to label their products respect to use in pregnancy, according to standards promulgated by the U and Drug Administration (FDA) (Table 30-2).[248] Similar classification sys have been developed in Sweden and Australia.[6 , 198 , 214] The original int the US regulations was to inform practitioners about the nature of the av evidence regarding risk in pregnancy; however, the general impression is the categories refer to teratogenic risk.[220] In this the FDA grading system been criticized for conveying an impression of a hierarchy of harmful effe of equivalence of risk within any category.[61 , 78 , 198 , 221] For example, US system, a category C medication is generally considered more danger than a category B medication in pregnancy, even though category C is th default category for medications about which there is little or no specific information available, and for which the risk is unknown. Approximately 9

medications are classified as category C.[141]

There is significant discordance between the useâ€“pregnancy labeling an teratogenic risk, as determined by clinical teratologists,[141] and the FDA s has been criticized for being too conservative.[78] Manufacturers may label medications as category X even when there is only limited information associating the medication with any adverse fetal or neonatal effects. For example, oral contraceptives generally carry a category X classification, e though they are not considered teratogenic. Certain agents with a categor classification may cause problems only at certain times during pregnancy medications that are classified as category D or X may only have a very l of teratogenicity or other adverse effect, and exposure to these agents, e during the first trimester, may not be a sufficient indication to terminate pregnancy. Specific current information on individual xenobiotics can be from

local and regional teratogen information services[124] and published books, [216 , 225] some of which also have online versions.[118 , 242] Motherisk is a Canadian program that uses specific information to advise women about actual risk to them of using a particular medication or xenobiotic in a cur planned pregnancy.[170 , 172]

A
No known risk
Multiple vitamins
Controlled studies show no risk. Adequate, well-controlled studies in pregnant women do not demonstrate a risk to the fetus and if animal stu exist, they do not demonstrate a risk.
B
Unlikely risk
Acetaminophen, penicillin
No evidence of risk in humans. Either animal studies show risk but hu studies do not, or if no adequate human studies have been done, animal show no risk.
C

Unknown risk
Albuterol
Risk cannot be ruled out. Animal studies may or may not show risk, bu human studies do not exist. However, benefits may justify the potential c unknown risk.
D
Known risk, but benefit may outweigh risk
Tetracycline
Positive evidence of risk. Investigational or postmarketing data or hum studies show risk to the fetus. Nevertheless, potential benefits may outw potential risk; for example, if the drug is needed in a life-threatening sit or serious disease for which safer drugs cannot be used or are ineffective
X
Known risk but risk significantlying outweighs benefit
Isotretinoin
Contraindicated in pregnancy. Studies in animals or humans or invest or postmarketing reports have shown fetal risk that clearly outweighs any possible benefit to the patient.
[a] Based on US Food and Drug Administration. Specific requirements on c and format of labeling for human prescription drugs. 21 CFR Ch. I (4â€“1 ed.) $ 201.57.

Category	Risk to Human Fetus	Example(s)	Basis

TABLE 30-2. FDA Use-in-Pregnancy Ratings[a]

The FDA is revising the approach to labeling medications, as well as the themselves. However, the questions raised during the revision process ar extraordinarily complex; for example: How should animal data in general evaluated? How should animal data be extrapolated to humans? How shou teratogenic risk be defined and quantified for any particular xenobiotic? H should the risk of not treating a particular disease be compared with the using a particular medication to treat that disease? How should any of thi information be communicated to practitioners and the public?[221]

Although most women are concerned about the teratogenic effects of medications, in utero exposure to therapeutic medications can have other pharmacologic effects on the newborn infant, such as hyperbilirubinemia withdrawal reactions.[32, 58, 170]

Estimates of substance use in pregnancy vary tremendously, depending o geographic location, practice environment, patient population, and screer method.[42, 132] Among a large national sample screened for xenobiotic us during pregnancy, 20% of pregnant women smoked, 20% drank ethanol, used marijuana, 0.5% used cocaine, 0.1% used methadone, and fewer th 0.1% used heroin. Women tend to decrease their exposure to xenobiotics they know they are pregnant.[26, 104, 107]

Placental Regulation of Xenobiotic Transfer the Fetus

With respect to the transfer of xenobiotics from mother to fetus, the plac functions like other lipoprotein membranes. Most xenobiotics enter the fe circulation by passive diffusion down a concentration gradient across the placental membranes. The characteristics of a substance that favor this p diffusion are low molecular weight, lipid solubility, neutral polarity, and lo protein binding.[176] Polar molecules and ions may be transported through interstitial pores.[245]

Xenobiotics with a molecular weight (MW) greater than 1000 Da do not d passively across the placenta, and this characteristic is used to therapeut advantage. For example, warfarin (MW 1000 Da) easily crosses the placer causes specific fetal malformations.[253] However, heparin (MW 20,000 Da) is too large to cross the placenta, is not teratogenic and, consequently, is preferred anticoagulant during pregnancy. Most therapeutic medications molecular weights between 250 and 400 Da and easily cross the placenta example, thiopental is highly lipid soluble and crosses the placenta rapidl plasma levels reach maternal levels within a few minutes. Muscle relaxan as vecuronium are more polar and cross the placenta slowly.[64]

Although the state of ionization is a limiting factor for diffusion, some hig

charged compounds can still diffuse across the placenta. Valproic acid (pK is nearly completely ionized at physiologic pH, yet there is rapid equilibra across the placental membrane. The small amount of xenobiotic that exist the nonionized form rapidly crosses the placenta; as equilibrium is reest a new, small amount of nonionized xenobiotic becomes available for diffu

Fetal blood pH changes during gestation. Embryonic intracellular pH is hig relative to the pregnant woman. During this developmental stage, weak a will diffuse across the placenta to the embryo and remain there because â€œion trapping.â€• Many teratogens, such as valproate, trimethadione, phenytoin, thalidomide, warfarin, and isotretinoin, are weak acids. Althou trapping does not explain the mechanism of teratogenesis, it may explain xenobiotics accumulate in an embryo. Late in gestation the fetal blood is 0.15 pH units more acidic than the mother's blood; this may permit weak xenobiotics to concentrate in the fetus during this period.[176]

The relative concentrations of protein binding sites in the pregnant woma fetus also have an impact on the extent of xenobiotic transfer to the fetu maternal free fatty acid concentrations increase near term, these fatty ac displace xenobiotics such as valproic acid or diazepam from maternal pro binding sites and make more free xenobiotic available for transfer to the Fetal albumin concentrations increase during gestation and exceed mater albumin concentrations by term. Because the fetus does not have high concentrations of free fatty acids to compete for protein binding sites, th sites are available for binding the xenobiotics. At birth, when neonatal fre acid levels increase 2- to 3-fold, they displace stored xenobiotic from the protein. In the cases of valproic acid and diazepam, the elevated concen of free xenobiotic have adverse effects on the newborn infant.[84 , 105 , 17

The placenta may also affect xenobiotic presentation to the fetus by ion and xenobiotic metabolism. The placenta blocks the transfer of some pos charged ions such as cadmium and mercury,[93] and may even accumulate This barrier does not necessarily protect the fetus, however, because the heavy metal ions interfere with normal placental function and may lead to placental necrosis and subsequent fetal death.[169]

The placenta contains xenobiotic-metabolizing enzymes capable of perfor both phase I and phase II reactions (Chaps. 9 and 26). However, the concentration of biotransforming enzymes in the placenta is significantly than that in the liver, and it is unlikely that the level of enzymatic activity protective for the fetus. Moreover, the fetus may be exposed to reactive intermediates that form during these processes. On the other hand, glut may also be present in the placenta and detoxify some of these reactive intermediates.[111]

Placental transfer of xenobiotics can have a positive effect when it provid therapy. For example, if a fetus is found to have supraventricular tachyca atrial flutter, digoxin can be given to the mother in order to treat the bab [205]

Effects of Xenobiotics on the Developing Organism

A basic premise of teratogenicity is that the particular toxic effects of a xenobiotic are determined by the organism's stage of development.[29 , 22] Although the fertilized ovum is generally thought to be resistant to toxic before implantation,[29] xenobiotics in the fallopian or uterine secretions m prevent implantation of the embryo. Xenobiotic exposure leading to cell lo chromosomal abnormalities may also lead to a spontaneous abortion, pos even before pregnancy has been detected. If the preimplantation embryo survives a xenobiotic exposure, the functional cells usually proceed to no development.[222] Teratogens that act in such a manner elicit an â€œall-o responseâ€•; that is, the exposed embryo will either die or go on to nor development.

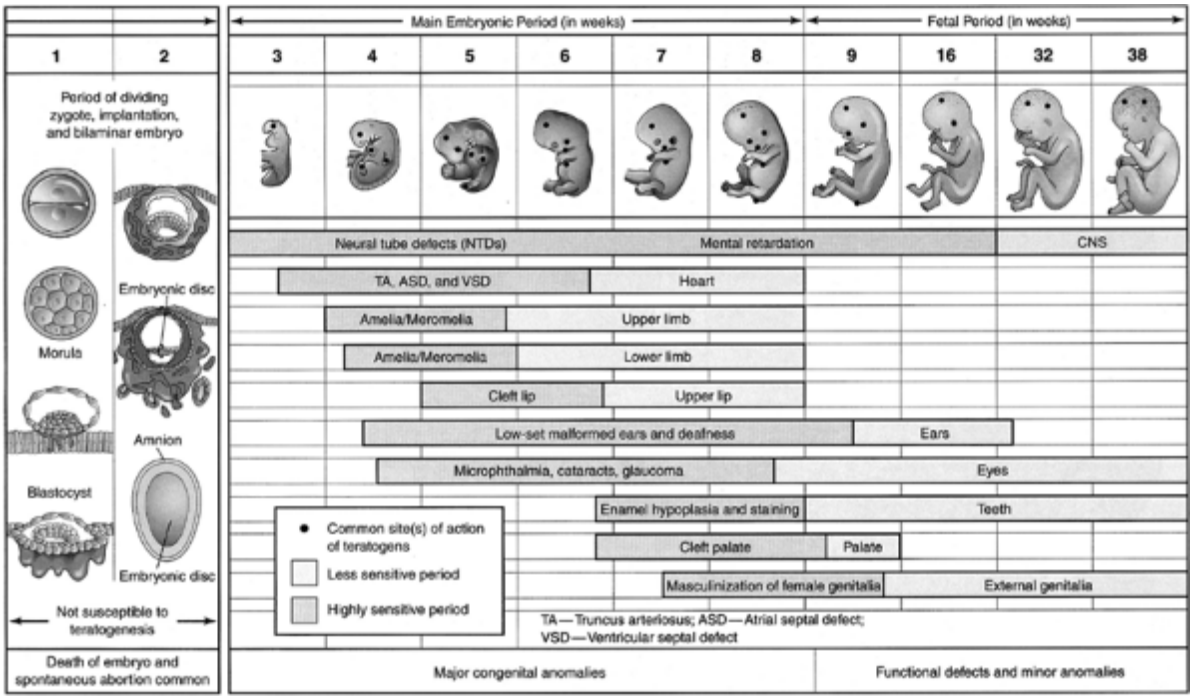

Figure 30-1. Critical periods of fetal development. *(Modified with permis from Moore KL, Persaud TVN: The Developing Human: Clinically Oriented Embryology, 7th ed. Philadelphia, WB Saunders, 2003, p. 520.)*

Teratogens generally behave according to a doseâ€“response curve; there threshold dose below which no effects occur and as the dose of the terat increases above the threshold, the magnitude of the effect increases. The might be the number of offspring that die or suffer malformations or the or severity of malformations. Strictly, teratogenic effects are those that c doses that do not cause maternal toxicity because maternal toxicity itself be responsible for an observed adverse or teratogenic effect on the deve organism.[29]

Organogenesis occurs during the embryonic stage of development betwee 18 and 60 of gestation. Most gross malformations are determined before although genitourinary and craniofacial anomalies occur later.[29] The perio susceptibility to teratogenic effects varies for each organ system (Fig. 30 For instance, the palate has a very short period of sensitivity, lasting approximately 3 weeks, whereas the central nervous system (CNS) rema susceptible throughout gestation.[29]

Theoretically, knowing the exact time of teratogen exposure during gesta would allow prediction of a teratogenic effect; this is true in animal mode where dose and time can be strictly controlled. It is also true for thalidor where different limb anomalies are specifically related to exposures on p days of gestation.[222] In many clinical situations, relating teratogenicity to particular xenobiotic exposure is difficult: Because the exact time of con is unknown, the exact time of exposure is unknown, both for xenobiotics administered intermittently and chronically.

During the fetal period, formed organs continue their cellular differentiati grow to functional maturity. Exposure to toxic agents such as cigarettes this period generally leads to growth retardation. Teratogenic malformatic death may still occur as a result of disruption or destruction of growing c as has been the result of exposure to the angiotensin-converting enzyme inhibitors during the second and third trimesters.[20]

Another concern during the fetal period is the initiation of carcinogenesis Significant cellular replication and proliferation lead to a dramatic growth of the organism. At the same time, when the fetus is exposed to xenobio development of biotransformation systems may expose the organism to metabolites that might initiate tumor formation. Some tumors, such as neuroblastoma, appear early in postnatal life, suggesting a prenatal origir pregnant rats given ethylnitrosourea during the embryonic period, lethal teratogenic effects occur.[193] If ethylnitrosourea is administered during th period, there is an increased incidence of tumors in the offspring. Clear c vaginal and cervical adenocarcinomas are seen in the female offspring of exposed to DES during pregnancy.[23]

Mechanisms of Teratogenesis

Cytotoxicity is one mechanism of teratogenesis and is the characteristic r exposure to alkylating or antineoplastic agents. Aminopterin, for example inhibits dihydrofolate reductase activity and leads to suppression of mitos cell death. If exposure to a cytotoxic agent occurs very early in developn

the conceptus may die, whereas sublethal exposure during organogenesis result in maldevelopment of particular structures. There is evidence that following cell death, the remaining cells in an affected region may try to the damage caused by the missing cellular elements. This â€œrestorative growthâ€• may lead to uncoordinated growth and exacerbate the origina malformation.

In the case of the cytotoxic agents, the mechanism of action is understoc although it is not always clear why particular agents affect particular str With other agents, the structural effects have a clearer relationship to the action. For instance, when glucocorticoids are administered in large doses some experimental animals during the period of organogenesis, malforma the palate occur. Glucocorticoid receptors are found in high concentrations palate of the developing mouse embryo.[188] Corticosteroid exposure can a cause cleft palate in humans at a low frequency.[183 , 225]

Caloric deficiency is not considered teratogenic during the period of organogenesis. However, specific nutritional or vitamin deficiencies can b teratogenic; an increased incidence of neural tube defects is seen with fo deficiency, and the incidence has been reduced following the use of folate supplementation before and during pregnancy.[142] Ethanol affects the fetu directly and indirectly. The craniofacial malformations seen in the fetal a syndrome probably result from the effects of ethanol during the period of organogenesis. Growth retardation may result from direct effects of ethar fetal growth, or from indirect effects resulting from ethanol-induced mate nutritional deficiencies.

Management of Acute Poisoning in the Pregnant Woman

Suicide and suicide attempts during pregnancy are uncommon. Each year number of women die during pregnancy or the postpartum period; 1â€“5% these pregnancy-related deaths may be the result of suicide. Between 2 a 12% of women who attempt or commit suicide may be pregnant.[119 , 186] Reported reasons for these suicide attempts include loss of a lover, econ

crisis, prior loss of children, and unwanted pregnancy and desire for an abortion.[53, 139, 262] In one series, 12% of ingestions were attempts to terminate pregnancy[186] (Chap. 28).

Medication ingestion is a common method of attempting suicide during pregnancy. Analgesics, vitamins, iron, antibiotics, and psychotropic med account for 50â€“79% of the reported ingestions by pregnant women.[186] These medications are frequently prescribed for, and used by, pregnant w

Managing any acute overdose during pregnancy provokes discussion of s questions. Is the general management different? Do altered metabolism a pharmacokinetics increase (or decrease) the woman's risk of morbidity or mortality from a medication overdose? Is the fetus at risk of poisoning fro maternal overdose? Is there a teratogenic risk to the fetus from an acute overdose or poisoning? Is the use of an antidote contraindicated, or shou be modified? When should a potentially viable fetus be emergently deliver prevent toxicity? When should termination of a pregnancy be recommend

As described above, physiologic changes during pregnancy affect pharmacokinetics; xenobiotics taken in overdose also have unpredictable toxicokinetics. In any significant overdose during pregnancy, pregnancy-alterations in pharmacokinetics are unlikely to protect the woman from significant morbidity or mortality.

Although a single high-dose exposure to a xenobiotic during the period of organogenesis might seem analogous to an experimental model to induce teratogenesis, most xenobiotics ingested as a single acute overdose do n induce physical deformities. Anticonvulsant agents are teratogenic and ma ingested in toxic doses, but their teratogenicity is probably related more chronic exposure. Ethanol teratogenicity may be related to binge drinking, single binge is unlikely to have significant effects. Acute acetaminophen intoxication in the first trimester may lead to an increased risk of sponta abortion,[196] suggesting a teratogenic effect similar to the all-or-none res described earlier. In general, however, it is extremely difficult to associat teratogenicity with a particular xenobiotic exposure following a single cas report. There is, for example, a report of multiple severe congenital malformations in the stillborn fetus of a woman who overdosed on isoniaz

during the 12th week of pregnancy.[136] However, because the backgrounc incidence of congenital malformations is 3â€“6%, it is almost impossible determine for a single case whether a particular xenobiotic exposure is th etiology of any observed malformations.[54] It is very unlikely that the sma of possible teratogenesis would ever lead to a recommendation for termi of pregnancy after an acute overdose of most xenobiotics.

In general, any condition that leads to a severe metabolic derangement in pregnant woman is likely to have an adverse impact on the developing fe Therefore, the management of overdose in a pregnant woman usually foll principles outlined in Chap. 4 , with close attention paid to the airway, oxygenation, and hemodynamic stability. The use of naloxone or dextrose not been specifically assessed in pregnancy, but should be guided by the considerations raised in managing the nonpregnant patient with alteration respiratory or neurologic function. Opioid-induced respiratory failure in th pregnant patient will lead to fetal hypoxia and adverse effects; opioid wi in a

pregnant woman, whether induced by abstinence or the use of naloxone, adversely affect the fetus or the pregnancy. Consideration of the benefits risks of the use of naloxone for an opioid-poisoned woman in respiratory or coma suggests that reduced morbidity, for both mother and fetus, may achieved by the use of carefully titrated doses of naloxone to minimize th likelihood of maternal withdrawal (see Chap. 38 and Antidotes in Depth: Antagonists).

Gastrointestinal decontamination is frequently a part of the early manage acute poisoning in the nonpregnant patient. Gastric lavage is not specific contraindicated for the pregnant patient; the usual concerns about protec airway apply to the pregnant patient. Even though the syrup of ipecac is longer recommended as a standard therapy for the management of inges pregnancy was previously considered a relative contraindication to its use because vomiting increases both intrathoracic and intraabdominal pressu

There is no specific contraindication to the use of activated charcoal in a pregnant woman. There may be a specific role for whole-bowel irrigation

management of several xenobiotic exposures, particularly in the treatmen iron overdose in pregnancy. The use of polyethylene glycol is safe in preg women.[178]

When considering the use of antidotes, the primary concern should be for health of the pregnant woman. Almost all antidotal agents are designated pregnancy-risk category C; that is, there is little specific information to g their use. Ethanol is labeled as category D (positive evidence of risk), alt this is presumably related to chronic use throughout pregnancy, not as an antidote. Fomepizole, which has replaced ethanol as the preferred antidot toxic alcohol poisoning, is labeled as category C. Pyridoxine and thiamine category A medications; *N* -acetylcysteine, magnesium, glucagon, and na are category B medications.

Thus far, there are no reports of adverse effects on the fetus from antido treatment of a poisoned pregnant woman. Conversely, in at least one cas withholding deferoxamine therapy may have contributed to the death of b woman and her fetus.[154 , 238] In the hypothetical case of a pregnant wor poisoned with a toxic alcohol for whom fomepizole is not available, the us ethanol is essential until hemodialysis can be performed, especially outsid the first trimester, although there are no data to predict outcome. In mos cases, the physician will need to weigh the short-term toxicity of high se ethanol concentrations against the unknown risk of fomepizole.

Acetaminophen

Acetaminophen is the most common analgesic and antipyretic agent used pregnancy and is one of the most common xenobiotics ingested in overdo during pregnancy.[164 , 196] There are two published series, as well as a n of individual reports, totaling more than 100 cases of acute acetaminoph overdose during all trimesters of pregnancy. In the two large series repr 112 acute and chronic overdoses, 33 patients had serum acetaminophen concentrations in the toxic range.[164 , 196] These studies, in addition to th reports described below, demonstrate that most pregnant women recover an acetaminophen ingestion without adverse effects to themselves or the babies.

In the two large series of acetaminophen overdose during pregnancy,[164] of 28 women who overdosed in the first trimester and continued their pr experienced spontaneous abortions, most within 2 weeks of the ingestion. 8 women, 5 had toxic serum acetaminophen concentrations; 1 woman re -acetylcysteine (NAC) within 8 hours, and 4 received NAC between 12 and hours after ingestion. In one of these cases there was both maternal and death. Five patients with toxic serum acetaminophen concentrations and nontoxic serum concentrations delivered healthy term newborns. Ten wom elective terminations of pregnancy.

The 2 large series include 32 second-trimester acute overdoses.[164 , 196] women who had nontoxic serum acetaminophen concentrations had spon abortionsâ€”one had symptoms of a threatened abortion several days prio the overdose, and the second was assaulted the day before the overdose aborted the next day. Six women with toxic serum acetaminophen conce delivered full-term healthy infants; 19 women with nontoxic serum concentrations delivered full-term babies, and 1 woman with a nontoxic s concentration delivered a premature infant 2 months after the overdose. women had elective terminations of pregnancy.

There are 3 case reports of women with acute overdoses in the second t One woman who overdosed at 15.5 weeks of gestation had a toxic serum acetaminophen concentration, was treated with intravenous NAC beginnin hours after the ingestion, and developed hepatotoxicity. She had a spont rupture of membranes at 31 weeks and delivered a male infant at 32 wee One woman who overdosed at 16 weeks had a toxic serum acetaminophe concentration, was treated with NAC within 8 hours, and did not develop hepatotoxicity.[201] She delivered a normal female infant at term. One wom overdosed at 20 weeks, received intravenous NAC starting some time bet and 18 hours after ingestion, and developed hepatotoxicity. She had labo induced at 41 weeks because of weight loss and delivered a male infant.[2 infant was irritable and developed hyperbilirubinemia, both of which reso after phototherapy.

The 2 large series described above included 39 third-trimester overdoses [196] Twelve women had toxic serum acetaminophen concentrations: 8 del

healthy term infants, 2 women who had no evidence of hepatotoxicity de premature infants 2 days after the overdose, 1 woman with hepatotoxicit delivered a moderately ill premature infant at 32 weeks of gestation, and woman with severe hepatotoxicity delivered a stillborn infant with hepatic necrosis at 33 weeks of gestation (Table 30-3). Twenty-seven women ha nontoxic serum acetaminophen concentrations; 2 delivered premature infa of whom had respiratory distress), and 25 delivered full-term infants. Of full-term infants, 1 developed a withdrawal syndrome, 1 developed pylori stenosis, and 3 had physical anomalies. Altogether, in these 2 series, 6 o women with third-trimester overdoses had premature delivery, usually wi to 3 days of the overdose.

In addition to the large series described, there are 11 case reports of thi trimester acetaminophen overdoses (Table 30-3). Three additional third- trimester cases are briefly described; 2 women had an acute overdose and a chronic overdose. All 3 women had toxic serum acetaminophen concen were treated with NAC, and delivered healthy infants while receiving NAC There are also several case reports of adverse pregnancy outcome in the of chronic use of acetaminophen, or acute overdose in the setting to othe chronic substance use.[41 , 100 , 127 , 148 , 196] It is difficult to interpret th reports with respect to specific acetaminophen effect because of the con of chronic disease, chronic use, or use of additional medications or subst

TABLE 30-3. Reported Cases of Third-Trimester Acetaminophe Overdose

Acetaminophen is a FDA use-in-pregnancy category B medication; at recommended doses, it is considered safe for use during pregnancy. How overdose, it may put the developing organism at risk. As the third-trimes cases described above demonstrate, acetaminophen crosses the placenta

reach the developing fetus. The clinical series[164, 196] suggest that there some increased risk of spontaneous abortion after overdose during the fi trimester. There is also a question about whether overdose during the fir trimester can lead to late sequelae, for instance, premature labor.

Some experimental work may help to explain early pregnancy loss after overdose. Acetaminophen prevented the development of preimplantation cell stage) mouse embryos in culture, an effect that was not associated v alterations in glutathione concentrations,[133] and also led to abnormal ne development in cultured rat embryos.[234] These data suggest that acetan may be directly toxic to the immature organism. However, other work re that similar embryotoxic effects were associated with reductions in gluta concentrations[258] and that *N* -acetyl-*p* -benzoquinoneimine (NAPQI) prod nonspecific toxicity when added to the rat embryo culture medium.[234]

The fetal liver has some ability to metabolize acetaminophen to a reactive intermediate in vitro. Cytochrome P450 (CYP) activity was detected in int hepatocytes, as well as in microsomal fractions isolated from the livers of fetuses aborted between 18 and 23 weeks of gestation.[203] Fetal CYP activ only 10% of the activity of hepatocytes isolated from adults without cere activity selected as kidney donors; fetal CYP activity increased with incre gestational age. In 2 clinical cases, cysteine and mercapturate conjugates identified in newborns exposed to acetaminophen in utero, suggesting tha fetus and neonate can metabolize acetaminophen through the CYP system data suggest that the fetus in utero and the neonate can generate a toxic metabolite; the clinical cases suggest that the fetal liver is susceptible to

This CYP activity has not been further characterized. However, CYP2E1, o the cytochromes responsible for acetaminophen metabolism, is present in fetal tissues as early as 16 weeks of gestation.[167] CYP3A4 and CYP1A2 ar involved in acetaminophen metabolism, but are not present in fetal liver. is a functional fetal form of the CYP3 family, but its metabolic activity wit respect to acetaminophen has not been studied.[91]

The most difficult questions relate to management of overdose during the trimester. Can acetaminophen overdose lead to premature labor even if a

pregnant woman does not have a toxic serum concentration or develop hepatotoxicity? Should a woman be emergently delivered following overd Does NAC treatment of the mother help the fetus? What is the appropriat treatment of a neonate exposed to acetaminophen in utero?

The clinical cases may help with at least the last two questions (see Table). Six women, all less than 36 weeks of gestation, developed hepatotoxic infants died in utero with evidence of severe hepatotoxicity, although wha in utero postmortem changes may have had on serum acetaminophen concentrations or liver pathology is unclear. One infant died on the secon of life with hepatotoxicity. The other 3 infants experienced problems ass with prematurity but did not develop obvious hepatotoxicity. One of these an exchange transfusion, and had an unexplained death at 3 months of a women, all at 36 or more weeks of gestation, did not develop hepatotoxi One infant had an exchange transfusion and did not develop hepatotoxicit died a â€œcot deathâ€• at 5 months of age. One infant received IV NAC had a transient elevation of aspartate aminotransferase (AST) and prothr time. Two infants were not treated; both did well, although 1 had a trans elevation of AST. One infant was born 6 weeks after the overdose and wa normal.

Severe maternal hepatoxicity that is associated with any sign of fetal dist an indication for urgent delivery. Although a fetus with prolonged exposur acetaminophen in utero is at risk of developing severe hepatotoxicity, not risk infants are affected. What role gestational age, maternal disease stat other maternal factors may play is unknown. Although there are insufficie data to suggest that acetaminophen overdose per se is an indication for delivery, there may be an indication for urgent delivery when the matern serum acetaminophen concentration is in the toxic range but hepatotoxici not yet developed.[241] Significant acetaminophen overdose with or withou hepatotoxicity can precipitate premature spontaneous labor, and even wo with nontoxic serum concentrations may be at a slightly increased risk.

In 2 cases, exchange transfusion was employed to treat the exposed neo both cases, the acetaminophen half-life was prolonged, and in neither cas this affected by the transfusion. Disturbingly, these 2 infants had unexpl

deaths at several months of age. There is insufficient information on whic base a recommendation regarding exchange transfusion as therapy for p exposure.

The pregnant woman with acute toxic acetaminophen ingestion should be with *N* -acetylcysteine (see Chap. 34 and Antidotes in Depth: *N* -Acetylcy). This is therapy to treat the mother. Although maternal hepatoxicity or NAC therapy may be associated with fetal toxicity,[196] there is insufficient information to indicate that prevention of maternal toxicity will prevent f toxicity in either the first or the third trimester. NAC was found in cord b after administration to 4 mothers before delivery,[100] although NAC did nc the sheep placenta in vivo[223] or the perfused human placenta in vitro.[104] NAC does cross the placenta, whether it prevents fetal hepatotoxicity is because not all exposed fetuses develop hepatotoxicity.

In 4 third-trimester cases where the mothers overdosed at or after 36 we gestation and did not develop hepatotoxicity, the infants did well. One in received NAC. There are anecdotal reports of infants who received NAC postnatally and did well. Current theory suggests that infants and young are less likely than teenagers or adults to develop hepatoxicity after acetaminophen overdose because of immature CYP activity and increased sulfation activity. It is intriguing to consider that this metabolic protectior extend to the newborn exposed to acetaminophen in utero. It also makes difficult to know to what extent postnatal NAC therapy for the prenatally newborn might prevent toxicity. Although there are no reported cases, it seem that the premature newborn exposed in utero is the best candidate postnatal NAC therapy.

Iron

Iron is another common ingestant during pregnancy; maternal toxicity is generally greater than fetal toxicity. In 2 reported cases, normal babies delivered although the mothers died.[182, 194] In another case, the mother severe iron toxicity with acidosis, shock, renal failure, and disseminated intravascular coagulation but was not treated with deferoxamine because concerns about its teratogenic risks. Instead, the mother received an exc

transfusion followed 45 minutes later by a spontaneous abortion of the 1 fetus.[154, 238] Neonatal and cord blood iron concentrations were not eleva several cases, pregnant women who had signs and symptoms of iron pois and elevated serum iron concentrations were treated with deferoxamine a subsequently delivered normal babies.[24, 116, 128, 190, 217, 247]

Although the placenta transports iron to the fetus efficiently,[171] it also b the transfer of large quantities of iron. In a sheep model of iron poisoning a small amount of iron was transferred across the placenta despite signif elevated serum iron levels.[52]

Deferoxamine is an effective antidote for iron poisoning (see Chap. 40 an Antidotes in Depth: Deferoxamine), but it is reported to be an animal te that causes skeletal deformities and abnormalities of ossification (FDA cla pregnancy risk). An animal model observed similar effects, but only with of deferoxamine that caused maternal toxicity.[27] Experimentally, in sheep transfer of deferoxamine across the placenta was demonstrated;[52] therefo reported fetal effects may be secondary to chelation of essential nutrients as trace metals) on the maternal side of the placenta.[241]

In clinical case reports of iron overdose for which deferoxamine was used have been no adverse effects on the fetus, although most have been eith second- or third-trimester poisonings.[24, 116, 128, 182, 190, 217, 247] In series of 49 patients with iron poisoning during pregnancy, few of the pa exhibited any clinical toxicity other than vomiting and diarrhea; 25 receiv deferoxamine, most by the oral route.[163] One woman with a first-trimest overdose, 8 women with second-trimester overdoses, and 12 women with trimester overdoses were treated with deferoxamine and subsequently d full-term infants. One infant whose mother overdosed at 30 weeks of ges had webbed fingers on one hand. One woman overdosed at 20 weeks, ha minimal clinical toxicity, received deferoxamine, and delivered a 2.5-kg n infant at 34 weeks. One woman with a first-trimester overdose and 2 wor with second-trimester overdoses elected to terminate their pregnancies.

Further support for the safe use of deferoxamine in pregnancy is the exp with its use for pregnant women with thalassemia. For many years Defer has been administered as part of the therapy for posttransfusion iron ov

without adverse effects.[229]

Deferoxamine is probably safe for use in pregnant women. Considering th potentially fatal nature of severe iron poisoning, deferoxamine should be administered when signs and symptoms indicate significant poisoning.

Iron overdose may be one of the few specific indications for whole-bowel irrigation because iron is not adsorbed to activated charcoal (see Antidote Depth: Activated Charcoal). A case report demonstrated elimination of p fragments following treatment of a pregnant woman with whole-bowel irrigation.[249]

Carbon Monoxide

Carbon monoxide is the leading cause of poisoning fatalities in the United In contrast to iron and most other xenobiotics, when pregnant women are exposed to carbon monoxide, the fetus may be at greater risk of toxicity the woman herself. There are reports of both the mother and fetus dying, mother surviving but the fetus dying, and both the mother and fetus surv but with adverse neonatal outcome, primarily brain damage resembling th following severe cerebral ischemia.[39 , 51 , 121 , 144 , 155 , 180 , 249 , 265 S clinical effects have also been observed in animal models.[63 , 85 , 145

The case literature suggests increased risk of poor fetal outcome with cli severe maternal poisoning or significantly elevated carboxyhemoglobin le , [180] Women with minimal symptoms and/or low levels of carboxyhemogl have a low risk of fetal toxicity, but a lower limit of exposure without effe not been specifically defined.[125]

In animal models, under physiologic conditions, the fetus has a carboxyhemoglobin concentration 10â€“15% higher than the mother. Afte exposure to carbon monoxide, the fetus achieves peak carboxyhemoglobi 58% higher than those achieved by the mother at steady state, and the t peak level is also delayed compared to the mother. Similarly, the elimina carbon monoxide occurs more slowly in the fetus than in the mother.[96 , One case report describes such a phenomenon: after 1 hour of suppleme

oxygen, the maternal carboxyhemoglobin was 7% and the fetal carboxyhemoglobin was 61% at the time of death in utero.[69]

Carbon monoxide leads to fetal hypoxia by several mechanisms: (a) mat carboxyhemoglobin leads to a decrease in the oxygen content of materna and therefore, less oxygen is delivered across the placenta to the fetus, normally has an arterial PO_2 of only 20â€“30 mm Hg; (b) fetal carboxyhemoglobin causes a decrease in fetal PO_2 ; (c) carbon monoxide the oxyhemoglobin dissociation curve to the left and decreases the releas oxygen to the fetal tissues (an exacerbation of the physiologic left shift f with normal fetal hemoglobin); and (d) carbon monoxide may inhibit cyt oxidase or other mitochondrial functions (Chap. 120).

The treatment for severe carbon monoxide poisoning is hyperbaric oxyge therapy (HBO) (see Chap. 120 and Antidotes in Depth: Hyperbaric Oxyge There are questions about the use of HBO in pregnant women because ar models suggest HBO adversely effects the embryo or fetus.[73 , 168 , 215 , applicability of the animal models to humans is difficult to assess; many o animal models employed hyperbaric conditions of greater pressures and than those clinically employed for humans.

HBO has been used therapeutically for carbon monoxide poisoning in pre with good results reported, although there are limited data on the long-te follow-up of the children.[34 , 72 , 81 , 88 , 97 , 125 , 250] One large series re 44 women who were exposed to carbon monoxide during pregnancy and treated with HBO, regardless of clinical severity or gestational age: 33 ha births; 1 had a premature delivery 22 weeks after HBO, during an episod maternal fever; 2 had spontaneous miscarriages (one 12 hours after sev poisoning and one 15 days after mild poisoning); 1 delivered a child with syndrome; 1 had an elective abortion; and 6 were lost to follow-up.[69] Unfortunately, details regarding trimester of exposure, maternal carboxyhemoglobin level, and severity of symptoms are not available, ma difficult to interpret the reported outcomes. Although HBO appears safe f pregnant women and seems to present little risk to the fetus, it is not cle whether HBO prevents carbon monoxide-related fetal toxicity for those at Carbon monoxide can have a severe impact on fetal health and developm

and, as noted above, the maternal carboxyhemoglobin level may not acc reflect the fetal carboxyhemoglobin level.

HBO should be considered for any pregnant woman exposed to carbon m especially for a woman with an elevated serum carboxyhemoglobin conc or any evidence of fetal distress. If HBO therapy is not available, 100% o should be administered to the mother for a period of time five times long the time needed for the maternal carboxyhemoglobin to return to the nor range.

Substance Use During Pregnancy

One of the most complex areas of toxicology deals with issues of substan during pregnancy, and its effects on the woman, on the pregnancy itself, fetal and postnatal development. This section reviews of some of the imp aspects of this topic.

Clinical research in the area of substance use during pregnancy is very d to perform. With the increased use of cocaine during the latter half of the and 1990s, there was great interest in determining the effects of cocaine during pregnancy. As research in this area progresses, many of the critic methodologic issues related to substance use research are highlighted.[74, 138, 179, 268]

Substance-using women often have multiple risk factors for adverse preg outcomes, such as low socioeconomic status, polysubstance use, ethanol cigarette use, sexually transmitted diseases, AIDS, malnutrition, and lack prenatal care. Lack of prenatal care is highly correlated with premature b and smoking is associated with spontaneous abortion, growth retardation, sudden infant death syndrome (SIDS).[115, 260] Other factors not specifica related to substance use such as age, race, gravidity, and prior pregnanc effect pregnancy outcome. Each of these factors represents a significant potential confounding variable when the effects of a particular agent such cocaine or marijuana are evaluated during pregnancy and must be contro in research design. Many of these factors are also significant confounders evaluation of postnatal growth and development.

There may be bias in the selection of study subjects. For example, if all t patients are selected from an inner-city hospital obstetric service, there i potential for overestimating the effects of the xenobiotic being studied. I cohorts are followed over a long time, study subjects are frequently lost follow-up. Are the ones who continue more motivated, or do they have m problems that need attention?

Categorizing patients into substance-use groups is difficult. Self-reporting substance use is frequently unreliable or inaccurate, and making determ about the nature, frequency, quantity (dose),

or timing (with respect to gestation) of xenobiotic exposure is difficult. E substance users frequently use multiple xenobiotics, it may be difficult to categorize subjects into particular xenobiotic-use groups, and patients us different xenobiotics may be grouped together. In fact, there may be no xenobiotic-free control groups.

When urine drug screens are used to identify substance users, there is a probability of false negatives because drug screens reflect only recent use factor is particularly important because substance use tends to decrease pregnancy, and a negative urine drug screen in the third trimester or at may fail to identify a woman who was using xenobiotics early in pregnanc Testing for xenobiotics in hair or meconium may improve the accuracy of analysis with regard to the entire pregnancy.[121 , 137]

Another bias involves selection of infants who are exposed to xenobiotics Evaluating newborns who are â€œat risk,â€• show signs of withdrawal, c positive urine drug screens will miss some exposed infants. When researc concerns the neurobehavioral development of children exposed in utero t substances, it is important that the examiners performing the evaluation blinded to the infants' xenobiotic exposure category.

Finally, there may be a bias against publishing research that shows a neg no significant effect.[122]

Ethanol

Chronic ethanol use during pregnancy produces a constellation of fetal e The most severe effects are seen in the fetal alcohol syndrome (FAS), wh characterized by (a) intrauterine or postnatal growth retardation, (b) me retardation or behavioral abnormalities, and (c) facial dysmorphogenesis, particularly microcephaly, short palpebral fissures, epicanthal folds, max hypoplasia, cleft palate, hypoplastic philtrum, and micrognathia.[108] A chil be diagnosed with FAS even when a history of regular gestational alcohol cannot be confirmed.

In an attempt to formalize diagnostic criteria for FAS and other gestation alcohol-related effects, the Institute of Medicine has proposed some add descriptors.[236] Partial FAS is applied to a child with some of the characte facial features and with either growth retardation, neurodevelopmental abnormalities, or other behavioral problems. Alcohol-related birth defects congenital anomalies other than the characteristic facial features describe above, such as cleft palate, which are sometimes seen with regular gesta alcohol use. Alcohol-related neurodevelopmental disorder describes neurodevelopmental abnormalities or other behavioral problems, which a sometimes seen with regular gestational alcohol use.

Differential expression of the syndrome may reflect the effects of differer ethanol doses at critical periods specific for particular effects. The cranio anomalies probably represent teratogenic effects during organogenesis, some central nervous system abnormalities and growth retardation may from adverse effects later in gestation.

The fully expressed syndrome may be related to consumption of the equi of 2â€“3 ounces of 100% ethanol (4â€“6 â€œstandardâ€• drinks of hard per day throughout pregnancy,[236] although binge drinking (at least 5 sta drinks per occasion), with a significantly elevated peak blood ethanol concentration, may be more important.[3 , 152] Approximately 20% of wom consume some ethanol during pregnancy;[175] only 1â€“2% consume 4 or drinks each day. In this regard, it might be more appropriate to attribute fetal alcohol syndromes described above to alcoholism, or chronic regular frequent binging, rather than to any level of gestational ethanol exposure matter how little or how infrequent.[3 , 4] Even so, a no-effect level for eth

has not been defined, and a safe level of ethanol use in pregnancy has no determined.[109]

The incidence of FAS is 0.5â€“3 per 1000 live births; 4% of women who heavily may give birth to children with FAS.[2 , 160] This means that severa hundred children with FAS and several thousand with fetal alcohol effects born each year; ethanol use is considered the leading preventable cause mental retardation in this country.[236] Although the primary determinant o and its effects is the level of maternal ethanol consumption, there is som evidence that paternal ethanol exposure may play a contributing role.[1]

Other effects of ethanol use during pregnancy include an increased incide spontaneous abortion, premature deliveries, and stillbirths,[50 , 140] neona ethanol withdrawal,[50] and possibly carcinogenesis.[117] Infants may be irri hypertonic and may have problems with habituation and arousal. Long-te behavioral and intellectual effects include decreased IQ, learning disabilit memory deficits, speech and language disorders, hyperactivity, and dysfunctional behavior in school.[159 , 237]

Brain autopsies of children with FAS demonstrate malformations of gray a white matter, a failure of certain regions (eg, the corpus callosum) to dev failure of certain cells (eg, cerebellar astrocytes) to migrate, and a tende tissue in certain regions to die. The mechanisms of ethanol-induced teratogenesis are not fully elucidated.[19 , 92] Much of the work in animals focused on the developing nervous system, where ethanol adversely affe nerve cell growth, differentiation, and migration, particularly in areas of neocortex, hippocampus, sensory nucleus, and cerebellum.[67 , 89]

Several mechanisms are potential contributors to ethanol's effects.[87] Eth interferes with a number of different growth factors which may affect ne migration and development.[261] In addition, ethanol interferes with the development and function of both serotonin and *N* -methyl-D-aspartate (receptors. Ethanol, or its metabolite acetaldehyde, may also cause necros certain cells directly or through the generation of free radicals and exces apoptosis.[48 , 94] In particular, craniofacial abnormalities may be related t apoptosis of neural crest cells, through the formation of free radicals, a deficiency of retinoic acid, or the altered expression of homeobox genes

regulate growth and development.

One integrative model of ethanol induced teratogenesis proposes that sociobehavioral risk factors, such as drinking behavior, smoking behavior, socioeconomic status, and cultural/ethnic influences, create provocative conditions, such as high peak blood ethanol concentrations, circulating to constituents, and undernutrition. These provocative factors exacerbate fe vulnerability to potential teratogenic mechanisms, such as ethanol-relate hypoxia or free radical-induced cell damage.[5]

Opioids

Opioid dependency remains a significant cause of both maternal and neo morbidity. Approximately 0.2% of pregnant women may use heroin or methadone, and up to 75,000 babies per year may be exposed to opioids, utero.[175] Pregnant opioid users are at increased risk for many medical complications of pregnancy, such as hepatitis, sepsis, endocarditis, sexua transmitted diseases, and AIDS, and may be at increased risk for obstetr complications, such as miscarriage, premature delivery, or stillbirth.[74,8] of

the obstetric complications may be related to associated risk factors in a to the opioid use.

The most common effect of maternal opioid use is on fetal growth.[86,268] is an increased incidence of low birth weight in babies born to opioid-usir mothers, compared to controls, and the effect is greater for heroin than t methadone. Women who receive low-dose methadone and good prenatal have birth outcomes similar to nonusers, but they are at increased risk fo pregnancy-related complications.[74]

The most significant acute neonatal complication of opioid use during pre is the neonatal withdrawal syndrome (NWS), characterized by hyperirrita gastrointestinal dysfunction, respiratory distress, and vague autonomic symptoms, including yawning, sneezing, mottling, and fever (Table 30-4 Myoclonic jerks or seizures may also signify neurologic irritability. Withd

infants are recognizable by their extreme jitteriness, despite efforts at consolation; ecchymoses and contusions may be found on the tips of thei fingers or toes, as a result of trauma from striking the sides of the bassi From 60 to 90% of opioid-exposed offspring will show some signs of withdrawal.[74]

Some of the manifestations of the neonatal withdrawal syndrome may be by enhanced Î±-adrenergic activity in the locus ceruleus. Firing of neuron this region of the brain leads to such NWS-like behaviors as wakefulness tremorsâ€”effects that are inhibited by opioid agonists. Chronic opioid administration leads to tolerance, as well as an increased number of $Î±_2$ adrenergic receptors. Presumably, withdrawal of opioids causes increasec stimulation of a large number of receptors in this region, leading to clinic of withdrawal.

Opioid withdrawal symptoms typically occur within 2 weeks of birth. Hero withdrawal usually occurs within the first 24 hours; however, methadone withdrawal may be delayed because it has a larger volume of distribution slower metabolism in the neonate, and therefore an increased half-life. Methadone withdrawal occurs when the plasma concentration falls below mg/mL.[204] The onset and severity of symptoms may be related to whethe heroin, methadone, or both were used; how much was used chronically; much was used near the time of delivery; the character of the labor; whe analgesic or anesthetic agents were used; and the maturity, nutrition, an medical condition of the neonate.[57] Acute neonatal withdrawal symptoms generally last from days to weeks, but some symptoms may persist for months.[10]

- Exaggerated Moro reflex
- Dehydration
- Frequent yawning and sneezing
- Diarrhea
- High-pitched crying
- Poor feeding
- Hyperactive deep tendon reflexes
- Poor weight gain

Increased muscle tone
Uncoordinated and constant
Increased wakefulness
sucking
Irritability
Vomiting
Seizures
Autonomic signs
Tremors
Fever
Increased sweating
Mottling
Nasal stuffiness
Temperature instability

Neurologic excitability Gastrointestinal dysfunction

TABLE 30-4. Signs and Symptoms of Neonatal Opioid Withdrawal

From 5â€“7% of babies showing signs of withdrawal experience seizures, generally by 10 days after birth.[95] Seizures may be more likely after me withdrawal than after heroin withdrawal.[267] These seizures do not neces predispose to idiopathic epilepsy; in one small study, children who had withdrawal seizures were normal at 1-year follow-up.[60]

Treatment of withdrawal begins with provision of a comforting environme swaddling or tightly wrapping the infant, minimal handling or stimulation, demand feeding. More severe symptoms may require pharmacologic ther One way of determining the need for therapy is the application of a seve scoring scale. In general, babies who are extremely irritable, have feedin difficulties, diarrhea, or significant tremors, or are crying continuously, a candidates for pharmacologic therapy.[10 , 112]

Opioid agonists such as morphine, methadone, tincture of opium and par

and sedative-hypnotic agents such as diazepam and phenobarbital have l used to treat withdrawal symptoms.[10, 112] Tincture of opium, diluted to dose of 0.4 mg/mL of morphine equivalent, may be the preferred agent l it is a pure opioid agonist, and the formulation has no additives. Howeve are few well-controlled trials evaluating the relative efficacy of the differ agents.[243]

Opioid agonists may be more effective at preventing withdrawal seizures heroin or methadone than from phenobarbital or diazepam.[95, 113] Howev sedative-hypnotic agents are commonly used by heroin users or adults maintained on methadone, and sedative-hypnotic withdrawal seizures ma contribute to the overall neonatal abstinence symptomatology. In this se there may be a role for phenobarbital. Because oral administration of phenobarbital may delay achieving a therapeutic level, parenteral admin may be required.

Infants of opioid-using mothers are at increased risk for SIDS compared controls.[114, 115] The relative risk is 3.6 for methadone and 2.3 for heroi mechanism may be related to a decreased medullary responsiveness to C the effect may be related to some condition of the postnatal environment [252]

Although young children born to opioid users do not seem to have signifi differences in behavior compared to controls, older children have increas learning problems and school dysfunction particularly related to behavior difficulties.[268]

Cocaine

Approximately 1% of pregnant women in the United States use cocaine s time during their pregnancy.[175] The rate may be as high as 15% in certa populations,[55] and it is estimated that more than 100,000 infants born in United States each year may be exposed to cocaine in utero.[42] The consequences of cocaine use during pregnancy have been extensively reviewed.[99, 102, 187]

The most commonly reported obstetric complications of gestational cocai

are abruptio placentae, premature delivery, and intrauterine growth reta Significant perinatal problems include seizures, cerebral infarctions, and CNS effects.[46, 187] A meta-analysis of studies published before 1989 cor that adverse effects on head circumference, gestational age, and birth w that had been attributed to the maternal use of cocaine during pregnancy related to polysubstance use, but not necessarily to cocaine.[147] In this a no increased risk of abruptio placentae was demonstrated. However, later which tried to control for polysubstance use although not always for smok ethanol use, suggested that there were significant effects of

gestational cocaine use on intrauterine growth and prematurity.[120, 187, The incidence of abruptio placentae may also be significant when related acute use.[226] It seems that good prenatal care can mitigate many of the effects of cocaine.[149, 195, 268]

Significant congenital malformations have been reported among some inf who were exposed to cocaine in utero, specifically genitourinary malform cardiovascular malformations, and limb-reduction defects.[36, 79] In one l population-based study, there was no increase in the incidence of malformations.[156]

Animal models have also identified teratogenic effects of in utero cocaine exposure. Decreased maternal and fetal weight gain and an increased fre of fetal resorption were demonstrated in rats;[71] sporadic physical anoma have also been observed.[47] Teratogenic effects similar to those observed humans were reported in mice: bony defects of the skull, cryptorchidism, hydronephrosis, ileal atresia, cardiac defects, limb deformities, and eye abnormalities.[75, 150, 151, 165] Cocaine caused hemorrhage, edema, and subsequently, limb-reduction defects in rats when administered during midgestation in the postorganogenic period.[255]

The perinatal effects of cocaine are probably mediated through a vascular mechanism. Cocaine administration in the pregnant ovine model causes increased uterine vascular resistance, decreased uterine blood flow, incre fetal heart rate and arterial blood pressure, and decreased fetal PO_2 and content.[14, 263] Similar effects have been seen in rats.[184] Fetal hypoxia r

cause rupture of fetal blood vessels and infarction in developing organ sy such as the genitourinary system[45 , 165 , 231] or the CNS.[44 , 59 , 256] Hyperthermia or direct effects of cocaine in the fetus may exacerbate the effects.[28] Limb-reduction defects similar to those attributed to cocaine ha been produced after mechanical clamping of the uterine vessels.[28 , 257] A developing concept is that following vasospasm and ischemia, reperfusion with the generation of oxygen free radicals and subsequent injury.[263 , 26

Despite the reported malformations and a possible mechanism, neither th human epidemiology, nor the effects observed in animal models, suggest specific teratogenic syndrome. The risk of a significant malformation from prenatal cocaine exposure is low, but the effect, if one occurs, may be se [, 65 , 79]

One of the greatest concerns about prenatal cocaine exposure is the pote adverse effect on the developing child, and this is an intensive area of epidemiologic research. The most common findings in early infancy are la state and autonomic regulation, decreased alertness and orientation, and abnormal reflexes, tone, and motor maturity; however, many studies sho effect.[70] For some children, these effects may manifest in later infancy as difficulty with information processing and learning. However, preliminary evidence suggests that, for school-age children, any observed cognitive may be more related to the home environment than to prenatal cocaine exposure, even for those children who showed some of the typical neona behaviors.[43 , 76 , 246] Nonetheless, there is also evidence of impairment modulating attention and impulsivity, which makes handling unfamiliar, c and stressful tasks more difficult,[162] and these effects are also observed animal models of prenatal cocaine exposure.[65 , 232] Cohorts of children e to cocaine in utero are now older and in school, and studies of developme behavior are in progress.

The mechanism of neurotoxicity has not been specifically elucidated. As described above, for many of the maternal and fetal physical defects, coc may have direct toxicity, or effects may be mediated through hypoxia or free radicals. Because cocaine interferes with neurotransmitter reuptake, likely that cocaine also disrupts normal neural ontogeny by interfering wit

trophic functions of neurotransmitters on the developing brain.[153, 161]

Breast-Feeding

In the United States, breast-feeding is the recommended method of infan nutrition because it offers nutritional, immunologic, and psychological be Many women use prescription and nonprescription medications while brea feeding, and are concerned about the possible ill effects on the infant of medications in the breast milk. This concern extends to the possible expo the infant to occupational and environmental xenobiotics via breast milk.[2] The response to many of these concerns can be determined by the answe following question: Does the risk to an infant from a xenobiotic exposure breast milk exceed the benefit of being breast-fed?[134]

Pharmacokinetic factors determine the amount of xenobiotic available for transfer from maternal plasma into breast milk; only free xenobiotic can the mammary alveolar membrane. Most xenobiotics are transported by p diffusion. A few xenobiotics, such as ethanol and lithium, are transported through aqueous-filled pores. The factors that determine how well a chen diffuses across the membrane are similar to those for other biologic mem such as the placenta: molecular weight, lipid solubility, and degree of io

Large-molecular-weight compounds, such as heparin or insulin, will not p breast milk. Lipid solubility is important not only for diffusion but also for xenobiotic accumulation in breast milk, because breast milk is rich in fat, especially breast milk that is produced in the postcolostral period (3â€“4 postpartum). With a pH near 7.0, breast milk is slightly more acidic than Consequently, weak acids in plasma exist largely as ionized molecules an cannot be easily transported into milk. Conversely, weak bases exist in p largely as nonionized molecules and are available for transport into breas Once in the breast milk, ionization of the weak base occurs, and the chen concentrated as a result of ion trapping. In other words, weak bases may concentrate in breast milk. Sulfacetamide (pK_a 5.4, a weak acid) has a concentration in plasma 10 times its concentration in breast milk, whereа sulfanilamide (pK_a 10.4, a weak base) is found in equal concentrations in plasma and breast milk.[134]

The net effect of these physiologic processes is expressed in the milk-to- (M/P) ratio. Xenobiotics with higher M/P ratios have relatively greater concentrations in breast milk. The M/P ratio does not, however, reflect th absolute concentration of a xenobiotic in the breast milk, and a xenobiotic high M/P *ratio* is not necessarily found at a high *concentration* in the bre For example, morphine has an M/P ratio of 2.46 (is concentrated in breas but only 0.4% of a maternal dose is excreted into the breast milk.[13] In g for most pharmaceuticals, approximately 1â€“2% of the maternally adm dose is presented to the infant in breast milk.[134]

The M/P ratio has several limitations. It does not account for differences xenobiotic concentration that may result from (a) repeat or chronic dosing breast-feeding at different times relative to maternal medication dosing, differences in milk production during the day or even during a particular feeding session, (d) the time postpartum (days, weeks, or months) when measurement is made, and (e) maternal disease.

While being cognizant of the limitations, a spot breast milk xenobiotic concentration or a concentration estimate based on the M/P ratio allows a simplistic estimation of the quantity of xenobiotic to which an infant is e assuming a constant breast-milk concentration:

Infant dose = Breast-milk concentration Ã— amount consumed

The effect of this dose on the infant depends on the bioavailability of the xenobiotic in breast milk, the pharmacokinetic parameters that determine xenobiotic levels in the infant, and the infant's receptor sensitivity to the xenobiotic. These parameters are often different in neonates than in adul may lead to xenobiotic accumulation; generally, absorption is greater, bu metabolism and clearance are reduced.[7] These effects are exaggerated in premature infants.[191 , 199] The amount of most xenobiotics delivered to in breast milk is adequately metabolized and eliminated.[134]

Many of the considerations above are theoretical, and the number of spe contraindicated xenobiotics is quite small.[11] Published guidelines on the advisability of breast-feeding during periods of maternal therapy are ger

based on the expected effects of full doses in the infant or on case report adverse occurrences. Interestingly, when the reports of adverse effects w reviewed, 37% of cases were in infants younger than 2 weeks old, 63% w infants younger than 1 month old, and 78% were in infants younger than months old; 18% were in infants 2 to 6 months old; and only 4% were in older than 6 months.[12] It seems, therefore, that adverse effects are most to be observed in the first few weeks of life, when an infant's metabolic is only 20â€“40% that of an adult.[7]

Every few years the American Academy of Pediatrics (AAP) publishes recommendations regarding breast-feeding in the setting of xenobiotic e In the latest revision, the AAP continues to discourage the use of xenobio such as cocaine or heroin during the breast-feeding period because of dir effects on the baby, as well as detrimental effects on the physical and en health of the mother and on the caregiving environment.[11] Although etha not specifically contraindicated for the breast-feeding mother, decreased production and adverse effects in the infant are noted with maternal consumption of large amounts of ethanol.[134]

The AAP recommends the temporary cessation of breast-feeding when the mother is exposed to metronidazole, an in vitro mutagen, or to certain radiopharmaceuticals, specifically isotopes of copper, gallium, indium, iod sodium, and technetium. In these cases, breast milk can be collected and before medication use for later feeding to the baby. Breast-feeding is res when the milk is no longer radioactive, generally 1 to 3 days for most of isotopes mentioned except gallium, after which radioactivity may be prese 2 weeks. Metronidazole can be administered as a single 2-g dose, allowin breast-feeding to be discontinued for only 12 to 24 hours.[134]

Although there are few data demonstrating specific effects, the AAP sugg caution with regard to breast-feeding while using sedative-hypnotic, antidepressant, and antipsychotic medications. These medications modula neurotransmitters in the CNS, which can adversely effect the developing system.

For most xenobiotics, a risk-to-benefit analysis must be made. For examp lithium is transferred in breast milk and may lead to measurable, althoug

subtherapeutic, serum concentrations in the breast-fed infant. Although t effects of such exposure to lithium are unknown, many practitioners belie the benefit of treating a mother's bipolar illness outweighs the potential r the infant.[134 , 218]

Similarly, the breast-fed infant of a woman who smokes is exposed to nic and other tobacco constituents, both by inhalation and via breast milk. A this child may be at increased risk for respiratory illness as a result of ex to tobacco smoke, some of the risk may be reduced by breast feeding.[11]

Many xenobiotics, including pharmaceuticals, foods, and environmental a have been found in breast milk, and Table 30-5 lists some of their effects addition to the effects listed, there may be a small increased risk of carcinogenicity associated with exposure to some environmental xenobio through breast milk.[202]

In most cases, women do not need to stop breast-feeding while using pharmaceuticals, such as most common antibiotics. However, â€œcompatibilityâ€• with breast-feeding is generally based on a lack of reported adverse effects, which may reflect limited clinical experience wit particular xenobiotic in breast-feeding patients. Therefore, in the setting limited information, exposure to a xenobiotic through breast milk should regarded as a small potential risk, and the infant should receive appropri medical follow-up. Not all â€œcompatibleâ€• medications are safe in all situations. For instance, phenobarbital can produce CNS depression in an if the mother's serum concentration is in the high therapeutic or supratherapeutic range, which often occurs while dosage adjustments are made. Such a concentration may or may not produce CNS depression in t mother. Nalidixic acid, nitrofurantoin, sulfapyridine, and sulfisoxazole, al generally safe, can cause hemolysis in a breast-fed infant with glucose-6- phosphate dehydrogenase deficiency.

Decisions on breast-feeding should be made with the informed involvemer the woman, her physicians, and, when necessary, a consultant with speci expertise in this field. Guidelines are available from several sources.[21 , 3 170]

Toxicologic Problems in the Neonate

Approximately 8% of all medication doses administered in neonatal inten care units (NICU) may be up to 10 times greater or lesser than the dose ordered.[174] As many as 30% of newborns in NICUs may sustain adverse effects, some of which may be life-threatening or fatal.[13] Physiologic dif between adults and newborn infants affect xenobiotic absorption, distribu and metabolism;[7 , 191] these pharmacokinetic differences account for sor cases of xenobiotic toxicity seen in the newborn infant.

GI absorption of xenobiotics in the neonate is generally slower than in ac [191] This delay may be related to decreased gastric acid secretion, decrea gastric emptying and transit time, and decreased pancreatic enzyme acti The GI environment of the newborn and young infant may allow the grow *Clostridium botulinum* and the subsequent development of infantile botul (Chap. 46). Infantile botulism has been reported in infants several weeks age.[101 , 244]

Although it is uncommon, cutaneous absorption of xenobiotics may be a r toxic exposure in the newborn.[68 , 211] Aniline dyes used for marking diap absorbed, causing methemoglobin-emia,[211] and contaminated diapers we responsible for one epidemic of mercury poisoning.[16] The absorption of hexachlorophene antiseptic wash has led to neurotoxicity with marked vacuolization of myelin seen microscopically.[131 , 157 , 228] The dermal application of antiseptic ethanol has caused hemorrhagic necrosis of the s

some premature infants. Iodine antiseptics have led to hypothyroidism in newborns.[40] An increased potential for absorption and toxicity has followe application of corticosteroids[82 , 209] and boric acid[66] to the skin of childr cutaneous disorders.

Use with Caution
5-Aminosalicylic acid
Diarrhea

Acebutolol, atenolol, nadolol, sotalol, timolol
Hypotension, bradycardia, tachypnea, cyanosis
Amiodarone
Possible hypothyroidism
Aspirin
Metabolic acidosis; may affect platelet function; rash
Bromocriptine
Suppresses lactation
Chloramphenicol
Potential risk for aplastic anemia or gray-baby syndrome[134]
Chlorpromazine
Galactorrhea in mother; drowsiness and lethargy in infant; decline in developmental scores
Cimetidine
Possible antiandrogenic effects[134]
Clemastine
Drowsiness, irritability, refusal to feed, high-pitched cry, meningismus
Clofazimine
Possible increased skin pigmentation
Cyclophosphamide, cyclosporine, doxorubicin, methotrexate
Neutropenia, thrombocytopenia, possible immune suppression; unknown on growth or association with carcinogenesis
Ergotamine
Vomiting, diarrhea, seizures; may inhibit prolactin secretion and lactatior
Fluoxetine
Colic, irritability, feeding and sleeping disorders, slow weight gain
Haloperidol
Decline in developmental scores
Lamotrigine
Potential therapeutic serum concentrations in infant
Lithium
Subtherapeutic concentrations in infant
Metronidazole, tinidazole
In vitro mutagen

Phenindione
Risk of hemorrhage
Phenobarbital
Sedation in exposed infants; withdrawal after weaning from phenobarbita containing milk; methemoglobinemia
Primidone
Sedation, feeding problems
Sulfapyridine, sulfisoxazole
Caution in infant with jaundice or G6PD deficiency and in ill, stressed, or premature infant
Sulfasalazine
Bloody diarrhea
Tetracycline
May cause staining of infant teeth after prolonged maternal use[134]
Thiouracil, methimazole
May cause thyroid suppression and goiter[134]

Use Is Compatible with Breast-feeding Despite Known Effect
Ethanol
Large doses: decreased milk ejection reflex; infant: drowsiness, diaphore decreased growth and weight gain
Bendroflumethiazide
Suppresses lactation
Caffeine
Irritability, poor sleeping pattern (no effect with usual amount of caffeina beverages)
Carbimazole
Goiter
Chloral hydrate
Sleepiness
Chlorthalidone
Excreted slowly
Contraceptive pills with estrogen/progesterone
Rare breast enlargement; decrease in milk production and protein conten

confirmed in several studies)
Danthron
Increased bowel activity
Dexbrompheniramine maleate with *d* -isoephedrine
Crying, irritability, poor sleeping pattern
Estradiol
Withdrawal vaginal bleeding
Indomethacin
Seizure
Iodine topical
Odor of iodine on infant's skin
Iodine, iodides
Goiter
Methyprylon
Drowsiness
Nalidixic acid
Hemolysis in infant with G6PD deficiency
Nitrofurantoin
Hemolysis in infant with G6PD deficiency
Phenytoin
Methemoglobinemia
Theophylline
Irritability

Specific Risk Categories
Aspartame
Caution if mother has phenylketonuria
Chocolate (theobromine)
Irritability or increased bowel activity if mother consumes large amounts
Fava beans
Hemolysis in infant with G6PD deficiency
Hexachlorobenzene
Skin rash, diarrhea, vomiting, dark urine, neurotoxicity, death
Lead

Possible neurotoxicity
Methylmercury, mercury
Possible neurodevelopmental toxicity
Polyhalogenated biphenyls
Lack of endurance, hypotonia, sullen expressionless facies
Silicone
Esophageal dysmotility
Tetrachloroethylene
Obstructive jaundice, dark urine
Vegetarian diet
Vitamin B_{12} deficiency

Xenobiotic Effect

TABLE 30-5. Xenobiotics Associated with Effects on Some Nurs Infants

Other routes of exposure have led to clinical poisoning. Several children aspirated talcum powder and died.[33, 173] Inhalation of mercury from inc thermometers may be a potential risk.[9] One child died following the opht instillation of cyclopentolate hydrochloride.[18]

Because of differences in total body water and fat compared to the adult, distribution of absorbed xenobiotics may differ in neonates. Water repres 80% of body weight in a full-term baby, compared to 60% in an adult. Approximately 20% of a term baby's body weight is fat, compared to only a premature baby. The increased volume of water means that the volume distribution for some water-soluble xenobiotics, such as theophylline or phenobarbital, is increased.

Protein binding of xenobiotics is reduced in newborns compared to adults: serum concentration of proteins is lower, there are fewer receptor sites t become saturated at lower xenobiotic concentrations, and binding sites h

decreased binding affinity.[191] Protein binding has potential relevance with respect to bilirubin, an endogenous metabolite that at very high concent can cause kernicterus; bilirubin competes with exogenously administered xenobiotics for protein binding sites. In vitro, certain xenobiotics, such as sulfonamides and ceftriaxone, displace bilirubin from protein receptor sit which might increase the risk of kernicterus, although this has not been demonstrated. Conversely, bilirubin may itself displace other xenobiotics, as phenobarbital or phenytoin, leading to increased plasma xenobiotic concentrations.

Newborn infants have decreased hepatic metabolic capacity compared to which may lead to xenobiotic toxicity. For instance, the newborn has limi ability to oxidize xenobiotics, so theophylline is metabolized primarily to active metabolite caffeine instead of methylxanthine and 1,3-dimethyluric which are the primary inactive metabolites in the adult. In addition, imm of the CYP system leads to increased elimination half-lives of xenobiotics phenytoin, phenobarbital, and theophylline.

Two syndromes related to immature metabolic function are described. Th â€œgasping baby syndrome,â€• characterized by gasping respirations, metabolic acidosis, hypotension, central nervous system depression, con renal failure, and, occasionally, death, is attributed to high concentrations benzyl alcohol and benzoic acid in the plasma of affected infants.[8 , 35 , 8] Benzyl alcohol, a bacteriostatic agent, was added to intravenous flush so and accumulated in newborns after repetitive doses. The high concentrati benzoic acid could not be further metabolized to hippuric acid by the imm liver. Immature glucuronidation in the neonate is responsible for the â€œ baby syndromeâ€• following high doses of chloramphenicol (Chaps. 31 a).[98]

The umbilical vessels are a common site of vascular access in sick neona Because blood drains into the portal vein, it is possible that IV medicatio experience a â€œfirst-passâ€• effect, although whether this route of xe administration affects metabolism or clearance has not been well studied. renal functions, including glomerular filtration rate and tubular secretion, relatively immature at birth;[106] the glomerular filtration rate of the newb

approximately 30% of that of an adult. Xenobiotics such as aminoglycosi antibiotics and digoxin are excreted unchanged by the kidney and, theref depend on glomerular filtration for clearance. Dosing of these agents in t newborn must account for these differences.

Very little information is available to guide the clinician in the manageme xenobiotic poisoning in the newborn infant. Cutaneous absorption is prob already complete by the time toxicity is noted, although further exposure prevented. Gastrointestinal decontamination is not generally performed i neonates, and the neonate may be at increased risk of fluid, electrolyte, thermoregulatory problems following gastric lavage or the use of catharti agents. Multiple-dose activated charcoal was used in a 1.4-kg 2-week-old premature infant to treat theophylline poisoning. Hemodialysis, hemoper and exchange transfusion are used in neonates to treat xenobiotic toxicit (Chaps. 10 and 31).

Summary

The use of xenobiotics in the pregnant or breast-feeding woman is a com area of medical practice and presents the clinician with potentially difficu management decisions. This chapter highlights some of the important pr of xenobiotic effects in both the pregnant woman and the fetus. Appropri management of many of the potential problems will be facilitated by the coordinated efforts of obstetricians, perinatologists, neonatologists, pediatricians, and toxicologists.

Chapter 31
Pediatric Principles

Jeffrey S. Fine

Because phone calls to poison centers regarding child exposures to poter xenobiotics are more frequent than those for any other age group, and b poisoning is a important cause of pediatric injury morbidity, pediatricians been active in helping to establish and promote the field of medical toxic as well as in supporting the need for and use of regional poison control c Although the basic approach to the medical management of toxicologic p outlined in Chap. 4 is generally applicable to both children and adults, th issues, such as abuse by poisoning, that are of particular concern regardi children and when special considerations may be appropriate. This chapte provides a pediatric perspective on the application of toxicologic principle

Epidemiology

To analyze the problem of pediatric poisoning, it is necessary to understa magnitude of the problem. When assessing the impact of a particular type injury such as poisoning, epidemiologists examine multiple parameters, su exposure, morbidity, mortality, and cost, to measure the injury's effects. parameters are difficult to measure accurately. An important source for

information on the extent and effects of poisoning exposures is the Amer Association of Poison Control Centers (AAPCC). Each year the AAPCC com standardized data collected from poison centers throughout the United S the 2003 annual review includes information submitted by 64 poison cent the following discussion, comments on AAPCC data refer to cumulative information from the last 5 published reports covering the years 1999 to (Chap. 130).

The AAPCC reports approximately 1.5 million potentially toxic exposures year for children and adolescents ages 0 to 19 years, and these pediatric exposures represent 67% of the reported exposures for all age groups. C younger than age 6 years account for 79% of all reported pediatric expos children between 6 and 12 years of age account for 10%, and adolescents 19 years of age account for 11% of reported pediatric exposures. Childre younger than age 6 years account for 53% of all reported pediatric and a poisoning exposures. Girls represent 47% of the reported poisoning expo among young children and 56% of the reported exposures among adoles

Almost 99% of the AAPCC-reported poisoning exposures in children youn than 6 years of age are unintentional. In contrast, only 51% of the repor adolescent poisoning exposures are unintentional; 45% of exposures are intentional, mostly the result of substance use or suicide attempts. This l frequency of suicidal intent has also been reported by others.[171] The rem 4% of adolescent exposures have miscellaneous causes, such as adverse reactions, or are unknown. These differences in the reason for exposure between young children and adolescents account for differences in the outcomes of these exposures (discussed below).

Approximately 11,000 exposures each year are classified as adverse drug reactions. These account for approximately 0.3% of exposures in children than 6 years of age and approximately 2% of exposures in older children adolescents.

Table 31-1 shows the leading causes of reported exposures in children ar adolescents. According to the AAPCC, approximately 56% of pediatric ex are to xenobiotics that are commonly found around the house, such as c products, cosmetics, plants, hydrocarbons, and insecticides, whereas

approximately 44% are to pharmaceutical agents. This is in contrast to hospitalizations and death rates the majority of which are accounted for l pharmaceutical xenobiotics.

Table 31-1 lists the most common reported *exposures* , but not all these products lead to serious morbidity and mortality (Table 31-2). For exam children frequently ingest cosmetic products, so the number of reported exposures is large, but cosmetics manufactured in the United States are nontoxic. For children younger than age 6 months, poisoning is unusual b result from the inadvertent administration of an incorrect drug or drug do a parent,[56] intentional administration of a drug by a parent or sibling,[15] , passive exposure, for instance, to the smoke of â€œcrackâ€• cocaine or phencyclidine.[13] , [70] , [115] , [148] , [178] Any poisoning in a child younger than year of age should be carefully evaluated for possible child abuse or negl (see below).[15]

Several characteristics associated with ingestions in toddlers differentiate from ingestions in adolescents or adults: (a) they are without suicidal int (b) there is usually only 1 xenobiotic involved; (c) the xenobiotics are us nontoxic; (d) the amount is usually small; and (e) toddlers usually preser evaluation within 1 hour after the ingestion or soon after the ingestion is discovered. As many as 30% of children who experience one ingestion wi experience a repeat ingestion.[77] Children who ingest poisons may also be risk for other types of injuries.[11] , [47] Adolescents may also be at risk for repeated ingestions.[57]

The peak age for childhood poisoning is between 1 and 3 years.[29] Uninter ingestion is unusual after age 5 years, although it can result from mistak consumption of a xenobiotic from a

mislabeled container.[24] Between the ages of 5 and 9 years, poisoning ma reflection of intrafamilial stress or suicidal intent. After age 9 years and adolescence, overdose or poisoning frequently results either from a suici gesture or attempt, or from an adverse effect while seeking drug-induced euphoria. Unintentional poisonings are largely preventable (Chap. 130).

TABLE 31-1. Average Annual Xenobiotic Exposures Reported to AAPCC (1999â€“2003)[a, b]

Because many children are exposed to nontoxic xenobiotics or to nontoxi amounts of toxic xenobiotics, it is not surprising that the relative number children and adolescents who suffer significant morbidity is small (Table However, because there are millions of exposures each year, the number children and adolescents reported by the AAPCC who suffer at least mode effects is approximately 33,000 per year. Fifty-six percent of these serio poisoned children are adolescents.

TABLE 31-2. Xenobiotics Responsible for Significant Pediatri Poisoning Morbidity and Mortality

Although the AAPCC is not the only source for epidemiologic data, there i detailed information available anywhere on poisoning morbidity. Estimates the rate of emergency department visits for poisoning and overdose are approximately 300â€“840 per 100,000 for children younger than 5 years and 290â€“360 per 100,000 for adolescents.[29, 48, 55, 108, 168] It has b estimated that between 100,000 and 170,000 children are seen in emerg

departments each year for poison-related injuries, and that between 10 a 20% are hospitalized.[28 , 108] Reported rates of hospitalization for young children range from 40â€“170 per 100,000.[30 , 48 , 57 , 131 , 171]

Following exposure to xenobiotics, adolescents are more frequently hosp than children.[57] However, it is unclear whether this reflects medical hospitalization for management of the poisoning or psychiatric hospitaliz The peak age for hospitalizing

young children exposed to xenobiotics is between 1 and 3 years, reflectin peak age of exposure. Hospitalized children younger than age 2 years are commonly exposed to nonpharmaceutical xenobiotics, whereas children o than age 2 years and adolescents are more commonly exposed to pharmaceuticals.[48 , 57 , 171]

TABLE 31-3. Outcome of Reported Pediatric Xenobiotic Exposu (1999â€“2003)[a]

Although the AAPCC reports outcome related to age, it does not generally stratify outcome with regard to age and xenobiotic. In one earlier multiye review, the AAPCC reported those xenobiotics causing the greatest numbe major and fatal effects in children younger than 6 years old.[100] Table 31- the xenobiotics that cause significant morbidity and mortality. Other repo hospitalized patients, primarily from the United States or Western Europe describe a similar distribution of agents causing significant morbidity.[30 , 183] However, there are some differences in other international reports. In Australia, for instance, quinine, digoxin, and eucalyptus oil were significa causes of hospitalization, whereas in India, kerosene was the leading cau poisoning-related hospitalizations.[27 , 66 , 114]

Poison-related deaths represent approximately 2.5% of annual childhood adolescent deaths from unintentional injury.[118] The AAPCC reported 508 in children younger than 6 years of age from 1983â€“2003, an average o 24 per year. These deaths represent 3.6% of the reported poisoning fata for all age groups for those years and a 94% decrease from a high of 456 1959.[29] This dramatic decrease in poisoning mortality may be the result improved poisoning prevention (eg, child-resistant closures) and improve medical care, or may reflect a decrease in reporting (discussed later; see 130).

Thirty-four percent of the AAPCC-reported childhood fatalities result from unintentional ingestions, 18% are from environmental exposures such as

monoxide poisoning, and 25% are caused by medication errors and adver reactions; the remaining 23% have miscellaneous causes or are unknown. contrast, 42% of AAPCC-reported adolescent fatalities are the result of s and 35% follow substance use; only 3% are related to environmental exp and only 4% are caused by medication errors and adverse reactions.

Although the AAPCC data provide a remarkable amount of epidemiologic information, there are questions about the accuracy of the data.[68, 69, 1 comparison to the AAPCC, the National Center for Health Statistics report that for the years 1999â€“2001, the most recent dataset available, there 220 poison-related deaths for children younger than 5 years old, 225 for children ages 5â€“14 years, and 1706 for adolescents ages 15â€“19 year For the same years, the AAPCC reported 70 deaths for children younger t age 6 years, 18 for children ages 6â€“12 years, and 167 for adolescents 13â€“19 years. It is difficult to compare these two datasets directly beca they are organized very differently, but the differences in the raw numbe dramatic.

The most serious concern when considering the reported numbers of pois is that many significant poisonings are not reported to poison centers. Fo instance, physicians managing â€œcommonâ€• toxicologic problems may feel the need for the assistance of a local or regional poison center and m feel compelled to participate in the reporting process. Therapeutic misadventures may also go unreported. In Rhode Island, only 45 of 369 poisoning deaths were reported to the regional poison center (Chap. 130

The most notable difference between the toxins listed in Table 31-2 and from the 1960s and 1970s is that salicylates are no longer a leading caus reported poisoning morbidity and mortality.[35, 40] This change may be re to federal regulations requiring child-resistant closures as well as to the decreased availability of aspirin at home for use in children following the recognition of its association with Reye syndrome (Chap. 35).[17, 75, 116

There are some significant etiologic differences in Table 31-2 between ch and adolescents, particularly with regard to the lethality of agents. The l three categories of xenobiotics for children are analgesic agents, carbon monoxide, and hydrocarbons, which account for 53% of all reported pois

deaths. The top three categories for adolescents are analgesic agents, stimulants/street drugs, and antidepressants (mostly tricyclic antidepres accounting for 61% of reported poisoning deaths. Importantly, the hydrc deaths in young children generally result from unintentional aspiration, b almost all the hydrocarbon deaths in adolescents are related to abuse of hydrocarbons such as trichloroethane or chlorofluorocarbons.

Poisoning also has an economic cost. Charges for hospitalized patients ra from $2000â€“$10,000, depending on length of stay and outcome.[84, 164] In a large economic analysis of the cost of injury in the United States, th estimated average lifetime cost was $495 per child and $10,839 per ado or young adult injured or killed by poisoning.[131]

Behavioral, Environmental, and Physical Issues

A simplistic approach to childhood poisonings is that unobserved toddlers exploring their environment inadvertently ingest toxins. This approach ig the complex interplay of factors that may contribute to some pediatric ingestions.

One approach to understanding injury causation, in general, that can be to poisoning, uses an infectious disease-like model.[67] According to this n there are three interacting factors: host, agent, and environment. These interact during three phases: preinjury, injury, and postinjury. The factor themselves contribute to the likelihood, nature, and magnitude of, as well the host response to, an injury.

In the case of a toddler ingestion, the host is a child of a particular age, certain developmental abilities and a certain temperament. The agent is a particular toxin, at a particular dose, with a particular likelihood of causir injury. The environment is usually the home with the additional particular regarding storage practices or supervision. These environmental factors a discussed below.

During the preinjury phase, there is an interaction of the host, agent, and environment. Under the proper circumstances, an injury can occur. Modi of these factors can lead to prevention of an injury. For example, if a 2-y child finds 2 pills on a bedside table, there is a fair chance the child will the tablets. However, if these pills are stored out of reach of the child, th ingestion can be prevented.

The injury phase covers both the ingestion and the initial pathophysiologi response. Again, the particular factors determine the nature and extent o injury. Continuing the above example, if the 2 pills are 325-mg acetamin tablets, the ingestion will not lead to injury. However, if the pills are 0.2- clonidine tablets, there is a high likelihood of toxicity.

The postinjury phase is concerned both with the ongoing host response a medical management of the poisoning. In this phase, it would be determi whether the 2-year-old child with a clonidine ingestion manifests signs of toxicity, such as coma or hypotension; whether the child requires treatm with activated charcoal, fluid, or naloxone; and whether the child require hospital admission.

This paradigm is only a model; it is often difficult to examine any individu factor independently and the relative contribution of these factors is not defined. Nonetheless, consideration of the individual factors of host, agen environment allows us to focus on several relevant aspects of pediatric poisoning.

Childhood and adolescence are times of tremendous growth and development.[184] Some of these physical and social changes place children teenagers at increased risk for poisonings. By 7 months of age, an infant up can pivot in order to grab an object; by 9â€“10 months of age, most can creep and crawl; by 15 months of age, most toddlers are walking qui competently and eagerly exploring. Between 9 and 12 months of age, a c developing a skillful pincer grasp with the thumb and forefinger, that allo child to pick up small objects. Throughout this period, one of the child's sensory experiences is sucking on or gumming objects that are placed in mouth. Thus, the combination of three developmental skillsâ€”the ability move around the home and go beyond the immediate view of a guardian,

ability to pick up and manipulate small objects, and the tendency of child put things in their mouthsâ€”places them at risk for both foreign-body aspiration and poisoning.

As children develop socially, they desire to become more like their parent they tend to imitate behaviors, such as taking medicine or using mouthw Children are taught that medicine is good for them when they are sick. M children's medicines are sweetened and flavored to make them more pal and many parents inappropriately encourage their children to take medici telling them â€œit tastes like candy.â€• Children have been observed â€œmaking teaâ€• from plants or â€œmaking pizzaâ€• with mushrooms the yard.[24]

As children become more mobile, agile, and curious, xenobiotics that wer previously outside their reach now become accessible, even when stored some difficult-to-reach places. There is some evidence to suggest that pa underestimate the developmental skills of their children.[47] The meaning o term â€œunintentionalâ€• with respect to childhood poisoning should als reconsideredâ€”the toddler quite purposefully intends to get to a pill and but the child does *not* intend to injure himself.

Some of the reasons why a child wants to ingest a pill are because it is t looks like candy or food, the parent takes pills, and taking medicine is considered good for health. These reasons may not be sufficient to explai a child does something that the child knows should not be done. Another of childhood poisoning that must be considered is the interaction between child's temperament and the child's social environment.

Many authors have tried to identify psychosocial predictors for childhood poisoning in general, and for repeat poisoning in particular.[20 , 49 , 79 , 16 many as 30% of children may have repeat episodes of ingestions, frequer the same xenobiotic. Certain risk factors have been identified for single a repeated episodes of childhood poisoning, such as hyperactivity, impulsiv taking behavior, rebelliousness, or negativistic attitude. Other factors see be associated more with the parents, such as medical illness, depression, social isolation. Finally, a stressful environment or major social problem also be a contributing factor.[154 , 160] It is not difficult to imagine a situat

when a parent is depressed, uses antidepressant medication that is kept a bedside, and cannot give adequate attention to a demanding child. In a b attention, or as an expression of anger or frustration, the child ingests so the parent's medication.

With regard to the agent, there are a number of issues that affect the pr and injury phases. It was stated above that modification of any one of th interacting factors of host, agent, or environment can potentially prevent reduce the severity of injury. In this regard, if household products of low toxicity are available around the house, the likelihood of injury is reduced of these products is ingested. For example, less-toxic rodenticides such a warfarin have replaced many more toxic ones such as thallium or sodium monofluoroacetate. Relatively nontoxic paradichlorobenzene mothballs ha largely replaced relatively more toxic camphor-containing mothballs.

It may also be possible to reduce the likelihood of ingestion by making a xenobiotic unpalatable. Denatonium benzoate (Bitrex), an aversive bitter agent, is added to some liquid chemicals such as windshield washer fluid antifreeze, with the expectation that this will prevent unintentional poiso Some trials show that older children respond negatively to these agents b that younger children may ingest 1â€“2 teaspoonfuls of a xenobiotic befo responding to the bitter flavor.[18 , 154] This is an important consideration because even this small an amount of a xenobiotic such as methanol can toxic (see below). The actual usefulness of the bittering agent denatoniur benzoate in poison prevention is largely unstudied.[139]

The problem of unintentional ingestions is compounded by poison â€œloo alikesâ€•; that is, xenobiotics that resemble candy or food products.[50] (ILLOOKALIKE in the Image Library at http://www.goldfrankstoxicology.co Some common examples are ferrous sulfate tablets that look like M&M ca prenatal vitamins that resemble Good and Plenty candies, and fuel oils th come in cans that resemble soft drink containers. Many shampoos and dishwashing detergents are given lemon or strawberry scents and have p of fruits on the labels. Children are not always capable of distinguishing â€œlook-alikesâ€• from real candies, fruits, and sodas, and may be attr to bright colors, pleasant smells, and appealing packages. Eliminating the

â€œlook-alikesâ€• might prevent some unintentional ingestions.

Probably the most significant change to the physical aspect of the agent been packaging of pharmaceuticals and some other xenobiotics with child resistant closures mandated by the Poison Prevention Packaging Act of 19 (Chap. 130). This legislation is credited with a significant reduction in morbidity and mortality related to poisoning from aspirin and other regul products, although this analysis has been challenged.[137 , 173] Child-resist

closures have reduced the number of toxic exposures to kerosene in Sout Africa.[92]

Nonetheless, problems with child-resistant closures include pharmaceutic being dispensed in nonresistant containers, child-resistant containers not properly closed, and medicines being left out of the child-resistant contai use.[28 , 157] Seventy percent of potentially toxic pharmaceuticals may be nonâ€“child-resistant or in improperly functioning child-resistant contain Several studies have identified poor functioning of the closures when ther sticky liquid or pill residue around the top or in the screw threads of the resistant container.[77 , 84 , 182]

Although child-resistant containers are a significant deterrent to unintent ingestions in toddlers, they are not completely effective, and even withou problems noted, some children can open them. A sense of security assoc with these closures may lead some parents to be less compulsive regardi storage of the containers. It has been recommended that a double barrier instituted, such as a unit-dose dispenser within a child-resistant container blister pack, for a few pharmaceuticals associated with a large number of significant poisonings (eg, iron and antidepressant agents).[84]

In fact, in 1997 the Food and Drug Administration (FDA) issued a regulati package products with 30 mg or more of elemental iron per tablet in unit packages such as blister packs.[1] The intent of this regulation was to redu likelihood of childhood iron poisoning. Over the past decade the number o childhood iron ingestions has declined significantly, although whether any decrease is specifically related to the packaging changes is unknown. This was overturned in 2003, when it was determined that the FDA did not hav

statutory authority to regulate a drug for the purpose of poison preventic will be unfortunate if there is an increase in the number of iron poisonings result of these statutory changes.

A discussion of containers and storage naturally leads to a consideration third factor in the injury-causation model discussed above, the environm which is particularly important in the preinjury and the injury phases. Approximately 80% of childhood pharmaceutical ingestions occur at home remainder occur at the homes of grandparents, other relatives, and friend medicine usually belongs either to the child or to the mother, although a significant number of medications, both at home and away from home, b to a grandparent.[77 , 99] Grandparents, other relatives, and family friends without children at home may not receive or keep medications in child-re containers and may not be attentive to safe-storage practices.

Medications are frequently kept in the kitchen or bedroom while they are used.[77 , 182] In the kitchen, medications are stored in the refrigerator, or table, or on the counter, and in the bedroom, medications are left on a c or bedside table. A mother's purse is another location where medications commonly found. Interestingly, there are no significant differences in the storage practices in the homes of children who ingest and those who do n ingest medicines, so storage practices alone cannot be used to predict th likelihood of childhood poisoning.[159 , 182]

One important caveat relates to the storage of nonpharmaceutical xenob particularly those in liquid form, such as pesticides, hydrocarbons, and s hydroxide. These types of xenobiotics should never be transferred for sto to familiar household containers, such as food jars or wine or soda bottle children and adults have been exposed to xenobiotics, such as sodium hydroxide and potassium cyanide, stored in bottles in the refrigerator.[169]

History of the Ingestion

The appropriate management of any poisoned patient is influenced by the history of the exposure. Parents or guardians who are not abusing childre generally provide information to the fullest extent possible. As a rule, in

case of children, the xenobiotic and time of ingestion are known. The nun pills, or the volume of liquid ingested, may not be as accurate. Clues to t amount ingested are the number of pills or volume of liquid in a bottle be and after an ingestion, the number of pills set out on the night table, or t area of a spot of liquid after a spill. When symptoms are suggestive of poisoning, but the history is inadequate, information about possible expo outside of the home, such as with a babysitter, grandparent, friend, or o relative, should be obtained because approximately 15% of childhood poisonings occur outside the home.[77 , 125]

In contrast, suicidal adolescents may be unreliable when relating the hist an ingestion. When caring for these patients, the clinician must use the h provided but should remain skeptical about the reported type and number xenobiotics ingested, as well as the time of ingestion.

In cases in which a child may be the victim of abuse, or intentionally pois by a caretaker, the healthcare provider must ensure that (a) the history o poisoning remains consistent over time and among those people providing details of the event, (b) the child's clinical presentation is consistent with history of the poisoning, and (c) the reported actions are consistent with child's developmental level.

Gastrointestinal Decontamination

Chapter 8 is devoted to a complete discussion of gastrointestinal decontamination. This section reiterates and emphasizes only a few impo points.

As described above, children generally ingest small quantities of single a For most of these ingestions, gastric emptying is unnecessary. Some exa of nontoxic ingestions are eating a crayon or the leaf of a jade plant, lick cap of a household bleach container, or swallowing 2 adult-strength acetaminophen tablets.

Orogastric lavage is the preferred method of gastric emptying when indic for most serious ingestions. Small children can generally tolerate orogast lavage with a large-bore 28-French or 34-French tube; however, the sma

â€œlarge-boreâ€• tubes may not be effective for removing large pills or fragments from the stomach of a small child. Placement of an orogastric t an unpleasant and frightening procedure for an infant or small child. Ther often some local trauma related to tube placement and, rarely, there can more serious injury, such as esophageal perforation. Also, many children during placement of an orogastric tube. The use of orogastric lavage shou limited to cases in which the risk of serious poisoning is high, in which th likelihood of benefit is at least moderate, and in which the likely risk of i to the child is small. This procedure should never be used as a form of punishment. To use orogastric lavage safely in a child with a diminished g reflex or depressed level of consciousness, the trachea should be intubate protect the airway.

At one time, administration of syrup of ipecac to poisoned patients was considered a primary emergency intervention. However, the AAPCC repor the use of syrup of ipecac for case management

declined from 13% in 1983 to 0.4% in 2003. This is not surprising, becau syrup of ipecac is contraindicated in cases where there is, or is likely to b hemodynamic instability, seizures, or a depressed level of consciousness, likely effects of almost any serious poisoning. In addition, although syrup ipecac is highly effective at making children vomit, the efficacy of prever morbidity after an ingestion is questionable.

Even though syrup of ipecac was used infrequently in the emergency department management of poisonings, it was, until recently, being advo for use at home at the direction of a poison center in order to prevent an unnecessary evaluation in an emergency department. However, in 2003, American Academy of Pediatrics came out against the availability and use ipecac at home, and in 2004, the American Academy of Clinical Toxicology the European Association of Poison Control Centres and Clinical Toxicolog came out against the general use of syrup of ipecac for the management poisoning.[4 , 6] The reasons for the new recommendations include (a) the unpleasantness of the therapy, (b) its rare side effects, (c) its unproven usefulness, (d) its administration when not indicated or when no therapy indicated because of lack of consultation with a poison center, (e) its abu

potential, and (f) its interference with and complication of subsequent emergency department evaluation.

Notwithstanding the position statements, some toxicologists believe there rationale for home use under specific limited circumstances.[136] Thus, ther still be a very limited role for the use of syrup of ipecac in the manageme particular cases (see Chap. 8 and Antidotes in Depth: Syrup of Ipecac).

Activated charcoal is a current mainstay of poison treatment.[3, 33] Childr generally will not drink activated charcoal willingly. Some children can be coaxed to do so if the activated charcoal is disguised in a baby bottle or drink container or sweetened with juice or sorbitol.[179] A nasogastric or orogastric tube may have to be inserted to administer activated charcoal. can be a small-bore tube because it is not intended for lavage, although smaller the bore, the more difficult it is to administer the thick slurry of activated charcoal. Placement of the tube, the presence of activated char the stomach, the effects of the xenobiotic, or the previous use of an eme may make the child vomit, making aspiration of activated charcoal or sto contents a risk. For activated charcoal to be used safely in a patient who comatose and who does not have a gag reflex, the trachea should be intu and the airway protected. Even activated charcoal alone is unnecessary fo nontoxic ingestion.

Activated charcoal is available for home use.[93, 163] Administration of ac charcoal at home or by prehospital personnel allows for administration significantly earlier than can be achieved after arrival and evaluation in t emergency department.[36, 163] Although it would seem to have potential as home therapy, activated charcoal is unpalatable, quite messy, and not always available, with the result that it has not achieved widespread use home.[120, 136] It is also unclear how well parents can administer activate charcoal at home.[146, 147, 162] Whether the earlier administration of act charcoal would affect outcome is unknown. If activated charcoal is to rep syrup of ipecac for home therapy, it will require a substantial reeducation on the part of pediatricians, toxicologists, and pharmacists.

Methods of Enhanced Elimination

For consequential poisoning with xenobiotics such as methanol, ethylene salicylates, lithium, and theophylline, either hemodialysis or charcoal hemoperfusion is the optimal technique to enhance elimination, depending the particular toxin. These techniques can be performed on newborns or infants in specially equipped centers with dedicated personnel. The prima limiting factor is the ability to obtain vascular access.[16 , 44 , 46 , 170] How even large centers that routinely do pediatric hemodialysis may not be ab manage the very small infant. There is a report of the use of peritoneal for the treatment of alcohol intoxication in a child,[65] but this technique is generally recommended.

Exchange transfusion is a technique that is occasionally used to enhance elimination. This technique might be useful when multiple-dose activated charcoal cannot be administered, the xenobiotic is poorly adsorbed to ch or access to specialized pediatric hemodialysis or hemoperfusion is not re available. Exchange transfusion has been used successfully for poisoning salicylates[45 , 107] and theophylline.[12 , 122 , 152] Another drug for which exchange transfusion may be a therapeutic alternative is chloral hydrate.

Xenobiotics that May be Toxic or Fatal in S Quantities

When children ingest small quantities of toxic xenobiotics, they potentiall ingest large doses relative to their small size. There are a number of xenobiotics that can cause significant toxicity or even death with as little pill or 1 teaspoonful.[10 , 97] Table 31-4 lists these xenobiotics.

Xenobiotics that May have Delayed Toxicity Children

There are several xenobiotics that warrant particular concern because th effects may be significantly delayed. Classic examples are atropine-diphenoxylate (Lomotil)[21 , 38 , 109] and antidiabetics such as glipizide.[63 , 166] Both of these xenobiotics can cause serious morbidity with initial sym

or recurrence of symptoms, delayed by as much as 24 hours after ingest

Children who have or may have ingested Lomotil or oral antidiabetic ager should be admitted for observation and monitoring, even if they are asymptomatic, because effects may not become apparent for 24 hours (C 38 and 48).

Antidiabetics (sulfonylurea agents)
Antihistamines
Benzocaine
Î²-Adrenergic antagonists (sustained release)
Calcium channel blockers (sustained release)
Camphor
Clonidine
Diphenoxylate/atropine (Lomotil)
Methanol/ethylene glycol
Methylsalicylate
Opioids (methadone, codeine, OxyContin)
Phenothiazines
Quinine/chloroquine
Theophylline

TABLE 31-4. Xenobiotics that Can Cause Severe Toxicity to an Ir After a Small Dose

With the advent of new modified-release formulations of calcium channel blockers and Î²-adrenergic receptor antagonists, concern for delayed tox has been extended to other drugs.

Xenobiotics that have Unusual or Idiosync Reactions in Children

Benzyl Alcohol: Gasping Syndrome

Benzyl alcohol is a preservative added to liquid pharmaceutical preparati for small-volume medications administered to adults, the benzyl alcohol is quite safe (Chap. 53). At toxic doses, benzyl alcohol can cause respira failure, vasodilation, hypotension, convulsions, and paralysis. Intravenous solutions containing benzyl alcohol were implicated as the cause of the â€œgasping syndromeâ€• in sick newbornsâ€”severe metabolic acidosis, encephalopathy, respiratory depression, and gasping.[5] The association wa made when infants with this syndrome were found to have elevated levels benzoic acid and hippuric acid, metabolites of benzyl alcohol.[26 , 58] Benzy alcohol is metabolized by the conjugation of benzoic acid with glycine to hippuric acid. This pathway may not be functional in premature infants. E alcohol administration has also been associated with kernicterus and intraventricular hemorrhage in premature infants.[72 , 78] Although benzyl has been removed from many of the medications used for neonates, there still preparations that may contain this agent.[177]

Imidazolines/Clonidine: CNS Effects

Imidazolines such as tetrahydrozoline, oxymetazoline, xylometazoline, ar naphazoline are nonprescription sympathomimetic agents used as nasal decongestants and conjunctival vasoconstrictors (Chap. 50). Clonidine is imidazoline derivative used as an antihypertensive agent (Chap. 60). In children, these agents can cause central nervous system depression, res depression, bradycardia, miosis, and hypotension.[9 , 106 , 180] The presum mechanism of action is through stimulation of central $\hat{I}\pm_2$ -adrenergic and imidazole receptors. Although naloxone has been reported to reverse som the CNS effects of clonidine, there are no reports of its successful use wit other imidazoline agents (Chap. 60).

Ethanol: Hypoglycemia

Ethanol is the primary component of alcoholic beverages, as well as a ma constituent of many liquid preparations, such as mouthwash, vanilla flav and perfume. Besides its well-known sedative-hypnotic effects, ethanol intoxication in children is associated with hypoglycemia.[37 , 96 , 104 , 174]

Ethanol-induced hypoglycemia can cause seizures and may exacerbate th CNS effects induced by ethanol intoxication. Hypoglycemia results from t inhibition of gluconeogenesis in the setting of alcohol intoxication. There not seem to be a blood alcohol concentration threshold for the developme hypoglycemia, which has been reported with blood alcohol concentrations as 20 mg/dL (Chaps. 48 and 75).[37]

Chloramphenicol: Gray Baby Syndrome

Chloramphenicol is a broad-spectrum antibiotic that has been used in pe because of its activity against *Haemophilus influenzae.* It has largely bee replaced by other antibiotics in the United States because of its associati aplastic anemia. When administered at high doses, chloramphenicol can the â€œgray baby syndromeâ€• â€”abdominal distension, vomiting, meta acidosis, progressive pallid cyanosis, irregular respirations, hypothermia, hypotension, and vasomotor collapse. Although these effects occur primar premature newborn infants, they can also occur in older children and adu (Chap. 54).

Gray baby syndrome is associated with serum concentrations greater thar mg/L. Increased chloramphenicol levels may result from (a) inadequate conjugation of chloramphenicol with glucuronic acid because of inadequat activity of glucuronyl transferase in the newborn liver and (b) decreased elimination of unconjugated chloramphenicol. The exact mechanism of to is unknown; there is speculation that free radicals produced during the metabolism of chloramphenicol may interfere with mitochondrial function

Medication Errors

Ever since the publication of the Institute of Medicine's report in 1999, increasing attention has been paid to the issue of medical errors in medi Although most of the research regarding medication errors has focused o adults (Chap. 134), this problem also affects children. Subsequent remar this section are generally limited to the pediatric literature.

In the 2003 AAPCC report, there were approximately 115,000 poison cen

calls related to therapeutic errors in children and adolescents, or approx 7% of all calls; 1139, or approximately 2% of these errors, are described â€œiatrogenic.â€• During the last 5 years of AAPCC reports, there were of 34 deaths attributed to therapeutic errors, representing 7% of all deatl children and adolescents. Although only 5% of the reported calls about y children were related to therapeutic errors, approximately 19% of the re deaths were related to therapeutic errors. This is in contrast to adolescer whom 9% of the calls but only 2% of the reported deaths were related to therapeutic errors.

Medication errors can occur at any phase of a process that includes orde order transcription, pharmacy dispensing, preparation and administration medication, and monitoring of medication effects. In fact, the same type errors can usually occur at different points in the process. Table 31-5 list types of errors that can occur, and Table 31-6 provides some examples o errors.

