Antidotes in Depth

Hyperbaric Oxygen

Stephen R. Thom

Hyperbaric oxygen (HBO) therapy is a treatment modality in which a person breathes 100% O_2 while exposed to increased atmospheric pressure. Treatments are performed in either a monoplace (single person) or a multiplace (typically 2â€“14 patients) chamber. Pressures applied while patients are in the chamber usually are 2 to 3 atmospheres absolute (ATA), defined as the sum of the atmospheric pressure (1 atmosphere = 14.7 PSI) plus additional hydrostatic pressure equivalent to 1 or 2 atmospheres. Treatments typically last for 2â€“8 hours, depending on the indication, and may be performed 1â€“3 times daily. Monoplace chambers usually are compressed with pure oxygen. Multiplace chambers are pressurized with air, and patients breathe pure oxygen through a tight-fitting face mask, a head tent, or endotracheal tube. During treatment, the arterial oxygen tension typically exceeds 2000 mm Hg, and levels of 200â€“400 mm Hg occur in tissues.[130]

HBO should be viewed as a treatment modality and the hyperbaric

chamber as a dosing device. Elevating tissue O_2 tension is a primary effect. Although this may alleviate physiologic stress to hypoxic tissues, lasting benefits of HBO appear to relate to abatement of underlying pathophysiologic processes.

In the context of an antidote, HBO is most commonly used for treatment of carbon monoxide (CO) poisoning. Experience using HBO for life-threatening poisonings from cyanide (CN), hydrogen sulfide (H_2S), or carbon tetrachloride (CCl_4) and in patients with high methemoglobin levels is limited. HBO has been suggested for management of diverse poisonings, but discussion of these applications is beyond the scope of this Antidotes in Depth because of the absence of supporting clinical or experimental evidence.[138]

Therapeutic mechanisms of action for HBO are based on elevation of both hydrostatic pressure and the partial pressure of oxygen. Elevation of the hydrostatic pressure causes a reduction in the volume of gas according to Boyle's law. This action has direct relevance to pathologic conditions in which gas bubbles are present in the body, such as arterial gas embolism and decompression sickness. All perfused tissues are subjected to elevated partial pressures of oxygen in association with HBO exposure. Under normal environmental conditions, hemoglobin is virtually saturated with oxygen on passage through the pulmonary microvasculature, so the primary effect of HBO is to increase dissolved oxygen content of plasma. Application of each additional atmosphere of oxygen increases the dissolved oxygen concentration in the plasma by 2.2 mL O_2/dL (vol%) (Chap. 22).

Mechanisms of HBO relevant to its use as an antidote are its ability to diminish hypoxic stress by increasing tissue oxygen tension and its ability to accelerate production of free radicals. Elevated concentrations of free radicals have been demonstrated in persons exposed to hyperoxia, and specifically those undergoing HBO therapy. Humans exposed to 100% O_2 versus air have ~38%

more nitric oxide (â€¢NO) in their exhaled breath.[104] Hyperbaric hyperoxia appears to increase â€¢NO-containing substances in both the pulmonary and systemic vascular beds. *S*-nitrosohemoglobin concentration is approximately doubled in arterial and venous blood of rats exposed to 3 ATA versus 1 ATA O_2.[120] Ascorbate free radicals are found in erythrocytes taken from persons exposed to 2.7 ATA O_2 for 60 minutes. The concentration of radicals diminishes to baseline within 10 minutes following exposure.[85] Oxidative stress from HBO causes DNA single strand breaks by the comet assay, and they have been shown to occur in circulating leukocytes following exposure to 2.5 ATA O_2 for 60 minutes. This insult does not occur with subsequent treatments, however, because the first hyperoxic exposure leads to adaptive changes in cells, including induction of heat shock protein-32 (heme oxygenase-1).[35,36,99]

Free radicals are generally perceived as toxic agents, and to suggest that they be purposefully generated as part of an alleged therapy may seem an anathema. Yet intracellular production of â€¢NO appears to be the basis for the inhibitory effect of HBO on neutrophil adhesion.[128] Exposure to 2.8â€“3.0 ATA O_2 for 45 minutes temporarily inhibits neutrophil adherence mediated by the activation-dependent Î²$_2$-integrins on the neutrophil membrane. This effect initially was demonstrated in rodents and subsequently in human studies.[24,129,134] Similar findings with humans have since been corroborated by two other groups.[60,65] Neutrophils remain viable, the effect is reversible, and functions such as degranulation and oxidative burst to chemoattractants appear to be unaltered.[129,134] The ability of HBO to inhibit function of neutrophil Î²$_2$-integrins ameliorates reperfusion injuries of brain, skeletal muscle, and intestine, as well as smoke-induced lung injury, decompression sickness, and encephalopathy resulting from CO poisoning in animals.[5,75,125,126,129,137,142,145,153,154 and 155] Alterations of neutrophil adherence by HBO may be the basis for benefits shown in several human clinical trials. HBO reduces

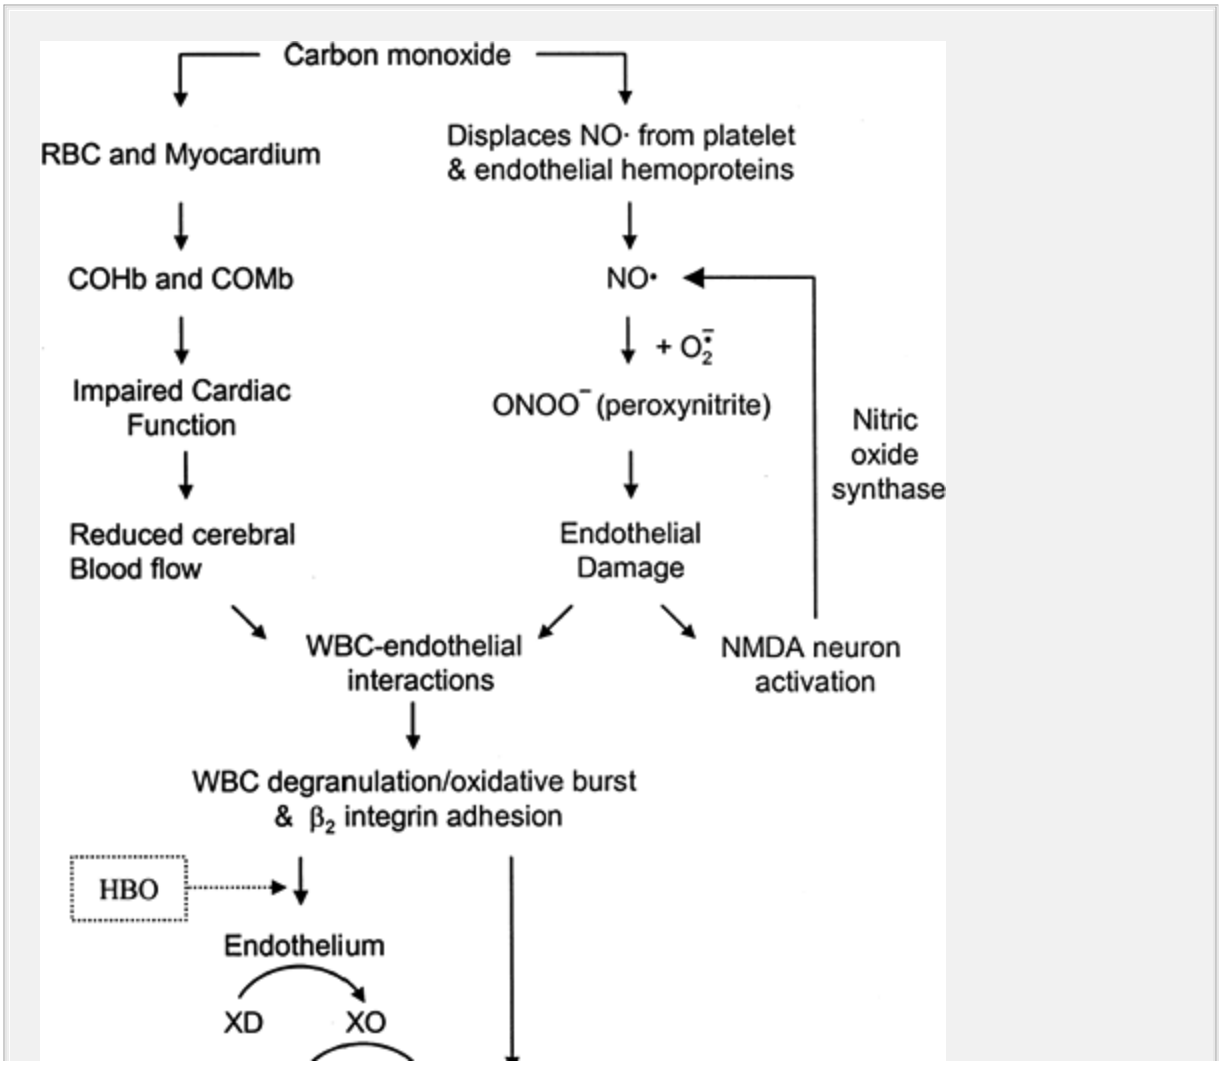
coronary artery restenosis after balloon angioplasty/stenting,[108,109] decreases muscle loss after thrombolytic treatment for myocardial infarction,[107,121] and reduces the incidence of CO-mediated encephalopathy.[150]