Most of the analyses of medication errors have occurred in inpatient sett The reported frequencies of medication errors vary widelyâ€”from 0.47 to of written orders and from 0.51 to 157/1000 patient-days.[51, 73, 80, 82] The variance largely depends on whether the definition of â€œerrorâ€• d does not include prescribing errors, regardless of whether or not they are corrected, and whether potential, or only actual, adverse drug events are included. The reported frequencies also vary depending on whether there active case finding or whether there is only voluntary reporting.

In a 2001 study of pediatric inpatients where orders were actively monitc a 6-week period, 5.7% of 10,778 prescriptions had errors in the order for medication, transcription of the order, dispensing or administration of the medication, or monitoring of medication effects (56/100 admissions, 157 patient-days);[82] 1.1% had the *potential* to cause an adverse effect (10/1 admissions, 29/1000 patient-days). Eighty-four percent of the errors occ during the ordering or transcription phase, so most

of the errors were intercepted and corrected before drug administration. were 26 true adverse drug events; only 5 were considered preventable e

(0.05%, 0.52/100 admissions, 1.8/1000 patient-days). Although the ove error rate was similar to that reported by the same group in a study of a the rate of errors with the *potential* to cause harm was three times great 41% of the errors with the potential to cause harm were not intercepted.

Based on Kaushal R, Bates DW, Landrigan C, et al: Medication errors and adverse drug events in pediatric inpatients. JAMA 2001;285:2114â€“212(Lesar TS: Errors in the use of medication dosage equations. Arch Pediatr Adolesc Med 1998;152:340â€“344; and Wilson DG, McArtney RG, Newcor RG, et al: Medication errors in paediatric practice: Insights from a contin quality improvement approach. Eur J Pediatr 1998;157:769â€“774.

TABLE 31-5. Medication Errors

Generally, error rates are higher in intensive care units where the sickest patients are cared for; these patients often receive multiple medications complex administration regimens.[51, 73, 82, 129, 144, 172, 181] Results to those from inpatient settings have been reported from pediatric emerg departments.[90, 150]

The studies cited above suggest that the *frequency* of significant errors t lead to significant adverse drug events is low; however, even a low frequ applied to a large population of patients can result in a large number of patients. The most important outcome of the analysis would be to try to the number of errors in order to reduce the number of adverse drug ever

1. Wrong drug. In one nursery, an epidemic mimicking neonatal sepsis caused when racemic epinephrine was inadvertently administered inst

vitamin E because both drugs were manufactured by the same compa distributed in nearly identical bottles, and stored near each other insi nursery refrigerator.[161]

2. Wrong drug formulation. Acetaminophen suppositories (120 mg) w ordered for a toddler, but adult-strength suppositories (650 mg) were distributed and administered every 4 hours. The child developed hepatotoxicity requiring hospitalization and therapy (Chap. 34).
3. Wrong dose. A 1-kg premature infant required sedation for a diagnc study. A high dose of chloral hydrate, 100 mg/kg, was miscalculated t g (1000 mg) instead of 100 mg. The child had a cardiopulmonary arre died. When drugs require milligram-per-kilogram dosing, it is easy to decimal mistakes in the calculation or in the transcription.
4. Wrong dose/wrong route. A recommendation was made to treat a with penicillin G benzathine, 50,000 U/kg IM. The recommendation w transcribed as â€œpenicillin G 50,000 units/kg.â€• The order was handwritten as â€œBenzathine Pen G 150,000 U IMâ€• but was misr misinterpreted as 1,500,000 U IV. The patient had a cardiopulmonary and died.[158]
5. Wrong dose. A patient had the dose of cyclosporine changed from 1(to 7 mg twice daily. The child received 70 mg (0.7 mL of solution) in of 7 mg (0.07 mL). When the prescription was refilled, the parents re a 5-mL syringe to use instead of a 1-mL syringe they had used previ

TABLE 31-6. Examples of Medication Errors

The causes of medication errors are numerous, varied, and complex; they organizational, environmental, and personal, and include such factors as of training, knowledge level, competence, time of day, workload, staff interactions, communications, number of distractions or interruptions, lev ambient noise, perceived levels of authority, drug formulation, drug pack etc. (Chap. 134).[39 , 53 , 60 , 86 , 175]

There are several reasons why children may be at increased risk of being exposed to a medication error: (a) Someone other than the child adminis

the medication, so at least with respect to oral formulations, there is littl opportunity to prevent or limit drug administration; (b) a young child car warn practitioners about possible problems such as allergies; (3) a young cannot inform practitioners when he or she is experiencing side effects; (pediatric medication ordering and administration frequently requires dose calculations; (5) inexperienced practitioners may be uncomfortable with pediatric dosing or related calculations; (6) incorrect measurement of liq preparations or dilution of concentrated stock solutions may still result in small volume that is not perceived as obviously incorrect.[31, 42, 60]

The most common error attributed to physicians is prescription of an inc dose, particularly in children, where almost every prescription requires a determination of weight and calculation of the dose.[82, 91, 95] In addition the mg/kg dose may vary depending on the age of the patient or the clin indication. Although pediatric doses are generally determined on a mg/kg if the weight is recorded in pounds and this weight is used in the calculat there will be a built-in 2-fold error. Calculation errors also occur when dr preparation requires dilution of a concentrated stock solution or special compounding. Further confusion can arise when *mg* is written or interpret *mL* or *mcg* in a calculation.

When an extra zero is added or a required zero is omitted from calculatic written or verbal prescriptions, or in dispensed and administered medicat 10-fold error occurs. These large errors are common and result in signific under- or overdosing; 10-fold

errors have been reported in testing scenarios, case series, and case rep [42, 62, 87, 88, 91, 117, 129, 133, 141, 144, 156, 158] These errors are particular concern because the risk of toxicity generally increases with significant overdose.

Because the causes of medication error are numerous and complex, the to the problem must be multifaceted and interdisciplinary. The approach t problem is contained within the field of human factors research and pote requires changes in individual factors such as knowledge, environmental such as interruptions, and system problems such as how medications are

ordered, stocked, and dispensed (Chap. 134).[86 , 165 , 175]

The most commonly recommended solutions to reduce the frequency of medication errors are computerized physician order entry (CPOE) with cl decision support systems, ward-based clinical pharmacists, and improved communication among physicians, nurses, and pharmacists.[81 , 94 , 135 , its simplest form, CPOE eliminates errors related to legibility. Decision su adds the ability to check the prescription against age, weight, dose, aller drugâ€“drug interactions, etc. It cannot prevent ordering the wrong drug, there is still a need for education and human oversight. In the study cite above, it was estimated that these 3 solutions would have prevented mor 90% of the potential errors,[52] and two clinical trials suggest that CPOE decreases medication prescribing errors.[85 , 126]

It will still be some years before all inpatient medication orders and outp prescriptions are transmitted electronically. Until that time, it will be nec to ensure that prescriptions are written legibly and correctly. The Joint Commission for the Accreditation of Hospital Organizations (JCAHO) and other groups have made a number of recommendations to reduce errors i medication ordering (Table 134-2).

Standardized tests of the math skills necessary to calculate doses and administer medications have demonstrated deficiencies in both nursing ar physician groups.[14 , 19 , 119 , 123 , 127 , 140 , 145] These kinds of tests may way to identify practitioners at risk for making calculation errors, highligl areas in need of remediation, and serve as an ongoing educational tool.

As described above, there may be an increased risk of medication errors critical care areas because of severity of illness and intensity of medicati therapy. In many cases, such as during resuscitations, critically ill patien require immediate therapy, verbal orders are common, and there is often insufficient time to carefully review all of the particulars related to medic ordering and administration.[91 , 124]

Critical care areas, including the emergency department, might benefit fr having precalculated dosing charts available for resuscitation medications for other commonly prescribed medications; this is a recommendation of

American Heart Association.[7] Many units have developed their own dosing schemes. Commercial products such as the Broselow-Luten system are al available and have been shown to reduce the number of medication errors least in simulated resuscitation scenarios.[101 , 102 and 103 , 151]

The previous discussion has been almost exclusively related to hospital-b medication use, although significant errors also can happen in the outpat setting.

Antipyretic medications are among the most frequently recommended medications for children. Although significant toxicity following unintentio toddler ingestions is rare, administration of multiple supratherapeutic dos acetaminophen is not uncommon and can cause significant hepatotoxicity

In fact, many parents have significant difficulty both calculating the appr dose of acetaminophen and measuring out the appropriate amount once calculated, despite having received appropriate instructions and graduate or oral-dosing syringes.[64 , 105 , 111 , 155] The most commonly used meas device is also the most inaccurate; the household teaspoon is not standa for volume and can easily be confused with a household tablespoon.[105] Although graduated syringes are considered the most accurate of the me instruments available and are recommended by the American Academy of Pediatrics for young children, acetaminophen and ibuprofen elixirs are ty packaged with a graduated cup for administration. Color-coded or prema syringes may be one way to ensure accuracy of parental medication dosi

Intentional Poisoning and Child Abuse

Intentional poisoning of children is an unusual, though significant, form o abuse. There are several types of intentional poisoning, some of which d pathologic characteristics of the caretaker: (1) undifferentiated child abu neglect, or impulsive acts under stress; (2) factitious illness (MÃ¼nchaus syndrome by proxy); (3) overt parental psychosis; (4) altruistic motivatio bizarre childrearing practices; and (5) the Medea complex, or the vengefu killing of a child out of spite for one's spouse.[15 , 167]

Intentional poisoning is rarely suspected unless the patient dies and an a

is performed, a wide-ranging drug screen is ordered, or the history is biz enough to raise suspicions. In many cases where children were later foun be poisoned, the initial diagnoses were sepsis, meningitis, seizures, intra hemorrhage, gastroenteritis, apnea, apparent life-threatening events, or metabolic derangements.[15] In addition to many pharmaceutical agents, s pepper, water, caffeine, ethylene glycol, herbs, plants, and traditional re have been used to poison children.[15 , 43] Although the death rate from unintentional poisoning in childhood is much less than 1%, the death rate inflicted poisoning may be as high as 20â€“30%.[15 , 43 , 167]

Intentional poisoning may be associated with other abuse; approximately of poisoned children may have evidence of physical abuse.[15 , 43] Of child presenting to the emergency department after presumed unintentional poisoning, 36% had previous emergency department visits for trauma, 7% poisoning, 6% for both trauma and poisoning, and 1.4% for failure to thr the time of the visit, only 7% were evaluated for possible abuse, and 2.7 were considered neglected.[15] These data do not prove an association bet poisoning and physical trauma; however, in some children, repeat episode trauma and/or poisoning may be a manifestation of significant intrafamili stress. Healthcare providers must remain vigilant to the possibility that a presumed unintentional poisoning may have been inflicted, especially in t setting of a repeat ingestion or when there have been previous evaluation trauma.

Substance abuse by a parent or guardian may play a role in unintentional intentional poisoning of children. Children have been intoxicated with coca phencyclidine by passive inhalation,[13 , 70 , 115 , 148 , 178] unintentional ingestion,[83 , 134] and rectal adminstration,[130] as well as through breast m Children have been given doses of alcohol, methadone, and other xenobio order to quiet them or to prevent withdrawal.[40 , 71 , 132] There are report babysitters blowing marijuana smoke into babies' faces to â€œget them highâ€• or to quiet them.[149]

Factitious illness (Munchausen syndrome by proxy [MSBP]) is a condition which a parent, usually the mother, fabricates a history

of a nonexistent disease in a child or creates the signs and symptoms of in a child.[112, 113, 143] This is usually a manifestation of the parent's co psychiatric illness, which may include Munchausen syndrome itself.[22, 61] may be only a fine line separating MSBP from an intentional poisoning wi intent to harm or kill a child. Regardless of the specific intent, this condit considered a form of child abuse.

A child's fabricated illness can lead to multiple medical evaluations by m physicians, frequent hospitalizations, unnecessary surgery and diagnostic testing, unnecessary prescribing and administration of medication, and, occasionally, the death of the child. Administration of exogenous drugs is frequently the mechanism of creating a particular set of signs and sympt Agents that have been used to create factitious illness include analgesics antidepressants, insulin, syrup of ipecac, Lomotil, phenothiazines, sedati hypnotics, warfarin, phenolphthalein, and hydrocarbons.[142] Several warn signals may suggest a diagnosis of MSBP (Table 31-7).

In one illustrative case of MSBP, a 29-month-old boy with a previous hist appendectomy was hospitalized multiple times for vomiting, diarrhea, an dehydration.[59] Evaluation included multiple laboratory evaluations of bloo stool, a gastric pH probe, CT, MRI, endoscopy, and upper GI series. On t fourth admission, a small bowel obstruction was identified, and the child lysis of adhesions. Nonetheless, symptoms recurred every 2â€“4 months, necessitating hospitalization. The child failed to thrive and required a nasoduodenal tube for feeding, which frequently became dislodged. The went on to have a jejunostomy tube and a permanent central venous cat placed. Eighteen months after his initial presentation, the child presented congestive heart failure with evidence of cardiomyopathy. A urine screen identified emetine and cephaline, components of syrup of ipecac. The chi recovered, was removed from his home to protective custody, and remai asymptomatic while receiving a regular diet.

Siblings of children being poisoned may also suffer or have suffered from factitious illness. In addition, significant psychiatric illness is manifested victim, the parents, and the siblings.[23, 110]

1. A persistent or recurrent illness that cannot be explained.
2. The history of disease or results of diagnostic tests are inconsistent w general health and appearance of the child.
3. The signs and symptoms cause the clinician to remark, â€œI've never anything like this before!â€•
4. The signs and symptoms do not occur when the child is separated fro parent.
5. The parent is particularly attentive and refuses to leave the child's b even for a few minutes.
6. The parent develops particularly close relations with hospital staff.
7. The parent seems less worried than the physician about the child's condition.
8. Treatments are not toleratedâ€”intravenous lines fall out frequently, prescribed medications lead to vomiting.
9. The proposed diagnosis is a rare disease.
10. â€œSeizuresâ€• are unwitnessed by medical staff and reportedly do respond to any treatment.
11. The parent has a complicated medical or psychiatric history.
12. The parent is or was associated with the healthcare field.

Adapted with permission from Meadow R: Munchausen syndrome by proxy Dis Child 1982;57:92â€“98.

TABLE 31-7. Factitious Illness (Munchausen Syndrome by Prox Suggestive Characteristics in Clinical Situations

Child abuse or neglect is part of the differential diagnosis in any case of childhood poisoning. Intentional poisoning should be considered for (a) an â€œingestionâ€• in a child younger than 1 year of age; (b) a case with a confusing history or presentation; (c) a child with a previous poisoning or whose siblings have been previously evaluated for poisoning; (d) a child w previous presentation for a rare or unexplained medical condition; (e) a with apnea, unexplained seizures, or an apparent life-threatening event; massive ingestion by a small child; (g) an ingestion of multiple xenobiotics small child; (h) an exposure to substances of abuse; (i) an intoxication w

xenobiotic to which a child could or would not have access; (j) â€œaccid ingestionsâ€• in the school-age child; (k) a history of previous trauma, abuse, or neglect; or (l) sudden infant death syndrome or an unexplained death.[15 , 71]

These considerations of child abuse notwithstanding, rare diseases do oc One child's rare, inherited metabolic disorder, methyl malonic acidemia, misdiagnosed as ethylene glycol poisoning because the chromatographic appearance of the metabolite propionic acid was similar to that of ethyler glycol.[153]

Summary

Children are frequently exposed to potentially toxic xenobiotics; fortunat most childhood exposures are ingestions of nonpoisonous xenobiotics or nontoxic quantities of potentially toxic xenobiotics. When a child sustains significant toxic exposure, management follows general toxicologic princi Although most childhood exposures are unintentional, the clinician should alert to the possibility of the intentional poisoning of a child with pharmaceutical or household agents.

The normal development of children puts them at risk for unintentional ingestions. A chaotic home environment or a disorganized social structure compound these risks. Small size puts a child at increased risk for medic dosing and dispensing errors, and their immature metabolic processes ma to unexpected toxicity from pharmaceutical agents.

Toxicologists should encourage parents to provide as safe a home enviro as possible to prevent unintentional ingestions, and must encourage practitioners to exercise special vigilance when administering medications children.

Chapter 32
Geriatric Principles

Judith C. Ahronheim

Mary Ann Howland

The population in developed countries is aging steadily. In the United States, those older than 65 years of age comprise not only an increasing proportion of the population at large (12%), but an increasing proportion of patients seen in medical practices. Patients older than 65 years of age account for 43% of emergency department visits and 48% of all critical care admissions from emergency departments.[64]

Although the elderly account for only a small minority of toxicologic exposures, once exposed, they have the highest mortality rate. Among exposures reported to poison control centers in 2003, the fatality ratio (number of cases divided by number of deaths) increased with age and is highest among people 80 years of age and older.[79] The American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) data may underestimate the serious consequences for elderly people exposed to toxic substances. First, there is a lack of

recognition of drug toxicity in the elderly.[3] Because of pharmacokinetic and pharmacodynamic changes that occur as one ages, a â€œstandardâ€• medication dose thought to be therapeutic may produce an unexpected serious effect. The presentation of toxicity may be atypical. Falls, a common presentation in the elderly, may be a presenting sign of drug toxicity; if the patient is cognitively impaired and the fall is unwitnessed, the immediate consequences of the fall may be adequately addressed, but the xenobiotic causing it may not,[39,56,58] because drug overdoses can result in focal neurologic deficits that may be attributed solely to structural cerebrovascular or cardiovascular disease, without identifying the toxicologic etiology.[69] Table 32-1 lists the drugs most commonly responsible for toxicity in the elderly.

The presentation of drug toxicity may be delayed in the elderly. Drugs with long half-lives may not reach a steady state and, hence, not achieve peak action until many days after the drug therapy is initiated. In some older patients, the active metabolite of flurazepam, desalkylflurazepam, has a half-life of up to 100 hours or longer, which requires days to achieve a steady state. When peak effects are delayed in this way, drug toxicity can easily be mistaken for nondrug-related illness.

Suicide and Intentional Poisonings

The risk of suicide by all methods increases steadily with age, particularly among white men.[49,54] Although data for individual ethnic groups are sparse, white men have a substantially higher risk of suicide than their same-age cohorts among the African American population.[49,53,54] Although suicide is more common among men than among women, women are more likely to attempt suicide. The male-to-female ratio of suicide attempts narrows with increasing age, so that in the oldest age groups, men attempt suicide slightly more often than women, when all methods of

attempted suicide are considered (Chap. 18).[24]

In the United States, firearms are the most frequent means of death by suicide. Among men older than age 65 years, firearms account for 73% of completed suicides, whereas drug overdose accounts for only 3%; among women, drug overdose is nearly as frequent a cause of death as firearms, each accounting for approximately 25% of successful suicides. When death by inhalation is included, poison exposure surpasses gunshot wounds as a cause of death among elderly women.[49] Drug overdose is an important factor in suicide attempts by the elderly of both sexes.[24] In other countries, firearms are only rarely used to commit suicide at any age, with methods such as drug overdose and inhalation consequently comprising a much greater proportion than in the United States.[71]

Among the elderly, the pattern of medications responsible for suicidal deaths may be changing, as safer serotonin reuptake inhibitors (SSRIs) are increasingly prescribed for depression instead of tricyclic antidepressants (TCAs), which are more likely to be lethal in overdose.[11] In Sweden, the relative fatality ratio for benzodiazepines was reported to be correspondingly increasing. Overdose of benzodiazepines is rarely fatal unless it is accompanied by alcohol or another toxic ingestion or occurs in the presence of serious medical problems. However, when all deaths from benzodiazepines are examined, they probably occur more often in older adults.[19]

Unintentional Poisoning and Adverse Drug Events

An adverse drug event (ADE) is defined as â€œan injury resulting from medical intervention related to a drug.â€•[5] This definition encompasses events that result from both inappropriate use of medications, such as a prescribing error, and from appropriate

use. It may be challenging for the clinician to distinguish poisoning from ADEs in the elderly. Compared to younger adults, the elderly are at increased risk of unintentional poisoning as well as other drug events. Life-threatening reactions may occur with therapeutic doses; examples include the serotonin syndrome and the neuroleptic

malignant syndrome. Typically, the serotonin syndrome occurs when two or more drugs that increase serotonin activity are used concurrently,[48] a more likely occurrence among the elderly for whom multiple medications are commonly prescribed.[8]

TABLE 32-1. Drugs Most Commonly Responsible for Toxicity in the Elderly[a]

Anticholinergics
Anticoagulants
Antidepressants
Antipsychotics
Cardiovascular medications
Î²-Adrenergic antagonists
Calcium channel blockers
Digoxin
Magnesium-containing antacids
Magnesium- and phosphate-containing laxatives
Nonsteroidal antiinflammatory drugs
Opioids
Salicylates
Sedative-hypnotics

[a] Polypharmacy increases toxicity as a result of diverse drugâ€“drug interactions.

The serotonin syndrome and neuroleptic malignant syndrome are relatively unpredictable and can occur at any age. However, other severe ADEs are more likely to occur among the elderly and are potentially avoidable if patients are carefully monitored. Examples include severe bleeding as a result of nonsteroidal antiinflammatory agents, metformin-induced lactic acidosis,[35] and prolonged hypoglycemia from sulfonylureas.[51,67,68]

Although reported poisoning exposures among the elderly are much less frequent than among other age groups, the incidence of ADEs increases steadily with age.[8,44] Moreover, when they occur, they are more likely to be serious. Serious ADEs, defined as those resulting in death, hospitalization, prolongation of hospitalization, or permanent or serious disability, are most prevalent among people 85 years of age and older.[8]

Substance Abuse in the Elderly

Substance abuse declines with age, but is important to consider in relevant clinical circumstances. Alcohol is the most common substance of abuse in people older than age 65 years. Abuse of alcohol, or other xenobiotics, may be a continuation of long-term habits, but some older adults in their 60s and 70s may first begin to use and abuse drugs late in life.[36]

Substance abuse in late life is probably underrecognized. In one Illinois study of patients presenting to a trauma facility, only 5% of those age 65 years and older were tested for alcohol or other substances, whereas among those younger than age 65 years, 22% were tested for alcohol and 29% for other substances.[82] However, almost half of the elderly patients tested for alcohol were positive and 72% of those had a blood alcohol level of 80 mg/dL (the legal limit in the study state of Illinois) or above, results that were comparable to those of younger patients who were studied, 75% of whom tested positive. For any given amount

of alcohol ingested, the blood alcohol concentration of a person age 65 years or older is higher than that of a younger adult because of pharmacokinetic changes, as discussed below. Moreover, because of an age-associated diminished tolerance to alcohol, the impact on cognitive or motor function tends to be greater.

In the same study, 11% of elderly patients who were tested had positive urine toxicology screening results compared to 43% of tested younger adults. The most common substances detected in the elderly were benzodiazepines, opioids, and barbiturates, which, like alcohol, are more likely to impair older than younger adults. The failure to consider use of these drugs, whether illicit or prescription, may have serious consequences. When admitted to hospitals, if a careful drug history is not elicited, withdrawal from these substances may occur, be misdiagnosed and hence inappropriately managed.

Pharmacokinetics

Age-related pharmacokinetic changes occur in the elderly. The most important and consistent pharmacokinetic change that occurs with aging is a decrease in renal function. Glomerular filtration rate (GFR) declines, on the average, by 50% between the ages of 30 and 80 years.[17,62] The GFR cannot be accurately predicted by serum creatinine because muscle mass, the source of serum creatinine, declines with age; consequently, in late life, serum creatinine may not be elevated even when the GFR is significantly impaired.

Because it is impractical and often difficult to measure 24-hour creatinine clearance before instituting therapy with an essential, renally excreted drug, clinicians commonly estimate creatinine clearance using age-adjusted formulas or nomograms. Frequently applied formulas are fairly predictive of renal function when renal function is stable.[55] However, age-related declines in GFR are not

universal, and data from longitudinal studies suggest that as many as 33% of the el-derly do not experience this age-related decline.[47] Predictive formulas could significantly overestimate actual creatinine clearance in chronically ill, debilitated elderly, especially those with renal insufficiency.[42] Because muscle mass declines even in healthy aging, more research is required to determine if predictive formulas have sufficient accuracy in healthier groups of elderly.[63] For all of these reasons, it is difficult to accurately predict the renal elimination of drugs or drug metabolites in the elderly. A practical solution is to assume that renal function has declined and to exercise caution when prescribing maintenance doses of drugs with a narrow therapeutic-to-toxic ratio (Table 32-2). Failure to do so is an important cause of toxicity.[46]

TABLE 32-2. Drugs with Narrow Therapeutic-to-Toxic Ratios and Potential for Accumulation in the Presence of Diminished Renal Function

Antimicrobials
Aminoglycosides
Imipenem
Pyrazinamide
Vancomycin
Benzodiazepines with active metabolites
Chlordiazepoxide
Clorazepate
Diazepam
Flurazepam
Halazepam
Digoxin
Enoxaparin
Lithium

Meperidine (active metabolite: normeperidine)
Metformin
Procainamide (active metabolite: *N*-acetyl procainamide)
Salicylates

Controversy exists regarding the impact of age-related hepatic changes on drug elimination. Liver mass decreases with an associated decrease in hepatic blood flow,[80] which results in decreased efficiency of drug removal by hepatic extraction. Enzymatic processes are often unpredictable,[38] and there is considerable controversy over the extent to which advanced age alters the ability of drugs to undergo hepatic metabolism, particularly oxidative processes.[66] Hepatic conjugation does not decline significantly with age, so drugs such as temazepam and oxazepam that are metabolized by these processes do not have a prolonged elimination half-life. In contrast, drugs such as diazepam and flurazepam, which are metabolized by hepatic oxidative enzymes, are eliminated more slowly with age,[28] but decreased renal elimination of active metabolites may be the most important factor. Studies that consider cofactors that could affect hepatic enzymes, such as concurrent medications or cigarette smoking, or that determine isozyme genotype, may demonstrate that there is no age-related change in hepatic oxidative enzyme function.[6]

Unlike conjugated metabolites, which tend to be inactive, products of oxidative metabolism are often active. Because these active metabolites are generally excreted by the kidney, the presence of active drug may be markedly prolonged. Other changes in enzyme systems may occur late in life. For example, a decline in gastric alcohol dehydrogenase leads to increased peak effect of ethanol in the elderly.[59] Decline in this enzyme is attributed to the increased incidence of gastric atrophy with age. Whether age-related

changes occur in metabolic enzymes that are present in many organ systems, such as intestine, brain, and kidney, and what impact such changes have on drug disposition, are likely to become active areas of research.

Age-related alterations in body composition can affect drug disposition in later life (Table 32-3). For example, lean muscle mass and total body water decline and the fat-to-lean ratio increases with advancing age.[57] Thus, highly lipid-soluble drugs tend to have an increased volume of distribution (Vd). As a result, there may be a delay before steady state is reached, and peak effect and toxicity may occur later than expected. This mechanism may be an additional reason drugs such as diazepam and flurazepam have prolonged half-lives in otherwise healthy elderly patients. In contrast, drugs that distribute in water, such as ethanol, have a smaller Vd, which may partly account for the more rapid and more pronounced peak effect of ethanol in the elderly.

Protein reserve diminishes with age, as a consequence of decreased muscle mass and decreased protein synthesis.[60] Although serum albumin remains in the normal range in the healthy elderly,[10] patients in this age group are more likely to experience a rapid decrease in albumin levels when there is acute or chronic illness or when protein intake does not keep up with demand.[81] A decline in serum protein increases the free or active fraction of drugs that are otherwise highly protein bound. Free drug is able to travel more readily to the liver and kidney for metabolism or excretion, so a gradual change in the serum protein level is unlikely to lead to a change in the patient's response to the drug. However, these changes may be clinically important for interpreting serum levels of highly bound drugs. Clinical laboratories typically measure total drug levels which include both free and bound drug. Because most drug is bound, the reported value reflects mostly bound drug and therefore, the total drug concentration may be in the therapeutic range, even though the active unbound fraction is actually elevated. Phenytoin, which is

highly bound to albumin, serves as an illustrative example. If the serum level of phenytoin is reported as subtherapeutic, the physician might order a dose increase even though the free fraction of phenytoin actually is in the therapeutic range. With a dose increase, the free or active fraction of the drug may increase to toxic levels.

TABLE 32-3. Special Pharmacokinetic Considerations in the Elderly

	Young	Elderly	Consideration
Fat (% of body weight)	15	30 (â†‘)	â†‘Vd for drugs distributing to fat (amitriptyline, diazepam)
Intracellular water (% of body weight)	42	30 (â†“)	â†“Vd for water-soluble drugs
Muscle (% of body weight)	17	12 (â†“)	â†“Vd for drugs distributing into lean tissue (acetaminophen, caffeine, digoxin, ethanol)
Albumin (g/dL)	4	â†“ With acute or chronic	â†‘ Free levels of drugs if >90% bound to albumin,

		illness	especially in overdose; interpretation of serum concentration altered
Liver	Normal	â†“Size â†“Hepatic blood flow	Liver enzymes not predictive; drugs with high extraction may increase (propranolol, triazolam)
Kidney	Normal	â†“Renal blood flow â†“GFR â†“ Tubular secretion	Accumulation (lithium, aminoglycosides, *N*-acetyl procainamide, ACE inhibitors, cimetidine, digoxin

Modified with permission from Mayersohn M: Special pharmacokinetic considerations in the elderly. In: Evans WE, Schentag JJ, Justo WJ, eds: Applied Pharmacokinetics: Principles of Therapeutic Drug Monitoring, 3rd ed. Vancouver, WA, Applied Therapeutics, 1992, pp. 1â€“43; and Fox FJ, Auestad A: Geriatric emergency clinical pharmacology. Emerg Med Clin North Am 1990;8:221â€“239.

Basic drugs are not bound to albumin but to Î±-acid glycoprotein (AAG), an acute-phase reactant that tends to increase, rather than decrease, with age.[1] However, the increase attributed to age is most likely related to underlying disease. These unpredictable changes would be expected to have the reverse effect on the ratio of bound to unbound drug in any laboratory report.[59] The correlation between clinical effect and free drug levels requires further study because there may be complex factors involved, including alterations in Vd and specific tissue concentrations.

The contribution of gastrointestinal absorption to drug toxicity is unknown. Absorption declines modestly, if at all, with advancing age. However, age-related changes in the gastric mucosa may account for enzymatic changes, as demonstrated in the case of alcohol dehydrogenase, noted above.

Pharmacodynamics

Pharmacodynamic factors may also affect a patient's response to a particular drug. In general, age-related physiologic changes in target or nontarget organs lead to increased sensitivity to a given drug, although sensitivity to some drugs may also be decreased. For

example, there is evidence that Î²-adrenergic receptor sensitivity declines with aging, leading to a diminished response to both Î²-adrenergic agonists and antagonists.[14,76] However, clinical experience demonstrates that the elderly respond normally to drugs of this category in terms of therapeutic response, adverse effects, and toxicity.[23]

TABLE 32-4. Pathophysiologic Disorders Exacerbated by Drugs in the Elderly

Disorder	Drug	Possible Outcome
ADH secretion (increased)	Antipsychotics, SSRIs	Hyponatremia
Androgenic hormones (males, decreased)	Digoxin, spironolactone	Gynecomastia
Baroreceptor dysfunction, venous insufficiency	Antipsychotics, diuretics, tricyclic antidepressants	Orthostatic hypotension
Bladder dysfunction	Diuretics	Incontinence
Cardiac disease	Thiazolidinediones	Congestive heart failure
Dementia	Sedatives, anticholinergics, and many others	Confusion
Gastritis (atrophic)	NSAIDs, salicylates	Gastric hemorrhage
Immobility, cathartic bowel	Anticholinergics, opioids	Constipation

Nodal disease (sinus or AV)	Î²-Adrenergic antagonists, digoxin, diltiazem, verapamil	Bradycardia
Parkinson disease	Antipsychotics, metoclopramide	Parkinsonism
Prostatic hyperplasia	Anticholinergics, tricyclic antidepressants, disopyramide	Urinary retention
Thermoregulation, disordered	Antipsychotics	Hypo- or hyperthermia
Venous insufficiency	Calcium channel blockers, others	Edema

The observation of enhanced sensitivity to drugs is probably related to altered pharmacokinetics in many, if not most, cases.[29] Proving that enhanced sensitivity is related to altered pharmacodynamics would require demonstrating that the concentration of drug at the tissue site was not increased as the result of diminished elimination.[21] Regardless of the mechanism, it is important to recognize that the response to a given drug might be altered in specific ways among the elderly. These altered responses are probably caused less by chronologic aging and more by an increased prevalence of disease in the elderly.[29] Table 32-4 provides examples of pathophysiologic changes that frequently occur in the elderly and are unmasked by medications.

Adverse Drug Events

The likelihood of experiencing an ADE increases with the increasing number of drugs prescribed for a patient.[32] Geriatric patients take more prescription and nonprescription drugs than any patient group.[8,37] A complicated drug regimen reduces adherence, increases medication errors, and increases the risk of clinically important drug interactions. ADEs may occur as a consequence of drugâ€“drug interactions, but the relationship between the two phenomena is sometimes difficult to quantitate.[32]

Concurrent disease in target or nontarget organs also may alter the patient's sensitivity to a drug,[33] resulting in a serious ADE even when the patient is given a standard or previously used dose of the drug. Coexistent disease is often subclinical, and the patient's enhanced sensitivity may not be anticipated. A patient with subclinical Alzheimer disease whose cognitive function is overtly normal may acutely develop delirium or symptoms of dementia when given ordinary doses of drugs such as sedative-hypnotics and tricyclic antidepressants. Delirium is a medical emergency and an important cause of emergency department visits by the elderly.[33]

Another contributing factor is physician lack of knowledge about principles of geriatric therapeutics.[22] In a series of hospitalized patients, failure to consider advanced age was the most common factor associated with clinically important prescribing errors, and inattention to abnormal renal function was the second most important.[35] New drugs deemed safer than older agents may be problematic, and inattention to risk factors can lead to significant morbidity. For example, the hypnotic agent, zolpidem, was marketed as a safe alternative to benzodiazepines for the elderly. However, like benzodiazepines, zolpidem may cause confusion, memory loss, and falls, leading to hip fracture.[77,78] Another example is enoxaparin, which has more predictable pharmacokinetics than unfractionated heparin, and is associated

with a lower rate of bleeding. Therapeutic monitoring via antifactor Xa activity is cumbersome and not recommended except in unusual circumstances,[31] and therefore, enoxaparin may be perceived as more convenient as well as safer. However, enoxaparin is eliminated by the kidney and repeated doses lead to progressive increases in antifactor Xa activity when creatinine clearance is â‰¤30 mL/min,[13] a degree of renal insufficiency that is common in frail elderly patients, despite normal serum creatinine concentration. It is notable that most reported cases of serious, unexpected enoxaparin-induced bleeding occur in elderly patients who are receiving â€œstandard,â€• and not age appropriate, dosing.[50,74,75] In addition to inadequate prescribing methods, physicians often prescribe drugs deemed inappropriate in the elderly at any dose,[16] such as tricyclic antidepressants, long-acting benzodiazepines, and anticholinergic agents.[12]

Compounding the problem of lack of knowledge is the fact that new drugs are often inadequately studied in the elderly (see Chap. 133 for further details).[65,73] Reactions occurring in a small percentage of patients in a special subgroup can easily be missed during the initial investigations. Even when a substantial number of subjects older than age 60 years are studied, much smaller proportions of patients older than age 70 years may be included in clinical trials.[2,45] Thus, the adults at highest risk for many forms of drug toxicity are those least-often studied. Subjects undergoing drug testing are generally young adults and disease free, so pharmacokinetic profiles do not reflect patterns of drug disposition that are characteristic of geriatric patients. Pharmacokinetic testing may be limited to a one-time dose, and frequently the evaluation takes place over a short time. On average, approximately 5 half-lives of a drug are necessary to achieve steady-state drug levels. Thus a drug with a half-life of 24 hours might not reach a steady state for 5 days, and in the presence of prolonged elimination associated with age-related factors, a steady state might not be reached for substantially longer. As a result,

even if the elderly are included in a drug trial, the ultimate effect of that drug might not be noted during testing intervals that are frequently designed for younger patients.

Morbidity and mortality occurring in elderly patients as a result of specific drugs might be avoided if the responsible drugs were studied under the predictably high-risk conditions typically present in the elderly. For example, benoxaprofen, a long-acting nonsteroidal antiinflammatory agent, was responsible for cholestatic jaundice and death in several elderly patients. Following the drug's introduction there was a substantial delay before the jaundice and other serious drug-related toxicities were recognized. Another example is the antibiotic temafloxacin. Temafloxacin was available for only 3 months before it was withdrawn following 3 reported deaths and more than 300 cases of hypoglycemia, many of which occurred in elderly patients with diminished renal function.

If pharmacokinetic studies identify vulnerable subgroups, safe maximum doses could be recommended for specific populations at risk, theoretically limiting the risk for these individuals.[4] As a result of these problems, the Food and Drug Administration (FDA) now requires sponsors of new drug applications to present effectiveness and safety data for important demographic subgroups, including the elderly, in their FDA submission data.[18]

Drugs involved in serious drug interactions, such as digoxin, warfarin, and diuretics, are commonly prescribed in the elderly population. This situation is complicated by the fact that elderly patients often have multisystem disease and may visit several physicians, who prescribe medications without specific knowledge of, or attention to, the remainder of the patient's drug regimen, thereby increasing the risk of inappropriate drug combinations.[72]

Herbal preparations also may interact with prescription medications.[25,52] The use of herbal preparations has increased

substantially in recent years, particularly among patients with illnesses that afflict the elderly, such as cancer, dementia, and depression. Very few patients voluntarily report use of these or other nonprescribed therapies to their physicians, and too often the physician fails to inquire specifically about such â€œalternativeâ€• or â€œcomplementaryâ€• therapies. Drug interactions involving herbals also occur with nonprescription preparations such as dextromethorphan, a common component of cough medicine, and St. John's wort (hypericum), a heavily promoted herbal remedy for depression that can reduce warfarin sensitivity.[43] Ginkgo biloba, commonly taken for memory loss, inhibits platelet function[40] and has the potential to enhance bleeding tendency when used with warfarin.[20,61] Combinations of herbals and SSRIs have been reported to cause serotonin syndrome.[9,25] Poisonings and other problems related to herbal preparations are discussed further in Chap. 43.

The use of nonprescription pharmaceuticals may cause serious adverse effects. For example, excessive use of magnesium-containing preparations can cause severe toxicity, often in older individuals. Impaired renal clearance, decreased gastrointestinal motility, and other medical comorbidities are just 3 risk factors that potentiate magnesium toxicity in the elderly. The source of magnesium in these cases may include the cathartics magnesium hydroxide (â€œmilk of magnesiaâ€•) and magnesium citrate, antacid preparations, and magnesium sulfate (Epsom salts).[26] Virtually all of the most popular nonprescription medications[37] are more likely to produce problems in the elderly than in younger patients, including gastrointestinal bleeding (aspirin and other nonsteroidal antiinflammatory agents), enhanced warfarin sensitivity (cimetidine), confusion and urinary retention (anticholinergic antihistamines), and cardiovascular symptoms (pseudoephedrine).

Outdated and discontinued drugs are an additional problem for the elderly who often retain products in their homes for decades.

Patients may be unwilling to change, or successive physicians may continue to renew the prescription without sufficiently reevaluating the patient.

Other age-related factors can increase the risk of unintentional poisonings in geriatric patients: impaired vision, hearing, and memory may lead to misunderstanding or the inability to follow directions concerning the use of prescription and nonprescription drugs. Dementia is an important risk factor in unintentional poisonings. In addition to cognitive impairment, patients with dementia sometimes exhibit abnormal feeding behaviors, including ingestion of inappropriate substances.

Management

Management decisions must be made with the foregoing principles in mind. Gastrointestinal decontamination should proceed as in younger patients. Because constipation is a more frequent problem in the elderly, when multiple-dose activated charcoal is indicated, particular attention must be paid to gastrointestinal function and motility. The specific precautions and contraindications in the basic management of gastrointestinal decontamination detailed in Chap. 8 are particularly pertinent for the geriatric population.

The presence of clinical or subclinical heart failure or renal failure may increase the risk of fluid overload when sodium bicarbonate is used. In the elderly, hemodialysis or hemoperfusion may be indicated earlier in cases of lithium or theophylline poisoning, where elimination may be hampered by a decreased creatinine clearance or reduced endogenous clearance, respectively.

A problem that may go unrecognized in geriatric patients is the development of alcohol or drug withdrawal symptoms. Because elderly patients are typically not perceived as drug users, the physician may not be aware of the chronic use of prescribed benzodiazepines or opioid analgesics, and consequently might fail

to consider the possibility of substance withdrawal when unanticipated complications occur during the hospitalization.

Strategies to limit unintentional toxic exposures in elderly patients with cognitive or sensory impairment should be similar to those employed in young children, who are at high risk for ingesting toxic substances or pharmaceuticals prescribed for others in the household. The strategies should include the removal of potentially dangerous substances and unnecessary drugs from the el-derly patient's environment. The physician should request that the patient or caregiver bring all medications to the office in the original bottles and then limit the number of pills dispensed. It may be necessary to limit medications such as antidepressants to a 1-week supply or to choose alternative medications with a safer therapeutic toxic index ratio. Administration and control of the medications by directly observed therapy may, of necessity, become the responsibility of the caregiver rather than the patient.

Admission Criteria

When geriatric patients are evaluated in the emergency department for poisonings or serious ADEs, the need for hospital admission should be guided by concerns about the patient's frailty, weighed carefully against the known hazards of hospitalization for the elderly.[15]

The physician should be particularly alert to certain situations that might mandate admission: elder abuse or neglect, unresolved mental status changes, inadequate home care manifested

by unexplained falls or overdose of medications with prolonged durations of action.

When there is concern that the established caregivers at home are abusing the patient, the patient will require further observation, removal from the environment, and possibly hospitalization. Signs

of actual physical abuse may be more obvious than signs of neglect.[41] Vulnerable elderly who are physically disabled or cognitively impaired may be brought to the hospital because of presumed illness, but the source of the problem may actually be the caregiver. The caregiver, frequently a family member, may be depleting the patient's funds for personal use. Patients may become ill because funds were diverted from the purchase of food or because the patient's prescription drugs were sold on the street. More direct abuse may take the form of intentional poisoning of the patient by overdose of the patient's own prescription drugs.

Unresolved mental status changes may require close observation and hospitalization. Elderly patients who are confused or unable to walk are sometimes mistakenly assumed to be chronically impaired. However, incomplete explanation of an altered mental status or physical impairment should prompt careful inquiry into the patient's baseline functional status. Functional deterioration should not be assumed to be age related. Many very elderly patients are cognitively normal, physically robust, and independent in all activities of daily living.

Overdose with long-acting agents requires careful monitoring. Because duration of action of certain drugs may be markedly prolonged among geriatric patients, a higher degree of vigilance is required. A classic example is associated with the use of the sulfonylurea, chlorpropamide, which has a half-life of 24â€“72 hours or more and can cause protracted hypoglycemia. This drug is rarely used today, but observational studies suggest that severe hypoglycemia (glucose <50 mg/dL), in the presence of neurologic or cardiac symptoms, is more common with glyburide than with other commonly used sulfonylurea agents,[27,67] possibly because of an active, renally eliminated metabolite.[34] Although comparable to glipizide in ideal conditions,[7] renal failure or use of concurrent medications that could potentiate hypoglycemia might elevate risk. Hypoglycemia leading to serious morbidity or death is an

important drug-related problem among the elderly and occurs with virtually all sulfonylurea agents.[67]

Summary

Older patients may account for only a small fraction of poisoning victims, but when poisoned, they have the highest mortality rate. More importantly, the elderly are much more likely to experience serious adverse drug events as a consequence of appropriate or inappropriate use of medications. Attention to risk factors is essential in this vulnerable population. Important risk factors include pharmacokinetic and pharmacodynamic changes; the presence of overt or subclinical disease, including dementia; patient and physician error; suicide risk; complex therapeutic drug regimens; and a general lack of knowledge about the principles of geriatric prescribing.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 33
Postmortem Toxicology

Rama B. Rao

Mark Flomenbaum

Intravenous phenytoin is administered to a 25-year-old man with a history of seizures, who is maintained on phenytoin in order to achieve a therapeutic concentration. Eight minutes after the beginning of the infusion, the man experiences a bradydysrhythmia followed by asystole. The infusion is immediately discontinued and resuscitation is attempted, but is unsuccessful.

Postmortem toxicology is the study of the presence, distribution, and quantification of a xenobiotic after death. This information is used to account for physiologic effects of a xenobiotic at the time of death, through its quantification and distribution in the body at the time of autopsy. Several variables may cause changes in xenobiotic concentrations during the interval between the time of death and subsequent autopsy. Toxicologists and forensic pathologists are frequently asked to interpret postmortem xenobiotic concentrations and decide whether these substances

were incidental or contributory to the cause of death.

The development of the field of forensic toxicology, and the improvement of laboratory technology, now permits more refined identification and quantification of xenobiotics. The interpretation of postmortem xenobiotic concentrations and their significance, however, continues to evolve.

This chapter reviews factors affecting xenobiotic concentrations identified on autopsy and discusses an approach for interpreting postmortem toxicologic reports as they relate to cause and manner of death.[37,39,45,46 and 47,53,61,71,89]

History and Role of Medical Examiners

The relationship between antemortem xenobiotic exposures and death has been a subject of investigation for centuries. In 12th century England, an appointee of the royal court, eventually named the â€œcoroner,â€• was designated to record and identify causes of death.[65] In suspicious circumstances coroners investigated poisonings, but scientific methods were primitive and conclusions regarding such deaths were conjecture, at best.

By the mid-19th century, however, techniques for detecting certain compounds in postmortem tissue were developed and focused generally on identifying heavy metals as a cause of death in homicides.[40,65,69,86,91] At this time, coroners were still elected or appointed individuals with little or no medical training. However, with better laboratory techniques and autopsies performed by trained pathologists, the specialty of forensic medicine continued to develop. In late 19th century Massachusetts, trained pathologists, referred to as medical examiners, ultimately replaced the coroner system and were empowered by the state to investigate deaths (medicolegal autopsies).[65] Currently in the United States, legal jurisdiction of death investigations is the responsibility of either a coroner or a

medical examiner, depending on the state and/or county, with 19 states using medical examiner systems almost exclusively.[44]

The medicolegal autopsy is performed by a forensic pathologist who attempts to establish cause and manner of death (Table 33-1). â€œCause of deathâ€• is the physiologic agent or event necessary for death to occur. For example, the presence of cyanide in the toxicologic evaluation may be sufficient to establish cardiorespiratory arrest from cyanide poisoning. â€œManner of deathâ€• is an explanation of how the death occurred and broadly distinguishes natural from nonnatural (or violent) deaths. Nonnatural deaths, depending on the jurisdiction, can be divided into several categories (Table 33-2). With the identification of cyanide, the manner of death cannot be considered natural, because a poisoning is a â€œchemically traumaticâ€• (violent) event. The medical examiner must make the best determination of the manner of death based on available evidence.[91,98] An unintentional exposure may be classified as an â€œaccidentâ€• (a legal term for some unintentional nonnatural deaths), and intentional self-exposure may be classified as a â€œsuicide.â€• If the circumstances indicate an exposure as a consequence of the acts of another person, the manner of death is classified as a â€œhomicide.â€•

Determination of manner of death has important consequences. Homicide necessitates involvement of law enforcement officials for further investigation. Cases deemed suicide not only impact survivors psychologically, but also may nullify life-insurance payments; conversely, a case deemed an â€œaccidentâ€• may have a double-indemnity insurance clause. Assignment of financial responsibility for workplace disasters may be similarly affected when illicit drugs are identified in the postmortem specimens of involved workers.

Recognition of xenobiotic-related deaths also has significant public health consequences. The forensic pathologist may be the first to

identify and report critical information regarding fatal drug reactions, medication errors, or rapidly fatal epidemics associated with illicit drug use. In cases of occupational and environmental xenobiotic-related fatalities, interventions can be implemented to prevent subsequent morbidity and mortality. In addition, the pathologist describes gross and microscopic autopsy findings that may elucidate mechanisms of xenobiotic toxicity.

TABLE 33-1. Information Used by Forensic Pathologists

Autopsy

Medical records
Police reports
Interviews with contacts

Postmortem toxicologic techniques also can be used in other types of investigations. For example, when carboxyhemoglobin is identified in the burned human remains of an airplane crash, a cabin fire before descent is more probable than a fire on impact. This type of postmortem analysis is useful in reconstruction of events leading to the crash.[8,51,57]

The Toxicologic Investigation

Ordinarily, toxicologic samples are collected as part of a complete autopsy. In the hospital, when a death is assumed to be from natural causes, the hospital pathologist may perform an autopsy

with consent of the family. In the medicolegal investigation, however, the forensic pathologist determines the need for a complete or partial autopsy and has the jurisdiction to act on that determination with or without familial consent. Occasionally, only fluid samples need be obtained if a complete autopsy is either unnecessary or the family has legal or religious grounds for objection. The precise list of xenobiotics screened in postmortem samples varies greatly by jurisdiction. Large cities may routinely screen for hundreds of illicit, therapeutic, and environmental xenobiotics. Occasionally the suspicions of the medical examiner warrant special assays that are performed only upon request.

The sampling of fluid and tissue may be obtained minutes to years after death. The â€œpostmortem interval,â€• defined by the degree of bodily decomposition, can vary, depending on environmental conditions, such as ambient temperature, humidity, and immersion under water.[58] Samples may be collected from a body during advanced stages of decomposition, after exhumation from a grave, or after embalming.[7,41,70] Knowing the condition of the body at the time of sampling assists in interpreting toxicologic findings. These postmortem changes are reviewed below.

Decomposition and Postmortem Biochemical Changes

The first stage of decomposition is *autolysis* where endogenous enzymes are released and normal mechanisms maintaining cellular integrity fail.[52] Chemicals move across leaky cellular membranes down relative concentration gradients. Glycolysis continues in red blood cells until intracellular glucose is depleted, and then lactate is produced. Ultimately, intracellular ions and proteins are released into the blood, and tissue and blood acidemia develops (Table 33-3).[91]

TABLE 33-2. Categories of Manner of Death

Natural
Nonnatural
Homicide
Suicide
Accident
Therapeutic complication[a]
Undetermined

[a] Not all jurisdictions recognize therapeutic complication as a manner of death.

TABLE 33-3. Postmortem Biochemical Changes Over First 3 Days[a]

Increased	Decreased	Stable	Variable
Amino acids	Cl^-	BUN/creatinine (vitreous)	Lipids
Ammonia	Glucose	Cholinesterases	T_3
Ca^{2+}	Na^-	Cortisol(serum)	
Epinephrine	pH	Proteins (serum)	

Hepatic enzymes	T_4	Sulfates	
Insulin (especially right-heart blood)			
K^+			
Mg^{2+}			
[a] In refrigerated bodies.			

The next stage of decomposition is *putrefaction.* This involves digestion of tissue by bacterial organisms that typically originate in the bowel or respiratory system. Later, other organisms may be introduced by insects or other external sources. As the putrefactive process advances, skin and organ colors change, epithelial blebs may form and separate from the underlying dermis, and gases may accumulate, forming foul odors and bloating.[91]

If death occurs in a very warm, dry climate, such as a desert or a comparably arid environment, the body may desiccate so rapidly that putrefactive changes may not occur. This results in *mummification*, and produces a lightweight cadaver with a tight, dry skin enveloping a prominent bony skeleton.[91]

If the environment is very cold and devoid of oxygen, such as at great depths under water, putrefaction will be slowed. Anoxic decomposition of fatty tissues occurs, forming a white cheesy material known as *adipocere.*

Another phase of decomposition, *anthropophagia*, occurs in unprotected postmortem environments where insects or other animals feed on the remains.[91]

Most postmortem changes are temperature dependent with increased temperatures accelerating the process, and cooler temperatures retarding it. In general, morgue refrigerators achieve low enough temperatures (40Â°F; 22Â°C) to prevent further gross decomposition and associated postmortem changes.

Another process that alters natural decomposition is *embalming*, a process of chemically preserving tissues that can be performed in a variety of ways.[42,43] Typically, blood is drained through large vessel pumps, and an embalming fluid is injected intravascularly to perfuse and preserve the face and/or other tissues. Intracavitary spaces may be injected with the preserving substances, and solid organs may or may not be removed.

Samples used for Toxicologic Analysis

Unless the medical examiner is suspicious about a death, only standard autopsy samples will be taken from an otherwise intact body.[23,36,49,54,74,89] These typically include samples of blood, gastric

contents, bile, urine, and, occasionally, solid organs such as the liver or brain. Less commonly, vitreous humor is obtained for analysis (Table 33-4). If the decedent was hospitalized prior to death, antemortem specimens may also be available for evaluation and comparison. These specimen analyses are reviewed in greater detail below.

TABLE 33-4. Sampling Sites [16,21,24,36,49,91]

Routine	Infrequent	Uncommon
Bile	Bone	Antemortem blood
Blood	CSF	Extravasated blood
Brain	Fat	Extravasated fluid
Liver	Hair	Casket fluid
Gastric contents	Kidneys	Insect larvae
Urine	Lungs	Pupae casings
Vitreous humor	Muscle	Soil
	Nails	
	Skin	

Blood

Postmortem cell lysis prevents the reporting of plasma concentrations, and â€œbloodâ€• concentrations are reported instead. Intravascular blood from the subclavian or femoral vessels is a common source for toxicologic examination. In patients with a prolonged postmortem interval, or in cases where

intravascular blood is coagulated, right-heart blood may serve as a sample site. Usually just 1 site is sampled unless an unusual xenobiotic with nonuniform distribution is suspected of causing the death.

Other sources of blood are sometimes available to the forensic pathologist. These other sources include antemortem samples and, occasionally, extravasated blood, which is unlikely to undergo extensive metabolism. Intracranial clots, in particular, serve as useful comparative samples in patients with a prolonged survival period following exposure to a xenobiotic.

In advanced states of decomposition blood from the abdominal or thoracic cavities is less useful, as it can be contaminated by bacteria or other substances that may affect xenobiotic recovery and/or analysis.

Vitreous Humor

Because of the relatively avascular and acellular nature of the fluid, the vitreous humor is well protected from the early decompositional changes that typically occur in blood.[16,21,24] When bodies are immediately refrigerated, creatinine, blood urea nitrogen, and sodium can be reliably approximated from vitreous humor samples for up to 3 or 4 days. Potassium concentrations are less reliable, as cell lysis causes intracellular release. When vitreous glucose is elevated, hyperglycemia at the time of death can be assumed. A low vitreous glucose is inconclusive with regard to the antemortem serum glucose concentration. A low vitreous glucose may be a result of either antemortem hypoglycemia or postmortem glycolysis, even in the relatively avascular vitreous.

The aqueous content of the vitreous is normally higher than that of blood and may affect partitioning of certain water-soluble xenobiotics.

Urine

Urine may be available at autopsy and can reveal renally eliminated substances or their metabolites. Because the bladder serves as a reservoir in which metabolism is unlikely to occur, the concentrations of xenobiotics obtained at autopsy reflect antemortem urine concentrations. An isolated urine sample is of limited quantitative value, but may be useful when compared to other sample sites.

Gastric Contents

The gross contents of the stomach are inspected for color, odor, and the presence or absence of pill fragments, food particles, activated charcoal, and other foreign materials.[89] Typically, gastric concentrations of xenobiotics are reported as milligrams of substance per gram of total gastric contents. Xenobiotic-induced pylorospasm, diminished intestinal motility, or decreased splanchnic blood flow all may decrease gastric emptying and affect the quantitative values obtained from sampling different parts of the GI tract.

Solid Organs and Other Sources

Xenobiotic concentrations in solid organs such as liver or brain are usually reported as milligrams of substance per kilogram of tissue. Other tissue samples, including hair and nails, are used for thiol-avid agents such as metals. Rarely, tracheal aspirates of gases can be analyzed to confirm inhalational exposures. Pleural fluid analysis of postmortem xenobiotics typically yields qualitative results in decomposed bodies, as redistribution of xenobiotics from the stomach and intestines may occur.[30,81]

Other Sampling Sources

In an embalmed body, either the organs that remain, such as muscle tissue, or the embalming fluid can be used for analysis. Some countries regulate the contents of embalming fluid to specifically avoid confounding postmortem analysis. Most embalming fluid in the United States consists of formaldehyde, sodium borate, sodium nitrate, glycerin, and water. When a body is disinterred, soil samples are usually obtained from above and below the coffin site to permit identification of chemicals that may have leeched into or out of the body.

On rare occasion, cremated remains, often referred to as cremains, will be the only source of sampling available. Most metallic implants such as pacemakers are removed prior to cremation, and only dental remains, particulate matter, and, occasionally, calcified blood vessels are available for analysis.[4,97] In most cremations performed in the United States, the incineration process is followed by grinding remains to form a fine particulate matter.[97] The ability to extract xenobiotics from such samples is markedly limited at best, and there are few published data on the subject. A new technique to identify such heavy metals as lead from cremains has been described but is not routinely used at present.[4,97]

Entomotoxicology

In putrefied bodies and in bodies that have undergone anthropophagy, fluids and insect parts can be analyzed. Forensic entomologists collect samples of these insects from the remains and after taking into account the stage of insect life, environmental conditions, and season, can extrapolate the approximate time of death. The species *Calliphoridae*, or bluebottle fly, is attracted to unprotected remains by a very fine scent that develops in the body

within hours of death. The adult fly lays eggs on mucosal surfaces

or in open wounds. Once the eggs hatch, the larvae feed on the decomposing tissue. Larval samples can be examined for the presence of toxins. To achieve accurate analysis, these samples must be collected and preserved immediately, because living larvae can continue to metabolize certain xenobiotics. In another phase of their life cycle, the larvae undergo pupation, secreting a substance that encloses them into pupal casings until they hatch as adults. These casings are often found in the soil beneath the body. Some toxins have been identified in the casings even after the adult fly has emerged (Table 33-5).[79] A variety of other anthropophagic insect species may demonstrate the presence of xenobiotics;[1,38,56] this process of analysis is termed *entomotoxicology.*

Interpretation of Postmortem

Toxicologic Results

Once fluid and tissue samples are collected and analyzed for the presence of xenobiotics, the process of interpreting the results begins. This complex task attempts to account for the clinical effects of a xenobiotic at the time of death by integrating medical history, autopsy findings, and toxicologic reports. Multiple confounding variables can affect the sample concentrations of xenobiotics from the time of death to that of the autopsy. Variables include the nature, metabolism, and distribution of the xenobiotic, the state of health of the decedent, and the techniques and findings of the autopsy (Tables 33-6 and 33-7).

Variables Relating to the Xenobiotic

Postmortem Redistribution

Xenobiotic blood concentration may be higher at autopsy than at the time of death if the agent undergoes significant postmortem redistribution.[50,73,96,103] Most often, redistribution occurs with substances that have large volumes of distribution and when decomposition results in release of intracellular xenobiotic into the extracellular compartment.[77] For example, amitriptyline may be released from tissue into the blood as autolysis progresses, resulting in a higher blood concentration at autopsy than at the time of death. If postmortem redistribution is not considered, xenobiotic concentrations obtained at autopsy may be misinterpreted as supratherapeutic or toxic, and the cause of death may be inappropriately attributed to this agent.

TABLE 33-7. Xenobiotic Stability and Laboratory Recovery[10,12,22,27,73,79,80,87]

Postmortem Metabolism

Less commonly, xenobiotic concentration may fall secondary to postmortem metabolism. For example after death, cocaine continues to be degraded by blood cholinesterases, which are

stable in postmortem tissue. Unless blood is collected immediately after the time of death in tubes containing enzyme inhibitors such as sodium fluoride, the concentration of cocaine will continue to fall and the analysis will not accurately reflect the concentration of the drug at the time of death.[55,63,94] Specific information that is available regarding postmortem redistribution or metabolism should be considered and the toxicologic results interpreted accordingly.

State of Absorption and Distribution

Both in the living and deceased, the state of absorption, distribution, and other toxicokinetic principles affect the sampling concentration of a xenobiotic. For a xenobiotic with minimal postmortem metabolism or redistribution, the phase of absorption is suggested by the relative quantity of the agent in different fluids and solid organs. For example, a high concentration of xenobiotic pill fragments in the gastric contents, with progressively lower concentrations in the liver, blood, vitreous, and brain, suggests an early phase of absorption at the time of death. When an agent is orally administered and the tissue concentration is highest in the liver, the relationship suggests a postabsorption phase but a predistribution concentration. A concentration found to be highest in the urine suggests that the xenobiotic was in an elimination phase at the time of death. Although this approach has limitations, it may be important for correlating the state of absorption and the expected clinical course of the xenobiotic. Unfortunately, multiple samples may not always be available at the time of autopsy or the interpretation of reports, and opportunities for subsequent sampling are often limited.

Xenobiotic Stability

Xenobiotic stability refers to the ability of an agent to maintain its molecular integrity despite changes during decomposition of the

body, storage conditions, or the addition of preservatives.[5,13,15,84,92,100,101 and 102] Postmortem xenobiotic stability was assessed in homogenized liver tissue infused with various concentrations of xenobiotics.[92] The samples were allowed to putrefy outdoors, and sequential sampling of xenobiotic concentrations was performed. The xenobiotics that decreased in concentration as putrefaction progressed were considered â€œlabile,â€• whereas samples with a constant concentration were considered stable. The authors proposed that the chemical moieties of a xenobiotic determine its stability. For example, labile agents share the molecular configuration of an oxygen-nitrogen bond, thiono groups, or aminophenols. Conversely, chemical structures that enhance stability include single-bonded sulfur groups, carbon-oxygen and carbon-nitrogen bonds, as well as sulfur-oxygen and hydrogen-nitrogen bonds. Although not explicitly studied in otherwise intact, putrefying bodies, logically, a less-stable xenobiotic may be recovered in a lower concentration than the actual concentration at the time of death. This must be considered when information regarding stability is available and the body of the decedent is in an advanced stage of decomposition.

Xenobiotic Chemical Interactions

An artifact may result from a chemical interaction with a xenobiotic added during the postmortem period, such as embalming fluid.[35] In a study of xenobiotic-spiked blood and formalin in test tubes, amitriptyline was formed through methylation of nortriptyline.[26] Identification of amitriptyline, which was not present at the time of death, could confuse the interpretation of toxicologic analyses.

Expected Clinical Effects of the Xenobiotic

For a fatality to be attributed to a xenobiotic, the expected clinical

course of the exposure should be consistent with the autopsy findings. For example, what are the implications if a person is found dead 90 minutes after having been seen ingesting pills and a large concentration of acetaminophen is identified in both the gastric contents and blood, but not in other tissues of a person? Although suicidal intent (manner) may be supported by this finding, the onset of death within minutes is inconsistent with a fatality from an acetaminophen overdose. Thus, another cause of death must be sought. Interpretation of postmortem toxicology must also incorporate clinically relevant consequences of xenobiotic interactions. For example, the combined ingestion of phenobarbital and ethanol can cause fatal respiratory depression. Although neither may be fatal alone, their clinical synergy must be acknowledged during toxicologic interpretation.

Variables Related to the Decedent

Comorbid Conditions

The clinical response to a xenobiotic may be affected by acquired and inherited physiologic conditions that are not always identified on autopsy. A thorough medical history is important, and may assist in interpreting the clinical effects of a xenobiotic exposure. Similarly, certain clinical conditions may produce substances that interfere with postmortmen laboratory assays. For example, an individual with a critical illness may produce digoxin-like immunoreactive substances (DLIS) which can cross-react with the postmortem digoxin assay.[6] Without knowledge of DLIS production, the results may confound toxicologic analysis.

Tolerance

Tolerance is an acquired condition in which higher and higher xenobiotic concentrations are required to produce a given clinical effect. It is an important consideration for deaths in the presence

of opioids, ethanol, and sedative-hypnotic agents. For example, respiratory depression and death from methadone is easily diagnosed in an opioid-naive individual with a history of methadone exposure and methadone-positive postmortem samples. However, the same methadone concentrations in a patient on chronic methadone maintenace therapy will not produce the same outcome. Unfortunately, there are no biochemical or histologic markers on autopsy that can be used to predict clinically dangerous xenobiotic concentrations in tolerant individuals. Complex postmortem assays analyzing opioid receptors are not routinely used.[34] Postmortem assessment of tolerance ultimately depends on knowledge of the patient, pharmacokinetics of the agent, and the best judgment of the investigator.

Pharmacogenetics

There is genetic variability in the expression of certain metabolic enzymes. For example, pharmacogenetic differences in metabolic enzymes such as CYP2D6 predispose some individuals to fatal hypotension from the inability to metabolize debrisoquine. Such distinctions are not routinely identifiable on autopsy.[28]

Variables Relating to the Autopsy

State of Decomposition

In decedents with advanced stages of decomposition, xenobiotics can diffuse from depot compartments such as the stomach or bladder into adjacent tissues and blood vessels, or secondarily affecting their sample concentrations.[22,67,68,76,77 and 78]

During putrefaction, bacteria cause fermentation of endogenous carbohydrates, resulting in ethanol formation. In decedents

without gross evidence of putrefaction, especially those in cool,

dry environments, endogenous ethanol production is minimal.[17,18] With a longer postmortem interval or in an environment more conducive to ethanol production, the distinction between endogenous and exogenous sources of ethanol becomes more difficult. Multiple sample sites are often useful in making the distinction.[93]

Handling of the Body

Inappropriate handling of the body can result in artifacts.[83,85] In one reported case, methanol was detected in the vitreous humor of a decedent, postembalming.[12] The methanol was subsequently traced to a spray cleanser that likely settled on the surface of open eyes during washing of the body.

In the United States, preservatives containing metals are currently banned for use in embalming because they can contaminate subsequent evaluation for metal poisoning. Formalin may also affect stability or quantitative identification of some xenobiotics. When necessary, an analysis of embalming fluid used by the mortician, or soil sampling around disinterred bodies, can facilitate the toxicological investigation.[19]

Autopsy Findings

In many xenobiotic-related deaths, the anatomic findings are nonspecific.[99] In some cases, the autopsy reveals confirmatory or supportive findings. A large quantity of undigested pills in the stomach is consistent with an intentional overdose, and suicide can be considered. Centrilobular hepatic necrosis may be found in decedents with a history of acetaminophen overdose. The autopsy may reveal other findings such as coronary artery narrowing, chronic hypertension, renal abnormalities, or a clinically silent myocardial injury. Such information may be useful to assess the potential effects of a xenobiotic in a patient with previously undiagnosed conditions. In other cases, the absence of a chronic

condition may be strongly suggestive of a xenobiotic-related death. For example, a decedent with an autopsy finding of aortic dissection, in the absence of chronic hypertensive findings or other predisposing conditions, may suggest a xenobiotic-induced hypertensive crisis, as may occur from use of cocaine or other sympathomimetics.

Artifacts Related to Sampling Sites

Site-specific differences in postmortem xenobiotic blood concentrations are common.[33] For example, blood drawn from femoral vessels may have a low glucose because of postmortem glycolysis, but the glucose concentration of blood removed from the right-heart chambers may be high as a result of the release of liver glycogen stores. Hyperglycemic states are more reliably assessed from sampling of the vitreous humor. An elevated vitreous glucose concentration suggests antemortem hyperglycemia. The individual interpreting the toxicologic report must know the exact site sampled.[20,54]

Ideally, more than one site is available for comparison. Multiple blood samples are not often routinely obtained. The comparison of concentrations from different sites may reveal important information regarding the state of xenobiotic absorption at the time of death, and acute versus chronic exposure.[9,10 and 11,20,25,29,48,59,63,72,74,76,77,80,81 and 82,87,88,93,95]

Other Considerations

Published therapeutic, toxic, and fatal postmortem xenobiotic concentrations are available to aid in interpretation of postmortem specimens.[3,62] However, the conditions associated with reported concentrations do not necessarily permit comparisons with those concentrations in a particular case under investigation. Thus, these resources are valuable, but should be used mainly as guidelines and not accepted as absolute values that define fatal

toxic concentrations. Similarly, formulas available for assessing xenobiotic doses or concentrations in the living, are not usually applicable when analyzing postmortem samples.

Other Limitations

Although there are generalized standards of practice in forensic investigations, specimen collection and laboratory methodology may vary.[2,3] Some xenobiotic concentrations may be falsely elevated or depressed, depending on chosen methodology.[30,64] Descriptions of specific laboratory toxicology techniques are beyond the scope of this chapter, but these variables must also be given consideration in postmortem toxicologic interpretations. Other limitations may include the lack of information relating to the circumstances of death, and possible compromises in specimen handling that affect the proper chain of custody, required in forensic autopsies.

Summary

To accurately interpret postmortem toxicologic reports, it is essential to understand potential biochemical changes and the artifacts that affect postmortem sampling. Unfortunately, because of the complexity and variety of mitigating circumstances, there is no single resource that can systematically correlate postmortem xenobiotic blood and tissue concentrations to those at the actual time of death. Postmortem toxicology is an evolving discipline that may only permit the most likely truths associated with the xenobiotic identified and the circumstances in question.[14,31,66]

Progress in this field depends on the continued collaboration between treating physicians, medical and forensic toxicologists, and forensic pathologists.

Case Discussion

A complete medical history was reported to the medical examiner including the details of his general health, why he presented to the hospital, and what transpired immediately prior to, and during the cardiac arrest. The tubing and all remaining fluid in the phenytoin infusion was saved for analysis, and the laboratory was informed to save all samples of antemortem and perimortem blood obtained during the hospitalization.

The postmortem blood from the right subclavian vein revealed lidocaine 8 Âµg/mL and phenytoin 16 Âµg/mL, but lidocaine is not commonly used during bradycardic arrests. The toxicologist therefore requested a complete medical record to determine whether this medication was administered during an attempt to restore circulation. If it was so used, lidocaine could be excluded as a cause of cardiac arrest and treated as a therapeutic artifact. Alternatively, lidocaine toxicity might have caused a bradydysrhythmia. The volume of distribution of lidocaine is between 1 and 2 L/kg and undergoes limited postmortem redistribution. If the toxicologist remains uncertain about causation, the remainder of the intravenous infusion can be analyzed for the presence of lidocaine and the possibility of a medication error. As it turned out, the resuscitation resulted in a transient episode of ventricular fibrillation that was treated with successive defibrillation and the administration of boluses of lidocaine. The remaining 40 mL of the original phenytoin infusion contained only phenytoin in a propylene glycol diluent. The conclusion was reached that the postmortem lidocaine concentration

was likely a result of resuscitative efforts and in the absence of any other autopsy findings, the bradycardic arrest was likely caused by rapid infusion of propylene glycol, as the diluent used with intravenous phenytoin.

Additional Case Discussions

Case A

A 72-year-old male with a history of atrial fibrillation is found dead 1 hour after his last dose of digoxin. The autopsy, performed the following day, demonstrated an enlarged heart and findings consistent with chronic hypertension. The postmortem right-heart blood digoxin concentration was 5.6 ng/mL. How should these results be interpreted?

This high blood concentration may reflect either the early state of absorption or postmortem redistribution of digoxin. Alternatively, the individual may have suffered death from chronic digoxin toxicity. Sampling another site, such as the vitreous humor, becomes important to make the distinction. The vitreous concentration will likely reflect the chronic concentration of digoxin as it equilibrates with blood over a period of hours after ingestion. If the vitreous humor concentration is 0.9 ng/mL and the vitreous creatinine is 0.8 mg/dL, it is unlikely that chronic digoxin toxicity was responsible for the patient's death.

Case B

A 50-year-old man with diabetes is found in an advanced stage of decomposition in his apartment during a warm summer month. The vitreous humor is cloudy and has a glucose concentration of 5 mg/dL. Right-heart ethanol concentration is 40 mg/dL. How do you interpret these values?

Unlike elevations in vitreous glucose, low vitreous glucose is inconclusive with regard to the glycemic state at the time of death. Thus, low vitreous glucose is inconclusive in establishing antemortem hypoglycemia even if the postmortem interval was relatively brief and the vitreous sample, clear. The ethanol could have been consumed prior to death, or it could have been

generated during the postmortem interval, but usually does not rise above 50 mg/dL. An ethanol sample from the brain and bladder (if available) in which ethanol undergoes less fermentation would be useful to make the distinction. Regardless of the source of the ethanol, a level of 40 mg/dL is unlikely to have caused death alone, but may be useful if aspiration, unusual bodily position, or other sedative hypnotics were also identified at autopsy.

Special Considerations: Organ Procurement from Poisoned Patients

Rama B. Rao

Xenobiotics can cause brain death because of the vulnerabilities of the central nervous system. With supportive care, however, such patients may be suitable candidates for organ donation.[8,26] Early identification of donors is critical, as the viability of transplantable tissue diminishes as duration of brain death progresses.[26] Timely identification may be further complicated by the presence of xenobiotics that mimic brain death (Tables SC-1 and SC-2).[3,5,24]

Protocols to establish brain death are reviewed elsewhere.[3,5,24] Once brain death is established, organ procurement personnel assist in obtaining familial consent, deciding which organs are most suitable for transplant, and maximizing physiologic support and perfusion until organ procurement occurs.[26]

Successful transplantation of organs is reported from poisoned donors associated with a multitude of xenobiotics (Table SC-3).[1,2,5,7,10,18,20,21,22 and 23] Although some xenobiotics, such as cyanide and carbon monoxide (CO), are highly toxic, transfer of

clinical poisoning to the organ recipient is not reported. This is likely a result of several factors, including xenobiotic metabolism, tissue redistribution or binding prior to procurement, as well as the means of handling organs during the transplantation process. For example, some xenobiotic clearance may occur in the myocardium during organ rinsing and cardiopulmonary bypass.[20] Furthermore, individual organs may not uniformly manifest toxicity in response to xenobiotic insults. For example, the heart of a CO-poisoned donor was examined after a transplantation failure from technical reasons. The myocardium did not demonstrate histologic signs of CO poisoning.[23]

TABLE SC-1. Conditions That Can Mimic Brain Death[3,5,24]

Guillain-BarrÃ© Syndrome
Hypoglycemia
Hypothermia
Poisonings
Amitriptyline
Bismuth salts
Inhaled anesthetics
Sedative hypnotics
Barbiturates
Benzodiazepines
Meprobamate
Chloral hydrate
Trichloroethylene
Pontine hemorrhage
Rabies
Tetrodotoxin

Probably more critical to transplantation success is adequate

tissue perfusion and well-maintained cellular morphology. For example, patients suffering brain death from acetaminophen poisoning are not suitable liver donors, given the specific destruction of hepatic cells. Alternatively, xenobiotics considered toxic to organ function by impairing enzymes have resulted in successful transplantation if the cellular structure is otherwise maintained. For example, a donor with cardioactive steroid poisoning did not preclude successful heart transplantation, even when the donor had a bradydysrhythmia, elevated serum digoxin concentration, and required cardiopul-monary resuscitation.[23] In another case, the liver of a patient poisoned with brodifacoum was transplanted after donor administration

of fresh-frozen plasma and vitamin K_1. The recipient's INR (international normalized ratio) after transplantation was 2 and corrected rapidly with supportive care. Recipient concentrations of brodifacoum were not reported and not clearly causative of the elevated INR.[20] In both the examples of brodifacoum and cardioactive steroids, the target of toxicity was enzymatic and the tissue morphology was otherwise minimally affected.

TABLE SC-2. Clinical Criteria for the Diagnosis of Brain Death

No alternative cause for the clinical condition (eg, hypothermia)
Poisoning not or no longer a consideration as the cause of the clinical condition
Coma: No motor responses to appropriate painful stimuli
Absence of brainstem reflexes
  Pupillary responses to light and pupils at midposition (4â€“6 mm)
  Corneal reflexes

Caloric (oculocephalic) responses
Gag reflex
Coughing in response to tracheal suctioning
Sucking and rooting reflexes
Apnea test
Respiratory drive at a $PaCO_2$ that is 60 mm Hg or 20 mm Hg above normal baseline values
Interval between 2 evaluations, according to patient's age

Term to 2 mo, 48 h	>1 yr to < 18 yr, 12h
> 2 mo to 1 yr, 24 h	â‰¥18 yr, interval optional
Confirmatory tests	
Term to 2 mo, 2 confirmatory tests	>1 yr to <18 yr, optional
>2 mo to 1 yr, 1 confirmatory test	â‰¥18 yr, optional

Confirmatory tests include:
Cerebral angiography
Electroencephalography
Cerebral scintigraphy
Transcranial Doppler ultrasonography

TABLE SC-3. Organs Transplanted After Donor Poisonings

Organ	Xenobiotics Identified
Cornea[a1,18,20,22]	Brodifacoum, cyanide
Heart[5,10,20,23]	Acetaminophen, benzodiazepines, Î²-adrenergic antagonists, brodifacoum, carbamazepine, carbon monoxide, clomethiazole, cyanide, digitalis, digoxin, ethanol, flurazepam, glyburide, insulin, meprobamate, methanol, organic phosphorus compounds, propoxyphene, thiocyanate
Kidney[a2,7,10,20,22]	Acetaminophen, brodifacoum, carbon monoxide, cyanide, ethylene glycol, methanol, tricyclic antidepressants
Liver[7,10]	Brodifacoum, carbon monoxide, cyanide, ethylene glycol, methanol, tricyclic antidepressants
Lung[4,10,20,21,22]	Brodifacoum, carbon monoxide, methanol
Pancreas[7,20]	Acetaminophen, brodifacoum, carbon monoxide, cyanide, ethylene glycol, methanol, tricyclic antidepressants

Skin[22]	Cyanide
[a]Can be cadaveric procurement.	

Most failures of transplant organs from poisoned donors are a result of rejection, sepsis, or technical reasons. The 1-year survival in recipients of transplant organs from poisoned donors approximates that of recipients of transplant organs from nonpoisoned donors, and in one series was reported at 75%.[7]

Ideally, a comprehensive international registry of transplant organs from poisoned donors will be established to improve understanding of transplanting organs from such patients. It appears that patients who suffer brain death from poisoning are potentially suitable donors when cellular infrastructure is preserved.[16,17,19,26] Consideration for organ procurement should not be limited by the xenobiotic itself.

Chapter 34
Acetaminophen

Robert G. Hendrickson
Kenneth E. Bizovi

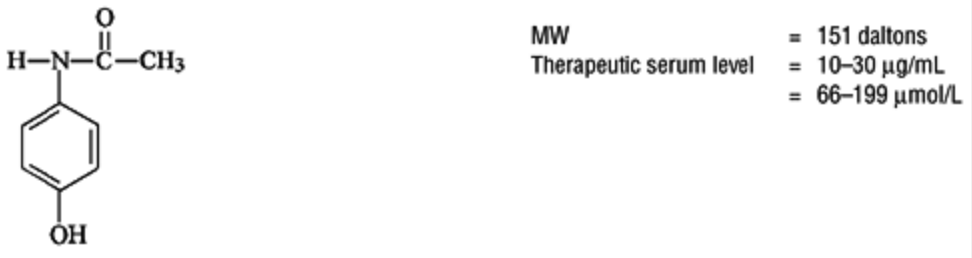

Figure. No Caption Available.

A 21-year-old woman was brought to the emergency department (ED) by her boyfriend when he learned that she ingested

approximately 30 (325-mg) acetaminophen tablets in an attempted suicide. He was unaware of any previous significant medical or psychiatric illness but reported that she was seen in another ED several days earlier for persistent headaches. He said that she did not abuse alcohol or any other drugs.

The patient was able to provide a history and admitted to taking approximately 30 tablets approximately 3 hours before coming to the hospital because she wanted to kill herself. Shortly after taking the tablets she developed a bad â€œstomach ache,â€• felt extremely nauseated, and vomited once. She denied taking any other medications or alcohol in the suicide attempt.

On physical examination the woman was diaphoretic and pale, and she appeared uncomfortable. Her vitals signs were blood pressure, 95/70 mm Hg; pulse, 100 beats/min; respiratory rate, 20 breaths/min; oral temperature, 98.6Â°F (37Â°C). Examination of the head, eyes, ears, nose, and throat was unremarkable. Her neck was supple, her lungs were clear, and the cardiac examination was within normal limits. Examination of the abdomen revealed only moderate midepigastric tenderness without peritoneal signs. Bowel sounds were normoactive. Cranial nerves were grossly intact and reflexes were 2+ bilaterally. She was oriented to time, place, and person.

The patient was given 50 g of oral activated charcoal along with 40 mL of 70% sorbitol. A 4-hour serum acetaminophen concentration was 215 Âµg/mL, and as a result the patient was treated with intravenous *N*-acetylcysteine (NAC) over 20 hours. The patient's aminotransferase concentrations remained normal, and after treatment was completed she was transferred to a psychiatric facility.

History and Epidemiology

Acetaminophen (*N*-acetyl-*p*-aminophenol [APAP]), a metabolite of phenacetin, was first used clinically in the United States in 1950. The well-known toxicity of phenacetin led to unfounded concerns about acetaminophen safety that delayed widespread acceptance of acetaminophen until the 1970s. Acetaminophen has since proved to be a remarkably safe drug at appropriate dosage, which has made acetaminophen the analgesic-antipyretic of choice in many circumstances. Acetaminophen is available alone in a myriad of single-agent dose formulations and delivery systems and in a variety of combinations with opioids, other analgesics, sedatives, decongestants, expectorants, and antihistamines.

The diversity and wide availability of acetaminophen products dictate that acetaminophen toxicity be considered not only after identified acetaminophen exposures but also after exposure to unknown or multiple drugs in settings of drug overdose, drug abuse, and therapeutic misadventures. The Toxic Exposure Surveillance System of the American Association of Poison Control Centers reports well over 100,000 calls to US poison centers each year resulting from potential acetaminophen exposures, and more hospitalizations are reported after acetaminophen overdose than after overdose of any other common pharmaceutic agent (Chap. 130).

Despite enormous experience with acetaminophen toxicity, many controversies and challenges are unresolved. In order to best understand the continuing evolution in approach to acetaminophen toxicity, it is critical to start with an analysis of certain fundamental principles and then to apply these principles to both typical and atypical presentations in which acetaminophen toxicity must be considered.

Pharmacology

Acetaminophen is an analgesic and antipyretic with weak peripheral antiinflammatory properties. Analgesic activity is

reported at a serum acetaminophen concentration ([APAP]) of 10 Âµg/mL and antipyretic activity at 4â€“18 Âµg/mL.

Antipyresis is mediated by central nervous system (CNS) inhibition of prostaglandin E_2 (PGE_2) synthesis via either direct inhibition of cyclooxygenase (COX)-2 or inhibition of membrane-associated PGE synthase.[10,93,104,148] PGE synthase inhibition may be a result of local reductions of glutathione concentrations initiated by conversion of APAP to reactive metabolites via the COX-2 enzyme.[104] Although binding and inhibition of COX-3 by APAP may have an antipyretic effect,[34,35,57] its clinical relevance remains unclear.[31,104]

The analgesic effect of acetaminophen is also mediated by its central inhibition of COX-2 and prostaglandin synthase and by possible indirect modulation of serotonergic pathways.[104] In animal models, several serotonin antagonists, as well as serotonin depletion, inhibit the analgesic effect of APAP.[2,30,192,193,230] This effect may be a result of decreased stimulation of serotonergic neurons from APAP-induced inhibition of prostaglandin synthesis.[104] Additional effects may be linked to indirect stimulation of descending opioid pathways.[212,213]

Although APAP functions as a central COX-2 inhibitor, it has mild peripheral antiinflammatory properties that are attributed to its mild inhibition of peripheral prostaglandin synthetase[96] and limited inhibition of peripheral COX.[64] APAP previously was considered a weak inhibitor of peripheral COX in general; however, its poor peripheral antiinflammatory properties more likely are the result of differences in receptor utilization (COX-1 and COX-2) in various cellular conditions.[103,104] In circumstances where peroxidase and arachidonic acid concentrations are low, such as in the CNS, prostaglandin is predominantly metabolized by COX-2,[178] and prostaglandin synthesis is blocked by APAP.[180] However, in peripheral inflammatory lesions, where peroxidase and arachidonic acid concentrations are elevated, COX-1 metabolism predominates,

and APAP is less effective in decreasing inflammation.[36,104,109]

Pharmacokinetics

Following oral ingestion, immediate-release acetaminophen is rapidly absorbed with a time to peak [APAP] of approximately 45 minutes.[4,77] Liquid acetaminophen has a time to peak of 30 minutes.[4,77] Extended-release acetaminophen has a time to peak of 1â€“2 hours but is almost entirely absorbed by 4 hours.[81] Time to peak is delayed by food[77] and coingestion of opioids or anticholinergic agents.[107,177] Oral bioavailability is 60â€“98%. Peak [APAP] after recommended dose ranges from 8â€“32 Âµg/mL. After administration of rectal suppositories in children, the time to peak [APAP] ranged from 107â€“288 minutes, with bioavailability of 30â€“40%. Peak [APAP] after single 20-mg/kg doses given rectally varied from 4.1â€“13.6 mg/L.[23] Acetaminophen has total protein binding of 10â€–30% that does not change in overdose.[167] APAP crosses both the placenta and the bloodâ€–brain barrier.[147]

First-pass metabolism removes 25% of a therapeutic dose. Once absorbed, approximately 90% of acetaminophen normally undergoes hepatic conjugation with glucuronide (40â€“67%) and sulfate (20â€–46%) to form inactive metabolites, which are eliminated in the urine.[231] A small fraction of unchanged acetaminophen (<5%) and other minor metabolites reaches the urine but is not thought to be clinically relevant.[204,231] The remaining fraction, which usually ranges from 5â€–15%, is oxidized by CYP2E1 (and, to a lesser extent, CYP3A4, CYP2A6 and CYP1A2),[114,159] resulting in the formation *N*-acetyl-*p*-benzoquinoneimine (NAPQI).[66] Glutathione quickly combines with NAPQI, and the resulting complex is converted to nontoxic cysteine or mercaptate conjugates, which are eliminated in the urine (Fig. 34-1).[166,173] The elimination half-life of acetaminophen is approximately 2â€–3 hours after a nontoxic dose[4,209] but may become prolonged in patients who develop hepatotoxicity.[209]

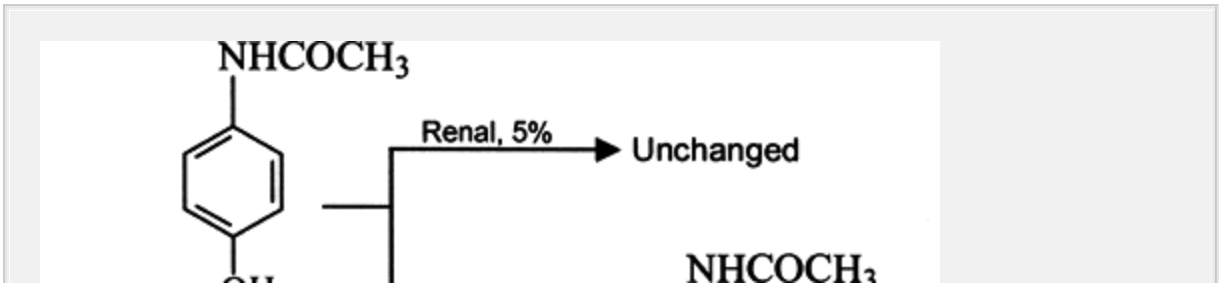
Biliary excretion is minimal, and breast milk contains <2% of the maternal dose.[184]

Toxicokinetics

Even after overdose, the majority of acetaminophen absorption occurs within 2 hours. Peak plasma concentrations generally occur within 4 hours, although later peaks are rarely documented in overdoses.[202,265] After clinically significant overdose, saturation of the normal nontoxic routes (sulfation) of metabolism becomes important in the development of toxicity.[200] The amount of NAPQI formed is increased out of proportion to the acetaminophen dose because maximal rates of sulfation are exceeded (see Fig. 34-1).[72] Glucuronidation, although initially believed to be saturatable, is likely only saturated in severely poisoned patients.[198] In addition to an increase in the formation of toxic metabolite, overall elimination is prolonged as normal metabolic systems become saturated.

An exact understanding of P450 metabolism, which is fundamental to assessing the relationship between ethanol or other

concomitant xenobiotic use and acetaminophen toxicity, continues to evolve. Evidence suggests that NAPQI production is largely the result of activity of the CYP2E1 enzyme following both therapeutic and supratherapeutic doses of APAP.[114,159] Contributions of CYP1A2, CYP3A4, and CYP2A6 to the production of NAPQI in humans are small and insignificant, but they may be variable depending on individual host factors and dosage.[114,188,214,262]



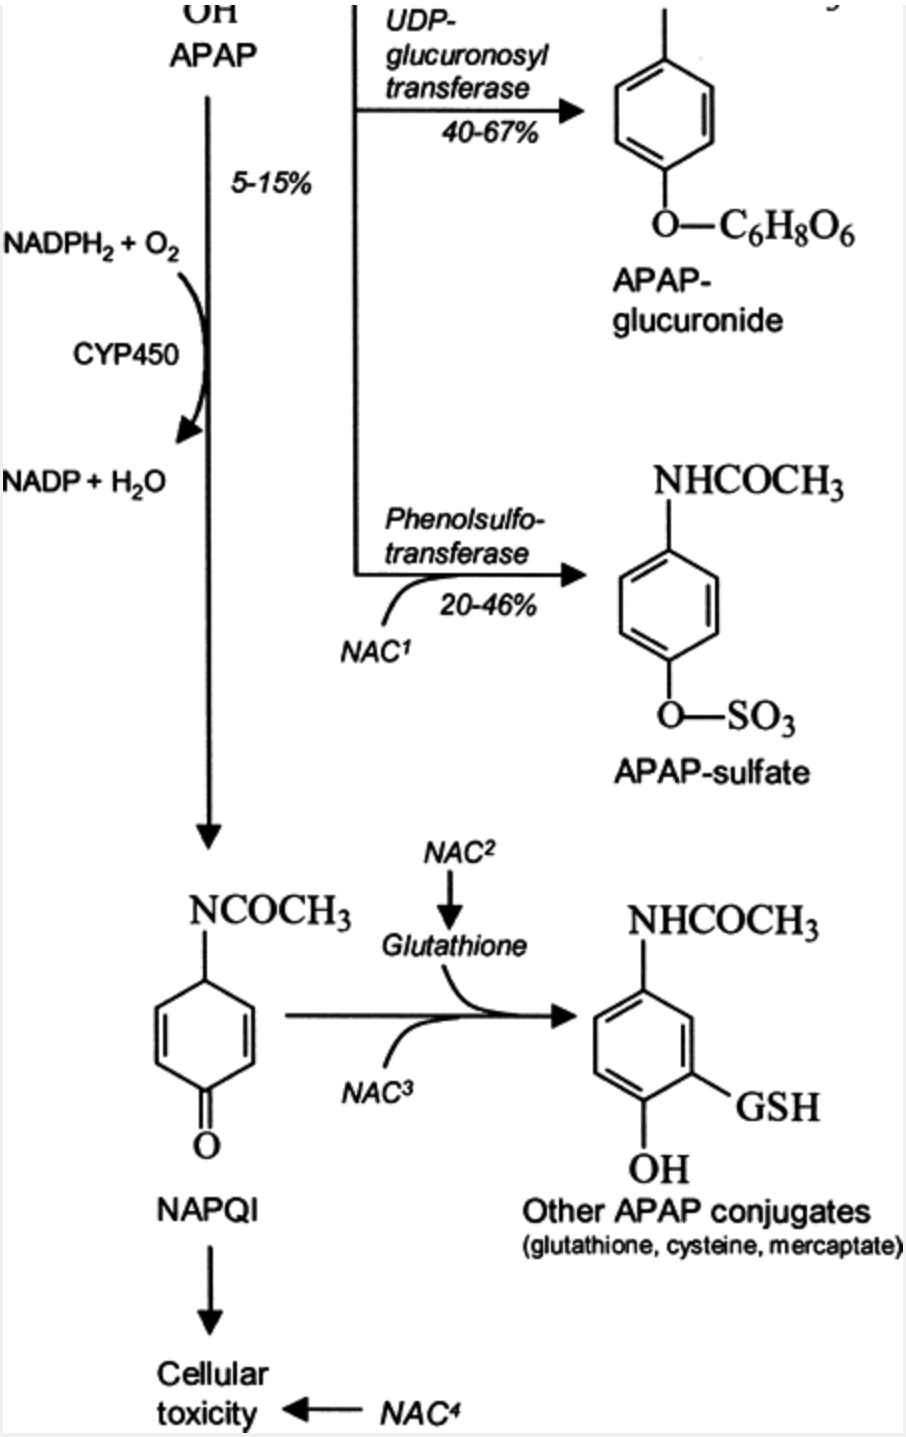


Figure 34-1. Important routes of acetaminophen metabolism in man and mechanisms of *N*-acetylcysteine (NAC) hepatoprotection. NAC[1] augments nontoxic sulfation. NAC[2] is a

glutathione (GSH) precursor. NAC[3] is a GSH substitute. NAC[4] improves multiorgan function during hepatic failure and possibly limits extent of hepatocyte injury. APAP = *N*-acetyl-*p*-aminophenol.

Pathophysiology

After the earliest reports,[70,257] a flurry of subsequent case reports, and the first reported series of acetaminophen toxicity,[154,209,210] an intensive research effort clarified the metabolic basis of both the pharmacologic safety and the toxicologic danger of acetaminophen (see Fig. 34-1).[125,171,172,196]

The safety of appropriate acetaminophen dosing results from the availability of electron donors such as reduced glutathione (GSH) and other thiol-containing compounds. After therapeutic acetaminophen dosing, GSH supply far exceeds that required to detoxify NAPQI, and no toxicity occurs. After overdose, the rate and quantity of NAPQI formation outstrip supply and regeneration of GSH, resulting in free NAPQI rapidly binding to hepatocyte constituents. In animal experiments of acetaminophen overdose, hepatic toxicity becomes evident only when hepatic GSH falls to â‰¤30% of baseline.[171] This affords acetaminophen a remarkably safe therapeutic index: A therapeutic acetaminophen dose is 10â€“15 mg/kg, whereas significant toxicity after a single acute overdose generally involves doses â‰¥150 mg/kg.[201]

Once NAPQI formation overwhelms the supply of thiol-containing compounds, it covalently binds and arylates critical cell proteins, inducing a series of events that result in cell death.[125] This covalent binding and arylation occurs rapidly after glutathione depletion and within hours of ingestion.[22,121,125,216] Once thought to be an irreversible process resulting directly from covalent binding of NAPQI, it now is clear that the events leading to cell

death are far more complex, and, most importantly, that the process can be prevented, interrupted, and even reversed after binding has occurred.[47,75,101,121,194,216]

Which, if any, single event is critical and commits the cell to death is unknown. NAPQI-induced oxidation of enzymes alters normal cell functions and impairs cell defenses against endogenous reactive oxygen species, resulting in further oxidation of vital proteins.[216,267] Selective arylation of critical cell proteins likely is more important than total covalent binding as a determinant of toxicity. Subsequent intracellular calcium dyshomeostasis[175,266] and lipid peroxidation[281] each has been demonstrated, but neither process is consistently required or sufficient to result in cell death.[45,106,110] Critical, possibly irreversible, events in cell death include DNA fragmentation[237] resulting from interactions with topoisomerase 2-Î±,[17] increases in mitochondrial permeability,[216] and mitochondrial injury,[78] but further work is required to reliably define the trigger(s) of acetaminophen-induced cell death. The final pathway of cell death may vary, with evidence for apoptosis early in APAP toxicity and direct necrosis later.[157,215] Macrophages, neutrophils, and inflammatory cells infiltrate after necrosis,[143] and destruction caused by secondary inflammation[295] and impairment of microcirculation[170] are demonstrated, although neither appears to be necessary for hepatic injury.[120,143,280]

Factors that may predispose patients to hepatotoxicity include increased frequency of acetaminophen dosing, prolonged duration of excessive dosing, increased capacity for CYP2E1 activation to NAPQI, decreased GSH availability, and decreased capacity for glucuronidation and sulfation. Potentially more important than the actual concentration of GSH or the activity of CYP2E1 is the balance of these two factors. Despite experimental evidence for all of the factors, clinical consideration of these factors is complex and controversial.

The pathophysiology of most organ dysfunction resulting from

acetaminophen toxicity results from the local formation of acetaminophen metabolites. Normally, most oxidative drug metabolism, and the majority of CYP2E1, is concentrated in hepatic zone III (centrilobular), and this zone is the first and the most profoundly affected by acetaminophen toxicity (Chap. 26). In more severe cases, necrosis may extend into zones I and II, destroying the entire liver parenchyma. In perhaps 25% of cases with significant elevated hepatic enzyme concentration, clinically evident renal injury also

occurs.[201] Evidence of mild renal injury may be evident even with little or no elevated aminotransferase concentrations after an acute overdose.[37] Renal CYP2E1 formation of NAPQI is the likely cause of acute proximal renal tubular necrosis after acute overdose;[43,87,117] however, several other nephrotoxic mechanisms are proposed.[113] Conversion of acetaminophen to nephrotoxic *p*-aminophenol[54] and renal conversion of hepatically derived acetaminophen-GSH,[174] both demonstrated in selected animal models, likely are not significant.[86,88,163] NAPQI formation via renal prostaglandin synthetase[274] or prostaglandin-mediated renal medullary ischemia[207] is also suspected of contributing to chronic analgesic nephropathy from acetaminophen alone or in combination with other analgesics.[97,217,229] Volume depletion and hepatorenal syndrome may be contributory cofactors.

Injury to other organs is rarely reported. Whether the etiology of these injuries is caused by local or circulating toxic metabolites is controversial. The mechanism causing myocardial damage, reported in some patients with acetaminophen-induced fulminant hepatic failure, is thought to be part of multisystem organ failure rather than being acetaminophen specific.[44,152] Pancreatic injury from acetaminophen, experimentally produced in mice, appears not to be the result of NAPQI formation,[94] and the paucity of human cases prevents analysis of the specific toxic mechanism. Glutathione depletion in rat brain[55] is suggested as a possible

cause of CNS effects of acetaminophen, but this finding is inconsistent,[21] and the mechanism of early manifestations of CNS depression associated only with massive acetaminophen overdoses is undefined. Similarly, an acetaminophen-induced metabolic acidosis may occur as an early manifestation after massive ingestion of APAP, typically in association with depression of mental status,[95,105,137,222,251] and may be a result of alterations in mitochondrial respiratory function.[51,91,253] The elevated anion gap acidosis may or may not be accompanied by lactic acidemia.

The remaining sequelae of severe toxicity are secondary effects of fulminant liver failure rather than direct acetaminophen effects, and the pathophysiology of these complex multisystem problems is well described.[144] The ability of NAC to ameliorate secondary multiorgan failure via extrahepatic mechanisms suggests that oxidation of vital thiols and loss of normal microvascular function are important components of secondary organ failure.[112]

Clinical Manifestations

Early recognition and treatment of patients with acetaminophen poisoning are essential in order to minimize morbidity and mortality. This task is made difficult by the lack of predictive clinical findings early in the course of acetaminophen poisoning, and clinicians should not be reassured by the absence of clinical symptoms shortly after ingestion. The first symptoms after acetaminophen overdose may be those of hepatic injury, which develop many hours after the ingestion when antidotal therapy will have diminished efficacy.

The clinical course of acute acetaminophen toxicity can be divided into four stages.[227] During *stage I* toxicity, hepatic injury has not yet occurred, and even patients who ultimately develop severe hepatotoxicity may be asymptomatic. Clinical findings, when present, are nonspecific and may include nausea, vomiting, malaise, pallor, and diaphoresis. Laboratory indices of liver

function are normal. In extremely rare cases of massive overdose, a decreased level of consciousness and metabolic acidosis may occur during this stage in the absence of signs or symptoms of hepatotoxicity.[95,137,222,251,293] These clinical findings should never be attributed to acetaminophen alone without thorough evaluation of other possible causes.

Stage II represents the onset of liver injury, which occurs in a fraction of those who overdose. When stage II occurs, onset is most common within 24 hours after ingestion but is nearly universal by 36 hours.[238] Symptoms and signs during stage II vary with the severity of liver injury but mimic other causes of hepatocellular injury such as infectious hepatitis. Aspartate aminotransferase (AST) is the most sensitive, widely available measure to detect the onset of hepatotoxicity, and AST abnormalities always precede evidence of actual liver dysfunction (prolonged prothrombin time [PT], elevated bilirubin concentration, hypoglycemia, and metabolic acidosis). Although uncommon, elevated AST concentrations may occur as early as 8â€“12 hours after ingestion in the most severely poisoned patients.[238] When discussing APAP, by convention *hepatotoxicity* is defined as a peak AST concentration >1000 IU/L. Although lower peak concentrations of AST represent some injury to hepatic tissue, they rarely have any clinical relevance.

Stage III, defined as the time of maximal hepatotoxicity, most commonly occurs between 72 and 96 hours after ingestion. The clinical manifestations of stage III include fulminant hepatic failure with encephalopathy, coma, or exsanguinating hemorrhage. Results of laboratory studies are variable: AST and alanine aminotransferase (ALT) concentrations >10,000 IU/L are common, even in patients without other evidence of liver failure. In fact, the highest reported ALT concentration caused by acetaminophen toxicity is >100,000 IU/L.[186] Much more important than the degree of aminotransferase concentration elevation, abnormalities of PT, bilirubin, glucose, lactate, and phosphate concentrations,

and pH indicate the degree of liver failure and are essential determinants of prognosis and treatment.

Fatalities from fulminant hepatic failure generally occur between 3 and 5 days after an acute overdose. Death results from either single or combined complications of multiorgan failure, including hemorrhage, acute respiratory distress syndrome, sepsis, and cerebral edema.[156] Patients who survive this period reach *stage IV*, defined as the recovery phase. Hepatic regeneration becomes complete in survivors. No cases of chronic hepatic dysfunction attributable solely to acetaminophen poisoning have been reported. The rate of recovery varies; in most cases, laboratory evaluation is normal by 5â€“7 days after an acute overdose. However, recovery may take much longer in severely poisoned patients, and histologic abnormalities may persist for months.[146,160,195]

Renal function abnormalities are rare overall[108,201] but occur in as many as 25% of patients with significant hepatotoxicity[69,208] and in >50% of those with hepatic failure.[156,285] Infrequently, mild renal insufficiency occurs without elevations in aminotransferase concentrations.[37] Renal abnormalities may be more common after sustained repeated excessive dosing.[203] When overt renal failure necessitating hemodialysis occurs, it nearly always does so among patients with marked hepatic injury.[53] In cases of acetaminophen-induced fulminant hepatic failure, the incidence of acute renal failure is nearly the same as among patients with hepatic failure of other causes.[285]

Serious clinical manifestations other than hepatic and renal injury are unusual. Electrocardiographic and histologic evidence of myocardial injury, first noted in early case reports,[63,190] is most often noted in patients with fulminant hepatic and multisystem failure, but never as an isolated problem.[152] Hyperamylasemia and pancreatitis[80,102] have been attributed to acetaminophen overdose

alone or in combination with ethanol abuse.[90] Clinical findings in these rare cases are typical of acute pancreatitis.

Diagnostic Testing

Assessing the Risk of Toxicity

Principles That Guide the Diagnostic Approach

Fatalities from acetaminophen overdose are common but preventable by timely diagnosis and treatment with NAC. At the same time, the overwhelming majority of acetaminophen exposures result in no toxicity. Therefore, an appropriate approach must avoid the enormous costs of unnecessary overtreatment while eliminating patient risk. To balance these seemingly divergent goals, the clinician must understand the basis for and sensitivity of current toxicity screening methods.

When considering risk determination, it is useful to separate different categories of acetaminophen exposure. There is an extensive body of experience and literature on acute overdose in typical circumstances, permitting a more systematic approach with demonstrated efficacy. For issues related to repeated excessive acetaminophen dosing, uncertain circumstances, patients with possible predisposition to toxicity, new acetaminophen formulations, and many other permutations, there is an important conceptual framework for decision making but little in the way of validated strategies. For these challenges, the central concepts and one approach are presented, with the understanding that they are dynamic and that more than one approach may have validity.

The clinician must rely solely upon the often unreliable ingestion history and measurement of [APAP] in the patient to assess the risk for subsequent toxicity and thus the need for treatment for

the following reasons: the amount and rate of NAPQI formation, the availability of hepatic GSH, the balance of NAPQI formation (CYP2E1 activity) and hepatic GSH supply, and the capacity for nontoxic metabolism are major determinants of toxicity.[169,225] Thus the ideal model for determining risk after acetaminophen overdose assesses each of these factors. At present, none of these measures is available to clinicians. The profile of urinary acetaminophen metabolites may reflect increased NAPQI formation,[72] but there is no indication that measurement is of any predictive value in any given case. Plasma GSH concentration can be measured but has an uncertain relationship to hepatic GSH availability.[246] Protein adducts, indicating binding of NAPQI to hepatocyte proteins, can be determined experimentally and are a marker of covalent binding[211,279] but are unlikely to prove useful as a screening measure. Because some degree of hepatocyte necrosis must precede the appearance of measurable serum adducts, the early warning value of the test is limited. Prior to actual hepatotoxicity, there are no reliable indirect measures of acetaminophen excess.

Risk Determination After Acute Overdose

Acute overdose usually is considered a single ingestion, although in fact many patients overdose incrementally over a brief period of time. For purposes of this discussion, an *acute overdose* is arbitrarily defined as one in which the entire ingestion occurs within a single 4-hour period. Figures of 7.5 g in an adult or 150 mg/kg in a child are widely disseminated as the lowest acute dose capable of causing toxicity.[7,151,201] These standards have stood the test of time as sensitive markers, but they are not based on human data and are quite conservative. Although there is wide interspecies variation in susceptibility to acetaminophen,[203] animal data suggest that a single dose of at least 15 g is required to cause consequential GSH depletion in a human adult.[173]

Higher dose cutoffs for consideration of risk would improve specificity; however, the value of improving specificity has not been weighed against the current, sensitive lower cutoff. In the face of an enormous variety of potential outliers, the near absence of screening failures almost certainly results from the use of these standards and of a very sensitive screening nomogram. The adult standard may be considered less controversial than that for children because massive ingestions, unreliable histories, and factors that might predispose to toxicity occur primarily in adults, justifying continued use of 7.5 g as a screening amount to avoid missing serious toxicity.

The dose history should be used in the assessment of risk only if there is reliable corroboration or direct evidence of validity. Therefore, dose estimates may be useful in determining risk in many cases of unintentional or therapeutic acetaminophen exposures, but this information is not sufficiently reliable in patients with attempted self-harm or drug abuse. When the history suggests possible risk, however, the reported dose is insufficient evidence on which to base treatment decisions; risk then should be assessed using determination of [APAP].

Interpretation of [APAP] after acute exposures is based on adaptation of the Rumack-Matthew nomogram (Fig. 34-2).[226] The original nomogram was based on the observation that untreated patients who subsequently developed AST or ALT concentrations >1000 IU/L could be separated from those who did not on the basis of the initial [APAP]. A nomogram was constructed that

plotted the ln [initial APAP] versus time since ingestion, and a discriminatory line was drawn to separate patients who developed hepatotoxicity from those who did not. The initial discriminatory line stretched from [APAP] of 300 Âµg/mL at 4 hours to 50 Âµg/mL at 12 hours but was lowered to between 200 Âµg/mL at 4 hours and 50 Âµg/mL at 12 hours after evaluation of additional patients.[225] The half-life of acetaminophen was not a factor in the

development of the nomogram, and the slope of the treatment line does not reflect any discriminatory APAP half-life or acetaminophen kinetics.[225] Although patients who develop hepatotoxicity tend to have half-lives greater than 4 hours,[206] use of a half-life to determine risk is not practical. At the time the nomogram was developed, acetaminophen absorption was known to be generally complete within 4 hours, so the nomogram does not begin until 4 hours after ingestion. The nomogram was later extrapolated to 24 hours using the same slope of the original nomogram line.[225]

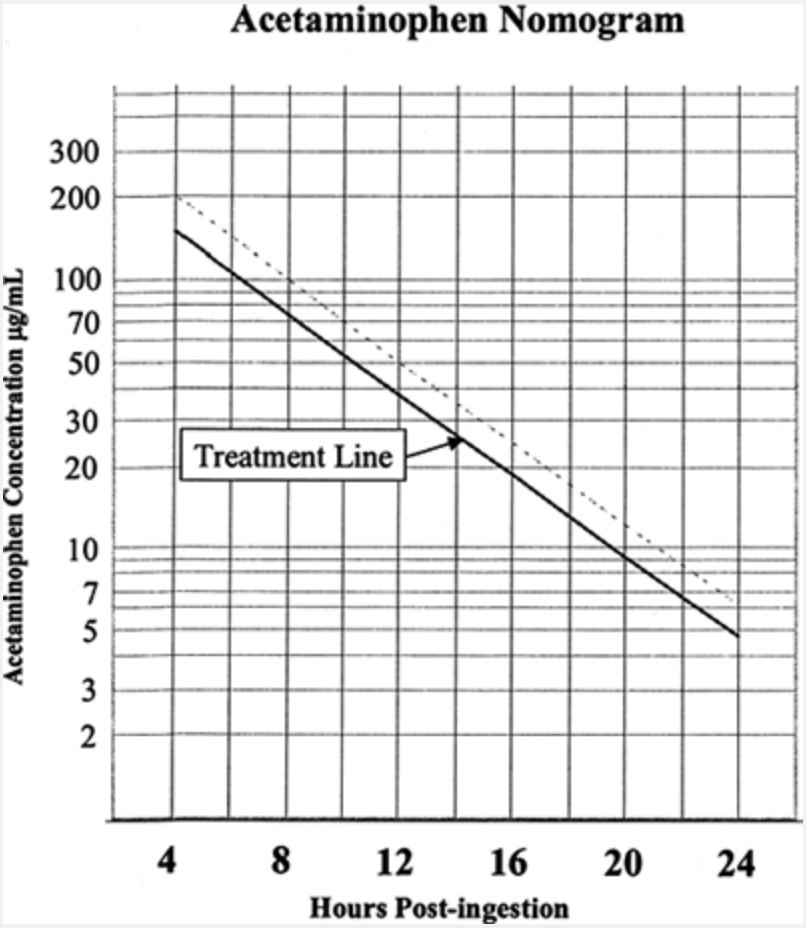

Figure 34-2. The Rumack-Matthew nomogram (reconstructed) for determining the risk of acetaminophen-induced

hepatoxicity following a single acute ingestion. Levels above the treatment line on the nomogram indicate the need for *N*-acetylcysteine therapy.

It is important to realize that the line was based on aminotransferase concentration elevation rather than on hepatic failure or death, and it was chosen to be very sensitive, with little regard to specificity. Without antidotal therapy, only 60% of those with an initial [APAP] above this original line will develop hepatotoxicity as defined by aminotransferase concentrations >1000 IU/L,[205] but the risk of hepatotoxicity is not the same for all such patients. Elevated aminotransferase concentration develops in virtually all untreated patients with [APAP] far above the line and serious hepatic dysfunction occurs frequently, whereas the incidence of hepatotoxicity among untreated cases with [APAP] immediately above the line is very low, and the risk of hepatic failure or death is far less.[201,205]

The original line is still used in the United Kingdom, Canada, Europe, Australia, and other locations. The line used in the United States runs parallel to the original but was arbitrarily lowered by 25% in order to add even greater sensitivity.[225,227] The lower line, subsequently referred to as the *treatment line*, starts at an [APAP] of 150 Âµg/mL at 4 hours postingestion; declines with a 4-hour half-life; and ends at 4.7 Âµg/mL, 24 hours after the overdose. The treatment line is one of the most sensitive screening tools used in medicine. The incidence of nomogram failures in the United States, using this line, is only 1â€“3% (depending on time to treatment) and most likely results predominately from inaccurate ingestion histories.[225] A vanishingly small number of anecdotal cases of nomogram failure involve special circumstances of increased risk,[59,162,179] questionable facts, or both.[241]

Cases of nomogram failure using the original line in the United

Kingdom are published. In some cases the patients described had no potentially predisposing factors,[46] and all had [APAP] above the *treatment line* and below the original line. Some authors suggest that the incidence of nomogram failures may be higher in the United Kingdom and recommend that the nomogram being used in the United Kingdom is not sensitive enough for patients with comorbid factors that potentially predispose to hepatotoxicity.[42,46,71,270] The validity of this observation is not adequately studied.

Based on these observations and more than 20 years of use, the treatment line should be considered an adequate screening device in nearly all cases and reliable when rigorously followed. When using the acetaminophen nomogram, it is essential to precisely define the time â€œwindowâ€• during which acetaminophen exposure occurred and, if the time is unknown, to use the earliest possible time as the time of ingestion. Using this approach, patients with [APAP] below the treatment line, even if only slightly so, do not require further evaluation or treatment for acute acetaminophen overdose. This also applies to most patients with factors that may predispose them to acetaminophen-induced hepatotoxicity. There appears to be adequate experience with acute acetaminophen overdose in the settings of potentially predisposing factors such as chronic alcohol abuse, chronic medication with CYP-inducing drugs, and inadequate nutrition to recommend that no special approach is required in such cases. Further study is needed to determine whether there are exceptions. Isolated case reports[179] suggest that chronic use of isoniazid, for example, may uniquely predispose patients to toxicity after acetaminophen overdose.[89,291]

The goal should be to determine [APAP] at the earliest point at which it will be meaningful in decision making. Measurement of [APAP] 4 hours after ingestion or as soon as possible thereafter is used to *confirm* risk of toxicity and thus the need to initiate NAC. There are no established guidelines for use of determinations

made less than 4 hours after ingestion, and because of variability in absorption such values will have less predictive value. Although it is optimal to start NAC therapy as soon as possible after confirmation of risk, most patients will have excellent outcomes if therapy is started earlier than 8 hours after the overdose.[243] Although this fact is not a license to delay the initiation of NAC treatment until 8 hours postingestion, it allows clinicians some leeway to wait for the laboratory results of [APAP] prior to starting therapy in patients in whom the history of ingestion suggests that concentration will fall below the treatment line. Factors that complicate diagnostic decision making after acute overdose include situations that prevent the return of an [APAP] measurement prior to 8 hours postingestion, inability to establish the time of ingestion, presentation more than 24 hours postingestion, and newer formulations of acetaminophen.

Only if the results of [APAP] determination cannot be obtained within 8 hours of the overdose should history alone be considered adequate to consider the patient at risk and as an indication to start NAC. In such cases, [APAP] still should be determined as soon as possible. The result, when it becomes available, should be interpreted according to the treatment line on the acetaminophen nomogram and NAC either continued or discontinued on the basis of this result. In the unusual circumstance where no determination of [APAP] can ever be obtained, evidence of possible risk by history alone is sufficient to initiate and complete a course of NAC therapy.

Early Measurement of [APAP]

Measurement of [APAP] between 1 and 4 hours after ingestion may be helpful only to exclude ingestion of APAP. If [APAP] is <10 Âµg/mL in this time frame, significant APAP overdose can be excluded. However, an [APAP] that is detectable between 1 and 4 hours cannot be interpreted and mandates a repeat [APAP] at 4

hours.

Determination of Risk When the Acetaminophen Nomogram is not Applicable

Risk Determined When Time of Ingestion Is Unknown

Another challenging variation on risk determination is the case where the time of ingestion simply cannot be determined. Although this is a common initial concern, it is unusual after thoughtful questioning of the patient, family, and others. It is almost always possible to at least establish a time window during which the exposure must have occurred and then use the earliest possible time as the time of ingestion for risk-determination purposes. If this time window cannot be established or is so broad that it encompasses a span of more than 24 hours, the following approach is suggested. Determine both [APAP] and AST concentration. If AST concentration is

elevated, regardless of [APAP], treat with NAC. If [APAP] is below the lower level of detection and AST concentration is normal, there is no evidence that subsequent consequential hepatic injury is possible and NAC is unnecessary. Although some authors speculate that subsequent liver injury could follow an interval during which [APAP] is negligible and AST concentration is normal, there are no documented cases of serious hepatotoxicity under these conditions. In all cases there has been either elevation of AST concentration and/or prolonged acetaminophen elimination resulting in a measurable [APAP] beyond 24 hours.

In the remaining cases in which the time of ingestion is completely unknown and [APAP] is detectable, it is prudent to assume that the

patient is at risk and to initiate treatment with NAC.

Risk Assessment After Extended-Release Acetaminophen

Previously, acetaminophen formulations were all immediate-release acetaminophen preparations, and exposures to these agents formed the basis for the nomogram and a successful diagnostic and therapeutic approach. An alternative extended-release formulation (Extended Relief Tylenol, Tylenol 8 Hour, Tylenol Arthritis Pain) consists of an outer 325-mg immediate-release acetaminophen dose and an inner 325-mg dose designed for delayed dissolution. These dissolution characteristics have given rise to concerns about whether the nomogram is an appropriate method for evaluating patients with suspected overdose of products containing this formulation.

The manufacturer initially recommended additional measurements of [APAP] if the 4-hour [APAP] was below the treatment line.[257] Treatment with NAC was recommended if the second value was above the treatment line. This approach was based on concern that an initial [APAP] below the line could be followed by a subsequent value above the line and place the patient at risk for hepatotoxicity. Critical evaluation of the available information confirms that such treatment line â€œcrossingâ€• is likely[56,271] in extended-release overdose and occurs in up to 10% of overdoses of immediate-release formulations.[49] However, despite intuitive concerns, there is no evidence of additional risk to the patient.

Reliance upon an initial [APAP] below the line that fails to detect a patient whose subsequent [APAP] is above the line is not the issue. What is important is whether reliance upon an initial [APAP] below the line would fail to detect a patient who subsequently might develop consequential liver injury. Although a single [APAP] will miss treatment line â€œcrossingâ€• because of limited early

absorption of acetaminophen and lack of late sustained elevations in [APAP],[56,81,252] such cases are very unlikely to place the patient at risk for toxicity. In addition, after ingestion of extended-release acetaminophen, absorption may be delayed but nevertheless is nearly complete at 4 hours.[56,81,252] The continued absorption likely will produce a 4-hour [APAP] that is higher than after ingestion of the same dose of immediate-release acetaminophen, making the treatment line more conservative than for immediate-release acetaminophen ingestions. Therefore, unless unusual circumstances are evident, a single [APAP] determination, plotted on the nomogram, should be adequate to exclude the need for antidotal therapy even after extended-release acetaminophen overdose. The validity of this conclusion requires ongoing evaluation, and any new type of extended-release acetaminophen formulation must be evaluated individually.

[APAP] Elimination Half-Life: Utility in Risk Assessment

Although it seems logical that the elimination half-life of acetaminophen would correlate with the risk of hepatotoxicity, serial [APAP] is not clinically useful in acute overdose for several reasons. First, even after massive overdose the half-life of acetaminophen is highly variable and may be less than 4 hours even in patients at risk for hepatotoxicity.[134] Second, the accuracy of determining a half-life using only two data points is variable because of the potential for multiplying inherent laboratory ranges in [APAP] testing. Finally, half-life testing adds little to the sensitivity of the nomogram. In one study, in order to equal the sensitivity of a single [APAP] plotted on the nomogram, a half-life cutoff of 2.5 hours or less would be necessary.[245]

Patients With Signs or Symptoms of Hepatic Injury After Acute Ingestion

Patients who present with signs or symptoms of hepatic injury after acute acetaminophen ingestion should be immediately started on NAC and measurements of AST concentration and [APAP] obtained. In patients with elevated AST concentration and [APAP] that is below the treatment line, the history should be reviewed with respect to the timing of ingestion and repeat excessive acetaminophen dosing. The patients should be thoroughly evaluated for causes of hepatic failure and for other causes of elevated AST concentration.

Risk Determination After Chronic Overdose Exposure

There are no well-established guidelines for risk determination after repeated acetaminophen exposures; nonetheless, careful interpretation of laboratory testing may make a relative risk assessment possible. In order to consider risk assessment after chronic APAP exposure, several factors must be considered. First, hepatotoxicity from repeated therapeutic dosing is remarkably rare given the extent of acetaminophen use. Second, therapeutic doses appear to be safe in most patients. Third, despite such patients representing only a small fraction of those using acetaminophen, nearly all reported cases of â€œchronicâ€• acetaminophen toxicity involve patients who ingested supratherapeutic doses and had factors that potentially predisposed them to acetaminophen-induced hepatic injury: infants with febrile illness who have received excessive dosing;[52,58,62,74,83,115,183,247,255] chronic alcohol users;[14,18,235,296] and patients taking CYP2E1-inducing medications chronically.[38,42] Short-term fasting is also suggested as a factor;[283] however, it is impossible to determine whether fasting was causal or was merely a marker of the severity of other associated conditions.

Conceptually, the groups that are at â€œhigh riskâ€• for hepatotoxicity after chronic overdosage of acetaminophen have

either potentially increased activity of CYP2E1, and therefore additional NAPQI formation, or decreased glutathione stores and turnover rate. However, these two risk factors cannot be taken in isolation because it is the balance of these two factors that determines the risk of hepatotoxicity. For example, malnourished patients have been theorized to be at high risk for hepatotoxicity after chronic overdosage of acetaminophen because of a decrease in glutathione stores.[283] However, evidence suggests that protein/calorie malnutrition leads to both decreased activity of CYP2E1[61] and decreased [GSH].[132] The interplay of these two factors in this and other conditions, and the impact on individual patients, is an important area of research.

Apart from these high-risk groups, the incidence of serious acetaminophen toxicity after repeated doses is negligible and appears to follow only massive dosing[68,145,153,161,278] or prolonged

excessive dosing.[20,38,41,68] Less serious hepatic abnormalities with atypical clinical or histologic features indicating other pathophysiologic mechanisms are reported at lower doses taken for months to years.[11,29,124]

The chronic ingestion of â€œmaximal therapeuticâ€• doses (4 g/d) in normal adults without the special circumstances appears to be safe. Several randomized controlled trials have used maximal therapeutic doses of APAP (4 g/d) in hundreds of patients over periods from 4 weeks to 2 years with no reported increase in adverse events or hepatic injury.[24,40,98,191,286] A short-term study of healthy patients given APAP 4, 6, and 8 g/d for 3 days found no alteration in APAP kinetics and no change in aminotransferases or creatinine.[99] Finally, several studies have evaluated recently abstaining chronic alcoholics administered APAP 4 g/d for 2â€“3 days without hepatotoxicity.[68,138]

Although recommended dosing of APAP appears to be safe, no

upper limit for safe repeated dosing has been established. Unlike acute dosing, not only is the total dose important but the interval between dosing and the duration of dosing also appears to be important. The interaction of an individual's CYP2E1 activity, and therefore NAPQI production, with the rate of glutathione turnover ideally should be considered as well but currently is not measurable. When interindividual variations such as CYP2E1 activity[100] and GSH supply and regeneration capacity[292] are considered, predicting the dose that will reach the critical threshold for development of toxicity becomes impossible.

Analysis is further complicated by the likelihood of unreliable information. A substantial proportion of cases of chronic toxicity involve parental dosing errors, iatrogenic errors, alcoholics, litigants in product liability cases, and other situations in which those providing the history may be unable or unwilling to accurately describe the dosing. Furthermore, because acetaminophen use is common after liver injury from alcoholism, acute infectious illnesses, and use of other medications with hepatotoxic potential, it is unclear in which cases acetaminophen is causative, contributory, or completely unrelated to hepatotoxicity. Analysis of these cases is further complicated because liver injury from any cause may lead to slowed metabolism and persistent elevation of [APAP]. Ultimately, resolution of this problem requires â€œgold standardâ€• laboratory markers of impending or actual acetaminophen-induced toxicity, but no such methods are yet available.

When there is concern about toxicity risk after repeated excessive acetaminophen dosing, several approaches are suggested. The goal should be to select patients at risk based on dosing history and other risk factors and then to use limited laboratory testing to determine the need for NAC. A logical screening laboratory evaluation consists of determination of [APAP] and AST concentration, with additional testing as indicated by these results and other clinical features. The objective is to identify the two

conditions that warrant NAC therapy: remaining acetaminophen yet to be metabolized and potentially serious liver injury. The predictive value of this approach depends almost entirely on proper selection of patients at risk.

Role of History and Physical Examination in Chronic Overdose

The first consideration when evaluating a patient with a history of repeated excessive acetaminophen dosing is the presence or absence of signs or symptoms of hepatotoxicity. Regardless of risk factors or dosing history, such findings should prompt treatment with NAC and laboratory evaluation. This is particularly important because most reported cases of serious toxicity after repeated dosing are symptomatic for more than 24 hours prior to diagnosis, and earlier diagnosis should improve outcome. In the asymptomatic patient, the next consideration should be the presence or absence of factors that potentially predispose the patient to toxicity. If no â€œhigh-riskâ€• factors are present, then asymptomatic adults who ingest 7.5 g or more in a 24-hour period should have laboratory evaluation. In fact, the adult dosing threshold for asymptomatic patients without potentially predisposing factors likely should be as high as 10â€“12 g in any 24-hour period, but a conservative approach is warranted.[68,155]

Despite the lack of verifiable data, logic and respect for anecdotal reports justify the use of a lower screening threshold in patients with potentially predisposing factors. Although some retrospective series and some reports from litigation suggest that toxicity can occur after recommended dosing,[233] this suggestion is not supported by other major studies or controlled trials with therapeutic and supratherapeutic APAP dosing.[24,40,68,98,99,138,191,286] Therefore, it is reasonable to use a history of a daily dose >4 g in adults or >90 mg/kg in children as a conservative cutoff for considering laboratory evaluation of

asymptomatic patients who are at *high risk.* The duration of dosing, any occurrence of large bolus dosing, presence of multiple potentially predisposing factors, and other features almost certainly affect risk, but until they can be adequately or quantitatively analyzed the lowest logical risk cutoff seems appropriate. These cutoff values (>4 g/d in adults and >90 mg/kg/d in children) are almost certainly substantially less than those required to cause toxicity,[155] but it is prudent to start from these sensitive cutoffs until better screening strategies are developed. This same approach should be used in patients who may be at high risk for hepatotoxicity from chronic overdosage of APAP, including chronic alcoholics, patients taking isoniazid, and infants and young children with febrile illnesses. Others deserving similar consideration include individuals with chronic malnutrition, AIDS, or other conditions that lead to GSH depletion.

Role of Laboratory Evaluation in Chronic Overdose

Using the strategy described here, patients with elevated AST concentrations are considered at risk, regardless of [APAP]. [APAP] is useful in patients with normal AST concentrations as a tool to determine only whether sufficient acetaminophen remains to lead to subsequent NAPQI formation and delayed hepatotoxicity. In some cases AST concentration is normal and [APAP] <10 Âµg/mL, obviating the need for NAC. Because no evidence in the literature or experience indicates that a patient with [APAP] <10 Âµg/mL and normal AST concentration developed consequential liver injury,[68] this value is appropriate as a sensitive cutoff to define the presence or absence of remaining acetaminophen. An alternative strategy that might increase specificity in reliable patients after repeated ingestions is to treat only patients with substantially elevated AST concentration (eg, 2 times normal) or elevated [APAP].[68] This strategy requires further study.

If AST concentration is normal, patients should be considered at risk if [APAP] is higher than expected. A definition of [APAP] that has a risk of hepatic injury is a concentration >10 Âµg/mL and higher than expected for an appropriate acetaminophen dose. After ingestion of a normal dose of acetaminophen, peak [APAP] should be <30 Âµg/mL 30â€“90 minutes after ingestion and <10 Âµg/mL 4â€“6 hours after ingestion. Patients who develop liver injury after chronic acetaminophen overdose should be evaluated and treated. Additional laboratory evaluation should include tests to assess hepatotoxicity and prognosis (creatinine, lactate, and phosphate concentrations, PT, and pH).

Determination of Risk Subgroups After Chronic Acetaminophen Exposure

Using a strategy that describes risk in a relative manner, we consider patients to be at *higher risk* in the following situations: AST concentration is more than twice normal even if the patient is asymptomatic; AST concentration is elevated and the patient is either symptomatic or [APAP] is >10 Âµg/mL; or [APAP] is higher than expected. In these cases, treatment with NAC is recommended. Patients who are asymptomatic and have less than expected [APAP] and a normal AST concentration or who have [APAP] <10 Âµg/mL and an AST concentration less than twice normal are considered *low risk.* Follow-up by telephone or by return visit in 24 hours is recommended for *low-risk* patients, who should be given discharge instructions to return immediately for any symptoms of hepatic injury such as nausea, vomiting, abdominal pain, and constitutional symptoms. Patients with normal AST concentration and [APAP] <10 Âµg/mL are at *minimal risk*, and NAC is not recommended. *Minimal-risk* patients should be instructed to return immediately if symptoms of hepatic injury arise. The theoretical patient with impending toxicity but without

signs or symptoms of toxicity, who might be missed by this approach, still can be detected in a timely manner by appropriate patient discharge instruction and follow-up.

Risk Determination After Acetaminophen Exposure in Children

Serious hepatotoxicity after acute overdose is less common in children than in adults, but whether this difference reflects relative hepatoprotection or merely results from differences in the characteristics of poisoning in children is unclear.[5] Serious hepatotoxicity or death after acute acetaminophen overdose is extremely rare in children.[9,27,150,224,258] When all cases with initial [APAP] above the treatment line are considered, the incidence of hepatotoxicity is lower in children younger than 5 years than in adults,[224] but there are insufficient documented pediatric cases with very high [APAP] or delays to NAC treatment to allow adequate comparison with adult data.

Among the several theories that have been advanced to explain the potential protection of children from acute acetaminophen-induced hepatotoxicity are the proportionately increased sulfation capacity[166] and glutathione supply in children;[140] however, no decrease in oxidation to NAPQI has been demonstrated in children,[273] and this proposed resistance remains controversial.

Although limited by methodology, studies advocate increasing the threshold acetaminophen dose requiring screening tests after pediatric acute overdose.[6,28] Similarly, because of the paucity of reported toxicity, some recommend screening children using the original, higher nomogram. Although both of these suggestions are statistically likely to be safe, currently we advocate continued use of 150 mg/kg as the risk-defining dose and use of the treatment line for [APAP] screening until valid data demonstrate that children are selectively protected or until accumulated experience with a

higher dose threshold for screening proves it to be safe.

Following excessive repeated acetaminophen dosing, there is no evidence that children are relatively protected. In fact, infants and children with acute febrile illnesses compose one of the few groups in which toxicity after repeated excessive dosing is well described.[52,58,62,74,83,115,116,183,219,247,255] Common sources of dosing errors include substitution of adult for pediatric preparations; substitution of drops (100 mg/mL) for elixir (32 mg/mL); overzealous dosing by amount or frequency in attempts to maximize effect; and failure to read the label and dose carefully.[5] It appears that age younger than 2 years is an independent risk factor for development of toxicity.[128] In almost all cases, the reported doses associated with toxicity are >150 mg/kg/d. Confounding factors make dose determination and acetaminophen attribution extremely difficult, particularly in reports of lesser dosing.

The frequency of toxicity after repeated excessive dosing in febrile children may simply reflect that these children constitute the most common setting for pediatric acetaminophen use and that children are at greater relative risk for excessive dosing because of their size. Although logically one can argue that inflammatory oxidant stress and short-term fasting during febrile infectious illnesses affect oxidative drug metabolism and decrease glutathione supply, these relationships are complex and not well defined. Of the reported cases of repeated excessive APAP dosing in children, hepatic injury likely was the result of infectious illness in some, acetaminophen in others, and both in still others.[3]

Risk Determination After Acetaminophen Exposure in Pregnancy

The initial risk of toxicity of a pregnant patient is similar to that of a nonpregnant patient, with a few exceptions. Little evidence

suggests that any alteration of the treatment line is necessary. In fact, there are no reported cases of fetal or maternal toxicity in women with [APAP] below the treatment line[164] or in those treated with NAC within 10 hours of an acute ingestion.[218] However, there is controversy in assessing the risk of fetal toxicity once the mother is determined to be at risk. In order to better understand the issues, a review of maternal-fetal physiology and pharmacokinetics related to APAP and NAC is necessary.

Acetaminophen is capable of crossing the human placenta,[12,147,182,220] and APAP may be present in concentrations that are similar to maternal serum concentrations within hours after ingestion.[12,182,220] Fetal metabolism of APAP probably is inefficient but is not completely understood. Fetal sulfation and oxidative metabolism of APAP are slower than in adults, and glucuronidation is undetectable until 23 weeks of gestation.[221] P450 enzymes that are capable of oxidizing APAP are present in the fetus as early as 18 weeks.[221] However, the activity of these enzymes is <10% that of adult enzymes at 18 weeks and increases to only 20% activity at 23 weeks.[221] How the opposing forces of decreased overall metabolism of APAP and decreased NAPQI formation impact fetal risk is unclear.

The mechanism of fetal risk in patients with [APAP] over the treatment line remains controversial. The degree of fetal toxicity that is attributable to fetal metabolism of APAP or to maternal illness is unclear. In clinical case series, the majority of pregnant women who overdose on APAP have uneventful pregnancies.[164,218] Pregnant women who develop APAP toxicity in the first trimester have an increased risk of spontaneous abortion,[218] and those who develop APAP toxicity in the third trimester have a potential risk of fetal hepatotoxicity because of fetal metabolism. However, reports of third-trimester fetal hepatotoxicity are rare[164,218] and are only associated with severe maternal toxicity.[218,277] The factors associated with poor fetal outcome after large APAP overdose are delayed treatment with NAC and early gestational age.

The decision to treat a pregnant woman with NAC requires consideration of what is known about the efficacy and beneficial effects as well as the adverse effects of NAC for both fetus and mother. There is every indication that NAC is both safe and

effective in treating the mother,[218] but there are inadequate data to evaluate efficacy in the fetus, although fetal outcome has generally been excellent after maternal treatment with oral NAC.[218] Given that NAC has been safely used in many pregnancies[164,218] and fetal mortality is linked to delays to treatment, NAC should be initiated in pregnant women whose [APAP] is over the treatment line. The necessary length of NAC therapy is difficult to determine. Although the 20-hour IV protocol probably is the most common NAC protocol used for pregnant women worldwide, there is a paucity of *published* experience with NAC treatment courses shorter than the oral 72-hour protocol.[164,218]

Ethanol and Risk Determination

The effects of ethanol on acetaminophen toxicity are complex and best described by clearly separating experimental animal data from actual human overdose experience, acute from chronic ethanol abuse, and single from repeated excessive acetaminophen dosing. Although not entirely consistent, most animal data indicate that simultaneous administration of ethanol with acetaminophen may be somewhat hepatoprotective,[263,269] presumably because ethanol competitively inhibits CYP2E1, preventing metabolism of acetaminophen to NAPQI. Chronic ethanol administration in animal models, however, increases the risk from acute acetaminophen dosing[149,235,269] on the basis of induced CYP2E1 metabolism of acetaminophen and/or decreased mitochondrial GSH supply or regeneration.[141,294] In humans who ingest APAP after recent abstinence from ethanol, NAPQI formation may increase by up to

22%.[261]

After acute acetaminophen overdose, these factors appear to be of little importance.[223,244,264] There is no evidence that chronic ethanol use should alter the approach after an APAP acute overdose. Because of the potential failure of the higher original nomogram to adequately screen alcoholics and those chronically taking P450 inducers, some authors suggest using a much lower standard.[59,71,270] However, there is only one reported case of nomogram â€œfailureâ€• in an alcoholic using the treatment line, and the actual events of the case are unclear.[59,241] Furthermore, unpublished data from a large series revealed no difference in incidence of hepatotoxicity among groups identified as chronic-acute (or acute-on-chronic ethanol users) and ethanol nonusers.[244] These observations indicate the treatment line is adequately sensitive for screening after an acute APAP overdose, regardless of the patient's pattern of ethanol use.

The relationship between chronic ethanol use and chronic APAP use is complex. Hepatotoxicity has been sporadically reported in patients with chronic ethanol abuse after repeated excessive acetaminophen dosing.[14,18,235,296] Complicating these reports are the clinical challenges of obtaining accurate histories in alcoholics, failure to exclude non-APAP causes of hepatotoxicity, and other factors. Evidence demonstrates minimal risk of hepatotoxicity in alcoholic patients who ingest therapeutic doses of APAP.[26,138] These trials were performed on recently abstaining alcoholics who theoretically have maximal CYP2E1 induction without inhibition of acute ethanol intake.[261] There was no increased risk of elevated AST concentration (although 40% of controls developed mildly elevated AST concentration <120 U/L) or hepatotoxicity in patients treated with APAP 4 g/day compared to the control group. Given the prevalence of both ethanol and acetaminophen use, further studies with the power to detect lower incidence of adverse effects are needed.

P450 Inducers and Risk Determination

Inducers of the P450 group of enzymes have long been theorized to increase the risk of toxicity from APAP because of a proportionally increased production of NAPQI.[226] A more refined knowledge of the hepatic enzyme systems has provided increasing evidence that enzyme induction of only specific subgroups of the P450 system is responsible for any increase in NAPQI production in humans.

Because APAP is metabolized to NAPQI largely by CYP2E1,[114,159] only induction of this enzyme is thought to increase the risk of hepatotoxicity. Ethanol and isoniazid are known inducers of CYP2E1 and hence may lead to increased NAPQI production during excessive chronic APAP use. As noted previously in the case of ethanol, there is no evidence that P450 inducers should alter the approach to acute ingestion of APAP, and the treatment line can be applied without modification for patients with acute overdoses of APAP who take these medications.

Several other medications, including phenytoin, carbamazepine, and phenobarbital, had been theorized to increase APAP toxicity because of nonspecific P450 induction activity. However, these medications do not induce CYP2E1 and, hence, are not expected to increase the risk of hepatotoxicity after APAP overdose. Evidence of any increased risk as a result of coingestion of phenytoin, carbamazepine, and phenobarbital has been inconclusive and largely based on animal data.[25,82,171,197] Clinical data, although scant, suggest that these medications are not factors that increase toxicity.[268]

Assessing Actual Toxicity: Critical Components of the Diagnostic Approach

Earlier protocols and guidelines recommended extensive and ongoing laboratory assessment after acetaminophen overdose.[151,227] Based on the pathophysiology and time course of toxicity, a simplified and far more cost-effective approach is logical.

Initial Testing

[APAP] should be measured in patients with acute acetaminophen overdose and no evident hepatotoxicity, but no other initial laboratory assessment is required. AST concentration should be measured in patients considered to be at risk for APAP toxicity according to the nomogram or history (in the case of repeated excessive dosing) or in those suspected of already having mild hepatotoxicity by history and physical examination. The first AST determination serves as a screen to detect preexistent hepatic dysfunction, which may indicate the patient requires closer monitoring. Also, as mentioned, AST determination serves as a key component of decision making after repeated excessive dosing and other unusual circumstances.

Unless evidence of serious hepatotoxicity is present, AST concentration is sufficient indication of hepatic conditions, and no additional testing is initially needed. Death of hepatocytes, resulting in release of measurable hepatic enzymes, precedes all cases of serious liver dysfunction. Even if abnormalities of other markers precede elevation of AST concentration, there is no evidence that their detection benefits the patient.[16] Mild renal toxicity may rarely occur without hepatotoxicity;[37] however, at least minimal elevation of AST concentration generally precedes evidence of clinically significant nephrotoxicity.[1,65] Exceptions are rare,[37,55,131,208] and routine screening of renal function in the absence of elevated AST concentration probably is unnecessary.

Acetaminophen overdose may lead to minor prolongation of PT even without causing hepatotoxicity.[284] This most commonly

occurs between 4 and 24 hours after ingestion and may be a result of

NAPQI-related inhibition of vitamin K-dependent Î³-carboxylation of factors II, VII, IX, and X.[260,284] These minor prolongations (resulting in PT that usually is less than twice control) are rarely clinically relevant, are not evidence of hepatotoxicity, and should not be used as prognostic factors or indications for NAC treatment. In fact, treatment with NAC may prolong PT[122,136] by interfering with the PT assay, by reversing an APAP/NAPQI effect,[260] or by direct NAC effects.[260] Clinical interpretation of these minor prolongations of PT is clouded by preexisting conditions, treatment with NAC, and laboratory error. Even in cases where PT is prolonged, if consequential liver injury does develop, elevation of AST concentration precedes serious liver dysfunction.

Ongoing Monitoring and Testing

If no initial elevation of AST concentration is noted, repeated AST determination aloneâ€”without other biochemical testingâ€”every 24 hours until completion of treatment is sufficient to exclude the development of hepatotoxicity. If elevated AST concentration is noted, then PT and creatinine concentration should be measured and repeated every 24 hours or more frequently if clinically indicated. Results of other liver tests, such as Î³-glutamyltransferase, alkaline phosphatase, lactic acid dehydrogenase, and bilirubin, which are useful when determining the etiology of liver abnormalities, will be abnormal in cases of serious acetaminophen-induced hepatotoxicity but provide little additional useful information if the etiology is certain.

If evidence of actual liver failure is noted, then careful monitoring of blood glucose, creatinine, phosphate, and lactate concentrations and acidâ€“base status are important in assessing extrahepatic organ toxicity and are vital in assessing hepatic function and the

patient's potential need for transplant (see Assessing Prognosis). In addition, meticulous bedside evaluation is necessary to detect and document vital signs, neurologic status, and evidence of bleeding. Many additional tests may be useful in the setting of liver failure, based on clinical condition and local protocols. Testing for other rare acetaminophen-associated conditions by electrocardiogram, lipase determination, or other studies should be performed on a case-by-case basis only.

Management

Limiting Gastrointestinal Absorption

In cases of very early presentation or coingestion of agents that delay gastrointestinal (GI) absorption, gastric emptying may be appropriate for some patients. In general, however, gastric emptying is not a consideration for patients with isolated acetaminophen overdose because of the very rapid GI absorption of acetaminophen and the availability of an effective antidote.

Administration of activated charcoal shortly after APAP ingestion appears to decrease the number of patients who have [APAP] above the treatment line.[48] Although activated charcoal is most effective when given within the first 1â€“2 hours after APAP ingestion, it may be reasonable to give activated charcoal any time prior to 4 hours postingestion as long as no contraindications exist. Significant concerns that activated charcoal may bind to orally administered NAC and decrease its effectiveness have been expressed, but these concerns are unfounded for several reasons.

In most cases, there should be no interaction because GI absorption of APAP is complete by 4 hours after ingestion, prognosis is determined by 4 hours after ingestion, and NAC typically is administered between 4 and 8 hours after ingestion. As a result, there generally is no difficulty separating the doses.

If delayed or repeated activated charcoal dosing is indicated because of suspected delayed absorption or because of coingestants, then a strategy using an IV NAC protocol should be strongly considered. Alternatively, if time (to start NAC) permits, separating oral NAC and activated charcoal doses by 1â€“2 hours is logical, as long as this timing can be accomplished safely. NAC is rapidly absorbed high in the GI tract and is unlikely to interact with activated charcoal if the doses are not administered simultaneously. However, NAC treatment should not be delayed by the activated charcoal dose because time to administration of NAC correlates with risk of hepatotoxicity.

In unusual cases, as a result of coingestants and timing of presentation, it may be important to administer NAC and activated charcoal simultaneously. To avoid any interaction, intravenous NAC should be used in these circumstances whenever possible. However, in cases where only oral NAC is available, the theoretical concern of an interaction probably is not clinically relevant. Although there is clear in vitro evidence of binding between activated charcoal and NAC[60,133,228,259] and volunteer data suggest that activated charcoal causes statistically significant decreases in NAC absorption,[85] there is no evidence that this interaction is clinically significant.[249]

Supportive Care

General supportive care consists primarily of controlling nausea and vomiting and managing the hepatic injury, renal dysfunction, and other manifestations. Treatment of these problems is based on general principles and is not acetaminophen dependent. Discussion of the management of liver failure is clearly beyond the scope of this chapter, but certain aspects deserve mention. Monitoring for and treatment of hypoglycemia as a result of liver failure are critical, as hypoglycemia is one of the most readily treatable of the life-threatening effects of liver failure. If adequate viable

hepatocytes are present, vitamin K may produce some improvement in coagulopathy; thus, trial dosing is logical as liver injury develops and as it resolves. Administration of fresh-frozen plasma (FFP) should be based on specific indications rather than PT alone.

One of the most important advances is use of prolonged NAC for treatment of fulminant hepatic failure. Parenteral NAC, other advances in supportive care, and successful liver transplantation programs appear to have substantially improved survival from APAP-related liver failure.[155]

Antidotal Therapy with NAC

Mechanism of Action of NAC

Conceptually, it is helpful to think of NAC as serving three distinct roles. During the metabolism of acetaminophen to NAPQI, NAC *prevents toxicity* by limiting the formation of NAPQI. More importantly, it *increases the capacity to detoxify* NAPQI that is formed (see Fig. 34-1). In fulminant hepatic failure, NAC *treats toxicity* through nonspecific mechanisms that preserve multiorgan function.

NAC prevents toxicity by serving as a glutathione precursor, leading to increased GSH availability.[139] NAC can also serve as a GSH substitute, combining with NAPQI and being converted to cysteine and mercaptate conjugates, just as GSH is converted.[50] NAC may also lead to increased substrate for nontoxic sulfation, allowing increased metabolism by this route and less metabolism by oxidation to NAPQI.[239] Each of these preventive mechanisms

must be in place early, and none is of benefit after NAPQI has initiated cell injury. Time is required to saturate nontoxic metabolism from excessive NAPQI, deplete GSH, and overcome GSH production; thus there is a window of opportunity after

exposure to an APAP overdose during which NAC can be initiated prior to the onset of liver injury, without any loss of efficacy. Based on large clinical trials, it appears that NAC efficacy is nearly complete as long as it is initiated within 8 hours of an acute overdose.[130,242,243] The efficacy of NAC almost certainly decreases with time even prior to 8 hours postingestion. Existing data support that short delays in NAC initiation, such as those that might result from GI decontamination (oral NAC only) or while awaiting results of [APAP] determination, pose little risk to the patient as long as NAC can be started within 8 hours of overdose. Despite this finding, however, the relationship between time to administration of NAC and the risk of hepatotoxicity should be considered a continuous variable,[250] with the risk of hepatotoxicity rising at some time near 8 hours postingestion. For this reason, NAC therapy should not be unnecessarily delayed until 8 hours if it can be safely administered earlier.[199]

Several observations illustrate the effectiveness of NAC by other mechanisms of action even after NAPQI formation and binding. NAC actually reverses NAPQI oxidation in both a mouse model[66] and an in vitro human hepatocyte model.[157] In a large clinical trial of the 18-dose oral NAC protocol,[244] the severity of hepatotoxicity among high-risk patients first treated with NAC between 16 and 24 hours after overdose was far less than had been observed in untreated historical controls or patients treated with the 20-hour IV NAC protocol.[205] More recent use of the 20-hour IV NAC protocol has suggested it also may be effective in treating late (16â€“24 hour after ingestion) APAP toxicity.[48] Other experimental work demonstrates that even after cell injury is initiated, late interventions could diminish hepatocyte injury.[47] Most significantly, a prospective, randomized trial found that even after fulminant hepatic failure was evident, starting IV NAC diminished the need for vasopressors and the incidences of cerebral edema and death.[129]

These dramatic findings were accompanied by a fascinating

observation: despite improved organ function and survival in the NAC-treated group, there was no apparent difference in the degree of hepatic injury. Elevations of enzyme concentration and prolongation of PT were equivalent in the two groups, suggesting that much of the benefit of NAC may not be derived from decreasing hepatic injury. Initial investigations supported this hypothesis, showing that oxygen delivery and utilization were enhanced by NAC.[76,112,248] Although this proposed mechanism of action has been challenged,[126,275,276] no subsequent studies have reevaluated or negated the impact of NAC on outcome.

Whether based on its nonspecific antioxidant effects, its ability to enhance GSH supply, or, more likely, its role in mediating microvascular tone, NAC improves function in several organs affected by multisystem failure.[67,76,272] As a result, NAC may be the agent of choice for cerebral edema after liver failure according to one study.[282] Even with aggressive hemodynamic treatment, hemodialysis, and use of widely available blood products, cerebral edema remains the most feared and most lethal manifestation of liver failure. In this setting, NAC may preserve cerebral blood flow and perfusion better than traditional therapies such as mannitol and hyperventilation, which may actually be detrimental.

Intravenous Versus Oral Administration

As with many issues related to acetaminophen toxicity, the choice of oral versus intravenous NAC is complex. Available information suggests each has advantages and disadvantages, and each may be more appropriate than the other in certain settings. Because no controlled side-by-side studies have compared IV and oral NAC, conclusions about relative benefit of each are largely speculative.

With the exception of established liver failure, for which only the intravenous route has been investigated, intravenous and oral NAC administration are equally efficacious in treating acetaminophen toxicity.[49,199] Initial concerns about the apparent superiority of

oral NAC over IV NAC when started 16â€“24 hours after overdose have been resolved by data showing equivalent results between the two protocols.[49] Any difference in outcome for these patients almost certainly is related to the duration and dose of NAC therapy rather than the route itself. The decision of which route to use should be dependent on the rate of side effects, safety, and ease of use and not efficacy.

Safety is the best understood of these issues. Oral NAC clearly has fewer severe side effects than IV NAC. Nausea and vomiting, sequelae of APAP ingestions, are typically present prior to NAC administration and occur in approximately half of patients treated with oral NAC. Diarrhea is prevalent, but there is no credible evidence of more serious complications resulting from oral NAC.[165] Reports of skin rash and unusual complications are rare.[176] In contrast, intravenous NAC is associated with a 17% rate of anaphylactoid reactions, most of which are mild but of which 1% are severe.[130] The anaphylactoid reactions, which typically are minor, include rash, flushing, vomiting, and bronchospasm,[13,130,240] but in rare instances they may lead to hypotension and death.[8,15,73,79,92,127,158,240,289] These reactions are attributed to both dose and concentration of NAC. However, although reaction rate may be decreased by using a more dilute NAC solution[127,130,289] and despite decreased adverse events after slowing NAC infusions in some studies,[49] prolongation of the loading infusion from 15 to 60 minutes did not decrease anaphylactoid rate significantly (from 18% to 14%) in one prospective study.[130] Minor reactions, such as rash, generally do not require treatment, rarely recur, and do not preclude administration of subsequent NAC doses.[13,240,289] Even when urticaria, angioedema, and respiratory symptoms develop, they usually are easily treated, and NAC can be subsequently restarted with a very low incidence of recurrence.[13] Although proper dosing of IV NAC is very safe, IV NAC nevertheless must be considered more dangerous than oral NAC because of the risk of dosing

errors. An additional safety concern with use of intravenous NAC is the potential problem associated with concomitant infusion of large volumes of free water to pediatric patients, in some instances leading to hyponatremic seizures.[254]

The main disadvantage of the oral formulation of NAC is the high rate of vomiting and the concern that vomiting may delay therapy.[199] Delays in administration of NAC are correlated with an increased risk of hepatotoxicity.[243] The intravenous route avoids an increased rate of vomiting in patients who typically are already nauseated and avoids the use of high-dose antiemetics that may alter mental status. Another potential disadvantage of oral NAC is that its absorption may be delayed up to 1 hour compared to IV NAC.[118] However, although short delays in delivery of NAC to the liver are probable in some instances, the equivalent rates of hepatotoxicity in patients treated with oral and IV NAC early after APAP ingestion[49,205,243] suggest the delays associated with the oral route may not be clinically relevant. Oral NAC doses may be difficult to administer to patients with alterations of mental status because of the risk of aspiration, so IV NAC offers a distinct advantage in these instances.

One theoretical, albeit unproven, advantage of oral NAC early in the course of toxicity is that direct delivery via the portal circulation yields a higher concentration of NAC ([NAC]) in the liver. Because of this first-pass clearance, oral NAC results in circulating [NAC] 20- to 30-fold lower than after IV dosing, suggesting that most oral NAC ended up in the liver.[32,118] However, elevated serum [NAC] may be an advantage of intravenous NAC administration when the liver is not the target organ of NAC, as with cerebral edema or in pregnancy.

Lower costs of care are emphasized as an advantage of oral NAC, particularly in the United States where the IV formulation is more expensive than the generic oral formulation.[142] Additional savings

include a potential reduction of inpatient costs related to IV care and monitoring. However, the shorter course of the IV NAC protocol (20 hours vs. 72 hours) significantly decreases the length of hospital stay and may significantly decrease the overall cost of care.

Historically, prior to the current intravenous formulation in the United States, the oral formulation had been used intravenously for years with an excellent safety profile[84,127,289] and without published evidence of infectious or febrile consequences.[33,84,127] This intravenous use of the oral formulation for this purpose is not generally recommended but is historically effective and may be necessary in cases where only the oral formulation is available and the patient has intractable vomiting or acetaminophen-induced hepatic failure.[142]

Specific Indications for IV NAC

In addition to decisions based on cost, duration, safety, and ease of use, three situations exist for which the available information suggests IV NAC is preferable to oral NAC: fulminant hepatic failure, inability to tolerate oral NAC, and acetaminophen poisoning in pregnancy. Each requires further study for validation, but all three seem well supported by current information.

Fulminant hepatic failure is an important indication for IV NAC. The choice of IV over oral NAC is based on several observations. Most importantly, IV is the only route that has been studied in liver failure. Oral NAC may prove effective but has not yet been demonstrated. Second, evidence that (some or all of) the benefit of NAC in liver failure is extrahepatic suggests that IV NAC is preferable. Intravenous NAC results in higher blood [NAC], which presumably leads to more NAC delivery to critical organs. Finally, concomitant GI bleeding, use of lactulose, and other factors make IV NAC more practical.

A more common indication for IV NAC use is for the patient with a

very high [APAP] who is approaching or is more than 8 hours from the time of ingestion and who is unable to tolerate oral NAC after a brief aggressive trial of antiemetic therapy. Use of IV NAC is logical to prevent further delays and resultant loss of NAC efficacy, even without proof that continued vomiting significantly limits NAC absorption.

The most controversial indication for IV NAC use is during pregnancy. Administration of IV NAC to the mother has the theoretical advantage of increased delivery to the fetus over oral NAC use. Intravenous administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations with IV dosing. Some studies have suggested that placental transfer of NAC to the fetus is limited.[123,236] However, one case series found that [NAC] in cord or neonatal blood after oral maternal NAC administration equaled the [NAC] seen in patients treated with oral NAC.[119] Of course, equivalent serum [NAC] does not prove adequacy of therapy. Unlike the neonates studied, patients treated with oral NAC have extensive first-pass hepatic uptake prior to NAC entry into the serum where [NAC] was measured.[32,118] Whether serum [NAC] in the neonates studied reflects any significant hepatic NAC delivery is uncertain.

Duration of NAC Treatment

Known mechanisms of action and the observation that all studied durations of NAC are effective, when started within 8 hours,[49] suggest that all courses of treatment currently published are effective when NAC is used for its early preventive actions. All available information indicates the conceptual basis for discontinuing NAC should be the completion of acetaminophen metabolism and the absence or resolution of consequential liver injury.[135] Once these conditions can be assured, discontinuation of NAC therapy is appropriate. Results from use of the traditional 20-

hour IV NAC protocol,[205] 48-hour and 36-hour IV NAC protocols studied in the United States,[187,240] one oral 20-hour protocol,[290] and other â€œshort-courseâ€• dosing protocols[287,288] indicate that all therapies are safe and effective in patients treated within 8 hours of an acute ingestion.[256,288]

Regardless of the protocol initiated (20-hour IV, 72-hour oral, 48-hour IV, 36-hour IV), [APAP] and AST concentration should be measured at the completion of the course, and NAC therapy should be continued beyond the prescribed protocol time if there is evidence of significant liver injury (AST concentration greater than normal) or acetaminophen metabolism is incomplete ([APAP] >10 Âµg/mL). This likely will not be an issue in the vast majority of cases, as the aminotransferases of approximately half of all NAC-treated patients with [APAP] above the treatment line will remain <100 IU/L.[242] In addition, patients with late rises in AST concentration should be detected even when the 20-hour protocol is used, as the 20 hours is measured as infusion time and so is typically 26â€“28 hours after the ingestion. This time frame should be adequate to detect early elevations of AST concentration that lead to significant hepatotoxicity, although this theory has not been adequately tested.

Both the oral NAC data and the liver failure study seem to confirm the importance of longer duration of NAC when treating already established liver injury. The IV NAC dosing protocol that has proved beneficial in liver failure is the same initial dosing as the 20-hour IV protocol, but with the IV infusion continued until resolution of liver failure. These observations suggest that, rather than a single duration of therapy for all patients, it is appropriate to extend treatment protocols based on the clinical course of the patient.

Once NAC therapy is extended beyond a set-length protocol, the decision to discontinue therapy should be entirely based on the patient's condition. For patients who develop liver failure, IV NAC

is continued until PT is near normal and encephalopathy, if present, is resolved.[155] For patients without liver failure but with elevated AST concentration, NAC is often continued until all liver abnormalities resolve (AST concentration is decreasing and <1000 U/L).

Assessing Prognosis

The availability and success of liver transplantation after acetaminophen-induced liver failure create an important need for early prognostic assessment. Survival without transplantation is certain if AST concentration is normal at the time of NAC initiation.[243] However, although this method identifies patients at the lowest risk, no accurate means of identifying early in the course those who will not survive without transplant are available. Earlier reports described poor prognostic features that are sensitive but have inadequate specificity and are based on

findings that develop too late in the course of toxicity to be useful.[63] Efforts to determine earlier or more specific markers of poor prognosis have improved our understanding; however, accurate early prediction of the need for transplant remains one of the greatest challenges related to acetaminophen toxicity.

A method for predicting hepatic encephalopathy has been developed using the time until treatment with NAC, decrease in PT, and early thrombocytopenia as markers.[232] These data are used to determine the prognostic index and subsequently the probability of hepatic encephalopathy. Although not predictive of the need for transplant alone, this prognostic tool may be clinically useful to determine patients in need of transfer to specialty care units. Hepatic encephalopathy requires increased supportive care, monitoring for progression of liver failure, and assessment for liver transplantation.

One strategy for prognostication that uses a combination of clinical

features of fulminant hepatic failure is the *King's College Hospital criteria.* The single criterion of pH <7.30 after fluid and hemodynamic resuscitation or the combination of PT >100 seconds, creatinine >3.3 mg/dL, and grade III or IV encephalopathy is predictive of a patient who will die without transplant.[155,185] Any patient who meets or approaches these criteria should be considered for transplant.

Blood lactate concentration may be used as a single marker to predict the need for transplantation. A blood lactate concentration >3.5 mmol/L at a median of 55 hours after APAP ingestion or blood lactate concentration >3.0 mmol/L after fluid resuscitation was shown to be both a sensitive and a specific predictor of patient death without transplant.[19] Whether earlier blood lactate concentrations are predictive remains to be studied.

An Acute Physiology and Chronic Health Evaluation (APACHE) II score >15 in isolated APAP ingestions may be as specific as the above Kings College Hospital criteria and slightly more sensitive.[168] These criteria may be beneficial in determining whether to transfer a patient to a transplant center because the score is easily calculated, is sensitive, and is available within the first days of admission; however, confounders such as coingestants may decrease its utility.

Other prognostic strategies use only the coagulation profile in an attempt to simplify the approach and, more importantly, to allow earlier intervention. Using this approach, a markedly abnormal PT that continues to rise on the fourth day after overdose indicates a very poor prognosis.[111] In most cases, however, other criteria of poor prognosis are evident by that time. For earlier screening, other authors suggest that any patient with a PT in seconds that exceeds the number of hours since ingestion should be considered at extreme risk.[181] Attempts to correlate individual clotting factor concentrations or ratios show promise but appear to offer no benefit over the use of PT alone.[39,189]

Interpretation of PT must include awareness of therapy with vitamin K or FFP. Use of vitamin K does not confuse interpretation. Vitamin K therapy, if effective, implies that transplant may be unnecessary because viable liver remains. If vitamin K is ineffective, PT can be used as discussed in the previous paragraph. Transfusion of exogenous clotting factors, such as FFP, alters interpretation because improvement in PT may not indicate improvement in liver function. Depending on the volume of factors transfused, the subsequent decline in factors must be considered when interpreting PT values. The prognostic importance of monitoring PT in this setting suggests that FFP should be given only with evidence of bleeding, with risk of bleeding from known concomitant trauma, or prior to invasive procedures, and not based merely on the PT value. Since survivors regenerate normal liver, no long-term laboratory monitoring is indicated after return to adequate function is demonstrated.

Another approach to predicting poor prognosis uses the serum phosphate concentration at 48 hours after ingestion and may be particularly helpful in determining the need for transplant or transfer to a transplant center early in the course of APAP hepatotoxicity. A serum phosphate concentration >1.2 mmol/L (3.75 mg/dL) on day 2 (48â€“72 hours) was both sensitive and specific for predicting patients who either received a transplant or died[2,3,4] of APAP hepatotoxicity. The elevation in phosphate concentration correlates with early acidosis and renal impairment. The predictive value of this test is based on the concept that serum phosphate concentration increases with early renal impairment, whereas a liver with regenerative capacity uses the phosphate for regeneration of adenosine triphosphate and hepatocytes. In patients who lack hepatic regenerative capacity, the phosphate remains elevated.[2,3,4]

Summary

Several key concepts will help the clinician effectively manage acetaminophen exposures. When managing intentional overdoses, measurement of [APAP] should be considered part of the patient's initial evaluation. In cases where risk assessment for acetaminophen toxicity is merited, treatment with NAC should be initiated as soon as possible and ideally within 8 hours from the time of ingestion. IV NAC should be preferentially used in cases of fulminant hepatic failure or intractable vomiting and in pregnant patients. Otherwise, the efficacy of the oral and IV formulations should be considered the same. Patients who present after repeated excessive APAP dosing should be assessed for evidence of hepatic injury and for the possibility of ongoing production of NAPQI. Factors that potentially predispose patients to hepatotoxicity after repeated dosing should be taken into account when deciding which patients to assess further for hepatic injury.

Patients showing evidence of severe hepatotoxicity or hepatic encephalopathy and those at risk for fulminant hepatic failure may require admittance to the ICU. All of these patients require frequent neurologic checks, monitoring of vital signs, and additional and repeated laboratory studies. Consultations with a regional poison center, gastroenterologist (or hepatologist) consultant, and regional transplant center are important to guide treatment strategies and to coordinate transplantation when needed. Early psychiatric consultation can be helpful in assessing transplant eligibility. Absolute indications for transplantation vary and should be discussed early with the appropriate local transplant center, poison control center, and hepatologist(s).

Although our understanding of acetaminophen toxicity has advanced significantly and additional therapeutic modalities (primarily IV NAC) have become more widely available, many important challenges remain. Development of an entirely new method of toxicity screening to accurately determine the risk of toxicity in atypical patients, high-risk patients, and those who present after repeated excessive dosing of APAP is needed.

Ongoing study of antidotal therapy dosing protocols is needed to assess the validity of many assumptions. Most importantly, improved methods to determine the indication for liver transplantation early after APAP ingestion are desperately needed. These and other issues predict that further changes are likely. Hopefully, the principles and current strategies

presented in this chapter will serve as a strong foundation for these important future advances.

N-acetylcysteine (NAC) is the cornerstone of therapy for patients with potentially lethal acetaminophen overdose. If administered early in the course of exposure, NAC can prevent significant acetaminophen-induced toxicity. Later, it can ameliorate toxicity. NAC also has a role in limiting toxicity caused by glutathione depletion and free radical formation, such as from carbon tetrachloride, chloroform, pennyroyal oil, and possibly valproic acid.[17,25,26,93] Finally, NAC is useful in the management of fulminant hepatic failure caused by toxicologic and nontoxicologic etiologies. Its beneficial effects are also under investigation in

critically ill patients with a variety of stress-induced disorders,[46,83,90] perhaps in the prevention of further renal impairment in patients with chronic renal insufficiency administered a radiographic contrast agent, and in those with hepatorenal syndrome.[32,33,76,86] Furthermore, NAC is potentially beneficial following exposure to certain metals such as cobalt.[45]

History

Shortly after the first case of acetaminophen hepatotoxicity was reported, Mitchell and coworkers described a protective effect of glutathione.[52,73] Prescott et al.[59] first suggested the use of *N*-acetylcysteine (NAC) for acetaminophen poisoning in 1974. Early experiments demonstrated that NAC could prevent acetaminophen-induced toxicity in mice when treatment was initiated within 4.5 hours of ingestion and that the oral and intravenous (IV) routes were equally efficacious when treatment was initiated within 1 hour of ingestion.[58] Mitchell et al.,[52] Prescott et al.,[59,62] and Rumack and Peterson[74] performed human research with oral and IV NAC in the 1970s. The United States Food and Drug Administration approved oral NAC in 1985 and IV NAC in 2004.

Cysteamine, methionine, and NAC, which are all glutathione precursors or substitutes, have been used successfully to prevent hepatotoxicity, but cysteamine and methionine both produce more adverse effects than does NAC therapy, and methionine is less effective than NAC. Therefore, NAC has emerged as the preferred treatment.[63,78,87]

Background: Toxicology

Ninety percent of a therapeutic dose of acetaminophen is metabolized to nontoxic glucuronide (approximately 60%) and sulfate (approximately 30%) conjugates.[60] Only 4% is metabolized by the cytochrome P450 mixed-function oxidase system (3A4 at

low doses; 2E1 predominantly at high doses)[51] to the potentially toxic reactive intermediate *N*-acetyl-*p*-benzoquinoneimine (NAPQI). This intermediate is conjugated with glutathione to form nontoxic cysteine and mercapturic acid conjugates. After acetaminophen overdose, both the fraction and the total amount of drug undergoing P450 metabolism increase, leading to glutathione depletion, binding of the highly reactive intermediate, liberation of reactive oxygen and nitrogen species, and resultant centrilobular hepatic necrosis.[18,35,64] It is postulated that the ensuing oxidative stress causes mitochondrial and other damage to cardiac, pulmonary, and hepatic tissues (Chap. 12).[9,27,64,79] NAC is a thiol-containing compound that is deacetylated to cysteine, a thiol-containing amino acid that is used intracellularly in addition to the amino acids glycine and glutamate to synthesize glutathione.[72] The availability of cysteine becomes the rate-limiting step in the synthesis of glutathione, and NAC is effective in replenishing diminished supplies of cysteine.

Mechanism of Action

When administered shortly following acetaminophen ingestion, NAC acts to prevent toxicity. Later in the clinical course, NAC modifies the subsequent xenobiotic-induced inflammatory response. NAC effectively prevents acetaminophen-induced hepatotoxicity if it is administered before glutathione stores are depleted to 30% of normal. This level of depletion occurs approximately 8 hours after toxic acetaminophen ingestion.[62,70,81] NAC acts as a precursor for the synthesis of glutathione,[41] as a substrate for sulfation,[80] as an intracellular glutathione substitute by directly binding to NAPQI,[15] and by enhancing the reduction of NAPQI to *N*-acetyl-*p*-aminophenol (APAP).[41]

After NAPQI covalently binds to hepatocytes,[70] NAC modulates the subsequent cascade of inflammatory events in a variety of ways.[29] The inflammatory damage can occur in many tissues. Antioxidants

function as electron donors and are oxidized preferentially to relatively less reactive and destructive species.[9] Examples of endogenous antioxidants include vitamins C and E and reduced

glutathione. Glutathione protects cells against electrophilic compounds by acting as both a reducing agent and an antioxidant.[72] Glutathione replenishment may protect against further cell damage but is incapable of completely restoring damaged tissues. In this second stage, NAC may act directly as an antioxidant; act as a reservoir for thiol groups; increase nitric oxide synthase to improve blood flow by combining with nitric oxide to form the potent vasodilator *s*-nitrosothiol; increase formation of essential endogenous antioxidants such as glutathione; and increase substances depleted by the oxidant stress such as endothelium-derived relaxing factor.[23,29] In this manner NAC can modulate the oxidative stress and inflammatory cascade while improving oxygen delivery and extraction in extrahepatic organs such as the brain, heart, and kidney.[46,76,83]

Clinical Use

If the patient's history suggests an acute acetaminophen ingestion â‰¥150 mg/kg and the results of blood tests will not be available within 8 hours of ingestion or if the serum [APAP] falls on or above the treatment line on the Rumack-Matthews nomogram, NAC should be instituted expeditiously. Aspartate aminotransferase and APAP concentrations should be determined in adults with chronic overdoses who ingest more than the recommended maximum daily dose of 4 g or children who ingest more than 90 mg/kg/d and are at high risk (increased NAPQI formation or reduced glutathione stores). NAC should be administered when hepatotoxicity is manifest by symptoms or liver enzyme elevations (Chap. 34). Interpretation of acetaminophen concentrations in these chronic overdoses is difficult, and the acetaminophen nomogram can never be applied.

Some patients who are at increased risk for acute or chronic acetaminophen poisoning may require administration of NAC at a lower threshold. Unfortunately, this threshold is not yet defined. Glutathione-deficient patients who are malnourished, have chronic alcoholism, or are receiving CYP2E1-inducing agents such as isoniazid or ethanol may theoretically be at increased risk for acetaminophen toxicity.[12,30,42,81] However, an analysis of a small number of patients who received anticonvulsants or chronically ingested alcohol did not demonstrate these patients to be at risk independent of acetaminophen dose.[49,82] Also currently no data indicate the need to lower the threshold when evaluating a patient with hepatic enzyme abnormalities.[82]

Pharmacokinetics

When administered, NAC is present in plasma in the reduced or oxidized state and is either free or bound with other thiols such as NAC-cysteine. NAC is metabolized to many sulfur-containing compounds such as cysteine, glutathione, methionine, cystine, disulfides, and conjugates.[23,56,61] Thus the pharmacokinetic study of NAC is complex.

Oral NAC is rapidly absorbed, but the bioavailability is low (10â€“30%) because of significant first-pass metabolism.[23,61] NAC has a relatively small volume of distribution (0.5 L/kg), and protein binding is 83%. Serum concentrations after IV administration of an initial loading dose of 150 mg/kg over 15 minutes reach approximately 500 mg/L.[61] A steady-state plasma concentration of 35 mg/L (10â€“90 mg/L) is reached in approximately 12 hours with the standard IV protocol.[61] Its elimination half-life is 5.7 hours. Severe liver damage does not appear to affect NAC elimination.[61]

Conflicting in vitro[16,39,75] and in vivo[14,22,54,66] data regarding the concomitant use of activated charcoal suggest that the resultant

bioavailability of NAC is either decreased or unchanged. This interaction is of limited importance now that IV NAC is available.

Oral NAC is being studied as a potential chemopreventive agent. Pharmacokinetics and pharmacodynamics of oral NAC were determined in a phase I trial in 26 adult volunteers at risk for development of cancer or recurrent cancer.[56] Absorption of NAC is rapid, with a mean time to maximum peak concentration of 1.4 Â± 0.7 hours and a mean elimination half-life of 2.5 Â± 0.6 hours that is linear with increasing dose up to 3200 mg/m^2/d given as a single daily dose. Intersubject plasma NAC concentrations vary 10-fold from a maximum concentration of 1.7â€“20.8 mg/L at a dose of 800 mg/m^2/d. Chronic administration leads to a decrease in plasma concentrations from a C_{max} of 8.9 mg/L at the end of 1 month to 5.1 mg/L at the end of 6 months.[56]

Oral Versus Intravenous *N*-Acetylcysteine

Although these approaches have never been directly compared, they appear to confer equal protection when either is administered within 8 hours.[95]

The 20-hour IV NAC protocol is 150 mg/kg loading dose over 15 minutes, followed by an additional dose of 50 mg/kg over 4 hours and then 100 mg/kg over 16 hours for a total dose of 300 mg/kg. The 72-hour regimen is 140 mg/kg loading dose followed by 70 mg/kg for 17 additional doses for a total dose of 1330 mg/kg. Both protocols are effective in preventing hepatic damage when given within 8 hours of acetaminophen ingestion.[62] A 48-hour IV regimen studied in the United States appears to be superior to the 20-hour regimen when the first dose is delayed until 16â€“24 hours after ingestion.[81] The 72-hour oral NAC regimen also appears superior to the 20-hour IV NAC protocol when started 16â€“24 hours postingestion. Perhaps most patients who receive

their first dose of NAC within 8 hours require only the short course because the inflammatory cascade is not initiated, whereas patients whose treatment is delayed benefit from a longer course of therapy and the associated benefits of the antiinflammatory/antioxidant effects of NAC. Some authors recommend a 36-hour oral course in low-risk patients with careful evaluation and follow-up, but this recommendation has not been adequately studied.

Only the IV route has been studied in hepatic failure.[28,38] The IV route achieves higher serum concentrations than the oral route. It is unclear whether oral or IV dosing results in superior drug delivery to the liver and whether the higher hepatic concentrations enhance drug efficacy.[57] The oral route often produces vomiting and requires antiemetics to complete therapy, but it is not usually associated with other serious adverse effects. Theoretically higher serum concentrations may be helpful for extrahepatic effects, whereas the oral route might provide higher intrahepatic concentrations.

We now recommend IV NAC for all adult patients without asthma[4] or other contraindication to IV NAC and in whom an anaphylactoid reaction would not be devastating. In children who do not tolerate oral NAC, IV NAC may be acceptable. However, the appropriate dilution of IV NAC in children is problematic. Currently, the package insert only provides dosing information down to a patient weight of 40 kg.[1] Hyponatremia is possible and has

been reported in a 13-kg child receiving the adult IV dosing volume (1700 mL), leading those authors to suggest a final concentration of NAC of approximately 4% in 5% dextrose in water (D_5W) to avoid the administration of excess free water and the potential for hyponatremia.[85] However, the pH of Acetadote (acetylcysteine injection, Cumberland Pharmaceuticals, Nashville, TN) is adjusted close to neutral where NAC is stable, resulting in an osmolarity of approximately 2600 mOsm/L for the 20%

solution. Therefore sodium concentrations and fluid requirements must be meticulously monitored. A 2% final NAC concentration in D_5W of Acetadote is approximately 485 mOsm/L and may be more appropriate.

Use in Pregnancy and Neonates

Untreated acetaminophen toxicity is a far greater threat to the fetus than is NAC treatment.[68] The risk of not treating pregnant women almost certainly far exceeds any potential risk to the developing fetus if a toxic ingestion has occurred. Although an earlier sheep model suggested otherwise, human data demonstrate that NAC traverses the placenta and produces cord blood concentrations comparable to maternal blood concentrations.[34] NAC is Food and Drug Administration (FDA) Pregnancy Category B. Limited data exist with regard to the management of neonatal acetaminophen toxicity,[5,43,71,77] although IV and oral NAC have been used safely.[1,5] No adverse effects were observed when preterm newborns were treated with IV NAC[1] (Chaps. 30 and 34). The elimination half-life of NAC in preterm neonates was 11 hours compared to 5.6 hours in adults.[1] IV administration has the advantage of assuring adequate antidotal delivery. Oral administration in general is associated with necrotizing enterocolitis in neonates.

Other Uses (Nonâ€“Acetaminophen)

Diverse investigations of NAC as a treatment for a number of xenobiotics associated with free radical or reactive metabolite toxicity are reported. Some of these xenobiotics include chloroform, carbon tetrachloride, 1,2-dichloropropane, acrylonitrile, doxorubicin, and cyclophosphamide.[17,23,89,93]

NAC is under study as a chemopreventive agent against amatoxins cancer, lung injury, cardiac injury, radiographic contrast

exposure,[86] and malnutrition.[2,20,21,46,72,83,84] NAC has extracellular antimutagenic effects, enhances repair of nuclear DNA damaged by carcinogens, and inhibits malignant cell invasion and metastases.[21,55,65] Oral NAC added to prednisone and azathioprine preserves vital capacity in patients with idiopathic pulmonary fibrosis.[21a]

Rescue NAC therapy is being studied with high-dose acetaminophen (â‰¤20 g/m^2) in patients with advanced malignancies.[40] Use of NAC in these settings may further enhance our understanding of the beneficial effects of NAC in both the early and late phases of acetaminophen poisoning.

Adverse Effects and Safety Issues

Oral NAC may cause nausea, vomiting, flatus, diarrhea, gastroesophageal reflux, and dysgeusia; generalized urticaria occurs rarely. Anaphylactoid reactions described after IV NAC dosing[3,10,11,19,24,31,48,50,61,67,88,91] are not noted after oral therapy and may be related to rate, concentration, or high serum NAC concentrations.[8,61]

Administration of oral NAC via the IV route produced cutaneous reactions in 4 of 76 patients and a generalized anaphylactoid reaction in 1 patient. None of these patients developed adverse hemodynamic effects.[94]

The IV route assures delivery, but rate-related anaphylactoid reactions are possible. Although the package insert for Acetadote recommends infusing the loading dose over 15 minutes, many authors, including ourselves, believe that infusion over 1 hour reduces the potential for life-threatening anaphylactoid reactions.[48] The manufacturer categorizes the number of anaphylactoid reactions occurring in 109 patients receiving the 15-minute loading dose as mild 6%, moderate 10%, and severe 1%.[1] Although similar findings are listed for the 60-minute loading dose

infusion, problems with study design cast doubt on these findings.[1,96] Of the adverse events occurring in more than 2000 patients who received IV NAC, vasodilation, rash, and pruritus account for approximately 10%, hypotension 4%, bronchospasm 6%, and angioedema 8%.[1]

If angioedema or an anaphylactoid reaction characterized by hypotension, shortness of breath, or wheezing, flushing, or erythema occurs, NAC should be stopped and standard symptomatic therapy instituted. Once the reaction resolves, NAC can be carefully readministered after 1 hour assuming NAC is still indicated. If the reaction persists or worsens, discontinue IV NAC and consider switching to oral NAC. Adverse reactions confined to flushing and erythema usually are transient, and NAC can be continued with meticulous monitoring for systemic symptoms that indicate the need to stop the NAC. Urticaria can be managed with diphenhydramine with the same precautions.[7]

Iatrogenic overdoses with IV NAC have resulted in comparable adverse events.[3,6,50] IV NAC decreases clotting factors and increases the prothrombin time in healthy volunteers and overdose patients without hepatic damage.[36,47,53,92] This effect occurs within the first hour, stabilizes after 16 hours of continuous IV NAC, and rapidly returns to normal when the infusion is stopped.[36] Because the prothrombin time is used as a marker of the severity of toxicity and is one of the criteria for transplantation, this adverse effect of NAC should always be considered when evaluating the patient's condition. An elevated prothrombin time without other indicators of hepatic damage probably is related to the NAC.

Dosing

The manufacturer recommends a loading dose of 150 mg/kg in 200 mL of D_5W (for adults) infused over 15 minutes, followed by a first maintenance dose of 50 mg/kg in 500 mL D_5W (for adults) infused

over 4 hours followed by a second maintenance dose of 100 mg/kg in 1000 mL D_5W (for adults) infused over 16 hours. We recommend infusing the loading dose over 60 minutes.

The appropriate dilution of IV NAC in children is problematic. Currently, the package insert only provides dosing information down to a patient weight of 40 kg.[1] Because of issues with osmolarity, sodium concentrations, and fluid requirements, meticulous monitoring is required. A 2% final NAC concentration in D_5W is approximately 485 mOsm/L and may be acceptable until further information becomes available.

When NAC is administered orally, the patient should receive a 140-mg/kg loading dose either orally or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg should be given every 4 hours for an additional 17 doses. The solution should be diluted to 5% with a soft drink to enhance palatability. If any dose is vomited

within 1 hour of administration, the dose should be repeated[44] or IV delivery used. Antiemetics (such as metoclopramide or a serotonin antagonist) should be used to ensure absorption. If the acetaminophen concentration is above the nomogram line, the standard approach is to administer 72 hours of therapy. Shorter courses may be acceptable (Chap. 34).

If hepatic failure intervenes, IV NAC should be administered at a dose of 150 mg/kg in D_5W infused over 24 hours and continued until the patient has a normal mental status (or recovers from hepatic encephalopathy),[29] the patient's international normalized ratio (INR) becomes <2.0,[69] or the patient receives a liver transplant.[13,28,38] Before the FDA approval of Acetadote, NAC approved for oral administration was administered by the IV route, often while using a 0.22-Âµm filter as a delivery precaution.[37,94] We would no longer recommend this practice except under unique circumstances.

Availability

Acetadote (NAC) is available as a 20% concentration in 30-mL single dose vials designed for dilution prior to IV administration. NAC for oral administration is available in 10-mL vials of 10% and 20% for oral administration.

Case

A 22-year-old woman came to the emergency department

complaining of abdominal pain, nausea, and vomiting. She had a history of depression but stated that she currently was not being treated by a psychiatrist or taking any psychiatric medications. Upon further questioning, the patient said that 6 hours earlier she had been severely depressed and had ingested at least half a bottle of aspirin tablets in a suicide attempt, after which she vomited once. She denied tinnitus but said that she was short of breath. She denied significant past medical or surgical problems.

On physical examination, the patient appeared to be well developed, well nourished, and diaphoretic. Vital signs were: blood pressure, 120/60 mm Hg; pulse, 110 beats/min; respiratory rate, 30 breaths/min; rectal temperature, 100.2Â°F (37.9Â°C). Examination of the head, eyes, ears, nose, and throat was unremarkable. The neck was supple, and there was no jugular venous distension. The chest was clear to auscultation and percussion. Cardiac examination revealed normal heart sounds and no murmurs, rubs, or gallops. Bowel sounds were normal, but the abdomen was diffusely tender, without guarding; stools were negative for occult blood. There was no clubbing, cyanosis, or edema. The patient was alert and fully oriented. No cranial nerve abnormalities were noted; deep tendon reflexes were intact and symmetric with plantar flexion of the toes; motor and sensory testing was normal.

An intravenous catheter was inserted. Blood was drawn and sent for determination of blood urea nitrogen (BUN), glucose, and electrolyte concentrations, complete blood count, coagulation studies, and salicylate and acetaminophen concentrations. Cardiac monitoring was instituted, and an arterial blood gas (ABG) specimen was obtained from the patient prior to administering supplemental oxygen. A Foley catheter was inserted, and a bedside ferric chloride test of the urine was positive. With the patient in the left lateral decubitus position, orogastric lavage was performed using a 40-French lavage tube. After food and particulate matter were recovered and a total of 2 L of fluid instilled and removed, the lavage fluid was clear. Sixty grams of activated charcoal in a slurry of water and 60 g sorbitol were

administered next, after which the lavage tube was removed.

The initial laboratory data revealed urine pH 5.5; specific gravity 1.025; 1+ protein; 2+ ketones; no red blood cells or white blood cells. ABG values on room air were: pH 7.51; PCO_2 11 mm Hg; PO_2 134 mm Hg. Serum electrolytes were Na^+ 144 mEq/L; K^+ 3.8 mEq/L; HCO_3^- 8 mEq/L; Cl^- 98 mEq/L; BUN 23 mg/dL; creatinine 0.9 mg/dL; glucose 88 mg/dL; calcium 9.6 mg/dL. Urine pregnancy test was negative.

A bolus of 88 mEq sodium bicarbonate was administered, and a bicarbonate drip consisting of 132 mEq sodium bicarbonate in 1 L of 5% dextrose in water (D_5W) was started at a rate of 250 mL/h. Potassium replacement was initiated.

After 2.5 hours, the patient's pulse had increased to 140 beats/min, and her blood pressure had dropped to 106/64 mm Hg. Although the salicylate concentration was not yet available, a nephrology consultation was requested. Fluid rates were increased, and a second dose of activated charcoal was administered. A repeat ABG determination revealed pH 7.48; PCO_2 13.9 mm Hg; PO_2 116 mm Hg.

Approximately 1 hour later (4 hours after presentation), a third ABG analysis on room air revealed pH 7.44; PCO_2 14 mm Hg; PO_2

93 mm Hg. At this time, the initial salicylate concentration was reported to be 107 mg/dL, and the acetaminophen concentration was negative. Arrangements for hemodialysis were made. Another ABG determination on room air 30 minutes later revealed pH 7.37; PCO_2 24 mm Hg; PO_2 64 mm Hg. At this time, rales could be auscultated at both bases. The bicarbonate infusion was reduced to 125 mL/h, and a third dose of activated charcoal was administered.

The patient became agitated shortly thereafter. A fifth ABG determination on 4 L nasal O_2 revealed pH 7.20; PCO_2 46 mm Hg; PO_2 92 mm Hg. ABG determination was immediately repeated, and the results were pH 7.10; PCO_2 63 mm Hg; PO_2 80 mm Hg.

Because of her rapidly deteriorating condition, the patient was intubated and hyperventilated, but her systolic blood pressure fell to 80 mm Hg by palpation and did not respond to a fluid bolus of 1 L of 0.9% sodium chloride solution. Postintubation ABG determination revealed pH 6.90; PCO_2 41 mm Hg; PO_2 182 mm Hg. Ventilation was increased, a second bolus of 88 mEq bicarbonate was administered, and an intravenous dopamine infusion was started. Systolic blood pressure was maintained at approximately 100 mm Hg while hemodialysis was started in the medical intensive care unit.

After 4 hours of hemodialysis, the patient's salicylate concentration was 22 mg/dL, and her ABG was pH 7.42; PCO_2 36 mm Hg; PO_2 190 mm Hg. Eight hours following hemodialysis completion, the patient appeared to be significantly improved clinically. A psychiatric consultation was obtained the next day. Three days later the patient was transferred to the psychiatric service from which she was later discharged home. One week after discharge, the patient returned to her job.

Epidemiology

Between 1999 and 2003 the number of analgesic exposures in the United States annually reported by the American Association of Poison Control Centers (AAPCC)/Toxic Exposure Surveillance System (TESS) increased from 214,066 to 269,982. During that same period, the number of analgesic-related deaths increased from 340 to 656 (Chap. 130). Since 2000, â€œanalgesicsâ€• has consistently ranked first among both the substances most frequently involved in human exposures and the substances responsible for the largest number of deaths. Of the analgesic-related deaths reported, acetaminophen, alone or in combination, accounts for slightly more than 50%, and aspirin, alone or in combination, accounts for approximately 12.6% (somewhat less than a decade ago). If â€œaspirin, alone or in combination with other analgesicsâ€• were listed as a separate category, it would be the seventh or eighth most common cause of

death from toxic exposures recorded by AAPCC/TESS.

Safety packaging, increasing use of nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, or other alternatives to aspirin for adults, and use of acetaminophen instead of aspirin for children to avoid Reye syndrome[10,59] have contributed to the decreased incidence of unintentional salicylate poisoning. On the other hand, the historic widespread availability of salicylate preparations without prescription, the increasing confusion regarding specific ingredients suggested by product names and brand names, and the toxicity caused by small increments in salicylate dosage when used chronically make salicylate poisoning a common and sometimes fatal occurrence.[64]

Over the past 2 decades, popular brand and product names previously associated exclusively with salicylates or acetaminophen have been applied to other analgesic-containing products. For example, the names Alka-Seltzer, Anacin, and Excedrin, which once were used exclusively for salicylate-containing products, now are used as brand names for products containing aspirin, acetaminophen, or both. Bayer, a company once associated exclusively with aspirin, now markets, in addition to its aspirin products, a line of products called Bayer Select, which contains ibuprofen or acetaminophen. Clinicians should be aware that parents and healthcare providers seeking to use acetaminophen for children with viral illnesses to avoid Reye syndrome may inadvertently select a product containing aspirin either alone or in combination with acetaminophen, and an overdose in this setting might involve aspirin.[23] Another source of confusion associated with salicylate toxicity concerns correct dosage: Terminology such as grains and milligrams, and â€œbaby,â€• â€œchildren's,â€• â€œjunior,â€• and â€œadultâ€• aspirin are confusing and often misinterpreted. Maximum doses of aspirin should never be based on age range; instead, doses should always be based on body weight.

Unintentional salicylate toxicity may occur in patients who are

unaware that fixed-dose cold preparations often contain aspirin and then ingest additional aspirin tablets. Another popular medication, Pepto Bismol, or bismuth subsalicylate, contains 8.7 mg of salicylic acid/mL[38] and travelers using large quantities (200â€“300 mL) of this antidiarrheal may expose themselves to high doses of salicylates.

Salicylate poisoning, particularly in children but also in adults, may result from the extensive application of salicylate-containing ointments, keratolytic agents, or other agents containing methyl salicylate (oil of wintergreen).[16] Liniments and products used in hot vaporizers contain high concentrations of methyl salicylate (up to 30% in liniments and 100% oil of wintergreen). The intentional or unintentional *ingestion* of such topicals is usually disastrous: approximately 1â€“2 teaspoons (5â€“10 mL) of methyl salicylate can be lethal for a young child.[20] In Hong Kong, medicated oils containing methyl salicylate accounted for 48% of acute salicylate poisoning cases treated in one hospital.[20]

Salicylates continue to be used frequently as antipyretics for children in developing countries. In one study in Kenya, 94% of 250 mothers who purchased drugs for a febrile child purchased nonprescription drugs containing salicylates and 21% administered a dose exceeding the recommended maximum daily dose. More than one salicylate preparation was given to 27% of children, of whom 35% received a dose higher than the recommended maximum.[34]

Serious adolescent and adult salicylate poisonings frequently result from suicide attempts. Even in this setting rapid diagnosis and appropriate therapy initiated quickly may reduce mortality. However, overdose management recommendations written and distributed by pharmaceutical companies may contain inadequate, misleading, or dangerous advice for managing salicylate overdoses, as demonstrated by a published report from Canada.[17] Salicylism must be considered in all patients who have neurologic abnormalities, tachypnea, acidâ€“base disorders, and acute lung injury (ALI),

particularly in older patients and children and adults who are candidates for chronic iatrogenic salicylate poisoning.

Pharmacokinetics of Salicylates

There are 2 types of salicylic acid esters: phenolic esters (eg, aspirin) and carboxylic acid esters, including methyl salicylate, phenyl salicylate, and glycosalicylate.[27] Most of the studies of salicylate metabolism in the literature involve the phenolic ester aspirin or acetylsalicylic acid.[27]

Therapeutic Doses of Aspirin

Ingested salicylates in the form of aspirin tablets are rapidly absorbed from the stomach. The pK_a of aspirin is 3.5, and approximately 50% of salicylates is nonionized in the acid stomach.[27,54,105] Absorption of salicylates may be less efficient in the small bowel because of its higher pH but occurs rapidly there as well because of the large surface area of the small bowel[82] and because the increase in pH increases the solubility of salicylates and dissolution of tablets.[101] The dosage form of salicylates (effervescent, enteric-coated) often influences the absorption rate.[98,102,120] Delayed absorption of enteric-coated aspirin may result from salicylate-induced pylorospasm, pyloric stenosis,[49,102] gastric outlet obstruction,[106] or bezoar formation.[13,98] Protein-binding abnormalities, urine and plasma pH variations, and delayed absorption all influence the maximum salicylate concentrations and the rates of decline.[82,98]

After ingestion of therapeutic doses of immediate-release salicylates, significant plasma concentrations are achieved in 30 minutes, and maximum concentrations are often attained in less than 1 hour.[27] The volume of distribution is 0.2 L/kg, and 80â€“90% is protein bound. Salicylates are conjugated with glycine and glucuronides in

the liver and eliminated by the kidneys. Approximately 10% of salicylates is excreted in the urine as free salicylic acid, 75% as salicyluric acid, 10% as salicylic phenolic glucuronides, 5% as acylglucuronides, and 1% as gentisic acid.[101] More than 30% of ingested salicylate may be eliminated as free salicylic acid in alkaline urine and as little as 2% in acidic urine.[101,116] Free salicylic acid is filtered through the glomerulus, reabsorbed from the proximal tubules, and secreted from the proximal tubules; salicylic acid elimination is dependent on urine pH and serum concentration. Salicylate conjugates (glycine and glucuronides) are filtered and secreted by the proximal tubules; salicylate conjugates are not reabsorbed across renal tubular cells because of poor lipid solubility and the amount eliminated is dependent on glomerular filtration rate and proximal tube secretion but not urine pH.

Neither age nor gender appeared to affect the absorption rate and plasma clearance of an acute 900-mg dose of aspirin,[82] and systemic availability of salicylate appears to be unaffected by aging alone. An increase in the apparent volume of distribution, a decrease in maximum plasma salicylate acid concentration, and a significant decrease in renal salicyluric acid clearance with age were observed in 22 men 30â€“85 years of age after a 600-mg oral dose of sodium salicylate. Nevertheless, the authors concluded that age alone does not have a major influence on salicylate deposition in healthy adult men.[1]

To achieve an antiinflammatory effect for chronic conditions such as rheumatoid arthritis, salicylates typically have been prescribed in doses of approximately two regular strength (325 mg Ã— 2 = 650 mg) aspirin tablets every 4 hours. The goal of such dosing is to achieve blood salicylate concentrations of 15â€“30 mg/dL, which is considered the therapeutic range.[73] Concentrations higher than 30 mg/dL are associated with signs and symptoms of toxicity. The Food and Drug Administration Advisory Panel on Internal Analgesic and Antirheumatic Products recommends that the maximum adult maintenance dose of aspirin for a 70-kg person not exceed 3900 mg

in 24 hours for more than 10 days. No more than 650 mg should be given every 4 hours, except for the initial dose, which should not exceed 1000 mg.

Toxicokinetics

In overdosage, peak serum concentrations may not be reached for 4â€“6 hours or longer. There is a decrease in protein (albumin) binding from 90% at therapeutic concentrations to less than 75% at toxic concentrations.[2,14,35] The apparent volume of distribution simultaneously increases from 0.2 L/kg at low concentrations to more than 0.3 L/kg (possibly as high as 0.5 L/kg) at higher concentrations.[75,109] Salicylates also have substantially longer apparent half-lives at toxic concentrations than at therapeutic concentrations, varying from 2â€“4 hours at therapeutic concentrations to as long as 20 hours at toxic concentrations.[29,74] As the concentration of salicylates increase, 2 of the 5 pathways of eliminationâ€”those for salicyluric acid and the salicylic phenolic glucuronideâ€”become saturated and exhibit zero-order kinetics. As a result of this saturation, overall salicylate elimination changes from first-order kinetics to zero-order kinetics.[72] Figure 35-1 illustrates the main features of salicylate metabolism. (Pharmacokinetics and toxicokinetics are discussed in Chap. 9). Finally, the pH of salicylic acid offers a unique opportunity to increase elimination by alkalinizing the urine (see â€œIncreasing Salicylate Elimination by Urine Alkalinizationâ€”â€˜Ion Trappingâ€™?â€•).

Topical salicylates used as keratolytics or liniments are rarely responsible for salicylate poisoning when used in the intended manner, as absorption through normal skin is very slow.[16] After 30 minutes of contact time, only 1.5â€“2.0% of a dose is absorbed, and even after 10 hours of contact with methylsalicylate, only 12â€“20% of the salicylates is systemically absorbed.[16,100] (Fig. 35-1 shows methylsalicylate metabolism). Although heat, occlusive dressings, young age, inflammation, and psoriasis all increase salicylate

absorption, the real danger of salicylate toxicity caused by salicylate-containing topicals results from its intentional or unintentional *ingestion*.[21] Methylsalicylate is rapidly absorbed from the gastrointestinal tract and much, but not all, of the ester is rapidly hydrolyzed to free salicylates. Onset of symptoms usually occurs within 2 hours of ingestion.[21] When ingested, 1 mL of 98% methylsalicylate is as potent as 1.4 g of acetylsalicylic acid. In a 10-kg child, the minimum toxic salicylate dose of approximately 150 mg/kg body weight can almost be achieved with 1 mL of oil of wintergreen, which results in 140 mg/kg of salicylates (Chap. 31).

Pharmacology

The glycoside salicin was extracted from the willow bark and used as an antipyretic beginning in the early 1800s, but acetylsalicylic acid was first synthesized and commercially introduced as aspirin by Bayer in 1899.[101] Aspirin and other salicylates are analgesics, antiinflammatories, and antipyretics, a combination of traits shared by all medications of varying structures known as â€œnonsteroidal antiinflammatory drugsâ€• (NSAIDs). Most of the beneficial effects of NSAIDs result from their ability to inhibit cyclooxygenase (COX), the enzyme that enables the synthesis of prostaglandins, which in turn mediate inflammation and fever. Independent of their effects on prostaglandins, salicylates and other NSAIDs may also directly inhibit neutrophils, contributing to their antiinflammatory effects. The type of pain for which salicylates and NSAIDs are purportedly most effective in treating is the pain that accompanies inflammation and tissue injury. Such pain is elicited by prostaglandins, which are liberated by bradykinin and cytokines. Fever is also mediated by cytokines such as interleukin (IL)-Î², IL-6, Î± and Î² interferons, and tumor necrosis factor-Î±, all of which increase synthesis of prostaglandin E_2.[101]

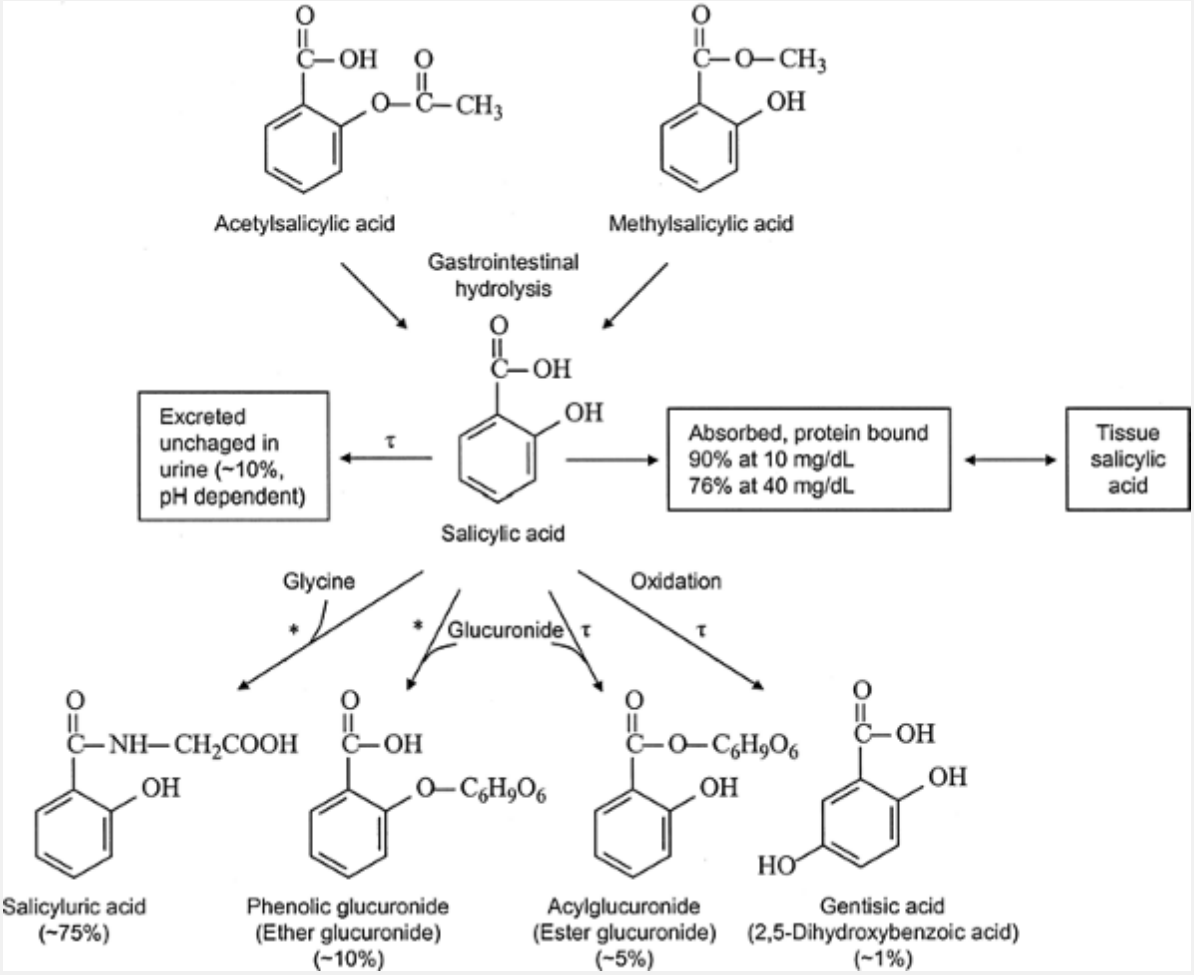

Figure 35-1. Salicylate metabolism. At excessive doses, the d mechanisms of salicylic acid metabolism are overloaded, leading to increased tissue binding, decreased protein binding, and increased excretion of unconjugated salicylic acid. * = Michaelis-Menten kinetics; Ï„ = first-order kinetics.

Because platelets cannot regenerate COX, a daily dose of as little as 40 mg of aspirin inhibits COX for the 8- to 11-day life of the platelet.[101] Frequent aspirin use appears to reduce the incidence of colon cancer, but the reason is not clear.