Administration of supplemental oxygen is the cornerstone for treatment of CO poisoning.[56] Its use is based on the affinity of CO for heme proteins and formation of carboxyhemoglobin (COHb). Elevated COHb can precipitate tissue hypoxia, and this stress appears to be responsible for fatalities, cardiac injuries, and the acute neurologic abnormalities that develop in approximately 14% of survivors of serious CO poisoning.[2,29,32,41] Oxygen inhalation hastens dissociation of CO from hemoglobin and provides enhanced tissue oxygenation. HBO causes COHb dissociation to occur at a rate greater than that achievable by breathing pure O_2 at sea-level pressure.[88] Additionally, HBO accelerates restoration of mitochondrial oxidative processes.[16]

Delayed neurologic sequelae are the most frequent form of CO-mediated morbidity. Studies indicate that between 23 and 46% of patients with CO poisoning develop impairments of concentration and learning, dementia, cog wheel rigidity, amnesia and/or depression, between 6 days and 7 weeks after poisoning.[25,43,54,78,79,84,95,135,150] Additional pathophysiologic mechanisms beyond COHb-mediated hypoxia are thought to exist for delayed neurological sequelae. COHb levels correlate poorly with clinical outcomes, and delayed neurological sequelae still occur even when CO poisoning appears to be relatively mild.[47,97,98,102,105,135] A number of clinical

studies using several different neuroimaging techniques on CO victims have found acute vascular abnormalities and atypical coupling between cerebral blood flow and neuronal O_2 demand.[37,73,112,115] This finding suggests that CO poisoning causes vascular injury.

Vascular abnormalities occur in animal models of CO poisoning. These changes precipitate neutrophil adherence, and activated neutrophils initiate a cascade of events that ultimately causes delayed neurologic dysfunction (Figure A34-1).[57,132,133] HBO inhibits CO-mediated neutrophil adherence and subsequent pathologic events.[129,131] Animals poisoned with CO and treated with HBO have more rapid improvement in cardiovascular status,[38] lower mortality,[90] and lower incidence of neurologic sequelae.[131] Benefits likely are based on both improved oxygenation and secondary effects pertaining to inhibition of neutrophil adhesion. These observations provide additional motivation for clinical use of HBO.



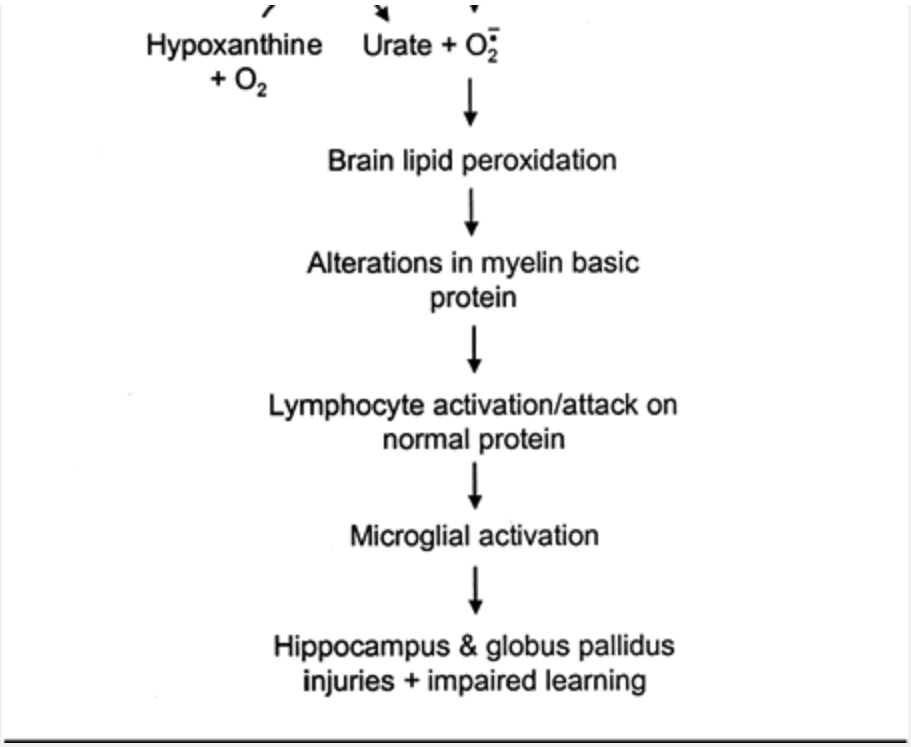


Figure A34-1. Cascade of events as identified in rat model of carbon monoxide poisoning.[57,132,133] COHb = carboxyhemoglobin; COMb = carboxymyoglobin; HBO = hyperbaric oxygen; NMDA = *N*-methyl-D-aspartate; NOÂ· = free radical nitric oxide; RBC = red blood cell; WBC = white blood cell; XD = xanthine dehydrogenase; XO = xanthine oxidase.

Since 1960, HBO has been used with increasing frequency for severe CO poisoning, as clinical recovery appeared improve beyond that expected with ambient-pressure oxygen therapy. Support for HBO use comes from this experience.[43,44,55,66,77,84,86,100] To date, six prospective studies have assessed the efficacy of HBO for acute CO poisoning.