Adverse effects of aspirin and some NSAIDs include gastrointestinal ulcerations and bleeding, interference with platelet adherence,[99] and a variety of metabolic and organ-specific effects described below in â€œGastrointestinal Effects.â€ •[101]

Pathophysiology

Acidâ€“Base Disturbances Caused by Salicylate Poisoning: Differences Between Adult and Pediatric Patterns

Salicylates stimulate the respiratory center in the brainstem, leading to hyperventilation and respiratory alkalosis.[113] In addition, salicylates are weak acids and in toxic concentrations replace 2â€“3 mEq per liter of plasma bicarbonate. Impaired renal function resulting from salicylate toxicity leads to accumulation of sulfuric and phosphoric acids, both strong acids.[101] Salicylates interfere with the Krebs cycle, which limits production of adenosine triphosphate (ATP),[62] and salicylates uncouple oxidative phosphorylation, which causes accumulation of pyruvic and lactic acids and generates large amounts of heat.[68] Salicylate-induced increased fatty acid metabolism generates ketone bodies: Î²-hydroxybutyric acid, acetoacetic acid, and acetone. The net result of all of these metabolic processes is a wide anion gap metabolic acidosis (Chaps. 17 and 103). A significant part of this metabolic acidosis is a ketoacidosis.

Although metabolic acidosis begins with the earliest stages of toxicity, a primary respiratory alkalosis predominates initially. At the time an adult patient typically presents to the hospital after a substantial acute salicylate overdose, this mixed respiratory alkalosis and metabolic acidosis is discernible by arterial blood gas (ABG) and serum electrolyte analysis.[45] It is important to understand that the respiratory alkalosis of salicylate poisoning is not merely compensatory for the metabolic acidosis (or vice versa), but that

adults acutely poisoned by salicylates characteristically present with 2 primary acidâ€“base disturbances.[45]

By the time children typically present to the hospital after salicylate poisoning, the predominant respiratory alkalosis that initially characterizes *adult* salicylate poisoning may be missed because the metabolic acidosis may already be significant.[46,110] Ultimately, a respiratory acidosis may replace the initial respiratory alkalosis

that is seen so typically early after adult salicylate poisonings. Possible reasons for not seeing a predominant respiratory alkalosis in children are that they may present later, the exposure to salicylates per body weight in children may be much larger, or children do not respond to salicylate poisoning with the same degree of sustained hyperventilation or hyperpnea as do adults. The typical acidotic presentation of a seriously poisoned child led some investigators in the past to incorrectly suggest that pediatric salicylate poisoning produces only a metabolic acidosis. Although some children present with a mixed acidâ€“base disturbance and a normal pH after a significant salicylate ingestion, most such children present with acidemia.[46]

Mixed respiratory alkalosis and metabolic acidosis is found in the majority of adults with serum salicylate concentrations <40 mg/dL[45] and respiratory alkalosis initially predominates. This pattern is so characteristic of adult salicylate poisoning that any salicylate-poisoned adult who presents early with a respiratory *acidosis* almost certainly has either salicylate-induced ALI (formerly called salicylate-induced pulmonary edema [SIPE]), central nervous system (CNS) depression from a mixed overdose, or severe fatigue from the strenuous exercise of hyperventilating for a prolonged period. Mixed xenobiotic overdoses in the adult population are fairly common, as demonstrated by the findings of one study that one third of patients with a presumed primary salicylate overdose had taken other xenobiotics;[45] benzodiazepines, barbiturates, alcohol, and cyclic antidepressants all appear to blunt the centrally induced

hyperventilatory response to salicylates, resulting in either an actual respiratory acidosis (PCO_2 >40 mm Hg) or a metabolic acidosis without the appropriate respiratory compensation (PCO_2 <40 mm Hg, but inappropriately high for the concomitant pH). The combination of metabolic *and* respiratory acidosis from salicylate poisoning in an adult resulting in severe and worsening acidemia indicates an exceedingly grave prognosis and almost invariably is a preterminal event.[92]

Glucose Metabolism

Salicylate poisoning appears to produce a discordance between plasma and cerebrospinal fluid (CSF) glucose concentrations. Despite normal plasma glucose, CSF glucose concentration fell 33% in salicylate-poisoned mice compared to controls.[114] In other words, the rate of CSF glucose use exceeded the rate of supply, even in the presence of normal serum glucose concentration. There was also a marked increase in oxygen consumption in mice, even with low salicylate concentrations.[52] A case report of refractory hypoglycemia secondary to poisoning from topical salicylate absorption underscores the problems of glucose metabolism caused by salicylates.[96]

Hepatic Effects

Salicylate-poisoned mice had a marked decrease in glycogen and a dramatic increase in lactate compared to controls[52] as increased glycolysis apparently compensates in part for the uncoupling of oxidative phosphorylation.[80] In humans, the increased metabolic demands resulting from salicylate poisoning stimulate peripheral use of glucose and fat with resultant hypoglycemia and ketosis. Salicylates reduce lipogenesis by blocking the incorporation of acetate into free fatty acids, inhibiting epinephrine-stimulated lipolysis in fat cells and displacing long-chain fatty acids from human plasma proteins. All of these effects lead to increased entry of fatty acids into muscle and liver and to their oxidation inside. As a result,

the concentrations of *plasma* free fatty acids, phospholipids, and cholesterol decrease. Ketone body oxidation is increased.[101]

Salicylate-induced hepatitis occurred in children who were being treated with high (average concentration, 30.9 mg/dL) or chronic doses of salicylates for rheumatic fever and juvenile rheumatoid arthritis.[48,76,104]

Another form of liver disease associated with salicylates, also primarily seen in children, is Reye syndrome, which is characterized by nausea, vomiting, hypoglycemia, elevated concentrations of liver enzymes [aspartate aminotransferase (AST), alanine aminotransferase (ALT)], fatty infiltration of the liver, and coma following a viral illness, usually influenza or varicella.[7,10] Although the nature of the link between Reye syndrome and salicylates has never been fully elucidated, the existence of such a link is fairly certain. The mean serum salicylate concentration in biopsy-proven Reye syndrome was 12.3 mg/dL, and the mean serum salicylate concentration in patients who died of or survived Reye syndrome with neurologic deficits was 15 mg/dL.[23,87]

Further evidence of a causal relationship between salicylate use for a viral illness and Reye syndrome is suggested by the finding that the incidence of Reye syndrome has fallen steadily concomitantly with the decreased use of salicylates in children.[10,97,117] From December 1980 through November 1991, 1207 cases of Reye syndrome were reported in the United States in patients younger than 18 years, with a peak incidence of 555 cases in 1980. Between 1994 and 1997, no more than 2 cases each year were reported.[10] However, the problem has not completely disappeared, as evidenced by 2 fatal cases reported in 2003.[12,23] In one case, a 3-year-old boy who presented in 1999 with signs of Reye syndrome had an initial salicylate concentration of 3.9 mg/dL.[12] In the case of a 10-year-old girl who presented in 2002, the *reported* amount of aspirin that she had knowingly ingested was two 325-mg tablets, which did not correlate with the serum salicylate concentration of 16 mg/dL obtained on

admission to the hospital 3 days later. The discrepancy may have resulted from confusion between brand or product labeling or an inability to accurately determine the contents of the nonprescription medications used.[23]

Neurologic Effects

Toxic doses of salicylates first stimulate and then depress the CNS. Confusion, dizziness, delirium, psychosis, and then ultimately stupor and coma may occur.[101]

Otolaryngologic Effects

The pattern of salicylate-induced auditory sensorineural alterations is different than the pattern characterizing other ototoxic drugs.[18] Tinnitus, loss of absolute acoustic sensitivity, and alterations of perceived sounds are the 3 effects resulting from exposure to large doses of salicylates.[18] Tinnitus followed by mild to moderate reversible hearing loss typically occurs with serum salicylate concentrations of 20â€“45 mg/dL or higher.[15,18,84] Occasionally investigators have questioned whether salicylate ototoxicity can be used as an indicator of serum salicylate concentration, only to note that some patients with therapeutic concentrations of salicylates complained of tinnitus and many with higher or toxic concentrations had no tinnitus. In a study of 94 patients with salicylate concentrations >30 mg/dL on one or more occasions, the majority (55%) had no tinnitus, which only correlated with blood salicylate concentrations in 30%, although audiologic testing results usually were abnormal regardless of the presence or absence of tinnitus. The authors concluded that symptomatic ototoxicity is

too nonspecific and too insensitive to serve as an indicator of serum salicylate concentrations.[47]

The mechanism of ototoxicity is not completely understood but

appears to be multifactorial. Inhibition of COX by salicylates prevents prostaglandin synthesis, which interferes with the Na^+-K^+-adenosine triphosphatase (ATPase) pump in the stria vascularis and the vasoconstriction decreases cochlear blood flow[15,19,36,61] Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti, which may impair otoacoustic emissions.[94,95] For a more complete description of the pathophysiology of salicylate-induced ototoxicity and sensorineural alterations and comparisons to the patterns of other ototoxic xenobiotics, see Chap. 21.

Pulmonary Effects

When a patient with salicylate poisoning presents with the clinical and radiographic manifestations of pulmonary edema or ALI, major etiologies that must be considered include aspiration pneumonitis, viral and bacterial infections, postictal and neurogenic ALI, and salicylate-induced ALI (formerly known as salicylate-induced pulmonary edema [SIPE] or noncardiogenic pulmonary edema)[57,63] (Chap. 22).

Many different causes of ALI result in increased pulmonary capillary permeability and subsequent exudation of high-protein edema fluid into the interstitial or alveolar spaces. Severe traumatic CNS injuries and elevation of intracranial pressure may be responsible for a form of â€œcentralâ€• ALI (formerly called postictal pulmonary edema).[58] Hypothalamic lesions from trauma, increased intracranial pressure, or salicylate poisoning may be the critical factor, with resultant adrenergic overactivity producing a shift of blood from the systemic to the pulmonary circulation, loss of left ventricular compliance with left atrial and pulmonary capillary hypertension, and subsequent pulmonary edema (Chap. 22).

In 111 consecutive patients with peak salicylate concentrations >30 mg/dL, ALI occurred in 35% of patients older than 30 years of age and none of the 55 patients younger than 16 years of age. Risk factors for developing ALI included cigarette smoking, chronic

salicylate ingestion, and presence of neurologic symptoms on admission. The average arterial blood pH was 7.37 Â± 0.022 in the 6 adult patients with ALI and 7.46 Â± 0.010 in the 30 adults without ALI. There was no significant difference in salicylate concentrations, which were approximately 57 mg/dL in both groups.[118] In a 2-year review of all salicylate deaths in Ontario, Canada, 51 patients were studied, with autopsies performed in 39. The autopsies revealed that 59% had pulmonary pathology. The presence of pulmonary pathology, mostly â€œpulmonary edema,â€• was significantly associated with therapy for >4 hours.[79]

Although the exact mechanism for ALI is obscure, hypoxia may be an important factor.[56,57] Hypoxia can result in pulmonary arterial hypertension and a local release of vasoactive substances. Severe salicylate poisoning has been identified as a distinct cause of ALI in children and in adults.[41]

Gastrointestinal Effects

Gastrointestinal manifestations of salicylate use include nausea and vomiting, which probably result from local gastric irritation at lower doses and from stimulation of the medullary chemoreceptor trigger zone at higher doses (27 mg/dL).[101] Hemorrhagic gastritis, decreased gastric motility, and pylorospasm also result from the direct gastric irritant effects of salicylates.[102] The effects appear more pronounced or consequential in the elderly.[64]

Renal Effects

The kidneys clearly play a major role in the handling and excretion of salicylates, and many believe in turn that salicylates are significantly nephrotoxic, but the majority of studies and experimental evidence do not strongly support this notion.[26,37,88] Most of the adverse renal effects historically associated with salicylates occurred with use of combination products such as aspirinâ€“phenacetinâ€“caffeine (APC)

tablets and appear to have been due mostly to the nonsalicylate ingredient(s), that is, phenacetin,[37] or to a synergistic effect contributed to by salicylates. The synergistic nephrotoxicity of aspirin and acetaminophen results from the effects of each on depleting glutathione.[33,89,121] Renal papillary necrosis (RPN) and chronic interstitial nephritis initially characterized by reduced tubular function and reduced concentrating ability are rarely seen in adults using aspirin or salicylates unless they have chronic illnesses that already compromise renal function.

Although extremely high doses of aspirin have produced RPN experimentally in 1 rat species, RPN has not been demonstrated following excessive doses of aspirin alone in humans or other species, or after lesser doses of aspirin in other rats.[26] Similarly, neither chronic nephrotoxicity nor an increased risk of end-stage renal disease (ESRD) from long-term use of aspirin alone has been demonstrated in humans, with the exception of 1 case control series demonstrating a low but statistically significant risk of ESRD. In adults with preexisting glomerulonephritis, cirrhosis, or chronic renal insufficiency and in children with congestive heart failure, short-term therapeutic doses of aspirin may precipitate reversible acute renal failure, possibly because of inhibition of the vasodilatory prostaglandins necessary to maintain renal blood flow in these conditions.[26] In healthy adults, however, short-term therapeutic doses of aspirin do not adversely affect creatinine clearance, urine volume, or sodium and potassium clearance. Aspirin doses >300 mg/kg can cause acute renal failure, and chronic aspirin poisoning can cause reversible or irreversible acute renal failure associated with a pseudosepsis syndrome.[26]

Hematologic Effects

Hematologic effects of salicylate poisoning include hypoprothrombinemia and platelet dysfunction.[44] Anemia in patients who chronically abuse salicylates may be a result of the effects of

both platelet dysfunction and gastric mucosal barrier breakdown (gastrointestinal bleeding),[44] particularly in the elderly.[6,25] Hemolysis is unusual, and alterations in leukocyte function are of no apparent clinical significance.[103]

Musculoskeletal Effects

Rhabdomyolysis after pure salicylate overdoses probably is another result of the dissipation of heat and energy from uncoupling oxidative phosphorylation.[71,80,81] Paratonia, characterized by extreme muscle rigidity, was present in 3 of the 51 cases of salicylate deaths reviewed in Ontario between 1983 and 1984.[79] Rapid rigor mortis and paratonia (which are not unique to salicylate poisoning) probably are related to the extreme depletion of ATP and the inability of the muscle fibers to relax.

Clinical Manifestations of Acute and Chronic Salicylate Poisoning

Acute Toxicity

The earliest signs and symptoms of salicylate toxicity include nausea, vomiting, diaphoresis, and tinnitus, which is a subjective sensation of ringing or hissing, with or without hearing loss.[15,44,110] As CNS salicylate concentrations increase, tinnitus is rapidly followed by diminished auditory acuity that sometimes leads to deafness.[15] Other early CNS effects may include vertigo and hyperventilation manifested as hyperpnea or tachypnea (Chap. 3), hyperactivity, agitation, delirium, hallucinations, convulsions, lethargy, and stupor. Coma is rare and generally occurs only after massive ingestions (serum salicylate concentrations >100 mg/dL) or mixed overdoses (Table 35-1).[44] A marked elevation in temperature resulting from the uncoupling of oxidative phosphorylation caused by salicylate

poisoning[80] is an indication of severe toxicity and typically a preterminal condition.

Unfortunately, many of the signs and symptoms of salicylate toxicity may be mistakenly attributed to the illness for which the salicylates were administered, with disastrous consequences.[24,110] In the review of all salicylate deaths in Ontario, Canada, in 1983 and 1984, the author noted that in 6 of the 23 (26%) patients who arrived alert, no salicylate determination appears to have been made and that probably neither the diagnosis nor severity of the lethal salicylate poisoning was recognized.[79]

TABLE 35-1. Clinical Manifestations and Diagnostic Testing Results of Salicylate Toxicity

Acidâ€“base and electrolyte disturbances
Anion gap increased
Metabolic acidosis
Metabolic alkalosis (vomiting)
Respiratory alkalosis (predominates early)
Respiratory acidosis (late, grave prognosis)
Hyponatremia or hypernatremia
Hypokalemia
CNS
Tinnitus
Diminished auditory acuity
Vertigo
Hallucinations
Agitation
Hyperactivity
Delirium
Stupor
Coma

Lethargy
Convulsions
Cerebral edema
Syndrome of inappropriate antidiuretic hormone
Coagulation abnormalities
Hypoprothrombinemia
Inhibition of factors V, VII, X
Platelet dysfunction
Gastrointestinal
Nausea
Vomiting
Hemorrhagic gastritis
Decreased motility
Pylorospasm
Hepatic
Abnormal liver enzymes
Altered glucose metabolism
Metabolic
Diaphoresis
Hyperthermia
Hypoglycemia
Hyperglycemia
Hypoglycorrhachia
Ketonemia
Ketonuria
Pulmonary
Hyperpnea
Tachypnea
Respiratory alkalosis
Acute lung injury
Renal
Tubular damage
Proteinuria
NaCl and water retention

Hypouricemia

Chronic Toxicity

Chronic salicylate poisoning most typically occurs in the elderly as a result of unintentional overdosing on salicylates used to treat chronic conditions such as rheumatoid arthritis and osteoarthritis.[5,32,64] Although neither age nor gender appears to affect the absorption rate or plasma clearance of acute therapeutic doses of aspirin (900 mg) administered to healthy adults,[82] when used chronically, a small increase in dosage (eg, in response to increasing pain) or a small decrease in metabolism or renal function can result in substantial increases in serum salicylate concentrations and toxicity.[64]

Presenting signs and symptoms of *chronic* salicylate poisoning include hearing loss and tinnitus, nausea, vomiting, dyspnea and hyperventilation, tachycardia, hyperthermia, and neurologic manifestations such as confusion, delirium, agitation, hyperactivity, slurred speech, hallucinations, seizures, and coma.[4,44,70] In one review, the authors went so far as to suggest that the diagnosis of salicylate poisoning should be borne in mind when an older patient presents with recent deterioration in activities of daily living of no known cause.[31] Although there is considerable overlap with some of the presenting signs and symptoms of *acute* salicylate poisoning, the slow onset and less severe appearance of some of these signs of chronic poisoning in the elderly frequently cause delayed recognition of the true etiology of the patient's presentation.[45]

Typically, ill patients who suffer from chronic salicylate poisoning may be misdiagnosed as having delirium, dementia, encephalopathy of undetermined origin, diseases such as sepsis (fever of unknown origin), alcoholic ketoacidosis, respiratory failure, or cardiopulmonary disease, especially congestive heart failure, acute pulmonary edema, or even unstable angina.[4,8,24,34,44]

In a study of 73 consecutive adults hospitalized with salicylate poisoning, 27% were not correctly diagnosed for as long as 72 hours after admission.[4] These patients manifested toxicity with standard or excessive therapeutic regimens and had significant associated diseases without a history of previous overdoses. In this group, 60% previously had a neurologic consultation before the diagnosis of salicylism was established. When diagnosis is delayed in the elderly, the morbidity and mortality associated with salicylate poisoning are high. Mortality was reported to be as high as 25% in the 1970s,[4] and no data suggest that survival after delayed diagnosis is substantially better today (Table 35-2).

Underrecognition or misdiagnosis of chronic salicylate poisoning is not confined to the elderly and may be a problem at the other end of the age spectrum. In one study of all children admitted to a district hospital in Kenya over a 3-month period with the primary diagnosis of severe malaria, 90% had detectable blood salicylate concentrations, and 6 of 143 had plasma concentrations â‰¥20 mg/dL. All 6 of the children with plasma salicylate concentrations of â‰¥20 mg/dL had neurologic impairment and metabolic acidosis, and 4 had hypoglycemia, suggesting that salicylates cause or contribute to those complications of malaria that are associated with high mortality.[34]

TABLE 35-2. Differential Characteristics of Acute and Chronic Salicylate Poisoning

	Acute	Chronic
Age	Younger	Older
Etiology	Overdose usually intentional	Therapeutic misadventures; iatrogenic
Diagnosis	Easily recognized	Frequently unrecognized
Other disease states	None	Underlying disorders (especially chronic pain conditions)
Suicidal ideation	Typical	No
Clinical differences	Rapid progression of signs	Acute lung injury (ALI) CNS abnormalities
Serum concentrations	Marked elevation	Intermediate elevation
Mortality	Uncommon when recognized, unless ingestion massive	Approximately 25%

Diagnostic Testing

Rapid Confirmation of Salicylate Use

Serum salicylate concentrations are relatively easy to obtain in most hospital laboratories and with proper attention to the units reported (mg/dL vs. mg/L) and concomitant arterial blood pH values, clinicians can quickly confirm or exclude toxic salicylate concentrations. Salicylate *use* may be rapidly confirmed qualitatively with a simple point-of-care ferric chloride ($FeCl_3$) test that uses several drops of 10% $FeCl_3$ added to 1 mL of urine. A purple color indicates the *presence* of salicylic acid, acetoacetic acid, or phenylpyruvic acid.[119] However, because this test is extremely sensitive to very small quantities of salicylates, a positive result indicates only salicylate usage and not necessarily poisoning or overdosage. A positive $FeCl_3$ test result must be confirmed by determination of actual serum salicylate concentration, whereas false-negative $FeCl_3$ results either do not occur or are exceedingly rare.[42] A false-positive $FeCl_3$ test may also result from use of a small quantity of urine that has already been subjected to dipstick analysis with N-Multistix or Bili Labstix reagent strips. Presumably in this instance impregnated chemical from the dipstick that has dissolved in the urine subsequently causes a false-positive $FeCl_3$ reaction.

When urine is not available for $FeCl_3$ testing (because of anuria or oliguria, too short a time after ingestion, or chronic use of salicylates), a possible salicylate-containing product itself can be tested with $FeCl_3$. All 15 of the salicylate-containing products tested in one study demonstrated a positive $FeCl_3$ reaction, whereas none of the 15 nonsalicylate containing controls did.[55] $FeCl_3$ reagent is rarely available in hospital emergency departments, and the unsupervised performance of $FeCl_3$ testing outside of a certified laboratory is not consistent with the federal Clinical Laboratory Improvement Amendments (CLIA) in the United States.

Another rapid colorimetric urine test for determination of salicylate usage is the Trinder spot test,[66] which uses a premixed reagent consisting of mercuric chloride, ferric nitrate, deionized water, and concentrated hydrochloric acid. When 1 mL of urine containing salicylates is mixed with 1 mL of Trinder reagent, it instantly turns violet or purple. The sensitivity of the test was 100% when applied to urine collected 2â€“4 hours after oral ingestion of 975 mg of salicylate by volunteers.[66] (Because of the composition of the testing reagents, this test presumably would be available only in a laboratory.)

â€œPoint-of-careâ€• determinations that may help rapidly indicate salicylate *poisoning* are (A) a positive urine ketone determination reflecting ketogenesis from increased fatty acid metabolism[53] and perhaps the ketone forms of salicylates present; (B) a whole-blood glucose and electrolyte determination performed on a handheld analyzer (I-stat and others); this test can quickly demonstrate decreased HCO_3^-[2] (indicating a possible wide anion gap metabolic acidosis) and other glucose and electrolyte abnormalities characteristic of salicylate toxicity; and (C) a whole-blood ABG determination performed on a handheld analyzer indicating acidâ€“base disturbance(s) characteristic of salicylate poisoning.

Serum Salicylate Concentrations and Correlation with Toxicity

Serum salicylate concentrations should be requested when clinically significant salicylate exposures are suspected and not as part of a general toxicologic screen. For some, the confusion in correctly identifying aspirin and acetaminophen products and the consequent possibility that either or both may be used in a suicide attempt, coupled with the initial absence (acetaminophen) or unreliability (salicylates) of clinical findings associated with these poisonings, make toxicologic analysis for both salicylates and acetaminophen reasonable when either one is implicated in an intentional poisoning.

The authors of two studies concluded that universal salicylate screening is not indicated for patients with acute self-poisonings (Hong Kong)[22] or patients with suicidal ingestions or altered mental status (United States).[107] The latter study found that 0.16% of patients with suicidal ingestions had a toxic salicylate exposure *not* suggested by history, compared to 0.3% of patients with potentially toxic acetaminophen exposures not suggested by history. Although these authors recommended universal acetaminophen screening to evaluate patients with suspected ingestions, they concluded that salicylate screening was unnecessary because severe salicylate exposures are less frequent and usually are accompanied by an elevated anion gap and altered mental status.[107]

Except in certain narrowly defined situations, the toxicity of salicylates correlates poorly with serum concentrations. The Done nomogram,[29] first published in 1960, continues to be republished in texts despite severely limited applicability. It was based on data from a predominantly pediatric population and intended to be applied only 6 hours or more after a single acute ingestion of nonenteric-coated, orally ingested aspirin. Moreover, the patient's blood pH must be approximately 7.4 or higher. Such conditions rarely apply to patients with serious acute and chronic salicylate overdoses and poisonings. An example of the shortcomings of the nomogram is a patient who presents with lethargy and/or a coagulation abnormality associated with salicylism. Such a patient can be classified on the Done nomogram as â€œmildâ€• or â€œmoderate,â€• although it is obvious clinically that the patient must be considered severely poisoned. The poor predictive value of the Done nomogram when applied retrospectively to a group of 55 predominantly adults with salicylate poisoning is evident from a 1989 study.[32]

Patients with acute exposures whose initial serum salicylate concentrations are considered acceptable, low, or moderate sometimes

deteriorate rapidly thereafter. For this reason, careful observation of the patient, correlation of the serum salicylate concentrations with blood pH values, and repeat determinations of serum salicylate concentrations every 2â€“4 hours are essential until the patient is clinically improving and has a low salicylate concentration in the presence of a normal or high blood pH. Methyl salicylate exposures have resulted in deaths in <6 hours, emphasizing the need for early determinations of salicylate concentrations in addition to frequent testing after such exposures. In all cases, once a peak serum salicylate concentration has been reached, at least one additional concentration should be obtained after several hours and more frequent concentrations obtained in managing the seriously ill patient to assess efficacy of treatment and possible need for hemodialysis (HD).

A concurrent arterial blood pH should be determined when a blood salicylate concentration is obtained because in the presence of acidemia, more salicylic acid leaves the blood and enters the CSF and other tissues (Fig. 35-2), increasing the toxicity. Therefore, meaningful interpretation of *serum* salicylate concentrations must take into account the effect of blood pH on salicylate distribution, unless the serum salicylate concentration is so high that HD is indicated regardless of the pH. A decreasing serum salicylate concentration may be difficult to interpret because it can reflect either an increased tissue distribution with increased toxicity or an increased clearance with decreased toxicity. A decreasing serum salicylate concentration accompanied by a decreasing or low blood pH should be presumed to reflect a serious or worsening situation, not a benign or improving one.

When the patient's clinical signs and symptoms are given the highest priority and the serum salicylate concentration is interpreted in conjunction with a simultaneously obtained arterial blood pH, the severity of toxicity usually can be predicted and the need for HD accurately determined.

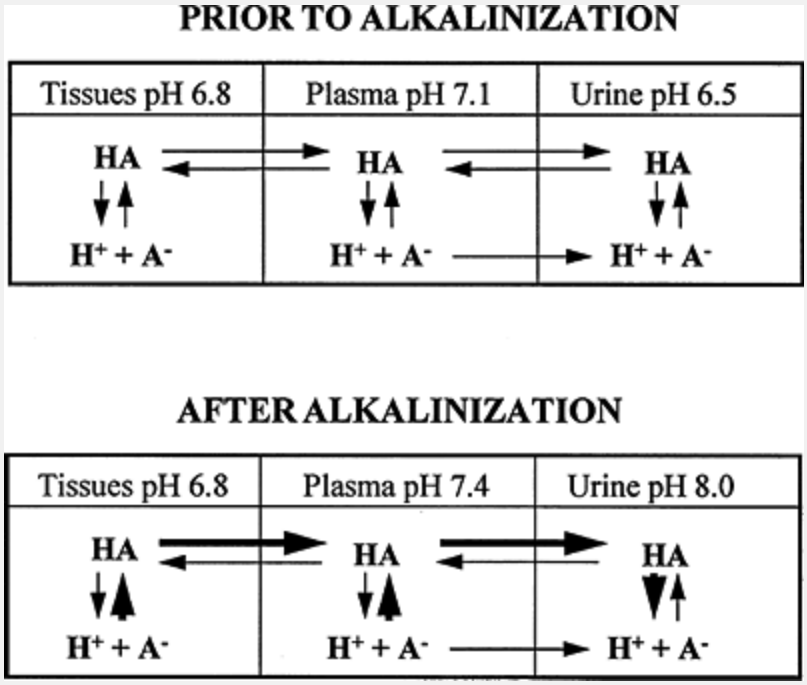

Figure 35-2. Rationale for alkalinization. Alkalinization of the plasma with respect to the tissues and alkalinization of the urine with respect to plasma shifts the equilibrium to the plasma and urine and away from the tissues (including the brain). This equilibrium shift results in â€œion trapping.â€• *(Adapted, with permission, from Temple AR: Acute and chronic effects of aspirin toxicity and their treatment. Arch Intern Med 1981;141:367.)*

Errors in Reporting Serum Salicylate Concentrations

Laboratory errors probably are more common and problematic when reporting serum salicylate concentrations compared to other drug concentrations. Analyzing and reporting salicylate concentrations as mg/L when the clinician is accustomed to receiving results as mg/dL or inadvertently reporting actual mg/L results erroneously as

â€œmg/dLâ€• multiplies the true salicylate concentration by 10 and suggests a toxic salicylate concentration in a patient whose serum salicylate concentration is actually within the therapeutic range (eg, â€œ165â€• instead of â€œ16.5â€•). Most errors can be eliminated prior to initiation of aggressive therapy, such as HD, by determining whether the reported salicylate concentration is consistent with the clinical presentation and ABG results and, when time permits, repeating the salicylate determination with appropriate consideration for methodology and conversion calculations.

Correlation Between CSF and Serum Salicylate Concentrations

Although peak serum salicylate concentrations may provide useful clinical correlations at a normal or high blood pH, serum salicylate determinations not reflecting the peak concentration may be of limited value. Experimentally, there appeared to be a critical CSF salicylate concentration that correlated closely with mortality.[52] In addition, the CSF salicylate concentration correlated best with the peak serum salicylate concentration and reequilibrated more slowly than the serum salicylate concentration. As noted above in â€œSerum Salicylate Concentrations and Correlation with Toxicity,â€• a serum salicylate concentration in the presence of acidemia may have little or no correlation with the CSF salicylate concentration. However, even if CSF salicylate concentrations in humans are more accurate predictors of toxicity, their use in clinical management is currently impractical.

Management

Gastric Decontamination and Use of Activated Charcoal

The use of gastric decontamination (orogastric lavage) and activated

charcoal (AC) are discussed throughout this text, but their effects on the absorption and elimination of salicylates probably have been studied more extensively than with any other xenobiotic. In vitro studies suggest that each gram of AC can adsorb approximately 550 mg of salicylic acid.[75,85] In vitro, aspirin is adsorbed to AC with moderate efficacy. In humans, AC reduces the absorption of therapeutic aspirin doses by 50â€“80%, effectively binding aspirin from enteric-coated and sustained-release preparations in addition to immediate-release tablets.[75] Presumably, the sooner AC is given after salicylate ingestion, the more effective it will be in reducing absorption. A 10:1 ratio of AC to salicylate ingested appears to result in maximal efficiency. Although peak serum concentrations are markedly decreased from predicted concentrations, aspirin desorption from the aspirinâ€“AC complex may diminish the impact on total absorption.[40,77,85] The addition of a cathartic to the initial dose of AC has been questioned and largely abandoned for most xenobiotics, but the benefits of adding sorbitol to AC in preventing salicylate absorption have been demonstrated in one study.[65]

Repetitive or multiple-dose activated charcoal (MDAC) appears to increase the elimination of unabsorbed salicylates over that achieved by single-dose AC,[9,53] although the charcoal used in one of these studies contained â€œsubstantial amounts of sodium bicarbonate.â€•[3,53] MDAC probably prevents desorption, which may reduce the concentration of initially absorbed salicylate to only 15â€“20%.[40] It is not clear, however, that MDAC enhances the excretion of salicylates that have already been systemically absorbed.[3,60]

In one volunteer study of 2800 mg of aspirin followed by 25 g of AC at 4, 6, 8, and 10 hours after ingestion, the total amount of salicylate excreted from the body increased by 9â€“18% but was not considered statistically significant.[67] The authors hypothesized that MDAC was more effective in enhancing salicylate excretion in the *overdose* situation, when more salicylate is available because of

decreased protein binding. However, in another study of the effects of MDAC on the clearance of high-dose intravenous aspirin in a porcine model, MDAC did not enhance the clearance of salicylates under alkaline conditions, that is, when the venous bicarbonate was kept at â‰¥15 mEq/L and urine pH kept at â‰¥7.5.[60] In contrast to the findings of both of these studies, two pediatric patients with salicylate overdoses were successfully treated with MDAC given every 4 hours for 36 hours, and the authors concluded that MDAC is effective in an overdose situation, even after alkalinization.[115]

Theoretical support may be found for use of whole-bowel irrigation (WBI) consisting of polyethylene glycol electrolyte lavage solution (PEG-ELS) in addition to AC to diminish potential desorption, particularly for enteric-coated aspirin preparations.[112] Moreover, WBI alone may be effective in preventing absorption of other xenobiotics. However, the addition of WBI to MDAC did not increase the clearance of *absorbed* salicylate.[77]

The value of MDAC in enhancing salicylate elimination may be considered controversial, and the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists (AACT/EAPCCT) position statement concludes that data are presently insufficient to recommend MDAC for salicylate poisoning.[3] Nevertheless, the use of MDAC probably is warranted in attempting to decrease gastrointestinal absorption of salicylate overdoses (see Antidotes in Depth: Activated Charcoal).

Fluid Replacement

There is a need to differentiate between restoration of fluid and electrolyte balance in salicylate-poisoned patients as opposed to increasing the fluid load presented to the kidneys in an attempt to achieve â€œforced diuresis.â€• Fluid losses from salicylate poisoning are prominent, especially in children, and can be attributed to tachypnea, vomiting, fever, a hypermetabolic state, hyperpnea, and insensible perspiration.[111] The kidneys also respond to salicylate

poisoning by excreting an increased solute load, including large quantities of bicarbonate, sodium, potassium, and organic acids, but renal tubular damage leading to renal failure is rare. Ketoacidosis, hypoglycemia, or hyperglycemia may occur.[5] For all of these reasons, the patient's volume status must be adequately assessed and corrected if necessary, along with any glucose and electrolyte abnormalities. As in other cases, accurate management of volume status in the poisoned patient may require invasive monitoring with a central venous pressure monitor or, preferably, a pulmonary artery catheter, especially in patients with cardiac disease, ALI, or renal compromise.

Increasing fluids *beyond* restoration of fluid balance in order to achieve a forced diuresis is a practice that was inappropriately promoted in the past. Although forced diuresis theoretically increases renal tubular flow and reduces the urine tubular cell diffusion gradient for reabsorption, renal excretion of salicylate depends much more on urine pH than on flow rate, and use of forced diuresis alone is not effective regardless of whether diuretics, osmotic agents, or fluid volumes are used to achieve the diuresis.[90] Although renal salicylate clearance varies in direct proportion to flow rate, its relation to pH is logarithmic.[69] In summary, although fluid imbalance must be corrected, forced saline diuresis does little more than oral fluids to enhance elimination over a 24-hour period[90] and subjects the patient to the hazards of fluid overload.

Salicylate Elimination by Urine Alkalinization

Because salicylic acid is a weak acid (pK_a 3.5), it will be ionized in an alkaline milieu and theoretically can be â€œtrappedâ€• there. Alkalinization of the blood by a substance that does not easily cross the bloodâ€“brain barrier (ie, intravenously administered sodium bicarbonate) can keep salicylates from entering the brain and CSF; alkalinization of the urine (defined as pH â‰¥7.5) will enhance

urinary salicylate excretion. Alkalinization with sodium bicarbonate for salicylate poisoning results in enhanced excretion of the ionized acid form of salicylate in an alkaline urine.

In 2004, an AACT/EAPCCT position paper on urine alkalinization concluded that to increase the urinary elimination of salicylates, â€œurine alkalinization should be considered as first line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis.â€• [93] The paper only briefly discusses how this is achieved and the specific role of ion trapping. However, in a separate paper, the coauthor of the AACT/EAPCCT position paper points out that salicylic acid is almost completely ionized within *physiologic* pH limits; therefore, alkalinizing the urine could not significantly increase the extent of ionization further, making impossible the conventional explanation for the increased excretion of salicylic acid in alkalinized urine.[91] At least one other investigator maintained many years ago that ion trapping alone does not account for the increased excretion caused by sodium bicarbonate.[78] In any case, renal excretion of salicylic acid *is* very dependent on urinary pH[90,116] (Fig. 35-2; see Antidotes in Depth: Sodium Bicarbonate).

Alkalinization increases free salicylate secretion from the proximal tubule but does not affect renal elimination of salicylate conjugates. The percentage of a single dose of 1.5 g of sodium salicylate administered to volunteers that was excreted unchanged increased from 2.3 Â± 1.5% under acidic conditions to 30.5 Â± 9.1% under alkaline conditions. When urine acidity was maintained using ammonium chloride, salicylic acid had a terminal plasma $t_{1/2}$ value of 3.29 Â± 0.52 hours, which was significantly reduced to 2.50 Â± 0.41 hours when an alkaline urine was maintained with sodium bicarbonate treatment. The total body clearance of salicylic acid was significantly less under acidic urine conditions (1.38 Â± 0.43 L/h) than under alkaline urine conditions (2.27 Â± 0.83 L/h).[116]

Alkalinizing the urine from a pH of 5 to 8 logarithmically increased

renal salicylate clearance from 1.3 to 100 mL/min.[83] Assuming an overdose Vd of 0.5 L/kg, this increased clearance would decrease salicylate half-life from 310 to 4 hours. However, alkalinizing the urine from a pH of 5 to 8 has a more modest

effect on *serum* salicylate clearance.[90] The apparent serum half-life decreased from 48 to 6 hours at a fixed rate of 2 hours per unit pH change. This difference between serum and renal half-lives reflects the fact that renal clearance only applies to free salicylate, whereas serum clearance applies to both free and protein-bound salicylate.

Because acidemia enhances salicylate transfer into tissue, and particularly into the brain, it must be treated aggressively by raising the blood pH compared to the brain pH, thereby shifting the equilibrium from the tissues to the plasma[50,110] (Fig. 35-2). To accomplish this, hyperventilation alone should not be relied upon, and $NaHCO_3$ (but not acetazolamide) should be used for alkalinization. Although the administration of acetazolamide, a noncompetitive carbonic anhydrase inhibitor, results in the formation of a bicarbonate-rich alkaline urine, it also causes a systemic metabolic acidosis and acidemia.[39,50] The effect of acetazolamide usually is self-limited and mild but nevertheless increases the concentration of freely diffusible nonionized molecules of salicylic acid, thereby increasing the volume of distribution and most probably enhancing the penetrance of salicylate into the CNS.[74] Because salicylate also appears to inhibit acetazolamide plasma protein binding and acetazolamide renal tubular secretion, older patients with diminished protein binding and renal function may be at even greater risk for significant metabolic acidosis from acetazolamide use.[50,108]

Alkalemia by Hyperventilation versus Sodium Bicarbonate and the Risks

Associated with Assisted Ventilation

Endotracheal intubation followed by assisted ventilation of a salicylate-poisoned patient poses particular risks and may contribute to mortality in several ways. Death has occurred following sedation during initial airway management.[11] Additionally, although early endotracheal intubation to *maintain* hyperventilation may aid in the management of patients whose respiratory efforts are faltering after many hours, few healthcare providers are trained or skilled at maintaining the appropriate concentration of hypocarbia and hyperventilation necessary for managing a salicylate-poisoned patient who is receiving assisted ventilation on a respirator. Even when achieved, a respiratory alkalosis sustained by hyperventilation (assisted or unassisted) alone should *never* be considered a substitute for use of either sodium bicarbonate (to achieve both alkalemia and alkalinuria) or HD (when indicated). Because sodium bicarbonate does not easily cross the bloodâ€“brain barrier whereas CO_2 does, sodium bicarbonate will create a compartmentalized environment conducive to keeping salicylates in the blood and away from the brain and liver (Fig. 35-2).

Alkalinization with intravenous sodium bicarbonate should be considered for patients whose serum salicylate concentration exceeds 35 mg/dL and for clinically suspected cases of salicylism until a salicylate concentration and simultaneously obtained blood pH are available to guide treatment. Patients on therapeutic regimens of salicylates who feel well with salicylate concentrations of 30â€“40 mg/dL and who do not manifest toxicity do not require intervention. Oral bicarbonate administration should never be substituted for intravenous bicarbonate to achieve alkalinization because the oral route may increase salicylate absorption from the gastrointestinal tract by enhancing dissolution.[101]

Alkalinization in hemodynamically stable adults and children with significant salicylate concentrations may be achieved with a bolus of 1â€“2 mEq/kg, followed by an intravenous infusion of 3 ampules of

sodium bicarbonate (132 mEq) in 1 L of 5% dextrose in water (D_5W), to run at 1.5â€“2 times maintenance fluid range. Urine pH must be maintained at 7.5â€“8.0 and hypokalemia must be corrected (see below) to achieve maximum salicylate excretion. Volume load should remain modest while repleting previous losses. Early HD must be considered when a patient cannot tolerate the increased solute load that results from alkalinization because of congestive heart failure, renal failure, or cerebral edema. However, even when the decision for HD has been made, alkalinization (when possible) helps to achieve a more rapid initial reduction in blood concentrations.[51]

Hypokalemia

Hypokalemia is a common complication of salicylate poisoning and prevents urinary alkalinization unless corrected. Hypokalemia results from the movement of potassium into cells in exchange for hydrogen ions in the presence of alkalemia, potassium loss in the urine, diarrhea as a result of sorbitol use, and vomiting with subsequent metabolic alkalosis and bicarbonaturia.[44] If urinary alkalinization cannot be achieved easily, hypokalemia, excretion of organic acids, and volume depletion should be considered possible reasons. Calcium should be monitored, because decreases in both ionized[30] and total serum calcium[43] are also complications of bicarbonate therapy.

Frequent blood gas monitoring is required for all patients exposed to significant amounts of salicylates. Although maintaining alkalemia clearly is essential for treatment, arterial pH probably should not be allowed to rise above 7.55, as alkalemia shifts the oxyhemoglobin dissociation curve to the left and may be otherwise detrimental. Note, however, that even with blood pH 7.45â€“7.50 in patients with moderately severe salicylism, boluses of bicarbonate have been given without necessarily further increasing the pH. Perhaps this is a result of sodium bicarbonateâ€“induced metabolic alkalosis causing a decrease in the amount of salicylates acting on the brainstem to cause hyperventilation and a resultant respiratory alkalosis. Frequent

reassessment of blood pH (and fluid status) almost always allows administration of more sodium bicarbonate than was initially thought possible.

Indications for Extracorporeal Measures

Extracorporeal measures are indicated if the patient is very ill, has a very high serum salicylate concentration, has severe fluid or electrolyte disturbances, or is unable to eliminate the salicylates (Table 35-3). In most instances of severe salicylate poisoning, HD is the extracorporeal technique of choice, not only to clear the xenobiotic but also to rapidly correct fluid, electrolyte, and acidâ€“base disorders that will not be corrected by hemoperfusion

(HP) alone. HP provides better clearance than HD and may be an advantage if a mixed overdose might be better treated with HP. The combination of HD and HP in series is feasible and theoretically may be useful for treating severe or mixed overdoses[28] but is rarely used. Favorable results in rapidly reducing serum salicylate concentrations in severely poisoned patients have been described with use of continuous venovenous hemodiafiltration. This technique may be especially valuable for patients who are too unstable to undergo HD or in situations where HD is unavailable.[122]

TABLE 35-3. Indications for Hemodialysis in the Salicylate-Poisoned Patient

Renal failure
Congestive heart failure (relative)
Acute lung injury
Persistent CNS disturbances
Progressive deterioration in vital signs
Severe acidâ€“base or electrolyte imbalance, despite appropriate treatment
Hepatic compromise with coagulopathy Salicylate concentration (acute) >100 mg/dL (in the absence of the above)

A combination of therapies that are both useful and practical is to ensure effective alkalinization with sodium bicarbonate while a patient is waiting and then undergoing HD. In one unique case report, a patient who overdosed twice on salicylates within a 2-month period was treated in the first instance with 4 hours of HD but no effective alkalinization and in the second instance with sodium bicarbonate alkalinization but no HD. In both instances, blood concentrations of salicylates were >65 mg/dL. Although similar decreases in salicylate concentrations were achieved with the two techniques, the rate of decline during the first 4 hours was faster with alkalinization.[51] Combining the two therapies makes sense even if part of the reason for the increased early effectiveness of sodium bicarbonate treatment is related to the rapidity with which it can be achieved compared to the 2â€“4 hours required to institute HD after a patient presents under even the most favorable circumstances.[51]

Peritoneal dialysis (PD) was sometimes suggested in the past as a simpler extracorporeal procedure for eliminating salicylates in the

setting of hemodynamic compromise, coagulopathy, or inability to perform HP or HD. However, PD is only 10â€“25% as efficient as HP or HD and not even as efficient as renal excretion itself. The 24-hour clearance of salicylates with PD is less than the 4-hour clearance of salicylates by HP or HD; therefore PD is not recommended (Chap. 10).

Pregnancy

Considered a rare event, salicylate poisoning during pregnancy poses a particular hazard to the fetus because of the acidâ€“base and hematologic characteristics of the fetus and placental circulation: salicylates cross the placenta and are present in higher concentrations in the fetus than in the mother. The respiratory stimulation that occurs in the mother after toxic exposures does not occur in the fetus, which has a decreased capacity to buffer acid. The ability of the fetus to metabolize and excrete salicylates is also less than in the mother. In addition to its toxic effects on the mother, including coagulation abnormalities, acidâ€“base disturbances, tachypnea, and hypoglycemia, repeated exposure to salicylates late in gestation displaces bilirubin from protein-binding sites in the fetus.

A case report describing fetal demise in a woman who claimed to ingest 50 aspirin tablets per day for several weeks during the third trimester of pregnancy supports the conclusion that the fetus is at greater risk from salicylate exposures than is the mother and that emergent delivery of near-term fetuses of salicylate-poisoned mothers should be considered very seriously[86] (Chap. 30).

Summary

Initial assessment of a patient who has ingested excessive amounts of salicylates includes a determination of the vital signs, particularly the depth and frequency of respiration, and temperature. The clinical

presentation of a patient with a salicylate overdose is characterized by early onset of nausea, vomiting, abdominal pain, blood-tinged vomitus or gross hematemesis, tinnitus, and lethargy. The presence of hyperventilation, hyperthermia, confusion, coma, seizures, and any other nonspecific neurologic presentation should heighten suspicion of salicylate poisoning (Tables 35-1 and 35-2). If either salicylism or salicylate poisoning is suspected, a bedside $FeCl_3$ test can confirm salicylate *exposure* (but may be unnecessary). Using a combination of symptoms, signs, bedside laboratory studies, and characteristic ABG findings, the clinician can rapidly confirm a significant salicylate ingestion, institute immediate alkalinization with sodium bicarbonate, achieve gastric decontamination by orogastric lavage (if indicated), AC, or MDAC (if indicated), and consider the need for HD (or perhaps hemodiafiltration) early in the course of management.

For the salicylate-poisoned patient who presents as severely ill, maintenance of the airway requires an extremely careful approach because during initial airway management, death has occurred following sedation.[11] In patients with pulmonary and CNS manifestations of salicylate toxicity, the protective nature of the hyperpnea or hyperventilation in maintaining alkalemia may be compromised by assisted ventilation, unless the clinician is extremely skilled at adjusting the ventilator to ensure hyperventilation, decreased PCO_2, and high pH (7.5) at all times. Moreover, any unnecessary study, such as obtaining a computed tomographic scan that delays definitive treatment aimed at immediately reducing the patient's burden of salicylates quickly by HD can only place the patient at greater risk of death. Urinary alkalinization with sodium bicarbonate to eliminate salicylates is important, even though use of sodium bicarbonate may further complicate electrolyte abnormalities. Maintenance of eukalemia is important to ensure success, and fluid and electrolyte replacement is essential.

Antidotes in Depth

Sodium Bicarbonate

Paul M. Wax

Sodium bicarbonate ($NaHCO_3$) is one of the most useful agents available for treatment of the poisoned patient. Unlike more specific antidotes in which utility usually is limited to antagonizing a single drug or toxin, sodium bicarbonate is a nonspecific antidote effective in the treatment of a variety of poisonings by means of a number of distinct mechanisms (Table A6-1). The support for its use in these settings is predominantly based on animal evidence, case reports, and opinion.[6] It is most commonly used in the treatment of tricyclic antidepressant (TCA) and salicylate poisonings. Sodium bicarbonate may also have a role in the treatment of phenobarbital, chlorpropamide, and chlorophenoxy herbicide poisonings and wide-complex tachydysrhythmias induced by type IA and IC antidysrhythmics and cocaine. Correcting the life-threatening acidosis generated by methanol and ethylene glycol poisoning and enhancing formate elimination are other important indications for sodium bicarbonate. Use of sodium bicarbonate in the treatment of rhabdomyolysis, lactic acidosis,

cardiac resuscitation, and diabetic ketoacidosis is controversial and is not a focus of this Antidote in Depth.[1,21,32,37,39,84,86]

Altered Drug Ionization Resulting in Altered Drug Distribution

Tricyclic Antidepressants

Sodium bicarbonate's most important role in toxicology appears to be its ability to reverse potentially fatal cardiotoxic effects of the TCA drugs and other type IA and IC antidysrhythmics. Use of sodium bicarbonate for TCA overdose developed as an extension of sodium bicarbonate use in the treatment of other cardiotoxic exposures. Noting similarities in electrocardiographic findings between hyperkalemia and quinidine toxicity (ie, QRS widening), investigators in the 1950s began to use sodium lactate (which is metabolized to sodium bicarbonate) for the treatment of quinidine toxicity.[2,5,89] In a canine model, quinidine-induced electrocardiographic changes and hypotension were consistently reversed by infusion of sodium lactate.[4] Clinical experience confirmed this benefit.[5] Similar efficacy in the treatment of procainamide cardiotoxicity was also reported.[89]

With the introduction of the TCAs during the late 1950s and early 1960s, conduction disturbances, dysrhythmias, and hypotension following overdose were reported. Extending the use of sodium lactate from the type I antidysrhythmics to the TCAs, uncontrolled observations in the early 1970s showed a decrease in mortality from 15% to <3% when sodium lactate was administered to patients with TCA poisoning.[24] In 1976, the first report of successful use of sodium bicarbonate in the treatment of a series of TCA-induced dysrhythmias in children was reported.[12] In this series, 9 of 12 children who had developed multifocal premature ventricular contractions (PVCs), ventricular tachycardia, or heart

block reverted to normal sinus rhythm with sodium bicarbonate therapy alone. An early animal experiment in amitriptyline-poisoned canines demonstrated resolution of dysrhythmias upon alkalinization of the blood to pH >7.40.[12] Other methods of alkalinization, including hyperventilation and administration of the nonsodium buffer tris (hydroxymethyl) aminomethane (THAM), was also effective in reversing the dysrhythmias.[13,36]

A better understanding of the mechanism and utility of sodium bicarbonate has come from a series of animal experiments during the 1980s. In amitriptyline-poisoned canines, sodium bicarbonate reversed conduction slowing and ventricular dysrhythmias and suppressed ventricular ectopy.[56] When comparing sodium bicarbonate, hyperventilation, hypertonic sodium chloride, and lidocaine, sodium bicarbonate and hyperventilation proved most efficacious in reversing ventricular dysrhythmias and narrowing QRS interval prolongation. Although lidocaine transiently antagonized dysrhythmias, this antagonism was demonstrable only at nearly toxic lidocaine concentrations and was associated with hypotension. In these studies, hypertonic sodium chloride failed to reverse dysrhythmias. Furthermore, prophylactic alkalinization protected against the development of dysrhythmias in a pH-dependent manner.

In desipramine-poisoned rats, the isolated use of either sodium chloride or sodium bicarbonate was effective in decreasing QRS duration.[61] Both sodium bicarbonate and sodium chloride also increased mean arterial pressure, but hyperventilation or direct intravascular volume repletion with mannitol did not. In further studies both in vivo and on isolated cardiac tissue, alkalinization and increased sodium concentration improved TCA effects on cardiac conduction.[72,73] Although respiratory alkalosis and sodium chloride each independently improved conduction velocity, this effect was greater when sodium bicarbonate was administered.

Another study on amitriptyline-poisoned rats demonstrated that

treatment with sodium bicarbonate was associated with shorter QRS interval, longer duration of sinus rhythm, and increased survival rates.[38] Sodium bicarbonate seems to work independently of initial blood pH. Animal studies show that cardiac conduction improves after treatment with sodium bicarbonate or sodium chloride in both normal pH and acidemic animals.[61] Clinically, TCA-poisoned patients who already were alkalemic also responded to repeat doses of sodium bicarbonate.[53]

Although several authors suggest that sodium bicarbonate's efficacy is modulated via a pH-dependent change in protein binding that decreases the proportion of free drug,[13,43] further study failed to support this hypothesis.[64] The administration of large doses of a binding protein Î±$_1$-acid glycoprotein (AAG) (to which TCAs show great affinity) to desipramine-poisoned rats only minimally decreased cardiotoxicity. Although the addition of AAG increased the concentrations of total desipramine and protein-bound desipramine in the serum, the concentration of active free desipramine did not decline significantly. A redistribution of TCA from peripheral sites may have prevented lowering of free desipramine concentration. The persistence of other TCA-associated toxicity, such as the anticholinergic effects and seizures, also

argues against changes in protein-binding modulating toxicity. In vitro studies performed in a protein-free bath further support that sodium bicarbonate's efficacy is independent of protein binding.[72]

TABLE A6-1. Sodium Bicarbonate in Toxicology: Mechanisms, Site of Action, and Uses

Mechanism	Site of Action	Uses

Altered interaction between drug and sodium channel	Heart	Amantadine Carbamazepine Cocaine Diphenhydramine Flecainide Mesoridazine Procainamide Propoxyphene Quinidine Quinine Thioridazine Tricyclic antidepressants
Altered drug ionization leads to altered tissue distribution	Brain	Formic acid Phenobarbital Salicylates
Altered drug ionization leads to enhanced drug elimination	Kidneys	Chlorophenoxy herbicides Chlorpropamide Formic acid Methotrexate Phenobarbital Salicylates
Correct life-threatening acidosis	Metabolic	Cyanide Ethylene glycol Methanol
Increase drug solubility	Kidneys	Methotrexate

Neutralization	Lungs	Chlorine gas, HCl
Reduce free radical formation	Kidneys	Contrast media

Sodium bicarbonate has a crucial antidotal role in TCA poisoning by increasing the number of open sodium channels, thereby partially reversing fast sodium channel blockade. This decreases QRS prolongation and reduces life-threatening cardiovascular toxicity such as ventricular dysrhythmias and hypotension.[56,61,72] The animal evidence supports two distinct and additive mechanisms for this effect: a pH-dependent effect and a sodium-dependent effect. The pH-dependent effect increases the fraction of the more freely diffusible nonionized drug. Both the ionized drug and the nonionized forms are able to bind to the sodium channel, but assuming TCAs act like local anesthetics, it is estimated that 90% of the block results from the ionized form. By increasing the nonionized fraction, less drug is available to bind to the sodium channel binding site. The sodium-dependent effect increases the availability of sodium ions to pass through the open channels. Decreased ionization should not significantly decrease the rate of TCA elimination because of the small contribution of renal pathways to overall TCA elimination (<5%).

Although many anecdotal accounts support the efficacy of sodium bicarbonate in treating TCA cardiotoxicity in humans,[30] these reports are all uncontrolled observations; controlled studies are not available. In one of the largest retrospective observational studies involving 91 patients who received sodium bicarbonate after TCA overdose, QRS prolongation corrected in 39 of 49 patients who had QRS duration >0.12 seconds, and hypotension corrected within 1 hour in 20 of 21 patients who had systolic blood pressure <90 mm Hg.[31] Use of sodium bicarbonate was not

associated with any complications in this study.

Prospective validation of treatment criteria for use of sodium bicarbonate after TCA overdose has not been performed. The most common indications are conduction delays manifested by QRS >0.10 seconds, amplitude of terminal R wave in lead aVR (R_{aVR}) = 3 mm, or right bundle-branch block, wide-complex tachydysrhythmias, and hypotension.[44] Because studies show that there is a critical threshold QRS duration at which ventricular dysrhythmias may occur (â‰¥0.16 seconds),[9] it seems reasonable that narrowing the QRS interval through use of sodium bicarbonate or hyperventilation may prophylactically prevent against development of dysrhythmias. Practice patterns vary considerably over use of sodium bicarbonate in situations where the QRS interval is <0.16 seconds.[76] Although sodium bicarbonate has no proven efficacy in either the treatment or prophylaxis of TCA-induced seizures, seizures often cause acidemia, which rapidly increases the risks of conduction disturbances and ventricular dysrhythmias. Administering sodium bicarbonate in situations where the QRS duration is â‰¥0.10 seconds may establish a theoretical margin of safety in the event the patient suddenly deteriorates, without adding significant demonstrable risk. In situations where the QRS duration is <0.10 seconds (given the negligible risk of seizures or dysrhythmias), prophylactic use of sodium bicarbonate is not indicated.

Because cardiotoxicity may worsen during the first few hours after ingestion, we recommend starting sodium bicarbonate immediately if QRS interval widens to >0.10 seconds. Because TCA-induced hypotension also responds to sodium bicarbonate, hypotension is another indication for sodium bicarbonate. However, no evidence supports a role for sodium bicarbonate in TCA-poisoned patients who present with altered mental status or seizures without QRS widening or hypotension.

Because the potential benefits of alkalinization in TCA overdose

usually outweigh the risks, sodium bicarbonate should be administered regardless of whether the patient has an acidemic or normal pH. The most commonly used preparations are an 8.4% solution (1 M), containing 1 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 2000 mOsm/L) and a 7.5% solution, containing 0.892 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 1786 mOsm/L). Fifty-milliliter ampules of the 8.4% and 7.5% solutions contain 50 and 44.6 mEq of $NaHCO_3$, respectively. One to two milliequivalents of sodium bicarbonate per kilogram body weight should be administered intravenously as a bolus over a period of 1â€“2 minutes.[62] Greater amounts may be required to treat unstable ventricular dysrhythmias. Sodium bicarbonate can be repeated as needed to achieve a blood pH of 7.50â€“7.55.[63,78] The end point of treatment is narrowing of the QRS interval. Excessive alkalemia (pH >7.55) and hypernatremia should be avoided. Because sodium bicarbonate has a brief duration of effect, a continuous infusion usually is required after the intravenous bolus. Three 50-mL ampules should be placed in 1 L of 5% dextrose in water (D_5W) and run at twice maintenance with frequent checks of QRS and pH depending on the fluid requirements and blood pressure of the patient. Frequent evaluation of fluid status should be performed to avoid precipitating pulmonary edema. Optimal duration of therapy has not been established. The time to resolution of conduction abnormalities during continuous bicarbonate infusion significantly varies, ranging from several hours to several days.[45] Sodium bicarbonate

infusion usually is discontinued once there is improvement in hemodynamics and cardiac conduction and resolution in altered mental status, although controlled data supporting such an approach are lacking.

Other Sodium Channel Blocking Drugs

Sodium bicarbonate is useful in treating cardiotoxicity from other drugs, with sodium channel blocking effects manifested by widened QRS complexes, dysrhythmias, and hypotension. Isolated case reports provide the bulk of the evidence in these situations. The utility of sodium bicarbonate in treating type IA and IC antidysrhythmics, diphenhydramine, propoxyphene, and quinine is demonstrated.[4,8,70,77,81,89]

Use of sodium bicarbonate in the treatment of amantadine overdose manifested by prolongation of the QRS and QTc intervals was associated with narrowing of the QTc but not the QRS interval.[19] Although the usefulness of sodium bicarbonate in reversing QTc prolongation occasionally observed during fluoxetine and citalopram overdose has been reported,[18,25] sodium channel disturbances are uncommon in most cases of selective serotonin receptor inhibitor (SSRI) overdose, and routine use of alkalinization therapy in this setting is unwarranted. Sodium bicarbonate may help in the management of other ingestions associated with type IA-like cardiac conduction abnormalities and dysrhythmias, such as the phenothiazines thioridazine and mesoridazine, and carbamazepine, but documentation of such benefit is lacking.

The role of sodium bicarbonate as an antidote has been studied in experimental models of calcium channel toxicity and Î²-blocker toxicity. In the calcium channel blocker study, hypertonic sodium bicarbonate increased mean arterial pressure and cardiac output in verapamil-poisoned swine.[82] Possible explanations for this beneficial effect include the increase in serum pH, reversal of a sodium channel effect, lowering of serum potassium concentration, and/or volume expansion. In a canine model of propranolol toxicity, sodium bicarbonate failed to increase heart rate or blood pressure.[46]

Cocaine (a local anesthetic with membrane-stabilizing properties resembling other type I antidysrhythmics) may cause similar conduction disturbances. In several canine models of cocaine toxicity, sodium bicarbonate 2 mEq/kg successfully reversed cocaine-induced QRS prolongation[3,60] and improved myocardial function.[91] Of interest, sodium loading by itself (sodium chloride 2 mEq/kg) failed to produce a benefit. Similar findings were demonstrated in cocaine-treated guinea pig hearts.[92] Patients with pH-dependent cocaine-induced cardiotoxicity responded to treatment with sodium bicarbonate.[35,59,88] In many of these cases, simultaneous treatment with sedation, active cooling, and hyperventilation confounds the contribution of the sodium bicarbonate to overall recovery.

Altered Drug Ionization Resulting in Enhanced Elimination

Salicylates

Although there is no known specific antidote for salicylate toxicity, judicious use of sodium bicarbonate is an essential treatment modality of salicylism. Sodium bicarbonate, through its ability to change the concentration gradient of the ionized and nonionized fractions of salicylates, is useful in decreasing tissue (eg, brain) concentrations of salicylates and enhancing urinary elimination of salicylates.[66] This therapy may limit the need for more invasive treatment modalities, such as hemodialysis.

Salicylate is a weak acid with pK_a = 3.0. As pH increases, more of the drug is in the ionized form. Ionized molecules penetrate lipid-soluble membranes less rapidly than do nonionized molecules because of the presence of polar groups on the ionized form. Consequently, weak acids, such as salicylates, may accumulate in an alkaline milieu, such as an alkaline urine, when the ionized

forms predominate.[50,79]

Although alkalinizing the urine to increase salicylate elimination is an important intervention in the treatment of salicylate poisoning, increasing the serum pH in patients with severe salicylism may prove even more consequential by protecting the brain from a lethal central nervous system (CNS) salicylate burden. Using sodium bicarbonate to â€œtrapâ€• salicylate in the blood (keeping it out of the brain) may prevent clinical deterioration of the salicylate-poisoned patient. Salicylate lethality is directly related to primary CNS dysfunction, which, in turn, corresponds to a â€œcritical brain salicylate level.â€•[29] At physiologic pH, where a very small proportion of the salicylate is in the nonionized form, a small change in pH is associated with a significant change in amount of nonionized molecules (eg, at pH = 7.4, 0.004% of the salicylate molecules is in the nonionized form; at pH = 7.2, 0.008% of the salicylate is in the nonionized form). In experimental models, lowering the blood pH produces a shift of salicylate into the tissues.[14] Hence, acidemia that is observed in significant salicylate poisonings can be devastating. In salicylate-poisoned rats, increasing the blood pH with sodium bicarbonate produced a shift in salicylate out of the tissues and into the blood.[28] This change in salicylate distribution did not result from enhanced urinary excretion because occlusion of the renal pedicles failed to alter these results.

Enhancing the urinary elimination of salicylate by trapping ionized salicylate in the urine also provides great benefit. Salicylate elimination at low therapeutic concentrations consists predominantly of first-order hepatic metabolism. At these low concentrations, without alkalinization, only approximately 10â€“20% of salicylate is eliminated unchanged in the urine. With increasing concentrations, enzyme saturation occurs (Michaelis-Menten kinetics); thus, a larger percentage of elimination occurs as unchanged free salicylate. Under these conditions, in an alkaline urine, urinary excretion of free salicylate becomes even

more significant, accounting for 60â€“85% of total elimination.[26,68]

The exact mechanism of pH-dependent salicylate elimination has generated controversy. The pH-dependent increase in urinary elimination initially was ascribed to â€œion trappingâ€•: the filtering of both ionized and nonionized salicylate while reabsorbing only the nonionized salicylate.[75] However, limiting reabsorption of the ionizable fraction of filtered salicylate cannot be the primary mechanism responsible for enhanced elimination produced by sodium bicarbonate.[47] Because the quantitative difference between the percentage of molecules trapped in the ionized form at pH = 5.0 (99% ionized) and pH = 8.0 (99.999% ionized) is small, decreases in tubular reabsorption cannot fully explain the rapid increase in urinary elimination seen at pH >7.0.

â€œDiffusion theoryâ€• offers a reasonable alternative explanation. Fick's law of diffusion states that the rate of flow of a diffusing substance is proportional to its concentration gradient. A large concentration gradient between the nonionized salicylate in the peritubular fluid (and blood) and the tubular luminal fluid is found

in alkaline urine. Because at a higher urinary pH, a greater proportion of secreted nonionized molecules quickly becomes ionized upon entering the alkaline environment, more salicylate (ie, nonionized salicylate) must pass from the peritubular fluid into the urine in an attempt to reach equilibrium with the nonionized fraction. In fact, as long as nonionized molecules are rapidly converted to ionized molecules in the urine, equilibrium in the alkaline milieu will never be achieved. The concentration gradient of peritubular nonionized salicylates to urinary nonionized salicylates continues to increase with rising urinary pH. Hence, increased tubular diffusion, not decreased reabsorption, probably accounts for most of the increase in salicylate elimination observed in the alkaline urine.[47]

Controversies regarding the indications for alkalinization in the treatment of salicylism persist. Although urinary alkalinization undoubtedly works to lower serum salicylate concentrations and enhance urinary elimination, the risks associated with alkalinization in the management of salicylism are of concern. Questions regarding excessive alkalemia, hypernatremia, fluid overload, hypokalemia, and hypocalcemia, as well as the potential delay in achieving alkalinization with sodium bicarbonate (as opposed to more rapid response achieved with hyperventilation), have all been raised.[22,42,62,68,75] Patients with pure respiratory alkalosis often have alkaluria, as well as alkalemia, and do not require urinary alkalinization. In the more common scenario in which patients present with a mixed respiratory alkalosis and metabolic acidosis, sodium bicarbonate must be administered cautiously. The young child, who rapidly develops a metabolic acidosis, often requires alkalinization but should be at less risk for complications of this therapy.[58]

Sodium bicarbonate is indicated in the treatment of salicylate poisoning for most patients with evidence of significant systemic toxicity. Although some authors have suggested alkali therapy for asymptomatic patients with concentrations >30 mg/dL,[90] there are limited data supporting this approach. For patients suffering from chronic poisoning, concentrations are not as helpful and may be misleading; clinical criteria remain the best indicators for therapy. Patients with contraindications to sodium bicarbonate use, such as renal failure and acute lung injury, should be considered for intubation and subsequent hyperventilation, but extracorporeal removal will often be required because of the difficulty and danger of intubation.

Dosing recommendations depend on the acidâ€“base status of the patient. For the patient with acidemia, rapid correction is indicated with intravenous administration of 1â€“2 mEq of sodium bicarbonate per kilogram of body weight.[83] Once the blood is

alkalinized or if the patient has already presented with an alkalemia, continued titration with sodium bicarbonate over 4â€“8 hours is recommended until the urinary pH reaches 7.5â€“8.0.[80,83] Alkalinization can be maintained with a continuous sodium bicarbonate infusion of 100â€“150 mEq in 1 L of D_5W at 150â€–200 mL/h (or about twice the maintenance requirements in a child). Obtaining a urinary pH of 8.0 is difficult but is considered to be the goal. Fastidious attention to the changing acidâ€“base status is required. Systemic pH should be kept below 7.55 to prevent complications of alkalemia.

Hypokalemia can make urinary alkalinization particularly problematic.[42,74] In the hypokalemic patient, regardless of total body potassium stores, the kidney preferentially reabsorbs potassium in exchange for hydrogen ions. Urinary alkalinization will be unsuccessful as long as hydrogen ions are excreted into the urine. Thus, appropriate potassium supplementation to achieve normokalemia may be required in order to alkalinize the urine.[93]

In the past, proper urinary alkalinization was thought to require forced diuresis in order to maximize salicylate elimination.[17,42] Suggestions included administering enough fluid (2 L/h) to produce a urine output of 500 mL/h. Because forced alkaline diuresis appears unnecessary and is potentially harmful as a result of its unnecessarily large fluid load, alkalinization at a rate of approximately twice maintenance requirements to achieve a urine output of 3â€“5 mL/kg/h is the goal.

Phenobarbital

Although cardiopulmonary support is the most critical intervention in the treatment of patients with severe phenobarbital overdose, sodium bicarbonate may be a useful adjunct to general supportive care. The utility of sodium bicarbonate is particularly important considering the long plasma half-life (approximately 100 hours) of phenobarbital. Phenobarbital is a weak acid (pK_a = 7.24) that

undergoes significant renal elimination. As in the case of salicylates, alkalinization of the blood and urine can reduce the severity and duration of toxicity. In a study of mice, the median anesthetic dose for mice receiving phenobarbital increased by 20% with the addition of 1 g/kg of sodium bicarbonate (raising the blood pH from 7.23 to 7.41), demonstrating decreased tissue concentrations associated with increased pH.[87] Extrapolating the animal evidence to humans has suggested that phenobarbital-poisoned patients in deep coma might develop a respiratory acidosis, secondary to hypoventilation, with the acidemia enhancing the entrance of phenobarbital into the brain, thus worsening CNS and respiratory depression. Alternatively, increasing the pH with bicarbonate and/or ventilatory support would enhance the passage of phenobarbital out of the brain, thus lessening toxicity. Given the relatively high pK_a of phenobarbital, significant phenobarbital accumulation in the urine is evident only when urinary pH is raised above 7.5.[7] As the pH approaches 8.0, a 3-fold increase in urinary elimination occurs. The urine-to-serum ratio of phenobarbital, although much higher in alkaline urine than in acidic urine, remains less than unity, thereby suggesting less of a role for tubular secretion than in salicylate poisoning.

Clinical studies examining the role of alkalinization in phenobarbital poisoning have been inadequately designed. Many are poorly controlled and fail to examine the effects of alkalinization, independent of coadministered diuretic therapy. In one uncontrolled study, a 59â€“67% decrease in duration of unconsciousness in patients with phenobarbital overdoses occurred in patients administered alkali compared to nonrandomized controls.[52] In other older studies, treatment with sodium lactate and urea reduced mortality and frequency of tracheotomy to 50% of controls, enhanced elimination, and shortened coma.[41,55] In a later human volunteer study, urinary alkalinization with sodium bicarbonate was associated with a decrease in phenobarbital elimination half-life from 148 to 47 hours.[23] However, this

beneficial effect was less than the effect achieved by multiple-dose activated charcoal (MDAC), which reduced the half-life to 19 hours.[23] In a nonrandomized study of phenobarbital-poisoned patients comparing urinary alkalinization alone, MDAC alone, and both methods together, both the phenobarbital half-life decreased most rapidly and the clinical course improved most rapidly in the group of patients who received MDAC alone.[51] Interesting, the combination approach proved inferior to MDAC alone but was better than alkalinization alone. The authors speculated that when both treatments were used together, the increased ionization of phenobarbital resulting from

sodium bicarbonate infusion may have decreased the efficacy of MDAC. These studies suggest that MDAC is more efficacious than urinary alkalinization in the treatment of phenobarbital poisoning, although both approaches are beneficial and indicated.

Sodium bicarbonate therapy does not appear warranted in the treatment of ingestions of other barbiturates, such as pentobarbital and secobarbital, each of which has pK_a >8.0 and is predominantly eliminated by the liver.

Chlorpropamide

Chlorpropamide is a weak acid (pK_a = 4.80) and has a long half-life (30â€“50 hours). In a human study using therapeutic doses of chlorpropamide, urinary alkalinization with sodium bicarbonate significantly increased renal clearance of the drug.[57] This study showed that nonrenal clearance was the more significant route of elimination at a urinary pH of 5.0â€“6.0 (only slightly above pK_a), whereas at pH = 8.0, renal clearance was 10 times that of nonrenal clearance. Alkalinization reduced the area under the curve almost 4-fold and shortened elimination half-life from 50 to 13 hours. Acidification increased the area under the curve by 41% and increased the half-life to 69 hours. Although not a study in

overdose patients, this report suggests that sodium bicarbonate may be useful in the management of patients with chlorpropamide overdose. The effect of urinary alkalinization on elimination of other sulfonylureas is unnecessary because the benefit presumably is limited as these agents are largely metabolized in the liver.

Chlorophenoxy Herbicides

Alkalinization is indicated in the treatment of poisonings from weed killers that contain chlorophenoxy compounds, such as 2,4-dichlorophenoxyacetic acid (2,4-D), or 2-(4-chloro-2-methylphenoxy) propionic acid (MCPP).[65] Poisoning results in muscle weakness, peripheral neuropathy, coma, hyperthermia, and acidemia. These compounds are weak acids (pK_a = 2.6 and 3.8 for 2,4-D and MCPP, respectively) that are excreted largely unchanged in the urine. In an uncontrolled case series of 41 patients poisoned with a variety of chlorophenoxy herbicides, 19 of whom received sodium bicarbonate, alkaline diuresis significantly reduced the half-life of each compound by enhancing renal elimination.[20] In one patient, resolution of hyperthermia and metabolic acidosis and improvement in mental status were associated with a transient elevation of serum concentrations of these compounds, perhaps reflecting chlorophenoxy compound redistribution from the tissues into the more alkalemic blood. The limited data suggest that the increased ionized fractions of the weak-acid chlorophenoxy compounds produced by alkalinization is trapped in both the blood and the urine (as demonstrated with salicylates and phenobarbital); thus its use ameliorates toxicity and shortens duration of effect.

Correcting Metabolic Acidosis

Toxic Alcohols

Sodium bicarbonate has two important roles in treating toxic

alcohol ingestions. As an immediate temporizing measure, administration of sodium bicarbonate may reverse the life-threatening acidemia associated with methanol and ethylene glycol ingestions. In rats poisoned with ethylene glycol, the administration of sodium bicarbonate alone resulted in a 4-fold increase in median lethal dose.[10] Clinically, titrating the endogenous acid with bicarbonate greatly assists in reversing the consequences of severe acidemia, such as hemodynamic instability and multiorgan dysfunction.

The second role of bicarbonate in the treatment of toxic alcohol poisoning involves its ability to favorably alter the distribution and elimination of certain toxic metabolites.[69] In cases of methanol poisoning, the proportion of ionized formic acid can be increased by administering bicarbonate, thereby trapping formate in the blood compartment.[34,48] Consequently, decreased visual toxicity results from removal of the toxic metabolite from the eye. In cases of formic acid (pK_a = 3.7) ingestion, sodium bicarbonate decreases tissue penetration of the formic acid and enhances urinary elimination.[54] Further investigation is required to delineate the beneficial effects of sodium bicarbonate in the treatment of toxic alcohol ingestions.

Early treatment of acidemia with sodium bicarbonate is strongly recommended in cases of methanol and ethylene glycol poisoning.[27] Sodium bicarbonate should be administered to toxic alcohol-poisoned patients with an arterial pH <7.30.[40] More than 400â€“600 mEq of sodium bicarbonate may be required in the first few hours.[33] In cases of ethylene glycol toxicity, sodium bicarbonate administration may worsen hypocalcemia, so serum calcium concentration should be monitored. Combating the acidemia, however, is not the mainstay of therapy, and concurrent administration of intravenous ethanol or fomepizole and preparation for possible hemodialysis are almost always indicated.

Increasing Drug Solubility

Methotrexate

Urinary alkalinization with sodium bicarbonate is routinely used during high-dose methotrexate cancer chemotherapy therapy. Methotrexate is predominantly eliminated unchanged in the urine. Unfortunately, it is poorly water soluble in acidic urine. Under these conditions, tubular precipitation of the methotrexate may occur, leading to nephrotoxicity and decreased elimination, increasing the likelihood of methotrexate toxicity. Administration of sodium bicarbonate (as well as intensive hydration) during high-dose methotrexate infusions increases methotrexate solubility and the elimination of methotrexate.[16,71]

Neutralization

Chlorine Gas

Nebulized sodium bicarbonate serves as a useful adjunct in the treatment of pulmonary injuries resulting from chlorine gas inhalation.[15,85] Inhaled sodium bicarbonate neutralizes the hydrochloric acid that is formed when the chlorine gas reacts with the water in the respiratory tree. Although oral sodium bicarbonate is not recommended for neutralizing acid ingestions because of the problems associated with the exothermic reaction and production of carbon dioxide in the relatively closed gastrointestinal tract, the rapid exchange in the lungs of air with the environment will facilitate heat dissipation. In a chlorine-inhalation sheep model, animals treated with 4% nebulized sodium bicarbonate solution demonstrated higher PO_2 and lower PCO_2 than did the normal, saline-treated animals.[15] There was no difference, however, in 24-hour

mortality or pulmonary histopathology. Anecdotal experience suggests that nebulized bicarbonate therapy may lead to improvement of symptoms.[85] In a retrospective review, 86 cases of chlorine gas inhalation were treated with nebulized sodium bicarbonate.[11] Sixty-nine patients were sent home from the emergency department, 53 of whom had clearly improved. Such uncontrolled observations do not provide convincing evidence for the efficacy of such an approach, but the nebulized sodium bicarbonate was well tolerated. Further clinical studies are required to further assess the efficacy and safety of this treatment.

Reduction in Free Radical Formation

Contrast Media

A study has suggested that sodium bicarbonate may be beneficial in preventing contrast-induced nephropathy.[49] A randomized trial on 119 patients compared an infusion of 154 mEq/L of either sodium bicarbonate or sodium chloride before (3 mL/kg for 1 hour) and after (1 mL/kg/h for 6 hours) iopamidol administration. Contrast-induced nephropathy, defined as a â‰¥25% increase in serum creatinine concentration within 2 days of contrast, occurred in 8 patients in the sodium chloride group and 1 patient in the sodium bicarbonate group. It is suggested that increasing medullary pH with sodium bicarbonate infusion might protect the kidney from oxidant injury by slowing free radical production. Further study of this treatment is warranted.

Summary

Despite the increasing tendency to avoid sodium bicarbonate administration in the critically ill acidemic patient, sodium bicarbonate remains an important agent in the treatment of a wide variety of xenobiotic exposures. In fact, its utility in the poisoned

patient continues to expand. Sodium bicarbonate is effective in the treatment of poisonings by TCAs and other sodium channel blockers through its effects on drug ionization and subsequent diffusion from the sodium channel binding site. Sodium bicarbonate is effective for salicylates, phenobarbital, and other weak acids because of its ability to ion trap in the blood or brain and keep toxin away from the target organ.[67] Sodium bicarbonate is effective as a neutralizing agent for inhaled acids such as chlorine gas. In the more common causes of metabolic acidosis (eg, lactic acidosis), specific therapy such as antibiotics, volume resuscitation, and inotropic support usually takes precedence over bicarbonate administration.

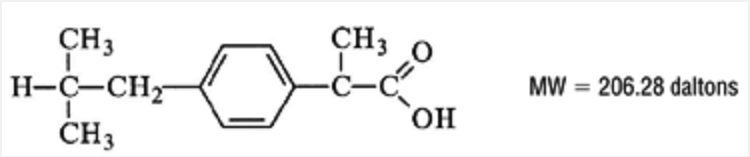
Chapter 36

Nonsteroidal Antiinflammatory Drugs

Martin G. Belson

William A. Watson



Ibuprofen

A 40-year-old man presented to the emergency department approximately 4 hours after ingesting approximately 100 ibuprofen tablets (400 mg each). He complained of diffuse abdominal pain and several episodes of vomiting. The patient had no other significant past medical history. His initial vital signs were: blood pressure, 125/75 mm Hg; pulse, 130 beats/min; respiratory rate, 24 breaths/min; temperature, 98.6Â°F (37Â°C). Shortly after arriving, the patient's mental status deteriorated, and he became lethargic but remained responsive to moderately painful stimuli. Physical examination revealed 4-mm normally reactive pupils, a supple neck, and no overt toxicologic syndrome. Neurologic examination revealed a depressed mental status, normal muscle tone in his extremities, and normal, symmetric reflexes.

A nasogastric tube was inserted, and stomach aspiration did not return pill fragments or blood. The patient was given 50 g of oral activated charcoal. Arterial blood gas analysis performed on 100% oxygen revealed pH, 7.30; PCO_2, 32 mm Hg; PO_2, 520 mm Hg, with a lactic acid concentration of 2.5 mmol/L. Serum chemistry analysis noted the following: sodium, 138 mEq/L; potassium, 3.5 mEq/L; chloride, 102 mEq/L; bicarbonate, 18 mEq/L, with an anion gap of 18 mEq/L. Blood urea nitrogen (BUN), creatinine, and serum glucose concentrations were normal (BUN, 12 mg/dL; creatinine, 1.4 mg/dL; serum glucose, 103 mg/dL). Complete blood count and calcium concentration were normal. Salicylate and acetaminophen concentrations were undetectable. The urine was negative for ketones and blood. An electrocardiogram noted sinus tachycardia but was otherwise normal.

The patient received 1 L of intravenous 0.9% sodium chloride followed by an infusion at 300 mL/h. On the second hospital day, the BUN concentration rose to 40 mg/dL and the creatinine concentration to 2.0 mg/dL. Without any specific treatment, both concentrations returned to baseline by the fourth hospital day. Hepatic aminotransferase concentrations and prothrombin time remained normal. Stool specimens remained negative for occult

blood.

An ibuprofen concentration of 900 Âµg/mL was reported 1 week later by a specialty laboratory (therapeutic reference range 20â€“30 Âµg/mL).

Nonsteroidal antiinflammatory drugs (NSAIDs) are a heterogeneous group of chemicals that share similar therapeutic properties. NSAIDs have analgesic, antipyretic, and antiinflammatory effects. The first NSAIDs commercially available inhibited cyclooxygenase (COX) in a nonselective fashion. With the realization that COX inhibition could be divided into COX-1 and COX-2 forms, and that most of the adverse gastrointestinal (GI) effects were mediated by COX-1, selective COX-2 inhibitors were introduced and marketed as having less GI toxicity than the older, less selective NSAIDs. Rofecoxib (Vioxx) and celecoxib (Celebrex) were launched in the United States in 1999 and valdecoxib (Bextra) shortly thereafter. The 2003 worldwide sales of Vioxx were $2.5 billion[42] and that of Celebrex were also several billion dollars. In the fall of 2004, the manufacturer of Vioxx voluntarily withdrew the drug from sale because of an increased cardiovascular (CV) mortality associated with Vioxx use. In April 2005, the FDA findings led the manufacturer of Bextra to withdraw that COX-2 inhibitor from the market, leaving Celebrex as the only COX-2 inhibitor available in the United States. Moreover, many nonselective NSAIDs have been implicated in increasing the risk of CV disease. Because many structurally different NSAIDs have been implicated but not every NSAID has been subjected to large epidemiologic studies, the problem appears to be with the class of drugs, rather than with an individual formulation. It appears that some NSAIDs are more prone to increasing cardiovascular risk than others.

History and Epidemiology

At the turn of the 20th century, aspirin (acetylsalicylic acid)

became the first available nonsteroidal antiinflammatory, antipyretic analgesic. Ibuprofen was first introduced in the United States in 1974 and was approved for nonprescription use in 1984.[41] With the ability to track exposure patterns provided by the Toxic Exposure Surveillance

System (TESS) since 1983, it has become apparent that nonsteroidal exposures are increasingly common, accounting for >3% of all reported cases in 2003 and ranking first among all pharmaceutical product exposures reported.[75] In 2003, >91,000 NSAID exposures (excluding aspirin) were reported to TESS, of which 77% involved ibuprofen, 15% naproxen, and 7% COX-2 inhibitors. Remarkably, only 48 deaths were reported, with all but one, presumably the result of a consequential coingestant[75] (Chap. 130).

Three NSAIDs (ibuprofen, naproxen, and ketoprofen) currently are available as both prescription and nonprescription products, and individually, as well as in combination with analgesics or analgesic cough and cold products. NSAIDs are available as veterinary products, and additional human exposures are occasionally secondary to inclusion of NSAID adulterants in patent herbal preparations.[48]

Pharmacology

The NSAID class includes at least 20 drugs that share the mechanism of COX inhibition (Table 36-1). Competitive inhibition of COX produces both the therapeutic and some of the toxic effects of this group of drugs.

Arachidonic acid is the precursor for the COX enzyme system. The process begins when arachidonic acid is cleaved from the phospholipid membrane of the cell by the action of phospholipase A (Figure 36-1). COX inhibition prevents the formation of prostaglandins, prostacyclins, and thromboxane A_2, but not

leukotrienes and other eicosanoids.[28,74] The two isoforms of COX are labeled COX-1 and COX-2.[64]

COX-1 is present in the kidney and GI tract and is responsible for vascular hemostasis, GI wall integrity, and renal homeostasis.[19] Inhibition of COX-1 decreases synthesis of thromboxane A_2 in platelets and interferes with their aggregation.

COX-2 is induced by inflammatory mediators and produces prostaglandins at the site of inflammation. The prostaglandins are responsible for mediating vasodilatation, increasing vascular permeability, and sensitizing pain fibers.[47] The discovery that inhibition of COX-2 is associated with both the analgesic and antiinflammatory actions of the NSAIDs led to the introduction of COX-2â€“specific inhibitors. COX-2 inhibitors demonstrate this property only at therapeutic doses; at very high concentrations the COX-2 specificity is lost.

An unanticipated finding of use of COX-2 selective NSAIDs was the finding that COX-2 NSAIDs increased the risk of CV disease. It now appears that this result probably is true of the entire class, although some drugs such as rofecoxib and valdecoxib appear to increase the risk more than others. Salicylates differ from the other NSAIDs in that they irreversibly bind to COX and produce an effect that lasts for the life of the platelet unless it can produce more enzyme. NSAIDs, such as diclofenac and indomethacin, also inhibit various lipoxygenase enzymes and decrease the production of leukotrienes in animals.[22,28] Acetaminophen inhibits COX in the central nervous system but does not have clinical antiinflammatory effects and therefore is not an NSAID. Acetaminophen and salicylates are described in Chaps. 34 and 35, respectively.

Pharmacokinetics and Toxicokinetics

NSAIDs are rapidly absorbed from the GI tract, with peak levels occurring within 2 hours of oral administration for most drugs.

Sustained-release indomethacin, enteric-coated diclofenac, mefenamic acid, piroxicam, and the prodrugs sulindac and nabumetone require 2â€“5 hours to reach peak levels.[7,68] All of these drugs are weakly acidic and highly protein bound (>90%), with volumes of distribution of approximately 0.1â€“0.2 L/kg. The NSAIDs cross the bloodâ€“brain barrier and are found in cerebrospinal fluid (CSF) and brain tissue. Peak CSF concentrations lag behind serum concentrations by at least 2 hours, and the relative ability of different NSAIDs to cross the bloodâ€“brain barrier is determined by lipophilicity.[2,40]

TABLE 36-1. Classes of Nonsteroidal Antiinflammatory Drugs

COX-1 and COX-2 inhibitors
- Salicylates
  - Acetyl salicylic acid (aspirin)
  - Nonacetylated derivatives (metabolized to salicylic acid)
    - Salsalate (Disalcid)
    - Sodium salicylate
    - Choline salicylate
    - Magnesium salicylate
    - Magnesium choline salicylate (Trilisate)
  - Diflunisal (Dolobid; not metabolized to salicylic acid)
- Pyrazolones
  - Phenylbutazone
- Fenamates (anthranilic acids)
  - Meclofenamate (Meclomen)
  - Mefenamic acid (Ponstel)
- Acetic acids
  - Diclofenac (Voltaren)
  - Etodolac (Lodine)

Indomethacin (Indocin)
Ketorolac (Toradol)
Nabumetone (Relafen)
Sulindac (Clinoril)
Tolmetin (Tolectin)
Propionic acids
Fenoprofen (Nalfon)
Flurbiprofen (Ansaid)
Ibuprofen (Motrin, Advil, Medipren)[b]
Ketoprofen (Orudis)[b]
Naproxen (Naprosyn, Anaprox)[b]
Oxaprozin (Daypro)
Oxicams
Piroxicam (Feldene)
COX-2 selective inhibitors
Celecoxib (Celebrex)
Meloxicam[a] (Mobic)
Rofecoxib (Vioxx)
Valdecoxib (Bextra)

[a] COX-2 preferential
[b]Nonprescription

Hepatic metabolism is the primary route for NSAID elimination, with renal elimination of unchanged drug accounting for <10% of clearance (except indomethacin with 10â€“20%).[28] The elimination half-life for the majority of NSAIDs is less than 8 hours; however, the half-lives of diflunisal, nabumetone, naproxen, and sulindac are between 8 and 30 hours, and the half-life of phenylbutazone and piroxicam is 30 hours.

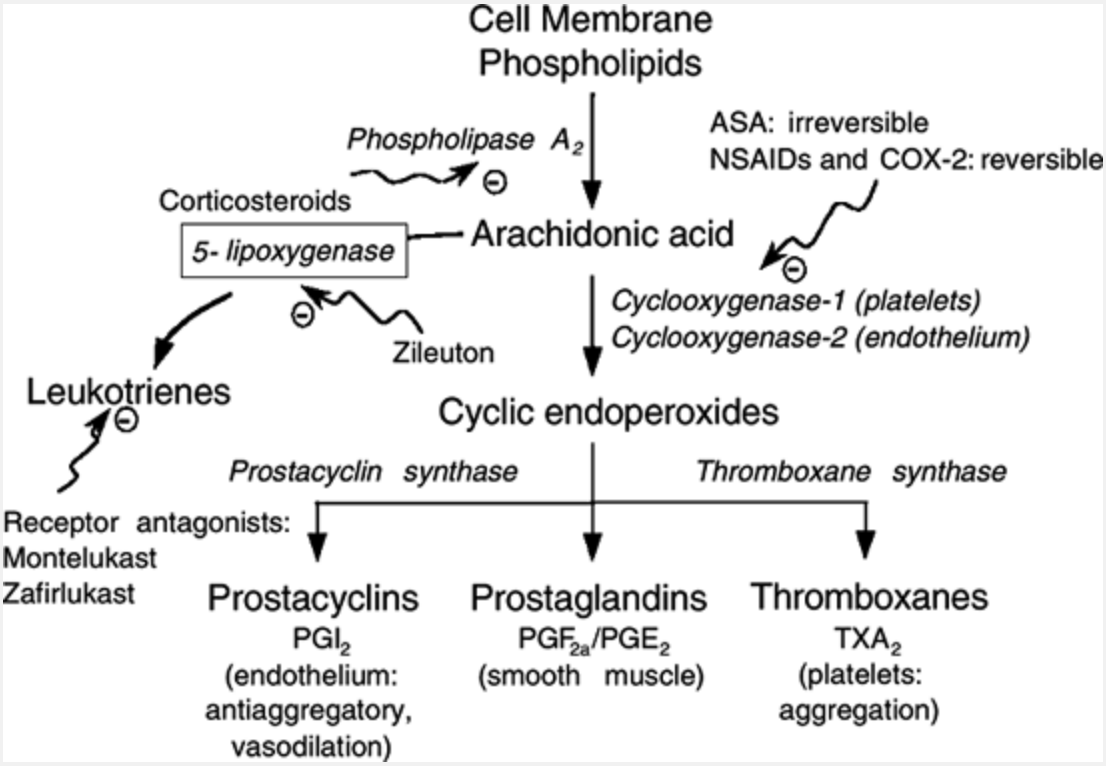


Figure 36-1. Mechanism of action of NSAIDs. Cyclooxygenase-1 (COX-1) is present in the kidney and GI tract. Cyclooxygenase-2 (COX-2) is induced by inflammatory mediators, such as cytokines and endotoxin, and produces prostaglandins at the site of inflammation. Most NSAIDs block these enzymes nonselectively, with the exception of the newer COX-2 inhibitors. Leukotrienes and other products of lipoxygenase are blocked by corticosteroids but not by salicylates or the newer COX-2 inhibitors. Leukotrienes may be involved in the sensitivity or asthmatic reactions produced by NSAIDs. Leukotriene receptor antagonists are designed to alleviate the effects of leukotrienes.

Some NSAIDs undergo extensive biliary-fecal elimination

(carprofen, indomethacin, piroxicam, sulindac), so theoretically, they should be susceptible to enhanced excretion with multiple-dose activated charcoal. However, toxicity rarely is severe enough to warrant this therapy.

The ingestion of a large dose alters the kinetics of some NSAIDs. The absorption rate of naproxen is slower with larger doses, delaying peak concentrations to 3â€“4 hours after the ingestion of 12 (250-mg) naproxen tablets.[61] Similar delays are found with ibuprofen, as determinations of serum concentrations in poisoning and overdose patients demonstrate continued absorption over at least the first 2 hours in some patients.[24,41]

Because NSAIDs are mostly bound to plasma proteins, the percentage of unbound drug likely will increase with increasingly larger doses, resulting in a larger volume of distribution.[51] Theoretically, this could result in a greater proportion of the dose available for distribution into tissue and the central nervous system and in a nonlinear doseâ€“toxicity curve. Renal elimination may be increased with naproxen overdose. In one study of 16 healthy volunteers, the rate of excretion tended to increase as naproxen levels rose.[61]

Ketorolac (Toradol) is available as the tromethamine salt in 10-mg tablets for oral administration and in solutions of 15â€“30 mg/mL for intramuscular and intravenous use. Similar to most other NSAIDs, ketorolac is well absorbed, is extensively metabolized by the liver to largely inactive metabolites, and has a short half-life (3.5â€“9.2 hours).[3]

Pathophysiology

Numerous reviews of adverse effects associated with NSAIDs are available[14,54,72,77] (Table 36-2). Many of the adverse effects, and probably all or most of the acute toxicities of the NSAIDs, are associated primarily with inhibition of COX-1. NSAIDs are directly

cytotoxic to the GI mucosa, and they inhibit formation of the cytoprotective prostaglandins PGI_2 and PGE_2 mediated by the COX-1 enzyme. Decreased concentration of these two prostaglandins in gastric tissue decreases mucus and bicarbonate production, promotes HCl secretion, and decreases gastric blood flow, resulting in loss of gastric cytoprotection. In addition to NSAID use, a risk factor for GI toxicity may be concomitant infection with *Helicobacter pylori*.[23] Statistically, the nonselective NSAIDs increase the relative risk of a serious GI hemorrhage by approximately 3-fold compared to control populations.[18,79] However, GI toxicity is not solely confined to COX-1 NSAIDs. GI bleeding is also associated with use of the selective COX-2 inhibitors rofecoxib and celecoxib.[4,17]

Chronic NSAID use frequently causes transient asymptomatic increases in hepatic aminotransferase activity, most commonly associated with phenylbutazone, diclofenac, and sulindac. Serious adverse drug events from chronic use are rare but occur more frequently with diclofenac.[59,60]

The acidosis associated with NSAID overdose occurs infrequently and usually is a high-anion-gap metabolic acidosis. It appears to result from mechanisms including the formation of NSAID metabolites that are weak acids, hypotension, and relative hypoxia.[27] No information indicates that inhibition of COX itself is responsible for production of the metabolic acidosis.

In the presence of renal vasoconstrictor substances such as angiotensin, prostaglandins produce vasodilation of renal arterioles.[45] In patients with normal mechanisms for maintaining renal blood flow, NSAIDs have little effect on renal blood flow and renal function because the concentrations of angiotensin are low in these situations. However, in patients with congestive heart failure, cirrhosis, intrinsic renal disease, or hypovolemia, which are characterized by high angiotensin and low intravascular volume, an NSAID-induced decrease in prostaglandins results in

vasoconstriction. This in turn causes a decrease in both renal blood flow and glomerular filtration rate, which may lead to renal failure, particularly in the elderly. This vasoconstrictive effect may also be caused by selective COX inhibitors of all classes and usually is reversible upon discontinuation of therapy.[57]

Acute and chronic forms of interstitial nephritis and nephrotic syndrome occur in NSAID users.[11,46] The term *analgesic nephropathy* has been used to describe the form of chronic renal disease

characterized by papillary necrosis and interstitial nephritis in patients with prolonged excessive consumption of combination antipyretic analgesics who have no other discernible cause of their disease.[63]

TABLE 36-2. Selected Adverse Effects of Nonsteroidal Antiinflammatory Drugs

Gastrointestinal
Dyspepsia
Ulceration
Perforation
Hemorrhage
Elevated hepatic aminotransferase concentrations (transient)
Hepatocellular injury (rare)
Renal
Acute renal failure
Fluid and electrolyte retention
Interstitial nephritis
Nephrotic syndrome
Papillary necrosis

Hypersensitivity/pulmonary
Asthma exacerbation
Anaphylactoid reaction
Pneumonitis
Hematologic
Increased bleeding time
Agranulocytosis
Aplastic anemia
Thrombocytopenia
Neutropenia
Hemolytic anemia
Central nervous system
Headache
Aseptic meningitis
Delirium
Cognitive dysfunction, especially in the elderly
Hallucinations
Drug interactions
Anticoagulants: NSAIDs increase risk of GI bleeding
Antihypertensives (especially diuretics, Î²-adrenergic antagonists, and ACE inhibitors): NSAIDs reduce antihypertensive effects
Sulfonylureas: NSAIDs increase hypoglycemic effect
Lithium: NSAIDs increase risk of lithium toxicity
Digoxin: NSAIDs increase risk of digoxin toxicity
Aminoglycosides: NSAIDs increase risk of aminoglycoside toxicity

NSAID use causes many hematologic effects. Inhibition of COX-1 results in decreased formation of thromboxane A_2 which is responsible for platelet aggregation. Therefore, bleeding problems and interactions with concomitant anticoagulant usage may occur. NSAIDs are associated with other hematologic abnormalities including aplastic anemia (indomethacin and etodolac),

agranulocytosis (naproxen), hemolytic anemia (mefenamic acid), methemoglobinemia (celecoxib), neutropenia (indomethacin), and thrombocytopenia (indomethacin, ibuprofen, and naproxen).[13,62,33,73] All of these are considered idiosyncratic reactions.

The most common central nervous system (CNS) signs and symptoms associated with the chronic use of NSAIDs are drowsiness, confusion, and headache.[24,35] Abnormal electroencephalogram waves have been described in one case of naproxen toxicity, similar to changes seen with CNS depressant overdoses.[8] Aseptic meningitis in patients with and without autoimmune disorders have been reported with the use of ibuprofen, sulindac, and tolmetin.[10,50] Some drugs can cause tinnitus (ibuprofen, naproxen, fenoprofen, sulindac, tolmetin) or transient hearing loss (ibuprofen and indomethacin).[28,53]

Visual disturbances associated with use of nonselective NSAIDs include toxic amblyopia, scotoma, and blurred vision. The causality and mechanism by which these effects are produced are unclear, although visual disturbances also occur with COX-2â€“selective drugs.[39]

Because uterine production of prostaglandins increases dramatically in the hours before parturition, NSAIDs are often used as tocolytics.[43] However, NSAID use may be associated with premature intrauterine closure of the fetal ductus arteriosus, renal failure, and oligohydramnios in neonates.[31]

Life-threatening anaphylactoid reactions can occur after NSAID administration. Up to 25% of adult asthmatics with nasal polyps or chronic urticaria develop acute bronchospasm minutes to hours after NSAID exposure.[71] These reactions are often accompanied by flushing of the head and neck, rhinorrhea, conjunctivitis, and/or angioedema. All NSAIDs regardless of COX selectivity pattern may function as haptens that are capable of inducing allergic sensitization.[5,34]

There are many potential clinically significant drug interactions with NSAIDs (Table 36-2).