The first prospective clinical trial involving HBO therapy failed to find HBO superior to ambient-pressure treatment.[95] This study has

been criticized because the authors used a low oxygen partial pressure (2 ATA) versus the more usual protocols with 2.5â€“3 ATA and because nearly half of the patients received hyperbaric treatments more than 6 hours after they were discovered.[15] In 1969, a retrospective study indicated that HBO reduced mortality and morbidity only if HBO was administered within 6 hours of CO poisoning.[44] HBO was effective in several prospective investigations. In a trial involving mildly to moderately poisoned patients, 23% of patients (7/30) treated with ambient-pressure oxygen developed neurologic sequelae, whereas no patients (0/30; $p < 0.05$) treated with HBO (2.8 ATA) developed sequelae.[135] In another prospective, randomized trial, 26 patients were hospitalized within 2 hours of discovery and were equally divided between 2 treatment groups: ambient-pressure oxygen or 2.5 ATA O_2.[37] Three weeks later, patients treated with HBO had significantly fewer abnormalities on electroencephalogram, and single-photon emission computed tomography (SPECT) scans showed that cerebral vessels had nearly normal reactivity to carbon dioxide, in contrast to diminished reactivity in patients treated with ambient-pressure oxygen.

A fourth trial randomized 191 CO-poisoned patients of different severity to daily HBO (3.0 ATA for 60 minutes) with intervening high-flow oxygen for 3 or 6 days versus high-flow normobaric oxygen for 3 or 6 days.[103] The outcome measure was neuropsychological testing after treatment one month later, and no benefit from HBO was documented. Multiple flaws in the design and execution of this study are discussed in the literature, so it is impossible to draw meaningful conclusions from the data.[48,82] For example, the CO poisonings were suicide attempts in 69% of the cases, and half of the patients had also ingested alcohol or other drugs. The presence of depression and psychoactive substances in many of the patients may have confounded the results of neuropsychological testing. Neither the HBO nor the normobaric oxygen protocol followed standard treatment recommendations,

and both regimens were potentially toxic. Finally, less than half (46%) of the patients completed the followup examination at one month.

One randomized trial has been reported only in abstract form at this time. This trial is the only multicenter study of treatment of CO poisoning.[78] At an interim analysis, 575 patients had been randomized to HBO treatment (90 minutes of O_2 at 2.5 ATA) versus 12 hours of normobaric oxygen administration. All patients were followed serially for one year. At three months, neurologic sequelae were significantly less in the HBO_2 treatment group (8.7%) than in the normobaric oxygen (NBO) group (15.2%, p = 0.016). The difference lessened by 6 months (6.4 vs. 9.5%; p = 0.09) and disappeared by 12 months.

Finally, a double-blind randomized trial demonstrated that HBO therapy reduces the incidence of neurologic sequelae after acute CO poisoning.[150] In this study, patients were stratified by age >40 years or <40 years, time to end of CO exposure, starting

treatment >6 hours or <6 hours, and history of unconsciousness. All patients were treated 3 times at 6- to 12-hour intervals in a monoplace chamber. CO poisoning questionnaires, functional outcome evaluations, and the neuropsychological test battery were given 2 weeks, 6 weeks, 6 months, and 12 months after CO poisoning. Cognitive sequelae were considered present if any 6-week neuropsychological subtest score was >2 standard deviations below the mean or if at least 2 subtest scores were each >1 standard deviation below the mean of demographically corrected standardized scores.

The pretreatment characteristics of the 152 patients enrolled in the trial were similar except that cerebellar dysfunction was more frequent in the NBO treatment group. The mean COHb was 25%, and 49% of the patients had sustained an interval of unconsciousness. The group treated with HBO had a lower

incidence of cognitive sequelae than the group treated with NBO after adjustment for prechamber cerebellar dysfunction and stratification (odds ratio 0.45, 95% confidence interval 0.22â€“0.92, p = 0.03). Post hoc subgroup analysis incorporating risk factors for which HBO therapy is generally recommended showed that HBO reduced cognitive sequelae in patients with any of the following: unconsciousness, COHb â‰¥25%, age â‰¥50 years, or base excess â‰¤2 mEq/L. HBO did not improve outcome in patients with none of these criteria.

HBO treatment of acute CO poisoning rests on a solid scientific rationale, basic science research, and randomized controlled clinical trials. However, important caveats remain for future investigations. As yet no objective method is available for staging the severity of CO poisoning, although preliminary reports suggest plasma markers may be used in the future.[17] Psychometric screening tests have not proved reliable because abnormalities during the initial screening do not correlate with development of delayed sequelae.[135] Along similar lines, the etiology and risk factors for delayed neurologic syndrome are unknown. Animal evidence suggests that the oxidative stress triggered by neutrophil adherence/activation in the cerebral vasculature causes brain lipid peroxidation, which has been linked to delayed neuropathology because it precipitates an adaptive immunologic response to normal and abnormal brain protein.[132,133] CO can also cause late programmed cell death in the brain.[91]

The optimal dose of HBO (ie, number of treatments and treatment pressure) and the time after which it is no longer effective therapy are not clearly defined. Randomized trials have treated patients as soon as possible after CO poisoning based on work suggesting the existence of a 6-hour window of greatest opportunity.[44] However, it is possible that the time of potential benefit goes beyond what has been investigated for some patients. The requisite number of treatment also remains unclear. Finally, the mechanisms of action remain unclear. Action for HBO therapy in CO poisoning may

include hastened dissociation of CO from hemoglobin and from cytochrome oxidase and temporary inhibition of leukocyte adhesion molecules to blunt the cascade of vascular injury.[16,88,129] Clinical indications for HBO in CO poisoning are reviewed in greater detail in Chap. 120 and specifically in Table 120-3.

Methylene Chloride

Methylene chloride (CH_2Cl_2) is an organic solvent used commercially in aerosol sprays, as a solvent in plastics manufacturing, photographic film production, and food processing, as a degreaser, and as a paint stripper. It is readily absorbed through the skin or by inhalation. It is metabolized by the cytochrome P450 oxidase system to yield CO.[123] This process is slow, and peak COHb levels of 10â€“50% may not be reached for 8 hours or more.[22,23,39,61,67,73,74,114,123] Methylene chloride toxicity can have many of the same acute manifestations as CO poisoning.[119] Acute signs and symptoms are attributable to the direct effects of this solvent on the central nervous system and to concomitant hypoxia. Effects that are present after 1 hour or more, especially if the COHb level is elevated, may be partially caused by CO toxicity. Treatment with HBO in this setting is reported.[53,101]

Combined Carbon Monoxide and Cyanide

CO and CN poisonings can occur concomitantly in victims of smoke inhalation.[3,4,7,8 and 9,11,26,31,64,70,72,80,113,116,147,151] Experimental evidence suggests that these xenobiotics can produce synergistic toxicity.[6,83,87,88,92] Toxicity from CN stems from binding to cytochrome a-a_3 thereby inhibiting oxidative phosphorylation. Animal studies demonstrate that ambient-

pressure 100% O_2 can enhance protection from CN toxicity[110] and also can enhance CN metabolism to thiocyanate when thiosulfate is used concomitantly.[13] HBO may have direct effects on reducing CN toxicity[30,58,59,117,127] or augmenting antidote treatments.[21,110,149] However, not all animal studies have found HBO improved outcome,[148] and clinical experience regarding CN treatment with HBO is sparse.[2] In a series of smoke-inhalation victims with both toxic CO and CN levels who received both HBO and treatment for CN involving sodium nitrite and sodium thiosulfate, 4 of 5 patients survived without apparent neurologic damage.[51] Clinical case reports where HBO was used along with standard antidote treatment (sodium nitrite plus sodium thiosulfate) for isolated CN poisonings are equivocal.[42,69,106,139] One case showed dramatic improvement,[139] but another showed no response.[69] Further research in this area is necessary. Because CN is among the most lethal poisons and toxicity is rapid, standard antidotal therapy for isolated CN poisoning is of primary importance. Hyperbaric oxygen may be an adjunct for consideration in refractory cases (Chap. 121).

Hydrogen Sulfide

Hydrogen sulfide (H_2S) binds to cytochrome a-a_3 and impairs oxidative phosphorylation. Hence, one of its mechanisms of toxicity is similar to that of CN, although it is more readily dissociated from cytochrome oxidase by O_2.[124] Clinical manifestations of toxicity are similar to those with CO and CN.[124] Management of patients with serious H_2S poisoning principally involves oxygenation and cardiovascular support, as well as consideration of sodium nitrite.[46] HBO may be more effective than sodium nitrite in preventing mortality in animals.[12] In several instances, HBO appeared to be beneficial.[20,45,119,152] Relatively late treatment with HBO (ie, â‰¥10 hours after poisoning) is reported to be beneficial in some[144] but not all cases.[1] No definitive data regarding use of HBO for H_2S poisoning are

available, but HBO should be considered in refractory cases.

Carbon Tetrachloride

Carbon tetrachloride (CCl_4) hepatotoxicity may be diminished by HBO. Mortality was decreased in a number of animal studies,[10,19,81,96]

and there are several case reports of patients surviving potentially lethal ingestions with HBO therapy.[68,122,140,156] HBO appears to inhibit the mixed-function oxidase system responsible for conversion of CCl_4 to hepatotoxic free radicals.[18,76] Because there are no proven antidotes for CCl_4 poisoning, HBO should be considered for potentially severe CCl_4 exposures. However, there may be a delicate balance between oxidative processes that are therapeutic and those that mediate hepatotoxicity.[14] Therefore, when HBO is being considered, it should be instituted before the onset of liver function abnormalities.

Patient Management

A fundamental aspect to emergency patient management and treatment is the knowledge and training of the healthcare team. Hyperbaric treatment centers typically have the ability to manage patients who require critical care support. Plans for treatment begin while the patient is still in the emergency department, before transport to the hyperbaric chamber is initiated. Issues to be addressed include informed consent, determination that all intravenous/arterial lines and nasogastric tubes/Foley catheters are secured, capping all unnecessary intravenous catheters, placing chest tubes to 1-way Heimlich valves, replacing air in endotracheal tube cuffs with water to prevent excessive air leakage at pressure, and adequately sedating or paralyzing the patient as clinically indicated. Substantial clinical experience demonstrates that patients can be transported without adverse

events.[118]

HBO therapy should never be considered unless proper supportive medical care can be delivered. Most chamber facilities today have equipment and treatment protocols analogous to an intensive care unit. Intensive care support for pediatric cases also can be achieved.[62,146] The inherent toxicity of O_2 and potential for injury resulting from elevations of ambient pressure must be addressed whenever HBO is used therapeutically. Preexisting conditions that require evaluation for possible management before initiation of HBO include claustrophobia, sinus congestion, and patients with scarred or noncompliant structures in the middle ear, such as otosclerosis.[63]

Middle ear barotrauma is the most common adverse effect of HBO treatment.[22] As the ambient pressure within the hyperbaric chamber increases, a patient must be able to equalize the pressure within the middle ear by autoinsufflation. When autoinsufflation fails, tympanostomy tubes must be placed. The incidence of tube placement is reported to be approximately 4% in one series.[28] Others report an overall incidence of aural barotrauma of between 1.2 and 7%.[93,141] Pulmonary barotrauma during HBO treatment is rare but should be suspected if any chest or hemodynamic alterations occur during, or shortly after, decompression. If pneumothorax is suspected, placement of a chest tube is appropriate. Preexisting pneumothorax should be treated with chest tube drainage prior to initiating therapy.

Biochemical toxicity resulting from O_2 can be manifested by injuries to the CNS, lungs, and eyes. CNS O_2 toxicity is manifested as a grand mal seizure and occurs at an incidence of approximately 1â€“4/10,000 patient treatments.[34,50,93] The risk is higher in hypercapnic patients and possibly in those who are acidotic or have compromise resulting from sepsis, as an incidence of 7% (23/322 patients) was reported in case series of HBO_2 treatment of gas gangrene.[33,49] Pulmonary insults can impair

mechanics (elasticity), vital capacity, and gas exchange (reviewed in reference 56). These conditions typically do not arise when standard treatment protocols are followed.[27,40,52,94] There is one report of reversible small airways changes in 4/21 patients treated daily for 90 minutes at 2.4 ATA for 21 days.[136] Progressive myopia may occur in patients undergoing prolonged daily therapy but typically reverses within 6 weeks after treatments are terminated.[71] Excessive treatments, exceeding a total of 150â€“200 hours, are associated with development of nuclear cataracts.[89] Although there is a theoretical risk for retrolental fibroplasia in neonates, experimental and clinical evidence does not indicate that typical HBO therapy protocols have detrimental effects on neonates or the unborn fetus.[143] As with any environment having an elevated concentration of O_2 there is a fire hazard, so scrupulous attention must be devoted to avoiding an ignition source. Over the past 20 years, no fires resulting in injury were reported in the United States, but 52 deaths were reported worldwide.[111] Virtually all these deaths were preventable. In 10 incidents, fire resulted when banned substances such as cigarettes and lighters were taken into the chamber.

In conclusion, the mechanisms of action and efficacy of HBO in toxicology continue to be investigated. Some research findings are provocative because they highlight the fact that traditional assessments of mechanisms for toxicity of some agents are incomplete. Questions persist on many issues. Further investigation is required to discern those cases where clear benefit arises with HBO treatment and to define the constraints that may limit its efficacious use.

Chapter 121
Cyanide and Hydrogen Sulfide

Christopher P. Holstege
Gary E. Isom
Mark A. Kirk

Cyanide

MW:	=	26.02 daltons
Whole blood:	=	<1 Âµg/mL
	=	38.5 Âµmol/L

Airborn

Immediately fatal	=	270 ppm
Life threatening	=	110 ppm >30 min

Hydrogen Sulfide

MW: = 34.08 daltons

Airborne concentrations:

Odor threshold = 0.02â€“0.13 ppm

Olfactory fatigue = 100â€“150 ppm

Immediately fatal = 700 ppm

Cyanide Poisoning

Case 1

A previously healthy 45-year-old chemistry professor was found unresponsive on the laboratory floor by his coworkers. They initiated cardiopulmonary resuscitation (CPR), with mouth-to-mouth breathing, until first responders arrived. Paramedics intubated the patient because of apnea. Prehospital vital signs were: blood pressure, 80 mm Hg by palpation; pulse, 110 beats/min. The patient did not respond to intravenous naloxone (0.8 mg) or dextrose (25 g). Systolic blood pressure increased to 100 mm Hg after bolus administration of 1000 mL 0.9% sodium chloride solution during transport. A telephone call to the emergency department (ED) prior to patient arrival reported that a partially empty 5-g vial of sodium cyanide was found on the patient's laboratory workbench, along with a suicide note.