COX-2 Selective Inhibitors and Cardiotoxicity

Atherosclerosis is a process with inflammatory features, and selective COX-2 inhibitors theoretically could have antiatherogenic effects by inhibiting inflammation. However, by decreasing vasodilatory and antiaggregatory prostacyclin production, COX-2 antagonists may lead to increased prothrombotic activity. The potential for COX-2 inhibitors to increase the risk for myocardial infarction (MI) has now been studied directly and indirectly in several large studies. The safety profile of the COX-2 inhibitors with regard to the risk of CV events first came into question in 2001.[44] Data from a major randomized trial in 2000, the Vioxx Gastrointestinal Outcomes Research (VIGOR) study (8076 patients), confirmed that the incidence of MI was significantly lower among patients with rheumatoid arthritis taking naproxen than among those taking rofecoxib.[6] Some researchers concluded that naproxen has a cardioprotective benefit rather than rofecoxib having a cardiotoxic effect.[30,37,76] This conclusion was also based on results from the company's rofecoxib development program in which 5435 osteoarthritis trial participants reportedly had similar rates of CV thrombotic events with rofecoxib, placebo, and nonselective NSAIDs (ibuprofen, diclofenac, and nabumetone).[76] A subsequent pooled analysis from 23 studies (including VIGOR) encompassing multiple disease states and including >14,000 patient-years at risk also demonstrated that rofecoxib was not associated with excess CV thrombotic events compared with either placebo or nonnaproxen NSAIDs.[76]

Since 2003, various studies have demonstrated (1) no detectable risk reduction for occurrence of MI with NSAID use,[20] (2) no increased CV risk with use of COX-2 inhibitors over nonnaproxen

NSAIDS,[66] or (3) increased risk of CV events with rofecoxib (Vioxx) use.[9,21,69] Dosages of rofecoxib >25 mg in the first 90 days of use have been associated with a higher risk for MI than dosages â‰¤25 mg.[69]

On September 30, 2004, Merck Pharmaceuticals announced the withdrawal of Vioxx based on 3-year data from a prospective,

randomized, double-blind, placebo-controlled clinical trial, the APPROVE (Adenomatous Polyp Prevention on Vioxx) trial.[42] In this trial, use of Vioxx in patients with colorectal adenomas was associated with an increased risk of thrombotic events beginning after 18 months of treatment, compared to those taking placebo (relative risk 1.92; p = 0.008).[9]

Clinical Manifestations

Although the severity and frequency of some clinical manifestations may differ, the toxic effects of the different nonselective NSAIDs are generally similar in acute overdose. Clinical effects typically occur within 4 hours of ingestion.[27,38,68] COX-2 receptor selectivity is lost at high concentrations, so overdoses of these drugs are expected to cause toxicity similar to the nonselective NSAIDs.

The most common toxic effects in acute overdose are GI distress (nausea, vomiting, epigastric pain, GI hemorrhage) and CNS depression.[24] Other CNS effects may include changes in cognition, hallucinations, muscle twitching, or seizures and are most frequent after mefenamic acid overdose.[1,12] Muscle twitching may be focal or generalized and in one series, lasted 3â€“10 minutes, with 20% of 54 patients progressing to grand mal seizures 2â€“7 hours postingestion. Reported doses as low as 2 g of mefenamic acid in a child and 6 g (over 24 hours) in an adult were implicated in the production of seizures.[1]

Coma, apnea, or metabolic acidosis developed in 9% of adults and 5% of children who overdosed on ibuprofen.[25] Patients who ingested >400 mg/kg of ibuprofen by history (especially in the pediatric population) were more likely to have seizures, apnea, hypotension, bradycardia, metabolic acidosis, and renal and hepatic dysfunction. The cause of the metabolic acidosis is undefined, but the serum lactic acid concentration generally is only mildly elevated. Because all of the NSAIDs are derivatives of organic acids (eg, ibuprofen is a propionic acid derivative), the NSAID itself or a metabolite, such as propionic acid, may be responsible. Fulminant hepatic failure is rarely seen in acute overdose.[59,60]

Before its removal from the US market in the 1970s, phenylbutazone was associated with the majority of severe toxicity attributed to NSAIDs. In a review of 99 cases, phenylbutazone overdoses were characterized by early GI symptoms, acidâ€“base and electrolyte disturbances, acute lung injury, dizziness, seizures, coma, hypotension, and respiratory and cardiac arrest.[12,56] Acute signs were followed by renal, hepatic, and hematologic dysfunction 2â€“7 days after overdose. At least 50 phenylbutazone-related fatalities have occurred in children.[55] The fatal dose in a 1-year-old was reported to be 2 g, with serious symptoms occurring in adults after ingestions of >4 g.[12,58,70] Although phenylbutazone has long been gone from the US market, it is still available from veterinary sources and for humans in other countries.[49]

Diagnostic Testing

Measurement of serum NSAID concentrations is unnecessary for the clinical assessment and management of patients with NSAID exposures. Although a nomogram describing ibuprofen serum concentrations and their relationship to toxicity is available,[26,29] serum ibuprofen assays correlate poorly with outcome.[65]

For the patient with intentional overdose, a complete blood count, prothrombin time, and serum electrolyte, creatinine, and BUN concentrations should be considered baseline parameters. A serum pregnancy test should be obtained for women of child-bearing age. If significant respiratory or CNS toxicity is present, acidâ€“base status should be assessed. A serum acetaminophen concentration should be obtained to determine whether there is concurrent acetaminophen ingestion, especially in patients with a history of recent painful or febrile conditions.[52] Baseline studies should be considered in children who unintentionally ingested >400 mg/kg.

Management

Most NSAID toxicity resolves with supportive care. Otherwise healthy patients with a history of NSAID poisoning generally require only GI decontamination with activated charcoal, fluid and electrolyte replacement, and supportive management of airway, breathing, and circulation as necessary. Patients who may have ingested a large dose of an NSAID, and who present with CNS or CV toxicity, or who have known risk factors for organ system toxicity associated with NSAIDs, should be considered at higher risk for complications.

Because of the rapid absorption of NSAIDs, symptoms should be evident by 4â€“6 hours after ingestion. Because of this rapid absorption, gastric decontamination by orogastric lavage probably is not indicated. In a human volunteer, comparative trial on the efficacy of activated charcoal alone versus activated charcoal and orogastric lavage after administration of 400 mg of ibuprofen, no difference in ibuprofen plasma concentrations were found 10 hours after ingestion between the two groups.[36] Administration of single-dose activated charcoal within approximately 1â€“2 hours of ingestion is most likely to be the safest and most efficacious means of decontamination after an overdose of NSAIDs.

The high degree of protein binding characteristic of all NSAIDs

makes hemodialysis ineffective in overdose, and experience with hemoperfusion is insufficient to determine its utility.

There is no antidote for NSAID poisoning. Several therapeutic interventions have been tried to prevent the adverse GI effects resulting from loss of cytoprotection from prostaglandins. Use of proton pump inhibitors has shown some success,[15,78] whereas H_2-receptor blockade was unsuccessful in 1920 patients.[67]

Concurrent administration of misoprostol, a PGE analog, may be effective in preventing GI side effects of NSAIDs. Other experimental efforts have involved the coadministration of nitric oxide[16] or substance P inhibitors.[32] These approaches to minimizing adverse effects have not been used for treatment of NSAID overdoses.

Summary

The NSAIDs are a large class of drugs that share similar clinical toxicity based on their ability to inhibit COX. The toxicity that results from overdose usually consists of epigastric pain, nausea or vomiting, and mild CNS depression. Uncommonly, severe overdoses result in metabolic acidosis and CNS toxicity, including seizures, apnea, and coma.

Necessary clinical management usually is limited to general supportive care and assessment for the presence of additional substances (especially acetaminophen) and risk factors for organ system toxicity. Activated charcoal is indicated as GI decontamination

if it can be administered within 1â€“2 hours after ingestion of large doses of NSAIDs. The presence of significant CNS effects or risk factors mandates a more comprehensive evaluation of acidâ€–base, fluid, renal, and electrolyte status.

Chapter 37
Colchicine and Podophyllin

Joshua G. Schier

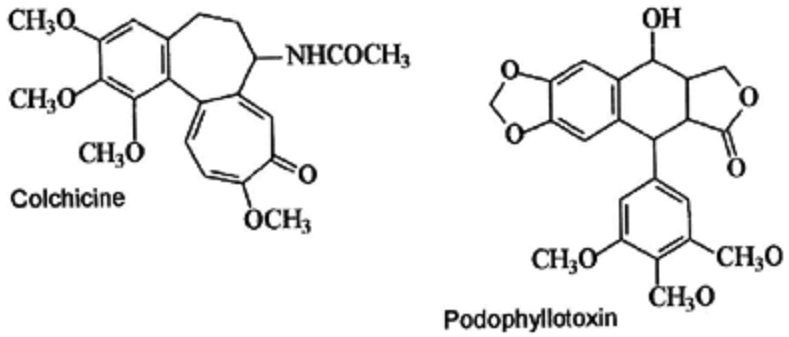

Figure. No Caption Available.

A 48-year-old man presented to the emergency department with chief complaints of uncontrollable nausea, vomiting, and diarrhea. The patient stated that approximately 30 hours earlier, while he was intoxicated with ethanol, he had taken 20 colchicine tablets (0.6 mg) for a gout exacerbation. He developed mild nausea and vomiting several hours after ingestion, followed by diarrhea 14 hours later. The patient

decided to seek medical attention 16 hours after the onset of diarrhea when his symptoms did not improve and he was unable to urinate. He had a medical history significant for gout and ethanol abuse and reported taking only colchicine, naproxen, and indomethacin.

On presentation, the patient was a well-nourished, anxious-appearing man in no acute distress. Vital signs were as follows: blood pressure, 117/53 mm Hg; pulse, 88 beats/min; respiratory rate, 22 breaths/min; temperature, 101.2Â°F (38.4Â°C). His physical examination was significant only for dry mucous membranes. Initial laboratory results revealed the following: sodium, 148 mEq/L; potassium, 4.5 mEq/L; chloride, 105 mEq/L; bicarbonate, 13 mEq/L; blood urea nitrogen, 20 mg/dL; creatinine 4.5 mg/dL. A complete blood count showed the following: white blood cell count, 15,500/mm^3 ; hematocrit, 62.3%; platelets, 394,000/mm^3 . Other laboratory results included prothrombin time, 18.7 seconds; activated partial thromboplastin time, 43.9 seconds; creatine kinase 883 IU/L; creatine kinase (MB fraction), 4.11 IU/L; aspartate aminotransferase, 336 U/L; alanine aminotransferase, 53 U/L; total bilirubin, 0.7 mg/dL; direct bilirubin, <0.1 mg/dL. Urinalysis revealed specific gravity of 1.029 and many red blood cells (11â€“25) per high-power field.

The patient was admitted to the hospital, and aggressive fluid resuscitation was begun. The nephrology and hematology services were consulted for renal failure and anticipated development of colchicine-induced pancytopenia. During the next 12 hours, the patient received approximately 5 L of intravenous 0.9% sodium chloride solution, and urinary flow improved minimally. However, the next morning the patient's electrolytes and renal function tests were essentially unchanged. His white blood cell count peaked at 30,400/mm^3 . The patient developed acral cyanosis and a fever 103.3Â°F (39.6Â°C) of unclear etiology. He was started on broad-spectrum antibiotics (vancomycin and cefepime), and continuous venovenous hemodialysis was instituted for renal failure. During the following several days, the patient's condition deteriorated. He became encephalopathic and developed respiratory failure, which required endotracheal intubation.

He also developed disseminated intravascular coagulation and was started on heparin and fresh-frozen plasma. Granulocyte colony-stimulating factor was started for colchicine-induced pancytopenia: white blood cell count, 3500/mm^3 ; hematocrit, 34%; platelets, 80,000/mm^3 . His white blood cell count eventually fell to 700/mm^3 .

The patient's clinical course continued to worsen, and he developed localized sloughing of his skin, consistent with a toxic epidermal necrolysis reaction. (See ILCOLCHICINE in the Image Library at http://www.goldfrankstoxicology.com) A skin biopsy revealed multiple keratinocytes in metaphase arrest. Despite aggressive respiratory, cardiovascular, and nephrologic support, the patient died on day 9 of his hospitalization.

Colchicine

History and Epidemiology

The origins of colchicine and its history in poisoning can be traced back to Greek mythology. Medea was the evil daughter (and a known poisoner) of the King of Colchis, a country that lay east of the Black Sea in Asia Minor. After she was betrayed by her husband Jason (Jason and the Argonauts), she killed their children and her husband's lover. Medea often used plants of the Liliaceae family, of which *Colchicum autumnale* is a member, to poison her victims.[15 , 99 , 132] Use of colchicum for medicinal purposes also is reported in *Pedanius Dioscorides De Materia Medica* , an ancient medical text, written in the 1st century A.D.[15 , 99 , 132] More extensive use of colchicum might have started as early as the 6th century A.D. by Alexander of Trallis, who recommended it for arthritic conditions.[15 , 22 , 85 , 132] However, colchicum fell out of favor, perhaps because of its pronounced gastrointestinal effects, until it was introduced for dropsy and various other nonrheumatic conditions by Baron von Storck of Vienna in 1763.[15 , 132] In the late 18th century, a colchicum-containing product known as

Eau Medicinale appeared, which reportedly had strong antigout effects.[132] Colchicine, the active alkaloidal component in colchicum, was isolated in 1820 by Pellstier and Caventou and rapidly became popular as an antigout medication.[99, 132] Benjamin Franklin reportedly suffered from gout and is credited with introducing colchicine in the United States for that reason.[99] Colchicine still is used in the treatment of gout as well as a multitude of other disorders, including amyloidosis, BehÃ§et syndrome, familial Mediterranean fever, pericarditis, arthritis, pulmonary fibrosis, vasculitis, biliary cirrhosis, pseudogout, certain spondyloarthropathies, calcinosis, and systemic scleroderma.[6, 15, 91, 95] Systematic data supporting the efficacy of colchicine therapy in many of these other diseases are lacking. Colchicine also has been touted as a â€œgrowth changerâ€• to increase the tetrahydrocannabinol (THC) component of adult marijuana plants by a popular Web site for illicit drugs.[102]

Colchicine is derived from two plants of the Liliaceae family: *Colchicum autumnale* (autumn crocus, meadow saffron, wild saffron, naked lady, son-before-the-father) and *Gloriosa superba* (glory lily).[132] Autumn crocus can contain different amounts of colchicine by weight, depending upon the plant part (bulb, 0.8%; flowers, 0.1%; seeds, 0.8%; and the corm or underground stem, 0.6%).[85, 99, 120] Colchicine concentrations within the plant peak during the summer months.[99] The leaves of *Colchicum autumnale* closely resemble those of the *Allium ursinum* or wild garlic and have been mistaken for them.[25, 26, 76] The tubers of *Gloriosa superba* can be confused with *Ipomoea batatas* (sweet potatoes).[132]

Good epidemiologic data on colchicine poisoning are lacking. The Toxic Exposure Surveillance System records several hundred exposures annually. The majority of these exposures are in adults older than 19 years of age and categorized as unintentional. Of these cases with a recorded outcome, approximately 10% were noted to be major or have resulted in death (Chap. 130)

Pharmacology

Colchicine is a potent inhibitor of microtubule formation and function, which interferes with cellular mitosis, intracellular transport mechanisms, and maintenance of cell structure and shape.[95,132] The ubiquitous presence of microtubules in cells composing various tissues and organs throughout the body presents a wide variety of targets for colchicine poisoning.[95,132] Colchicine accumulates in leukocytes and has inhibitory effects on leukocyte adhesiveness, ameboid motility, mobilization, lysosome degranulation, and chemotaxis.[15,31,39,57,64,95,100,101,129,130 and 131,133] At concentrations used clinically, colchicine can inhibit neutrophil and synovial cell release of chemotactic glycoproteins.[135,154] Colchicine also reduces symptoms by inhibiting microtubule polymerization, which disrupts inflammatory cell-mediated chemotaxis and phagocytosis.[139] It reduces expression of adhesion molecules on endothelial and white blood cells and affects polymorphonuclear cell cytokine production.[4,16,114] Colchicine also can act as a competitive antagonist at Î³-aminobutyric acid type A ($GABA_A$) receptors.[172]

Pharmacokinetics/Toxicokinetics

Colchicine is rapidly absorbed in the jejunum and ileum, undergoes extensive first-pass hepatic metabolism, and has a bioavailability generally between 25% and 50%.[15,92,132,143] It is highly lipid soluble.[11,15,132] The volume of distribution has been reported to range from 2.2â€“12 L/kg and, in overdose, may increase to 21 L/kg.[119,132,136,137,163,169] Initial studies reported plasma elimination half-lives ranging from 9â€“108 minutes.[9,74,132,143,169] On closer examination, however, these times probably more accurately reflect a rapid initial distribution phase. The drug undergoes a more delayed terminal elimination phase, which ranges from 1.7â€“30 hours, depending upon the individual, compartment model used to estimate elimination, and amount of colchicine absorbed.[1,62,132,137,141,143,163] Colchicine can remain in measurable tissue

quantities for a long time as evidenced by its detection in white blood cells after 10 days and in urine 7â€“10 days after exposure.[57 , 132] Colchicine can cross the placenta and is secreted in breast milk, but it is not dialyzable.[95] Postmortem examination of colchicine-poisoned patients reveals high concentrations within the bone marrow, testicle, spleen, kidney, lung, brain, and heart.[136]

Colchicine binding to plasma proteins approaches 50%.[15 , 95 , 115 , 132] Colchicine binds principally to albumin, although some binding to $\hat{I}\pm_1$ -glycoprotein acid and other lipoproteins is reported.[143] Colchicine is taken up by white and red blood cells in concentrations 5â€“10 times higher than serum during the first several hours after acute overdose.[143] Peak plasma concentrations following ingestion occur between 1â€“3 hours.[95] Toxic effects usually do not occur with concentrations <3 ng/mL.[58 , 115 , 168]

Colchicine is primarily metabolized through the liver, with up to 20% of the ingested dose excreted unchanged through the urinary system.[84 , 132 , 163] Colchicine undergoes demethylation by the cytochrome P450 3A4 (CYP3A4).[84 , 95 , 162] Detoxification mainly occurs through deacetylation, demethylation, biliary secretion, and excretion in the stool.[84 , 95 , 112 , 141 , 143 , 162] The reliance on biliary excretion strongly suggests that some amount of enterohepatic recirculation must exist, although this elimination pathway is incompletely studied.[1 , 132] Individuals with severe renal failure and liver cirrhosis may have an elimination half-life that is prolonged up to 10-fold.[95]

Xenobiotic and Substrate Interactions

Colchicine metabolism is susceptible to drug interactions. The reliance of colchicine on detoxification through CYP3A4 makes colchicine susceptible to xenobiotics that alter the function of this enzyme, such as erythromycin, clarithromycin, and grapefruit juice.[33 , 52 , 69 , 95] The multidrug

resistant (MDR) gene codes for a cellular efflux pump protein known as

P-glycoprotein.[95] This protein is able to expel certain chemotherapeutic agents, and certain drugs such as cyclosporine can affect its function. Cyclosporine and other agents that can affect MDR expression and function can interfere with colchicine metabolism and ultimate biliary excretion, thereby increasing colchicine toxicity.[95 , 152 , 153] P-glycoprotein inhibition also might play a role in the macrolide interactions.[138]

Pathophysiology

Microtubules play a vital role in cellular mitosis and possess a high amount of dynamic instability.[13 , 56 , 86 , 148] Microtubules are made up of tubulin protein subunits; the three known to exist are Î±, Î², and Î³.[86 , 108 , 148] These structures are highly dynamic with Î±,Î²-tubulin heterodimers, constantly being added at one end and removed at the other.[86 , 87] This equilibrium is needed for multiple cell functions, including cell support, transport, and mitotic spindle formation for cell replication.[86] Xenobiotics that bind to specific regions on tubulin can interfere with microtubule structure and function, thereby causing mitotic dysfunction and arrest.[108 , 148] This leads to cellular dysfunction and death.[148] Colchicine binds to tubulin (specifically on the Î²-subunit) in a specific region known as the *colchicine-binding domain* .[77 , 86 , 125 , 148 , 164] This binding is relatively slow, temperature dependent, and irreversible, resulting in an alteration of the protein's secondary structure.[77 , 86 , 125 , 144] Colchicine also can bind at a second, reversible, but lower-affinity site on tubulin.[86 , 98] Conformational changes in both tubulin and colchicine result, which might weaken the lateral bonds at the microtubule end.[108 , 148] This can prevent adequate binding of the next tubulin subunit and result in cessation of microtubule growth.[108 , 148]

These conformational changes ultimately result in disassembly of the microtubule spindle in metaphase of cellular mitosis, cellular dysfunction, and death.[60 , 77 , 86 , 125 , 144 , 148] Colchicine's effects are dose dependent, with high concentrations inhibiting further

microtubule polymerization and inducing depolymerization of already-formed microtubules.[97] Low concentrations can simply affect new microtubule formation and have no effect on preestablished polymer mass.[97] Colchicine also inhibits microtubule-mediated intracellular granule transport.[15 , 95] Some in vitro animal studies also have shown that colchicine might inhibit DNA synthesis by changing cell regulatory events at a critical time during the mitotic cycle.[55 , 61 , 79 , 97]

Toxic Dose

The toxic dose for colchicine is not well established. An early case series suggested that patients with colchicine ingestions >0.8 mg/kg uniformly died, and those with ingestions >0.5 mg/kg but <0.8 mg/kg survived if they were given supportive care.[19] This information was based on a limited series of patients and likely is not generalizeable.[117] Later literature suggests that severe toxicity and even death can occur with smaller doses, and patients may survive ingestions in excess of 0.8 mg/kg.[48 , 70 , 73 , 81 , 117 , 155] This inability to accurately quantify the toxic dose in humans likely results in great part from difficulty with dose estimation based on the patient's history.

Clinical Presentation

The clinical findings in colchicine poisoned patients is commonly described as triphasic (Table 37-1).[81 , 104 , 119 , 155] Gastrointestinal irritant effects, such as nausea, vomiting, abdominal distress, and diarrhea, initially occur within several hours following an overdose.[2 , 24 , 26 , 46 , 51 , 65 , 88 , 104 , 109 , 166] This can lead to severe volume depletion.[69 , 83 , 101 , 117 , 119 , 121 , 155 , 171] This first stage usually persists for the first 12â€“24 hours following ingestion.[83 , 104] The second stage is characterized by widespread organ system dysfunction, particularly of the bone marrow, and lasts for several days.[26 , 48 , 117 , 119 , 155] The final phase is characterized by recovery or death, and the progression usually can be defined within 1 week.[81 , 83 , 104 , 155]

I
0â€“24 h
Nausea, vomiting, diarrhea
Antiemetics
Consider GI decontamination
Dehydration
Intravenous fluids
Leukocytosis
Close observation for leukopenia
II
1â€“7 d
Possible risk of sudden cardiac death (24â€“36 h)
ICU admission and appropriate resuscitation
Pancytopenia
G-CSF
Renal failure
Hemodialysis
Sepsis
Antibiotics
Acute respiratory distress syndrome
Oxygen, mechanical ventilation
Electrolyte imbalances
Repletion as needed
Rhabdomyolysis
Intravenous fluids, hemodialysis
III
>7 d
Alopecia
Follow-up
Myopathy, neuropathy, or myoneuropathy
EMG testing, biopsy and neurologic follow-up as needed
Interval time course is not absolute, and overlap of symptom presentation may occur.

Phase Time Signs/Symptoms Therapy

TABLE 37-1. Colchicine Poisoning: Common Clinical Findings, Timing of Onset, and Treatment

Colchicine's hematopoietic effects after overdose are characterized by an initial peripheral leukocytosis, which is followed by a profound leukopenia, commonly accompanied by pancytopenia, usually beginning 48â€“72 hours after overdose.[15 , 24 , 62 , 69 , 80 , 104 , 122] The hematopoietic manifestations occur as a result of colchicine's effects on bone marrow division, presumably from arrest of cell division.[22 , 83 , 136 , 107 , 171] A rebound leukocytosis and recovery of other cell lines occur if the patient survives.

Colchicine poisoning is associated with the development of dysrhythmias and cardiac arrest.[22 , 81 , 83 , 104 , 119] Sudden cardiovascular collapse from colchicine typically occurs between 24â€“36 hours after ingestion.[22 , 32 , 104 , 107 , 117] Profound hypovolemia and shock can contribute to this collapse;[15 , 69 , 117 , 119 , 155] however, colchicine has direct toxic effects on skeletal and cardiac muscle, causing rhabdomyolysis.[21 , 40 , 103 , 110 , 118 , 171]

Myopathy,[27 , 28 , 147] neuropathy,[7 , 97] and a combined myoneuropathy[5 , 41 , 47 , 54 , 93 , 94 , 134 , 151 , 176] result from both long-term therapy and acute poisoning with colchicine.[97] A combined myoneuropathy is reported considerably more often, with myopathy dominating the clinical picture.[5 , 41 , 47 , 54 , 93 , 94 , 134 , 151 , 176] The myoneuropathy often is initially misdiagnosed as polymyositis or uremic neuropathy (because of coexistent renal insufficiency).[5 , 94] Myoneuropathy usually develops in the context of chronic, therapeutic dosing in patients with some baseline renal impairment.[5 , 41 , 47 , 54 , 93 , 94 , 134 , 151 , 176] Patients can present with proximal limb weakness, distal sensory abnormalities, distal areflexia, and nerve conduction problems consistent with an axonal neuropathy.[94 , 127]

A small amount of myelin degeneration is reported on autopsy, which

suggests a myelinopathic component.[23] The myopathy is characterized by vacuolar changes on biopsy, accompanied by lysosome accumulation.[5 , 54 , 94 , 176] Elevated serum creatine kinase activity is present concurrently with symptoms.[94 , 119] Weakness usually resolves within several weeks of drug discontinuation.[94]

Other neurologic effects, including delirium, stupor, coma, and seizures, might be at least partly attributable to the multisystem disease caused by poisoning and not necessarily a direct effect of colchicine.[27 , 122 , 132 , 149] The etiology of seizures is unclear, but they might partly result from antagonism of $GABA_A$ receptors.[172]

Acute respiratory distress syndrome occurs with colchicine toxicity.[10 , 46 , 80 , 112 , 145 , 149] The etiology is not well understood, but the syndrome may result from several factors, including respiratory muscle weakness, multisystem organ failure, and possibly a direct toxic effect.[46 , 104 , 112 , 145 , 161] Other indirect effects of colchicine are renal failure and various electrolyte abnormalities resulting from fluid loss and impaired kidney function.[15 , 48 , 69 , 97 , 119]

Alopecia, which usually is reversible, is a well-described complication that occurs 2â€“3 weeks after poisoning in survivors.[15 , 62 , 69 , 70 , 83 , 98 , 160] Dermatologic complications range in severity from epithelial cell atypia to toxic epidermal necrolysis reactions.[3 , 8 , 60 , 68 , 140]

Other reported complications of colchicine poisoning include bilateral adrenal hemorrhage,[43 , 158] disseminated intravascular coagulation,[83 , 132 , 149] pancreatitis,[122] and liver dysfunction.[27 , 119 , 132]

Diagnostic Testing

Colchicine concentrations in body fluids are not readily available in a clinically relevant fashion and have no well-established correlation to severity of illness. However, effective steady-state plasma concentrations for treatment of various illnesses are reported as 0.5â€“3 ng/mL.[115] Concentrations >3 ng/mL are associated with development of toxicity.[58 , 115 , 168] Initial laboratory monitoring

should include a complete blood count; serum electrolyte concentrations; renal and liver function tests; creatine kinase, phosphate, calcium, and magnesium concentrations; prothrombin time; activated partial thromboplastin time; and urinalysis. The need for other laboratory studies, such as arterial blood gases, serum troponin, serum lactate, and fibrinogen concentrations, and fibrin split products, should be considered, depending upon the situation. An electrocardiogram and chest radiograph should be ordered. Frequent complete blood counts should be ordered (at least every 12 hours) to watch for the development of depression in cell lines.

Management

Treatment for patients with colchicine poisoning is mainly supportive and includes intravenous fluid replacement, vasopressor use, hemodialysis (for renal failure), antibiotics for suspected secondary infection, and adjunctive respiratory therapy (endotracheal intubation, positive end-expiratory pressure), as indicated. Consultation with nephrology and hematology specialists should be obtained in cases of impaired renal function and/or evidence of hematotoxicity.

Gastrointestinal Decontamination

Because most patients with an acute oral colchicine overdose present several hours after ingestion, vomiting has already begun, and the usefulness of gastrointestinal decontamination at this time is inadequately defined. However, given the extensive morbidity and mortality associated with colchicine overdose, orogastric lavage probably should be performed in patients who present within 1â€“2 hours of ingestion and are not vomiting.[20 , 165] A dose of activated charcoal should be administered following lavage, or, in its place, multiple-dose activated charcoal (MDAC) should be considered because enterohepatic recirculation might occur.[1 , 132] The delay in presentation to a healthcare facility, coupled with the presence of gastrointestinal symptoms of poisoning (such as vomiting), significantly complicates use

of MDAC as an effective tool. However, antiemetic medications can be given to control emesis and facilitate activated charcoal administration.

Antidotal Therapy

Experimental colchicine-specific antibodies can restore colchicine-affected tubulin activity in vitro also these same colchicine-specific Fab fragments were successfully used in a single case of severe colchicine poisoning.[12] Administration of Fab fragments was temporally associated with a dramatic improvement in clinical and hemodynamic status. This improvement was associated with a significant increase in plasma colchicine concentrations, which suggests a redistribution of peripheral drug to the intravascular space.[12] Unfortunately, this therapy is not commercially available.

Granulocyte colony-stimulating factor (G-CSF) has been of some success in the treatment of colchicine-induced leukopenia and thrombocytopenia.[45, 75, 90, 175] The dose of G-CSF, the dosing frequency, and the route of administration were variable in the reported cases.[45, 75, 90, 175] G-CSF should be started if the patient begins to manifest evidence of leukopenia. Dosing should be determined by specialists in hematology and in conjunction with the manufacturer's instructions.

Extracorporeal Elimination

Hemodialysis and hemoperfusion are not useful options for colchicine poisoning, based on its large volume of distribution and large degree of protein binding.[14, 17, 18, 136, 137, 163, 169]

Disposition

Because of the severe morbidity and mortality associated with colchicine toxicity, all symptomatic patients with suspected or known significant overdose should be admitted to the hospital for observation. There may be an elevated risk of sudden cardiovascular collapse within

the first 24â€“48 hours,[117] and monitoring in the intensive care unit is recommended for all symptomatic patients for at least this initial time period. Poisoned patients will manifest gastrointestinal signs and symptoms within several hours of ingestion and should be observed for at least 8â€“12 hours. Patients who do not manifest gastrointestinal signs and symptoms within that time period after ingestion likely were not significantly poisoned.

Podophyllum Resin or Podophyllin

History and Epidemiology

Podophyllin is the name often used to refer to a resin extract from the rhizomes and roots of certain plants of the genus *Podophyllum* .[49 , 72] Examples include the North American perennial *Podophyllum peltatum* (mayapple or mandrake), the related Indian species *Podophyllum emodi* , and the Taiwanese *Podophyllum pleianthum* .[49] It is more descriptive to refer to it as *podophyllum resin* .[49 , 72] Podophyllum resin, or podophyllin, contains at least 16 physiologically active

compounds.[35 , 49 , 72] These include a variety of lignins and flavonols, including podophyllotoxin, picropodophyllin, Î±- and Î²-pellatins, desoxypodophyllotoxin, and quercetin.[34 , 35 , 49 , 72] Podophyllotoxin is a potent microtubular poison, similar to colchicine, and causes analogous effects in overdose.[49]

The first reported medicinal use of podophyllin preparations was as a laxative in the 19th century.[34 , 35 , 131] Its cathartic properties, as well as its potential toxicity, were noted as early as 1890, when the first fatality from podophyllin was recorded.[53 , 150] Podophyllin has been used historically to treat a variety of other health conditions, including liver disease, scrofula, syphilis, warts, and cancer.[49] Etoposide and teniposide are semisynthetic derivatives of podophyllotoxin[49] and have been investigated for efficacy in the treatment of certain cancers.[49]

Poisoning usually results from systemic absorption following topical application, ingestion of the resin or plant, and consumption of a commercial preparation of the extract. Systemic toxicity is described after unintentional dispensing of the incorrect herb and after ingestion of herbal preparations containing podophyllin.[36, 38, 50]

Pharmacology

Podophyllin is used in modern pharmacopeia primarily as a topical treatment for verruca vulgaris and condyloma acuminatum.[34, 59, 96] The active ingredient is believed to be podophyllotoxin.[11, 49, 89, 150, 159, 167, 174] Numerous synthetic and semisynthetic derivatives of podophyllotoxin exist; however, the most important probably are the chemotherapeutic agents etoposide and teniposide.[49] The antitumor effect of etoposide and teniposide results from interaction with topoisomerase II and free radical production, resulting in DNA strand breakage, an effect not shared by podophyllin and colchicine.[30, 49] Etoposide and teniposide also can induce cessation of cell growth in the late S or early G2 phase of the cell cycle.[30, 49, 67] These agents are discussed further in Chap. 52.

Pharmacokinetics/Toxicokinetics

Limited information exists regarding the pharmacokinetics of podophyllin as a preparation and its major active ingredient podophyllotoxin. Podophyllotoxin is a highly lipid-soluble compound that can easily cross cell membranes.[59, 71, 123, 150] Podophyllotoxin exists in the plant as a Î²-D-glucoside[59, 89, 150] and is reported to be eliminated through the bile with a half-life of 48 hours.[34, 42] However, the referenced articles cited failed to adequately support this statement and may have been based solely on clinical course.[42]

Systemic absorption of podophyllotoxin was measured in 7 men after application of various amounts of a 0.5% ethanol podophyllotoxin preparation for condylomata acuminata.[167] Peak serum concentrations

of 1â€“17 ng/mL were achieved within 1â€“2 hours after administration of doses ranging from 100â€“1500 ÂµL (0.5â€“7.5 mg).[167] Patients treated with â‰¤ 50 ÂµL had no detectable podophyllotoxin in their serum. Administration of 100 ÂµL yielded peak serum concentrations up to 5 ng/mL within 1â€“2 hours and up to 3 ng/mL at 4 hours. Administration of 1500 ÂµL yielded peak serum concentrations ranging from 5â€“9 ng/mL within 1â€“2 hours, concentrations of 5â€“7 ng/mL at 4 hours, 3â€“4.5 ng/mL at 8 hours, and 3.5 ng/mL at 12 hours.[167]

Pathophysiology

The components of podophyllin have numerous actions within the cell, including inhibition of purine synthesis, inhibition of purine incorporation into RNA, reduction of cytochrome oxidase and succinoxidase activity, and inhibition of microtubule structure and function.[34, 67, 170] Podophyllotoxin causes toxicity similar to colchicine[49, 174] because it is able to bind to tubulin subunits and interfere with subsequent microtubule structure and function.[49, 174] Interestingly, radiolabeled podophyllotoxin can inhibit colchicine binding to tubulin, suggesting that the binding sites for the two agents at least overlap.[49] Podophyllotoxin binds more rapidly than colchicine, and binding is reversible in contrast to colchicine.[49] Podophyllotoxin also inhibits fast axoplasmic transport similar to colchicine by interfering with microtubule structure and function.[128] Many other compounds, such as the vinca alkaloids (see Chap. 52) cryptophycins, and halichondrins, also inhibit microtubule polymerization in a similar manner.[87]

Clinical Presentation

Toxicity is described following ingestion[29, 38, 50, 63, 82, 105, 142, 173] and after systemic absorption from topical application of podophyllin.[66, 106, 113, 116, 126, 156, 157] Toxicity also is reported after intravenous administration of podophyllotoxin[146] and ingestion of mandrake root or herbal remedies containing podophyllin.[50, 53, 63]

Nausea, vomiting, abdominal pain, and diarrhea usually begin within several hours after ingestion.[42 , 53 , 66 , 71 , 82 , 106 , 111 , 113 , 142 , 146 , 150 , 156 , 173] Symptoms of poisoning might be delayed for 12 hours or more after topical exposure to podophyllin and often are the result of improper usage (excessive topical exposure, interruption in skin integrity, or failure to remove the preparation after a short period).[106 , 111 , 116 , 150] Initial clinical findings are not necessarily dictated by the route of exposure.[106]

Alterations in central and peripheral nervous system function tend to predominate in podophyllin toxicity. Patients might present with, or rapidly progress to, confusion, obtundation, and coma.[29 , 42 , 50 , 66 , 105 , 111 , 113 , 116 , 142 , 156 , 157 , 159 , 173]

Delirium and both auditory and visual hallucinations are also reported during the initial presentation.[44 , 59 , 157] Patients develop paresthesias, lose deep tendon reflexes, and might develop a Babinski sign.[29 , 35 , 38 , 42 , 50 , 66 , 105 , 113 , 116 , 124 , 150 , 157] Cranial nerve involvement, including diplopia,[35] nystagmus,[42] dysmetria,[38] dysconjugate gaze,[157] and facial nerve paralysis,[44] are all reported. Patients who recover from the initial event are at risk for developing a peripheral sensorimotor axonopathy.[38 , 42 , 50 , 59 , 66 , 105 , 113 , 123 , 124 , 150 , 157] The reported duration for recovery from podophyllin-induced axonopathy is variable but can take several months.[42 , 50 , 66 , 113 , 123] Dorsal radiculopathy[71] and autonomic neuropathy are reported.[96] The neuropathy may have a mild myelopathic component.[37]

Hematologic toxicity from podophyllin most likely results from its antimitotic effects. A review of the limited available literature suggests podophyllin is similar to colchicine but not nearly as consistent in its pattern, severity, and frequency. An initial leukocytosis[66 , 113 , 116 , 150] after poisoning can occur, which can be followed by leukopenia, thrombocytopenia, and/or generalized pancytopenia.[82 , 96 , 111 , 113 , 150 , 156] In patients who recover, cell lines tend to reach their nadir within 4â€“7 days after exposure.[59 , 66 , 82 , 113 , 156]

Other complications of poisoning include fever,[111] ileus,[59 , 111 , 157]

elevated liver enzymes,[50 , 82 , 113 , 156 , 173] hyperbilirubinemia,[82] coagulopathy,[82] seizures,[44 , 142] and renal insufficiency/failure.[111 , 173] Teratogenic effects resulting from exposure during pregnancy can occur.[35 , 89]

Diagnostic Testing

Podophyllin or podophyllotoxin concentrations are not readily available. Routine testing for suspected or known podophyllin

poisoning should include routine laboratory tests and other targeted testing, as needed. Serial cell blood counts should be obtained in cases of poisoning to watch for pancytopenia.

Typical Routes of exposure
Oral
Oral and topical
Intravenous
Intravenous
Initial symptoms
GI[a]
GI[a] and/or neurologic (obtundation delirium)
GI[a] ; fever; neurologic
GI[a] ; fever; myalgias; neurologic
Initial symptom onset
Several hours after ingestion; delayed presentation beyond 12 h very unlikely
Several hours after ingestion; delayed presentation (past 12 h) possible, especially with cutaneous route of exposure
Usually within 24â€“48 h
Usually within 24â€“48 h
Hematotoxic effects
Leukocytosis (24â€“48 h postingestion); pancytopenia (beginning 48â€“72 h postingestion)
Similar to colchicine, but not well characterized and reported less

frequently
May occur; *less* severe compared to vinblastine
May occur; *more* severe compared to vincristine
CNS effects
Late (after 48â€“72 h after ingestion); obtundation, confusion, and lethargy secondary to progression of MSD
Can be early (<12 h after ingestion); obtundation, confusion, delirium; may occur later, secondary to progression of MSD
Variable; cranial neuropathies; seizures; obtundation, and confusion can occur due to progression of MSD
Variable; cranial neuropathies; obtundation, and confusion can occur due to progression of MSD
Delayed PNS effects
Myoneuropathy most common; reported most often in chronic colchicine users with renal insufficiency
Peripheral sensorimotor axonopathy
Autonomic and ascending peripheral neuropathy; *increased* severity compared to vinblastine
Can see autonomic and peripheral neuropathy; *decreased* severity compared to vincristine
Clinical course
Recovery or multisystem organ dysfunction and death
Recovery or multisystem organ dysfunction and death
Recovery or MSOF and death; may develop SIADH
Recovery or MSOF and death; may develop SIADH
Management
Supportive; consider GI decontamination; G-CSF for neutropenia
Supportive; consider GI decontamination
Supportive; unintentional intrathecal administration requires CSF drainage
Supportive; unintentional intrathecal administration requires CSF drainage

[a] Gastrointestinal (nausea, vomiting, diarrhea, abdominal discomfort).
[b] See Chaps. 19 and 52 .

CNS = central nervous system; G-CSF = granulocyte colony-stimulating factor; MSOF = multisystem organ failure;
PNS = peripheral nervous system.

Colchicine	Podophyllum Resin	Vincristine[b]	Vinblastine[b]

TABLE 37-2. Comparison of Antimitotic Xenobiotics in Overdose

Management

Management primarily consists of supportive and symptomatic care. Orogastric lavage should be considered if presentation occurs within 1 hour of ingestion. If the patient presents within 1â€“2 hours of ingestion, a dose of activated charcoal should be given. Any topically applied podophyllin should be removed and the area thoroughly cleansed. Supportive and symptomatic care should be instituted, as needed. Patients either progress to multisystem organ dysfunction and death, or they recover with supportive care.

A few case reports of treatment with extracorporeal elimination techniques exist. These treatments include resin hemoperfusion[78] and charcoal hemoperfusion.[113 , 150] The role these procedures played in the patient's clinical course is unclear. No recommendation regarding the use of these techniques can be made at this time.

Disposition

Significant ingestions of podophyllin can result in gastrointestinal symptoms within a few hours,[38 , 53 , 63 , 82 , 124 , 173] but patients also can present with primarily neurologic symptoms, such as confusion and obtundation.[29 , 34 , 59 , 106] An isolated number of cases suggest the onset of toxicity can be delayed for as long as 12 hours.[29 , 34 , 42 , 50] Dermal exposure might result in even further delayed toxicity, as systemic absorption is delayed and symptom onset is more insidious.[59]

, 66 , 96 , 116 , 150 , 156 , 157 Patients probably should be observed for toxicity for at least 12 hours after ingestion and perhaps even longer after significant dermal exposure.

Summary

Colchicine and podophyllotoxin exert their primary toxicity by binding to tubulin and interfering with microtubule structure and function. The ubiquitous nature of microtubules within human cells and the heavy reliance on them for maintenance of normal cell functions present numerous opportunities for these xenobiotics to cause dysfunction at the cellular, organ, and organ system levels in a dose-dependent fashion. Colchicine toxicity may be evident several hours after ingestion and consists of severe nausea, vomiting, diarrhea, and abdominal pain, followed several days later by pancytopenia. Colchicine-poisoned patients may have a higher risk for sudden cardiac death, especially during the period between 24â€“36 hours after ingestion. Patients poisoned with podophyllin, or more accurately podophyllotoxin, may initially present with gastrointestinal and/or neurologic signs and symptoms, depending on dose and route of exposure (see Table 37-2).

Management and treatment for toxicity resulting from both agents is generally similar. Early gastrointestinal decontamination and supportive treatment are the hallmarks of therapy for both agents since no antidote is commercially available. Serial cell blood

counts should be obtained to watch for the development of cytopenias. G-CSF may be beneficial for colchicine-induced neutropenia.

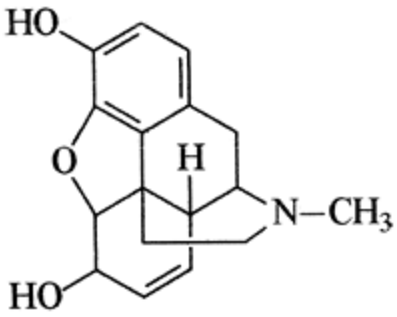
Chapter 38
Opioids

Lewis S. Nelson



Morphine

Emergency Medical Services (EMS) was called to provide assistance to a comatose 23-year-old man. EMS found that the patient was hypoventilating (2 breaths/min) and cyanotic, and he had miotic pupils. Earlier the same day, the patient had been evaluated at another hospital for a similar condition. The patient had been discharged after he supposedly responded to naloxone.

In the current emergency department (ED), the patient was ventilated by bag-valve-mask while preparations were made to perform

endotracheal intubation. Naloxone 0.4 mg was administered intravenously, and the patient became alert with a respiratory rate of 24 breaths/min. At that point, the patient looked uncomfortable, he developed diaphoresis, and his pupils dilated. Physical examination revealed piloerection, hyperactive bowel sounds, and bilateral pulmonary rales. Cardiac examination was normal. An electrocardiogram demonstrated sinus tachycardia., Arterial blood gas analysis revealed pH, 7.38; PCO_2 , 28 mm Hg; PO_2 (on 40% Ventimask), 140 mm Hg. A portable chest radiograph showed diffuse patchy infiltrates.

The patient received continuous low-flow oxygen therapy for 24 hours in the intensive care unit, and his oxygen saturation was maintained in the normal range at all times. His lungs cleared over the observation period. The patient was discharged after an additional day of observation and given a referral back to his methadone maintenance treatment program.

History and Epidemiology

The medicinal value of opium, the dried extract of the poppy plant *Papaver somniferum* , was first recorded around 1500 B.C. in the Ebers papyrus.[150] Raw opium typically is composed of at least 10% morphine, but extensive variability exists according to growing region.[111] Although reformulated as laudanum (deodorized tincture of opium; 10 mg morphine/mL) by Paracelsus, paregoric (camphorated tincture of opium; 0.4 mg morphine/mL),[139] Dover's powder (pulvis Doveri), and Godfrey's cordial in later centuries,[150] the contents remained largely the same: phenanthrene poppy derivatives, such as morphine and codeine. Over the centuries since the Ebers papyrus, opium and its components have been exploited in two distinct manners: medically to produce profound analgesia and nonmedically to take advantage of their psychoactive effects.

Currently the widest clinical application of opioids is for acute or chronic pain relief. Opioids are available in various formulations that

allow administration by virtually any route: epidural, inhalational, intranasal, intrathecal, oral, parenteral (ie, subcutaneously [SC]/IV/IM), rectal, transdermal, and transmucosal. Patients also may benefit from several of the nonanalgesic effects engendered by certain opioids. For example, codeine is widely used as an antitussive agent and diphenoxylate as an anti-diarrheal drug.

Unfortunately, the history of opium and its derivatives is marred by mankind's endless quest for drugs that produce pleasurable effects. Opium smoking was so problematic in China by the 1830s that the Chinese government attempted to prohibit the importation of opium by the British East India Company. This act led to the Opium Wars between China and Britain. China eventually accepted the importation and sale of the drug and was forced to turn over Hong Kong to British rule. The euphoric and addictive

potential of the opioids is immortalized in the works of several famous writers, such as Thomas de Quincey (*Confessions of an English Opium Eater* , 1821), Samuel Coleridge (*The Rime of the Ancient Mariner* , 1798), and Elizabeth Barrett Browning (*Aurora Leigh* , 1856).

Because of mounting concerns of addiction and toxicity in the United States, the Harrison Narcotic Act, enacted in 1914, made nonmedicinal use of opioids illegal. Since that time, recreational and habitual use of heroin and other opioids have remained at epidemic levels in the United States and worldwide despite extensive and diverse attempts to curb their availability.

Morphine was isolated from opium by Armand SÃ©quin in 1804.[150] Charles Alder Wright synthesized heroin from morphine in 1874.[226] Ironically, the development and marketing of heroin as an antitussive agent by Bayer, the German pharmaceutical company, in 1898 legitimized heroin's medicinal role.[226] Subsequently, various agents with opioidlike effects were marketed, each promoted for its presumed advantages over morphine. This assertion proved true for fentanyl because of its pharmacokinetic profile. However, in general

the advantages of such agents have fallen short of expectations, particularly with regard to abuse potential.

The terminology used in this chapter recognizes the broad range of agents commonly considered to be opiumlike. The term *opiate* specifically refers to the relevant alkaloids derived directly from the opium poppy: morphine, codeine, and, to some extent, thebaine and noscapine. *Opioids* are a much broader class of agents that are capable of either producing opiumlike effects or binding to opioid receptors. A *semisynthetic opioid*, such as heroin or oxycodone, is created by chemical modification of an opiate. A *synthetic opioid* is a chemical compound, not derived from an opiate, that is capable of binding to an opioid receptor and producing opioid effects clinically. Synthetic opioids, such as methadone and meperidine, bear little overt structural similarity to the opiates. Opioids include the naturally occurring animal-derived opioid peptides such as endorphin and nociceptin/orphanin FQ. The term *narcotic* refers to a sleep-inducing agent and initially was used to connote the opioids. However, law enforcement and the public currently use the term to indicate any illicit psychoactive substance. The term *opioid* as used hereafter encompasses the opioids and the opiates.

Pharmacology

Opioid-Receptor Subtypes

Despite nearly a century of opioid studies, the existence of specific opioid receptors was not proposed until the mid-20th century.[13] Beckett and Casy[13] noted a pronounced stereospecificity of existing opioids (only the L-isomer is active) and postulated that the drug needed to â€œfitâ€• into a receptor. In 1963, after studies on the clinical interactions of nalorphine and morphine, the theory of receptor dualism[155] postulated the existence of two classes of opioid receptors. Such opioid binding sites were not demonstrated experimentally until 1973.[185] Intensive experimental scrutiny using

selective agonists and antagonists continues to permit refinement of receptor classification. The current, widely accepted schema postulates the coexistence of three major classes of opioid receptors, each with multiple subtypes, and several poorly defined minor classes.

Initially, the reason such an elaborate system of receptors existed was unclear, because no endogenous ligand could be identified. However, evidence for the existence of such endogenous ligands was uncovered in 1975 with the discovery of metenkephalin and leuenkephalin[102] and the subsequent identification of Î²-endorphin and dynorphin. As a group, these endogenous ligands for the opioid receptors are called *endorphins* (*endo* genous mo*rphine*). Each is a 5-amino-acid peptide, cleaved from a larger precursor peptide: proenkephalin, proopiomelanocortin, and prodynorphin, respectively. More recently, a minor related endogenous opioid (nociceptin/orphanin FQ) and its receptor ORL have been described.

All three major opioid receptors have been cloned and sequenced. Each consists of 7 transmembrane segments, an amino terminus, and a carboxy terminus. Significant sequence homology exists between the transmembrane regions of opioid receptors and those of other members of the guanosine triphosphate (GTP)-binding protein (G-protein)-binding receptor superfamily. However, the extracellular and intracellular segments differ from one another. These nonhomologous segments probably represent the ligand-binding and signal transduction regions, respectively, which would be expected to differ among the three classes of receptors. The individual receptors have distinct distribution patterns within the central nervous system and peripherally, mediating unique but not entirely understood clinical effects. Until recently, researchers used varying combinations of agonists and antagonists to pharmacologically distinguish the different receptor subtypes. However, knockout mice (mutant mice lacking the genes for an individual opioid receptor) promise new insights into this complex subject.[72]

Because multiple opioid receptors exist and each elicits a different effect, determining the receptor to which an opioid agent preferentially binds should allow prediction of the drug's clinical effects. However, drug binding typically is not limited to one receptor type, and it is the relative affinity of a drug for differing receptors that accounts for the drug's clinical effects (Table 38-1). Even the endogenous opioid peptides exhibit substantial crossover among the receptors.

Although the familiar pharmacologic nomenclature derived from the Greek alphabet is used throughout this textbook, the International Union of Pharmacology (IUPHAR) Committee on Receptor Nomenclature has twice recommended a nomenclature change from the original Greek symbol system to make opioid receptor names more consistent with those of other neurotransmitter systems.[247] In the first new schema, the receptors were denoted by their endogenous ligand (*o* pioid *p* eptide [OP]), with a subscript identifying their chronologic order of discovery.[48] The Îº receptor was renamed OP_1 , the Îº receptor was renamed OP_2 , and the Âµ receptor was renamed OP_3 . However, adoption of this nomenclature met with significant resistance, presumably because of problems that would arise when merging previously published work that had used the Greek symbol nomenclature. The currently proposed nomenclature suggests the addition of a single letter in front of the OP designation and the elimination of the number. In this schema, the Âµ receptor is identified as MOP. In addition, the latest iteration formally recognizes the nociceptin/orphanin FQ or NOP receptor as a fourth receptor family.

Mu Receptor (Âµ, MOP, OP_3)

The early identification of the Âµ receptor as the *m* orphine binding site gave this receptor its designation.[156] Although many exogenous agents produce supraspinal analgesia via Âµ receptors, the endogenous ligand is elusive. Nearly all of the recognized endogenous

opioids have some affinity for the Âμ receptor, although none is selective for the receptor. Endomorphin-1

and endomorphin-2 are nonpeptide ligands present in brain that may represent the endogenous ligand.[269]

1996 Conventional Name	Proposed IUPHAR Name[a]	IUPHAR Name[a]	Important Clinical Effects of Receptor Agonists

TABLE 38-1. Clinical Effects Related to Opioid Receptors

Experimentally, two subtypes (Âµ$_1$ and Âµ$_2$) are well defined, although currently no agents have sufficient selectivity to make this dichotomy clinically relevant. Experiments with knockout mice suggest that both subtypes derive from the same gene and that either posttranslational changes or local cellular effects subsequently differentiate them.[122] The Âµ$_1$ subtype appears to be responsible for supraspinal (brain) analgesia and for the euphoria sometimes engendered by these agents. Although stimulation of the Âµ$_2$ subtype produces spinal-level analgesia, it also produces respiratory depression. All currently available Âµ agonists have some activity at

the Âμ$_2$ receptor and therefore produce some degree of respiratory compromise. Localization of Âμ receptors to regions of the brain involved in analgesia (periaqueductal gray, nucleus raphe magnus, medial thalamus[81]), euphoria and reward (mesolimbic system), and respiratory function (medulla) is not unexpected.[169] Predictably, Âμ receptors are found in the medullary cough center, peripherally in the gastrointestinal tract, and on various sensory nerve endings, including the articular surfaces (see discussion of analgesia under Clinical Manifestations below).

Kappa Receptor (Îº, KOP, OP$_2$)

Although dynorphins now are known to be the endogenous ligands for Îº receptors, these receptors originally were identified by their ability to bind ketocyclaz-ocine and thus were labeled Îº.[156] Kappa receptors exist predominantly in the spinal cord of higher animals, although they also are found in the antinociceptive regions of the brain and the substantia nigra.[256] Stimulation is responsible for spinal analgesia, miosis, and diuresis (via inhibition of antidiuretic hormone release). Unlike Âμ-receptor stimulation, Îº-receptor stimulation is not associated with significant respiratory depression or constipation. The Îº receptor currently is subclassified into three subtypes. The Îº$_1$ receptor subtype is responsible for spinal analgesia. This analgesia is not reversed by Âμ-selective antagonists,[166] supporting the role of Îº receptors as independent mediators of analgesia. Although the function of the Îº$_2$ receptor subtype is largely unknown, stimulation of cerebral Îº$_2$ receptors by agents such as pentazocine and salvinorin A produces psychotomimesis in distinction to the euphoria evoked by Âμ agonists.[187, 214] The Îº$_3$ receptor subtype is found throughout the brain and participates in supraspinal analgesia. This receptor is primarily responsible for the action of nalorphine, an agonistâ€“antagonist opioid.[184] Nalbuphine, another agonistâ€“antagonist, exerts its analgesic effect via both Îº$_1$ and Îº$_3$ agonism, although both nalorphine and nalbuphine are antagonists to morphine at the Âμ receptor.[189]

Delta Receptor (Î´, DOP, OP_1)

Little is known about Îº receptors, although the enkephalins are known to be their endogenous ligands. Opioid peptides identified in the skin and brain of *Phyllomedusa* frogs, termed *dermorphin* and *deltorphin*, respectively, are potent agonists at the Îº receptor. Delta receptors may be important in spinal and supraspinal analgesia (probably via a noncompetitive interaction with the Âµ receptor[80]) and in cough suppression.[113] Delta receptors may mediate dopamine release from the nigrostriatal pathway, where they modulate the motor activity associated with amphetamine.[173] Delta receptors do not modulate dopamine in the mesolimbic tracts and have only a slight behavioral reinforcing role. Subpopulations, specifically $Î´_1$ and $Î´_2$, are postulated based on in vitro studies but presently are not confirmed in vivo.[247]

Nociceptin/Orphanin FQ Receptor (ORL_1, OP_4)

The ORL_1 receptor was identified in 1994, based on sequence homology during screening for opioid-receptor genes with DNA libraries.[24] It has a similar distribution pattern in the brain and uses similar transduction mechanisms as the other opioid-receptor subtypes. It binds many different opioid agonists and antagonists. Its insensitivity to antagonism by naloxone, often considered the sine qua non of opioid character, delayed its acceptance as a valid opioid-receptor subtype. Simultaneous identification of an endogenous ligand, called *nociceptin* by the French discoverers and *orphanin* FQ by the Swiss investigators, allowed the designation OP_4. A clinical role has not yet been defined, but anxiolytic and analgesic properties have been described.[37, 163]

Sigma Receptor (Ï*f*)

Although originally conceived as an opioid subtype, the Ïƒ receptor is no longer considered opioid in character, and it has not been given an IUPHAR OP designation. Investigation of this receptor revealed that it is insensitive to antagonism by naloxone, prefers ligands with a dextrorotatory stereochemistry, and has no endogenous ligand, all features in contradistinction to the other opioid receptors. Nonetheless, the effects of the Ïƒ receptor are relevant to opioid pharmacology because certain opioids, such as dextromethorphan and pentazocine, are Ïƒ-receptor agonists. Stimulation of the Ïƒ receptor is implicated in psychotomimesis and movement disorders, effects that are reported with both dextromethorphan and pentazocine independently.[91]

Hallucinogens, such as ibogaine,[19] and antipsychotic agents, such as haloperidol, are known Ïƒ-receptor antagonists.

Other Receptors (Epsilon [Îµ], Zeta [Î¶])

Two other opioid-receptor subtypes are largely uncharacterized in humans but ultimately may prove to be important. The Îµ receptor is postulated based on in vivo binding assays and has no known clinical role.[244] The Î¶ receptor has been proposed and may serve as an opioid growth factor receptor.[270]

Opioid-Receptor Signal Transduction Mechanisms

Figure 38-1 illustrates opioid-receptor signal transduction mechanisms. Continuing research on the mechanisms by which an opioid receptor induces an effect has produced confusing and often contradictory results. Despite the initial theory that each receptor subtype is linked to a specific transduction mechanism, individual receptor subtypes may use one or more mechanisms, depending on several factors, including receptor localization (eg, presynaptic vs

postsynaptic). As noted, all opioid-receptor subtypes are members of a superfamily of membrane-bound receptors that are coupled to G proteins.[247] The G proteins are responsible for signaling the cell that the receptor has been activated and for initiating the desired cellular effects. The G proteins are generally of the pertussis toxin-sensitive, inhibitory subtype known as G_i or G_o , although coupling to a cholera toxin-sensitive, excitatory G_S subtype has been described.[39] Regardless of subsequent effect, the G proteins consist of three conjoined subunits, Î±, Î², and Î³. The Î²Î³ subunit is liberated upon GTP binding to the Î± subunit. When the Î± subunit dissociates from the Î²Î³ subunit, it modifies specific effector systems,

such as phospholipase C or adenylate cyclase, or it may directly affect a channel or transport protein. GTP subsequently is hydrolyzed by a GTPase intrinsic to the Î± subunit, which prompts its reassociation with the Î²Î³ subunit and termination of the receptor-mediated effect.

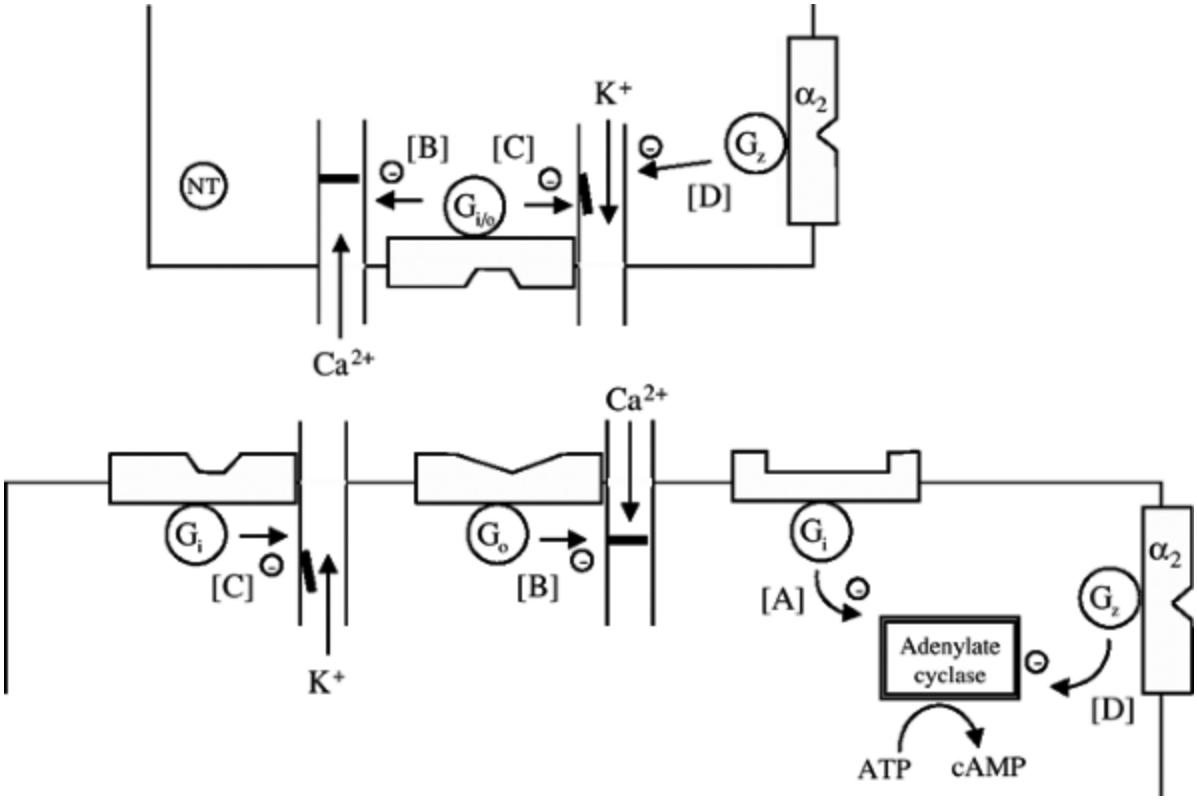

Figure 38-1. Opioid-receptor signal transduction mechanisms. Upon

binding of an opioid agonist to an opioid receptor, the respective G protein is activated. G proteins may (A) reduce the capacity of adenylate cyclase to produce cAMP; (B) close calcium channels that reduce the signal to release neurotransmitters; (C) open potassium channels and hyperpolarize the cell, which indirectly reduces cell activity. Each mechanism has been found coupled to each receptor subtype, depending on location of the receptor (pre/postsynaptic), and the neuron within the brain (see text). Note that $\hat{I}\pm_2$ receptors (D) mediate similar effects, using a different G protein (G_z). NT = neurotransmitter.

Adenylate cyclase/cAMP (A)

Inhibition of adenylate cyclase activity by G_i or G_o is the classic mechanism for postsynaptic signal transduction invoked by the inhibitory Âμ receptors. However, this same mechanism also has been identified in cells bearing either Î´ or Îº receptors. Activation of cAMP production by adenylate cyclase, with subsequent activation of protein kinase A, occurs following exposure to very-low-dose opioid agonists and produces excitatory, antianalgesic effects.[39]

Calcium (Ca^{2+}) channels (B)

Presynaptic Âμ receptors inhibit norepinephrine release from the nerve terminals of cells of the rat cerebral cortex. Adenylate cyclase does not appear to be the modulator for these receptors because inhibition of norepinephrine release is not enhanced by raising intracellular cAMP levels by various methods.[208] Opioid-induced blockade is, however, prevented by increased intracellular calcium levels that are induced either by calcium ionophores, which increase membrane permeability to calcium, or by raising the extracellular calcium concentration.[208] This implies a role for opioid-induced closure of N-type calcium channels, presumably via a G_o protein. Reduced intraterminal concentrations of calcium prevent the neurotransmitter-laden vesicles from binding to the terminal membrane and releasing their contents. Nerve terminals containing dopamine appear to have an analogous relationship with inhibitory Îº

receptors, as do acetylcholine-bearing neurons with Î´ opioid receptors.[208]

Potassium (K^+) channels (C)

Increased conductance through a potassium channel, generally mediated by G_i or G_o, results in membrane hyperpolarization with reduced neuronal excitability. Alternatively, protein kinase Aâ€“mediated reduction in membrane potassium conductance enhances neuronal excitability.

Clinical Manifestations

Table 38-2 outlines the clinical effects of opioids.

Therapeutic Effects

Analgesia

Although classic teaching attributes opioid analgesia solely to the brain, opioids actually appear to modulate cerebral cortical pain perception at supraspinal, spinal, and peripheral levels. The regional distribution of the opioid receptors confirms that Âµ receptors are responsible for most of the analgesic effects of morphine within the brain. They are found in highest concentration within areas of the brain classically associated with analgesiaâ€”the periaqueductal gray, nucleus raphe magnus, locus caeruleus, and medial thalamus.[183] Microelectrode-induced electrical stimulation of these areas[198] or iontophoretic application of agonists into these regions results in profound analgesia.[15] Specifically, enhancement of inhibitory outflow from these supraspinal areas to the sensory nuclei of the spinal cord (dorsal roots) dampens nociceptive neurotransmission. Additionally, inactivation of the Âµ-opioidâ€“receptor gene in embryonic mouse cells results in offspring that are insensitive to morphine analgesia.[157]

Interestingly, blockade of the *N* -methyl-D-aspartate (NMDA) receptor, a mediator of excitatory neurotransmission, enhances the analgesic effects of Âμ-opioid agonists and may reduce the development of tolerance (see Dextromethorphan below).[1 , 194] Even more intriguing is the finding that low-dose naloxone (0.25 Âμg/kg/h) actually improves the efficacy of morphine analgesia.[68] Administration of higher-dose, but still low-dose, naloxone (1 Âμg/kg/h) obliterated its opioid-sparing effect. Although undefined, the mechanism may be related to selective inhibition of G_S -coupled excitatory opioid receptors by extremely low concentrations of opioid-receptor antagonist.[39 , 40]

TABLE 38-2. Clinical Effects of Opioids Drugs

Delta and Îº receptors also are responsible for mediation of analgesia, but they exert their analgesic effect predominantly in the spinal cord. Conceptually, these receptors modulate nociceptive impulses in transit to the thalamus via the spinothalamic tract, reducing the brain's perception of the pain. Agents with strong binding affinity for Îº receptors in humans produce significantly more analgesia than morphine administered intrathecally.[171] Indeed, the use of spinal and epidural opioid analgesia is predicated on the direct administration of opioid near the Îº and Î´ receptors in the spinal cord. Agonistâ€“antagonist agents, with agonist affinity for the Îº receptor, and antagonist effects at the Âµ receptor, maintain analgesic efficacy.

Interestingly, communication between the immune system and the peripheral sensory nerves occurs in areas of tissue inflammation. In response to inflammatory mediators (eg, interleukin-1), immune cells locally release opioid peptides, which bind and activate peripheral opioid receptors on sensory nerve terminals.[248] Agonism at these receptors reduces afferent pain neurotransmission and may inhibit the release of other proinflammatory compounds, such as substance P.[232] Of note, intraarticular morphine (1 mg) administered to patients after arthroscopic knee surgery produces significant, long-lasting analgesia that can be prevented with intraarticular naloxone.[231] The clinical analgesic effect of 5 mg of intraarticular morphine is equivalent to 5 mg of morphine given intramuscularly.[32 , 112] Intraarticular analgesia is locally mediated by Âµ receptors.[57]

Despite their well-defined analgesic properties and their recommendation by many clinical practice guidelines, opioids continue

to be underprescribed for patients with acute and chronic pain. Reluctance often stems from the fear that patients may develop addiction or abuse. However, despite extensive investigation, this concern is unfounded.[108 , 130] Furthermore, opioid analgesics often are better tolerated, safer, and less expensive than the alternatives, such as the nonsteroidal antiinflammatory drugs.

Euphoria

The pleasurable effects of many drugs used by humans are mediated by the release of dopamine in the mesolimbic system.[16] This final common pathway is shared by all opioids that activate the Âµâ€“Î´ receptor complex in the ventral tegmental area, which, in turn, indirectly promotes dopamine release in the mesolimbic region. Opioids also may have a direct reinforcing effect on their self-administration through Âµ receptors within the mesolimbic system.[94]

The sense of well-being and euphoria associated with strenuous exercise appears to be mediated by endogenous opioid peptides and Âµ receptors. This so-called â€œrunner's highâ€• is reversible with naloxone.[213] Naloxone may also reverse euphoria or even produce dysphoria in nonexercising, highly trained athletes. Even in normal individuals, high-dose naloxone (up to 4 mg/kg) may produce dysphoria.[34]

Exogenous opioids do not induce uniform psychological effects. Some of the exogenous opioids, particularly the highly lipophilic agents such as heroin, are euphorigenic, whereas morphine is largely devoid of such pleasurable effects.[223] However, morphine administration results in analgesia, anxiolysis, and sedation. Because heroin has little affinity for opioid receptors and must be deacetylated to morphine for effect, these seemingly incompatible properties likely are related to pharmacokinetic differences in bloodâ€“brain barrier penetration.[179] Chronic users note that fentanyl produces effects that are subjectively similar to those of heroin.[135] This effect may explain the higher prevalence of fentanyl, as opposed to other accessible opioids, as an

anesthesiologists who were studied in the 1970s.[251] In distinction, certain opioids (eg, pentazocine) produce dysphoria, an effect that is related to their affinity for Îº or Ïƒ receptors.[187]

Antitussive

Codeine and dextromethorphan are two opioid agents with cough-suppressant activity. Cough suppression likely is not mediated via the Âμ$_1$ opioid receptor because the ability of other opioids to suppress the medullary cough centers is not correlated with their analgesic effect. Various models suggest that cough suppression occurs via agonism of the Âμ$_2$ or Îº opioid receptors, or antagonism of the Î´ opioid receptor,[113] and that the Ïƒ or NMDA receptors also are involved.[114 , 197]

Toxic Effects

When used correctly for medical purposes, opioids are remarkably safe and effective agents.[12 , 142] However, excessive dosing for any reason may result in serious toxicity. Most adverse or toxic effects are predictable, based on â€œopioidâ€• pharmacodynamics (eg, respiratory depression), although several agents produce unexpected â€œnonopioidâ€• or agent-specific responses. Determining that a patient is suffering from opioid toxicity is generally more important than identifying the specific agent involved. Notwithstanding some minor variations, patients poisoned by all available opioids predictably develop a constellation of signs, known as the *opioid syndrome* (Chap. 3). Mental status depression, hypoventilation, miosis, and reduced bowel motility are the classic elements.

Respiratory Depression

Experimental use of various opioid agonists and antagonists

consistently implicates Âμ$_2$ receptors in the respiratory depressant effects of morphine.[144] Through these receptors, opioid agonists reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors to hypercapnea.[254] In addition to loss of hypercarbic stimulation, opioids depress the ventilatory response to hypoxia.[254] The combined loss of hypercarbic and hypoxic drive leaves virtually no stimulus to breathe, and apnea follows. Among the available opioid agonists, equianalgesic doses of all agents produce approximately the same degree of respiratory depression.[54 , 216] This reasoning is supported by experiments in MOR-deficient knockout mice.[202] Patients chronically exposed to opioid agonists, such as those on methadone maintenance, experience chronic hypoventilation, although tolerance to loss of hypercarbic drive may develop over several months.[152] However, such patients never develop complete tolerance to loss of hypoxic stimulation.[205] Although some opioids (notably the agonistâ€“antagonists and partial agonists) demonstrate a ceiling effect on respiratory depression, such sparing generally occurs at the expense of analgesic potency.[67] The different activity profiles likely are a result of differential activities at the opioid-receptor subtypes; that is, agonistâ€“antagonists are predominantly Îº-receptor agonists and either partial agonists or antagonists at Âμ sites.

It is important to recognize that ventilatory depression may be secondary to a reduction in either respiratory rate or tidal volume. Thus, although respiratory rate is more accessible for clinical measurement, it is not an ideal index of ventilatory depression. In fact, morphine-induced respiratory depression in humans initially is related more closely to changes in tidal volume.[216] Large doses of opioids also result in a reduction of respiratory rate.

Acute Lung Injury

Reports linking opioids with the development of acute pulmonary abnormalities became common in the 1960s, although the first report was made by William Osler in 1880.[181] Almost all opioids are

implicated, and opioid-related acute lung injury is reported in diverse clinical situations. Typically, the patient regains normal ventilation following a period of profound respiratory depression, either spontaneously or following the administration of an opioid antagonist, and over the subsequent several minutes to hours develops hypoxemia and pulmonary rales. Occasionally, classic frothy, pink sputum is present in the patient's airway or in the endotracheal tube of an intubated patient. Acute lung injury was described in 71 (48%) of 149 hospitalized heroin overdose patients in New York City.[53] The outcome generally is dependent on comorbid conditions and the delay to adequate care. Acute lung injury may be an isolated finding or may occur in the setting of multisystem organ damage.

No single mechanism can be consistently invoked in the genesis of opioid-associated acute lung injury. Several prominent theories are each well supported by experimental data. Although several authors ascribe acute lung injury to naloxone, the majority of affected patients had already suffered respiratory arrest and had been given naloxone to reestablish spontaneous breathing. In these patients, naloxone likely â€œuncoveredâ€• the clinical findings of acute lung injury that were not evident because an adequate examination could not be performed. Other evidentiary cases involve surgical patients given naloxone postoperatively who subsequently awoke with clinical signs of pulmonary edema. In addition to presumably receiving the naloxone for ventilatory compromise or hypoxia, these patients received multiple intraoperative medications, further obscuring the etiology.[195] Although naloxone ordinarily is safe when administered to nonopioid-tolerant individuals, the production of acute opioid withdrawal may be responsible for â€œnaloxone-inducedâ€• acute lung injury. In this situation, as in patients with â€œneurogenicâ€• pulmonary edema, massive sympathetic discharge from the central nervous system occurs and produces â€œcardiogenicâ€• pulmonary edema from the acute effects of catecholamines on the myocardium. In an interesting series of experiments, precipitated opioid withdrawal in nontolerant dogs was associated with dramatic cardiovascular

changes and abrupt elevation of serum catecholamine concentrations.[167, 168] The effects were more dramatic in dogs with an elevated PCO_2 than in those with a normal or low PCO_2, suggesting the potential benefit of adequately ventilating patients prior to opioid reversal with naloxone. Similar effects occur in humans undergoing ultrarapid opioid detoxification (UROD ; see below).[56]

Even though abrupt precipitation of withdrawal by naloxone may contribute to the development of acute lung injury, it cannot be the sole etiology. Alveolar filling was noted in 50â€“90% of the postmortem examinations performed on heroin overdose patients,[93, 97] many of whom were declared dead before arrival to medical care and thus never received naloxone. In addition, neither naloxone nor any other opioid antagonist was available when Osler and others described their initial cases of pulmonary edema. Alternatively, the negative intrathoracic pressure generated by attempted inspiration against a closed glottis creates a large pressure gradient across the alveolar membrane and draws fluid into the alveolar space.[129] This mechanical effect, also known as the *MÃ¼ller maneuver*, was invoked as the etiology of ventilator-associated acute lung injury prior to the advent of demand ventilators and neuromuscular blockers. In the setting of opioid poisoning, glottic

laxity may prevent adequate air entry during inspiration. This effect may be especially prominent at the time of naloxone administration, in which case breathing may be reinstituted before the return of adequate upper airway function.

Cardiovascular

Arteriolar and venous dilation secondary to opioid use may result in mild reduction in blood pressure.[252] This effect is clinically useful for treatment of acute cardiogenic pulmonary edema. However, although patients typically do not develop significant supine hypotension, orthostatic changes in blood pressure and pulse routinely occur.[272]

Bradycardia is unusual, although a reduction in heart rate is common as a result of the associated reduction in central nervous system stimulation. Opioid-induced hypotension appears to be mediated by histamine release,[58] although induction of histamine release does not appear to occur through interaction with an opioid receptor. It may be related to the nonspecific ability of certain compounds to activate mast cell G proteins,[10] which induce degranulation of histamine-containing vesicles. Many agents share this ability, which seems to be conferred by the presence of a positive charge on a hydrophobic molecule. Accordingly, not all opioids are equivalent in their ability to release histamine.[10] After administration of 1 of 4 different opioids to 60 healthy patients, meperidine produced the most hypotension and elevation of plasma histamine concentrations, whereas fentanyl produced the least.[62] The combination of H_1 and H_2 antagonists is effective in ameliorating the hemodynamic effects of opioids in humans.[188]

Prominent cardiovascular toxicity may occur with use of propoxyphene, which causes wide-complex dysrhythmias and negative contractility through sodium channel antagonism similar to that of type IA antidysrhythmic agents (see Propoxyphene below). Adulterants or coingestants also may produce significant cardiovascular toxicity. For example, quinine-adulterated heroin is associated with dysrhythmias.[149, 203, 215] Cocaine, surreptitiously added to heroin, may cause significant myocardial ischemia or infarction.[99] Similarly, concern that naloxone administration may â€œunmaskâ€• cocaine toxicity in patients simultaneously using cocaine and heroin (â€œspeedballâ€•) probably is warranted but rarely is reliably reported.[165]

Certain opioids at therapeutic concentrations, particularly methadone, can interfere with normal cardiac repolarization and produce QTc interval prolongation, an effect that predisposes to the development of torsade de pointes.[133, 175] Many patients who receive methadone experience minor increases in QTc interval, although a small percentage of patients experience a substantial increase to >500

msec.[151] Methadone and levo-Î±-acetylmethadol (LAAM) both prolong the QTc interval via interactions with cardiac K^+ channels.[116, 119] LAAM was given a black box warning because of its association with torsade de pointes; this action essentially removed LAAM from use in the United States. Additionally, certain opioids, primarily propoxyphene, can alter the function of myocardial Na^+ channels in a manner similar to that of the antidysrhythmics (Chap. 61).

Miosis

The mechanisms by which opioids induce miosis remain controversial. Support for each of several mechanisms can be found in the literature. Stimulation of parasympathetic pupilloconstrictor neurons in the Edinger-Westphal nucleus of the oculomotor nerve by morphine produces miosis. Additionally, morphine increases firing of pupilloconstrictor neurons to light,[138] which increases the sensitivity of the light reflex (central reinforcement of light reflex).[255] Although sectioning of the optic nerve may blunt morphine-induced miosis, the consensual reflex in the denervated eye is enhanced by morphine. Because opioids classically mediate inhibitory neurotransmission, hyperpolarization of sympathetic nerves or of inhibitory neurons to the parasympathetic neurons (removal of inhibition) ultimately may be found to mediate the classic â€œpinpoint pupilâ€• associated with opioid use.

Not all patients using opioids present with miosis. Meperidine has a lesser miotic effect than other conventional opioids, and propoxyphene use does not result in miosis.[75] Use of agents with predominantly Îº-agonist effects, such as pentazocine, may not result in miosis. Mydriasis may occur in severely poisoned patients secondary to hypoxic brain insult. Additionally, concomitant drug use or the presence of adulterants may alter pupillary findings. For example, the combination of heroin and cocaine (â€œspeedballâ€•) may produce virtually any size pupil, depending on the relative contribution by each drug. Similarly, patients ingesting diphenoxylate

and atropine (Lomotil) or those using scopolamine-adulterated heroin[86] routinely develop mydriasis.

Seizures

Seizures are a rare complication of therapeutic use of most opioids. In patients with acute opioid overdose, seizures most likely are caused by hypoxia. However, experimental models demonstrate a proconvulsant effect of morphine[101] in that it potentiates the convulsant effect of other xenobiotics.[263] These effects are variably inhibited by naloxone, suggesting the involvement of a mechanism other than opioid receptor binding. In humans, morphine-induced seizures are reported in neonates and are reversible by naloxone, although opioid withdrawal seizures in neonates are more common.[41]

Seizures should be anticipated in patients with meperidine, propoxyphene, or tramadol toxicity. Naloxone antagonizes the convulsant effects of propoxyphene in mice, although it is only moderately effective in preventing seizures resulting from meperidine or its metabolite normeperidine.[76] Interestingly, naloxone potentiates the anticonvulsant effects of benzodiazepines and barbiturates, although in a single study, it antagonized the effects of phenytoin.[106] The ability of fentanyl and its analogs to induce seizures is controversial. They are used to activate epileptiform activity for localization in patients with temporal lobe epilepsy who are undergoing surgical exploration.[162] Electroencephalograms (EEGs) performed on patients undergoing fentanyl anesthesia did not identify seizure activity even though the clinical assessment suggested that approximately one third had seizures.[225] It appears likely that the rigidity and myoclonus associated with fentanyl are readily misinterpreted as a seizure.

Movement Disorders

Patients may experience acute muscular rigidity with rapid intravenous injection of certain high-potency opioids, especially

fentanyl and its derivatives.[238] This condition is particularly prominent during induction of anesthesia[7] and in neonates.[59] This rigidity primarily involves the trunk and may impair chest wall movement sufficiently to exacerbate hypoventilation. Chest wall rigidity may have contributed to the lethality associated with epidemics of fentanyl-adulterated heroin. Although the mechanism of muscle rigidity is unclear, it may be related to blockade of dopamine receptors in the basal ganglia. Other postulated mechanisms include Î³-aminobutyric acid (GABA) antagonism and NMDA agonism.[64] Opioid antagonists generally are

therapeutic[59 , 174] but may produce adverse hemodynamic effects, withdrawal phenomena, or uncontrollable pain, depending on the situation.

Although not a problem for patients taking stable doses of methadone,[70] rapid escalation of methadone doses may produce choreoathetoid movements.[17] The movement disorder may be related to the opposing effects on GABAergic interneurons produced by Âμ and Îº receptors. Methadone, a Âμ agonist, inhibits the release of GABA, an inhibitory neurotransmitter, within the striatum and mesolimbic system. The ultimate effect is enhancement of striatal dopamine release. This possibility is intriguing, given the developing concept that many forms of addiction result from the final common pathway of enhanced mesolimbic dopamine neurotransmission.

Gastrointestinal Effects

Historically, the morphine analog apomorphine was used as a rapidly acting emetic whose clinical use was limited by its tendency to depress the patient's level of consciousness. Emesis induced by apomorphine is mediated through agonism at D_2 receptor subtypes within the chemoreceptor trigger zone of the medulla. Many opioids, particularly morphine, produce significant nausea and vomiting when used therapeutically.[27] Whether these effects are inhibited by

naloxone is not clearly established, but they likely are not.

Although diphenoxylate and loperamide are widely used therapeutically to manage diarrhea, opioid-induced constipation is most frequently a bothersome side effect of both medical and nonmedical use of opioids. Constipation, mediated by $\hat{A}\mu_2$ receptors within the smooth muscle of the intestinal wall,[100] is ameliorated by oral naloxone. Provided the hepatic glucuronidative capacity is not exceeded (at doses of approximately 6 mg), enteral naloxone is poorly bioavailable and thus induces few, if any, opioid withdrawal symptoms.[164] Methylnaltrexone and alvimopan are bioavailable, peripherally acting opioids that antagonize the peripheral effects of other opioids on the gastrointestinal tract.[261, 266] Opioid withdrawal does not occur because methylnaltrexone and alvimopan cannot cross the bloodâ€“brain barrier.

Diagnostic Testing

Laboratory Considerations

Although it is always tempting to seek laboratory confirmation of an ingested substance in acutely poisoned patients, current laboratory methodology suffers from several important limitations and the potential for many confounding variables. The most apparent impediment to use of laboratory testing in the acute care setting is the lack of timely reporting of results. Patients may suffer grave consequences if therapy is withheld pending test results. Opioid-poisoned patients are particularly amenable to rapid clinical diagnosis because of the uniqueness of the opioid syndrome. Additionally, even in situations where the assay results are available rapidly, the fact that several distinct classes of agents can produce similar opioid effects limits the use of laboratory tests, such as immunoassays, that rely on structural features to identify drugs. Furthermore, because opioids may be chemically detectable long after their clinical effects have dissipated, assay results cannot be considered in isolation but rather viewed in the clinical context. Several well-described problems with laboratory testing of opioids are described below and in Chap. 7 .

Cross-Reactivity

Many opioids share remarkable structural similarities. Interestingly, structurally similar agents, such as methadone and propoxyphene, do not necessarily share the same clinical characteristics (Figure 38-2). Because most clinical assays depend on structural features to identify a drug, structurally similar agents may be detected in lieu of the desired drug. Whether a similar drug is noted by the assay depends on the sensitivity and specificity of the assay used and the serum

concentration of the agent. Some cross-reactivities are predictable, such as that of codeine with morphine, on a variety of screening tests. Other cross-reactivities are less predictable, as with the cross-reaction of dextromethorphan and the phencyclidine (PCP) component of the fluorescence polarization immunoassay (Abbott TDx),[206] a widely used drug-abuse screening test (Chap. 7).

Congeners and Adulterants

Commercial opioid assays, which are specific for morphine, likely will not detect most of the semisynthetic and synthetic opioids. In some cases, epidemic fatalities involving fentanyl derivatives remained unexplained despite obvious opioid toxicity until the ultrapotent fentanyl derivative, Î±-methylfentanyl (although initially misidentified as 3-methylfentanyl), was identified by more sophisticated testing.[132 , 154] Oxycodone, hydrocodone, and other common morphine derivatives have variable detectability by different opioid screens.[224]

Drug Metabolism

A fascinating dilemma may arise in patients who ingest moderate to large amounts of poppy seeds.[124] These seeds, which are widely used for culinary purposes, are derived from poppy plants and contain both morphine and codeine. Following ingestion of a single poppy seed bagel, patients may develop elevated serum morphine and codeine concentrations[170] and test positive for morphine.[201] Because the presence of morphine on a drug-abuse screen may suggest illicit heroin use, the implications are substantial. Federal workplace testing regulations thus require corroboration of a positive morphine assay with assessment of another heroin metabolite, 6-monoacetylmorphine, prior to reporting a positive result.[172 , 246] Humans cannot acetylate morphine and therefore cannot synthesize 6-monoacetylmorphine, but humans can readily deacetylate heroin, which is diacetylmorphine.

A similar problem may occur in patients taking therapeutic doses of codeine. Because codeine is demethylated to morphine by CYP2D6, a morphine screen may be positive as a result of metabolism and not structural cross-reactivity.[69] Thus, determination of the serum codeine or 6-monoacetylmorphine concentration is necessary in these patients. Determination of the serum codeine concentration is not foolproof, however, because codeine is present in the opium preparation used to synthesize heroin.

Forensic Testing

Decision making regarding the cause of death in the presence of systemic opioids often is complex.[42] Variables that often are incompletely defined contribute substantially to the difficulty in attributing or not attributing the cause of death to the opioid. These variables include the specifics regarding the timing of exposure, the preexisting degree of sensitivity and/or tolerance, the role of cointoxicants including parent opioid metabolites, and postmortem redistribution and metabolism.[51, 118] Interesting techniques to help further elucidate the likely cause of death that have been studied include the application of postmortem pharmacogenetic principles[107] and the use of alternative specimens (Chap. 33).

Management

The consequential effects of acute opioid poisoning are central nervous system and respiratory depression. Although early support of ventilation and oxygenation is generally sufficient to prevent death, prolonged use of bag-valve-mask ventilation and endotracheal intubation may be avoided by cautious administration of an opioid antagonist. Opioid antagonists, such as naloxone, competitively inhibit binding of opioid agonists to opioid receptors, allowing the patient to resume spontaneous respiration. Naloxone competes at all receptor subtypes, although not equally, and is effective at reversing almost all adverse effects mediated through opioid receptors.

(Antidotes in Depth: Opioid Antagonists contains a complete discussion of naloxone and other opioid antagonists.)

Because many clinical findings associated with opioid poisoning are nonspecific, the diagnosis requires clinical acumen. Differentiating acute opioid poisoning from other etiologies with similar clinical presentations may be challenging. Patients manifesting opioid toxicity, those found in an appropriate environment, or those with characteristic physical clues such as fresh needle marks require little corroborating evidence. However, subtle presentations of opioid poisoning may be encountered, and other entities superficially resembling opioid poisoning may occur. Hypoglycemia, hypoxia, and hypothermia are common clinical presentations that share features with opioid poisoning and may exist concomitantly. Each can be rapidly diagnosed with routinely available, real-time testing, but the proof of their existence does not exclude opioid toxicity. Other drugs responsible for similar clinical presentations include clonidine, PCP, pheno-thiazines, and sedative-hypnotic agents, primarily benzodiazepines. In such patients, clinical evidence usually is available to assist in diagnosis. For example, nystagmus nearly always is noted in PCP-intoxicated patients, hypotension or electrocardiographic abnormalities in phenothiazine-poisoned patients, and coma with virtually normal vital signs in patients poisoned by benzodiazepines. Most difficult to differentiate on clinical grounds may be toxicity produced by the centrally acting antihypertensive agents such as clonidine (see Clonidine below and Chap. 60). Additionally, a myriad of traumatic, metabolic, and infectious etiologies may occur simultaneously and must always be considered and evaluated appropriately.

Antidote Administration

The goal of naloxone therapy is not necessarily complete arousal; rather, the goal is reinstitution of adequate spontaneous ventilation. Because precipitation of withdrawal is potentially detrimental and

often unpredictable, the lowest practical naloxone dose should be administered initially, with rapid escalation as warranted by the clinical situation. Most patients respond to 0.05 mg of naloxone administered intravenously, although the requirement for ventilatory assistance may be slightly prolonged because the onset may be slower than with larger doses. Administration in this fashion effectively avoids endotracheal intubation and allows timely identification of patients with nonopioid causes of their clinical condition yet diminishes the risk of precipitation of acute opioid withdrawal. Subcutaneous administration may allow for smoother arousal than the high-dose intravenous route[250] but is unpredictable in onset and likely prolonged in offset. Prolonged effectiveness of naloxone by the subcutaneous route can be a considerable disadvantage if the therapeutic goal is exceeded and the withdrawal syndrome develops.

In the absence of a confirmatory history or diagnostic clinical findings, the cautious empiric administration of naloxone may be both diagnostic and therapeutic. Naloxone, even at extremely high doses, has an excellent safety profile in patients with nonopioid-related indications, such as those with spinal cord injury[20] or acute ischemic stroke. Thus, administration in an empiric fashion to most nonopioid-poisoned patients likely will not be harmful. However, administration of naloxone to opioid-dependent patients may result in adverse effects; obviously, precipitation of an acute withdrawal syndrome should be anticipated. The resultant agitation, hypertension, and tachycardia may produce significant distress to both the patient and the clinical staff and occasionally may be life threatening. Additionally, emesis, a common feature

of acute opioid withdrawal, may be particularly hazardous in patients who do not rapidly regain consciousness after naloxone administration. For example, patients with concomitant ethanol or sedative-hypnotic exposure, or those with head trauma, are at substantial risk for pulmonary aspiration of vomitus if their airway is

unprotected.

Identification of patients likely to respond to naloxone conceivably would reduce the unnecessary and potentially dangerous precipitation of withdrawal in opioid-dependent patients. Routine prehospital administration of naloxone to all patients with subjectively assessed altered mental status or respiratory depression was not beneficial in 92% of patients.[264] Alternatively, although not perfectly sensitive, a respiratory rate â‰¤12 breaths/min in an unconscious patient presenting via EMS best predicted a response to naloxone.[98] Interestingly, neither respiratory rate <8/min nor coma was able to predict a response to naloxone in hospitalized patients.[257] Whether the discrepancy between the latter two studies is a result of the demographics of the patient groups, or whether patients with prehospital opioid overdose present differently than patients with iatrogenic poisoning, is unclear. Regardless, relying on the respiratory rate to assess the need for ventilatory support or naloxone administration is not ideal because hypoventilation secondary to hypopnea may precede that caused by bradypnea.[199 , 220] The decision to discharge a patient who awakens appropriately following naloxone administration is based on practical considerations. Patients presenting with profound hypoventilation or hypoxia are at risk for development of acute lung injury or posthypoxic encephalopathy. Thus, it seems prudent to observe these patients for at least 24 hours in a medical setting. Patients manifesting only moderate signs of poisoning, who remain normal for at least several hours following parenteral naloxone, likely are safe to discharge. However, the need for psychosocial intervention in patients with uncontrolled drug use, or following a suicide attempt, may prevent discharge from an ED.

Patients with recurrent or profound poisoning by long-acting opioids, such as methadone, or patients with large gastrointestinal burdens (eg, â€œbody packersâ€• or those taking sustained-release preparations), may require continuous infusion of naloxone to ensure continued adequate ventilation (Table 38-3). An hourly infusion rate of two thirds of the initial reversal dose of naloxone is sufficient to

prevent recurrence.[79] Titration of the dose may be necessary as indicated by the clinical situation. Although repetitive bolus dosing of naloxone may be effective, it is labor intensive and subject to error.

Despite the availability of long-acting opioid antagonists (eg, naltrexone and nalmefene[117]) that theoretically permit single-dose reversal of methadone poisoning, the attendant risk of precipitating an unrelenting withdrawal syndrome hinders their use as agents for initial opioid reversal. However, these agents may have a clinical role in the maintenance of consciousness and ventilation in opioid-poisoned patients already awakened by naloxone. Prolonged observation and perhaps antidote readministration may be required in order to match the pharmacokinetic parameters of the two agents. Otherwise well children who ingest short-acting opioids may be given a long-acting opioid antagonist initially because they are not expected to develop a prolonged, potentially hazardous withdrawal. However, the same caveats remain regarding the need for extended hospital observation periods if ingestion of methadone or other long-acting opioids is suspected.

1. If a naloxone bolus (start with 0.05 mg IV and titrate) is successful, administer two thirds of the effective bolus dose per hour by IV infusion; frequently reassess the patient's respiratory status.
2. If respiratory depression is not reversed following the bolus dose:
   Intubate the patient, as clinically indicated.
   Administer up to 10 mg of naloxone as an intravenous bolus. If the patient does not respond, do not initiate an infusion.
3. If the patient develops withdrawal following the bolus dose:
   Allow the effects of the bolus to abate.
   If respiratory depression recurs, administer half of the initial bolus dose and begin an intravenous infusion at two thirds of the initial bolus dose per hour. Frequently reassess the patient's respiratory status.
4. If the patient develops withdrawal signs or symptoms during the

infusion:

Stop the infusion until the withdrawal symptoms abate.

Restart the infusion at half the initial rate; frequently reassess the patient's respiratory status.

Exclude withdrawal from other xenobiotics.

5. If the patient develops respiratory depression during the infusion:

Readminister half of the initial bolus and repeat until reversal occurs.

Increase the infusion by half of the initial rate; frequently reassess the patient's respiratory status.

Exclude continued absorption, readministration of opioid, and other etiologies as the cause of the respiratory depression.

TABLE 38-3. How to Use a Naloxone Infusion

Rapid and Ultrarapid Opioid Detoxification

The concept of antagonist-precipitated opioid withdrawal is promoted extensively as a â€œcureâ€• for opioid (particularly heroin and oxycodone) dependency. Rather than slow, deliberate withdrawal, or detoxification, from opioids over several weeks, antagonist-precipitated withdrawal occurs over several hours or days.[218] The purported advantage of this technique is a reduced risk of relapse to opioid use because the duration of discomfort is reduced and a more rapid transition to naltrexone maintenance can be achieved. Although most studies find excellent short-term results, relapse to drug use is very common.[161] This finding may suggest a need for improved aftercare or may reflect a fundamental flaw in the mechanistic rationalization of the therapy. In addition, selection bias; the lack of randomization, control groups, or blinding; and variations in treatment protocols and end points hinder the external applicability of

much of the available research on antagonist-precipitated opioid withdrawal.[178]

Rapid opioid detoxification techniques are usually offered by outpatient clinics and typically consist of naloxone- or naltrexone-precipitated opioid withdrawal, tempered with varying amounts of clonidine, benzodiazepines, antiemetics, or other drugs. UROD uses a similar concept but involves the use of deep sedation or general anesthesia for greater patient control and comfort. Unique to this setting, and perhaps to unintentional precipitated opioid withdrawal following therapeutic naloxone, is the development of delirium, a clinical effect that is absent when opioid withdrawal develops more slowly.[78] Mechanistic explanations for the rapid detoxification strategies include withdrawal-induced catecholamine depletion, rapid normalization of receptor regulation, and enhanced endogenous opioid release,[237] but each is based largely on unsubstantiated evidence. Both techniques are costly; UROD under anesthesia commonly costs thousands of dollars.

The risks of these techniques are not fully defined but are of substantial concern. Massive catecholamine release, acute lung injury, renal insufficiency, and thyroid hormone suppression are

reported following UROD, and many patients still manifest opioid withdrawal 48 hours after the procedure.[56, 85, 160, 186] As with other forms of opioid detoxification, the loss of tolerance following successful completion of the program paradoxically increases the likelihood of death from heroin overdose of these individuals compared to those who do not complete a detoxification program.[236]

The Opioids

The vast majority of opioid-poisoned patients follow predictable clinical courses that can be anticipated based on our understanding of opioid receptor pharmacology. However, certain opioids taken in overdose may produce atypical manifestations. Therefore, careful

clinical assessment and institution of empiric therapy usually are necessary to ensure proper management (Table 38-4).

Buprenorphine (Buprenex)
P/AA
Semisynthetic
0.4 IM
Opioid substitution therapy requires 6â€“16 mg/d
Butorphanol (Stadol)
AA
Semisynthetic
2 IM

Codeine
Ag
Natural
120 PO
Often combined with acetaminophen; requires demethylation to morphine by CYP2D6
Dextromethorphan (Robitussin DM)
NEC
Semisynthetic
Nonanalgesic (10â€“30 PO)
Antitussive; psychotomimetic via Ïƒ or NMDA receptor
Diphenoxylate (Lomotil)
Ag
Synthetic
Nonanalgesic (2.5 PO)
Antidiarrheal agent, combined with atropine; difenoxin is potent metabolite
Fentanyl (Sublimaze)
Ag
Synthetic
0.125 IM
Very short-acting (<1 h)

Heroin (Diamorph)
Ag
Semisynthetic
5 SC
Diacetylmorphine, used therapeutically in some countries, schedule I in the United States
Hydrocodone (Vicodin, Hycodan)
Ag
Semisynthetic
10 PO

Hydromorphone (Dilaudid)
Ag
Semisynthetic
1.3 SC

LAAM (Orlaam)
Ag
Synthetic
(Flexible oral dosing[d])
L-Î±-Acetylmethadol or levomethadyl acetate; 3 times per week dosing for substitution therapy; long acting, potent metabolites; no longer distributed in US because of QTc interval prolongation
Levorphanol (Levodromoran)
Ag
Semisynthetic
2 SC/IM

Loperamide (Imodium)
Ag
Synthetic
Nonanalgesic (2 PO)
Antidiarrheal agent
Meperidine, pethidine (Demerol)

Ag
Synthetic
75 SC/IM
Seizures due to metabolite accumulation
Methadone (Dolophine)
Ag
Synthetic
10 IM
Very long-acting (24 h)
Morphine
Ag
Natural
10 SC/IM

Nalbuphine (Nubain)
AA
Semisynthetic
10 IM

Nalmefene (Revex)
Ant
Semisynthetic
Nonanalgesic (0.1 IM)
Long-acting antagonist (4â€“6 h)
Nalorphine
AA
Semisynthetic
15 IM
Historically used as an opioid antagonist[a]
Naloxone (Narcan)
Ant
Semisynthetic
Nonanalgesic (0.1â€“0.4 IV/IM)
Short-acting antagonist (0.5 h)

Naltrexone (Trexan)
Ant
Semisynthetic
Nonanalgesic (50 PO)
Very long-acting antagonist (24 h)
Oxycodone (Percocet, OxyContin)
Ag
Semisynthetic
10 PO
Often combined with acetaminophen; OxyContin is sustained release
Oxymorphone (Numorphan)
Ag
Semisynthetic
1 SC

Paregoric (Parapectolin)
Ag
Natural
25 mL PO
Tincture of opium (0.4 mg/mL)
Pentazocine (Talwin)
AA
Semisynthetic
50 SC
Psychotomimetic via Ïƒ receptor
Propoxyphene (Darvon)
Ag
Synthetic
65 PO
Seizures, dysrhythmias; combined with acetaminophen
Tramadol (Ultram)
Ag
Synthetic
50â€“100 PO

Seizures possible with therapeutic dosing

[a] Agonistâ€“antagonists, partial agonists, and antagonists may cause withdrawal in tolerant individuals.

[b] Typical dose (mg) for agents without analgesic effects is given in parentheses.

[c] Duration of therapeutic clinical effect 3â€“6 hours unless noted; likely to be exaggerated in overdose.

[d] Although approximately equipotent with methadone, LAAM is not used as an analgesic.