Upon arrival to the ED, the patient was transferred to the decontamination room, where he was thoroughly irrigated with water while resuscitation was continued. The initial survey revealed a comatose man with vital signs of blood pressure, 90 mm Hg by palpation; pulse, 74 beats/min; rectal temperature 98.8Â°F (37.1Â°C); pulse oximetry 99% on 100% oxygen. The bedside rapid reagent glucose concentration was 276 mg/dL (after dextrose

bolus). A detailed physical examination was remarkable for dilated and sluggish pupils, roving ocular movements, occasional nonpurposeful movement, and bilateral decorticate posturing. The remainder of the examination was normal. Initial arterial blood gas (ABG) analysis showed pH, 7.01; PCO_2, 21 mm Hg; PO_2, 575 mm Hg on 100% oxygen. Whole blood lactate concentration was 10 mmol/L. The patient received 100 mEq sodium bicarbonate intravenously and the cyanide antidote kit, which included 300 mg sodium nitrite IV and 12.5 g sodium thiosulfate IV.

Serum electrolytes sent for analysis prior to antidote administration were normal except for serum bicarbonate 8.9 mEq/L. ECG revealed nonspecific ST changes. Computed tomography of the head was normal. Repeat ABG analysis and cooximetry 30 minutes after administration of the cyanide antidote kit demonstrated improvement in pH to 7.17 with a methemoglobin level of 6.5%. A second bolus of sodium thiosulfate and sodium nitrite was given at half the initial dose. The metabolic acidosis resolved over the next 12 hours. Serum acetaminophen, salicylate, toxic alcohol, and urine drug-abuse screens were negative.

The coworker who performed mouth-to-mouth assisted breathing on the patient also was evaluated in the ED. The coworker complained of dyspnea, palpitations, chest pain, near syncope, and tingling of his fingers and toes. On examination, he was anxious and tremulous, with vital signs of blood pressure, 156/95 mm Hg; pulse, 148 beats/min; respiratory rate; 48 breaths/min. Concern regarding the potential for oral mucosa absorption of residual cyanide during mouth-to-mouth resuscitation prompted the initial healthcare workers to consider administration of the cyanide antidote kit to the second patient.

However, the attending physician performed ABG analysis, which showed pH, 7.61; PCO_2, 14 mm Hg; PO_2, 575 mm Hg; bicarbonate, 25 mEq/L on a non-rebreather oxygen mask. The patient's symptoms resolved, and he was diagnosed with acute stress

reaction.

The remainder of the acute course of the patient who ingested the sodium cyanide was uneventful. At 5-month followup, however, he complained of difficulty with memory and limb stiffness. Physical examination revealed generalized bradykinetic movements consistent with secondary parkinsonism.

History and Epidemiology

In 1782, the Swedish chemist Carl Wilhelm Scheele first isolated hydrogen cyanide. He reportedly died from the adverse health effects of cyanide poisoning in 1786. Napoleon III was the first to use hydrogen cyanide as a chemical warfare agent. Hydrogen cyanide was used on the battlefield in World War I and later as a genocidal agent (Zyklon B) by the Germans during World War II.

The majority of reported cyanide exposures are unintentional (Chap. 130). These events frequently involve chemists or technicians working in laboratories where cyanide salts are common reagents.[22,31,53,54,77,156] The potential for cyanide poisoning also exists following smoke inhalation.[10,42,91,121,138] The combustion of materials such as wool, silk, synthetic rubber, and polyurethane releases cyanide.

Approximately 10% of documented cyanide exposures are suicidal in etiology (Chap. 130). Potassium cyanide (KCN) was used in the 1978 Jonestown mass suicide, in which more than 900 people died. Seven deaths resulting from consumption of cyanide-tainted acetaminophen occurred in 1982,[28] and a death from a cyanide-laced decongestant occurred in 1991.[40] Cyanide has also been used for illicit euthanasia.[25]

Ingestion of cyanogenic chemicals (eg, acetonitrile, acrylonitrile, and proprionitrile) is another source of cyanide poisoning.[21,34,38,151] Acetonitrile (C_2H_3N) and acrylonitrile (C_3H_3N) are themselves nontoxic, but biotransformation via cytochrome

P450 liberates cyanide (Figure 121-1).[161] Numerous reports of unintentional poisoning of children ingesting acetonitrile-based, artificial nail remover are published.[38,59,87,90]

Many plants, such as the *Manihot* spp, *Linum* spp, *Lotus* spp, *Prunus* spp, *Sorghum* spp, and *Phaseolus* spp contain cyanogenic glycosides.[146] The *Prunus* species (eg, apricots, bitter almond, cherry, and peaches) have pitted fruits containing the glucoside amygdalin (D-mandelonitrile-Î²-*d*-glucoside). When ingested, amygdalin is biotransformed by intestinal Î²-*d*-glucosidase to glucose, aldehyde, and cyanide (Figure 121-1). Laetrile, which contained amygdalin, was a purported antineoplastic available in the 1970s. It was administered as intravenous infusion, bypassing the necessary enzymes in the gastrointestinal tract to liberate cyanide, although when ingested it was associated with cyanide poisoning.[66] Despite data demonstrating its lack of utility in the treatment of cancer,[102] it still is available via the Internet.

Cassava (*Manihot esculenta*) root is a major source of food for millions of people in the tropics. It is a hardy plant that can remain in the ground for up to 2 years and needs relatively little water to survive. Because the shelf life of a cassava root is very short once it is removed from the stem, cassava root must be processed and sent to market as soon as it is harvested. However, proper processing must occur to assure the food's safety. Processed cassava is called *Gari.* Linamarin (2-hydroxyixo-buty-nitrite-Î²-D-glycoside) is the major cyanogenic glycoside in cassava roots. It is hydrolyzed to hydrogen cyanide and acetone in two steps during the processing of cassava roots.[159] Soaking peeled cassava in water for a single day releases approximately 45% of the cyanogens, whereas soaking for 5 days causes 90% loss.[3] If processing is inefficient, linamarin and cyanohydrin, the immediate product of hydrolysis of linamarin, remain in the food.[113,114] Consumed linamarin is hydrolyzed to cyanohydrins by Î²-glucosidases of the microorganisms in the intestines. Cyanohydrins present in the food and formed from linamarin then dissociate spontaneously to cyanide in the alkaline

pH of the small intestines.[3,6,30,112]

Iatrogenic cyanide poisoning may occur during use of nitroprusside as a vasodilator given to reduce blood pressure and afterload. Each nitroprusside molecule contains five cyanide molecules, which are slowly released in vivo. If endogenous sulfate stores are depleted, as in the malnourished or postoperative patient, cyanide may accumulate even with therapeutic nitroprusside infusion rates (2â€“10 Âµg/kg/min).

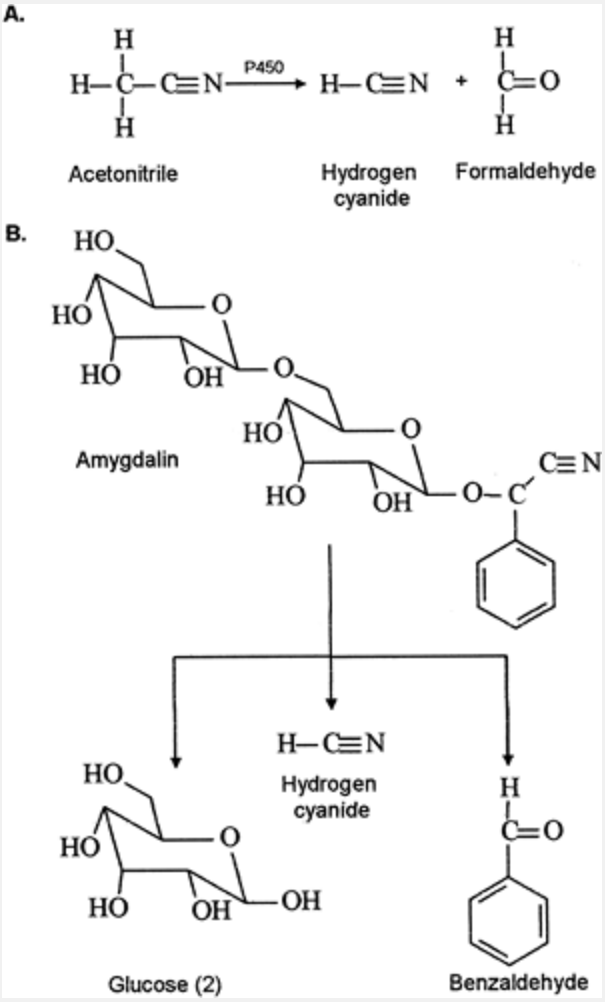

Figure 121-1. Biotransformation of cyanogens (A) acetonitrile and (B) amygdalin to cyanide.

Pharmacology

The dose of cyanide required to produce toxicity is dependent on the form of cyanide (gas or salt), the duration, and the route of

exposure. However, cyanide is an extremely potent toxin; even small exposures lead to symptoms. An adult oral lethal dose of KCN is approximately 200 mg. An airborne concentration of 270 ppm (Âµg/mL) hydrogen cyanide (HCN) may be immediately fatal, and exposures >110 ppm for more than 30 minutes are generally considered life threatening. The threshold limit value for hydrogen cyanide is 10 ppm during an 8-hour day.

Acute toxicity occurs through a variety of routes, including inhalation, ingestion, dermal, and parenteral.[24,139] Hydrogen cyanide, a gas under standard temperature and pressure, readily crosses membranes because it has a low molecular weight (27 daltons) and is nonionized. After absorption and dissolution in blood, cyanide exists in equilibrium as the cyanide anion (CN^-) and undissociated HCN. Hydrogen cyanide is a weak acid with a pK_a of 9.21. Therefore, at physiologic pH 7.4, it exists primarily as HCN. Rapid diffusion across alveolar membranes followed by direct distribution to target organs accounts for the rapid lethality associated with HCN inhalation.

Pharmacokinetics and Toxicokinetics

Cyanide is eliminated from the body by multiple pathways. A number of minor pathways of metabolism (<15% of total) account for cyanide elimination including conversion to 2-aminothiazoline-4-

carboxylic acid, incorporation into the 1-carbon metabolic pool, or in combination with hydroxycobalamin to form cyanocobalamin.

The major route for detoxification of cyanide is the enzymatic conversion to thiocyanate. Two sulfur transferase enzymes, rhodanese (thiosulfate-cyanide sulfurtransferase) and Î²-mercaptopyruvate-cyanide sulfurtransferase, catalyze this reaction. The primary pathway for metabolism is thought to be rhodanese, which is widely distributed throughout the body and has the highest concentration in the liver. This enzyme catalyzes the transfer of a sulfane sulfur from a sulfur donor (eg, thiosulfate) to cyanide to form thiocyanate. In acute poisoning, the limiting factor in cyanide detoxification by rhodanese is the availability of adequate quantities of sulfur donors. The endogenous stores of sulfur are rapidly depleted, and cyanide metabolism slows. Hence, sodium thiosulfate's efficacy as an antidote stems from its normalization of the metabolic inactivation of cyanide. The sulfation of cyanide is essentially irreversible, and the sulfation product thiocyanate has relatively little inherent toxicity. Thiocyanate is eliminated in urine.

Limited human data regarding the cyanide elimination half-life are available. Elimination appears to follow first-order kinetics,[86] although it varies widely in reports (range 1.2â€“ 66 hours).[10,62,65,86] Disparity in values may result from the number of samples used to perform calculations and the effects of antidotal treatment. The volume of distribution of cyanide varies according to species and investigator, with 0.075 L/kg reported in humans.[48]

Pathophysiology

Cyanide is an inhibitor of multiple enzymes, including succinic acid dehydrogenase, superoxide dismutase, carbonic anhydrase, and cytochrome oxidase.[164] Cytochrome oxidase is an iron-containing metalloenzyme essential for oxidative phosphorylation and, hence, aerobic energy production. It functions in the electron transport chain within mitochondria, converting catabolic products of glucose

into adenosine triphosphate (ATP). Cyanide induces cellular hypoxia by inhibiting cytochrome oxidase at the cytochrome a_3 portion of the electron transport chain (Figure 121-2).[120,164] Hydrogen ions that normally would have combined with oxygen at the terminal end of the chain are no longer incorporated. Thus, despite sufficient oxygen supply, oxygen cannot be utilized, and ATP molecules are no longer formed.[93] Unincorporated hydrogen ions accumulate, contributing to acidemia.

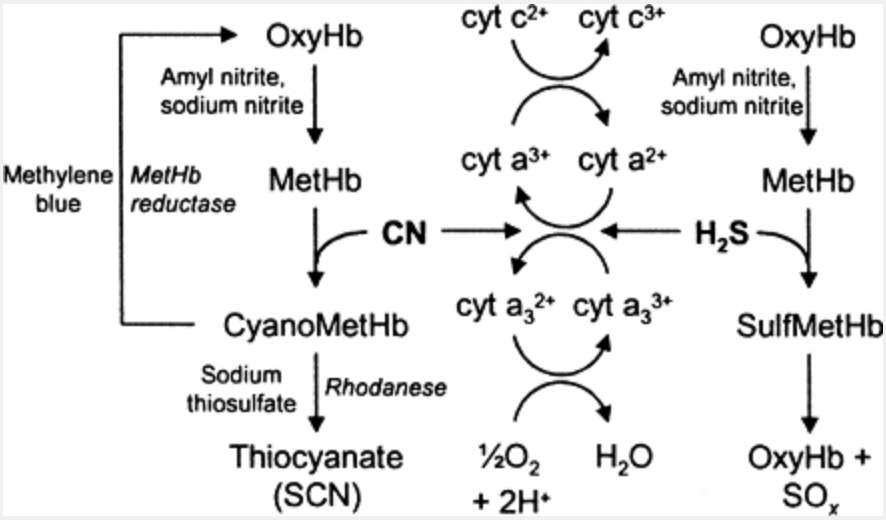

Figure 121-2. Pathway of cyanide and hydrogen sulfide toxicity and detoxification.