Ag=full agonist (Âμ$_1$, Âμ$_2$, Îº); AA=agonist antagonist (Îº agonist, Âμ antagonist); Ant=full antagonist (Âμ$_1$, Âμ$_2$, Îº antagonist); P=partial agonist (Âμ$_1$, Âμ$_2$ agonist, Îº antagonist); NEC=not easily classified.

Opioid (Representative Trade Name)	Type[a]	Derivation	Analgesic Dose (mg) (via route, equivalent to 10 mg morphine SC[b])	Comments[a],[c]

TABLE 38-4. Classification, Potency, and Characteristics of Opioids

Morphine/Codeine

Morphine is poorly bioavailable by the oral route because of extensive first-pass elimination. Morphine is hepatically metabolized primarily to morphine-3-glucuronide (M3G) and, to a lesser extent, to morphine-6-glucuronide (M6G), both of which are cleared renally. Unlike M3G, which is essentially devoid of activity, M6G has Âμ-agonist effects in the central nervous system.[3] However, M6G administered peripherally

is significantly less potent as an analgesic than is morphine.[219] The polar glucuronide has a limited ability to cross the bloodâ€“brain barrier and P-glycoprotein is capable of expelling M6G from the cerebrospinal fluid. The relative potency of morphine and M6G in the brain is incompletely defined, but the metabolite is generally considered to be several-fold more potent.[3] Interestingly, glucuronidation occurring in the brain

may account in part for the increased clinical effect of heroin over morphine.[204]

Codeine itself is an inactive opioid agonist, and it requires metabolic activation by *O* -demethylation to morphine by CYP2D6 (Figure 38-3). This typically represents a minor metabolic pathway for codeine metabolism. *N* -demethylation into norcodeine by CYP3A4 and glucuronidation are more prevalent but produce inactive metabolites. The need for conversion to morphine explains why approximately 5â€“7% of white patients, who are devoid of CYP2D6 function,[105] cannot derive an analgesic response from codeine.[147] Rarely, ultrarapid CYP2D6 metabolizers produce unexpectedly large amounts of morphine, with resulting life-threatening opioid toxicity.[69]

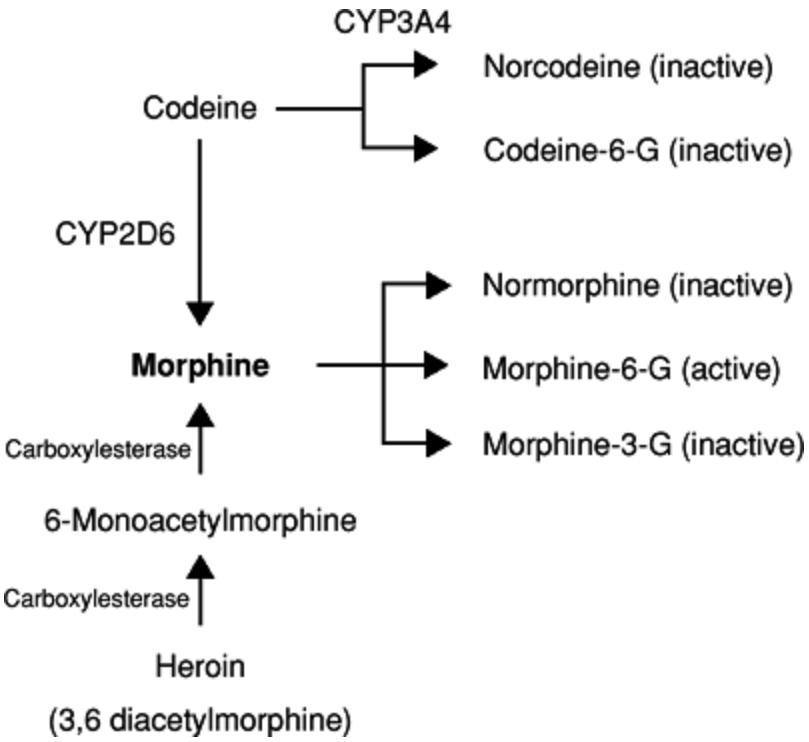

Figure 38-3. Opiate/opioid metabolism. Codeine can be *O* -methylated to morphine, *N* -demethylated to norcodeine, or glucuronidated to codeine-6-glucuronide. Morphine can be *N* -demethylated to normorphine or glucuronidated to either morphine-3-glucuronide or morphine-6-glucuronide. Heroin is converted to morphine by a two-step process involving pseudocholinesterase and two human liver carboxylesterases known as human carboxylesterase-1 and human carboxylesterase-2.

Heroin

Heroin is 3,6-diacetylmorphine, and its exogenous synthesis is performed relatively easily from morphine and acetic anhydride. Heroin has a lower affinity for the Âμ receptor than does morphine, but it is rapidly metabolized by pseudocholinesterase and liver human carboxylesterase (hCE)-2 to 6-monoacetylmorphine, a more potent Âμ agonist than morphine[212] (Figure 38-3). Users claim that heroin has an enhanced euphorigenic effect, often described as a â€œrush.â€•

This effect likely is related to the enhanced bloodâ€“brain barrier penetration occasioned by the additional organic functional groups of heroin[179] and its subsequent metabolic activation within the central nervous system. Interestingly, cocaine and heroin compete for metabolism by pseudocholinesterase and the two human liver carboxylesterases hCE-1 and hCE-2. This interaction may have pharmacokinetic and clinical consequences in patients who â€œspeedball.â€•[14,115]

Heroin can be obtained in two distinct chemical forms: base or salt. The hydrochloride salt form typically is a white or beige powder and was the common form of heroin available prior to the 1980s.[109] Its high water solubility allows simple intravenous administration. Heroin base, on the other hand, now is the more prevalent form of heroin in most regions of the world. It often is brown or black. â€œBlack tar heroinâ€• is one appellation referring to an impure South American import available in the United States. Because heroin base is virtually insoluble in water, intravenous administration requires either heating the heroin until it liquefies or mixing it with acid. Alternatively, because the alkaloidal form is heat stable, smoking or â€œchasing the dragonâ€• is gaining popularity as an alternative route. Street-level heroin base frequently contains caffeine or barbiturates,[109] which improves the sublimation of heroin and enhances the yield.[103]

Widespread intravenous use has led to many significant direct and indirect medical complications, particularly endocarditis and AIDS, in addition to fatal and nonfatal overdose. Nearly two thirds of all long-term (>10 years) heroin users in Australia had self-overdosed on heroin,[44] whereas among recent-onset heroin users, 23% had overdosed on heroin and 48% had been present when someone else overdosed.[82] Risk factors for fatality following heroin use include the concomitant use of other drugs, particularly ethanol,[140] recent abstinence, as occurs during incarceration,[210] and perhaps unanticipated fluctuations in the purity of available heroin.[43,200] Because most overdoses occur in seasoned heroin users, and as many as 85% occur in the company of other users,[44] a trial distribution of

naloxone to heroin users was initiated. Although earlier administration of antidote could be beneficial, certain issues make this approach controversial. For example, despite the acknowledged injection skills of the other users in the â€œshooting gallery,â€• their judgment likely is impaired. In one survey, summoning an ambulance was the initial response to overdose of a companion in only 14% of cases.[45] A survey of heroin users suggested they lacked an understanding of the pharmacology of naloxone, which might lead to inappropriate behaviors regarding both heroin and naloxone administration.[209]

Recognition of the efficacy of intranasal administration, or snorting, has fostered a resurgence of heroin use, particularly in suburban communities.[65 , 230] The reasons for this trend are unclear, although it is widely suggested that the rising purity of the available heroin has rendered it more suitable for intranasal use.[50] However, because intranasal administration of a mixture of 3% heroin in lactose produces clinical and pharmacokinetic effects similar to an equivalent dose administered intramuscularly,[36] the relationship between heroin purity and price and intranasal use is uncertain.[200] Needle avoidance certainly is important, reducing the risk of transmission of various infectious diseases, including HIV.[120] Heroin smoking also has increased in popularity in the United States, albeit not to the extent in other countries (see â€œChasing the Dragon â€• below).

Celebrities and musicians have popularized intranasal heroin use as a â€œsafeâ€• alternative to intravenous use. This usage is occurring despite a concomitantly reported rise in heroin deaths in regions of the country where its use is prevalent. Although intranasal use may be less dangerous than intravenous use from an infectious disease perspective, it is clear that both fatal overdose and drug dependency remain common.[241]

Adulterants, Contaminants, and â€œHeroinâ€• Substitutes

The history of heroin adulteration and contamination has been

extensively described. Street-level heroin almost always contains

adulterants or contaminants. What differentiates the two is the intent of their admixture. Adulterants typically are benign because inflicting harm on the consumer with their addition would be economically and socially unwise, although adulterants occasionally are responsible for epidemic death. Interestingly, most heroin overdose fatalities do not have serum morphine concentrations that substantially different from those of living users, raising the possibility that the individual death is related to an adulterant or contaminant.[46]

Historically, alkaloids, such as quinine and strychnine, were used to adulterate heroin in order to mimic the bitter taste of heroin and to mislead clients. Quinine may have first been added in a poorly reasoned attempt to quell an epidemic of malaria among intravenous heroin users in New York City in the 1930s.[93] That quinine adulteration was common is demonstrated by the common practice of urine screening for quinine as a surrogate marker for heroin use.[260] However, quinine was implicated as a causative factor in an epidemic of heroin-related deaths in the District of Columbia between 1979 and 1982.[203] Toxicity attributed to quinine in heroin users includes cardiac dysrhythmias (Chap. 23), amblyopia, and thrombocytopenia. Quinine adulteration currently is much less important than it was in the past. Trend analysis of illicit wholesale and retail (street-level) heroin adulteration over a 12-year period in Denmark revealed that although caffeine, acet-aminophen, methaqualone, and phenobarbital all were prevalent adulterants, quinine was not found.[109] Recent data on adulteration in the United States are unavailable. Many other adulterants or contaminants, including thallium,[196] lead,[182] cocaine,[99] and amphetamines,[31] have been reported.

Poisoning by scopolamine-tainted heroin reached epidemic levels in the northeastern United States in 1995.[86] Exposed patients presented with acute psychosis and unmistakable anticholinergic signs. Several patients were treated with physostigmine, with excellent therapeutic results.

â€œChasing the Dragon.â€•

Intravenous injection and insufflation are the preferred means of heroin self-administration in the United States. In other countries, including the Netherlands, the United Kingdom, and Spain, the prevalent method is â€œchasing the dragon.â€• When chasing the dragon, users inhale a thick, white pyrolysate that is generated by heating heroin base on aluminum foil using a hand-held flame. Although some of the heroin effluvium is dissipated into the surroundings, this means of administration produces heroin pharmacokinetics similar to those observed following intravenous administration.[95] Chasing the dragon is not a new phenomenon, but it has gained acceptance recently among both intravenous heroin users and drug-naive individuals.[235] The reasons for this shift are diverse but probably are related to the avoidance of injection drug use with its concomitant infectious risks. The increasing availability of the smokable base form of heroin is clearly associated, but whether it is a cause or an effect of this trend is unknown.

In the early 1980s, an unexplainable cluster of spongiform leukoencephalopathy occurring solely in individuals who smoked heroin was identified in the Netherlands.[262] Other causes of this unique clinicopathologic entity include various viral infections (eg, bovine spongiform leukoencephalopathy), hexachlorophene, pentachlorophenol, and metal poisoning, although none appeared responsible for this phenomenon. Since the initial report, similar cases have been reported in other parts of Europe and in the United States.[134 , 146] Initial findings may occur after as few as 2 weeks of use and include bradykinesia, ataxia, abulia, and speech abnormalities. Of those whose symptoms do not progress, half may recover. However, in others progression to spastic paraparesis, pseudobulbar palsy, or hypotonia may occur over several weeks. Approximately half of individuals in this group do not develop further deficits or improve, whereas death occurs in approximately 25% of

reported cases. The prominent symmetric cerebellar and cerebral white matter destruction noted on brain imaging with CT and MRI[121] corresponds to that noted at necropsy. The syndrome has the characteristics of a point-source toxic exposure, but no culpable contaminants have been identified.[22] Although initially postulated to be related to excessive exposure to aluminum fumes, neither the dose inhaled nor the serum concentrations support this hypothesis. Furthermore, the widespread administration of heroin by this route without notable adverse effect and the clustering of cases argue against the involvement of aluminum. A component or pyrolysis product unique to certain batches of â€œheroinâ€• is likely.[22] Treatment is largely supportive. Based on the finding of regional mitochondrial dysfunction on functional brain imaging and an elevated brain lactate concentration, supplementation with coenzyme Q 300 mg qid has purported benefit[134] but has not undergone controlled study.

Other Opioids

Fentanyl and Its Analogs

Fentanyl is a short-acting, highly potent opioid agonist that is widely used in clinical medicine. Fentanyl has approximately 50â€“100 times the potency of morphine. It is well absorbed by the transmucosal route, accounting for its use in the form of a â€œlollipop.â€• Fentanyl is widely abused as a heroin substitute and is the controlled substance most often abused by anesthesiologists.[18]

Transdermal fentanyl in the form of a patch (Duragesic) was approved in 1991. It is widely used by patients with chronic pain syndromes, including those with cancer-related pain. It has adequate solubility in both lipid and water for transdermal delivery. The transdermal pharmacokinetics differ markedly from those of the more conventional routes.[131] A single patch contains an amount of drug to provide a transdermal gradient sufficient to maintain a steady-state plasma

concentration for approximately 3 days (eg, a 50 Âµg/h patch contains 5 mg). However, even after the patch is considered exhausted, approximately 50% of the total initial fentanyl dose remains.[153] Interindividual variation in dermal drug penetration[137] and errors in proper use (excessive patches, warming of the skin[63]) may lead to iatrogenic fentanyl overdose. Not unexpectedly, fentanyl patch abuse occurs either by direct application of one or more patches to the skin or indirectly by withdrawal or extraction of the fentanyl from the patch for subsequent administration.[11 , 240]

Sufentanil and alfentanil are anesthetic opioids with increased potency compared to fentanyl. In some regions of the country, fentanyl and both licit and illicit fentanyl analogs (eg, 3-methylfentanyl and para-fluorofentanyl) are common drugs of abuse. Experienced heroin users could not easily differentiate fentanyl from heroin, although in one study, the heroin was noted to provide a more intense â€œrush.â€• [135] Although unconfirmed, the agent used by Russian authorities to overcome terrorists and subdue a hostage situation in Moscow in October 2002 may have been carfentanil, a potent Âµ-receptor agonist that is commonly used as a positron emission tomography (PET) scan radioligand.[253]

Regional epidemics of heroin substitutes with â€œsuperpotentâ€• activity occasionally produce a dramatic rise in â€œheroin-relatedâ€•

fatalities. Epidemic deaths among heroin users first appeared in Orange County, California, in 1979 and were traced to Î±-methylfentanyl sold under the brand name China White.[132] Similar epidemics of China White poisoning occurred in Pittsburgh in 1988 and in Philadelphia in 1992, although the adulterant in these cases was 3-methylfentanyl, another potent analog. A later epidemic in New York City marked the reappearance of 3-methylfentanyl under the brand name Tango and Cash. Typically, patients present comatose and apneic, with no opioids detected on routine blood and urine analysis. In such cases, unsuspecting users had administered their usual â€œdose of heroin,â€• measured in 25-mg â€œbagsâ€• that

contained variable amounts of the fentanyl analog. Because of the exceptional potency of this fentanyl analog (as much as 6000 times greater than that of morphine), higher than usual doses of naloxone may be needed to successfully compete for the opioid receptor.

Oxycodone and Hydrocodone

Although media reports highlight the abuse of these and other prescription pharmaceutical opioids by sports figures and other personalities, this trend has reached epidemic levels in regions of the country where heroin is difficult to obtain (thus the term â€œHillbilly heroinâ€•).[92] Although many users initially receive oxycodone or hydrocodone for legitimate pain management, the majority obtain the drugs illicitly.[21 , 192] Regulatory agencies, law enforcement, and the drug manufacturer have made tremendous efforts to control drug diversion to illicit use.[73] Physicians have been charged criminally with complicity for inappropriately writing prescriptions for patients with the intent to sell or abuse these drugs.[73] Many of these agents are sold in fixed combination with acetaminophen (eg, Percocet [oxycodone 5 mg], Vicodin [hydrocodone]), raising concerns about the complications of acetaminophen hepatotoxicity. Unlike most immediate-release prescription opioids, oxycodone can be obtained in a controlled-release form (OxyContin) that contains as much as 80 mg (a 160-mg tablet was removed from the market). Abusers typically crush the tablet, which destroys the sustained-release matrix and liberates large amounts of insufflatable or injectable oxycodone. The psychoactive effects of these agents are similar to other Âμ-receptor agonists[267] and often are used as a substitute for heroin.[21] Opioid dependence, overdose, and death are common sequelae of oxycodone abuse.[35 , 228]

Clostridial Infections

Heroin-related clostridial infections, although uncommon, present in a manner similar to those of conventional botulism or tetanus but may

be atypical (Chap. 46). Interestingly, during the 1950s and early 1960s, users of quinine-adulterated heroin in New York City[30] and Chicago[141] were substantially more likely to develop tetanus than were users of nonquinine-adulterated heroin. This likely is a result of the extensive tissue destruction caused by subcutaneous quinine administration, which also occurs in patients receiving therapeutic intramuscular quinine.[265] â€œBlack tar heroin,â€• an impure form of heroin, is implicated in multiple epidemics of wound botulism.[26] Whether the minimally processed heroin was contaminated with *Clostridium botulinum* or whether it led to improved anaerobic growing conditions for the spores is not known. Early antitoxin therapy is associated with improved outcome.[29] Other *Clostridia* (eg, *C. novyi* and *C. sordellii*) are responsible for epidemics of necrotizing fasciitis that are common among users of black tar heroin. Nearly half of the victims of necrotizing fasciitis die of the disease.[123]

Body Packers

In an attempt to transport illicit drugs from one country to another, â€œmules,â€• or body packers, ingest large numbers of multiple-wrapped packages of concentrated cocaine or heroin. After they arrive at their destination, they administer cathartics so that the packets can be passed and delivered. When the authorities discover such individuals or when individuals in custody become ill, they may be brought to a nearby hospital for evaluation and management. Although these patients generally are asymptomatic on arrival, they are at risk for delayed, prolonged, or lethal poisoning as a consequence of packet rupture.[243] An abdominal radiograph usually is sufficient to confirm gastrointestinal smuggling,[96] but occasional false-negative radiographic results occur, even in patients with enormous packet counts.[159] Patients who are suspected body packers should be observed, even in the absence of packets on plain abdominal radiograph. Computed tomography can identify packets but should be considered only in suspicious cases with negative radiographs or potentially to document packet clearance from the

gastrointestinal tract. Computed tomography may provide information about the contents of the packets. However, although heroin, cocaine, and hashish can be differentiated by their Hounsfield unit values in vitro, there is no evidence that such measurements are accurate in the clinical setting. Magnetic resonance imaging also can identify packets but cannot differentiate their contents. Ultrasonography does not offer any advantage over radiography and is both user dependent and more difficult to perform.[96] Rapid urine testing for drugs of abuse may assist in determining the packet content,[74] but the same information usually is obtained more rapidly by simply asking the patient or by identifying clinical syndromes (almost invariably opioid vs sympa-thomimetic). In the past, determining the country of origin of the current journey was nearly diagnostic of packet content. However, because most of the heroin imported into the United States now originates from South America, which is also the major source of imported cocaine, the discernment from cocaine on this basis is impossible. Given the current greater revenue potential of heroin, the vast majority of body packers carry heroin.[77] Still, given the common source of the two drugs, body packers may be â€œdouble breasting,â€• that is, carrying both heroin and cocaine packets simultaneously.

Regardless of the content, appropriate treatment for asymp-tomatic patients should include whole-bowel irrigation with polyethylene glycol solution (Chap. 4).[60] Subsequent management differs based on the presumed packet content. Patients body-packing cocaine who develop symptoms require immediate surgical packet removal (Chap. 74), whereas those with heroin packets often can be managed nonoperatively with continuous infusion of naloxone, oral activated charcoal, and whole-bowel irrigation.[243] Intestinal perforation or obstruction by the packets requires surgical intervention. Packets that do not progress beyond the stomach probably should be removed surgically, although endoscopic removal of a single or small number of packets may be carefully performed. The need to remove multiple packets requires repeated insertions of the endoscope, possibly

increasing the likelihood of packet rupture by the endoscope. However, most modern packets are constructed solidly and unlikely to tear or rupture.

Agonistâ€“Antagonists

The opioid agonists in common clinical use tend to have specific binding affinity toward the Âµ-opioidâ€“receptor subtype. The

agonistâ€“antagonist agents differ in that they interact with multiple receptor types and may have different effects at each receptor. Thus, although most opioids typically produce either agonist or antagonist effects, the agonistâ€“antagonists generally have agonist effects at the Îº-receptor subtype and antagonistic effects at the Âµ-receptor subtype. Therefore, agents such as pentazocine (Talwin) may elicit a withdrawal syndrome in a Âµ-opioidâ€“tolerant individual because of antagonist effects at the Âµ receptor. This effect forms the basis of the claim offered by many methadone-dependent patients that they are â€œallergic to Talwin.â€• However, this same drug can act as an analgesic in nonopioid-using patients through its agonist effects at the $Îº_1$ -receptor subtype. Although the clinical effects following overdose resemble those of the other opioid agents, the agonistâ€“antagonists are significantly less likely than the full agonists to produce severe morbidity or mortality because of their ceiling effect on respiratory depression (see Respiratory Depression above).

Pentazocine

Historically, patients abusing pentazocine (Talwin) administered it with tripelennamine, a blue capsule, accounting for the appellation â€œT's and Blues.â€• Although this mixture has largely fallen out of favor, pentazocine abuse occurs occasionally, and newer combinations, such as pentazocine with methylphenidate, are reported.[25, 28] The psychotomimetic effects noted with high doses of pentazocine likely are mediated by $Îº_2$ or perhaps Ï*f* receptors.

Because pentazocine can be readily dissolved, intravenous injection was a preferred route for its abuse until the commercial formulation was altered to include 0.5 mg naloxone (Talwin NX).[191] When ingested, the naloxone is eliminated by first-pass hepatic metabolism; if injected, naloxone prevents the euphoria sought by users.

Agents Used in Opioid Substitution Therapy: Methadone, LAAM, Buprenorphine

Two contrasting approaches to the management of patients with chronic opioid use exist: detoxification and maintenance therapy. Detoxification probably is most appropriate for patients motivated or compelled to discontinue opioid use. It can be performed either by tapered withdrawal of an opioid agonist or with the assistance of opioid antagonists. Maintenance therapy may include use of a long-acting opioid antagonist, such as naltrexone, to pharmacologically proscribe opioid use. Alternatively, and more commonly, maintenance therapy involves opioid substitution therapy.

Methadone is a synthetic Âµ-opioidâ€“receptor agonist used both for treatment of chronic pain and as a maintenance substitute for opioid dependence. Methadone has been available for the latter use for more than 40 years through methadone maintenance treatment programs (MMTPs).[49] In MMTPs, methadone replaces the opioid with a legal, oral, and long-acting agent. This agent allows patients to abstain from activities associated with procurement and administration of the abused opioid and eliminates much of the morbidity and mortality associated with illicit drug use. Although often successful, some methadone users continue to use heroin or other illicit substances.[2, 118]

Although therapeutic methadone is generally safe, rapid dose escalation during induction in the treatment program may unintentionally produce toxicity and, rarely, fatal respiratory

depression. This adverse effect is generally the result of the long duration of effect of methadone and the time lag for development of tolerance.[52] Similarly, acute overdose results in clinical findings typical of opioid poisoning of a duration substantially longer than expected following overdose of prototypical therapeutic opioids. Following an appropriate response to the administration of naloxone, recurrence should be expected because naloxone's duration of effect is only approximately 1 hour. In many cases, continuous infusion of naloxone or possibly administration of a long-acting opioid antagonist is indicated to maintain adequate ventilation.

Intentional, nonsuicidal methadone overdosage ironically may be related to the manner in which MMTPs dispense the drug. Most patients attending MMTPs are given supratherapeutic doses to prevent surreptitious heroin or other opioid use.[5 , 234] Additionally, many MMTPs supply their established patients with sufficient methadone to last through a weekend or holiday without the need to revisit the program. Taken together, such dosing regimens may allow diversion of portions of the dose without the attendant risk of opioid withdrawal because the entire daily dose of methadone is not needed to suppress opioid withdrawal. Furthermore, home storage of this surplus drug in inappropriate containers, such as juice containers or baby bottles,[88] is a cause of unintentional methadone ingestion by children. Such events can be anticipated because methadone is frequently formulated as a palatable liquid and may not be distributed in child-resistant containers. The primary reason for distribution as a liquid, as opposed to the pill form given to patients with chronic pain syndromes, is to ensure dosing compliance at the MMTP. Unfortunately, death is frequent in children who overdose.[143]

LAAM (Orlaam), also known as levomethadyl acetate, is used in heroin substitution programs in a manner analogous to methadone.[55] LAAM is a long-acting synthetic opioid agonist, an effect partly attributable to its metabolism to two separate active metabolites, nor-LAAM and dinor-LAAM. LAAM rapidly produces characteristic opioid effects that are due to the parent compound. The peak effect, due to the

metabolites, is achieved in several hours.[249] The opioid effects of LAAM may be more resis-tant to reversal by naloxone than are those caused by methadone,[249] but they probably will respond to escalating antagonist dosing. Its duration of effect approaches 4 days, allowing thrice weekly dosing. Predictably, reemergence of opioid intoxication following naloxone therapy is common. Although LAAM still is available in certain countries, it was removed from the US market by its distributor, Roxane Laboratories, because of the drug's consequential effect of QTc interval prolongation. This effect occurs even with therapeutic LAAM use and is associated with ventricular dysrhythmias, particularly torsades de pointes.

Because prescription of methadone is in great part restricted to certain federally licensed programs, it is inaccessible and inconvenient for many patients. Buprenorphine was approved in 2000 as a schedule III agent for office-based prescription, providing an attractive alternative for patients with substantially broader potential for obtaining outpatient therapy. However, because of the novelty of the delivery (private office and not clinic based), limitations on patient volume, requirement for physician certification, and possibly the hesitation on the part of community physicians to welcome patients with substance use problems into their practices, many of the purported benefits of buprenorphine therapy over methadone have not been realized.[61]

Buprenorphine (Subutex), a partial Âμ-opioid agonist, in doses of 8â€“16 mg is effective at suppressing both opioid withdrawal symptoms and the covert use of illicit drugs.[83 , 110] Because buprenorphine competes with the extant opioid for the Âμ receptor

and may produce acute opioid withdrawal, the initial dose typically is administered in the presence of a physician. Following the initial doses of buprenorphine, tablets containing both buprenorphine and naloxone (Suboxone) are prescribed to prevent their intravenous use. The withdrawal syndrome from buprenorphine itself may be milder than that occurring following naloxone. Buprenorphine has been

suggested as a gentler agent for use in rapid opioid detoxification.[4]

Buprenorphine at therapeutic doses produces nearly complete occupancy of the Âμ opioid receptors, where it prevents other opioids from binding.[84] Interestingly, naloxone may prevent the clinical effects of buprenorphine but is relatively ineffective at reversing the effects once they are manifest.[66] This finding likely is related to the very slow dissociation of buprenorphine from the Âμ receptor. Furthermore, it is consistent with buprenorphine's long duration of clinical effect (allowing thrice-weekly dosing) despite its elimination half-life of 3 hours and mild withdrawal syndrome. Buprenorphine is administered by the sublingual route because of its poor oral bioavailability.

As a partial agonist, buprenorphine has a ceiling effect on respiratory depression, particularly at lower doses, although respiratory depression may occur at higher doses.[242 , 245] Although most fatal poisonings with buprenorphine are linked to polysubstance use,[190] some cases of isolated buprenorphine overdose are reported.[125 , 242] Death appears to be more common after intravenous injection of crushed pills than after oral overdose.[125]

Clonidine, a presynaptic $Î±_2$ -adrenergic agonist of the imidazoline class, is widely used by both clinicians and patients to reduce the disturbing autonomic effects of opioid withdrawal. Although clonidine is not structurally related to any opioid, in overdose clonidine produces a clinical syndrome identical to that produced by the Âμ-active opioids.[127 , 259] Mechanistically, there is functional overlap between $Î±_2$ and Âμ receptors within the brain (Figure 38-1). For these reasons, clonidine is commonly used to ameliorate the autonomic effects of opioid withdrawal. However, although the autonomic abnormalities can be normalized with this approach, the psychological aspects of withdrawal, including drug craving and poor judgment, may not be alleviated.

Specific or Unique Agents

Meperidine

Meperidine, also called pethidine outside of the United States, is widely used for treatment of chronic and acute pain syndromes. Meperidine produces clinical manifestations typical of the other opioids and may lead to greater euphoria.[268] Pupillary constriction is less pronounced and, if it occurs, is less persistent than that associated with morphine.[75] However, normeperidine, a toxic, renally eliminated hepatic metabolite, accumulates in patients receiving chronic high-dose meperidine therapy, such as those with sickle cell disease or cancer. A similar accumulation occurs in patients with renal insufficiency, in whom the elimination half-life increases from a normal of 14â€“21 hours to 35 hours.[239] Normeperidine causes excitatory neurotoxicity, which manifests as delirium, tremor, myoclonus, or seizures. Based on animal studies, the seizures should not be expected to respond to naloxone.[76] In fact, experimental evidence suggests that naloxone may potentiate normeperidine-induced seizures, presumably by inhibiting an anticonvulsant effect of meperidine.[38] Hemodialysis using a high-efficiency membrane may be of limited clinical benefit but rarely, if ever, is indicated because the toxicity generally is self-limited.[89]

Although primarily an opioid, meperidine is capable of exerting effects at other types of receptors. The most consequential nonopioid-receptor effects occur through the serotonin receptor. Blockade of the presynaptic reuptake of released serotonin may produce the serotonin syndrome, characterized by muscle rigidity, hyperthermia, and altered mental status, particularly in patients using monoamine oxidase inhibitors (MAOIs) (Chap. 69). However, dextromethorphan (see Dextromethorphan below) also may produce this syndrome. Conversely, the simultaneous use of MAOIs and morphine, fentanyl, or methadone is not expected to produce the serotonin syndrome based on the currently appreciated pharmacology of these drugs. Despite its purported (and likely overstated) beneficial effects on biliary tract physiology, meperidine offers little to support its clinical

use and has significant disadvantages. Meperidine use has been dramatically reduced or is closely monitored in many institutions[217] and has been eliminated in other centers because of its pharmacologic and toxicologic disadvantages. Paradoxically, and with significant liability, it has been used in some institutions for patient-controlled analgesia.[211]

MPTP

In 1982, several cases of acute, severe parkinsonian symptoms were identified in intravenous drug users.[136] The patients were labeled â€œfrozen addictsâ€• because of the severe bradykinesia, and extensive investigations into the etiology of the problem ensued. This ultimately led to the discovery of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an inadvertent product of presumed errors in the attempted synthesis of the illicit meperidine analog MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine). MPTP is metabolized to the ultimate toxicant MPP^+ by monoamine oxidase-B in glial cells. Toxicity is inhibited by pretreatment with deprenyl, a monoamine oxidase-B inhibitor. MPP^+ is a paraquatlike agent capable of selectively destroying the dopamine-containing cells of the substantia nigra by inhibiting mitochondrial oxidative phosphorylation.[207] The index cases initially responded to standard antiparkinsonian therapy, but none improved substantially and the effects of the medications waned.[9] Although calamitous for exposed patients, MPTP has proved to be invaluable in the development of experimental models for the study of Parkinson disease.[258] Several of the original â€œfrozenâ€• patients subsequently underwent stereotactic implantation of fetal adrenal tissue grafts into their basal ganglia, with significant clinical improvement.

Dextromethorphan

Dextromethorphan is devoid of analgesic properties altogether, even though it is the optical isomer of levorphanol, a potent opioid

analgesic. Based on this structural relationship, dextromethorphan is commonly considered an opioid, although its receptor pharmacology actually is extremely complex. At high doses, dextromethorphan does bind to opioid receptors to produce miosis, respiratory depression, and central nervous system depression. Reversal of these opioid effects by naloxone is reported. Binding to the PCP site on the NMDA receptor, and subsequent inhibition of calcium influx through this receptor-linked ion channel, causes sedation. This same activity may account for its antiepileptic properties and for its neuroprotectant effects in ischemic brain injury. Because NMDA receptor blockade also enhances the analgesic effects of Âμ-opioid agonists, combination therapy with morphine and dextromethorphan (MorphiDex) has been introduced.

Blockade of presynaptic serotonin reuptake by dextromethorphan may elicit the serotonin syndrome in patients receiving

MAOIs.[227] Movement disorders, described as choreoathetoid or dystonialike, occasionally occur and presumably result from alteration of dopaminergic neurotransmission. Dextrorphan, the active *O* -demethylation metabolite of dextromethorphan, is produced by CYP2D6, an enzyme with a well-described genetic polymorphism.[6] Patients with the extensive metabolizer polymorphism appear to experience more drug-related psychoactive effects, whereas poor metabolizers suffer more adverse effects related to the parent compound.[271]

Dextromethorphan is available without prescription in cold preparations, primarily because of its presumed lack of significant addictive potential. However, abuse of dextromethorphan is increasing, particularly among high school students.[8] This increase in use likely is related to the drug's easy availability and its limited toxicity. Abundant promotional information is available on the Internet. Pure, powdered dextromethorphan is available without substantial regulatory oversight. Common street names include â€œDXM,â€• â€œdex,â€• and â€œroboshots.â€• Users often have

expectations of euphoria and hallucinations, not the PCP-like dysphoria that commonly occurs.[177] Reports of substantial cold medicine consumption raise several considerations, including acetaminophen poisoning,[126] opioid dependency, and bromide toxicity.[104] This last concern relates to the common formulation of dextromethorphan as the hydrobromide salt and is most easily recognized as a dramatically elevated serum chloride concentration when measured on certain autoanalyzers[176] (Chap. 7).

Tramadol

Tramadol (Ultram) is a novel synthetic analgesic agent with both opioid and nonopioid mechanisms responsible for its clinical effects. Although it binds only weakly to Âμ opioid receptors, tramadol exhibits cross-tolerance with morphine in rats, suggesting an opioid-mediated mechanism of analgesia.[128] The demethylated tramadol metabolite M1 exhibits higher-affinity binding to Âμ receptors in vitro and may be important in patients chronically using the drug. However, the role of M1 as an acute analgesic is not well defined. Naloxone only partially reverses tramadol-induced analgesia in mice and in humans, suggesting that an independent, nonopioid mechanism is also involved in mediating the clinical effects of tramadol.[180] This effect appears to be inhibition of reuptake of biogenic amines, specifically serotonin and norepinephrine. This mechanism is supported by the nearly complete reversal of analgesic efficacy by yohimbine, an Î±$_2$ -adrenergic antagonist that inhibits release of these neurotransmitters.[47] Patients using MAOIs may be at risk for development of the serotonin syndrome.

A large number of spontaneous reports to the FDA suggest that therapeutic use of tramadol may cause seizures, particularly on the first day after initiating therapy. However, epidemiologic studies have not confirmed this association.[71] Tramadol-related seizures are not responsive to naloxone but are suppressed with benzodiazepines. In fact, the package insert cautions against using naloxone in tramadol

overdose because, in animals treated with naloxone, the risk of seizure is increased. Correspondingly, one patient in the prospective series had a seizure that was temporally related to naloxone administration.[229] Acute overdose of tramadol is generally considered nonâ€“life threatening, and most fatalities were associated with polysubstance overdose.[33]

Tramadol abuse is reported but its extent is undefined.[23 , 221] In a review of physician drug abuse in several states, tramadol was the second most frequent opioid reported.[221] Opioid users recognized tramadol as an opioid only when given in an amount that was 6 times the therapeutic dose, but at this dose the users did not develop opioidlike clinical effects such as miosis.[193] Patients may develop typical opioid manifestations after a large overdose. Significant respiratory depression is uncommon and should respond to naloxone.[229] Urinary drug screening generally is negative for opioids in tramadol-exposed patients.

Propoxyphene

Like its structural analog methadone, propoxyphene binds Âμ-opioid receptors and produces the expected opioid clinical findings. However, unanticipated properties of propoxyphene manifest after overdose. Propoxyphene and its hepatic metabolite, norpropoxyphene, produce myocardial sodium channel blockade identical to the type IA antidysrhythmic agents.[148] This process results in QRS complex widening and negative inotropy. QRS prolongation was identified in 42 (19%) of 222 propoxyphene-overdosed patients.[222] These symptoms can be corrected with parenteral administration of hypertonic sodium bicarbonate[233] or with lidocaine. As in patients with tricyclic antidepressant overdose, the sodium ion component of the sodium bicarbonate enhances sodium influx through a partially occluded sodium channel by augmenting the extracellular to intracellular sodium concentration gradient. The paradoxical effect of lidocaine, another sodium channel blocker, can be explained by the very

different dissociation constants of these two agents with the sodium channel. Lidocaine, a class IB agent, may competitively displace propoxyphene and norpropoxyphene, both more highly toxic sodium channel blockers (Chap. 61). Naloxone has never been shown to be effective therapy for the cardiotoxic effects of propoxyphene, although hemodynamic improvement in one reported case probably was related to naloxone-induced propoxyphene withdrawal.[87]

Propoxyphene overdose may produce acute central nervous system toxicity that usually manifests as seizures. In one study of propoxyphene-overdosed patients, 10% of the subjects developed seizures.[222] Although the exact mechanism is unclear, experimental models demonstrate that only propoxyphene, and not norpropoxyphene, is capable of inducing seizures.[148] Therapy for seizures should follow standard management strategies, including benzodiazepines or barbiturates. High-dose naloxone (60 mg/kg intraperitoneally) prevents experimental propoxyphene-induced seizures,[76] but its role in seizure termination is undefined.

Propoxyphene use and overdose in the United States is relatively uncommon compared with the other opioids. However, in the United Kingdom, propoxyphene overdose may account for up to 5% of all suicides.[90] Propoxyphene often is formulated with acetaminophen (Darvocet-N, Coproxamol) or salicylates (Darvon compound) to enhance the analgesic effects. Patients who overdose on the combinations may suffer toxicity from either of these two nonopioid analgesics. Because patients consequently may be acetaminophen poisoned, yet be asymptomatic or manifest only opioid toxicity, empiric quantitative serum analysis for acetaminophen is indicated. Delayed peak serum acetaminophen concentrations after ingestion of combination opioid products may occur. The precise clinical implication of this delay is unclear (Chap. 34). Furthermore, propoxyphene's respiratory depressant effects may hinder the ability to detect salicylate poisoning by clinical examination, suggesting a situation where empiric laboratory testing for salicylates may be indicated.

Diphenoxylate and Loperamide

Although diphenoxylate is structurally similar to meperidine, its extreme insolubility limits

absorption from the gastrointestinal tract. This factor may enhance its use as an antidiarrheal agent, which presumably occurs via a local opioid effect at the gastrointestinal Âμ receptor. However, the standard adult formulation may result in significant systemic absorption and toxicity in children, and all such ingestions should be deemed consequential. Diphenoxylate is formulated with a small dose (0.025 mg) of atropine (as Lomotil), both to enhance its antidiarrheal effect and to discourage illicit use.

Because both components of Lomotil may be absorbed and because their pharmacokinetic profiles differ somewhat, a biphasic clinical syndrome is occasionally noted.[158] Patients may manifest atropine poisoning (anticholinergic syndrome), either independently or concomitantly with the opioid effects of diphenoxylate. Delayed, prolonged, or recurrent toxicity is common and is classically related to the delayed gastric emptying effects inherent to both opioids and anticholinergic agents. However, these effects are more likely explained by the accumulation of the hepatic metabolite difenoxin, which is a significantly more potent opioid than diphenoxylate and possesses a longer serum half-life. Still, the relevance of gastroparesis is highlighted by the retrieval of Lomotil pills by gastric lavage as late as 27 hours postingestion.

A review of 36 pediatric reports of Lomotil overdoses found that although naloxone was effective in reversing the opioid toxicity, recurrence of central nervous system and respiratory depression was common.[158] This series included a patient with an asymptomatic presentation 8 hours postingestion who was observed for several hours and then discharged. This patient returned to the ED 18 hours postingestion with marked signs of atropinism. In this same series,

children with delayed onset of respiratory depression and other opioid effects were reported, and others describe cardiopulmonary arrest 12 hours postingestion. Naloxone infusion may be appropriate for patients with recurrent signs of opioid toxicity. Because of the delayed and possibly severe consequences, all children, and adult patients with potentially significant ingestions, should be admitted for monitored observation in the hospital.

Loperamide (Imodium) is another insoluble meperidine analog that is used to treat diarrhea. This agent is available without a prescription, and the paucity of adverse patient outcomes reported in the medical literature suggests the safety profile of this agent is extremely high.[145]

Summary

Opioid use is widespread. Overdose and toxicity, both intentional and unintentional, remain major causes of drug-related morbidity and mortality. Lethality related to opioids is primarily caused by respiratory depression. Thus mechanical ventilation, or administration of a short-acting opioid antagonist such as naloxone, should be adequate initial therapy. An appreciation of the pharmacologic differences between the various opioids allows for the identification and appropriate management of patients poisoned or otherwise adversely affected by these agents.

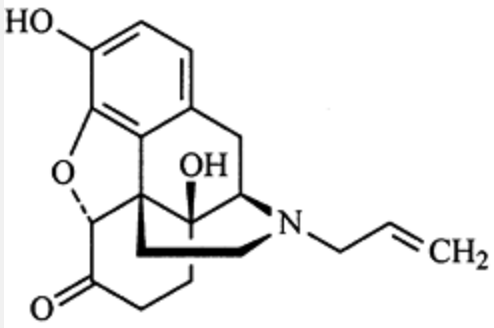
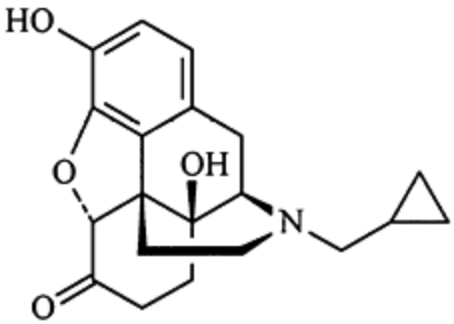
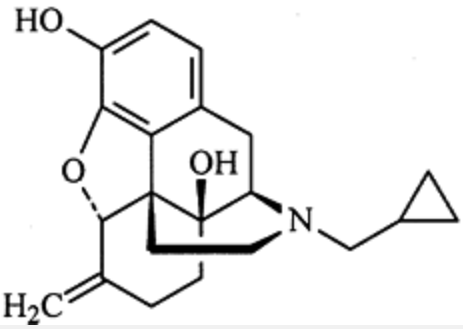
Morphine



Naloxone



Naltrexone



Nalmefene

Figure. No Caption Available.

Naloxone, nalmefene, and naltrexone are pure competitive opioid antagonists at the mu (Âμ), kappa (Îº), and delta (Î´) receptors. Naloxone is used to reverse respiratory depression in patients manifesting opioid toxicity. The parenteral dose should be titrated to maintain adequate airway reflexes and ventilation.[22] Dose titration, beginning with 0.05 mg and increasing as indicated to 0.4 mg, 2 mg, and finally 10 mg, prevents abrupt opioid withdrawal. This method of administration limits withdrawal-induced adverse effects, such as vomiting and the potential for aspiration pneumonia, and a surge in catecholamines with the potential for cardiac dysrhythmias and acute lung injury. Naltrexone is used orally for patients following opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence. Nalmefene is a parenteral agent whose duration of action falls between that of naloxone and naltrexone.

History

The effects of opium were recognized as early as the 3rd century B.C.[39] By the 19th century, morphine (named for Morpheus, the god of dreams) was isolated from opium. In the 20th century, the presence of endogenous opioid peptides and families of opioid receptors, including Âμ, Î´, and Îº, were elucidated. The 20th century also witnessed an ever-evolving series of complications of opioid addiction and abuse. Awareness of these social problems resulting from opioid abuse and the ability to understand structureâ€“activity relationships led to the synthesis of many new drugs in the hope of producing potent opioid agonists free of abuse potential. Although this goal has not been achieved, opioid antagonists and partial agonists were developed. *N*-Allylnorcodeine

was the first opioid antagonist synthesized by J. Pohl in 1915. The pharmacology of *N*-allylnormorphine (nalorphine) was characterized in the 1940s.[43,86] Nalorphine was recognized as having both agonist and antagonist effects in 1954.[39] This recognition eventually led to the development of levallorphan, naloxone, naltrexone, and nalmefene. Naloxone was synthesized in 1960, and naltrexone was synthesized in 1963.[8]

Chemistry

Minor alterations can convert an agonist into an antagonist.[42] The substitution of the *N*-methyl group on morphine by a larger group led to nalorphine and converted the agonist levorphanol to the antagonist levallorphan.[39] Naloxone, naltrexone, and nalmefene are derivatives of oxymorphone.

Pharmacology

Naloxone, naltrexone, and nalmefene are pure competitive opioid antagonists at the Âμ receptors, which are responsible for analgesia,

sedation, miosis, feeding, euphoria, respiratory depression, and decreased GI motility. Îº Receptors are responsible for weaker analgesia, sedation, miosis, feeding, decreased GI motility, dysphoria, anxiety, nightmares, and hallucinations. Î´ Receptors are responsible for analgesia and hunger.[39] These antagonists are most potent at the Âμ receptor, often necessitating higher doses for effects at the Îº and Î´ receptors. They all bind to the opioid receptor in a competitive fashion, preventing the binding of agonists, partial agonists, or mixed agonistâ€“antagonists without producing any independent action. Naloxone, naltrexone, and nalmefene are similar in their antagonistic ability but differ primarily in their pharmacokinetics. Both nalmefene and naltrexone have longer durations of action than naloxone.

Naltrexone can be administered orally. Selective antagonists for Âµ, Îº, and Î´ are available experimentally and are undergoing investigation.[49,71]

Both nalorphine and levallorphan are weak competitive antagonists at the Âµ receptor and are agonists at the Îº receptor. Nalorphine and levallorphan are no longer marketed because of undesirable Îº agonist properties.

In the proper doses, pure opioid antagonists reverse all of the effects of endogenous and exogenous opioid agonists at the Âµ, Îº, and Î´ receptors, except for those of buprenorphine, which has a very high affinity for, and slow rate of dissociation from, the Âµ receptor.[26,39,70,71] Effects on other receptors and receptor subtypes are under investigation.[49] Actions of opioid agonists that are not mediated by interaction with opioid receptors, such as direct mast-cell liberation of histamine or the sodium channel-blocking effects of propoxyphene, are not reversed.[4] Opioid-induced seizures in animals tend to be antagonized by opioid antagonists, with the exception of seizures caused by meperidine and tramadol.[9,33,39,85] A report of two newborns who developed seizures associated with fentanyl and morphine infusion demonstrated abrupt resolution following administration of naloxone.[16] Both patients underwent electroencephalographic monitoring during the seizures, and the documented burst-suppression pattern apparently was terminated after naloxone administration.

Opioids operate bimodally on opioid receptors.[14] At low concentrations, stimulation is excitatory and actually antianalgesic. This antianalgesic effect is modulated through a G_s protein and usually is less important clinically than the well-known inhibitory actions that result from coupling to a G_o protein at usual analgesic doses. Extremely low doses of opioid antagonists (ie, 0.25 Âµg/kg/h of naloxone) enhance the analgesic potency of the opioid and attenuate or prevent the development of tolerance and

dependence.[14,32] Coadministration of these very low doses of antagonists or derivatives (ie, methylnaltrexone) with the opioid also limit opioid-induced adverse effects such as nausea, vomiting, constipation, and pruritus.[14,28,32,97] These beneficial effects are hypothesized to result from modulation of the opposing excitatory effects of opioids.

Research investigating the ability of Î´ and Îº opioid agonists to produce cardioprotective effects through their action at the sarcolemmal and mitochondrial K^+(ATP) channels is ongoing.[72,75,77] Nonselective opioid antagonists may negate these protective effects.

Pharmacokinetics and Pharmacodynamics

Oral naloxone is poorly bioavailable because of extensive first-pass effect.[23] The bioavailability of sublingual naloxone is 10%.[41] Naloxone is well absorbed by all other parenteral routes of administration, including intramuscular, subcutaneous, endotracheal, intranasal, intralingual, and nebulized. The onset of action after IV administration is extremely fast and occurs within 1â€“2 minutes. The distribution half-life of approximately 5 minutes is rapid because of its high lipid solubility, and the volume of distribution is 0.8â€“2.64 L/kg.[34,36,67] The elimination half-life is 60â€“90 minutes in adults and approximately 2â€“3 times longer in neonates.[13,66] A dose of 13 Âµg/kg in an adult occupied approximately 50% of the available opioid receptors, as demonstrated by positron detection system.[57] Naloxone is metabolized by the liver to several compounds, including a glucuronide.[13] The duration of action of naloxone is approximately 20â€“90 minutes[7,24] and depends on the dose of the agonist, the dose and route of administration of the naloxone, and the rates of elimination of the agonist and naloxone. The onset of action with the various routes of administration are subcutaneous,

approximately 5.5 minutes; intralingual, 30 seconds; intranasal, 3.4 minutes; nebulization, 5 minutes (when 2 mg is mixed with 3 mL of 0.9% sodium chloride solution); endotracheal, 60 seconds; and intramuscular, no precise data available.[54,64,82,94]

Naltrexone is rapidly absorbed, with peak plasma concentrations occurring at 1 hour and oral bioavailability of 5â€“60%.[37,59,91,93] Distribution is rapid, with a volume of distribution of approximately 15 L/kg and low plasma-protein binding.[48,52] Naltrexone is metabolized in the liver to Î²-naltrexol (with 2â€“8% activity) and 2-hydroxy,3-methoxy-Î²-naltrexol.[90] Naltrexone has an enterohepatic cycle.[31,93] The plasma elimination half-life is 10 hours for naltrexone and 13 hours for Î²-naltrexol.[59,91,93] The terminal phase of elimination is 96 hours for naltrexone and 18 hours for Î²-naltrexol.[2]

Nalmefene is a derivative of naltrexone, with an oral bioavailability of 40%. After oral administration, peak plasma concentrations usually are reached within 1â€“2 hours.[18] Protein binding is approximately 45%.[18] Following oral administration, the half-life is 8â€“9 hours and demonstrates first-order kinetics up to 300-mg doses.[18] Although one study showed the half-life was 108Â±38 minutes after IV dosing, the study design may have been inadequate to determine the half-life.[34] Another study demonstrated a terminal half-life of 10.8 Â± 5 hours after a 1-mg IV dose.[65] The apparent volume of distribution (Vd) is 3.9 L/kg for the central compartment and 8.6 L/kg at steady state. Nalmefene is metabolized in the liver to an inactive glucuronide conjugate that probably undergoes enterohepatic recycling, accounting for approximately 17% of the amount of drug in the feces. Less than 5% is excreted unchanged in the urine.

Adverse Drug Effects

Opioid antagonists prevent the actions of opioid agonists if administered as pretreatment, reverse the effects of endogenous

and exogenous opioids, and cause the manifestations of opioid withdrawal in opioid-dependent patients. Pure opioid antagonists produce no clinical effects in the nonopioid-dependent, nonstressed patient, even when administered in high doses.[18,19,55,90] Antagonists stimulate the release of hormones from the pituitary, resulting in increased levels of leuteinizing hormone, follicle-stimulating hormone, and adrenocorticotropic hormone and stimulate the release of prolactin in women.[39] Adverse effects, excluding withdrawal and resedation, are rare. Patients tolerant of opioid agonists, such as morphine, exhibit opioid withdrawal reactions (yawning, lacrimation, diaphoresis, rhinorrhea, piloerection, mydriasis, vomiting,

diarrhea, myalgias, mild elevations in heart rate and blood pressure, insomnia) when exposed to opioid antagonists or agonistâ€“antagonists such as pentazocine. An â€œovershootâ€• phenomenon is described in which reversal leads to a transient increase in catecholamines, resulting in hyperventilation, tachycardia, and hypertension to higher levels than prior to baseline, with the potential for myocardial ischemia.[39] Ultrarapid heroin detoxification is associated with fatalities occurring in the postoperative period. This rapid form of enforced detoxification discussed in Chap. 38 differs significantly from the usual transient opioid withdrawal associated with volitional personal opioid abstinence.

If vomiting occurs because of withdrawal while the patient's airway is unprotected, aspiration pneumonia may complicate the patient's recovery. Resedation is a function of the relative duration of action of the opioid antagonist and the opioid agonist. Most opioid agonists have a duration of action longer than that of naloxone and shorter than that of naltrexone, whereas the relationship is variable with nalmefene. A long duration of action is advantageous when the antagonist is used to promote abstinence (naltrexone) but is unwanted when an inappropriately large dose is

administered to an opioid-dependent patient (nalmefene).

Rare case reports describe acute lung injury (previously termed *noncardiogenic pulmonary edema*), hypertension, and cardiac dysrhythmias in association with naloxone administration.[3,15,29,59,60,73,76,81] Acute lung injury occurs following heroin overdose in the absence of naloxone and can be exacerbated by naloxone in certain patients. The exact contribution of naloxone to the problem is unclear because naloxone may be unmasking the acute lung injury previously induced by the opioid but which was unrecognized because of the patient's respiratory depression.[21]

Hypertension and cardiac dysrhythmias are most frequently reported following anesthesia and opioid reversal in patients with underlying cardiac or pulmonary disorders. The clinical complexities of the setting and case reports make it difficult to analyze and attribute these adverse effects solely to naloxone.[13] Unmasking an underlying clinical condition may reveal a logical cause of cardiac dysrhythmias developing after naloxone-induced heroin reversal in a patient simultaneously abusing cocaine.[58]

Delirium, although rarely reported, may occur when naloxone is used to reverse effects in patients tolerant of high doses of opioids or during rapid opioid detoxification.[11,35]

Considering the large number of naloxone doses administered, naloxone has a remarkably safe profile, especially when used in low doses and titrated to effect.[12]

Use for Opioid and Ethanol Abstinence

Opioid dependence is managed by detoxification and prolonged opioid abstinence or by substitution with either methadone or naltrexone.[56] Any pure opioid antagonist could be substituted, but naltrexone is chosen because of its oral absorption and long duration of action compared to that of naloxone or

nalmefene.[47,55,74] Naloxone 1 mg administered intravenously blocks 25 mg of IV heroin for 1 hour, whereas 50 mg of oral naltrexone blocks this dose of heroin for 24 hours; 100 mg has a blocking effect for 48 hours, and 150 mg is effective for 72 hours. Nalmefene blocks the actions of 2 Âµg/kg of IV fentanyl with a duration of action that is also dose dependent: 0.5 mg IV, 2 mg IV, and 50 mg orally last 4, 8, and 50 hours, respectively.[30,31] Before naltrexone can be administered, the patient must be detoxified from the opioid dependence. Then naloxone usually is administered intravenously to confirm that the patient is no longer physically dependent. Opioid withdrawal, if it occurs, will be short lived following naloxone, whereas it will be prolonged following naltrexone or nalmefene. Naltrexone does not produce tolerance, although prolonged treatment with naltrexone produces upregulation of opioid receptors.[96]

Naltrexone is used as adjunctive therapy in ethanol dependence, based on the theory that the endogenous opioid system modulates ethanol intake.[52,69] Naltrexone reduces ethanol craving, the number of drinking days, and relapse rates.[62,92] Naltrexone induces moderate to severe nausea in 15% of these patients, possibly as a result of alterations in endogenous opioid tone induced by prolonged ethanol ingestion.[69]

Miscellaneous Uses

Endogenous opioids, including endorphins, dynorphins, and enkephalins, are involved in the regulation of many bodily functions.[87] Opioid receptors are found not only in the central nervous system but also throughout the body. Often these receptors and endogenous opioids work in concert with other neurotransmitter systems to modulate many effects.[23,25,88,90] For instance, during shock, the release of circulating endorphins produces an inhibition of central sympathetic tone by stimulating Îº receptors within the locus caeruleus, resulting in vasodilation.

Also, by stimulating the nucleus ambiguus, vagal tone is enhanced. However, the benefits of naloxone treatment in patients with septic shock are variable; treatment may result in adverse effects, especially in patients who are opioid tolerant.[17,66,84] Naloxone may have a temporizing effect via elevation of mean arterial pressure.[40]

Although promising in animal models of spinal cord injury, an investigation of naloxone at doses approximately 100 times that used in the management of overdoses failed to demonstrate improvement in neurologic recovery in humans.[10]

Opioid antagonists are used infrequently in the management of overdoses with nonopioids such as ethanol,[5,20,63,79] clonidine,[78,95] captopril,[89] and valproic acid.[1,61] In none of these instances was improvement as dramatic or consistent as in the reversal of the toxic effects of an opioid.

Opioid antagonists are used infrequently for treatment of morphine-induced pruritus resulting from systemic or epidural opioids and for treatment of the pruritus associated with cholestasis.[45,46,53]

Low doses of oral naloxone and peripherally acting opioid antagonists such as methylnaltrexone are used to prevent or treat the constipation that occurs as a side effect of opioid pain management.[38,97]

Dosing

The initial dose of antagonist is dependent on the dose of agonist and the relative binding affinity of the agonist and antagonist at the opioid receptors. The presently available antagonists have a greater affinity for the Âμ receptor than for the Îº or Î´ receptors. Therefore, the presence of an opioid with a greater affinity for the Îº or Î´ receptor, such as pentazocine or butorphanol, requires a larger than ordinary dose of antagonist to cause reversal.[62] The

dose of antagonist necessary for a child may equal the dose for an adult because antagonists are competitive and dependent on the size of the ingested dose of agonist. The duration of action of the antagonist

depends on many drug and patient variables, such as the dose and clearance of both antagonist and agonist.

A dose of naloxone 0.4 mg IV will reverse the respiratory depressant effects of most opioids and is an appropriate starting dose in the nonopioid-dependent patient. Naloxone can also be administered intranasally.[6] However, this dose in an opioid-tolerant patient usually produces withdrawal. The goal is to reverse respiratory depression without inducing withdrawal. Therefore, 0.05 mg is a practical starting dose in most patients, increasing to 0.4 mg, 2 mg, and finally 10 mg. If the patient has no response to 10 mg, then an opioid likely is not responsible for the respiratory depression. A practical way to administer 0.05 mg if using 0.4 mg/mL naloxone is to draw up 3 mL of 0.9% sodium chloride solution in a 5-mL syringe and then draw up 1 mL of the 0.4 mg/ mL naloxone, creating 0.4 mg naloxone in 4 mL, which is equivalent to 0.05 mg in 0.5 mL. If using the 1 mg/ mL concentration, first draw up 4.5 mL of 0.9% sodium chloride solution in a 5-mL syringe, then draw up 0.5 mL (0.5 mg) of naloxone, creating 0.5 mg in 5 mL, which is equivalent to 0.05 mg in 0.5 mL.

Evaluation of the return of respiratory depression should be monitored continuously. Resedation should be treated with either repeated doses of the antagonist or, if necessary, with another bolus followed by a continuous infusion. What constitutes an observation period depends on many factors. Following IV naloxone, observation for 2 hours should be adequate to determine whether sedation and respiratory depression will return. Following an oral opioid overdose, return of sedation and respiratory depression may be less predictable and the observation

period should therefore be extended.

Return of respiratory depression requires repeated bolus doses or a continuous infusion.[50] Two thirds of the bolus dose of naloxone that resulted in reversal, when given hourly, usually maintains the desired effect.[79] Naloxone is stable in 0.9% sodium chloride solution at a variety of concentrations for up to 24 hours.[27,80]

This dose can be prepared for an adult by multiplying the effective bolus dose by 6.6, adding that quantity to 1000 mL, and administering the solution intravenously at an infusion rate of 100 mL/h. Titration upward or downward is easily accomplished as necessary to maintain adequate ventilation and avoid withdrawal. A continuous infusion of naloxone is not a substitute for continued vigilance. An arbitrary period of 12â€“24 hours often is chosen for observation based on the presumed opioid, the route of administration, and the dosage form. The patient must be observed for 2 hours after naloxone is discontinued to ensure that respiratory depression does not recur. Body packers are a unique subset of patients who must have special individualized management strategies (Chap. 38).

Naloxone is a pregnancy category C drug.[66] A risk-to-benefit analysis must be considered in pregnant women, particularly those who are opioid tolerant, and their newborns. Inducing opioid withdrawal in the mother probably will induce withdrawal in the fetus and should be avoided. Likewise, administering naloxone to newborns of opioid-tolerant mothers will induce withdrawal[44] (Chaps. 30, 31, and 38).

Use of longer-acting opioid antagonists, such as naltrexone and nalmefene, has substantial risks for protracted withdrawal syndromes and should be reserved for special indications associated with extended periods of observation.

An oral dose of naltrexone 150 mg generally lasts 72 hours and should be adequate as an antidote for the majority of ingestions

except for opioids, such as levo-Î±-acetylmethadol (LAAM), which have extremely long durations of action. Naltrexone should never be administered to a patient who is opioid tolerant.[83] Naltrexone is administered orally in a variety of dosage schedules for treatment of opioid dependence. A common dosing regimen is 50 g daily Monday through Friday and 100 mg on Saturdays. Alternatively, 100 mg every other day or 150 mg every third day can be administered.

The initial IV dose of nalmefene is 0.1 mg in a 70-kg person in whom opioid dependency is suspected. If withdrawal does not ensue, 0.5 mg can be given, followed by 1 mg in 2â€“5 minutes as necessary. If IV access is unavailable, the intramuscular or subcutaneous route can be used, but the onset of action is delayed by 5â€“15 minutes after a 1-mg dose. For reversal of postoperative opioid depression, a starting dose of 0.25 Âµg/kg is used, followed by incremental doses of 0.25 Âµg/kg every 2â€“5 minutes to the desired effect or to a total of 1 Âµg/kg.

The experience with nalmefene is too limited to estimate an adequate observation time, although 24 hours seems prudent.

Availability

Naloxone (Narcan) for IV, intramuscular, or subcutaneous administration is available in concentrations of 0.02, 0.4, and 1 mg/mL, with and without parabens in 1-mL and 2-mL ampules; and in 10-mL multidose vials with parabens. Naloxone can be diluted in 0.9% sodium chloride solution or 5% dextrose to facilitate continuous IV infusion. Any prepared solution should be used within 24 hours.

Nalmefene (Revex) is available in a 1-mL ampule containing 100 Âµg/mL and in a 2-mL ampule containing 1 mg/mL.

Naltrexone is available as a 50-mg capsule-shaped tablet.

Acknowledgment

Richard S. Weisman, PharmD, contributed to this Antidotes in Depth in a previous edition.

Chapter 39
Dieting Agents and Regimens

Christine Haller

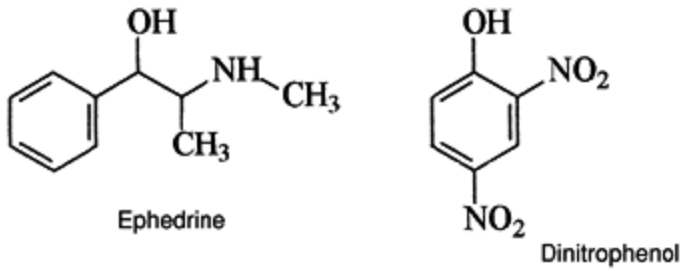

Figure. No Caption Available.

A 46-year-old woman who was found unconscious on the floor of her bedroom after she failed to show up for work was brought to the emerge department. The patient previously was healthy and had no medical conditions other than obesity. She was a nonsmoker and took no illicit substances. She was taking no prescription medications, although she dic use Metabolife 356 (which contains Ma-huang, guarana, vitamin E, chromium picolinate, bee pollen, ginseng, ginger, lecithin, bovine comple damiana [*Turnera* spp.], and sarsaparilla) twice per day for the past mon

for weight loss. Although her dosing history was not clear, she recently m have doubled her usual dose; if so she was consuming approximately 96 of ephedrine per day.

Her examination was notable for lethargy, aphasia, left hemiparesis, and visual loss. Her vital signs were: blood pressure, 117/61 mm Hg; pulse, 6 beats/min; respiratory rate, 20 breaths/min; oral temperature, 96.9Â°F (36Â°C). Neurologic examination revealed flaccid paralysis of the left upp and lower extremities, and the patient had difficulty swallowing. A head C showed infarction of the brain in the distribution of the anterior portion o the right middle cerebral artery but no intracerebral hemorrhage. Urine toxicology screening was negative. Laboratory values were within normal limits, except for creatine kinase concentration of 242 U/L (reference ran 40â€“150 U/L).

She was admitted for evaluation and treatment of a massive right-sided stroke. Because no other etiology was identified, the stroke was presume to be related to ephedrine use. She improved gradually over the course o weeks and was transferred to a rehabilitation facility. Three months after the stroke, she continued to have left arm weakness and left visual impairment, and she required assistance with walking. She had profound psychomotor impairment, including short-term memory loss, impulsivity, emotional lability, and poor judgment. She was unable to resume work or live independently.

Americans are the most overweight people in the world. One third of adu are overweight (defined as having a body mass index [BMI] between 25 a 29.9 kg/m^2), and another 27% of adults are obese (BMI >30 kg/m^2).[67] The proportion of Americans who are obese has grown almost 10% since 1980,[50] representing 58 million Americans and contributing to 325,000 deaths annually.[4] Americans are not alone; obesity is also an increasing problem throughout the world. A particularly disturbing trend is the grow obesity problem in children. Because obesity is linked to a number

of health risks, including type II diabetes, atherosclerotic cardiovascular disease, hypertension, and certain cancers, it can be considered a leading

preventable health risk, second only to cigarette smoking. Americans spe $33 billion per year on weight loss therapies and modalities. Dieting and weight loss are attempted by many more people than just those who are overweight and obese by medically defined criteria.

Sympathomimetics
Diethylpropion (Tenuate)
Mazindol (Mazanor, Sanorex)
Phentermine (Fastin, Adipex)
Increased release of norepinephrine and dopamine
Schedule IV prescription drug
Dry mouth, tremor, insomnia, headache, agitation, palpitations, hypertension, stroke, dysrhythmias
Contraindications: MAOI use within 14 days, glaucoma, hyperthyroidism
Bitter orange extract (*Citrus aurantium*)
Contains synephrine increased thermogenesis and lipolysis (unproven)
Dietary supplement
Hypertension, cerebral ischemia, myocardial ischemia, prolonged QTc interval
Guarana
Contains caffeine, which may increase thermogenesis
Dietary supplement
Nausea, vomiting, insomnia, diuresis, anxiety, palpitations
Serotonergics
Sibutramine (Meridia)
Inhibits reuptake of serotonin and norepinephrine
Schedule IV prescription drug
Anxiety, dry mouth, insomnia, headache, hypertension, palpitations, dysmenorrhea Contraindications: Same as sympathomimetics
GI Agents
Orlistat (Xenical)
Inhibits gastric and pancreatic lipases
Prescription drug
Abdominal pain, oily stool, fecal urgency or incontinence; fat-soluble vitamin loss

			Contraindications: Cholestasis, chronic malabsorptive states
Chitosan	Insoluble marine fiber that binds dietary fat	Dietary supplement	Decreased absorption of fat-soluble vitamins Contraindications: Shellfish allergy
Fibers/Other Supplements			
Glucomannan	Expands in stomach to increase satiety	Dietary supplement	GI obstruction with tablet form Contraindications: Abnormal GI anatomy
Garcinia cambogia	Increases fat oxidation (unproven)	Dietary supplement	None reported
Chromium picolinate	Improves blood glucose and lipids; produces fat loss (unproven)	Dietary supplement	Dermatitis, hepatitis, possibly mutagenic in high doses

[a] Trade names or Latin binomials are given in parentheses.

[b] All agents are contraindicated during pregnancy and lactation.

Drug or Supplement[a]	Mechanism of Action	Regulatory Status	Adverse Effects/Contraindications

TABLE 39-1. Approved Weight Loss Drugs and Dietary Supplements

Obesity and attempts at weight loss probably have existed since antiquity One of the earliest accounts of weight loss therapy dates back to 10th-century Spain. King Sancho I, who was obese, underwent successful treatment with a â€œtheriacaâ€• thought to contain plants and possibly opioids, administered with wine and oil. In addition, he was closely

supervised and treated by a physician.[41]

Currently, medicinal weight loss therapies (Table 39-1) are available as prescription medications (sibutramine, phentermine) and nonprescription dietary supplements (*Citrus aurantium* , chitosan, *Garcinia cambogia*). U of natural weight loss remedies has undergone a resurgence since passag of the Dietary Supplement Health and Education Act (DSHEA) of 1994. Th DSHEA created a new category separate from food and drugs. The new category includes vitamins, minerals, herbs, and amino acids, which are minimally regulated by the Food and Drug Administration (FDA). As a res of the DSHEA, numerous botanicals and other substances are offered to consumers as weight loss aids, some with no proven efficacy and some w potentially serious toxicity.

Although dieting aids can be divided into disparate classes, they generally act through one or more of the following mechanisms: (1) appetite suppression, known as *anorectics;* (2) alteration of food absorption or elimination; or (3) increased energy expenditure. Dieting aids that are anorectic agents are designed to decrease appetite and calorie intake. Anorectic agents may be serotonergic drugs (sibutramine), or sympathomimetics (amphetamines and derivatives). They have the potential to cause adverse stimulant effects and dependence. Certain agents, such as â€œstarch blockersâ€• and â€œfat blockersâ€• (orlista chitosan), inhibit absorption of ingested nutrients. Dietary fiber pills act l absorbing large amounts of water and expanding in the stomach and intestinal tract. They produce the satiety sensation of a large meal and a causally linked to intestinal obstruction. Very-low-calorie diets, high-prot liquid supplements, and â€œdieter's teasâ€• containing laxatives are associated with dehydration, severe electrolyte disturbances, and sudden cardiac death. Dinitrophenol and thyroid hormone have been used to increase basal energy expenditure and are associated with severe toxicity

A number of weight loss therapies were withdrawn or banned by the FDA because of serious adverse health effects (Table 39-2). The unapproved use of fenfluramine-phentermine (Fen-Phen) was linked to cardiac valvulopathy and primary pulmonary hypertension. Î³-Hydroxybutyrate

(GHB) and its congeners initially were sold as a dietary supplement (Chap 78) and promoted to body builders as a means to â€œconvert fat into muscle.â€• Because of overdose toxicity and its association with drug-facilitated sexual assault,

GHB is strictly controlled as a schedule I agent, with limited availability a a schedule III drug for narcolepsy (Xyrem). Clenbuterol is an unapproved long-acting $Î²_2$ -adrenergic agonist with stimulant properties that is abus by body builders as an energy source and anorectic agent[40 , 74] (Chap. 4).

Amphetamine
Increased release of NE and dopamine
Sympathomimetic effects, psychosis, dependence
Schedule II
Benzphetamine (Didrex)
Increased release of NE and dopamine
Sympathomimetic effects, psychosis, dependence
Schedule III
Clenbuterol
$Î²_2$ -Adrenergic agonist activity
Tachycardia, headache, nausea, vomiting; may be prolonged
Not approved
Dexfenfluramine (Redux)
Promotes central serotonin release and inhibits its reuptake
Valvular heart disease, primary pulmonary hypertension
Withdrawn September 1997
Dieter's teas (senna, cascara, aloe, buckthorn)
Stimulant laxative herbs that promote colonic evacuation
Diarrhea, vomiting, nausea, abdominal cramps, electrolyte disorders, dependence
FDA required label warningâ€”June 1995
Dinitrophenol
Alters metabolism by uncoupling oxidative phosphorylation
Hyperthermia, cataracts, hepatotoxicity, fatalities

Drug or Supplement[a]	Mechanism of Action	Adverse Effects	Regulation Status DE Schedule or Withdrawal Date
Not approved			
Ma-huang (*Ephedra sinica*)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Banned by FDAâ€”April 2004
Fenfluramine (Pondimin)	Increased release and decreased reuptake of serotonin	Valvular heart disease, primary pulmonary hypertension	Withdrawn September 1997
Guar gum (Cal-Ban 3000)	Hygroscopic polysaccharide swells in stomach, producing early satiety	Esophageal and small bowel obstruction, fatalities	Banned by FDAâ€”July 1990
Lipokinetix (sodium usniate, norephedrine, 3,5-diiodothyronine, yohimbir caffeine)	Unknown	Acute hepatitis	FDA warningâ€”November 2001
Phendimetrazine (Adipost, Bontril)	Increased release of NE and dopamine	Sympathomimetic effects, psychosis	Schedule III
Phenylpropanolamine (Dexatrim, Acutrim)	Î ±$_1$ -Adrenergic agonist	Headache, hypertension, myocardial infarction, intracranial hemorrhage	Withdrawn November 2000

[a] Trade names are given in parentheses.

NE = norepinephrine.

TABLE 39-2. Unapproved Weight Loss Drugs and Supplements

Sympathomimetics

Although controversial, certain sympathomimetic amines still carry officia indications for short-term weight reduction according to physician prescribing information (Table 39-1).[73] Sympathomimetic amines share Î²-phenylethylamine parent structure and include phentermine, diethylpropion, and mazindol, which are restricted as schedule IV agents and carry warnings that advise prescribers to limit use to only a few wee Regardless of their source and legal status, sympathomimetics generally share a spectrum of toxicity and produce adverse effects similar to amphetamine (Chap. 73).

Sympathomimetic amines that act at Î±- and Î²-adrenergic receptors are clinically effective in promoting weight loss but have numerous side effec that limit their clinical use. Soon after its introduction as a pharmaceutica for nasal congestion in the 1930s, the prototype sympathomimetic drug amphetamine (Figure 39-1) was noted to cause weight loss (Chap. 73). The weight loss effect of amphetamine also was well demonstrated in ear animal studies, although tolerance to the anorectic effects was noted.[88] T primary mechanism of action of the weight loss effects of sympathomime drugs is central nervous system stimulation, resulting from increased release of norepinephrine and dopamine.[86] The effects include direct suppression of the appetite center in the hypothalamus and reduced taste and olfactory acuity leading to decreased interest in food. Increased ener and euphoriant effects of the stimulant drugs also contribute to weight lo However, the rate of weight loss diminishes within a few weeks of initiati therapy. Significant side effects and abuse potential severely limit the therapeutic use of this class of drugs.

Absence of polar hydroxyl groups from a sympathomimetic amine increas its lipophilicity; therefore, unsubstituted or predominantly alkyl group-substituted compounds (eg, amphetamine, ephedrine, phenylpropanolam [PPA]) have greater central nervous system activity. Mild cardiovascular and central nervous system (CNS) stimulant effects include headache, tremor, sweating,

palpitations, and insomnia. More severe effects that may occur after overdose of sympathomimetic amines include anxiety, agitation, psychos seizures, palpitations, and chest pain (Chap. 73).[49 , 64 , 72 , 76] Cardiac ischemia, dysrhythmias, and stroke are reported.[28 , 56 , 64 , 91] Life-threatening drug interactions with monoamine oxidase inhibitors[22] may occur.

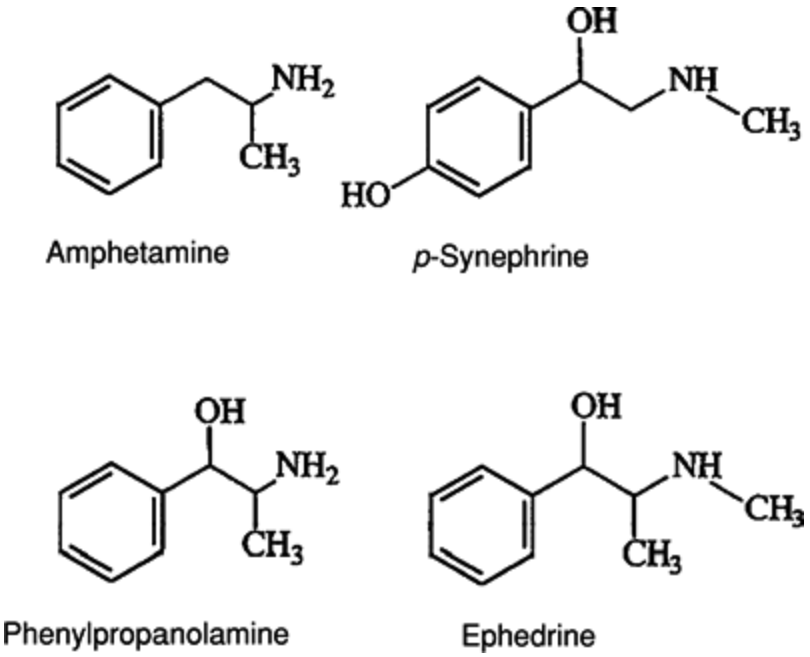

Figure 39-1. Sympathomimetic amines formerly and currently used for weight loss.

Hypertension is common following overdose and occasionally following therapeutic use. Patients may present with confusion and altered mental status as a result of hypertensive encephalopathy. Reflex bradycardia aft exposure to agents with predominantly Î±-adrenergic agonist effects may accompany the hypertension and provides a clue to the diagnosis. Childre with unintentional ingestions may be at especially high risk for hypertens episodes because of the relatively significant dose per kilogram of body weight. Other manifestations include chest pain, palpitations, tachycardia syncope, hypertension, mania, psychoses, convulsions, and coronary

vasospasm.[12 , 16 , 25 , 69 , 98]

Clinically significant hypertension should be treated aggressively with eit phentolamine, a rapidly acting Î±-adrenergic antagonist, or nitroprusside Analogous to the management of cocaine toxicity, Î²-adrenergic antagoni should be avoided because the resultant unopposed Î±-adrenergic agonis effects may lead to greater vasoconstriction and increased hypertension.[3] Agitation, tachycardia, and seizures should be treated with benzodiazepines.

Phenylpropanolamine

Phenylpropanolamine, a sympathomimetic amine (Figure 39-1), was available until 2000 as a nonprescription diet aid (eg, Dexatrim, Acutrim) It is both a direct-acting agent, via stimulation of Î±-adrenergic receptor and an indirect-acting agent, through release of norepinephrine. Both of these actions tend to cause a net increase in blood pressure when given i high doses. PPA-induced anorexia is mediated via Î±-adrenergic receptors in the hypothalamus.[96] PPA was formally available in various doses from 25â€“75 mg for appetite suppression and nasal decongestion. PPA was voluntarily withdrawn after its use was linked to increased risk of hemorrhagic stroke in women.[47]

Reported toxicity associated with PPA generally results from severe hypertension.[27 , 28 and 29 , 35 , 42 , 46 , 64] A comprehensive review of more than 100 case reports of adverse drug effects involving PPA reveale 24 intracranial hemorrhages, 8 seizures, and 8 fatalities between 1965 a 1990.[34 , 52] Some adverse events occurred following ingestion of diet preparations that contained both PPA and caffeine, which have pharmacokinetic and pharmacodynamic interactions.[48 , 53] Cardiac toxicit although less common, was reported in 2 young patients who suffered myocardial injury following therapeutic daily dosing in 1 and acute overd in the other.[56] Hypertensive emergencies resulting from adverse drug interactions between PPA and drugs such as monoamine oxidase inhibitor have been reported.[84]

Ephedrine

Ephedra *(Ephedra sinica)* , or Ma-huang in Chinese herbal nomenclature, a plant that contains 6 sympathomimetic amines, known collectively as *ephedra alkaloids.* The two primary alkaloids are ephedrine and pseudoephedrine (Figure 39-1). Ephedra was popular as a weight loss dietary supplement (eg, Metabolife 356, Xenadrine RFA, Ripped Fuel) unt the FDA banned ephedra-containing products in April 2004 because of a large number of reported cases of serious cardiovascular toxicity[12 , 16 , 1 , 20 , 25 , 36 , 91 , 98] as well as acute hepatitis[65] associated with use of these products. In a review of 140 adverse events reported to MedWatch following use of ephedra, 31% of the cases were considered to be definit or probably related to the use of ephedra supplements, including 4 stroke 5 cardiac arrests, 2 myocardial infarctions, and 3 fatalities.[36] The ban wa partially overturned by the courts in 2005, and the final fate of ephedra l yet to be determined. Ephedra still can be obtained from practitioners of complementary medicine as a traditional Chinese herbal medicine for sho term treatment of wheezing and nasal congestion associated with asthma allergies, and colds. Synthetic ephedrine is available as a nonprescription medication (eg, Primatene) for asthma. Although it is approved in the United States for treatment of obesity, ephedrine in combination with aspirin and caffeine was formerly available as a weight loss product in ot countries. Because ephedrine is abused for its amphetaminelike stimulant properties and is used in the illicit manufacture of methamphetamine (Chap. 73), its nonprescription sale is restricted in many states.

Since ephedra was banned, herbal weight loss supplements have been reformulated. Many now contain an extract of bitter orange (*C. aurantiun*), a natural source of the sympathomimetic amine synephrine, often in combination with caffeine, willow bark (containing salicylates), diuretics, and other constituents. The dried fruit peel of bitter orange, known in Chinese herbal medicine as Zhi shi, is a traditional remedy for gastrointestinal ailments. The predominant constituent, *p*- synephrine (Figure 39-1), is structurally similar to norepinephrine. Its isomer *m* - synephrine (phenylephrine or Neo-Synephrine) is used extensively as a

vasopressor and nasal decongestant. Although synephrine's physiologic actions are not fully characterized, synephrine appears to interact with trace amine receptors in the brain and acts at peripheral Î±1 -adrenergic receptors, resulting in vasoconstriction and increased blood pressure.[30] Some evidence indicates that synephrine may also have Î²3 -adrenergic agonist activity, which could increase lipolysis, although this activity has not demonstrated in humans.[30] Adverse effects associated with use of *C. aurantium* -containing weight loss products have been reported, including case of cerebral ischemia in a 38-year-old man,[10] 1 case of exercise-induced syncope and QTc interval prolongation in a 22-year-old woman,[66] and a possible case of myocardial infarction in a 55-year-old woman.[68]

Serotonergic Agents

Drugs that affect central release and reuptake of serotonin are approved a number of indications, including depression, anxiety, nicotine addiction and premenstrual dysphoric syndrome. Although these drugs all reduce fo intake to varying degrees, sibutramine (Meridia) is the only FDA-approve serotonergic agent specifically indicated for treatment of obesity.

Sibutramine acts by blocking the reuptake of both serotonin and norepinephrine, but it does not promote neuronal release of serotonin. It clinical effects include reduced appetite and increased satiety. This prescription drug is recommended in doses of 10â€“15 mg per day for obese patients with BMI >30 kg/m^2 without comorbid conditions, and for patients with BMI >27 kg/m^2 with comorbid diseases of diabetes mellitus dyslipidemia, or hypertension. Its effectiveness in producing weight loss demonstrated in several randomized, double-blind studies.[55 , 60] Patients receiving intermittent sibutramine therapy have significantly fewer adver effects than patients who take sibutramine continuously.[97] Clinical use of sibutramine for more than 1 year is unstudied.

The pharmacologic activity of sibutramine results from hepatic first-pass metabolism by cytochrome P450 (CYP3A4) transforming sibutramine into the 2 active metabolites, mono-desmethylsibutramine and di-

desmethylsibutramine, which have half-lives of 14 and 16 hours, respectively. These metabolites are further metabolized and renally excreted. Medications that inhibit CYP3A4, such as cimetidine, erythromycin, and ketoconazole, may slow sibutramine metabolism. Moderate hepatic or renal impairment does not significantly alter the pharmacokinetics of sibutramine or its active metabolites.

Sibutramine use is associated with psychosis,[87] hypertension, cardiac ischemia, and death.[37] Since Meridia was approved in 1998, 397 serious adverse reactions have been reported to the FDA, including 29 deaths. Nineteen of the deaths were due to cardiovascular causes, including 3 deaths in women younger than 30 years.[37] Sibutramine was banned in It in March 2002 after 2 cardiovascular deaths, and its use as a weight loss drug is being scrutinized in other European countries and in the United States. Because sibutramine raises heart rate and blood pressure, it shou not be used in patients with poorly controlled hypertension, coronary art disease, glaucoma, or previous stroke. Use of sibutramine is contraindicated in patients with anorexia nervosa, severe hepatic or rena dysfunction, or seizure disorders. Sibutramine taken in combination with monoamine oxidase inhibitors or selective serotonin reuptake inhibitors, any drug that affects serotonin release or reuptake, could induce seroton syndrome, which is characterized by agitation, hyperthermia, autonomic instability, and myoclonus.

Serotonergic drugs used in the past to treat obesity include dexfenfluramine (Redux) and fenfluramine (Pondimin), but these agents have been withdrawn because of postmarketing reports of serious cardiac effects associated with their therapeutic use.[11, 14, 20, 24, 31, 95] The diet drug combination known as â€œFen-Phenâ€• for its two-drug prescription regimen of fenfluramine and phentermine (an amphetamine derivative) was popular in the 1990s because of the presumed improved side effect profile and efficacy achieved with lower doses of each drug. Th drug combination was never approved by the FDA for treatment of obesit and fenfluramine was withdrawn in 1997 when an unusual cardiac valvulopathy was described in 24 women taking Fen-Phen.[20] All of the women presented with new heart murmurs and either right- or left-sided

valvular abnormalities. Eight of the 24 women also developed newly documented pulmonary hypertension. Several of these patients required cardiac surgery and were found to have plaquelike encasement of the leaflets and chordae, with preservation of valvular structure. These pathologic findings are identical to those described in patients with ergotamine-induced valvular disease and in those with carcinoid syndrom Although subsequent studies confirmed this association, the reported magnitude of risk associated with these drugs has varied.[44, 45, 95] Case of regression of these valvular lesions with cessation of the drugs are reported,[15] and limited evidence indicates that the valvular effects are milder than initially described.[31]

Primary pulmonary hypertension has been described in association with fenfluramine and dexfenfluramine since 1981.[6, 14, 24, 63, 75] Primary pulmonary hypertension in association with another anorectic drug aminorex fumarate, was reported earlier in Europe.[35] In one multicenter case control study of patients with primary pulmonary hypertension, use anorectic drugs such as dexfenfluramine and fenfluramine for more than months was associated with a 30-fold increased risk of primary pulmonar hypertension in these patients compared with nonusers.[1] Several theorie are proposed to explain the mechanism of pulmonary toxicity of these agents,[14] namely, serotonin-mediated constriction of pulmonary arteries, [62] serotonin-mediated platelet aggregation, and vasoconstriction in the lungs leading to microembolization, elevated pulmonary vascular resistance, and pulmonary hypertension.[62]

Agents that Alter Food Absorption, Metabolism, and Elimination

Fat Absorption Blockers

Orlistat (Xenical) was approved by the FDA in 1999 for treatment of obesity. At the time of this writing, orlistat is the only FDA-approved drug that alters the absorption, distribution, and metabolism of food. Orlistat is

potent inhibitor of gastric and pancreatic lipase, thus reducing lipolysis a increasing fecal fat excretion.[17] The drug is not systemically absorbed bu exerts its effects locally in the gastrointestinal tract. It inhibits hydrolysis of dietary triglycerides and reduces absorption of the products of lipolysis monoglycerides, and free fatty acids. Several clinical trials demonstrate that orlistat reduces gastrointestinal fat absorption by as much as 30%.[9] When taken in association with a slightly calorie-restricted diet, weight lo of approximately 10% body weight can be achieved in 1 year.[82]

Orlistat should be taken only in conjunction with meals that have a high- content; it should not be consumed in the absence of food intake. Advers effects correlate with the amount of dietary fat consumption and include abdominal pain, oily stool, fecal incontinence, fecal urgency, flatus, and increased defecation. Concomitant use of natural fibers (6 g of psyllium mucilloid dissolved in water) may reduce the gastrointestinal side effects orlistat.[18] Because orlistat reduces absorption of fat-soluble food constituents, daily ingestion of a multivitamin supplement containing vitamins A, D, and K, and Î²-carotene is advised to prevent resultant deficiency.

Chitosan is a weight loss dietary supplement derived from exoskeletons o marine crustaceans. It is thought to act similarly to orlistat by binding to dietary lipids in the gastrointestinal tract and reducing breakdown and absorption of fat. Some evidence indicates that chitosan may decrease to serum cholesterol concentration in overweight people, but the majority o clinical studies indicate chitosan is ineffective for weight loss in the abse of dietary and lifestyle modifications.[80] Chitosan is contraindicated in people with shellfish allergy.

Dietary Fibers

Guar gum is derived from the bean of the *Cyamopsis psorabides* plant. It was marketed in pill or tablet form as Cal-Ban 3000 until it was banned b the FDA in 1992 because of its potential to cause gastrointestinal obstruction. The guar gum in Cal-Ban 3000 is a hygroscopic polysacchari that expands 10â€“20-fold in the stomach, forming a gelatinous mass. Th

purpose of ingesting guar was to cause gastric distension and create the sensation of satiety in the dieter, thus decreasing appetite and food intak Guar gum resulted in numerous cases of esophageal and small-bowel obstruction both in patients with preexisting anatomical lesions such as strictures and in individuals with normal gastrointestinal anatomy.[32 , 57 77 , 79]

Glucomannan is a dietary fiber consisting of glucose and mannose, which derived from konjac root, a traditional Japanese

food. Edible forms of glucomannan include konjac jelly and konjac flour, which is mixed with liquid prior to ingestion. Purified glucomannan is available in capsule form and is found in various proprietary products marketed for weight loss. On contact with water, glucomannan swells to approximately 200 times its original dry volume, turning into a viscous liquid. It lowers blood cholesterol and glucose concentrations and decrea systolic blood pressure,[5 , 93] but significant weight loss benefits have not been demonstrated. Following several reports of esophageal obstruction, oral glucomannan tablets were banned in Australia in 1985.[38] Serious adverse effects are not described with encapsulated glucomannan, presumably because slower dissolution allows for gastrointestinal transit prior to expansion. Glucomannan capsules are available as a nutritional supplement in the United States, although adequate safety and efficacy studies are not published.

Dinitrophenol

One of the earliest attempts at a pharmaceutical treatment for obesity wa 2,4-dinitrophenol (DNP), which was popularized as a weight loss adjuvant the 1930s.[90] This chemical, which is used in dyes, wood preservatives, herbicides, and explosives, was never approved as a drug product but wa legally available as a diet remedy prior to enactment of the US Federal Food, Drug, and Cosmetic Act of 1938. By increasing metabolic energy expenditure in doses of 100 mg three times per day, it reportedly produc weight loss of 1â€“2 pounds per week.[21] DNP increases metabolic work b

uncoupling oxidative phosphorylation in the mitochondria via its action as an ionophore. Through this mechanism, the hydrogen ion gradient that allows ATP synthesis is dissipated, preventing the proton motive force fro creating high-energy phosphate bonds (Chap. 13). Because the energy l resulting from inefficient substrate utilization is dissipated as heat, eleva temperature and, occasionally, life-threatening hyperthermia can occur.[89] DNP reportedly was administered to Russian soldiers during World War II keep them warm during winter battles.[51] Symptoms related to DNP toxici include malaise, skin rash, headache, diaphoresis, thirst, and dyspnea. Severe toxic effects include hyperpyrexia, hepatotoxicity, agranulocytosis respiratory failure, coma, and death.[8 , 33 , 51 , 89] Delayed-onset cataract was a frequent and serious complication of DNP use.[8]

Use of DNP as a dieting aid reemerged in the 1980s when a physician in Texas processed industrial DNP into tablets and distributed them at his weight loss center under the trade name Mitcal. An intentional overdose fatality with Mitcal in 1984 led a Texas court to stop the use of this chemical for weight loss.[51] DNP continues to reappear sporadically as a weight loss treatment, and cases of serious toxicity still are reported. Tw recent cases include a 22-year-old man who developed fever, agitation, a delirium 16 hours after taking DNP, and a 17-year-old girl who developed fever, hypotension, and seizures.[61 , 70] Both young victims died despite maximal resuscitative efforts. Intensive care management and emergent cooling are required in patients who present with hyperthermia after use a weight loss product containing DNP.

Hypocaloric Diets and Cathartic/Emetic Abuse

Medication abuse among individuals with various eating disorders is common.[13] Starvation, as well as abuse of laxatives, syrup of ipecac, diuretics, and anorectic agents, has led to many fatalities, often in young patients.[29 , 43] Fad diets and laxative abuse should be strongly considere in young people with unexplained dehydration, syncope, hypokalemia, an metabolic alkalosis. A variety of extreme calorie-restricted diets resulting

profound weight loss were very popular in the late 1970s, but reports of possible association between these diets and sudden death followed.[81] Myocardial atrophy was a consistent finding on autopsy. Torsades de pointes and other ventricular tachycardias as a result of hypokalemia[81], and protein-calorie malnutrition of the heart are proposed causes of deat in these cases.[26, 81, 85]

Following the negative reports and FDA warnings, the enthusiasm for liqu protein diets waned. Several current diets (Atkin's plan, South Beach diet advocate intake of high protein, high fat, and low carbohydrates while allowing unlimited amounts of meat, fish, eggs, and cheese. Lack of carbohydrates induces ketosis, which results in diuresis and dehydration, giving the user the appearance of rapid weight loss. With rehydration and resumption of a normal diet, weight gain generally occurs. In addition, dehydration may cause orthostatic hypotension and ureterolithiasis.[2] Atherosclerosis and hypercholesterolemia may occur as a result of substitution of high-calorie, high-fat foods for carbohydrates.

Dieter's teas that contain combinations of herbal laxatives, including senn and *Cascara sagrada*, can produce profound diarrhea, volume depletion, and hypokalemia. They are associated with cases of sudden death, presumably as a result of cardiac dysrhythmias. Despite FDA warnings of the dangers of these weight loss regimens, dieter's teas remain available retail stores that sell nutritional supplements and are easily accessible to adolescents.

Chronic laxative use can result in an atonic colon (â€œcathartic bowelâ€ and development of tolerance, with the subsequent need to increase dosi to achieve catharsis. Because cathartics do not decrease food absorption, these agents have limited effects on weight control.[7] Various test metho can be used to detect laxative abuse.[23] Phenolphthalein can be detected a pink or red coloration to stool or urine following alkalinization. Colonoscopy reveals the benign, pathognomonic â€œmelanosis coli,â€• dark staining of the colonic mucosa secondary to anthraquinone laxative abuse.

Chronic use of syrup of ipecac to induce emesis by patients with eating

disorders, such as bulimia nervosa, leads to the development of cardiomyopathy, subsequent dysrhythmias, and death.[29, 71] Emetine, a component of syrup of ipecac, is the alkaloid responsible for the severe myopathy experienced by these patients. In addition, chronic administrat of syrup of ipecac results in tolerance to the emetic effects and increased systemic absorption of emetine.[71] Emetine can be detected in serum by high-pressure liquid chromatography or thin-layer chromatography. It persists for weeks to months after ingestion. In 2003, an FDA advisory committee recommended that the nonprescription drug status of syrup of ipecac be rescinded because of its use by patients with bulimic disorders.

Novel Therapeutic Approaches to Weight Loss

Leptin and the leptin gene have been explored as a basis for obesity and a therapeutic strategy. Genetically leptin-deficient mice are obese, and leptin replacement produces weight loss. Subcutaneous leptin supplementation appears to induce weight loss in lean and obese adults.[3] Leptin replacement therapy in three humans with genetically based obesi resulted in profound weight loss and normalization of endocrine function.[5] Because Î²3 -adrenergic

receptors mediate lipolysis in adipose tissue, Î²3 -selective agonists also are under investigation as weight loss agents.[78] Neuropeptide Y, a peptid found in the arcuate and paraventricular nucleus of the hypothalamus, is potent central appetite stimulant. Future drug therapy may target these genes, receptors, and proteins to modify metabolism. As obesity research proceeds and the biologic basis for obesity is defined, new approaches ar mechanisms for drug therapy may be identified.

Other Herbal Remedies

Several herbal remedies for weight loss have resulted in serious toxicity. France, germander (*Teucrium chamaedrys*) supplements taken for weigh

loss resulted in 7 cases of hepatotoxicity.[54] A â€œslimming regimenâ€• first prescribed in a weight loss clinic in Belgium produced an epidemic of progressive renal disease, known as Chinese herb nephropathy, when botanical misidentification led to the substitution of *Stephania tetrandra* with the nephrotoxic plant *Aristolochia fangji* .[92] The toxic constituent, identified as aristolochic acid, is implicated in numerous cases of renal failure and urothelial carcinoma.[59] A case of profound digitalis toxicity occurred with a laxative regimen contaminated with *Digitalis lanata* .[83] U regulation of herbal products is improved and manufacturing practices worldwide are standardized, sporadic reports of herb-related toxicity like will continue (Chap. 43).

Summary

Although obesity is a major health challenge and a major cause of preventable morbidity and mortality, unproven weight loss treatments ar fraught with failure and potential toxicity. There probably is no appropria substitute for a balanced weight loss plan that encompasses decreased caloric intake with increased energy expenditure through exercise. Clinicians should be aware of the lack of regulation of most available diet remedies and should report adverse events involving these products to poison control centers and to the FDA MedWatch system so that appropri regulatory actions can be taken to prevent further instances of toxicity. A historical review of compounds used as weight loss agents readily uncov numerous examples of poorly conceived drug regimens, popular misunderstanding of the benefits and risk of the drugs involved, and relatively poor postmarketing surveillance leading to unnecessary morbid and mortality.

Chapter 40

Iron

Jeanmarie Perrone

Iron

MW = 55.85 daltons

Serum normal = 80â€“180 Âµg/dL

= 14â€“32 Âµmol/L

A 17-month-old boy was found by his mother playing with a bottle of iron supplements. The mother noted greenish discoloration around the child's lips and pill fragments in his mouth. She brought him to the emergency department (ED). En route to the hospital, spontaneous vomiting of pill fragments and hematemesis occurred. In the ED, the boy was noted to be lethargic with the following vital signs: blood pressure, 95/55 mm Hg; heart rate, 130 beats/min; respiratory rate, 35 breaths/min; temperature, 96.9Â°F (36Â°C). High-flow supplemental oxygen was given, IV access obtained, and fluid resuscitation (20 mL/kg) initiated. An abdominal radiograph revealed a large number of radiopaque fragments in the stomach.

Orotracheal intubation, orogastric lavage (with removal of more green pill fragments), and whole-bowel irrigation were performed. An arterial blood gas following intubation revealed significant metabolic acidosis: pH, 7.15; PCO_2, 34 mm Hg; PO_2, 441 mm Hg.

Chelation with deferoxamine 135 mg/h (15 mg/kg/h) was started intravenously. Small amounts of dark brownish red urine from a Foley catheter were noted. Transfer of the patient to a tertiary care pediatric intensive care unit (ICU) was arranged. Other significant laboratory values were: white blood cell count (WBC), 22,000/mm^3; hemoglobin, 11.6 g/dL; serum bicarbonate concentration, 10 mEq/L; glucose, 384 mg/dL; international normalized ratio (INR), 4.5; iron, 18,570 Âµg/dL; alanine aminotransfersase (ALT), 700 IU/mL. Upon arrival in the tertiary care pediatric ICU 3.5 hours after initial presentation, the patient was tachycardic with a pulse of 188 beats/min (normal 80â€“150 beats/min). He was hypotensive with a systolic blood pressure of 70 mm Hg (normal for age 80â€“110 mm Hg). Additional fluid boluses, transfusions of fresh-frozen plasma, and 2 units of packed red blood cells were administered. A repeat abdominal radiograph revealed persistent radiopaque pill fragments in the gut lumen (Figure 40-1). Lavage was performed again with upper gastrointestinal (GI) endoscopy, but pill fragments were adherent to the gastric mucosa. The patient was taken to the operating room, and a gastrotomy was performed to remove the remaining pill fragments (Figure 40-2). Sixteen hours postingestion, his oxygenation and hemodynamic status deteriorated. Acute lung injury was noted on chest radiograph. Oxygenation worsened despite maximal ventilatory support on 100% FIO_2: pH, 7.18; PCO_2, 41 mm Hg; PO_2, 37 mm Hg. Hypotension refractory to vasopressors and further transfusions of red blood cells and fresh-frozen plasma developed. A fatal cardiac arrest ensued approximately 20 hours postingestion. The patient's terminal serum iron concentration was 4000 Âµg/dL.

History and Epidemiology

Iron has been used therapeutically for thousands of years and continues to be available, both with and without prescription, for the prevention and treatment of iron-deficiency anemia in patients of all ages. Despite this long history of use, the first reports of iron toxicity only occurred in the mid-20th century. Since then, numerous cases of iron poisoning and fatalities have been reported, most of them in children.[56,57] In 1950, the manufacturer of â€œfersolateâ€• included a package warning: â€œExcessive doses of iron can be dangerous. Do not leave these tablets within reach of young children, who may eat them as sweets with harmful results.â€•[84]

The incidence of iron exposures continued to increase in the 1980s, and in the 1990s iron exposure became the leading cause of poisoning deaths in children younger than 6 years. This finding was publicized by a case series of tragic fatalities involving 5 toddlers in Los Angeles during a 6-month period in 1992. All cases involved prenatal vitamins containing iron.[91] This association highlights the availability of these potentially lethal medications in the homes of families with young children, paradoxically as a result of more attentive prescribing of prenatal iron. A case control

study in Canada identified a 4-fold increase in the risk of iron poisoning to the older sibling of a newborn during the first postpartum month.[41] The authors concluded that almost half of all hospital admissions of young children for iron poisoning could be prevented by safer storage of iron supplements in the year before and the year after the birth of a sibling.

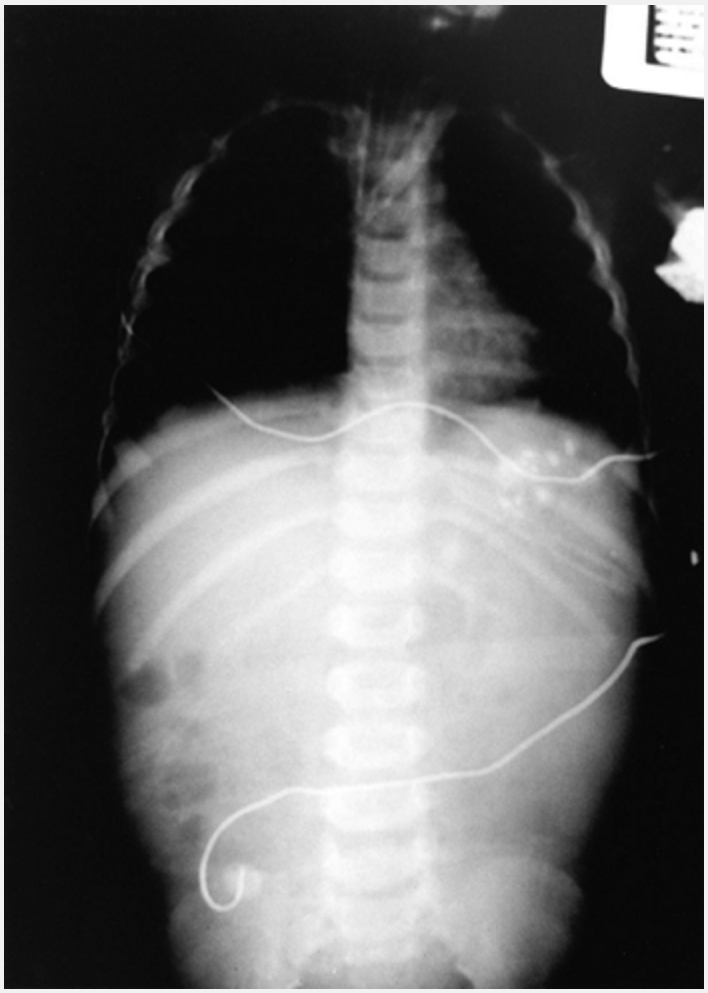

Figure 40-1. A 17-month-old boy presented to the hospital with lethargy and hematemesis following a large ingestion of iron supplement pills. Despite orogastric lavage and whole-bowel irrigation, iron pills and fragments can be visualized in the stomach 4 hours postingestion.

In 1997, the Food and Drug Administration (FDA) mandated that all iron salt-containing preparations have warning labels regarding the dangers of pediatric iron poisoning.[23] In addition to the warning labels, the FDA launched an educational campaign to alert caregivers

and prescribers of the potential toxicity of iron supplements.[22] Other preventive initiatives instituted by the FDA in 1997 included unit dosing (blister packs) of prescriptions containing more than 30 mg of elemental iron and limitations on the number of pills dispensed (ie, maximum 30-day supply).[23] These efforts to prevent unintentional exposure dramatically decreased the incidence of poisoning and are pivotal in decreasing morbidity and mortality associated with iron poisoning (Chap. 130 and associated references). Unfortunately, in 2003 the FDA rescinded the blister packaging requirement in response to a lawsuit charging that the FDA did not have jurisdiction over the packaging of dietary supplements.[21] Although isolated fatalities continue to occur,[55] the trend in American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) data suggests they are becoming less common (Chap. 130 and associated references).

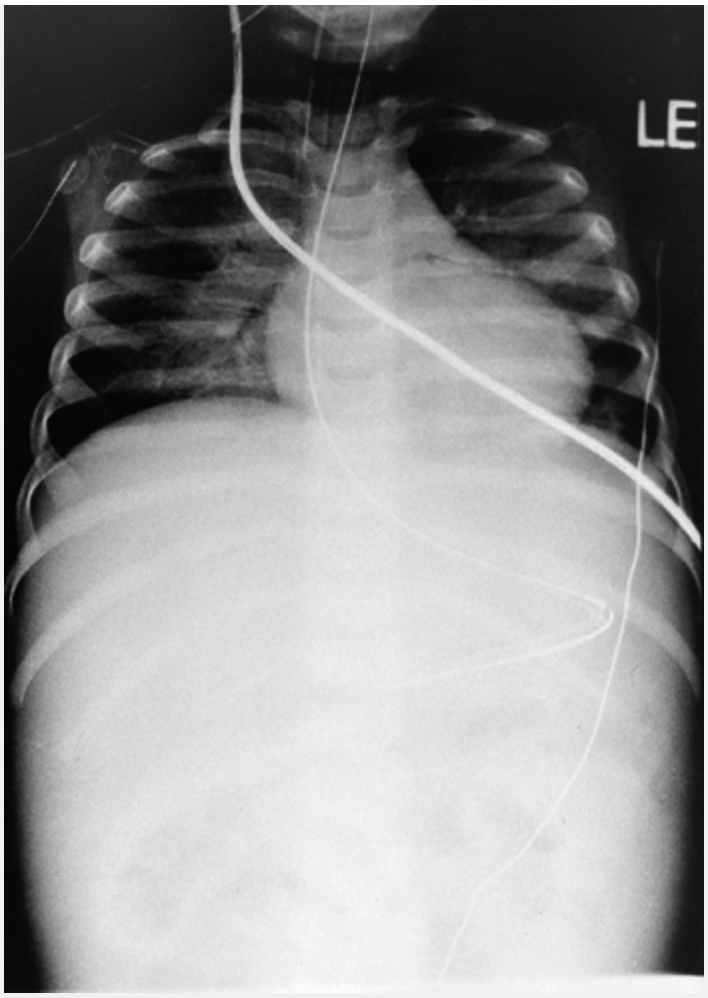

Figure 40-2. Ten hours postingestion. Persistent iron pills were removed from the stomach by gastrotomy. No further radiopaque fragments can be visualized; however, acute lung injury is now visible.

Iron poisoning can occur after ingestion of other iron salts, such as ferric chloride, used in industry.[99] Parenteral iron, such as iron dextran, administered intravenously to patients with renal failure and chronic anemia, also can result in toxicity, especially anaphylactoid reactions. Newer parenteral formulations, including iron sucrose and sodium ferrous gluconate, appear to be safer.[20] Iron supplements

are available in two nonionic forms, carbonyl iron and iron polysaccharide, both of which appear to be less toxic following overdose than are iron salts.[74]

Pharmacology and Toxicokinetics

Iron is an element critical to organ function. As a transition metal, iron can easily accept and donate electrons, thereby shifting from a ferric (Fe^{3+}) to a ferrous (Fe^{2+}) state (Chap. 12). This redox interchange allows iron to fulfill its role in multiple protein and enzyme complexes, including cytochromes and myoglobin, although it is principally found incorporated into hemoglobin in erythrocytes. Insufficient iron availability results in anemia, whereas excess total body iron results in hemochromatosis.

The body cannot directly excrete iron, so body iron stores are regulated by controlling iron absorption from the gastrointestinal tract. Iron absorption, which occurs predominantly in the duodenum, is determined by the body's iron requirements. In iron deficiency, iron uptake into intestinal mucosal cells may increase from a normal of 10â€“35% to as much as 80â€“95%. Following uptake into the intestinal mucosal cells, iron is either stored as ferritin and lost when the cell is sloughed, or released to transferrin, a serum iron-binding protein. In therapeutic doses, some of these processes become saturated, and absorption into the intestinal cell may be limited. However, in overdose the oxidative effects of iron on gastrointestinal mucosal cells lead to dysfunction of this regulatory balance, and increased passive absorption of iron occurs down its concentration gradient[78] (see Pathophysiology below).

Iron supplements are available as the iron salts ferrous gluconate, ferrous sulfate, and ferrous fumarate, and as the nonionic preparations carbonyl iron and polysaccharide iron. Additional sources of significant quantities of iron are vitamin preparations, especially prenatal vitamins (Table 40-1). Toxic effects of iron

poisoning occur at doses of 10â€“20 mg/kg elemental iron (elemental iron is a measure of the amount of iron present in an iron salt; Table 40-1). Significant gastrointestinal symptoms occurred in human adult volunteers who ingested 10â€“20 mg of elemental iron/kg.[9,49] In one volunteer study, 6 subjects who ingested 20 mg/kg elemental iron developed nausea and voluminous diarrhea within 2 hours, and 5 of the 6 subjects had serum iron concentrations above 300 Âµg/dL.[9]

Chewable vitamins continue to entice children with their sweet taste and recognizable character shapes, increasing the risk of significant exposure. Children's chewable multivitamins contain less iron per tablet (10â€“18 mg elemental iron) than typical prenatal vitamins (65 mg elemental iron). Toxicity still results when large quantities are ingested, but fatalities are not reported.[2] One animal study paradoxically demonstrates higher iron concentrations following ingestion of equivalent doses of chewable versus solid iron tablets.[59] This finding was attributed, in part, to the limited gastric irritation associated with the chewable iron preparations, resulting in less vomiting and higher iron concentrations.

Iron polysaccharide and carbonyl iron appear to be safer formulations than iron salts despite their high elemental iron content.[45] Carbonyl iron is a form of elemental iron that is highly bioavailable in therapeutic doses because of its high elemental iron content and its very fine, spherical particle size (5 Âµm). However, toxicity is limited in overdose because carbonyl iron has poor solubility and a slow rate of conversion to the toxic ionic form that occurs in the acid milieu of the stomach. This delayed oxidation is the rate-limiting step that prevents excess absorption.[33] In a rat model of iron toxicity, carbonyl iron had an LD_{50} (median lethal dose for 50% of test subjects) of 50 g/kg compared with an LD_{50} of 1.1 g/kg for ferrous sulfate.[94] No significant toxicity in humans exposed to carbonyl iron has been reported.[74]

TABLE 40-1. Common Iron Formulations and Their Elemental Iron Contents

Iron Formulation	Elemental Iron
Ionic	
Ferrous chloride	28%
Ferrous fumarate	33%
Ferrous gluconate	12%
Ferrous lactate	19%
Ferrous sulfate	20%
Nonionic	
Carbonyl iron	98%[a]
Iron polysaccharide	46%[a]

[a]Although these nonionic iron formulations contain higher elemental iron content than ionic formulations, carbonyl iron and iron polysaccharide have better therapeutic-to-toxic ratios.

Iron polysaccharide contains approximately 46% elemental iron by

weight. It is synthesized by neutralization of a ferric chloride carbohydrate solution. This form of iron also appears to have much lower toxicity than iron salts. The estimated LD_{50} in rats is more than 5 g/kg body weight. Retrospective poison center data have shown little toxicity from either of these products.[45]

Pathophysiology

As a transition metal, iron can assume one of several different oxidation, or valence, states. It is an active participant in reduction-oxidation (redox) reactions. In particular, iron's participation in the Fenton reaction and Haber-Weiss cycle explains its toxicologic effects as a generator of oxidative stress and inhibitor of several key metabolic enzymes (Chaps. 12 and 90). Reactive oxygen species oxidize membrane-bound lipids and cause loss of cellular integrity and tissue injury (Chap. 12).[68,70]

The initial oxidative damage to the gastrointestinal epithelium produced by iron-induced reactive oxygen species permits iron ions to enter the systemic circulation. Iron ions are rapidly bound to circulating binding proteins, particularly transferrin. Once transferrin is saturated with iron, â€œfreeâ€• iron (iron not bound to a transport protein) is widely distributed to the various organ systems, where it promotes damaging oxidative processes. A postmortem series of 11 patients following iron ingestion substantiated these findings with measurements of elevated iron concentrations in most major organs examined: stomach, liver, brain, heart, lung, small bowel, and kidney.[63] Consistent with oxidative damage, congestion, edema, necrosis, and iron deposition in the gastric and intestinal mucosa, as well as hemorrhage and congestion in the lungs, are noted on postmortem examination.[30,31,51]

Iron ions disrupt critical cellular processes such as mitochondrial oxidative phosphorylation. Subsequent buildup of unused hydrogen ions normally incorporated into the synthesis of ATP, leads to liberation of H^+ and development of metabolic acidosis (Chap. 13).

In addition, absorption of iron from the gastrointestinal tract leads to conversion of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}). Ferric iron ions exceed the binding capacity of plasma, leading to formation of ferric hydroxide and production of three protons ($Fe^{3+} + 3H_2O$ â†' $Fe(OH)_3 + 3H^+$).[68,78]

Decreased cardiac output contributes to hemodynamic shock in animals.[88,97] Although this finding has been attributed to decreased venous filling pressures, decreased preload, and relative bradycardia,[88] a direct negative inotropic effect of iron on the myocardium also is demonstrated in animal models.[3] Reports of early coagulopathy unrelated to hepatotoxicity[80] led to the identification of free iron inhibition of thrombin formation and the effect of thrombin on fibrinogen.[71]

Clinical Manifestations

Classic teaching posits five clinical stages of iron toxicity based on the pathophysiology of iron poisoning.[6,40,66] Although these stages

are conceptually important, they are of limited benefit to the clinician managing a poisoned patient. A clinical stage should never be assigned based on the number of hours postingestion because patients do not necessarily follow the same temporal course through these stages.

The first stage of iron toxicity is characterized by nausea, vomiting, abdominal pain, and diarrhea. The â€œlocalâ€• toxic effects of iron predominate, and subsequent salt and water depletion contribute to the ill appearance of the iron-poisoned patient. Intestinal ulceration, edema, transmural inflammation, and, in some extreme cases, small-bowel infarction and necrosis may occur.[24,69,82] Hematemesis, melena, or hematochezia may cause hemodynamic instability. Gastrointestinal symptoms always follow significant overdose. Conversely, the absence of symptoms, specifically vomiting, in the first 6 hours postingestion, essentially excludes serious iron toxicity.

The second or â€œlatentâ€• stage of iron poisoning commonly refers to the period 6â€“24 hours following resolution of gastrointestinal symptoms and before development of overt systemic toxicity. Delineation of this stage may have evolved from early case reports of patients whose gastrointestinal symptoms had resolved prior to subsequent deterioration.[84] This second stage is not a true quiescent phase, as ongoing cellular organ toxicity occurs during this phase.[6] Although clinicians should be wary of patients who no longer have active gastrointestinal complaints following iron overdose, most such patients have recovered and are not in the latent phase. Patients in the latent phase generally have lethargy, tachycardia, or a metabolic acidosis. They should be readily identifiable as clinically ill, despite resolution of their gastrointestinal symptoms. In summary, patients who have remained well since ingestion and who have stable vital signs, a normal mental status, and a normal acidâ€“base balance will have a benign clinical course.

Patients who progress to the third or â€œshockâ€• stage of iron poisoning have profound toxicity. This stage may occur in the first few hours after a massive ingestion or 12â€“24 hours after a more moderate ingestion. The etiology of shock may be multifactorial, resulting from hypovolemia, vasodilation, and poor cardiac output,[88,97] with decreased tissue perfusion and an ongoing metabolic acidosis. An iron-induced coagulopathy may worsen bleeding and hypovolemia.[80] Systemic toxicity produces CNS effects with lethargy, hyperventilation, seizures, or coma.

The fourth stage of iron poisoning is characterized by hepatic failure, which may occur 2â€“3 days following ingestion.[30] The hepatotoxicity is directly attributed to iron uptake by the reticuloendothelial system in the liver, where it causes oxidative damage.[26,98]

The fifth stage of iron toxicity rarely occurs. Gastric outlet obstruction, secondary to strictures and scarring from the initial gastrointestinal injury, can develop 2â€“8 weeks following ingestion.[29,35,82]

Patients with chronic iron overload are at increased risk for *Yersinia enterocolitica* infection. Iron is a required growth factor for *Y. enterocolitica;* however, the bacterium lacks the siderophore to solubilize and transport iron intracellularly. Because deferoxamine is a siderophore, it fosters the growth of *Y. enterocolitica*. Patients with chronic iron overload or acute poisoning develop *Yersinia* infection or sepsis as a complication of iron poisoning or deferoxamine therapy.[10,53,55,76] *Yersinia* infection should be suspected in patients who experience abdominal pain, fever, and diarrhea following resolution of iron toxicity. In this setting, cultures should be obtained and appropriate antibiotic therapy initiated.

Diagnostic Testing

Radiography

Iron is available in many forms, and the different preparations vary with respect to radiopacity on abdominal radiography.[75] Factors such as time since ingestion and amount of elemental iron also play a role.[58,75] Liquid iron formulations and chewable iron tablets typically are not radiopaque.[18] A retrospective review of iron ingestions in children revealed that abdominal radiographs were positive in only 1 of 30 patients who ingested chewable vitamins.[18] Because adult preparations have a higher elemental iron content and do not readily disperse, they tend to be more consistently radiopaque.[58] Finding radiopaque pills on an abdominal radiograph is helpful in guiding and evaluating the success of gastrointestinal decontamination.[36] However, the absence of radiographic evidence of pills is not a reliable indicator to exclude potential toxicity[58,62] (Chap. 6).

Laboratory Studies

Many different laboratory studies are used as surrogate markers to assess the severity of iron poisoning. An anion-gap metabolic acidosis resulting primarily from lactate is a common finding in

patients with serious iron ingestions. Serial electrolyte concentrations can be used to assess progression and response to volume replacement. Anemia can result from gastrointestinal blood loss but may not be evident initially because of hemoconcentration secondary to plasma volume loss.

Although one small retrospective study of iron-poisoned children found that WBC >15,000/mm^3 or blood glucose concentration >150 mg/dL was 100% predictive of iron concentration >300 Âµg/dL,[48] three subsequent studies that similarly examined this issue were unable to validate this association.[11,47,62] In practice, an elevated WBC or glucose concentration should raise concern about an elevated serum iron concentration; however, assessment of the signs and symptoms of the patient probably is more reliable.

Although iron poisoning remains a clinical diagnosis, serum iron concentrations can be used effectively to gauge toxicity and the success of treatment.[6] In the previously mentioned human volunteer study of 6 adults who ingested 20 mg/kg elemental iron, all 6 adults demonstrated significant gastrointestinal toxicity, and the 4 who required intravenous fluid resuscitation had peak serum iron concentrations in the range of 300 Âµg/dL between 2 and 4 hours after ingestion.[9] In another study of human volunteers who ingested 5â€“10 mg/kg elemental iron in the form of chewable vitamins, peak serum iron concentrations occurred between 4.2 and 4.5 hours in all subjects.[49] In overdose, peak concentrations of iron are thought to occur 2â€“6 hours after ingestion, depending on the iron preparation.[9,49] Serum iron concentrations between 300 and 500 Âµg/dL usually correlate with significant gastrointestinal toxicity and modest systemic toxicity. Concentrations between 500 and 1000 Âµg/dL are associated with pronounced systemic toxicity and shock.[92] Concentrations >1000 Âµg/dL are associated with significant morbidity and mortality.[92] Although elevated serum iron concentrations may be an additional indicator of potentially serious toxicity, lower concentrations cannot be used to exclude the possibility of serious toxicity. A single serum iron concentration may

not represent a peak concentration or may be falsely lowered by the presence of deferoxamine, unless an atomic absorption technique is used for measurement.[28,34]

Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that can be bound by transferrin in a given volume of serum.[19] Previously, clinical iron toxicity was thought not to occur if the serum iron concentration was less than the TIBC because insufficient circulating â€œfreeâ€• iron was present to cause tissue damage. Although this may be conceptually true, further research has clarified the limitations of TIBC values. Most importantly, the in vitro value of TIBC factitiously increases as a result of iron poisoning and thus has a tendency to apparently falsely rise above a concurrently measured serum iron concentration.[9,83] Because of many confounding issues, the TIBC as currently analyzed has no value in the assessment of the iron-poisoned patient.

Management

Initial Approach

As with any serious ingestion, initial stabilization must include supplemental oxygen, airway assessment, and establishment of intravenous access. Evidence of hematemesis or lethargy following an iron exposure may be a manifestation of significant toxicity. Intravenous volume repletion should begin while orogastric lavage and whole-bowel irrigation (WBI) are considered. In any lethargic patient who likely will deteriorate progressively, early orotracheal intubation may facilitate safe gastrointestinal decontamination measures. An abdominal radiograph can be used to estimate the iron burden in the gastrointestinal tract given the caveats discussed earlier. Laboratory values including chemistries, hemoglobin, iron concentration, coagulation, and hepatic profiles are necessary in the sickest patients. An arterial blood gas, venous blood gas, or stat

electrolytes rapidly detects a metabolic acidosis. Patients who appear well or had only 1â€“2 brief episodes of vomiting can be observed pending discharge. Alternatively, a serum iron concentration can be measured.

Limiting Absorption

Gastrointestinal decontamination procedures should be initiated following stabilization. Adequate gastric emptying is critical following ingestion of substances, such as iron, that are not well adsorbed to activated charcoal. Because vomiting is a prominent early symptom in patients with significant toxicity, little benefit is expected from induced emesis, and this technique is no longer recommended. Orogastric lavage is more effective but can be limited because of the large size and poor solubility of most iron tablets, their ability to form adherent masses,[24,87] and their movement into the bowel several hours after ingestion.[42] The presence and location of radiopaque pills on abdominal radiograph can help guide lavage. Lavage likely will not be successful once iron tablets move past the pylorus, so WBI may be more effective (Figures 40-1 and 40-2).

Many strategies used in the past attempted to improve the efficacy of orogastric lavage. At the present time, no data support the use of oral deferoxamine,[32,39,95,96,101] bicarbonate,[14,15] phosphosoda,[4,27] or magnesium.[12,73,90] Although some of these techniques demonstrate efficacy, the associated risks mandate use of only 0.9% sodium chloride solution or tap water for orogastric lavage.

Use of WBI in patients with iron poisoning is supported primarily by case reports and one uncontrolled case series.[17,42,79,80] However, the rationale for WBI use is logical, especially considering the limitations of other gastric decontamination modalities. The usual dose of WBI with polyethylene glycol electrolyte lavage solution is 500 mL/h in children and 2 L/h in adults. This rate is best achieved by starting slowly and increasing as tolerated, often using a nasogastric tube and an infusion pump to administer large volumes.

Antiemetics such as metoclopramide or serotonin antagonists can be used to treat nausea and vomiting. A large volume (44 L) of WBI was administered safely over a 5-day period to a child who had persistent iron tablets on serial abdominal radiographs[42] (Antidotes in Depth: Whole-Bowel Irrigation).

For patients who demonstrate persistent iron in the gastrointestinal tract despite orogastric lavage and WBI, upper endoscopy or gastrotomy and surgical removal of iron tablets adherent to the gastric mucosa may be necessary and lifesaving.[24,64,87]

Deferoxamine

Deferoxamine has been available since the 1960s as a specific chelator for patients with acute iron overdose or chronic iron overload (eg, multiple transfusions). Deferoxamine, which is derived from culture of *Streptomyces pilosus*, has high affinity and specificity for iron. In the presence of ferric iron (Fe^{3+}), deferoxamine forms the complex ferrioxamine, which is excreted by the kidneys,[43] imparting a reddish-brown color to the urine. (See ILD fourine in the Image Library at http://www.goldfrankstoxicology.com)
Deferoxamine chelates free iron and the iron transported between transferrin and ferritin,[50,65] but not the iron present in transferrin, hemoglobin, hemosiderin, or ferritin.[5,43] Deferoxamine may work by other mechanisms in addition to binding excess systemic iron.
Because 100 mg deferoxamine mesylate chelates approximately 8.5 mg ferric iron, recommended or typical therapeutic dosing of deferoxamine does not produce significant excretion of chelated iron in the urine, yet it does often result in dramatic clinical benefits (Antidotes in Depth: Deferoxamine). Sufficient evidence suggests that deferoxamine can reach intracytoplasmic and mitochondrial free iron, thereby limiting intracellular iron toxicity.[50]

Intravenous administration of deferoxamine should be considered in iron-poisoned patients with any of the following findings: metabolic acidosis, repetitive vomiting, toxic appearance, lethargy,

hypotension, or signs of shock. Deferoxamine administration also should be considered for any patient with an iron concentration >500 Âµg/dL. In patients manifesting serious signs and symptoms of iron poisoning, deferoxamine should be initiated as an intravenous infusion, starting slowly and gradually increasing to a dose of 15 mg/kg/h. Hypotension is the rate-limiting factor as more rapid infusions are used.[37,93,95] Intramuscular administration of deferoxamine once was a popular method of therapy and part of the â€œdeferoxamine challengeâ€• test but is no longer recommended. The â€œchallengeâ€• test consisted of administration of an IM dose of deferoxamine 1â€“2 g (90 mg/kg), followed by collection of urine samples to assess for a color change indicating the availability of free iron.[25] Patients who appear toxic and/or have serum iron concentrations >500 Âµg/dL should be treated with deferoxamine intravenously. Patients who have concentrations <500 Âµg/dL or who do not appear toxic should be treated supportively without administration of parenteral deferoxamine (Figure 40-3).

Clinicians have attempted to define the earliest clear end points for deferoxamine therapy because of possible deferoxamine toxicity. In one report, a urine iron-to-creatinine ratio (U_I/Cr) was used to determine if free iron excretion into the urine continued during deferoxamine therapy.[100] This ratio is a more objective measure of the presence of ferrioxamine in the urine than the less reliable and more subjective use of urinary color change.[16,46,89] This method

must be further studied clinically before its use can be advocated. Most authors agree that deferoxamine therapy should be discontinued when the patient appears clinically well, the anion-gap acidosis has resolved, and urine color undergoes no further change.[54] In patients with persistent signs and symptoms of serious toxicity after 24 hours of intravenous deferoxamine, continuing therapy should be undertaken cautiously and perhaps at a lower dose (Antidotes in Depth: Deferoxamine).

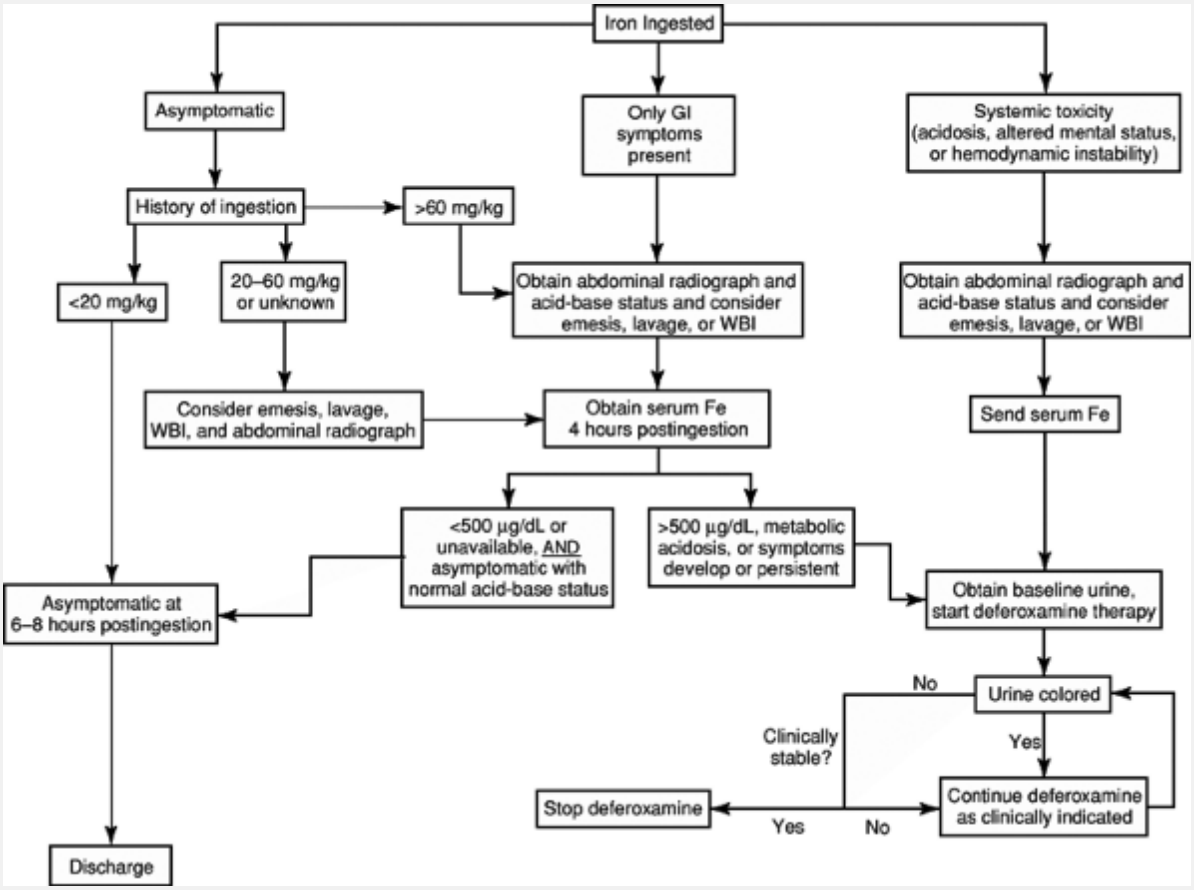

Figure 40-3. Algorithm for decision analysis following iron ingestion.

Patient Disposition

Many patients who ingest iron do not develop significant toxic effects. Recommendations for hospital referral of toddlers who ingest iron range from potential exposures of 20 mg/kg[6] up to 60 mg/kg.[46] These wide ranges probably result from the interpretation of retrospective studies in possibly â€œexposedâ€• toddlers for whom the actual doses were estimated. Many authors suggest that dose was overestimated in patients who subsequently did not develop

toxicity (Chap. 130). If a toddler remains asymptomatic or develops minimal or no gastrointestinal manifestations after a 6-hour observation period in the ED, discharge to an appropriate home situation can be considered. Patients who develop gastrointestinal symptoms and signs of mild poisoning (vomiting, diarrhea) should be observed as inpatients on regular hospital services. Patients who manifest signs and symptoms of significant iron poisoning, such as metabolic acidosis, hemodynamic instability, or lethargy, should be monitored and treated in an intensive care unit. Except in the case of carbonyl iron, hospital evaluation is recommended for any child with an estimated unintentional ingestion of >40 mg/kg elemental iron. Children who appear well with unintentional ingestions between 10 and 20 mg/kg elemental iron and <2 episodes of vomiting should be closely followed at home in consultation with the poison control center.

Pregnant Patients

The frequent diagnosis of iron-deficiency anemia during pregnancy has led to serious and even fatal iron ingestions in pregnant women.[8,44,60,67,85] In all cases of toxic exposures during pregnancy, maternal resuscitation should always be the primary objective, even if an antidote poses a real or theoretical risk to the fetus. Completely unfounded concerns regarding possible deferoxamine toxicity to the fetus have inappropriately, and at times, disastrously delayed therapy.[60,77] These fears about fetal deferoxamine toxicity are not supported in either human or animal studies,[13,52,86] demonstrating that neither iron nor deferoxamine is transferred to the

fetus in appreciable quantities. An animal study demonstrated that fetal serum iron concentrations were not elevated and fetal deferoxamine concentrations could not be detected in pregnant near-term ewes poisoned with iron and treated with deferoxamine. Fetal demise under these circumstances presumably results from maternal iron toxicity and not from direct iron toxicity to the fetus. Thus,

deferoxamine should be used to treat serious maternal iron poisoning and should never be withheld because of unfounded concern for fetal exposure to deferoxamine.

Adverse Effects of Deferoxamine

Most adverse effects of deferoxamine are reported in the setting of chronic administration for treatment of hemochromatosis.[38,61,72] The same effects, such as acute lung injury and acute respiratory distress syndrome (ARDS), also are described after treatment for acute iron overdose.[81] Four patients with serum iron concentrations ranging from 430â€“620 Âµg/dL developed ARDS after intravenous administration of deferoxamine for 32â€“72 hours. An animal study revealed significantly increased pulmonary toxicity when high-dose deferoxamine therapy was administered in the presence of high concentrations of oxygen (75â€“80% FiO_2).[1] The authors suggested that this effect was mediated via an oxygen free radical mechanism (Antidotes in Depth: Deferoxamine).

Alternative Therapies

Another modality used experimentally for treatment of iron intoxication is continuous arteriovenous hemofiltration (CAVH). In a study of five iron-poisoned dogs, increased elimination of ferrioxamine in the ultrafiltrate was demonstrated when increasing doses of deferoxamine were infused into the arterial side of the system.[7] This technique is not described in iron-poisoned humans. Theoretically, ferrioxamine in the blood could be dialyzable with new high-molecular-weight (large-pore) dialysis filters, but this technique has not been studied.

In toddlers with severe poisoning, exchange transfusion may help to physically remove free iron from the blood while replacing it with normal blood. Exchange transfusion in children is effective for poisonings (eg, with theophylline) where the volume of drug

distribution is small and removal from the blood compartment can be expected. However, removal of blood volume may not be well tolerated by iron-poisoned patients, who tend to have hemodynamic instability.

Summary

Despite FDA-mandated warnings on iron preparations, morbidity and mortality secondary to iron exposures continue. A toddler presenting to the ED after presumed iron exposure who has evidence of gastrointestinal toxicity and lethargy is at high risk for significant iron toxicity and possibly death. Although iron is available in multiple formulations (prenatal vitamins, ferrous gluconate supplements), toxicity is determined by the amount of elemental iron present; signs and symptoms occur after ingestions of 20 mg/kg elemental iron. After the patient's condition is stabilized, gastrointestinal decontamination, including orogastric lavage and WBI (polyethylene glycol electrolyte lavage solution), should be initiated when indicated because activated charcoal is ineffective in binding iron. An abdominal radiograph may be helpful in determining the iron burden in the GI tract with preparations that are radiopaque. After iron is absorbed, gastrointestinal symptoms of nausea, vomiting, diarrhea, hematemesis, and abdominal pain are prominent. Systemic iron toxicity leads to metabolic acidosis, hypotension, coagulopathy, and multiorgan system failure. Diagnosis and treatment of shock and acidosis, as well as chelation with deferoxamine, may be lifesaving. Education of parents, caregivers, and prescribers may decrease the incidence of serious iron ingestions in the future.

Figure. No Caption Available.

History and Chemistry

The development of deferoxamine (DFO or desferrioxamine B)

resulted from analysis of the metabolites of actinomycetes. DFO is the colorless compound that results when the trivalent iron is chemically removed from ferrioxamine B (Figure A8-1).[33] Ferrioxamine is a brownish-red compound containing trivalent iron (ie, ferric, Fe^{3+}) and 3 molecules of trihydroxamic acid isolated from the organism *Streptomyces pilosus*.[33]

DFO is a water-soluble hexadentate chelator with a molecular weight of 561 daltons. The commercial formulation is the mesylate salt with a molecular weight of 657 daltons. One mole of DFO binds 1 mole of Fe^{3+}; therefore, 100 mg DFO as the mesylate salt theoretically can bind 8.5 mg Fe^{3+}.

DFO has a far greater affinity constant for iron (10^{31}) than for zinc, copper, nickel, magnesium, or calcium (10^{2}â€“10^{14}).[33] Thus, at physiologic pH values, DFO complexes almost exclusively with ferric iron.[24,68]

Mechanism of Action

DFO binds Fe^{3+} at the 3 Nâ€“OH sites, forming an octahedral iron complex (Figure A8-1). Once bound, the resultant ferrioxamine is very stable. DFO appears to benefit iron-poisoned patients by chelating free iron (nontransferrin plasma iron) and iron in transit between transferrin and ferritin (chelatable labile iron pool),[27,39,54] while not directly affecting the iron of hemoglobin, hemosiderin, or ferritin.[33] In vitro studies suggest that DFO removes iron from ferritin and transferrin but only very little from hemosiderin.[44] However, in vivo experiments demonstrate that DFO cannot remove iron once the iron is bound to transferrin.[4] DFO does bind â€œfree ironâ€• found in the plasma as nontransferrin plasma iron after transferrin is saturated. This situation occurs in the overdose setting or in chronic iron overload syndromes.[27] In vitro studies demonstrate that DFO chelates and inactivates cytoplasmic and mitochondrial iron, preventing disruption of mitochondrial function and injury.[39] In chronic iron

overload, DFO chelates iron deposited in the reticuloendothelial cells found in the spleen, liver, and bone marrow and excretes it in the urine as ferrioxamine.[27] Whether DFO actually chelates the iron within the reticuloendothelial cells or after liberation into the plasma is unclear. In vitro studies demonstrate that the liver can donate iron to DFO, and chelation subsequently may lead to biliary excretion and fecal elimination.[27,43]

Pharmacokinetics

The volume of distribution of DFO ranges from 0.6â€“1.33 L/kg.[33,36,51] The initial distribution half-life of DFO is 5â€“10 minutes.[35,58] The terminal elimination half-life of DFO is approximately 6 hours in healthy patients[2] but approximately 3 hours in patients with thalassemia. DFO is metabolized in the plasma to several metabolites (Aâ€“F), of which metabolite B is believed to be toxic.[33,36,51,52] Unchanged DFO undergoes glomerular filtration and tubular secretion.[43]

In comparison, ferrioxamine has a smaller volume of distribution than DFO. In nephrectomized dogs, the volume of distribution of ferrioxamine was calculated to be 19% of body weight compared to 50% of body weight for DFO.[33] This finding implies that DFO has a more extensive tissue distribution. The different pharmacokinetic patterns may be related to the potential for penetrance of the straight-chain molecule DFO compared to that of the octahedral ferrioxamine.[52] Experiments in dogs demonstrate that intravenous (IV) ferrioxamine is entirely eliminated by the kidney within 5 hours[33] via glomerular filtration and partial reabsorption.[43]

The pharmacokinetics of DFO and ferrioxamine differ in healthy versus iron-overloaded patients. Plasma DFO concentrations in healthy patients are approximately twice the concentrations noted in patients with thalassemia major, whereas ferrioxamine concentrations are 5 times greater in patients with thalassemia

major compared to healthy patients.[33,59]

Some investigators suggest that DFO can be administered during hemodialysis to remove ferrioxamine.[69] Although hemodialysis[14,58] and hemoperfusion[14] both are effective in ferrioxamine removal, whether these interventions are indicated is unclear.

Animal Studies

Studies in guinea pigs given LD_{50} and LD_{100} oral doses of ferrous sulfate show dramatically improved survival rates after administration of oral DFO in a dose calculated to bind most of the iron, which is substantially less than the DFO dose that is given clinically.[44] Mortality rates in this study and in a similar study in swine[18] directly correlate with the delay in DFO administration.[44]

In 2 subsequent canine studies by the same authors, dogs that received the ironâ€“DFO complex orally had 40â€“100% mortality.[68,69] When both oral and IV DFO were administered, the mortality rate was 67%.[67] A similar followup study demonstrated a 50% mortality rate in dogs given a lethal dose (225 mg/kg) of iron, followed by oral DFO (2.6 g) and IV DFO (0.75â€“1.5 mg/kg/min for 8â€“12 hours).[69] Study results have discouraged substantial interest in the use of oral DFO despite the more favorable results in noncanine species.[5,29,44,63]

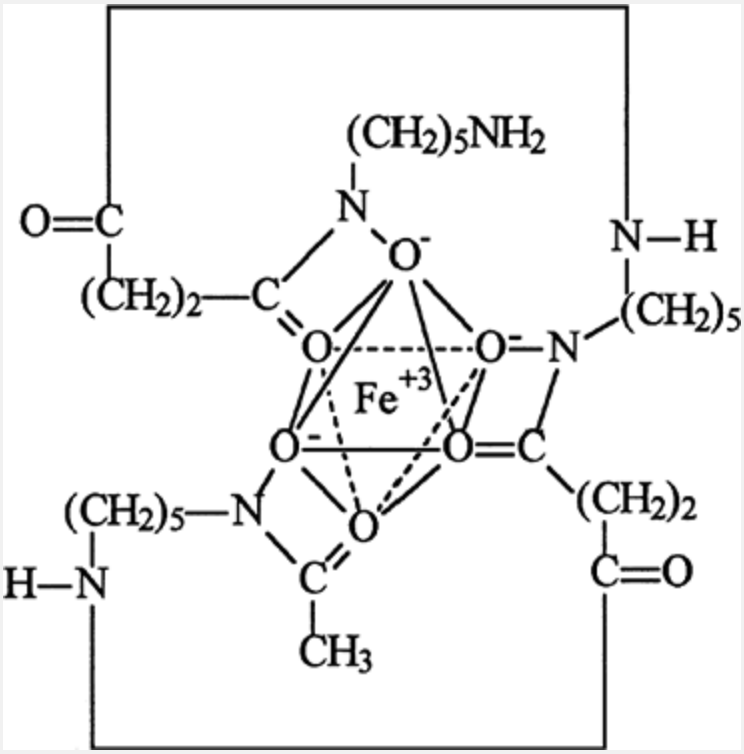

Figure 8-1. Ferrioxamine.

Early Human use and History of Dosing Recommendations

In one of the earliest case series, 172 children who were not severely poisoned and who were hemodynamically stable were treated with 5â€“10 g oral DFO and either 1 or 2 g intramuscular (IM) DFO every 3â€“12 hours.[67] One gram DFO administered intravenously at a maximum of 15 mg/kg/h every 4â€“12 hours, was continued for 2â€“3 days as necessary for patients who were in shock or severely ill. Of the 28 patients who developed coma, shock, or both, only 3 died. One of the 3 patients who died had

received late treatment with DFO.

This case series was expanded to 472 patients, and guidelines for DFO dosing were formulated based on this clinical experience.[66] The recommended IM dose of DFO was suggested as 1 g initially, followed by 0.5 g 4 and 8 hours later and then every 4â€“12 hours as necessary, not to exceed 6 g in 24 hours. For patients in shock, IV DFO was recommended at an initial dose not to exceed 1 g and a rate not to exceed 15 mg/kg/h, followed by two 0.5-g doses separated by 4 hours, and a total dosage not to exceed 6 g in 24 hours. These recommendations for total dosages were not scientifically developed and appear to be based on arbitrary assumptions. However, the manufacturer continues to recommend these doses.[19]

Urinary Color Change

To further define the role of DFO, investigators studied urinary samples. A vin rosÃ© color to the urine following DFO was found to be indicative of 10â€“30 mg urinary iron excretion per 24 hours.[44] In a review of 107 patients with acute iron poisoning who had received 5 g DFO orally and 90 mg/kg DFO IV, at a rate not greater than 15 mg/kg/h,[41] the appearance of a vin rosÃ© color in urine or a serum iron concentration >500 Âµg/dL prompted chelation for at least 24 hours. Further studies investigated the correlation between urinary iron concentrations and systemic toxicity.[71] Most data suggest that the absence of a urine color change following DFO administration, indicates very little renal excretion of ferrioxamine.[23] Unless a baseline urine is obtained prior to DFO administration, post-DFO administration comparisons of urine color are unreliable. No relationship between urinary iron excretion, clinical iron toxicity, and the effectiveness of DFO has been established.

IM Versus IV Administration

Prior to 1976, IM DFO was the preferred route of administration and IV DFO was reserved for patients in shock. However, when transfusion-induced iron overload was studied and IM and IV DFO administration were compared, IV DFO significantly enhanced urinary iron elimination.[55] This study provided compelling arguments against IM dosing, as did data showing higher peak concentrations and more stable levels with IV infusions. A single patient was given 425 mg/kg IV over 24 hours without incident, although the increase in urinary iron excretion seen when the DFO dose increased from 4 to 16 g/d appeared to be of limited consequence.

Duration of Dosing

Optimum duration of DFO administration is unknown. In canine models, serum iron concentrations peak within 3â€“5 hours and then fall quickly as iron is transported out of the blood into the tissues.[64,70] In one human study, initial iron concentrations of approximately 500 Âµg/dL fell to approximately 100 Âµg/dL within 12 hours.[37] Other case reports also suggest that most of the easily accessible iron is distributed out of the blood compartment by 24 hours.[20] Although severely poisoned patients have received DFO for more than 24 hours, pulmonary toxicity has been associated with prolonged DFO infusions.[26,49,61] Intuitively, in patients with acute iron overdose DFO should be administered early and for a shorter duration while the iron is easily accessible in the blood. In patients with chronic iron overdose, prolonged infusions of smaller DFO doses are necessary to act as a sink and to slowly remove iron from the labile pool and tissue stores.[30]

Adverse Effects

DFO administration to patients with acute iron overdose is associated with rate-related hypotension, pulmonary toxicity, and infection. DFO administration to patients with chronic iron overload

is associated with auditory, ocular, and pulmonary toxicity and infection.[9,30]

Significant hypotension was first noted in 1965 in 2 children who were administered approximately 80â€“150 mg/kg DFO intravenously over 15 minutes.[68] The mechanism for rate-related hypotension is not fully understood, although histamine release is implicated. Elevated histamine concentrations were documented in a canine experiment, but pretreatment with diphenhydramine was not protective.[69] Intravascular volume depletion due to iron toxicity also contributes to the hypotension. No experiment has determined the maximum safe rate of DFO administration. Adverse effects of DFO were reported when DFO was infused rapidly, including tachycardia, hypotension, shock, erythema, and urticaria,[67] resulted in the current recommendations for less rapid IV infusions of DFO not exceeding 15 mg/kg/h.[67,68 and 69] Currently suggested IV infusion rates are somewhat empirical because of the lack of robust evidence. Higher rates were administered successfully in critically ill patients when time was of the essence.[11,15,20]

Acute lung injury (ALI) has been described in the setting of acute iron overdoses following IV administration of DFO (15 mg/kg/h) therapy for >24 hours.[3,32,61] Usually iron concentrations returned to therapeutic levels in these patients within 24 hours, and the rationale for continued administration of DFO was not reported. Examination of the nontoxicologic literature reveals other instances of ALI occurring in patients receiving continuous IV DFO for hemosiderosis and malignancies.[13,22,65] Administration of continuous IV doses of DFO for prolonged (>24 hours) periods was common to all of these patients. The mechanism for development of pulmonary toxicity after DFO is unknown. Pulmonary toxicity may result from excessive DFO chelation of intracellular iron and depletion of catalase, resulting in oxidant damage[25] or generation of free radicals.[1]

DFO therapy may lead to infection with a number of unusual organisms, including *Yersinia enterocolitica*, *Zygomycetes*, and *Aeromonas hydrophilia.* The virulence of these organisms is facilitated when the DFOâ€“iron complex acts as a siderophore for their growth.[38,42,45] Most cases of septicemia occurred when DFO was used for treatment of aluminum toxicity in patients receiving chronic hemodialysis.[43] Several cases of *Yersinia* sepsis were reported following acute iron overdose and treatment with DFO.[42,45]

Ocular toxicity characterized by decreased visual acuity, night blindness, color blindness, and retinal pigmentary abnormalities has occurred in patients who received continuous IV DFO for thalassemia and other nonacute iron- and aluminum-excess conditions.[8,12,17,48,50] Ototoxicity documented by abnormal audiograms indicating partial or total deafness has been reported.[52,53] However, neither ocular toxicity nor ototoxicity has been reported in the acute toxicologic literature.

Use in Pregnancy

A review of the literature identified 61 cases of intentional iron overdose in pregnant women.[62] Serious iron toxicity with organ involvement is associated with spontaneous abortion, preterm delivery, and maternal death. No evidence indicates that DFO is teratogenic.[62] Neither iron nor DFO appears to cross the ovine placenta.[16] A case report of a pregnant woman with thalassemia and a review of 40 other pregnant patients with thalassemia treated extensively with DFO found no evidence of teratogenicity.[57] DFO should be administered to pregnant women with acute iron overdose for the same indications as for nonpregnant women.

Use in Aluminum Toxicity

Patients with renal insufficiency are at high risk for aluminum toxicity.[72] Acute aluminum toxicity resulting from bladder irrigations with alum for hemorrhagic cystitis is also reported. Chronic aluminum toxicity is reported from administration of aluminum salts as phosphate binders or from hemodialysis with a water source containing aluminum. DFO binds aluminum to form aluminoxamine, analogous to Fe and ferrioxamine. The chelate is a 1:1 octahedral complex with aluminum.[72] Aluminoxamine is excreted renally. In patients with renal insufficiency, hemodialysis (especially with a high-flux membrane) is effective in removing the aluminoxamine and should be used to prevent aluminum redistribution to the CNS and other tissues.[46] The dosing of DFO should be tailored to the patient's serum aluminum concentrations, symptomatology, and response.[46] DFO doses of 15 mg/kg/d, infused over 1 hour and 6â€“8 hours before hemodialysis, have been successful and maximize aluminoxamine removal.[46]

Indications and Dosing

The indications and dosage schedules for DFO administration are largely empirical.[6,56] Systemic toxicity associated with acute iron poisoning manifested by coma, shock, or metabolic acidosis warrants IV infusion of DFO. The duration of therapy probably should be limited to 24 hours to maximize effectiveness while minimizing the risk of pulmonary toxicity. Some investigators have suggested that more than the recommended dose of 15 mg/kg/h be infused during the first 24 hours for life-threatening iron toxicity, but this recommendation remains to be validated experimentally.[30] Although patients with mild toxicity can be treated with IM injections of DFO 90 mg/kg (maximum 1 g in children or 2 g in adults), this volume of antidote cannot be given intramuscularly with ease or painlessly in children. Therefore, few clinicians administer DFO IM and most choose the preferable IV route (Chap. 40). The total daily parenteral dose is limited by the infusion rate in children (if manufacturer's recommendations are

followed). Conservative recommendations in adults limit the dose to 6â€“8 g/d, although doses as high as 16 g/d with diverse dosing regimens have been administered without incident.[15,20,40,49,55,60]

Availability

Deferoxamine mesylate (Desferal) is available in vials containing 500 mg or 2 g sterile, lyophilized powder. Adding 5 or 20 mL of sterile water for injection to either the 500-mg or the 2-g vial, respectively, results in a 100 mg/mL solution. This solution is isotonic, clear, and colorless to slightly yellowish.[19] The resulting solution can be diluted further with 0.9% NaCl solution, glucose in water, or Ringer lactate solution for IV administration. For IM administration, a smaller volume of solution is preferred. Adding 2 or 8 mL of sterile water for injection to the 500-mg or 2-g vial, respectively, results in a stronger yellow-colored solution containing 250 mg/mL.

Additional Iron Chelators

New iron chelators are being investigated. Pyridoxal isonicotinylhydrase and pyridoxal benzoylhydrazone are potent lipophilic chelators. Lipophilicity increases iron mobilization but may also increase toxicity. Deferiprone is a bidentate oral iron chelator. Three moles of deferiprone are required to bind 1 mole of ferric ion to form a stable complex.[27] Inappropriate ratios of drug to iron may be ineffective or even harmful because of the formation of potentially toxic intermediates.[27] Preliminary animal studies of acute toxicity are contradictory.[10,21,31,34] The effectiveness and long-term safety of deferiprone for chronic iron overload associated with thalassemia major have been questioned.[7,35,47] Other hexadentate drugs and prodrugs are under investigation.[27]

Summary

DFO is the parenteral chelator of choice for treatment of iron poisoning. Although DFO has been used to treat acute iron overdose

for many years,[28] no controlled studies have evaluated efficacy or dosing. Much of our knowledge derives from animal studies and case series in the 1960s and early 1970s and from limited case reports throughout the ensuing years. DFO is used for chelation of aluminum in patients with chronic renal failure.

Chapter 41
Vitamins

Beth Y. Ginsburg

Vitamins are essential for normal human growth and development.[36] By definition, a vitamin is a substance that is present in small amounts in natural foods, is necessary for normal metabolism, and whose lack in the diet causes a deficiency disease.[30] According to the American Medical Association, healthy men and nonpregnant women who eat a varied diet do not need supplemental vitamins.[8] However, millions of people in the United States regularly ingest quantities of vitamins in great excess of the recommended dietary allowances (RDAs) (Table 41-1). Many of these individuals share the mistaken beliefs that vitamin preparations provide extra energy or promote muscle growth. Fortunately, for the most part, even large doses of vitamins do not lead to significant toxicity. However, some vitamins are associated with significant adverse effects when ingested in very large doses.

Vitamins can be divided into two general classes. Most of the vitamins in the *water-soluble* class have minimal toxicity because they are stored to only a limited extent in the body. Thiamine, riboflavin,

cyanocobalamin (vitamin B_{12}), pantothenic acid, folic acid, and biotin are not reported to cause any toxicity following oral ingestion.[36] Ascorbic acid (vitamin C), nicotinic acid, and pyridoxine (vitamin B_6) are associated with toxicity syndromes. The *fat-soluble* vitamins can bioaccumulate to massive degrees. As a result, the potential for toxicity greatly exceeds that of the water-soluble group. Vitamins A, D, and E but not K are associated with toxicity in the setting of very large overdoses. Adverse effects secondary to vitamin K are limited to severe, and sometimes fatal, anaphylactoid reactions with administration of the intravenous (IV) preparation.[58]

Vitamin A

MW	= 272.43 daltons

Figure. No Caption Available.

History and Epidemiology

The term *vitamin A*, classically used to refer to the compound retinol, now is also used to describe other naturally occurring derivatives of retinol. Vitamin A activity is expressed in retinol equivalents (RE). One RE corresponds to 1 Âµg of retinol or 3.3 international units (IU) of vitamin A activity as retinol. As a group, these compounds are called *retinoids.* They have specific sites of action and varying degrees of biologic potency. Vitamin A, in the form of 11-*cis*-retinal, plays a critical role in retinal function.[187] Deficiency results in

nyctalopia, which is decreased vision in dim lighting, more commonly known as *night blindness.* Retinoic acid is primarily responsible for maintaining normal growth and differentiation of epithelial cells in mucus-secreting or keratinizing tissue.[122] Vitamin A deficiency results in the disappearance of goblet mucous cells and replacement of the normal epithelium with a stratified, keratinized epithelium. Dermal manifestations are the earliest to develop and include dry skin and hair and broken fingernails. In the cornea, hyperkeratization is called *xerophthalmia* and can lead to permanent blindness. Alterations in the epithelial lining of other organ systems may lead to increased susceptibility to respiratory infections, diarrhea, and urinary calculi.

Two independent groups discovered vitamin A in 1913.[126 , 144] They reported that animals fed an artificial diet with lard as the sole source of fat developed a nutritional deficiency characterized by xerophthalmia. They found that this deficiency could be corrected by adding to the diet a factor contained in butter, egg yolks, and cod liver oil. They named this substance â€œfat soluble vitamin A.â€• The chemical structure of vitamin A was determined later in 1930.[99] Preformed vitamin A is also found in liver, fish, cheese, and whole milk. In the United States, many breakfast cereals, margarine, and most fat-free milk and dried nonfat milk solids are fortified with vitamin A.[193] In some developing countries, sugar, oil, margarine, milk, wheat and corn flours, noodles, and rice are fortified with vitamin A.[6] In addition, infant formulas and cereals usually are fortified with vitamin A. Vitamin A content varies widely among different food types. A 3-oz serving of cooked beef liver contains 30,325 IU of vitamin A, whereas 1 cup of whole milk contains 305 IU of vitamin A. Fish-liver oils, such as swordfish and Black Sea bass, have extremely large amounts of vitamin A and may contain more than 180,000 IU of vitamin A per gram of oil. Carotenoids, vitamin A precursors, are present in yellow and green fruits and vegetables. A raw carrot has a high Î²-carotene content of approximately 20,250 IU. One half-cup serving of spinach contains approximately 7395 IU of Î²-carotene, whereas an apricot or peach

contains 500â€“600 IU. The average American diet provides about half of its daily vitamin A intake as carotenoids and about half as preformed vitamin A.[34] The RDA of vitamin A is 900 Âµg RE/d (3000 IU/d) for adult men and 700 Âµg RE/d (2300 IU/d) for women (Table 41-1).[62] The tolerable upper intake level for adults is 3000 Âµg/d (9900 IU/d).[62]

TABLE 41-1. Recommended Dietary Daily Allowances/Adequate Daily Intakes

Hypervitaminosis A can occur in people who ingest large doses of vitamin A in their daily diets. Vitamin A toxicity is believed to occur in the Inuit population whose diet includes polar bear liver. Polar Eskimos in the 16th century recognized that ingestion of large amounts of polar bear liver caused a severe illness characterized by headaches and prostration.[59] Arctic explorers in the 1800s knew of the poisonous qualities of polar bear liver and described an acute illness following its ingestion.[66] However, the toxic substance in polar bear liver was not identified as vitamin A until 1942.[158] The vitamin A content of polar bear liver is as high as 34,600 IU/g, supporting the view that vitamin A is the toxic factor in liver.[159] Hypervitaminosis A also is implicated in the etiology of pibloktoq, or â€œarctic hysteria,â€• as some somatic and behavioral effects of vitamin A toxicity closely parallel many of the symptoms reported in Inuit patients diagnosed with pibloktoq.[108]

Vitamin A toxicity was reported in an adult who chronically ingested large amounts of beef liver.[93] Symptomatology consistent with vitamin A toxicity was reported following ingestion of the liver of the grouper fish *Cephalopholis boenak* , which has an average vitamin A

content high enough to cause acute toxicity.[31] Ingestion of sea whale and seal liver, as well as the livers of large fish, such as shark, tuna, and sea bass, also is associated with development of hypervitaminosis A.

The majority of cases of vitamin A toxicity result from use of vitamin supplements.[14, 16] In the United States, approximately 5% of adults take vitamin A supplements.[76] Vitamin A is prescribed for some people for dermatologic and ophthalmic conditions. Hypervitaminosis A often occurs in adults who continue to use the vitamin without medical supervision.[67]

Isotretinoin (Accutane), 13-*cis* -retinoic acid, is prescribed for treatment of severe cystic acne. Of great concern is the teratogenicity associated with its use. According to the National Disease and Therapeutic Index, 38% of isotretinoin users are females aged 13â€“19 years. The high likelihood of pregnancy in this group underscores the need to inform all users of the contraindication of this drug's use during pregnancy and the need to demonstrate the absence of pregnancy prior to initiating treatment. In addition, patients must consider the consequences of unintentional pregnancy while they are taking isotretinoin.

Pharmacology and Toxicokinetics

Absorption of vitamin A in the small intestine is nearly complete. However, some vitamin A may be eliminated in the feces when large doses are taken. The majority of vitamin A is ingested as retinyl esters, the storage form of retinol.[122] Retinyl esters undergo enzymatic hydrolysis to retinol by digestive enzymes in the intestinal lumen and brush border of the intestinal epithelial wall. A small portion of retinol is absorbed directly into the circulation, where it is bound to retinol-binding protein (RBP) and transported to the liver. Most of the retinol is taken into intestinal epithelial cells by the carrier protein cellular RBP.[141] Subsequently, retinol is reesterified and incorporated into chylomicrons, which are taken up by the liver.

doses, significant amounts of retinyl esters circulate in association with low-density lipoproteins (LDLs) and are delivered to the liver. Approximately 90% of the body's total vitamin A content is stored in the liver as retinyl esters. Vitamin A is released into the plasma for delivery to other tissues as needed.

Carotenoid absorption requires the presence of bile and absorbable fat in the intestinal tract. Only a portion of these vitamin A precursors is cleaved into retinaldehyde, which subsequently is reduced to retinol. This process occurs in the intestinal wall. Retinol then is absorbed and transported by RBP or converted to retinyl esters and transported by lipoproteins via lymphatics to the liver and other tissues. Massive doses of carotenoids are not converted rapidly enough to produce vitamin A toxicity. However, high blood concentrations of carotenoids are achieved. Hypercarotenemia produces a yellow-orange skin discoloration that can be differentiated from jaundice by the absence of scleral icterus.

The normal plasma retinol concentration is approximately 30â€“70 Âµg/dL.[169] Blood concentrations are maintained at the expense of hepatic reserves when insufficient amounts of vitamin A are ingested. A normal adult liver contains enough vitamin A to fulfill the body's requirements for approximately 2 years.[132] Thus symptoms of vitamin A deficiency can be prevented for many months. Excessive intake of vitamin A is not initially reflected as elevated blood concentrations because vitamin A is soluble in fat but not in water. Instead, hepatic accumulation is increased. This storage system allows for cumulative toxic effects. Although no relationship exists between the magnitude of liver stores and blood concentrations of vitamin A, in chronic hypervitaminosis A, serum concentrations are generally > 3.49 Âµmol/L (95 Âµg/dL).[16] Vitamin A has a half-life of 286 days in the blood.[171 , 191]

Clinical toxicity correlates well with total body vitamin A content,

which is a function of both dosage and duration of administration. Hypervitaminosis A is rare, with a reported average incidence of <10 cases per year from 1976 to 1987.[16] A randomized double-blind trial, in which 390 women who received 400,000 IU of vitamin A as a single dose were compared with 380 women who received placebo, suggested that dosing at this level is well tolerated by postpartum women.[92] It has been demonstrated that 100,000 IU of vitamin A in children aged 6â€“11 months and 200,000 IU of vitamin A every 3 to 6 months for children aged 12â€“60 months results in few side effects and is effective in reducing mortality.[15] The minimal dose required to produce toxicity in humans is not established. However, an animal study has shown that the median lethal acute dose in monkeys weighing between 1.0 and 1.8 kg is 560,000 IU (168 mg) per kg body weight.[119] In this study, all monkeys receiving > 300 mg/kg died, whereas none died at a dose of 100 mg/kg. Hepatoxicity can occur in humans following an acute ingestion of a massive dose of vitamin A (>600,000 IU).[105]

Hypervitaminosis A may occur more frequently secondary to chronic ingestions of vitamin A. Hepatotoxicity typically requires vitamin A ingestions of at least 50,000â€“100,000 IU/d for months or years.[6] , [105] One study found that in patients with vitamin A-induced hepatotoxicity, the average daily vitamin A intake was higher in patients who developed cirrhosis (135,000 IU/d) compared to patients who developed noncirrhotic liver disease (66,000 IU/d).[67] However, case reports have documented hepatotoxicity resulting from vitamin A doses as low as 25,000 IU/d,[67] , [105] a dose widely available in vitamin A preparations found in health food stores.

Pathophysiology

The mechanism of action for many of vitamin A's toxic effects may be at the nuclear level. Retinoic acid influences gene expression by combining with nuclear receptors.[122] Retinoids also influence expression of receptors for certain hormones and growth factors. Thus

they are able to influence growth, differentiation, and function of target cells.[117]

In epithelial cells and fibroblasts, retinoids affect changes in nuclear transcription, resulting in enhanced production of proteins such as fibronectin and decreased production of other proteins such as collagenase.[121] Excessive concentrations of retinoids lead to the presence of goblet cells, production of a thick mucin layer, and inhibition of keratinization. In addition, lipoprotein membranes have increased permeability and decreased stability, resulting in extreme thinning of the epithelial tissue.

In vitro studies in bone demonstrate that high doses of vitamin A are capable of directly stimulating bone resorption and inhibiting bone formation. This effect is secondary to increased osteoclast formation and activity and inhibition of osteoblast growth.[138 , 143 , 165]

Hepatotoxicity may develop secondary to an acute overdose or ingestion of â€œlowâ€• or â€œtherapeuticâ€• doses if taken over a prolonged time.[67 , 105] Ninety percent of hepatic vitamin A stores are located in the Ito, or fat-storing, cells of the liver, which are located in the perisinusoidal space of Disse, and are responsible for maintaining normal hepatic architecture.[79] Ito cells undergo hypertrophy and hyperplasia as vitamin A storage increases.[105] This results in transdifferentiation of the Ito cell into a myofibroblastlike cell that secretes a variety of extracellular matrix components, leading to narrowing of the perisinusoidal space of Disse, obstruction to sinusoidal blood flow, and noncirrhotic portal hypertension (Figure 41-1).[40 , 71 , 89 , 100 , 105 , 162] Continued ingestion of vitamin A and hepatic storage may lead to obliteration of the space of Disse, sinusoidal barrier damage, perisinusoidal hepatocyte death, fibrosis, and cirrhosis.[89 , 96 , 105 , 160]

Vitamin A toxicity is associated with idiopathic intracranial hypertension (IIH). Although vitamin A's role in the development of IIH is not definitively understood, serum concentrations of vitamin A are significantly higher in patients with IIH compared to healthy

controls.[94] In addition, cerebrospinal fluid (CSF) concentrations of vitamin A are significantly elevated in patients with IIH compared to patients with normal intracranial pressure (ICP) or patients with other causes of elevated ICP.[190] Unbound, circulating retinol and

retinyl esters are proposed to be capable of interacting with cell membranes and producing damage by membranolytic surface-active properties.[94] In the central nervous system (CNS), disruption of cell membrane integrity might lead to disruption of CSF outflow, thereby producing signs and symptoms consistent with IIH.[69 , 94 , 103 , 120]

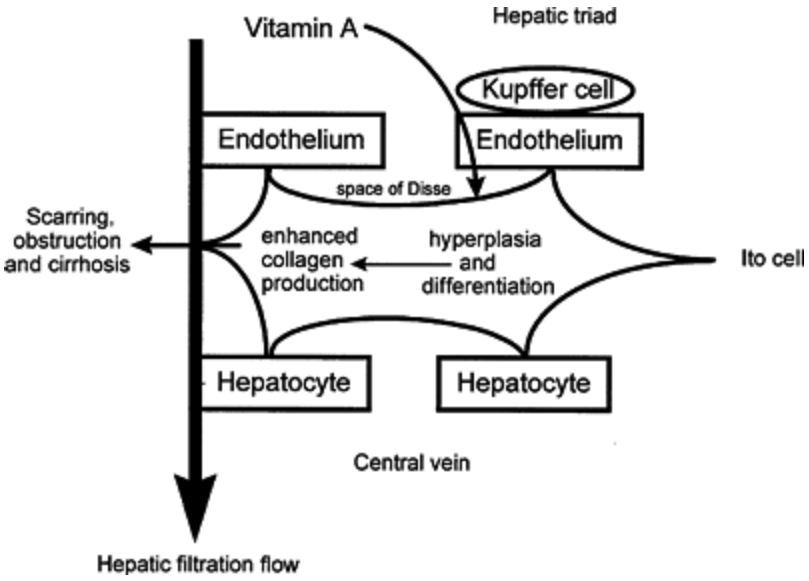

Figure 41-1. Schematic demonstration of hepatotoxicity resulting from excessive deposition of vitamin A in the Ito cells of the liver.

Clinical Manifestations

Hypervitaminosis A affects the skin, hair, bones, liver, and brain. The most common skin manifestations include xerosis, which is associated with pruritus and erythema, skin hyperfragility, and desquamation.[45 , 46 , 195] Retinoid toxicity may cause hair thinning and even diffuse hair loss in 10â€“75% of patients.[61 , 70 , 102] In addition, the

characteristics of the hair may change after regrowth. Hair sometimes becomes permanently curly or kinky.[10] Nail changes include a shiny appearance, brittleness, softening, and loosening.[55] Dryness of mucous membranes develops with chapped lips and xerosis of nasal mucosa, which sometimes is associated with nasal bleeding.[38]

Epidemiologic studies are consistent with bone loss and a resulting increase in fracture risk. In northern Europe, the region with the highest incidence of osteoporotic fractures, dietary intake of vitamin A is high. A study of this population demonstrated that the risk of first hip fracture was increased by 68% for every 1 mg increase in RE intake.[128] This study also showed that compared to intake <0.5 mg/d, intake >1.5 mg/d reduced bone mineral density by 10% at the femoral neck, 14% at the lumbar spine, and 6% for the total body, and doubled the risk of hip fracture. These findings are supported by other studies demonstrating an increased risk of hip fracture among women with elevated serum vitamin A concentrations and in women ingesting large daily amounts of vitamin A.[56 , 142] One study found that among women not taking supplemental vitamin A, a diet rich in vitamin A was also associated with an increased fracture risk.[56]

Other musculoskeletal findings include skeletal hyperostoses, most commonly affecting the vertebral bodies of thoracic vertebrae, extraspinal tendon and ligament calcifications, soft-tissue ossification, cortical thickening of bone shafts, periosteal thickening, and bone demineralization.[38 , 132 , 134] Many of these findings are apparent on radiographs. Patients often complain of bone and joint pain and muscle stiffness or tenderness. Hypercalcemia, with low parathyroid hormone (PTH) concentrations, is thought to be secondary to increased osteoclast activity and bone resorption.[23] Premature epiphyseal closure in children is reported.[151] Teratogenic effects include interference with skeletal differentiation and growth.[23]

The degree of hepatotoxicity appears to correlate with the dose of vitamin A and chronicity of use. With large doses, cirrhosis develops and may lead to portal hypertension, esophageal varices, jaundice,

and ascites.[41, 67, 105] Hepatotoxicity may be manifested by elevations in bilirubin, aminotransferases, and alkaline phosphatase concentrations.

Idiopathic intracranial hypertension, previously known as pseudotumor cerebri and benign intracranial hypertension, is characterized by elevated ICP in the absence of a focal lesion, infective process, or hydrocephalus. It occurs in patients with altered endocrine function, systemic diseases, impaired cerebral venous drainage, or ingestion of various xenobiotics, including excessive vitamin A[5] (Table 41-2). The syndrome is most common in young obese women, but the etiology remains unknown in the majority of cases. The first case of IIH associated with vitamin A toxicity was described in 1954.[66] However, the symptoms were first described in 1856 by an Arctic explorer who noted vertigo and headache after eating polar bear liver.[168] Patients typically present with headache and visual disturbances, including sixth nerve palsies, visual field deficits, and blurred vision, and have a normal mental status. Despite severe papilledema, visual loss often is minimal. However, blindness may result from optic atrophy.[118] Other symptoms of neurotoxicity include ataxia, fatigue, depression, irritability, and psychosis.[21]

TABLE 41-2. Drugs and Toxins Associated with Intracranial Hypertension

Isotretinoin is effective in the management of acne. However, its use is associated with teratogenecity. It is thought to interfere with cranial-neural-crest cells, which contribute to the development of both the ear and the conotruncal area of the heart and may cause malformed or absent external ears or auditory canals and conotruncal heart defects.[107] Although studies have not shown a teratogenic risk with topical preparations, case reports describe fetal malformations associated with their use during pregnancy.[11, 28, 97, 116, 167] In addition, mucocutaneous abnormalities, IIH, corneal opacities, hypercalcemia, hyperuricemia, musculoskeletal symptoms, liver function abnormalities, elevated triglyceride concentrations, and spontaneous abortion are reported.[3, 60, 65, 74, 75]

Treatment with tretinoin (all-*trans* -retinoic acid), followed by anthracycline and cytarabine, improves the complete remission rate and reduces the incidence of relapse in cases of acute promyelocytic leukemia.[54] Retinoic acid syndrome is the main adverse effect and may occur in up to 25% of patients who receive tretinoin without prophylactic measures. The syndrome is characterized by dyspnea, pulmonary effusions and infiltrates, fever, weight gain, renal failure, pericardial effusions, and hypotension.[53] Elevated leukocyte counts at diagnosis or rapidly increasing counts during tretinoin treatment predict the development of retinoic acid syndrome. Its etiology is thought to be related to cytokine release by maturing blast cells. Addition of dexamethasone to the treatment regimen decreases the incidence of this syndrome to approximately 15% and its mortality to 1%.[54]

Symptoms of an acute overdose often develop within hours to 2 days after ingestion.[132] Initial signs and symptoms include headache, papilledema, scotoma, photophobia, seizures, anorexia, drowsiness, irritability, nausea, vomiting, abdominal pain, liver damage, and desquamation.[132] Additional signs and symptoms are associated with chronic toxicity.[132] Nonspecific symptoms include fatigue, fever, weight loss, edema, polydipsia, dysuria, hyperlipidemia, anemia, and menstrual abnormalities.

Diagnostic Testing

An elevated serum vitamin A concentration is greater than 80 Âµg/dL. However, because the liver has a large storage capacity for excess vitamin A, hepatotoxicity may occur prior to an elevation in the serum concentration, which may be normal or even low, in the setting of an acute overdose. As the liver's storage capacity is overwhelmed, the serum concentration may rapidly rise in a nonlinear fashion. The diagnosis of vitamin A hepatotoxicity is supported by histologic evidence of Ito cell hyperplasia with fluorescent vacuoles on liver biopsy.[67] Laboratory testing should also include serum electrolytes, including calcium; liver function tests; and a complete blood cell count. Further evaluation should be guided by the clinical presentation and may include bone radiographs, computed tomography of the brain, and lumbar puncture.

Treatment

Management of an acute, large overdose should begin with gastrointestinal decontamination. This can be accomplished with a dose of activated charcoal. In extremely large overdoses that are expected to produce significant toxicity, gastric lavage may be considered. Although most signs and symptoms of hypervitaminosis A resolve within 1 week of vitamin A discontinuation and with supportive care, papilledema and skeletal abnormalities may persist for several

months. Visual impairment secondary to optic atrophy may be a permanent sequela of vitamin A toxicity. Hypercalcemia should be treated with IV fluids, loop diuretics, and prednisone 20 mg/d.[20] Bisphosphonates may be beneficial in refractory cases.

IIH may require more aggressive therapy, similar to that of other causes of increased ICP. Depending on the severity of the syndrome, patients may require dexamethasone (0.25â€“0.5 mg/kg/d in children <40 kg and 12â€“16 mg/d in adults); an initial adult dose of 250 mg acetazolamide, which can be increased to 500 mg 3 times per day; 40 mg IV furosemide; and 1 g/kg mannitol.[168] Tapering doses of hydrocortisone or prednisone are alternatives to dexamethasone. Acetazolamide decreases CSF formation but may be associated with a transient increase in ICP. Patients with extremely high ICP may benefit from daily lumbar punctures with CSF drainage.

Vitamin D

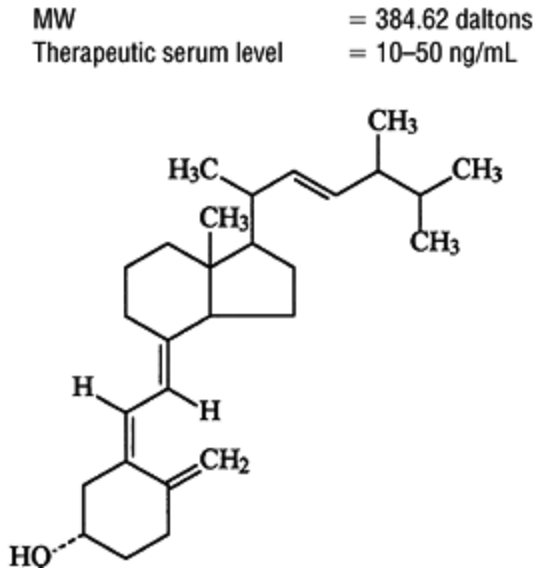

Figure. No Caption Available.

History and Epidemiology

Vitamin D is the name given to both cholecalciferol (vitamin D_2) and ergocalciferol (vitamin D_3). In humans, both forms of vitamin D have the same biologic potency. Vitamin D is used for the prophylaxis and treatment of rickets, osteomalacia, and osteoporosis, treatment of hypoparathyroidism, and skin conditions including psoriasis. Rickets, a disease of urban children living in temperate zones, was thought to result from the lack of a dietary factor or adequate sunshine. In 1919, two independent groups demonstrated that rickets could be prevented or cured by either the addition of cod liver oil to the diet or exposure to sunlight.[91 , 129] Vitamin D is found in other foods, including butter, cheese, and cream, which contain 12â€“50 IU/100 g; eggs, which contain 25 IU/100 g; and fatty fish, such as salmon and mackerel, which contain 150â€“550 IU/100 g and 1100 IU/g, respectively. Some foods typically are fortified with vitamin D, including cereals, bread, and milk.[84]

Vitamin D deficiency should not occur in individuals who are exposed to adequate sunlight and eat a well-balanced diet. Casual exposure of cutaneous tissues to ultraviolet light during the summer months should produce adequate vitamin D storage for winter months.[72] Total body sun exposure provides the vitamin D equivalent of 250 Âµg/d (10,000 IU/d).[185] The body only requires a total vitamin D supply of 100 Âµg/d (4000 IU/d).[185] Breast-fed infants may require supplemental vitamin D if they have limited exposure to sunlight because the vitamin D content of human milk is extremely low.[36] Other groups susceptible to vitamin D deficiency include the elderly, vegans, and persons without adequate sunlight exposure. The daily adequate intake of vitamin D is 5 Âµg/d (200 IU/d).[62] This dose approximates the vitamin D content of a half-teaspoon of cod liver oil.[145] These doses appear to prevent rickets and osteomalacia. However, larger doses may be required for treatment of osteoporosis or hypoparathyroidism.

Rickets has been eliminated as a major public health concern in children in Europe and North America since the fortification of milk with vitamin D. Outbreaks of vitamin D poisoning subsequently

occurred in Europe in the 1950s because of excessive fortification of milk and cereals to compensate for wartime nutritional deprivation of children.[42] This vitamin D poisoning led to a period of prohibition of vitamin D fortification of foods.[84] More recently, a study showed that milk and infant formulas rarely contain the amount of vitamin D stated on the label and may be either significantly underfortified or overfortified, leading to hypovitaminosis or hypervitaminosis D.[84] One case series demonstrated vitamin D toxicity in 8 patients who drank local dairy milk that was excessively fortified with vitamin D_3 .[95] Many cases of vitamin D toxicity are iatrogenic, resulting from oversupplementation of vitamin D and calcium given for treatment of hypoparathyroidism, osteoporosis, and osteomalacia without adequate patient followup.[39 , 111 , 147] Two reports describe vitamin D toxicity in families secondary to use of a highly concentrated vitamin D preparation in nut oil that was not intended for human consumption.[44 , 148] Another case report describes vitamin D poisoning secondary to contamination of table sugar with crystalline vitamin D_3 .[183] Vitamin D toxicity can occur secondary to vitamin D_3 exposure in the form of rodenticides (Chap. 104).

Pharmacology

Given adequate sunlight exposure, humans should not require exogenous sources of vitamin D because they can synthesize it in vivo. In addition, vitamin D itself is not biologically active but

must go through extensive metabolism to an active form, whether it is ingested from a food source or synthesized in the body. Vitamin D_3 is synthesized in the skin from 7-dehydrocholesterol (provitamin D_3) in a reaction catalyzed by ultraviolet B irradiation (Figure 41-2).[111] Vitamin D_3 then is bound to vitamin D-binding protein, a protein that also binds vitamin D from the diet, and afterward enters the circulation. In the endoplasmic reticulum of the liver, vitamin D_3 is metabolized to 25-hydroxyvitamin D [25(OH)D] by vitamin D-25-hydroxylase.[63] Once formed, 25(OH)D is again bound to vitamin D-

binding protein and transported to the proximal convoluted tubule in the kidney for hydroxylation to 1,25-dihydroxyvitamin D [1,25(OH)$_2$ D], or calcitriol, by 25(OH)D-1Î±-hydroxylase.[63] Once formed, 1,25(OH)$_2$ D is secreted back into circulation, bound to vitamin D-binding protein, and delivered to target cells where it binds to receptors.

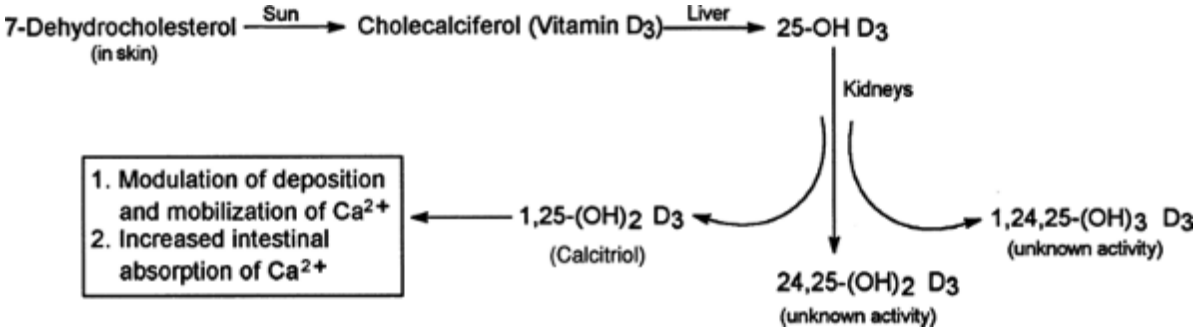

Figure 41-2. Schematic representation of the increased physiologic response to vitamin D resulting in increased calcium absorption and increased 25-hydroxyvitamin D.

Vitamin D might be more appropriately called a hormone rather than a vitamin because it is synthesized in the body, circulates in the blood, and then binds to receptors in order to evoke its biologic action. The primary role of vitamin D is regulation of calcium homeostasis via interactions with the intestines and bones. Protein-bound calcitriol is taken up by cells and then binds to a specific nuclear vitamin D receptor protein that, in turn, binds to regulatory sequences on chromosomal DNA.[111] The result is induction of gene transcription and translation of proteins that carry out the cellular functions of vitamin D. In the intestines, calcitriol increases the production of calcium-binding proteins and plasma membrane calcium pump proteins, thereby increasing calcium absorption through the duodenum.[98] In the bone, calcitriol stimulates osteoclastic precursors to differentiate into mature osteoclasts.[85] Mature osteoclasts, together with PTH, lead to mobilization of calcium stores from bone, thereby raising serum concentrations of calcium. Given sufficient serum concentrations of

calcium, calcitriol promotes bone mineralization by osteoblasts, resulting in increased deposition of calcium hydroxyapatite into the bone matrix.[85] Calcitriol also binds to a vitamin D receptor in the parathyroid glands, which leads to decreased synthesis and secretion of PTH.[137] The vitamin D receptor is actually present in most cells of the body.[161] Vitamin D receptors are found in lymphocytes, epidermal skin cells, and tumor cells. Binding of calcitriol can inhibit proliferation and induce terminal differentiation.[150] Although the role of vitamin D has not been elucidated in all cells, abnormalities present during vitamin D deficiency may help identify the function of vitamin D in various tissues.

Vitamin D deficiency results in hypocalcemia, leading to increased secretion of PTH, which acts to restore plasma calcium at the expense of bone. In children, this situation leads to rickets in which newly formed bone is not adequately mineralized and results in bone deformities and growth defects. Adults develop osteomalacia, a disease characterized by undermineralized bone matrix. Patients typically present with bone pain and tenderness and proximal muscle weakness. Bone deformities are limited to the advanced stages of disease.

Pathophysiology

The hallmark of vitamin D toxicity is hypercalcemia. Vitamin D in the form of $1,25(OH)_2$ D promotes calcium absorption from the gut and mobilization of calcium from bone. In hypervitaminosis D, the plasma concentration of 25(OH)D may be 20 times higher than normal, whereas the concentration of $1,25(OH)_2$ D remains normal, increased, or decreased.[63, 148] 25-Hydroxyvitamin D can mimic the action of $1,25(OH)_2$ D when it is present in excess and can bind to receptors usually specific for $1,25(OH)_2$ D.[63, 111] Alternatively, 25(OH)D, which has a higher affinity for vitamin D-binding protein compared to $1,25(OH)_2$ D, may preferentially bind to vitamin D-binding protein when it is present in elevated concentrations, displacing $1,25(OH)_2$ D

and allowing it to circulate in an unbound form, or loosely bound to albumin.[184] A study of patients with vitamin D toxicity who had normal or near-normal total $1,25(OH)_2$ D levels had elevated free $1,25(OH)_2$ D levels.[148] The availability of $1,25(OH)_2$ D to its receptors likely is increased, resulting in vitamin D toxicity.

The literature regarding the toxic dose of vitamin D varies, with little scientific data available for corroboration. The current â€œno observed adverse effect levelâ€• was conservatively set at 50 Âµg/d (2000 IU/d),[185] but this level did not take into account data showing that doses as high as 110 Âµg/d (4400 IU/d) and 2500 Âµg (100,000 IU) for 4 days did not result in adverse effects.[173, 180, 185] Case reports describe toxicity in the setting of vitamin D intake of 50,000â€“150,000 IU, or simply, doses in the milligram range, daily for prolonged periods.[39, 147]

Clinical Manifestations

Patients with vitamin D toxicity present with signs and symptoms characteristic of hypercalcemia.[111] Early manifestations include weakness, fatigue, somnolence, irritability, headache, dizziness,

muscle and bone pain, nausea, vomiting, abdominal cramps, and diarrhea or constipation. As the calcium concentration increases, hypercalcemia may induce polyuria and polydipsia. Diuresis results in salt and water depletion, further impairing calcium excretion. Severe hypercalcemia may present with ataxia, confusion, psychosis, seizure, coma, and renal failure. In addition, cardiac dysrhythmias result from a shortened refractory period and slowed conduction. ECG findings include increased PR intervals, widening of QRS complexes, QTc shortening, and flattened T waves.[139] Patients can develop metastatic calcification of the kidneys, blood vessels, myocardium, lung, and skin. Several patients with vitamin D toxicity have presented with anemia.[152, 163] Proposed mechanisms for anemia include a direct effect of vitamin D on hematopoietic cells and inhibition of

erythropoietin production.[152]

Diagnostic Testing

Hypervitaminosis D should be considered in patients presenting with signs and symptoms of hypercalcemia. Laboratory results may reveal hyperphosphatemia, given that vitamin D facilitates phosphate absorption in the small intestine, enhances its mobilization from bone, and decreases its excretion by the kidney.[124] The diagnosis should be suspected in children with nephrocalcinosis and hypercalcuria even if serum calcium and phosphorus concentrations are normal.[135]

Management

Treatment of hypercalcemia in patients with vitamin D toxicity should include discontinuation of vitamin D and calcium supplementation, maintenance of a low-calcium diet, and administration of adequate volumes of oral or IV fluid to increase calcium clearance.[111] Following rehydration, a loop diuretic can be added to promote calcium excretion.[111] Corticosteroids, in doses of hydrocortisone, 100 mg/d; or prednisone, 20 mg/d; improve hypercalcemia and hypercalcuria in vitamin D poisoning. Studies have attempted to explain this effect as being a result of either decreased intestinal calcium absorption or inhibition of bone resorption.[101, 176] Bisphosphonates, such as pamidronate and coldronate, have been used successfully in cases of severe hypercalcemia.[110, 156] These drugs inhibit bone resorption via actions on osteoclasts. Their use may preclude the need for hemodialysis in refractory cases of hypercalcemia. Calcitonin, a hypocalcemic hormone secreted by the thyroid gland that directly inhibits osteoclast activity, can be used to decrease bone resorption. Salmon calcitonin was successfully used to treat refractory hypercalcemia in a pediatric patient with vitamin D poisoning.[130]

Antioxidants (Vitamins E and C)

The antioxidants include vitamins E and C, and Î²-carotene. During the 1990s, the idea that antioxidants had a protective effect against atherosclerosis and carcinogenesis was widely promoted. This notion was based on the â€œoxidative-modification hypothesisâ€• of atherosclerosis, which proposes that atherogenesis is initiated by lipid peroxidation of LDLs.[43] Unregulated or prolonged production of cellular oxidants leading to oxidant-induced DNA damage is thought to be responsible for carcinogenesis.[104] Epidemiologic evidence seems to support the use of antioxidants for these indications.[106, 154, 172] However, several prospective, randomized, placebo-controlled clinical trials, designed to test for the effect of antioxidant vitamins on cardiovascular disease and cancer, have consistently shown that commonly used antioxidant regimens do not significantly reduce or prevent overall cardiovascular events or cancer.[26, 77, 81, 140, 178, 196]

Vitamin E

MW	= 430.69 daltons
Therapeutic serum level	= 0.5–2.0 mg/dL

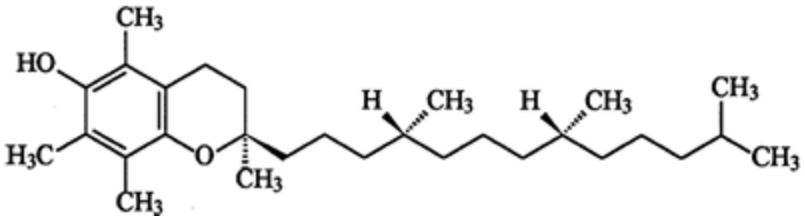

Figure. No Caption Available.

History

Vitamin E includes eight naturally occurring compounds in two classes, tocopherols and tocotrienols, which have differing biologic activities. The most biologically active form is RRR-Î±-tocopherol, previously known as d-Î±-tocopherol, which is the most widely

available form of vitamin E in food. Synthetic forms of vitamin E typically are composed of an approximately equal mixture of 8 stereoisomeric forms of Î±-tocopherol. The existence of vitamin E was first demonstrated in 1922.[50] Female rats deficient in a dietary principal were unable to sustain a pregnancy. Testicular lesions in male rats were described in deficiency states, and vitamin E was referred to as the â€œantisterility vitamin.â€•[122] Vitamin E was first isolated from wheat-germ oil in 1936.[49] The richest sources of vitamin E include nuts, wheat germ, whole grains, vegetable and seed oils, including soybean, corn, cottonseed, and safflower, and the products made from these oils. In general, animal products are poor sources of vitamin E.

Vitamin E deficiency occurs in patients with malabsorption syndromes, which may occur in the presence of pancreatic insufficiency or hepatobiliary disease, such as biliary atresia.[22] Patients with abetalipoproteinemia are at risk for vitamin E deficiency.[12] In this rare disease, absorption and transport of vitamin E are impaired secondary to a lack of chylomicron and Î²-lipoprotein formation. Manifestations of deficiency are variable but seem to have the most effect in organ systems that rely on vitamin E for normal functioning.[122] The clinical syndrome is primarily manifested by a peripheral neuropathy and spinocerebellar syndrome that improves with supplemental vitamin E.[131] Symptoms include ophthalmoplegia, hyporeflexia, gait disturbances, and decreased sensitivity to vibration and proprioception.[22]

Vitamin E is an essential nutrient. It is believed to be necessary for normal functioning of the nervous, reproductive, muscular, cardiovascular, and hematopoietic systems. Use of vitamin E has been proposed for a wide range of conditions. In most cases, scientific rationale for its use is lacking or is based on in vitro or animal data that have not been validated in humans or have demonstrated equivocal results.[22] As examples, vitamin E has been used for treatment of recurrent abortion, hemolytic anemias, claudication, wound healing, tardive dyskinesia, epilepsy, and adult respiratory

distress syndrome. In addition, much research over the past decade has focused

on the use of vitamin E for the prevention and treatment of cardiovascular disease and cancer, with disappointing results.[179]

Pharmacology

Vitamin E absorption is dependent on the ingestion and absorption of fat. The presence of bile also is essential. Vitamin E is passively absorbed in the intestinal tract into the lymphatic circulation by a nonsaturable process. Approximately 45% of a dose is absorbed in this manner and subsequently enters the bloodstream in chylomicrons, which are taken up by the liver. Vitamin E then is secreted back into the circulation, where it is primarily associated with LDLs. Vitamin E is distributed to all tissues, with the greatest accumulation in adipose tissue, liver, and muscle.

The primary biologic function of vitamin E is as an antioxidant. It prevents damage to biologic membranes by protecting polyunsaturated fats within membrane phospholipids from oxidation.[27] It accomplishes this task by preferentially binding to peroxyl radicals and forming the corresponding organic hydroperoxide and tocopheroxyl radical, which, in turn, interacts with other antioxidant compounds, such as ascorbic acid, thereby regenerating tocopherol. Vitamin E may be responsible for cell growth and proliferation by combating the inhibitory effects of lipid peroxidation.[131] Vitamin E may have a negative role in the regulation of cellular proliferation through its nonoxidant properties, such as inhibition of protein kinase C activity.[131]

Pathophysiology

In vitro studies demonstrate that vitamin E in high doses may have a prooxidant effect.[2, 25, 133] The prooxidant effect of vitamin E on

LDLs is related to the production of Î±-tocopheroxyl radicals, which normally are inhibited by other antioxidants such as vitamin C. High doses of vitamin E may displace other antioxidants, thereby disrupting the natural balance of the antioxidant system and increasing vulnerability to oxidative damage.[90] High doses of vitamin E may inhibit human cytosolic glutathione S-transferases, enzymes that are active in the detoxification of drugs and endogenous toxins.[182]

Clinical Manifestations

The RDA for vitamin E in adults is 15 mg/d Î±-tocopherol equivalents for men and women.[62] One IU is equivalent to 1 mg DL-Î±-tocopherol acetate. Human milk, in contrast to cow's milk, has sufficient Î±-tocopherol to meet the needs of breast-fed infants.[122] Supplementation should not be necessary in persons who consume a well-balanced diet. Large amounts of vitamin E, ranging from 400â€“800 IU/d for months to years, have been taken without apparent harm.[36] Vitamin E supplementation results in few obvious adverse effects, even at doses as high as 3200 mg/d.[17] In several species, the oral median lethal dose was 2 g/kg or more, and significant adverse effects were observed only when daily doses were >1 g/kg, equivalent to 200â€“500 mg/kg in humans.[132] However, a meta-analysis reveals that all-cause mortality may increase at doses â‰¥400 IU/d.[133]

Gastrointestinal symptoms, including nausea and gastric distress, were reported in patients who had received vitamin E 2000â€“2500 IU/d.[82 , 192] Diarrhea and abdominal cramps were reported in patients who received a dose of 3200 IU/d.[9] Reports of other adverse effects, including fatigue, weakness, emotional changes, thrombophlebitis, increased serum creatinine concentration, and decreased thyroid hormone concentrations, have not been reproduced in other case series or clinical trials.[132]

The most significant toxic effect of vitamin E, at doses exceeding 1000 IU/d, is its ability to antagonize the effects of vitamin K.[36]

Vitamin E appears to increase the epoxidation of vitamin K to its inactive form, thereby increasing the vitamin K requirement several-fold.[17 , 186] Although high oral doses of vitamin E typically do not produce a coagulopathy in normal humans with adequate vitamin K stores, coagulopathy may develop in vitamin K-deficient patients or those taking warfarin.[17 , 35 , 52 , 186] Animal studies demonstrate that absorption of both vitamins A and K is impaired by large doses of vitamin E.[22 , 157]

Use of an IV vitamin E preparation (E-Ferol) was associated with a severe epidemic of unexplained thrombocytopenia, renal dysfunction, hepatomegaly, cholestasis, ascites, hypotension, and metabolic acidosis in low-birth-weight infants in several neonatal intensive care units in the early 1980s.[24] Use of polysorbate 20 and polysorbate 80 for emulsification of lipids and fat-soluble vitamins in this IV vitamin E product was implicated as the cause of this syndrome, rather than vitamin E. The product was removed from the market and the syndrome disappeared. No cases developed with oral administration of vitamin E.

Vitamin C

MW = 176.12 daltons
Therapeutic serum level = 0.4–2.0 mg/dL

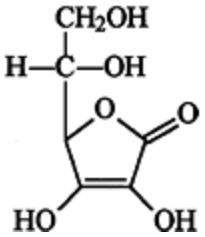

Figure. No Caption Available.

History

Vitamin C, also known as *ascorbic acid* , is ingested in the form of vitamin supplements by 35% of the US population.[175] Approximately 91% of all people using vitamin supplements take vitamin C, making it the most widely consumed nutrient within this group of people.[36] Vitamin C has long been used as a â€œcureâ€• for the common cold. Interestingly, an extensive review of 14 studies of the role of vitamin C in the treatment of the common cold suggested that only 8 were valid investigations, and none of the studies demonstrated any therapeutic benefit.[29] Its function as an antioxidant has led to its use for the prevention and treatment of cardiovascular disease and cancer. Unfortunately, human data from clinical trials have failed to demonstrate that vitamin C significantly reduces or prevents overall cardiovascular events or cancer. Vitamin C may have a role as a reducing agent in the treatment of idiopathic methemoglobinemia. However, it is less effective than standard treatment with methylene blue and therefore not employed.[123] Vitamin C is popularly used to promote wound healing, treat cataracts, combat chronic degenerative diseases, counteract the effects of aging, and increase mental attentiveness and decrease stress.[36 , 132] However, little, if any, objective data demonstrate a benefit of treatment for many of these indications.[36]

Vitamin C has long been associated with prevention of scurvy.[123] In 1747, James Lind, a physician in the British Royal Navy, analyzed the relationship between diet and scurvy and confirmed the protective and curative effects of citrus fruits. Vitamin C was isolated from cabbage in 1928 and subsequently shown in 1932 to be the active antiscorbutic factor in lemon juice. It was given the name *ascorbic acid* to indicate its role in preventing scurvy. Other dietary sources of vitamin C include tomatoes, strawberries, and potatoes. Today, those at risk for developing scurvy include the elderly, alcoholics, chronic drug users, and others with inadequate diets, including infants fed formula diets with insufficient concentrations of vitamin C.[123] Symptoms include gingivitis, poor wound healing, bleeding, and

petechiae and ecchymoses. Musculoskeletal symptoms, consisting of arthralgia, myalgia, hemarthrosis, and muscular hematomas, develop in 80% of cases.[51] Children experience severe pain in their lower limbs secondary to subperiosteal bleeding.[51]

Pharmacology and Toxicokinetics

Following ingestion, intestinal absorption of vitamin C occurs via an active transport system that is saturable.[155] The absorptive capacity is reached with oral ingestions of approximately 3 g/d. When given as a single oral dose, absorption decreases from 75% at 1 g to 20% at 5 g. Vitamin C is distributed from the plasma to all cells in the body. Tissue uptake is also a saturable process.[132] Metabolic degradation of vitamin C to oxalate accounts for 30â€“40% of oxalate excreted daily.[73] Because metabolic conversion is saturable, large ingestions of vitamin C do not significantly increase oxalate production.[166] Only a small amount of vitamin C is filtered through the glomeruli, and tubular resorption, a saturable process that may compete with uric acid, usually is almost complete.[19] Plasma concentrations of vitamin C typically are maintained at approximately 1 mg/dL. The kidney efficiently eliminates excess vitamin C as unchanged ascorbic acid.

Vitamin C is a cofactor in several hydroxylation and amidation reactions by functioning as a reducing agent.[113 , 114] As a result, vitamin C plays an important role in the synthesis of collagen, carnitine, folinic acid, and norepinephrine. It also influences the processing of hormones such as oxytocin, antidiuretic hormone, and cholecystokinin. Vitamin C reduces iron from the ferric to the ferrous state in the stomach, thereby increasing intestinal absorption of iron. Vitamin C may be involved in steroidogenesis in the adrenals. Vitamin C also has a prooxidant effect in vivo.[149] This effect is not believed to occur at doses <500 mg/d but may occur in the setting of overdose.

Clinical Manifestations

The RDA for vitamin C in adults is 90 mg/d for men and 75 mg/d for women.[62] Vitamin C in the form of dietary supplements is commonly taken in doses of 500 mg/d. Higher doses are fairly well tolerated because excess vitamin C is not absorbed and does not undergo metabolic degradation to oxalate to a significant extent. Therefore, the possibility of oxalate nephrolithiasis should not be a significant clinical concern.[65] Reports of high urine oxalate concentrations likely were erroneous because of conversion of ascorbate to oxalate in alkaline urine samples left standing after collection.[189] Individual case reports documenting the presence of oxalate stones in the setting of vitamin C overdose have involved either IV administration or patients with chronic renal failure.[13, 64, 109, 125, 132, 177] A prospective study on the risk of kidney stones in men did not support an association between high daily vitamin C intake and stone formation.[37] Gastrointestinal tract effects of high doses of vitamin C may include localized esophagitis, given prolonged mucosal contact with ascorbic acid, and an osmotic diarrhea.[88, 188]

Vitamin B_6

MW = 169 daltons
Therapeutic serum level = 3.6–18 ng/mL

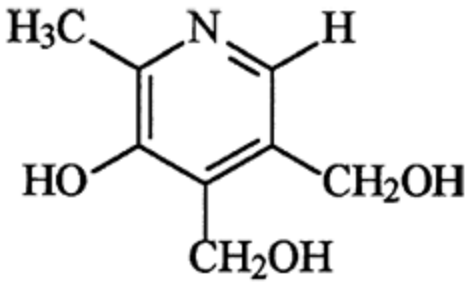

Figure. No Caption Available.