Hyperlactemia occurs following cyanide poisoning because of failure of aerobic energy metabolism. During aerobic conditions, when the electron transport chain is functional, lactate is converted to pyruvate by mitochondrial lactate dehydrogenase. In this process, lactate donates hydrogen moieties that reduce nicotinamide adenine dinucleotide (NAD^+) to NADH. Pyruvate then enters the tricarboxylic acid cycle, with resulting ATP formation. When cytochrome a_3 within the electron transport chain is inhibited by cyanide, there is a

relative paucity of NAD^+ and predominance of NADH, favoring the reverse reaction, in which pyruvate is converted to lactate as a result of stimulation of anaerobic glycosis.[10,20,40,59,62,87,137,139]

Cyanide is a potent neurotoxin. It exhibits a particular affinity for regions of the brain with high metabolic activity and regions with a high affinity to cyanide.[124,170] Central nervous system (CNS) injury occurs via several mechanisms, including impaired oxygen utilization, oxidant stress, and enhanced release of excitatory neurotransmitters. Cranial imaging of survivors of cyanide poisoning reveals that injury occurs in the most oxygen-sensitive areas of the brains, such as the basal ganglia, cerebellum, and sensorimotor cortex.[17,26,53,132,133]

Cyanide enhances *N*-methyl-D-aspartate (NMDA) receptor activity and directly activates the NMDA receptor,[5,117,118] which increases release of glutamate[116] and inhibits voltage-dependent magnesium blockade of the NMDA receptor.[171] This NMDA receptor stimulation results in Ca^{2+} entry into the cytosol of neurons. Cyanide also activates voltage-sensitive calcium channels[75] and mobilizes Ca^{2+} from intracellular stores.[95,125] As a result, cytosolic Ca^{2+} rises and activates a series of biochemical reactions that lead to the generation of reactive oxygen species and nitrous oxide.[82,101,123,134,135] These reactive oxygen species initiate peroxidation of cellular lipids, which together with cyanide-induced inhibition of the respiratory chain adversely affect mitochondrial function, initiating cytochrome c release and execution of apoptosis, necrosis, and subsequent neurodegeneration.[8,75,122,123,136] Experimental studies demonstrate that NMDA inhibitors (eg, dextrorphan and dizocilpine), antioxidants, and cyclooxygenase inhibitors protect neurons against cyanide-induced damage.[71,89,160]

Sulfurtransferase metabolism via rhodanese is crucial for detoxification. However, the aforementioned cyanide-induced metabolic derangement may decrease enzyme detoxification.

Decreased ATP and reactive oxygen species and increased cytosolic calcium stimulate protein kinase C activity, which in turn inactivates rhodanese.[92]

Clinical Manifestations

Acute Exposure to Cyanide

The amount of cyanide, duration of exposure, route of exposure, and premorbid condition of the individual influence the time to onset and severity of illness. A critical combination of these factors overwhelms endogenous detoxification pathways, allowing cyanide to diffusely affect cellular function within the body. No reliable pathognomonic symptom or toxic syndrome is associated with acute cyanide poisoning.[60,61] Clinical manifestations reflect dysfunction of oxygen-sensitive organs, with central nervous and cardiovascular findings predominating. The time to onset of symptoms typically is seconds with inhalation of gaseous HCN or intravenous injection of a water soluble cyanide salt and several minutes following ingestion of an inorganic cyanide salt. The clinical effects of cyanogenic chemicals often are delayed, and the time course varies among individuals (range 3â€“24 hours), depending on their rate of biotransformation.[151] Clinically apparent cyanide toxicity may occur within hours to days of initiating nitroprusside infusion, although concurrent administration of thiosulfate or hydroxocobalamin may prevent toxicity (Chap. 60).[130]

CNS signs and symptoms are typical of progressive hypoxia and include headache, anxiety, agitation, confusion, lethargy, seizures, and coma. A centrally mediated tachypnea occurs initially, followed by bradypnea.

Cardiovascular responses to cyanide are complex. Studies of isolated heart preparations and intact animal models show that the principal cardiac insult is slowing of rate and loss of contractile force. Several reflex mechanisms, including catecholamine release

and central vasomotor activity, may modulate myocardial performance and vascular response in patients with cyanide poisoning. In laboratory investigations, a brief period of increased inotropy caused by reflex compensatory mechanisms occurs before myocardial depression. Clinically, an initial period of bradycardia and hypertension may occur, followed by hypotension with reflex tachycardia, but the terminal event is consistently bradycardia and hypotension. Ventricular dysrhythmias do not appear to be an important factor.

Both cardiogenic pulmonary edema and acute lung injury (ALI) are found at necropsy.[38,53,61,137] In cyanide poisoning ALI may be neurogenic in origin or result from membrane leak from direct pneumocyte toxicity. Inhalation of HCN may be associated with mild corrosive injury to the respiratory tract mucosa.

Gastrointestinal toxicity may occur following ingestion of inorganic cyanide and cyanogens and include abdominal pain, nausea, and vomiting.[3,38,59,62,78,87,90,137] These symptoms are caused by hemorrhagic gastritis identified on necropsy and are thought to be secondary to the corrosive nature of cyanide salts.[54] However, if death occurs rapidly, this gastritis may not be seen at autopsy because development of inflammation occurs over time.[60,61]

Cutaneous manifestations may vary. Traditionally, a cherry-red skin color is described as a result of increased venous hemoglobin oxygen saturation, which results from decreased utilization of oxygen at the tissue level.[31,139] This phenomenon may be more evident on funduscopic examination, where veins and arteries may appear similar in color. Despite the inference in the name, cyanide does not directly cause cyanosis. The occurrence of cyanosis in some cases likely is secondary to shock.[156,167]

Delayed Clinical Manifestations of Acute Exposure

Survivors of serious, acute poisoning may develop delayed neurologic sequelae.[17,26,39,53,63,98,132,133,170] Parkinsonian symptoms, including dystonia, dysarthria, rigidity, and bradykinesia, are most common. Symptoms typically develop over weeks to months, but subtle findings can be present within a few days. Cranial computerized tomography and magnetic resonance imaging consistently reveal basal ganglia (globus pallidus, putamen, and hippocampus) damage, with radiologic changes appearing several weeks after onset of symptoms. Extrapyramidal manifestations may progress or resolve. Response to pharmacotherapy with antiparkinsonian agents is generally disappointing. Whether delayed manifestations result from direct cellular injury or secondary hypoxia is unclear.

Chronic Exposure to Cyanide

Chronic exposure to cyanide may result in insidious syndromes, including tobacco amblyopia, tropical ataxic neuropathy, and Leber hereditary neuropathy. Tobacco amblyopia is a progressive loss of visual function that occurs almost exclusively in men who smoke cigarettes. Affected smokers have lower plasma cyanocobalamin and thiocyanate concentrations than unaffected smoking counterparts, suggesting a reduced ability to detoxify cyanide. Cessation of smoking and administration of hydroxocobalamin often reverses symptoms. Tropical ataxic neuropathy is a demyelinating disease associated with improperly processed cassava consumption [112,147] Neurologic manifestations include Parkinson disease, spastic paraparesis, sensory ataxia, optic atrophy, and sensorineural hearing loss.[157] Concomitant dermatitis and glossitis suggest an association of high dietary cassava with low vitamin B_{12} intake. Elevated thiocyanate concentrations in affected individuals further implicate cyanide as the etiology. Removal of dietary cassava and institution of vitamin B_{12} therapy alleviates symptoms.[52] Leber hereditary optic atrophy, a condition of subacute visual failure affecting men, is thought to be caused by rhodanese

deficiency.[55,169]

Chronic exposure to cyanide is associated with thyroid disorders.[2,81] Thiocyanate is a competitive inhibitor of iodide entry into the thyroid, thereby causing the formation of goiters and the development of hypothyroidism.[81,146] Chronic exposure to cyanide in animals is associated with hydropic degeneration in hepatocytes and epithelial cells of the renal proximal tubules; however, these morphologic lesions are not linked to functional alternations.[146]

Diagnostic Testing

Because of nonspecific symptoms and delay in laboratory cyanide confirmation, the clinician must rely on historical circumstances and some initial findings to raise suspicion of cyanide poisoning and institute therapy (Table 121-1).