History

Pyridoxine, pyridoxal, and pyridoxamine are related compounds that have the same physiologic properties. Although all three compounds are included in the term vitamin B_6 , the vitamin has been assigned the name *pyridoxine* . This vitamin was discovered in 1936 as the water-soluble factor whose deficiency was responsible for the development of dermatitis in rats.[123] In humans, deficiency is characterized by a seborrheic dermatitis around the eyes, nose, and mouth, cheilosis, stomatitis, glossitis, and blepharitis.[170] More importantly, pyridoxine deficiency is associated with seizures.

Pyridoxine is found in several foods, including meat, liver, whole-grain breads and cereals, soybeans, and vegetables.[123] The RDA for adults is 1.3 mg/d, and 1.7 mg/d for men >50 years and 1.5 mg/d for women >50 years.[62] Deficiency should not occur in humans who eat a well-balanced diet.[170]

Pyridoxine is popularly used as a component of bodybuilding regimens and for treatment of premenstrual syndrome and carpal tunnel syndrome.[1 , 47] High doses have been used for treatment of schizophrenia and autism with variable results.[57 , 112]

Pharmacology

All forms of vitamin B_6 are well absorbed from the intestinal tract. Pyridoxine is rapidly metabolized to pyridoxal, pyridoxal phosphate (PLP), and 4-pyridoxic acid.[197] PLP accounts for approximately 60% of circulating vitamin B_6 and is the primary form that crosses cell membranes.[123] Most vitamin B_6 is renally excreted as 4-pyridoxic acid, with only 7% excreted unchanged in the urine.[123 , 197] Experiments in anephric rats demonstrate an up to 10-fold increase in susceptibility to pyridoxine-induced neurotoxicity, suggesting a need for caution when prescribing pyridoxine to patients with renal failure.[115]

PLP is the active form of vitamin B_6 . It is a coenzyme required for the synthesis of Î³-aminobutyric acid (GABA), an inhibitory

neurotransmitter. Decreased GABA formation in the setting of pyridoxine deficiency may contribute to seizures.[123] Isoniazid and other hydrazines inhibit the enzyme responsible for conversion of pyridoxine to PLP.[86] Therefore, pyridoxine should be administered concomitantly with isoniazid. Seizures resulting from isoniazid overdose often are successfully treated with pyridoxine (Antidotes in Depth: Pyridoxine).

Pathophysiology

Interestingly, pyridoxine toxicity is also characterized by neurologic symptoms. The pathophysiology of pyridoxine neurotoxicity is not well defined. However, studies indicate that the mammalian peripheral sensory nervous system is vulnerable to large doses of pyridoxine.[164] Histopathology in dogs reveals sensory distal axonopathy with relative sparing of the cell body.[87] Peripheral sensory nerves may be particularly vulnerable to circulating toxins because of the permeability of their associated blood vessels.[164] Compared to the CNS, these nerves lack the bloodâ€“brain barrier. In addition, the nerves of the CNS may be relatively shielded from pyridoxine toxicity because pyridoxine is transported into the CNS by a saturable mechanism.[164]

Clinical Manifestations

Chronic overdoses of pyridoxine are associated with progressive sensory ataxia and severe distal impairment of proprioception and vibratory sensation. Touch, pain, and temperature sensation may be minimally impaired, and reflexes may be diminished or absent. These findings were first described in 1983 in a case series of 7 patients who were taking pyridoxine 2â€“6 g/d for 2â€“40 months.[164] Nerve conduction and somatosensory studies in these patients showed dysfunction in the distal sensory peripheral nerves. Nerve biopsy showed widespread, nonspecific axonal degeneration. This syndrome

has since been reported with pyridoxine doses as low as 200 mg/d.[146] In most cases, symptoms gradually improve over several months with abstinence from pyridoxine. However, symptoms may still progress for 2â€“3 weeks after pyridoxine discontinuation.[18]

Acute neurotoxicity may occur when a massive amount of pyridoxine is administered as a single dose or given over a few days.[4] Large overdoses of pyridoxine are associated with incoordination, ataxia, seizures, and death.[181] Administration of IV pyridoxine 2 g/kg in 2 patients resulted in permanent dorsal root and sensory ganglia deficits.[4]

Nicotinic Acid

MW	= 123 daltons
Therapeutic levels	= ?

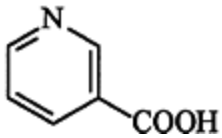

Figure. No Caption Available.

History

Nicotinic acid, or niacin, was discovered to be an essential dietary component in the early 1900s.[68] A deficiency of this vitamin, also known as vitamin B_3 , causes pellagra, which is characterized by dermatitis, diarrhea, and dementia. This disease had been prevalent for centuries in countries that heavily relied on maize as a dietary staple. It was determined that pellagra could be prevented by increasing dietary intake of fresh eggs, milk, and fresh meat, including liver.[123] Other food sources of nicotinic acid include fish, poultry, nuts, legumes, and whole-grain and enriched breads and cereals. Supplementation of flour with nicotinic acid in 1939 probably is responsible for the near eradication of this disease in the United

States. Chronic alcohol users are known to still get pellagra, likely secondary to malnutrition. The RDA of niacin is 16 mg/d for men and 14 mg/d for women.[62]

Niacin was introduced as a treatment for hyperlipidemia in 1955.[7] Nicotinic acid reduces triglyceride synthesis, with a resultant drop in very-low-density lipoprotein cholesterol and LDL cholesterol and a rise in high-density-lipoprotein cholesterol.[68] Therapy usually is started with single doses of 100â€“250 mg. Frequency of dose and total daily dose are gradually increased until a dose of 1.5â€“2.0 g/d is reached. If the LDL cholesterol concentration is not sufficiently decreased with this dosing regimen, the dose is further increased to a total dose of 3.0 g/d. These doses of niacin are 100-fold higher than the amount necessary to meet adult nutritional needs.[153]

Pharmacology and Toxicokinetics

Nicotinic acid is well absorbed from the intestinal tract and is distributed to all tissues. With therapeutic dosing, little unchanged vitamin is excreted in the urine. When extremely high doses are ingested, the unchanged vitamin is the major urinary component. Nicotinic acid ultimately is converted to nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADPH), which are the physiologically active forms of this vitamin. NAD and NADPH act as coenzymes for proteins that catalyze oxidation-reduction reactions that are essential for tissue respiration.[123]

Clinical Manifestations

The most common adverse effects associated with niacin use are vasodilatory side effects, which include cutaneous flushing and pruritus. These symptoms are mediated by prostaglandins and may occur at doses of 0.5â€“1.0 g/d.[127] Flushing occurs because of the predilection for the skin as a source of prostaglandin D_2 production

after niacin ingestion.[174] A single dose of aspirin taken 30 minutes before ingestion of niacin diminishes flushing.[194] Vasodilatory side effects have been noted in up to 100% of patients, particularly when given an immediate-release form of niacin.[127] Although tolerance to flushing usually develops over several weeks, 25% of patients discontinue niacin use because of vasodilatory symptoms.[127, 153]

Because rapid absorption of niacin seems to be related to development of flushing, time-release preparations of niacin were developed. Unfortunately, these preparations are more likely to produce gastrointestinal side effects, such as epigastric distress, nausea, and diarrhea.[127] In addition, niacin-induced hepatotoxicity occurs more frequently and is more severe in patients treated with modified-release niacin rather than immediate-release niacin.[32, 153] Elevated liver enzyme concentrations may occur with doses as low as 1 g/d, whereas symptoms of hepatic dysfunction occur at doses of 2â€“3 g/d.[127] These patients may have elevated serum bilirubin and ammonia concentrations and a prolonged prothrombin time. They may present with fatigue, anorexia, nausea, vomiting, and jaundice. In most cases, liver function improves following niacin withdrawal.[48, 127] Severe cases have progressed to fulminant hepatic failure and hepatic encephalopathy.[33, 83, 136] Niacin also causes amblyopia, hyperglycemia, hyperuricemia, coagulopathy, myopathy, and hyperpigmentation.[80]

Summary

Healthy adults consuming a well-balanced diet do not require vitamin supplementation. However, vitamins are popularly believed to be a panacea and are commonly taken in megadoses. Because the therapeutic index is large, toxicity generally does not develop unless very large doses are taken for sustained periods. Physicians should consider hypervitaminosis in the differential diagnosis when patients present with symptomatology consistent with a vitamin toxicity

syndrome. A thorough history, with emphasis on diet and prescribed and supplemental vitamin use, is important.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 42
Essential Oils

S. Eliza Halcomb

A 2-year-old boy presented to the emergency department with altered mental status. His mother reported that the boy had developed a low-grade fever earlier that evening. He was given a bath and some ibuprofen. After the bath, the boy's grandmother rubbed him down with a â€œgenerousâ€• amount of eucalyptus oil. The child liked the smell and licked his arms. Shortly thereafter, he became lethargic and had a seizure.

Upon presentation to the emergency department, the child was sleepy but arousable. His vital signs and results of physical examination, laboratory studies, and head CT were all normal. He was hospitalized for observation overnight and had no further seizure activity. He was discharged home the next day with no further sequelae.

History and Epidemiology

â€œWhat got you in trouble?â€• says the

baldhead to t'other.

â€œWell I'd been selling an article to take the tartar off the teethâ€”and it does take it off, too, and generly the enamel along with itâ€¦â€•

--Mark Twain,[74]; Huckleberry Finn

Essential oils are a class of polyaromatic hydrocarbons extracted through steam distillation or cold pressed from the leaves, flowers, bark, wood, fruit, or peel of a single parent plant. These organic compounds are a complex mixture of chemicals with structures that give the oil its aroma, therapeutic properties, and occasionally cause toxicity. More than 500 oils exist and can be categorized into five chemical groups: terpenes, quinines, substituted benzenes, aromatic/aliphatic esters, and phenols and aromatic/aliphatic alcohols.

Use of plant-derived essential oils in the practice of herbal medicine has a long and colorful history, dating back thousands of years. The virtues of these extracts have been mentioned in ancient Egyptian and Greek medical literature and throughout the Bible.

Essential oils were used to treat everything from asthma to snakebites until the early 20th century. In America â€œIndian doctorsâ€• frequently sold these products, claiming they learned medicinal secrets from local Native American tribes. These remedies were advertised at medicine shows and demonstrated by troupes such as the famous Kickapoo Indian Medicine Company. The purpose of these traveling caravans was to sell patent medicines, which typically contained substantial quantities of ethanol, in addition to other substances of uncertain therapeutic value. A bottle of Kickapoo Oil sold at the beginning of the 20th century purportedly contained â€œcamphor, ether, capsicum, oil of cloves, oil of sassafras and myrrh.â€• Needless to say, many patients did rather poorly with the administration of these tonics,

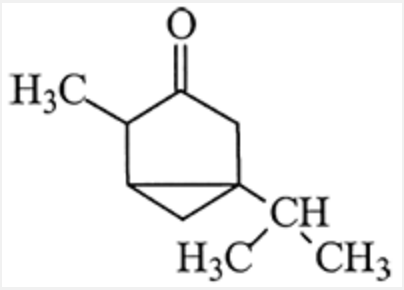
and the â€œdoctorsâ€• who sold them quite rightly earned a reputation for quackery.[76]

With the ascent of scientific research, many essential oil remedies fell from use. More recently, trends in globalization and natural healing have led to a popular resurgence in the use of essential oils in developed countries. Essential oils currently are marketed for use in aromatherapy and certain complementary medicines. The reintroduction of these agents into mainstream society has highlighted the need for research and toxicity studies to ensure that appropriate decision making and care can be provided to exposed patients.

Absinthe; Oil of Wormwood

History

Absinthe is an emerald green liqueur made from the extract of the wormwood plant *Artemisia absinthium.* The earliest references to wormwood date to 1500 B.C., when its antihelminthic properties were described. It is thought that Napoleon's soldiers popularized the drink upon their return from Algeria, where they had added wormwood extract to their wine to avoid helminthic infections during the war.[35]



Thujone

Absinthe reached its pinnacle of popularity by the late 19th century in Europe. Famous artists and authors, including Lautrec, Van Gogh, Baudelaire, Wilde, and Hemingway, sat for hours in the cafes of Paris, drinking the green liqueur and romanticizing its aphrodisiac effects. However, recognition of the devastating side effects led the French, Swiss, and American governments to ban its sale by the early 1900s.[35] Absinthe is still sold in its dethujonized form, Pernod.

Many people have speculated on the cause of Vincent Van Gogh's bizarre behavior. Some have concluded that his fondness for absinthe may have contributed to his seizures and psychotic episodes.

Toxicokinetics

The toxic component in oil of wormwood is thujone, a monoterpene ketone, which exists in Î±- and Î²-diastereoisomeric forms.[34] After oral absorption, both isomers undergo species-specific hydroxylation reactions by the cytochrome P450 system,

followed by glucuronidation in the hepatocyte, leading to production of several renally eliminated nontoxic metabolites.[34]

Pathophysiology

The Î±-stereoisomer is generally accepted to be the more toxic of the two isomers and the parent compound antagonizes the Î³-aminobutyric acid $(GABA)_A$ receptor at the picrotoxin site on the chloride channel, leading to neuroexcitation that may manifest as hallucinations or seizure activity, presumably in a dose dependent fashion.[34] Interestingly, ethanol enhances GABA activity and may have a protective effect by reducing seizure activity in mice.[34]

Thujones are implicated in the development of porphyrialike syndromes by inducing the synthesis of 5-aminolevulinic acid synthetase, leading to increased porphyrin production. This finding suggests that individuals with defects in heme synthesis may unmask a porphyrialike syndrome upon ingestion of thujones.[10]

Clinical Features

Case reports of toxicity reflect a recent resurgence in the popularity of the absinthe liquor, which has reappeared on the market in several European countries and is available on the Internet. Clinical features of acute toxicity are similar to those of ethanol intoxication, including euphoria and confusion, which may progress to restlessness, visual hallucinations, and delirium. Chronic abusers may suffer from seizures, hallucinations, and erratic behavior.[4]

Rhabdomyolysis and acute renal failure have occurred following ingestion of oil of wormwood intended for preparation as absinthe.[80] The etiology of the rhabdomyolysis has not been elucidated.[80]

Camphor

History

One of the first western references to camphor is found in Marco Polo's description of his travels.[26] Camphor was traded widely throughout Asia. Historically it was used as a rubefacient, antiseptic, decongestant, and moth repellent. It gained immense popularity as a liniment during the American Civil War, and the US government signed a contract with China to buy the entire camphor output of Formosa (Taiwan).

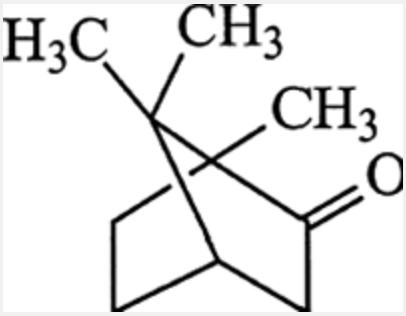


Figure. No Caption Available.

The French introduced camphor to Europe in 1879.[24] Vincent Van Gogh's epileptiform illness may have been exacerbated by his continuous exposure to camphor. Camphor belongs to the terpene family and is capable of causing central nervous system (CNS) toxicity.[35] Camphor oil is extracted from an evergreen tree from the Laurel family *Cinnamomum camphora*,[17] which is native to eastern China, Japan, and Taiwan. It is primarily used today in nasal decongestant ointments such as Vicks Vapo-Rub, although in the recent past it was widely used in moth repellents (Chap. 99).

Toxicokinetics

Camphor is a monoterpene ketone, which is rapidly absorbed from the gastrointestinal (GI) tract and then undergoes extensive first-pass metabolism. After hydroxylation and glucuronidation in the liver, its inactive metabolites undergo urinary excretion.[59,71]

Pathophysiology

Camphor toxicity is reported after its ingestion, inhalation, and nasal administration. It is rapidly absorbed from the GI tract or through mucous membranes. Camphor is highly lipid soluble and readily crosses the bloodâ€“brain barrier and placenta. Seizure activity is common postingestion, although the specific mechanism of action is not elucidated. Cellular respiration is inhibited by camphor and similar compounds, resulting in increased excitability of neuronal tissue.[63] Other studies suggest that camphor binds noncompetitively to nicotinic acetylcholine receptors, inhibiting an intracellular influx of calcium and sodium, although the investigations fail to explain how this process would be epileptogenic.[55]

Children seem particularly prone to hepatotoxicity because of the relative immaturity of their hepatic enzyme systems, and they may develop hepatotoxicity resembling Reye syndrome.[37] The fetus is thought to be susceptible to toxicity through the same mechanism. Several cases of camphor use as an abortifacient and a single case of fetal demise after ingestion are reported.[58,81]

Clinical Features

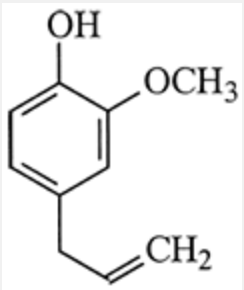
Camphor ingestion results in rapid onset of nausea and vomiting, followed by headache, agitation, and seizure activity.[16] Symptom onset usually occurs within minutes of ingestion. Seizures can occur in isolation without antecedent gastrointestinal effects.[5] Inhalational and dermal exposures typically result in local

irritation.

Oil of Clove

History

Cloves once were considered one of the world's most important commodities second only to nutmeg in Medieval and Renaissance Europe. Clove oil is extracted from the plant *Syzygium aromaticum*, also known as *Eugenia aromatica.* This evergreen plant is native to the islands of the Malaccan Straits. Its unopened buds, when dried, are known as cloves. Eugenol, the main constituent of clove oil, has been used for centuries as a remedy for toothache and in multiple dental products.[8]



Eugenol

Toxicokinetics

Eugenol, a phenol, is the principal component of clove oil. Very little available data on the metabolism of eugenol is available. An in vitro study found that incubation of isolated rat hepatocytes

with eugenol resulted in a glucuronic acid conjugate, although other conjugates with sulfate and glutathione were found.[69]

Pathophysiology

Little is known about the pathophysiology of eugenol toxicity. Intravenous infusion and intratracheal instillation

of eugenol in rats has led to the development of hemorrhagic pulmonary edema, which is thought to result from oxidative damage.[42,83]

In vitro studies of hepatic cell cultures incubated with eugenol demonstrated marked glutathione depletion, covalent bonding of conjugates to cell proteins, and cell death. These findings indicate that a reactive intermediate might be formed, leading to toxicity.[69]

Nerve conduction studies performed with frog sciatic nerves demonstrated that eugenol blocked impulse conduction irreversibly. Eugenol has been demonstrated to inhibit peripheral sensory nerve conduction at low doses, but has been associated with CNS manifestations at higher doses.[40]

Clinical Features

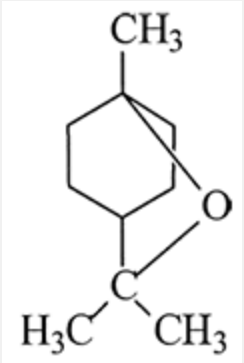
A case report on the neurotoxicity of eugenol described a 24-year-old woman who spilled a small amount of clove oil on her face in an attempt to relieve a toothache. The topical spillage resulted in permanent infraorbital anesthesia and anhidrosis.[36] Likewise, inhibition of the pharyngeal reflex by inhalation of clove cigarettes has been reported to cause aspiration pneumonitis.[30]

Inadvertent oral administration of 1â€“2 teaspoons of clove oil resulted in marked CNS depression, metabolic acidosis, and elevation of aminotransferases in 2 children.[32,41]

Oil of Eucalyptus

History

The eucalyptus tree is native to Australia. Its extracts were historically used as an aboriginal fever remedy. In 1778, the Surgeon-General of the First Fleet arrived in Australia and noted that these unusual trees produced a gumlike resin, which he distilled into a quart of oil and sent back to England for further examination. The introduction of eucalyptus oil to the west led to an increased demand for the product to relieve the symptoms of the common cold and influenza. Eucalyptol is found in many nonprescription cough preparations and is widely used for treatment of upper respiratory infections because of its purported antiinflammatory effects.[38] Although oral administration of eucalyptol-containing products rarely causes toxicity, ingestion of eucalyptus oil has resulted in morbidity and mortality.



Eucalyptol

Toxicokinetics

Eucalyptus oil contains up to 70% eucalyptol, a monocyclic terpene compound with an ether bridge between carbons 1 and 8. Eucalyptol, also known as 1,8 cineole, is rapidly absorbed from the gastrointestinal tract. It undergoes oxidation in the liver to form hydroxycineole, and subsequently undergoes further glucuronidation and excretion.[79] In rats, the main urinary metabolites have been characterized as 2-hydroxycineole, 3-hydroxycineole, and 1,8-dihydroxycineol-9-oic acids.[45] Rabbits excrete 2-exo-hydroxycineole and 2-endo-hydroxycineole, as well as 3-exo-hydroxycineole and 3-endo-hydroxycineole, in the urine after oral administration of eucalyptol.[51]

The lowest lethal doses reported are 4â€“5 mL[46] in adults and 1.9 g eucalyptus oil in a 10-year-old boy.[52] However, ingestion of higher doses in another case series caused less severe effects.[78] Ingestion of <1 teaspoon (5 mL) of eucalyptus oil has resulted in severe toxicity.[1,6,23]

Pathophysiology

The mechanism of toxicity is unclear because little toxicity seems to be associated with eucalyptol.[20]

Clinical Features

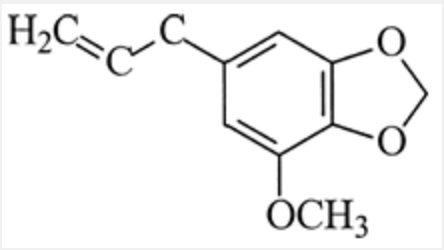
Symptoms develop rapidly and include headache and lightheadedness progressing to CNS depression. Serious poisoning is marked by respiratory depression and vomiting, which heighten the risk of aspiration.[62,70]

Oil of Nutmeg

History

During the Middle Ages, spices were prized for their medicinal and preservative qualities. Chief among these spices was nutmeg,

which, after silver and gold, was the most valued commodity in the western world. In addition to its soporific and emetic properties, nutmeg was purported to be a prophylactic against the plague. Nutmeg has been used unsuccessfully as an abortifacient and abused as a hallucinogen.



Myristicin

In 1510, a European explorer named Ludovico de Varthema described seeing the nutmeg tree flourishing in the Indonesian archipelago on the Bandas Islands, which was the only place on Earth that the spice could be found. This discovery spawned a gold rush of sorts, with intense competition among the great navies of Europe to dominate the spice trade.[61]

Toxicokinetics

Nutmeg oil is extracted from the fruit of the evergreen tree *Myristica fragrans.* Its main active ingredient is thought to be myristicin, although other putative toxins derived from the extraction process include mace, eugenol, and other terpenes.[57] Case reports of toxicity suggest that patients become symptomatic 3â€“6 hours after ingestion of 1â€“3 whole nuts or 1â€“2

tablespoons of ground nutmeg. Myristicin is oxidized in the hepatic P450 system to 5-allyl-1-methoxy-2,3-dihydroxybenzene,[84] which then undergoes glucuronidation and urinary excretion.

Pathophysiology

Animal studies have suggested that myristicin-induced CNS toxicity may result from increased serotonin concentrations in the brain.[72] Myristicin has been shown to inhibit monoamine oxidase,[73] which theoretically could lead to an adverse reaction if combined with another monoamine oxidase inhibitor. Another in vitro experiment showed that myristicin was converted to the amphetamine derivative 3-methoxy-4,5-methylene dioxyamphetamine,[12] which may explain its euphoric effects. Other animal studies have demonstrated fatty degeneration of the liver.[77]

Clinical Features

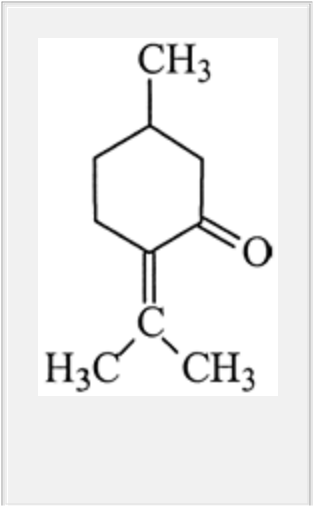
CNS effects tend to be the predominant clinical features of nutmeg poisoning. Nutmeg toxicity may mimic anticholinergic toxicity, with flushing, dryness, tachycardia, hypertension, agitation and altered mental status.[56] One feature that may help differentiate anticholinergic toxicity from nutmeg ingestion is that the pupils often are small.

Escalating doses result in increasing drowsiness that may progress to coma. Abdominal pain is frequently reported, but nausea and vomiting are uncommon. The toxic syndrome typically resolves within 24 hours, although resolution may be delayed.[28] A single fatality is reported in the literature.[19]

Oil of Pennyroyal

History

References to pennyroyal oil date back to antiquity when Pliny the Elder wrote about its insect repellent effects in book 20 of his masterpiece *The Natural History.* Its scientific name *Mentha pulegium* is derived from the Latin *pulex*, which means flea. Both the fresh plant and smoke from the burning leaves were used as early insect repellents. Over the centuries this essential oil also developed a reputation for being an abortifacient and an emmenagogue.[11] The 16th-century English herbalist Gerard noted, â€œPennie Royall boiled in wine and drunken, provoketh the monthly terms, bringeth forth the secondine, the deade childe and unnatural birth.â€• [18] An early American 19th-century pamphlet recommended a recipe that included drinking a pint of pennyroyal water to induce abortion.[67] The toxic effects of pennyroyal were first described in a case report to *The Lancet* in 1897.[2] Today, Internet searches for pennyroyal oil lead to multiple web sites where women relate their experiences with the substance for inducing abortion. The Seattle-based grunge band Nirvana, whose lead singer wrote the song â€œPennyroyal Teaâ€• for the aptly titled album In Utero, immortalized the oil with the following lyrics:



Pulegone

Sit and drink pennyroyal tea

Distill the life inside me.

Toxicokinetics

The active ingredient in pennyroyal oil is R-(+)-pulegone, a monoterpene commonly found in mint oils. Toxicity predominately results from ingestion of pennyroyal for the purposes of inducing abortion, although cases of oil administration to children with gastrointestinal complaints are reported.[7] Toxicity is noted in mice when 300â€“500 mg/kg is administered, and a human fatality was reported at an approximate dose of 500 mg/kg.

After ingestion, pulegone is metabolized by the P450 system in the liver to methofuran and other reactive metabolites, which in turn are excreted in the urine.

Pathophysiology

The reactive metabolites of pulegone bind to cell proteins, disrupting normal cellular function and resulting in significant cellular damage.[3] Methofuran also appears to be associated with pennyroyal-induced pulmonary toxicity, which is manifested as bronchiolar necrosis.[27]

Electrophilic reactive metabolites of pulegone deplete hepatic glutathione concentrations by reacting with the nucleophilic cysteinyl sulfhydryl group on glutathione, further worsening hepatotoxicity.[68] This hepatotoxicity is manifested as centrilobular necrosis, which occurs in both mouse and human specimens.[27]

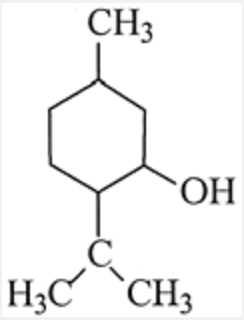
Clinical Features

Case reports in the literature describe a variety of symptoms after ingestion of pennyroyal oil. The most common symptoms of significant toxicity seem to include abdominal discomfort, nausea, vomiting, dizziness, syncope, and coma. Ingestion of 5â€“10 mL has been associated with coma and seizure activity, and ingestion of 15 mL may cause death.[3,7,65] Early symptoms are manifested by gastrointestinal and CNS toxicity,[7] followed by the development of hepatic and renal dysfunction.[65,75] In fatal ingestions, patients have developed disseminated intravascular coagulation and hepatic failure manifested as purpuric rash, epistaxis, vaginal bleeding, and oozing at venipuncture sites.[3,65,75]

Oil of Peppermint

History

Plants in the mint family have been used as medicinal herbs for centuries. One of the first known references to the medicinal qualities of mint comes from the Ebers Papyrus, an ancient Egyptian pharmacopoeia dating back to 1552 B.C. In this document, mint is mentioned as one of the recommended remedies for indigestion and nausea. According to ancient Greek mythology, Hades, the god of the underworld, fell in love with the beautiful nymph Minthe. The affair was short-lived, however, as Hades' jealous wife Persephone turned Minthe into a plant. Hades tempered the curse on the nymph by making the plant fragrant. Peppermint oil is extracted from the plant *Mentha piperita* and is widely used in flavorings and aromatherapy.



Menthol

Toxicokinetics

Menthol, the active ingredient in peppermint oil, is a cyclic terpene alcohol that is rapidly absorbed from the GI tract when ingested. In the liver, menthol undergoes hydroxylation to form *p*-menthane-3,8-diol and 3,8-dihydroxy-*p*-menthane-7-carboxylic acid by the P450 microsomal enzyme system. These metabolites subsequently are glucuronidated by UDP (uridine diphosphate)-glucuronyl transferase and excreted in the urine.[21]

Pathophysiology

Menthol's unique cooling property adds to its commercial value and is one of the most studied features of the

oil. Electrophysiologic investigations have shown that menthol has a dose-dependent effect on calcium concentrations across cell membranes. Inhibition of calcium efflux results in depolarization and, in turn, increases electrical discharges from cold receptors.[21] The increased electrical activity in the trigeminal nerve is thought

to be responsible for the subjective impression that menthol has a decongestant effect on the nasal passages.[21] Research has shown that menthol actually increases nasal congestion and causes an inhibition of upper airway muscle reflexes.[50]

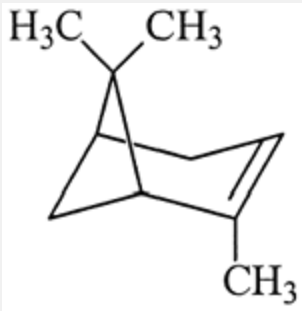
Clinical Features

Rare case reports of menthol toxicity appear in the literature. The reported symptoms of toxicity include CNS effects, such as ataxia, confusion, and coma,[53] and gastrointestinal distress, such as nausea and vomiting.[49,60]

Oil of Pine

History

Pine oil and turpentine are distilled from the wood of pine trees. Turpentine has been historically used as a solvent and paint thinner, whereas pine oil is used as a disinfectant.



Î±-Pinene

Toxicokinetics

The main active ingredient in pine oil is Î±-pinene, a monoterpene hydrocarbon that is absorbed via the GI tract or through inhalation. The lipophilicity of this compound results in its accumulation in adipose tissue and slow metabolism. The primary modes of metabolism include hydration, hydroxylation, and acetylation reactions, after which inactive metabolites undergo renal excretion.[39]

Pathophysiology

Pine oil and turpentine are volatile hydrocarbon compounds with low viscosity. Inhalational injury is common when low-viscosity hydrocarbons are ingested or inhaled, because of inhibited surfactant production in the alveoli.[13] Household cleaning products containing pine oil used as additives to increase the solution's viscosity tend not to cause inhalational injury. However, significant risk of pulmonary injury is associated with turpentine ingestion and inhalation.[25]

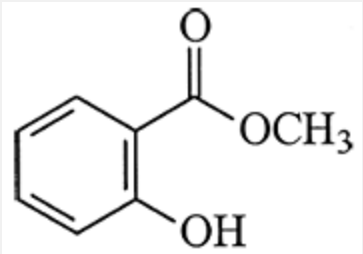
Clinical Features

Pine oil ingestion results in a characteristic pine odor on the breath,[82] whereas turpentine ingestion reportedly causes the urine to smell of violets.[54] Significant ingestions may result in CNS depression that progresses from headache, dizziness, and blurry vision to lethargy and coma.[14] Aspiration resulting in pneumonitis, acute lung injury, and acute respiratory distress syndrome reportedly causes development of pneumatocoeles.[13,82] Inhalational exposure to turpentine fumes causes increased airway resistance and irritation of the oral mucosa in study subjects.[22] Further details on the management of hydrocarbon aspiration are given in Chap. 102.

Oil of Wintergreen

History

European botanists became fascinated by medicinal plants upon the discovery of the New World. John Bartram established the first botanical garden in the United States in 1728 and was named the â€œBotanizer Royal for Americaâ€• in 1765. His collection included the *Gaultheria procumbens*, a fragrant ground cover plant whose leaves were steamed. The distilled product, oil of wintergreen, was used topically to relieve the symptoms of rheumatism.[9] Oil of wintergreen is found in topical preparations worldwide, such as Tiger Balm and Ben-Gay, which are used to treat myalgias. The active ingredient in oil of wintergreen is methyl salicylate, which has a pleasant smell and taste, posing a significant hazard to the pediatric population.



Methyl Selicylate

Five milliliters of oil of wintergreen is equivalent in salicylate content to 7 g aspirin, and numerous case reports of fatalities after even small ingestions are reported.[29,47,64]

Toxicokinetics

Methyl salicylate is absorbed from the GI tract. Dermal absorption occurs,[48] and reportedly causes significant toxicity.[15,33] Once absorbed, methyl salicylate enters the circulation and is transported to the liver, where it undergoes hydrolysis to form salicylic acid. The salicylic acid undergoes conjugation with glycine and glucuronic acid, forming salicyluric acid, salicyl acyl, and phenolic glucuronide.[43] Salicylates are predominantly excreted by the kidney as salicyluric acid (75%), free salicylic acid (10%), salicylic phenol (10%) and acyl (5%) glucuronides, and gentisic acid (<1%).[44]

Pathophysiology

An extensive discussion of salicylate pathophysiology is given in Chap. 35.

Clinical Features

Oil of wintergreen overdose can result in a toxic syndrome identical to that of salicylate poisoning, characterized by nausea, vomiting, tinnitus, hyperpnea, and tachypnea. Patients often present with diaphoresis and mental status changes. Severe toxicity is associated with seizures, cerebral edema, acute lung injury, coma, and death. Further details on the laboratory tests and treatment of salicylate toxicity are given in Chap. 35.

Diagnostic Testing

Laboratory studies are of limited value in essential oil toxicity. Generally, blood or urine concentrations of the active ingredients are not available in a meaningful time frame. However, the patient's clinical status should determine which laboratory studies are to be ordered. Patients who present with altered mental status or seizures warrant a complete evaluation, including a head CT

and lumbar puncture to address other serious potential etiologies.

In patients who present with respiratory distress, chest radiographs and continuous pulse oximetry are warranted.

A few of the essential oils require specific studies:

- *Absinthe:* Laboratory studies should include a complete blood count (CBC), chemistry panel, creatine phosphokinase concentration, and glucose monitoring in patients who present with seizures. Urinalysis should be performed to evaluate for myoglobinuria.
- *Camphor, Nutmeg:* Useful laboratory studies include a chemistry panel to evaluate hydration status and liver enzyme concentrations (nutmeg and chronic camphor exposure).
- *Pennyroyal:* CBC and liver function studies, including the aminotransferases, bilirubin, and prothrombin time, and partial thromboplastin time, are indicated.
- *Wintergreen:* Salicylate concentrations and acidâ€“base status should be determined.

Treatment

Treatment of symptomatic essential oil toxicity is generally supportive, including administration of intravenous fluids and supplemental oxygen. A dose of activated charcoal may be helpful in alert patients with an intact airway. Benzodiazepines are the mainstay of treatment in patients who present with agitation and seizures.

A few of the essential oils require specific treatment:

- *Absinthe:* If rhabdomyolysis is present, hydration and urinary alkalinization may be appropriate, depending on the clinical

severity.

- *Clove:* In patients who exhibit signs of hepatotoxicity, *N*-acetylcysteine (NAC) should be administered. Although no definitive studies on NAC use in this patient population are available, the suggestion that NAC is protective in the rat model,[69] combined with the safety profile of this antidote, probably warrant its use in the setting of eugenol-induced hepatotoxicity.
- *Pennyroyal:* Patients who present with a recent history of pennyroyal ingestion should undergo gastric decontamination with gastric lavage and administration of activated charcoal. NAC therapy is warranted following significant pennyroyal oil ingestions, given the depletion of hepatic glutathione stores.[3,31] Administration of NAC should continue until the patient's clinical status improves or hepatotoxicity resolves. NAC should be administered in the same doses used for acetaminophen toxicity because no trials have demonstrated the optimal dose in the setting of pennyroyal poisoning. If no signs of hepatic or renal toxicity develop, the traditional 20-hour course of intravenous NAC should suffice. If oral NAC is administered, a 24- to 36-hour period of administration should prevent hepatotoxicity, given the 1- to 2-hour half-life of pennyroyal and its metabolites.[3] In asymptomatic patients with minimal ingestions, a brief observation period of 3â€“6 hours is sufficient. An animal study demonstrated that treatment of mice with a combination of disulfiram and cimetidine prior to pennyroyal administration, diminished the hepatotoxic effects, but whether these treatments would be beneficial in human toxicity is uncertain.[66]

Summary

Essential oils are increasingly being used as an alternative form of

medical therapy. In general, the topical use of these products is associated with minimal toxicity. However, ingestion or prolonged inhalation of essential oils may result in significant morbidity and mortality. Suspected cases of essential oil toxicity should be reported to the regional poison center to enhance our very limited epidemiologic understanding of essential oil toxicity.

Chapter 43
Herbal Preparations

Oliver L. Hung

Neal A. Lewin

A 21-year-old woman, 5â€“6 weeks pregnant by dates, presented to the complaining of a 2-day history of abdominal pain and bilious vomiting. Sh from an herbalist several abortifacients, including â€œslippery elmâ€• pov â€œblue cohoshâ€• tincture for ingestion, and â€œparsleyâ€• and â€œes previous 4 days, she had ingested daily approximately 15 cups of slippery cohosh. She had used the parsley and slippery elm douches the day befo having any medical illness or allergies, or using any conventional medica

On examination, the patient was flushed and diaphoretic. Her vital signs Hg; pulse, 148 beats/min; respiratory rate, 24 breaths/min; rectal tempe sounds were normal, and her lungs were clear to auscultation. She had t muscles. The gynecologic examination was unremarkable. Neurologic exa weakness. Her pupils were equal, reactive, and normal size. Laboratory concentrations and complete blood count, were normal. The electrocardio tachycardia without conduction abnormalities. Urinalysis revealed high co was admitted to the hospital for intravenous hydration. Sonography reve Following appropriate advice regarding her desire to terminate her pregn

she was discharged home without complications the following day.

The patient's clinical presentation suggests poisoning by a nicotinelike ag use of an herbal preparation and the development of illness suggests the constituent of one or more of the herbs. Although the popularity of herba to the belief that they are safe, one of the herbal products used by this Blue cohosh (*Caulophyllum thalictroides*) is also known as squaw root a native American herb found in the woods of eastern North America. Histo American Indians to facilitate childbirth. It continues to be used today as antirheumatic, emmenagogue, and abortifacient.[11] The oxytocic activity o by the glycosides caulosaponin and caulophyllosaponin, which are derivat The plant also contains the nicotinelike alkaloid methylcytisine, which has nicotine.[11] Many other herbal preparations are popularly used as abortifa black cohosh, cantharidin, compound Q, ergots, feverfew, juniper, mugwo rue, sage, and white cohosh.

Definition

The botanical definition of the term *herb* is specific for certain leafy plant herbal preparations often include nonherb plant materials, even animal ar terms, herbals include any â€œnaturalâ€• or â€œtraditionalâ€• remedy, defined. Although these products often are called *medications* , this term misleading. Many herbal preparations purportedly are used for their nor properties (ie, they help the body return to a normal state by resisting s Because many herbal users and herbalists do not consider herbal prepara term *herbal medicine* by the clinician may convey a different, and perhap reasons, it may be inappropriate and without benefit to refer to these pr

Herbal preparations are a subset of alternative medical therapies. These interventions that are neither widely taught in medical schools nor genera Alternative medical therapies are divided into several major domains: alt Ayurveda, homeopathy), mindâ€“body interventions (e.g., prayer, hypnos herbal preparations, diet therapies), manipulative and body-based metho chiropractic, massage), and energy therapies (eg, therapeutic touch).[118] conjunction with conventional medical therapies, alternative medical thera *complementary* or *integrative* medical therapies.[117]

For regulatory purposes, herbal preparations are recognized by the Food a type of dietary supplement, which reflects their classification as nutrients not all dietary supplements are herbal preparations. Many nonherbals, su supplements, and food additives, are also dietary supplements (Chaps. 3

The study of herbal preparations is complicated by the lack of standardiz of common,

proprietary, and botanical names may increase the confusion. A single pla common names, in addition to its botanical name. For example, *Datura* s weed, Angel's trumpet, datura stramonium, apple of Peru, Jamestown we Likewise, a common name for a plant, such as gordolobo, may refer to s *Verbascum thapsus* and *Gnaphalium macounii* .[79] The mandrake refers no alkaloidâ€“containing *Mandragora officinarum* but also the podophyllum- Thus, accurate classification of herbal preparations is very difficult, which

Historical Background

Since ancient times and perhaps since prehistoric times, people of all cul to treat disease and promote health.[41] A 60,000-year-old Iraqi burial site plants, suggesting very early historical usage.[151] The earliest surviving w the Egyptian Ebers papyrus, circa 1500 B.C., which lists dozens of medici In India, the *Vedas* , epic poems written in approximately 1500 B.C., cor preparations of the time. In China, the *Divine Husbandman's Classic* , wr 252 herbal preparations. In ancient Europe, herbal medicines were the ma century, the Greek physician Dioscorides wrote one of the first European which listed 600 herbals and was translated into many languages. Shaman Americas, Africa, Australia, and Asia continue to include herbals for spirit on oral traditions passed from generation to generation.

During the Scientific Revolution, European scientists began to isolate puri use as medicinal agents. In 1804 and 1832, morphine and codeine were i plant *Papaver somniferum* .[139] In the mid-18th century, Edward Stone de of the Royal Society of Medicine the successful use of the bark of the wil (fever).[81] In 1829, salicin, the active ingredient of the willow bark, was salicylate was marketed in 1875 as a treatment for rheumatic fever and

success of this drug led to the synthesis of acetylsalicylic acid in 1899. Tl
cetyl-*spiric* acid), is said to have been derived from *Spiraea* , the plant g
was prepared. Even today, plant preparations still are being investigated
drugs. Sweet wormwood (*Artemisia annua* , qing hao) was first described
in 168 B.C.[89] In 1971, the active parent compound artemisinin was first

to recent negative publicity concerning the dangers associated with ephedr
of specific popular herbal preparations, such as ginkgo and St. John's wo

Although the FDA does not classify these preparations as medications, they
preventing or treating medical illness. Despite reports of toxicity associate
evaluation of herbal efficacy or safety is required. Because patients often

as medications, they may not provide a history of usage unless they are survey, 21.7% of respondents reported using herbal preparations. For 15. preparation was being used specifically to treat aspects of the patient's seven percent of herbal users reported that their physicians were unawar usage.[76] A survey of outpatients in a veteran's affairs hospital revealed t at least 1 dietary supplement with prescription medications. Of those taki potential for drugâ€“dietary supplement interactions compared to the re medications.[131]

Herbal preparation use appears to vary greatly, depending on the commu Mississippi and southwestern West Virginia reported that 71% and 73% herbal preparations in the past year.[32 , 33 , 44] Among Chinese Americans Americans in west Texas, herbal preparation use was reported to be very respectively.[104 , 132] Herbal preparations use appears to be higher among AIDS, rheumatoid arthritis, and cancer.[85 , 87 , 167] In the United States, preparation usage is associated with multiple factors, including concurren and cultural influences.

Given their pharmacologic constituents, it is not surprising that herbal pr treatment of certain medical

conditions. Saw palmetto may be as effective as finasteride in the treatm hyperplasia.[172] Glucosamine and chondroitin may be useful in the treatm Chinese herbal medicines may be effective in the treatment of irritable b associated with preliminary studies having systematic flaws that limit the scientific evidence is required to prove their effectiveness by current sci

In 1998, Congress established the National Center for Complementary an the National Institutes of Health to stimulate, develop, and support resea alternative medicines.[105] In 2002, an NCCAM-funded study revealed that effective in treating depression than was placebo.[80] A sampling of currer *Ginkgo biloba* for delaying the progression of dementia (phase 3), glucos of osteoarthritis (phase 3), shark cartilage for treatment of lung cancer (of hepatic disease (phase 2), valerian root for treatment of insomnia (pha migraine headaches, echinacea for treatment/prevention of upper respirat cohosh for treatment of menopausal hot flashes (phase 2), pycnogenol fo

2), and Ayurvedic medicine for treatment of type II diabetes mellitus (ph

Regulation of Herbal Preparations

Very little proactive federal regulation of the herbal industry exists. In 19 Supplement Health and Education Act (DSHEA), which reduced the FDA's dietary supplements.[58] Dietary supplements include vitamins, minerals, he product that had been sold as a â€œsupplementâ€• before October 15, new ingredient intended for use in dietary supplements requires notificatio 75 days in advance of marketing. The FDA must review within this time ingredient is reasonably expected to be safe under the intended condition contained in dietary supplements were in use prior to 1994, the vast maj subject to premarket safety evaluations. After marketing, if the FDA dete supplement is unsafe, the agency can warn the public, suggest changes t the manufacturer to recall the product, recall the product, or ban the pro

On several occasions the FDA has urged manufacturers to stop producing unsafe products. In July 2001, the FDA warned dietary supplement manu containing aristolochic acid because of nephrotoxicity and to remove comf because of hepatotoxicity. In November 2001, the FDA warned the manu phenylpropanolamine, caffeine, yohimbine, diiodothyronine, usnic acid) to marketplace because of reports of associated hepatotoxicity. In 2002, the healthcare providers of the risk of hepatotoxicity associated with the use However, the FDA did not ban the development of kava-containing product States. In March 2004, the FDA â€œwarnedâ€• dietary supplement man androstenedione or face enforcement actions.[162] To ban a dietary supple must prove that the product is unsafe. In April 2004, the FDA â€œbanned supplements containing ephedra. This was the first prohibition of any sup

Because the law requires the FDA to consider dietary supplements food p production methods are governed by the Current Good Manufacturing Pra However, these regulations only ensure that foods, and thus dietary supp sanitary conditions; they do not guarantee the purity, safety, or efficacy o pharmaceuticals. In fact, 2 studies suggest that many herbal preparations quantities of the listed herb. In one study of 54 ginseng products, 60% o pharmacologically insignificant amounts of ginseng and 25% contained no

echinacea preparations determined that 10% of preparations contained n assayed species was consistent with labeled content in 52% of the sample standard described by the label.[62]

Herbal products can be marketed without any proof of testing for efficacy claims to cure or prevent a specific disease is not permitted unless appro affects the â€œbody's structure or functionâ€• are permissible. Substanti challenged by regulators,[160] but their methodology and requirements are corroborated by a study evaluating herbal advertising on the Internet. The sites marketing dietary supplements made 1 or more health claims withou these sites, 55% made specific claims to treat, prevent, or cure specific

In March 1999, the FDA implemented new dietary supplement labeling ru must provide a statement of identity (eg, ginseng); net quantity of conte structureâ€“function claims with disclaimers that the product has not beer for use; supplements fact panel (list of serving size, amount, and active and name and place of business of manufacturer, packer, or distributor. I dietary supplement manufacturers not to make pregnancy-related claims o the FDA sent warning letters to 8 companies for making unsubstantiated the use of dietary supplement products for weight loss. In addition, it ser dietary supplements suggesting that it may take enforcement action agai â€œintent on starting a program of inspection of retail establishments to unsubstantiated claims in their labeling.â€• Finally in November 2004, th for dietary supplements. First, the FDA intends to change its regulatory with other agencies to improve the evidentiary base it uses to make safe dietary supplements. Second, the FDA announced a meeting to seek public evidence manufacturers should provide the FDA in a new dietary ingredie intends to fully implement the DHSEA by asking for comments on what t require to substantiate a structureâ€“function claim under DHSEA.[163]

Background of Herbal Toxicology

Awareness of the widespread use of herbal preparations in the United Sta physician seeks information about the use of these products only after t Some well-publicized examples of toxicity from herbal preparation usage

poisoning from contaminated Paraguay tea in New York City in 1994;[22] , bradycardia following consumption of *Jin Bu Huan* tablets in Colorado in agranulocytosis with 1 death following consumption of *Chui Fong Tou Ku* Although few studies have examined this issue, most herbal preparations to be safe. From 1983â€“1989, the National Poisons Unit, London, receiv exposures to herbal extracts, of which 270 (25.2%) patients were sympt to demonstrate a probable association between exposure and effect in only Hong Kong in 1990, Chinese herbal medicines and proprietary medicines a medical admissions despite their use by 40â€“60% of the population. W for 4.4% of acute medical admissions.[36] , [37] In the United States, a mul reported in 2003 collected 2253 calls involving dietary supplements inclu exposures were determined to be caused by dietary supplement and were seizures, 8 cases of coma, and 9 cases of hepatotoxicity.[129] The overall supplement cases was greater compared to outcomes of other poison ce However, in developing countries where herbal usage is much greater, re preparation usage also is much higher. In South Africa, traditional medicin poisonings and were responsible for 51.7% of all deaths from acute poisc

Pharmacologic Principles

The pharmacologic activity of herbal preparations (plant containing) can b classes: volatile oils, resins, alkaloids, glycosides, and fixed oils.[153]

- Volatile oils are aromatic plant ingredients. They are also called eth evaporate at room temperatures. Many are mucous membrane irritant (CNS) activity. Examples of herbs containing volatile oils include penn catnip (*Nepeta cataria*), chamomile (*Chamomilla recutita*), and garli
- Resins are complex chemical mixtures of acrid resins, resin alcohols, resenes. These substances are often strong gastrointestinal irritants. include dandelion (*Taraxacum officinale*) elder (*Sambucus* spp), and *racemosa*)
- Alkaloids are a heterogeneous group of alkaline, organic, and nitrog compound usually is found throughout the plant. This class consists c toxic compounds. Examples of alkaloid-containing herbs include aconi

goldenseal (*Hydrastis canadensis*), and jimson weed (*Datura stramo*

- Glycosides are esters that contain a sugar component (glycol) and a one or more sugars during hydrolysis. They include the anthroquinor and lactone glycosides. The anthroquinones (senna [*Cassia acutifolia* irritating cathartics. Saponins (licorice [*Glycyrrhiza lepidota*] and gir *quinquefolius*]) are mucous membrane irritants, cause hemolysis, ar glycosides found in apricot, cherry, and peach pits release cyanide. L [*Dipteryx odorata*]) have anticoagulant activities. Cardiac glycosides (Chap. 62) are found in foxglove (*Digitalis* spp) and oleander (*Nerium*
- Fixed oils are esters of long-chain fatty acids and alcohols. Herbs co as emollients, demulcents, and bases for other agents. Generally, they of all herbal preparations. Examples include olive (*Olea europaea*) a

Factors Contributing to Herbal Toxicity

The toxicity of a plant may vary widely and depends on conditions such as developmental stage at which the plant is collected.[79] The pyrrolizidine a varies widely from month to month and year to year.[79] In some cases, or prepare an herbal preparation are responsible for its toxicity. For exampl comfreyâ€“pepsin capsules varies from 270 to 2900 mg/kg, depending on used in the preparation.[78] The area in which the plant is collected may a from Gardner Canyon, Arizona, may contain up to 18% pyrrolizidine alkal recorded for any *Senecio* plant species (normal concentration is 0.5%). F storage may affect its toxicity. The toxicity of *Crotalaria* decreases with s pyrrolizidines.

Few poisonings likely result from the inherent toxicity of the herbal, beca active ingredient and the known safety of the chosen herb (Table 43-1). from the misuse, misidentification, misrepresentation, or contamination o poisonings from lead, cadmium, mercury, copper, zinc, and arsenic are a usage.[37 , 46 , 50 , 52 , 130 , 133 , 138] High levels of these elements may re manufacturing process of some herbal or patent medications (ready-made Chinese herbalists). In some cases, as with cinnabar (mercuric sulfide) a these ingredients are intentionally included for purported medicinal bene

contain pharmaceutical medications, such as acetaminophen, aspirin, an Many of these medicines are not listed on the packaging and may not eve States. For example, 4 cases of agranulocytosis followed consumption of preparation that contains aminopyrine (which is not approved for nonpres and phenylbutazone (which was withdrawn) but

which are not listed on the packaging.[142] Both aminopyrine and phenylbu agranulocytosis.

Herbal Preparation Suggested Laboratory Analysis Antidote

TABLE 43-1. Laboratory Analysis and Treatment Guidelines for S
Their Critical Contaminants

Classification of Toxicity

Herbal preparations are associated with a wide variety of toxicologic mar addition, many individual herbal preparations are associated with multiple better understand these effects, it may be useful to organize herbal toxi

Indirect Health Risks

Herbal usage may adversely impact health by altering previous conventi A patient may discontinue or become less compliant with previous therap Alternatively, the addition of an herbal preparation may affect the pharma bioavailability or clearance of concurrently used medications, with resultin Coadministration of St. John's wort, an inducer of CYP3A4, with the prote metabolized by this enzyme, may result in decreased plasma indinavir c decreased antiretroviral activity.[136]

Direct Health Risks

Direct health risks include pharmacologically predictable and dose-depen toxic reactions, long-term toxic effects, and delayed toxic effects. For exa the suggested dose, causes tachydysrhythmias and hypotension. Idiosyncr predicted on the basis of principal pharmacologic properties. For example in anaphylaxis in a small subset of patients with probable allergies to the effects result only after chronic usage. For example, long-term use of he muscular weakness from hypokalemia. Delayed toxic effects include carc example, prolonged consumption of *Aristolochia* causes urothelial cancers

TABLE 43-2. Selected Herbal Preparations, Popular Use,

Top-Selling Herbal Supplements

The top-selling herbal supplements (food, drug, and mass-market retail ou are listed below in order of sales.[14]

- Garlic (*Allium sativum*) ($34,509,288)â€”Garlic has been used as a times. As an herbal, it is used for treatment of infections, hypertensio cells of garlic contain the odorless, sulfur-containing amino acid de sulfoxide, also known as *alliin.* When crushed, alliin is converted to has antibacterial and antioxidant activity and gives the herb its chara effects of garlic extracts include contact dermatitis, gastroenteritis, n constituents of garlic, such as ajoene, possess antiplatelet effects. Co risk of bleeding in individuals who are also taking antiplatelet agents
- Ginkgo (*Ginkgo biloba*) ($32,998,528)â€”This herbal contains ginkgo *ginkgolides* , that are reputed to have antioxidant properties, inhibit circulation. It is a popular supplement for Alzheimer disease and peri major study in 2002 failed to find any improvement in cognitive func without cognitive impairment.[152] Ginkgo in appropriate doses appears increase the risk of bleeding in individuals who are also taking antipl [110 , 126]
- Echinacea (*Echinacea purpurea, angustifolia*) ($32,448,966)â€”Echin and is a popular herbal remedy for cold and flu symptoms. Echinacea doses.[67] Rare individuals develop allergic reactions when taking echi
- Soy (*Glycine max*) ($28,252,518)â€”Soy contains 2 popularly adver isoflavones. Diets high in soy protein are associated with decreased lipoprotein concentrations. Soy isoflavone supplements (genisten, dai estrogens) that currently are suggested as alternative remedies for t There is current concern regarding how high levels of isoflavones will cancer in postmenopausal women.

- Saw palmetto (*Serenoa repens*) ($23,053,036)â€”Saw palmetto is a benign prostatic hypertrophy. Saw palmetto inhibits 5-Î±-reductase. Sa appropriate doses.[110 , 126]
- Ginseng (*Panax ginseng*) ($21,686,192)â€”Ginseng is the common of the genus *Panax*. *Panax ginseng* is native to Korea, China, Japan, the common ginseng species in North America and grows abundantly regions of Canada and the United States. Ginseng preparations have b respiratory illnesses, gastrointestinal disorders, impotence, fatigue, a effectâ€•). It is regarded as a tonic and panacea (hence the name *Pa* Its only recognized use in the United States is as an external demulc good example of the complexity of the biochemistry and pharmacologi components of ginseng are called *ginsenosides* and include panaxin, sapogenin, and ginsenin. Its general metabolic effects include decreas cholesterol concentrations; increasing erythropoiesis, hemoglobin prod the gut; increasing blood pressure and heart rate; GI motility; and C syndrome (GAS), which consists of hypertension, nervousness, sleepl been described following long-term use of ginseng.[63 , 148] Ginseng us anticoagulant effect.[82 , 177]
- St. John's wort (*Hypericum perforatum*) ($14,969,575)â€”St. John's for treatment of depression and as topical remedy for cuts, bruises, a popular as an AIDS treatment because of the lack of clinical efficacy.[6 hyperforin and hypericin. Its antidepressant properties likely derive fr inhibit the reuptake of serotonin, dopamine, norepineprine, Î³-aminob major study in 2002 demonstrated that St. John's wort is ineffective toxicity appears limited to photosensitization reactions. St. John's wor with medications metabolized by this enzyme (eg, indinavir, oral co John's wort is a weak monoamine oxidase inhibitor, raising concerns serotonin reuptake inhibitors.[136]
- Black cohosh (*Cimicifuga racemosa*) ($12,333,188)â€”Black cohosh of premenstrual syndrome and as an estrogen replacement therapy a perimenopausal symptoms. It also is used as a treatment for arthritis cohosh appears to be safe in appropriate doses.[77]
- Cranberry (*Vaccinium macrocarpon*) ($11,857,782)â€”Cranberry is a

urinary tract infections. Cranberry appears to be safe in appropriate

- Valerian (*Valeriana officinalis*) ($8,120,329)â€”Valerian is a popular and is also used as a sleeping aid. Valerian appears to be safe in ap potentiate sedation in patients taking sedative-hypnotics.[126]
- Milk thistle (*Silybum marianum*) ($7,762,350)â€”Milk thistle contain for treatment of liver dysfunction. It appears to be safe.
- Evening primrose (*Oenothera biennis*)â€”Evening primrose contain prostaglandin E_1 precursor. This herbal is a popular remedy for treat diabetes, eczema, and rheumatoid arthritis. Evening primrose appears This herbal may lower the seizure threshold in epilepsy.
- Kava kava (*Piper methysticum*) ($4,423,427)â€”Kava kava is a pop and muscle relaxant. Kavalactones are the active ingredients. Kava ka patients taking sedative-hypnotics.[110] Long-term use of kava at high and yellowish discoloring of the skin, ataxia, hair loss, partial loss of weight reduction. The dermatologic signs of excessive kava use are k *kavaism* and usually are reversible with discontinuation of use.[123] In hepatoxicity, including 4 deaths associated with the consumption of k

reported worldwide.[106] Consequently, sales of kava were restricted i Canada, Switzerland, Japan, New Zealand, Singapore, and France.[69] not restricted sales of kava but issued a consumer advisory in March

Toxicity of Specific Herbal Preparations

Cardiovascular Toxins

Aconite

Aconites (caowu, chuanwu, and fuzi) are the dried rootstocks of the *Acon* usually is derived from *Aconitum carmichaelii* (chuan wu) or *A. kuznezoff* States, aconite is derived from *A. napellus*, commonly known as *monksh* most toxic part of the plant, When ingested, both cardiac and neurologic

far more common in Asia, especially China.[40] In Hong Kong, it is respons poisonings from Chinese herbal preparations.[35 , 38 , 40]

Aconite toxicity is caused by C19 diterpenoid-ester alkaloids, including a hypoaconitine.[19] Mechanistically, aconitine increases sodium influx throug inotropy while delaying the final repolarization phase of the action poten excitation.[73] Sinus bradycardia and ventricular dysrhythmias can occur.[39] minutes to 4 hours after ingestion. Paresthesias of the oral mucosa and e nausea, vomiting, diarrhea, and hypersalivation, and then by progressive may occur with doses as low as 5 mL aconite tincture, 2 mg pure aconite, of value in treating bradycardia or hypersalivation.[156] Although no antido suggest the use of amiodarone, flecainide, bretylium, lidocaine, and proc tachydysrhythmias.[156 , 176] Pharmacologic principles support the use of t case of aconite-induced refractory tachydysrhythmias was successfully ma device.[57] In a case series of 2 aconite-poisoned patients, use of charcoa removal was described as reversing aconite-induced ventricular dysrhyth

Ch'an Su

Ch'an su is a traditional herbal remedy derived from the secretions of the the toad *Bufo bufo gargarizans* or *Bufo melanosticus.* This remedy is trad congestive heart failure.[91] Ch'an su contains two groups of toxic compo consisting of bufadienolides and the hallucinogenic compound bufotenin. are similar to cardioactive steroid poisoning, including gastrointestinal syr also marketed as an aphrodisiac for its purported topical anesthetic effects â€œStone,â€• â€œLove Stone,â€• â€œBlack Stone,â€• and â€œRock H New York City, several fatalities were associated with the ingestion of Ch' aphrodisiac.[24] Severe toxic reactions or death are reported after mouthir eating an entire toad, toad soup, or toad eggs.[17] Assays for serum digox bufadienolides but may qualitatively assist in making a presumptive diagr digoxin-specific Fab was successfully used to treat Ch'an su poisoning an for any suspected case of Ch'an su cardiotoxicity or other cardioactive st

Central Nervous System Toxins

Absinthe

Wormwood (*Artemisia absinthium*) extract is the main ingredient in absi outlawed in the United States in 1912. This volatile oil is a mixture of Î±- Both tetrahydrocannabinol and thujone have an affinity for a common CNS similar oxidative metabolic pathways.[175]

Chronic absinthe use caused absinthism, which was characterized by ps deterioration, and seizures. The most famous victim of absinthism may ha thought to have suffered from this disorder in the later part of his life.[4] A now is used for flavoring vermouth and pastis. A case of wormwood-indu acute renal failure was described involving a patient who purchased and essential oil of wormwood from the Internet, assuming it was absinthe li supportive.

Anticholinergic Agents: Henbane, Jimson Weed

Many plants contain the belladonna alkaloids: atropine (DL-hyoscyamine), hyoscine). They may still be used therapeutically for treatment of asthma included in herbal teas.[34] Signs and symptoms of anticholinergic poisonin bowel sounds, urinary retention, dry mouth, flushed skin, tachycardia, ar usually require only supportive care and CNS sedation with intravenous physostigmine reverses anticholinergic poisoning; however, its use should to severely symptomatic cases because inappropriate use may cause seiz

Ephedra

Members of the genus *Ephedra* are generally erect evergreen plants rese include sea grape, ma-huang, yellow horse, desert tea, squaw tea, and M long history of use as stimulants and for management of bronchospasm. and, in some species, pseudoephedrine.[159] In large doses, ephedrine ca insomnia, dizziness, palpitations, skin flushing, tingling, vomiting, anxiety psychosis. The treatment is similar to that for other CNS stimulants (Chap reports of adverse events associated with ephedra use submitted to the F considered â€œprobableâ€• or â€œpossiblyâ€• related to ephedra use. commonly reported adverse effect (17 cases), followed by palpitations or

cases), and seizures (7 cases). Ten reported cases resulted in death. Thi disability.[71] In 2002, the FDA banned the sale of ephedra-containing die herbal preparations, such as bitter orange *(Citrus aurantia)* , contain ep are still widely available.[115 , 125] Exposures may result in cardiovascular

Khat

A common form of drug abuse in East Africa involves chewing the leaves a) plant and swallowing the juice.[53 , 101] Khat is used by herbalists to tre gastric ulcers. The two active compounds in khat are cathine (norpseudo aminopropiophenone), the more active stimulant (an extensive discussion

Labeled Ingredient Scientific Name Usage Active Ingredients

TABLE 43-3. Constituent Psychoactive Xenobiotics in Herbal Prep

Nicotinic Agents: Betel Nut, Blue Cohosh, Bro Tobacco

Betel (*Areca catechu*) is chewed by an estimated 200 million people wor herbal, it used as a digestive aid and as a treatment for cough and sore arecoline, a direct-acting nicotinic agonist. The betel leaf also contains a capable of producing sympathomimetic reactions Arecoline is a bronchoc methacholine, and may exacerbate bronchospasm in asthmatic patients c betel nut toxicity is supportive. Long-term use of betel nut is associated carcinoma of the oral mucosa.[122]

Many other herbal preparations have nicotinic effects. Examples of plants include blue cohosh, methylcytisine; broom, L-sparteine; chestnut, esculir tobacco/nicotine.

Other herbals possessing CNS activity include valerian (sedation), kava k (seizures), nutmeg (hallucinations),[171] mace (hallucinations), and iboga

Gastrointestinal Toxins

Goldenseal

Goldenseal (*Hydrastis canadensis*) originally was used by the Cherokees dye and an internal remedy.[64] Today, it is used as an astringent, as a re gastrointestinal tract disorders, and as treatment for menorrhagia. Golden presence of illicit drugs on urinary drug screens, although multiple studie the results of urinary drug screens.[42 , 118 , 128] This myth originated in *the Pike* (1900), which was written by the internationally

known plant pharmacist Uri Lloyd. In this novel, one of the major charact poisoning with strychnine but is posthumously exonerated with evidence in goldenseal) and morphine cross-react to produce a positive color assay of this herbal is thought to be safe, but ingestion of large amounts can paralysis, and respiratory failure. In those cases, the patient should rece care.

Hepatotoxins

Pennyroyal

Pennyroyal oil is a volatile oil extract from the leaves of *Mentha pulegium* Herbalists use pennyroyal oil as an abortifacient and to regulate menstruat flea/mosquito repellant and as a fragrance. The abortive effect is thought contraction of the uterus.[155] Pennyroyal usually is ingested as a strong te the oil itself. It is cited as the causative agent in several well-documente ingestion of as little as 15 mL of the oil.[2,6] The postulated mechanism i glutathione depletion from the cyclohexanone pulegone and its cytochrom CYP2C19)-dependent toxic metabolites that include menthofuran.[88] On a matter of the midbrain is reported in both a fatal human exposure and in pulegone depletes hepatic glutathione stores, *N*-acetylcysteine treatment in Depth: *N*-Acetylcysteine). In an animal model, pretreatment with cy (CYP1A2, CYP2C19) and disulfiram (CYP2E1) reduced pulegone-induced reasonable to consider use of cytochrome P450 inhibitors in the treatme however, evidence of clinical benefit in humans currently is lacking.

Pyrrolizidine Alkaloids

Pyrrolizidine alkaloids are hepatotoxins found in many plants, including *H* and *Symphytum* .[135,140] Examples of other plants and products contair borage (*Borago officinalis*), coltsfoot (*Tussilago farfara*), and T'u-san-ch

The alkaloids undergo metabolism to pyrroles, which serve as biologic al hepatic sinusoidal hypertrophy and venous occlusion, resulting in hepatic hepatomegaly, cirrhosis, and possibly hepatic carcinoma. Chronic low dos resulting in pulmonary artery hypertension and right ventricular hypertro tea, prepared from the leaves of the *Crotalaria* plant, is considered an er Epidemics have also occurred in Afghanistan and India, where ingestion *Heliotropium* and *Crotalaria* seeds resulted in reports of 1632 and 60 ca respectively.[112,157] In western countries, ingestion of herbal products led to several cases of hepatic venoocclusive disease.[135] Treatment of he supportive but may require liver transplantation in severe cases.

Other Hepatotoxins

Several herbal preparations are associated with hepatotoxicity.[94] These p
(*Larrea tridentata*),[23,65] germander (*Teucrium chamaedrys*),[95] impilia
(*Atractylis gummifera*), and sassafras (*Sassafras albidum*).[147]

Renal Toxins

Aristolochia

An epidemic of renal failure in Belgium was linked to the substitution of *A*
birthwort, heartwort, and fangchi, for another Chinese herbal, *Stephania*

weight-loss regimen.[165, 166] Of 70 identified cases of renal fibrosis, 30 failure. Aristolochic acid in *Aristolochia* causes renal fibrosis which typica 12â€“24 months after the initial injury. Patients with *Aristolochia* -induce increased risk for developing urothelial cancer.[121]

Miscellaneous

Chamomile Tea

Chamomile tea is a popular herbal drink made from chamomile flower he occur in patients allergic to ragweed, asters, chrysanthemums, or other r , [21] Such reactions are rare but can be life threatening. The patient need highly atopic to experience a cross-reaction.

Rattlesnake Capsules

Rattlesnake capsules are a common Mexican folk remedy used to treat c These capsules contain dried, pulverized rattlesnake powder and are sold vibora de cascabel, polvo de

vibora, and carne de vibora, without prescriptions. Infection with *Salmone* ingestion.[10, 43, 124, 143, 169]

Chinese Patent Medications

Chinese patent medicines, a component of traditional Chinese medicine, formulated into tablets, capsules, syrups, powders, ointments, and plaster by poorly regulated Chinese pharmaceutical agencies and are highly susc contamination (Table 43-4). They are often sold by nonherbalists at con incomplete documentation of ingredients, and, typically, they are not label California Department of Health Services investigated 260 Asian patent r determined that 32% contained undeclared pharmaceutics or heavy meta determined that 24% of 2609 samples collected were contaminated by at

Jin Bu Huan is a traditional Chinese preparation used as a sedative and a an isoquinoline alkaloid L-tetrahydropalmatine (L-THP), is responsible for

Bu Huan. In 2 case reports, 3 pediatric patients developed life-threatenin developed hepatitis while using Jin Bu Huan.[26, 27] Hepatotoxicity may be structurally similar to the hepatotoxic pyrrolizidine alkaloids.[173] Although in these cases indicate that *Polygala chinensis* was the plant source for L L-THP. Plants from the genera *Stephania* and *Corydalis* are also known as appreciable amounts of L-THP. The product implicated in the case reports by the manufacturer.

Nan Lien Chiu Fong Toukuwan (now withdrawn from the market) was fou phenacetin, phenylbutazone, indomethacin, mefenamic acid, diazepam, mercuric sulfide, lead, and cadmium, depending on the manufacturer.[38] S were reported following ingestion of this preparation.[142] Dr. Tong Shap Y contain theophylline.[38] Leng Pui Kee cough pills were found to contain b

Tung Shueh (black ball) contains diazepam and mefenamic acid and is a
nephritis.[51] Gan Mao Tong Pian, an herbal cold remedy, contains phenylb
in one child.[119] Chui Feng Su Ho Wan, which contains *Glycyrrhiza glabra*
induced torsade de pointes in an elderly woman.[38]

Several Chinese patent medicines contain the mercurials cinnabar (mercu
chloride). Tse Koo Choy and Qing Fen, which contain calomel, are associa
poisoning.[84]

Many Chinese medicated oils contain oil of wintergreen, which is methyls
intended for external use, it is a common practice to ingest a few drops u
general tonic or specific remedy. Examples of medicated oils include White
wintergreen, 30% menthol, 6% camphor), Red Flower Oil (67% oil of wi
Kwan Loong Medicated Oil (menthol 25%, methylsalicylate 15%, camphor

Herbal Preparations and AIDS Therapies

Many patients infected with human immunodeficiency virus (HIV) have tu
hope of finding less toxic therapy than the conventional modalities current
positive patients in a university-based AIDS clinic, 22% used 1 or more h
period.[85] Twenty-four percent of these patients were unable to state whic
effects included dermatitis, nausea, vomiting, diarrhea, thrombocytopenia

mental status, hepatotoxicity, and electrolyte imbalances. Twenty percent were unaware of their use of herbs. A more recent study reported that m were taking alternative medicines, and 24% of AIDS patients were taking botanicals.[66]

Current popular herbal preparations and dietary supplements for treatmer include *Lactobacillus acidophilus* , adrenal cortex, aloe vera, *Artemisia* , *A* blue-green algae, cat's claw, *Chlorella* , coenzyme Q10, colloidal silver, (DHEA), echinacea, elderberry, evening primrose oil, flaxseed oil, garlic, glucosamine, glutamine, glutathione, glycyrrhizin, grapeseed, green tea, palmetto, Siberian ginseng, and silymarin and are used for treatment of

Treatment

A specific treatment strategy should emphasize identification of the specif patient, concurrent medication(s), and medical illness(es). Because herba depending on the preparation used, careful examination may be aided by preparation. In most cases, supportive care and discontinuation of the h Some herbal toxicities require specific laboratory analysis and therapy (Ta

All adverse events associated with herbal preparations should be reported or to FDA MedWatch by phone at 1-800-FDA-1088 or online at http://w

Summary

The popularity of herbal preparations is expected to increase in the fores users will suffer no ill effects, both herbal users and clinicians should be pharmacologically active and have the potential for toxicity. They may in to increase the toxicity of the medication or decrease its therapeutic effe conditions may have increased risk for toxicity when using herbal prepar

Herbal users should be aware that these preparations are poorly studied. for most preparations. No standards exist for their manufacture, quality, not contain the purported amount of the active ingredient. Some herbal p active ingredient. Herbal products are reported to be adulterated with pr contaminants such as heavy metals.

Many herbal stores are staffed by untrained personnel who may dispense unfounded claims concerning their products.[134] Herbalists (eg, Chinese h remedies with the potential for serious toxicity as the result of improper improper preparation of the herbal product by the herbalist or herbal use herbalists may be unaware of the potential for toxicity of their product.

Clinicians should be familiar with herbal preparations and their potential effects. This is especially important because standard herbal reference te on the management of poisoning or other adverse effects.[70] Every patien assessing the concurrent or recent past use of herbal preparations.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 44
Athletic Performance Enhancers

Susi U. Vassallo

Case

A 17-year-old boy presented to the emergency department complaining of chest pain while he was playing basketball. The patient stated that he had basketball court at his high school and had experienced chest discomfort rest. Because of the chest discomfort, the patient decided a few minutes instead of playing more basketball. He again developed chest pain with w ceased his activities. He went home and reported the experience to his m mother brought her son to the emergency department and was present at history obtained in the presence of his mother revealed that this was the had experienced chest discomfort. No one in his family had died suddenly family history of structural cardiac abnormalities. Upon questioning, the drug use but stated that he took vitamin supplements. He denied anabolic he had been considering taking growth hormone to grow taller and bigge examination was remarkable for a well-developed, well-conditioned muscu athletic physique of normal height. Vital signs were as follows: blood pres pulse 60 beats/min; respiratory rate 14 breaths/min; temperature 98.6Â examination was unremarkable. Electrocardiogram and chest radiograph w

patient asked to be discharged to complete his mid-term examinations ar exercise regimen. An echocardiogram was planned for the following day.

The desire to improve athletic performance in a scientific manner is a re development. The emphasis on, and study of, human physical and menta centered on the importance of manual work and military service. The role inconsequential, except for its potential in improving military preparedne comes from the Dutch word *doop* , a viscous opium juice used by the an

Public interest in extraordinary athletic achievement fuels the modern-da performance enhancement in sports. In spite of the prohibition of doping, they would use a banned substance to win if they would not be caught.[15]

History and Epidemiology

Controversy surrounding the systematic use of performance-enhancing dru participating athletes has marred many sporting events. Since the Interr Committee (IOC) began testing for drugs during the 1968 Olympic games have been sanctioned and even stripped of their Olympic medals because for banned substances. However, from a public health perspective, the us enhancing drugs among athletes of all ages and abilities is a far more se highly publicized cases involving a few world-class athletes. The majority epidemiology of performance-enhancing substances have investigated an steroid use. *Androgenic* means masculinizing and *anabolic* means tissue *process* stimulates protein synthesis, promotes nitrogen deposition in lean decreases protein breakdown.[248] Studies of high school students documen seniors have used anabolic steroids, and 35% of these individuals were n organized athletics.[32] Others find rates of androgenic steroid use in adol from 3%â€“19%.[124 , 112 , 182 , 243 , 247 , 248] According to the 2005 surv Collegiate Athletic Association (NCAA), 1.2% of college athletes use anab use ephedrine.[161] The Drug Enforcement Agency (DEA) reported that 30â androgenic anabolic steroids and human growth hormone sold illegally do purport.[61]

Sudden Death in Athletes

Sudden unexpected death in athletes younger than 35 years is underesti

presence of other drugs. However, one drug may have several expected

diuretics may be used to mask the presence of other agents by forcing th may be used to reduce weight. Clenbuterol is an anabolic agent, but it als because of its Î²2 -adrenergic agonist effects. Bromontan is another stimul a masking agent. Depending on the xenobiotic, it is used either before c future performance or during competition to improve immediate results.[2

According to the World Anti-Doping Agency (WADA) World Anti-Doping Co method constitutes doping and can be added to the prohibited list if it me following three criteria: it enhances performance; its use presents a dang health; and it is contrary to the spirit of sport[245] (Table 44-1).

Some of the substances on the WADA 2005 Prohibited List are used to tr frequently encountered in athletes.[244] Many athletes have sought to expl test by claiming the substance was prescribed for a medical condition, suc modafinil, a stimulant, for the sleep disorder narcolepsy. However, some medical conditions that may require treatment. For example, the prevalen increasing in athletes. At least 10â€“15% of Olympic athletes have exer , [216] Salbutamol (albuterol) is the most commonly used asthma medicine adrenergic agonists are commonly used for treatment of asthma, these a during and out of competition. In the Olympics, use of inhaled Î²2 -adren an abbreviated Therapeutic Use Exemption (TUE). With the TUE, the inhal if the athlete provides medical justification for therapeutic necessity and investigations performed to establish the diagnosis of asthma. Neverthele concentration (free salbutamol concentration plus glucuronide level > 100 considered a positive test and an adverse finding unless the athlete prove value results from therapeutic use of the drug.[244] Systemic administration such as prednisone, is not permitted. Topical preparations of glucocortico

Anabolic Xenobiotics

Androgenic Steroids

Androgenic anabolic steroids (AAS) increase muscle mass, lean body weig nitrogen retention.[155] Testosterone is the prototypical androgen, and mo steroids are synthetic testosterone derivatives. The androgenic effects of responsible for male appearance and secondary sexual characteristics suc

of body hair and subsequent deepening of the voice.

In the 1970s and 1980s, federal regulation of anabolic steroids was under Food and Drug Administration (FDA). Because of increasing media reports anabolic steroids in sports, particularly by high school students and ama enacted the Anabolic Steroid Control Act of 1990, which amended the Co Act and classified anabolic steroids as schedule III. Schedule III implies th currently accepted medical use in the United States and has less potential drugs categorized as schedule I or II. The Anabolic Steroid Control Act of steroid precursors, such as androstenedione and dihydrotestosterone, to t substances that are considered illegal without a prescription. Possession

or other metabolic precursors called *prohormone drugs* is considered a f by jail. Distributing these substances is a felony that may result in up to the first offense. Nevertheless, anabolic steroids are still available illicitly and over the Internet from international marketers, veterinary pharmace some legitimate US manufacturers (Table 44-2). The US FDA estimates t AAS amounts to $300â€“500 million annually.[46]

Physiology and Pharmacology

The Leydig cells of the testis produce 95% of endogenous male testoster comes from the adrenal glands. Normally 4â€“10 mg testosterone and 1â androstenedione are produced daily in men. Women secrete approximatel testosterone and 2â€“4 mg androstenedione daily from their ovaries and

Testosterone is rapidly degraded in the liver. The plasma half-life is less Therefore, in order to create a substance that is useful clinically, testoste the 17-hydroxy position, forming a hydrophobic compound that can be ad vehicle for gradual release.[12] Most of these esters of testosterone must b intramuscularly to avoid extensive first-pass hepatic metabolism associate administration.[14] The alternative to esterification at the 17-hydroxy positi position. Alkylated androgens can be administered orally because they are hepatic metabolism. These agents, more commonly used by athletes, are majority of complications associated with AAS use[12] (Table 44-2).

Antiestrogens and Antiandrogens

In sports, the general purpose of taking androgens is to increase the ana avoid the unwanted side effects of feminization, such as gynecomastia, c secondary sexual characteristics such as facial hair and deepening voice. that completely dissociates the desired from the undesired effects has no Therefore, athletes are directed on the use of agents to manipulate the r androgen metabolism and decrease unwanted side effects by combining antiestrogenic or antiandrogenic activity. Such xenobiotics are divided in such as anastrozole (Arimidex) and aminoglutethimide (Cytadren), select modulators (SERMs) such as tamoxifen and raloxifene, and other antiest such as clomiphene (Clomid). These agents are prohibited for all athletes indirectly increasing gonadotropin release, is most commonly used by ath endogenous testosterone upon discontinuation of androgenic anabolic st such as the 5Î±-reductase inhibitor cyproterone acetate, prevent masculi athletes (Figure 44-1). Internet web sites have extensive discussions on substances as part of the AAS regimen for muscle building.

Administration

Approximately 50% of AASs are taken orally. The remainder is administe injection, with one fourth of intramuscular AAS users sharing needles.[62] needles and syringes exchanged in a needle-exchange program in Wales steroids.[171] Unlike therapeutically indicated regimens, which consist of fix intervals, athletes typically use AASs in cycles of 6 to 8 weeks.[12] For exa use steroids for 2 months and then abstain for 2 months. Cycling is based individual preferences

and not on any validated protocol. *Stacking* implies combining the use of time, often with both oral and intramuscular administration. To prevent *p* developing tolerance, to any one drug, some athletes who take AASs use different AASs simultaneously. The doses used are frequently hundreds of

scientifically based therapeutic recommendations.[2 , 242] *Pyramiding* impli a low dose, increasing the dose many times, and then tapering once aga may require several months to be totally excreted, whereas water-soluble only days to weeks to be cleared by the kidney. Water-soluble testosteror â€œbridging therapy.â€• *Bridging* refers to the practice of halting the a lasting alkylated testosterone formulations so that urine analyses at a spe evidence of use, while injections of shorter-acting testosterone esters are orally administered alkylated formulations. This strategy, which was used German Democratic Republic, is documented in a review of the subject b research of previously classified records.[75] Clearance profiles for testoste determined for each athlete. In general, the daily injection of testosteron when termination of the more readily detectable synthetic alkylated test was necessary to avoid a positive doping test. These daily injections of were halted 4â€“5 days before competition. Testosterone-to-epitestosteror determined upon the athletes' departure to a sporting event. A few days European Swimming Championships, the urine samples of 4 female swimn Olympic Gold medals) had T/E ratio > 6. Corrupt officials involved in dopi values would decrease to acceptable levels in time for the event, based o athletes' clearance of testosterone esters. Epitestosterone propionate inj to bring the T/E ratio back to < 6:1, the acceptable ratio at that time.[75] > 4:1 is considered positive.[244]

Clinical Manifestations of Androgenic Anab

Musculoskeletal

Without question, supraphysiologic doses of testosterone, when combined training, increase muscle strength and size.[23] The most common muscul of steroid use are tendon and ligament rupture.[77 , 99 , 129 , 134]

Hepatic

Hepatic subcapsular hematoma with hemorrhage is reported.[201] Peliosis h blood-filled sinuses in the liver that may result in fatal hepatic rupture, c with alkylated androgens and may not improve when androgen use is sto

This condition is not associated with the dose or duration of treatment.[12] Cyproterone acetate is a chlorinated progesterone derivative that inhibits reportedly causes hepatotoxicity.[12 , 81 , 85]

Infectious

Local complications from injection include infected joints,[71] cutaneous ab *Candida albicans* endophthalmitis.[241] Injection of steroids using contamin to transmission of infectious diseases such as HIV and hepatitis B and C.[1 [204 , 207] Severe varicella may occur in long-term AAS users.[110]

Dermatologic

Cutaneous side effects are common and include keloid formation, sebace seborrheic furunculosis, folliculitis, and striae.[203] Acne is associated with sometimes is referred to as â€œgymnasium acne.â€•[43 , 175] A common and gynecomastia occurs. The production of sebum is an androgen-deper dihydrotestosterone is active in sebaceous glands.[12]

Endocrine

Conversion of AAS to estradiol in peripheral tissues results in feminizatior Gynecomastia may be irreversible. AAS use causes negative feedback inh gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimula the hypothalamus. This process results in testicular atrophy and decreas which may be reversible. In females, menstrual irregularities and breast AAS use causes virilization in females.[220]

Cardiovascular

Cardiac complications include acute myocardial infarction and sudden car [107 , 136 , 138 , 151] Autopsy examination of the heart may reveal biventri extensive myocardial fibrosis, and contraction-band necrosis. Myofibrillar hypertrophy of the interventricular septum and left ventricle are present. and use of AAS impair diastolic function by increasing left ventricular wal models and in vitro myocardial cell studies show similar pathologic chang

[227 , 228] Doppler echocardiography shows that several years after streng using AAS, concentric left ventricular hypertrophy remains, compared to athletes not using AAS.[227] Growth hormone may potentiate the effects of increase concentric remodeling of the left ventricle.[115] In addition to dire vasospasm or thrombosis may occur.[152] Alkylated androgens lower the c density lipoprotein (HDL) cholesterol and may increase platelet aggregati Thromboembolic events such as pulmonary embolus,[59 , 83] central nervou events such as stroke,[119 , 120 , 206] carotid arterial occlusion,[128] cerebral popliteal artery entrapment,[133] and poststeroid balance disorder occur.[26

Neuropsychiatric

Distractibility, depression or mania, delirium, irritability, insomnia, hostili lability, and aggressiveness (â€œroid rageâ€•) may occur.[17 , 79 , 178 , 1 neuropsychiatric effects do not appear to correlate with plasma AAS con Withdrawal symptoms from AAS include decreased libido, fatigue, and m

Cancer

An association between AAS use and development of cancer has been ob animals.[191] Testicular and prostatic carcinomas are reported in more freq [82 , 190] Hepatocellular carcinoma,[111 , 165] peliosis hepatis, and cholangio [91] Wilms tumor and renal cell carcinoma are reported in young AAS users

Specific Anabolic Xenobiotics

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a precursor to testosterone (Figure 4 by the FDA in 1996, this drug subsequently was marketed as a nutritiona available for purchase without a prescription.[220] DHEA is converted to a then to testosterone by the enzyme 17Î²-hydroxysteroid dehydrogenase.[Administration of androstenedione in dosages of 300 mg/d increases test concentrations in some men and women.[132]

Women with adrenal insufficiency given DHEA replacement at a dose of 50 months demonstrated increased serum concentrations of DHEA, androste and dihydrotestosterone. Serum total and HDL cholesterol concentrations decreased. Some women experienced androgenic side effects, including gr hirsutism.[10] Sense of well-being and sexuality increased in men and wome treatment.[10 , 157 , 158] The neuropsychiatric effects of DHEA have been d animals. Increased hypothalamic serotonin, anxiolytic effects, antagonism aminobutyric acid type A ($GABA_A$) receptor, and agonism of the *N* -met receptor are demonstrated.[10 , 140 , 153]

Clenbuterol

Clenbuterol is a $Î²_2$ -adrenergic agonist that decreases fat deposition and breakdown in animal models.[6 , 41] Clenbuterol is also a potent *nutrient p* term implying it can increase the amount of muscle and decrease the am per pound of feed given to cattle and other animals.[78 , 189] Use of clenbu is illegal. Nevertheless, the consumption of veal liver contaminated with resulted in sympathomimetic symptoms and positive urine tests in affect Clenbuterol increases the glycolytic capacity of muscle and causes hyper growth of fast-twitch fibers.[141 , 251] $Î²_2$ -Adrenergic receptors are present and may mediate the anabolic effect of this class of drugs. Athletes typica 60â€“100 Âµg/d clenbuterol and in some cases as much as 600 Âµg/d. C characterized by the typical symptoms of sympathomimetic overdose[40] , Several drug users became ill when they used a substance they thought v was determined to contain only clenbuterol.

Other $Î²_2$ -adrenergic agonists, such as oral albuterol, have similar anab however, the half-life of oral albuterol is much shorter, making it less att agent.[156] The half-life of clenbuterol is approximately 27 hours, whereas albuterol is 3â€“6 hours. Inhalational use of $Î²_2$ -adrenergic agonists has demonstrated to share the anabolic properties associated with parenteral [235]

Peptides and Glycoprotein Hormones

Creatine

Creatine is an amino acid formed by combining the amino acids methioni glycine. It is synthesized naturally by the liver, kidneys, and pancreas. Cr protein-containing foods such as meat and fish.[154] In its phosphorylated f the resynthesis of adenosine triphosphate (ATP) from adenosine diphosph Supplemental creatine bound to phosphorous acts as a substrate to dona formation of ATP.[219] Because ATP is the immediate source of energy for creatine is used by athletes to increase energy during short, high-intensi than 2.5 million kg of creatine is consumed annually in the United States. have admitted to using creatine as part of their training nutritional regim by athletes at all levels. Creatine supplementation increases total creatine muscle by up to 20%.[33 , 93] Numerous studies demonstrate improved pe creatine supplementation, particularly in sports requiring short, high-inte [, 126 , 150 , 231]

Creatine is found in skeletal muscle and in the heart, brain and kidney. T stored primarily as phosphorylated creatine (PCr) and the remainder as f Consuming carbohydrates with creatine supplements increases total creatir skeletal muscle.[93] This process explains why creatine is marketed in com carbohydrate. Human endogenous creatine production is 1 g/d, and norm meat and fish offer another 1 to 2 g/d as dietary intake. From 1â€“2 g o daily by irreversible conversion to creatinine.[237]

Creatine supplementation is most commonly accomplished with creatine r of 20â€“25 g/d can increase the skeletal muscle total creatine concentrati Creatine uptake in skeletal muscle occurs via the creatine transporter pro sarcolemma. Creatine stores do not increase in some individuals despite supplementation. Creatine transporter expression and activity, as well as influence the uptake of creatine and the effect of creatine loading on ath [211 , 214]

One adverse effect of creatine supplementation is weight gain, which is t primarily from water retention.[95 , 150] However, evidence indicates that r partially responsible for the weight gain associated with long-term creatir was the most commonly reported side effect of creatine use in one study

athletes. Other complaints were muscle cramping and dehydration, althou no complaints.[113]

Creatine supplementation increases urinary creatine and creatinine excreti serum creatinine concentrations by 20%.[95, 114] Long- and short-term cr supplementation does not appear to have an adverse effect on renal func patient who had been taking creatine 5 g/d for 4 weeks developed inters improved with cessation of creatine use. Whether ingestion of creatine ca unknown.[125] A young man with focal segmental glomerular sclerosis deve creatinine concentration and decreased glomerular filtration rate (GFR) w supplementation was started. The values returned to baseline upon cessa supplementation.[181] The possibility of developing decreased renal functior concern. Ingestion of large amounts of creatine may result in formation substance *N* -nitrososarcosine, which induces esophageal cancer in rats.[8]

Human Growth Hormone

Human growth hormone (hGH) is an anabolic peptide hormone secreted b pituitary gland. It causes its anabolic effect by stimulating protein synthe growth and muscle mass in children. Recombinant human growth hormon since 1984. It is commonly used therapeutically for children with growth daily doses of 5â€“26 Âµg/kg body weight.[232]

Growth hormone secretion is stimulated by growth hormone-releasing hor by somatostatin. Growth hormone receptors occur in many tissues, includ of hGH to hepatic receptors causes secretion of insulinlike growth factor-1 potent anabolic effects and is the mediator responsible for many of the a

Human growth hormone is released in a pulsatile manner, mainly during stimulates hGH release, and more intense exercise causes proportionately [, 51, 220]

Amino acids such as ornithine, L-arginine, tryptophan, and L-lysine, incre through an unknown mechanism and often are ingested for this purpose.[5]

Human growth hormone stimulates protein synthesis and tissue growth b and increased movement of amino acids into tissue. The effects on increa

size are well proven in growth hormone-deficient individuals, but studies c resultant increase in strength related to the increase in muscle size.[49, 1 hormone improves muscle and cardiac function, increases red cell mass capacity, stimulates lipolysis, normalizes serum lipid concentrations, and subcutaneous fat. It also improves mood and sense of well-being.[49, 50,

Growth hormone is used by athletes for its anabolic potential. As an agent particularly attractive because laboratory detection is difficult. In one surv gyms used hGH for body building.[70] In another survey of adolescents, 5% had used hGH.[188] Recombinant human growth hormone (rhGH) was found Chinese swimmers at the 1998 World Swimming Championships and of cy France in 1998, suggesting use of hGH by elite athletes.[238] Pituitary-derive illicitly sold as recombinant growth hormone on the black market.

Human growth hormone administration may cause myalgias, arthralgias, syndrome, and edema.[106] The effects of hGH on skeletal growth depend c preadolescence, excessive hGH may cause increased bony growth and gig excessive hGH may cause acromegaly.[228, 230] Growth hormone may cau and hyperglycemia. Skin changes, such as increased melanocytic nevi and occur.[174] Lipid profiles may be adversely affected. HDL concentrations are associated with increased risk of coronary artery disease.[252] Because hGH parenterally, there is risk of transmission of infection.[137] The illicit sale c pituitary-derived growth hormone is associated with a risk of Creutzfeldt Long-term users of hGH may be at increased risk for prostate cancer beca complications associated with IGF-1.[90]

Insulinlike Growth Factor

IGF-1 is a peptide chain structurally related to insulin. Parenteral adminis approved for clinical treatment of dwarfism and insulin resistance. Childre antibodies to recombinant growth hormone may respond to IGF-1.

IGF-1 is produced in the liver and many other cell types. A recombinant Human growth hormone is the primary stimulus for release of IGF-1, alth nutrition play a role.[193] The effects of growth hormone are primarily med binds principally to the type I IGF receptor, which has 40% homology wit

and a similar tyrosine kinase subunit.[223] IGF-1 also binds to insulin recep 1% of insulin's affinity for the insulin receptor. IGF-1 increases glucose u the movement of glucose into cells, increasing amino acid uptake and st synthesis.

The actions of IGF-1 can be classified as either anabolic or insulinlike.[193] and DHEA increase IGF-1 levels.[157]

Side effects are similar to those associated with use of growth hormone a acromegaly. Other effects include headache, jaw pain, edema, and altera A potentially serious side effect of IGF-1 is hypoglycemia. High endogeno are associated with an increased risk for prostate cancer.[38]

In one group of 189 weightlifters, 14.3% had taken what they believed to knowledge of the substance, and most said they would consider using it i studies on the efficacy of IGF-1 in improving the conditioning of athletes attractive to female athletes because it does not cause virilization.[220]

Insulin

Insulin is used by body builders for its anabolic properties. It has been c magazinesâ€• as â€œthe most powerful anabolic hormone on the planet identified anabolic androgenic steroid users in 1 gym, 5 (25%) who had r take insulin reported using it to increase muscle mass.[186] These individua had injected insulin from 20â€“60 times over the 6 months prior to the s was to inject 10 U regular insulin and then eat sugar-containing foods af

Insulin inhibits proteolysis and promotes growth by stimulating movement acids into muscle and fat cells. It increases the synthesis of glycogen, fat proteins[53] (Chap. 48).

Two cases of hypoglycemia have been reported in body builders using ins 80 U regular insulin in both thighs every hour over a 3- to 4-hour period eating large amounts of carbohydrates on each of the previous 2 days. On presentation, he had injected 320 U regular insulin over the previous 4 h The patient had a seizure at the gym and arrived comatose in the emerg serum glucose concentration was 18 mg/dL.[183] Another young body build posthypoglycemic encephalopathy after using intravenous insulin.[66]

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is a glycoprotein that stimulates t in men. In women, hCG is secreted by the placenta during pregnancy. Hu gonadotropin may be used by male athletes to prevent testicular atrophy androgen administration.[121] Analysis of hCG in 740 urinary specimens of abnormal concentrations in 21 individuals. This finding prompted the IOC l 1987.[31 , 51] Presently, distinguishing exogenous hCG administration from early pregnancy is not possible, so the urine samples of women are not t

Very small amounts of hCG are normally present in men and nonpregnan measurement is made by immunoenzymatic assay. The decision limit, the which the test is considered positive, is set at 5 IU/mL urine. Trophoblast nontrophoblastic tumors can increase hCG concentrations, and this possib considered in the evaluation of elevated urinary hCG concentration.[57]

Although administration of hCG causes an increase in the total testostero ratio is unchanged because epitestosterone production also is stimulated.

Oxygen Transport

Erythropoietin (EPO)

EPO induces erythropoiesis by a receptor-mediated mechanism that stimu develop into mature red blood cells (RBCs). EPO has been available since human erythropoietin (rhEPO). Its use in international competition has b 1990. Because EPO increases exercise capacity and hemoglobin production athletes, often with additional iron supplementation, for these purposes. increased hematocrit occur several days after administration.[80 , 167] EPO oxygen uptake by 6â€“7%, an effect that lasts approximately 2 weeks af administration is completed.[64]

Two EPO analogs exist. Darbopoietin, also known as *new erythropoiesis-s* (NESP), differs from EPO by 5 amino acids. It has a much longer half-life

weekly.[169] Another protein known as synthetic erythropoiesis protein (SEP protein structure to EPO. The protein polymers created in this molecule h immunogenicity, fewer biologic contaminants, and more predictable pha

EPO is secreted primarily by the kidney, although some is produced by o the liver. The mean half-life of EPO is 4.5 hours following IV administratic subcutaneous administration.[195]

In patients with renal failure who are on dialysis, a typical dose is approx weight given 3 times per week.[100 , 195] EPO enhances endothelial activati reactivity and increases systolic blood pressure during submaximal exerc effects, in addition to the increase in hemoglobin, increase the risk for t hypertension, and hyperviscosity syndromes.[21 , 148 , 167] Evidence indicat rhEPO might pose a risk for decreased endogenous EPO production and of reticulocytosis and anemia.[36 , 167]

Increases in hematocrit subsequent to EPO use are believed to have cont of a number of competitive cyclists in Europe. Nineteen Belgian and Dutch uncertain causes between 1987 and 1990.[63] The 1998 Tour de France wa discovery of widespread EPO use by members of several different cycling

An EPO overdose occurred in a patient who self-administered 10,000 U/d of time as a result of a dosing error. The patient presented to the hospita with a plethoric appearance, blackened toes, decreased pulses, and a her Emergent erythropheresis was performed and resulted in rapid reduction improvement in the patient's condition.[250] Another report of deliberate of an unknown dose of rhEPO resulted in a hematocrit of 70%. The patier emergently with phlebotomy and intravenous hydration and improved.[30]

Artificial Oxygen Carriers

Artificial oxygen carriers are blood substitutes that supplement the oxyge RBCs.[202] Artificial oxygen carriers fall into two categories: hemoglobin-ba (HBOC) and perfluorocarbon (PFC) emulsions. Athletes may experiment w to increase endurance.

Hemoglobin can be genetically engineered or obtained from cattle or outc hemoglobin may serve as a source for human HBOC products. Hemoglobin

subunits, 2 Î±-chains and 2 Î²-chains. When removed from erythrocytes, unstable and dissociates into dimers. Therefore, hemoglobin must be stab variety of methods before an exogenous therapeutic agent is created. Th modification of hemoglobin by polymerization, conjugation, or cross-linki of human purified hemoglobin with glutaraldehyde, surface conjugation of polyethylene glycol, or linking of recombinant hemoglobin with short pepti hemoglobin stabilization. The life of HBOCs is much shorter than that of hemoglobin has a half-life of 12 hours, and surface-modified hemoglobin In comparison, erythrocytes may survive 120 days. In 1 report, healthy suffered no ill effects from infusion of Hemopure, a product of purified b cross-linked to glutaraldehyde.[106] HBOCs cause vasoconstriction resulting and pulmonary pressures.[202 , 217]

The differences in molecular weights of native hemoglobin and stabilized determined by size-exclusion high-performance liquid chromatography, whi primary methods of doping analysis for HBOCs.[233]

Perfluorocarbons

PFCs are synthetic oxygen-carrying compounds that can be used as RBC liquids, which are composed of 8â€“10 carbon atoms with fluorine substit serve as excellent solvents for gases.[92] In 1966, it was shown that mice fully submerged in PFCs infused with oxygen.[42] Compared to RBC transfus without risk of infection, require no cross-matching, and do not increase PFCs are stable at room temperature and have a shelf life of greater thar that make them convenient to use.

Several cyclists have been hospitalized for illnesses that were possibly as Symptoms included transient back pain, malaise, flushing, and fever of s duration.[92] Dose-related thrombocytopenia is transient and occurs 3â€“4 administration.[209]

PFCs increase vascular tone, which may cause hypertension. Both system vascular resistance is increased.[92] For unclear reasons, intravenous infusi can cause cardiac arrest.[224] Allergic reactions are reported to the egg yo [, 163 , 202]

Because PFCs are perceived by the immune system as foreign substances cleared by the reticuloendothelial system. The plasma half-life is approxin accumulate in the liver and spleen and are slowly transported to the lung. months to years, the PFCs are eliminated unchanged in the expired air an expired air by thermal conductance or in blood by using gas chromatogra spectrometry.[224 , 202]

Autotransfusion