Laboratory findings suggestive of cyanide poisoning reflect the known metabolic abnormalities, which include metabolic acidosis, elevated lactate concentration, and increased anion gap. Elevated venous oxygen saturation results from reduced tissue extraction.[66,77,94]

A venous oxygen saturation >90% from superior vena cava or pulmonary artery blood indicates decreased oxygen utilization. This finding is not specific for cyanide and could represent cellular poisoning from other agents (eg, carbon monoxide, clenbuterol, hydrogen sulfide, and sodium azide) or medical conditions such as sepsis or high-output cardiac syndromes.

TABLE 121-1. Cyanide Poisoning: Emergency Management Guidelines

When to suspect cyanide

Sudden collapse of laboratory or industrial worker

Fire victim with coma or acidosis

Suicide with unexplained coma or acidosis

Ingestion of artificial nail remover

Ingestion of seeds or pits from *Prunus* species

ICU patient with altered mental status, acidosis, and tachyphylaxis to nitroprusside

Supportive care

Control airway, ventilate, and give 100% oxygen

Crystalloids and vasopressors for hypotension

Administer $NaHCO_3$; titrate according to ABG and serum HCO_3

Antidote

Amyl nitrite pearls are included in the kit for prehospital use. For hospital management, sodium nitrite is the preferred methemoglobin inducer and is given in lieu of the pearls.

Give sodium nitrite ($NaNO_2$) as a 3% solution over 2â€“4 minutes IV:

Adult dose: 10 mL (300 mg)

Pediatric dose: See TABLE 121-2

Caution: Monitor blood pressure frequently and treat hypotension by slowing infusion rate and giving crystalloids and vasopressors. Obtain methemoglobin level 30 minutes after dose and consider possible excessive methemoglobin formation if patient deteriorates during therapy.

Give sodium thiosulfate (NaS_2O_3) as a 25% solution IV:

Adult dose: 50 mL (12.5 g)

Pediatric dose: 1.65 mL/kg

Decontamination

Protect healthcare provider from contamination

Cutaneous: carefully remove all clothing and flush the skin

Ingestion: lavage with a large-bore orogastric tube and instill 1 g/kg activated charcoal

Laboratory
Arterial blood gas
Electrolytes and glucose
Blood lactate
Whole-blood cyanide concentration (for later confirmation only)
Consider a central venous blood gas

Lactic acidosis is found in numerous critical illnesses and typically is a nonspecific finding. However, a significant association exists between blood cyanide and plasma lactate concentrations.[11] In a small group of patients in whom the diagnosis of cyanide poisoning was strongly suspected clinically, a plasma lactate concentration >72 mg/dL (8 mmol/L) was associated with sensitivity 94%, specificity 70%, positive predictive value 64%, and negative predictive value 98% for a blood cyanide concentration >1.0 Âµg/mL. ABG analysis may provide additional information. Arterial pH correlates inversely with cyanide concentration.[11] The finding of a narrow arterialâ€“venous oxygen difference also may suggest cyanide toxicity.

Cyanide results in nonspecific electrocardiographic findings. Bradycardia, tachycardia, myocardial injury pattern, or atrioventricular conduction block may occur.

Blood cyanide determination can confirm toxicity, but this determination is not available in a sufficiently rapid manner to affect initial treatment. Whole blood or serum usually is analyzed. In mammals, including primates, whole-blood concentrations are twice serum concentrations[9] as a result of cyanide sequestration in red blood cells. Background whole-blood concentrations in nonsmokers range between 0.02 and 0.5 Âµg/mL.[62,67,91] Higher blood concentrations suggest toxicity. Coma and respiratory depression are associated with concentrations >2.5 Âµg/mL and death with concentrations >3 Âµg/mL. Detecting urinary cyanide is

difficult, and urinary thiocyanate is a more readily detectable and useful marker of cyanide exposure. Serum thiocyanate concentrations are of little value in assessing patients with acute poisoning because of little correlation with symptoms but are useful in confirming exposure.

A semiquantitative assay that uses calorimetric paper test strips may immediately detect cyanide. Cyantesmo test strips currently are used by water treatment facilities to detect cyanide. An investigation of the utility of these strips in clinical practice found that the test strips incrementally increased to a deep blue color over a progressively longer portion of the test strip with increasing concentrations of cyanide.[128] These strips accurately and rapidly detected, in a semiquantifiable manner, CN concentrations >1 Âµg/mL.

Management

Because cyanide poisoning is rare, it is easy to overlook the diagnosis unless there is an obvious history of exposure. Thus, the most critical step in treatment is considering the diagnosis in high-risk situations (Table 121-1) and initiating empiric therapy with 100% oxygen and the cyanide antidote kit which contains both nitrites. The initial care (Table 121-1) of the cyanide-poisoned patient begins by directing attention to airway patency, ventilatory support, and oxygenation. Oxygen and sodium bicarbonate also are critical for cyanide treatment, enhancing the antidotal effect of nitrite and thiosulfate.[36] Acidemia should be treated with adequate ventilation and sodium bicarbonate administration.

Intravenous access should be rapidly obtained and blood samples sent for renal function, glucose, and electrolyte determinations. A whole-blood cyanide concentration can be obtained for later confirmation of exposure. ABG analysis and serum lactate concentration will help assess acidâ€“base status. Initiation of crystalloid and infusion of vasopressor for hypotension are

warranted.

First responders should exercise extreme caution when entering potentially hazardous areas such as chemical plants and laboratories where a previously healthy person is â€œfound down.â€• Exposure to cyanide may occur by multiple routes, including ingestion, inhalation, dermal, and parenteral. For patients with inhalation exposure, removal from the area of exposure is critical. Further decontamination is generally unnecessary. Decontamination of the cyanide-poisoned patient occurs concurrently with initial resuscitation. The healthcare provider should always be protected from potential dermal contamination by using personal protective devices such as water-impervious gowns, gloves, and eyewear. For patients with cutaneous exposure, remove their clothing, brush any powder off from the skin, and flush the skin with water. Particular attention should be given to open wounds because CN^- or HCN is readily absorbed through abraded skin.

Instillation of activated charcoal often is considered ineffective because of low binding of cyanide (1 g activated charcoal adsorbs 35 mg cyanide).[4] However, a potentially lethal oral dose of cyanide (ie, a few hundred milligrams) is within the adsorptive capacity of a 1 g/kg dose of activated charcoal. Prophylactic activated charcoal administration improved survival in animals given LD_{100} doses of KCN.[88] Based on the potential benefits and minimal risks, activated charcoal may be considered in the patient with an intact airway.

The cyanide antidote kit should be administered as soon as cyanide poisoning is suspected (Tables 121-1 and 121-2). The kit contains amyl nitrite, sodium nitrite, and sodium thiosulfate. Both thiosulfate and nitrite individually have antidotal efficacy when given alone in animal models of cyanide poisoning, but they have even greater benefit when they are given in combination.[43] Thiosulfate donates the sulfur atoms necessary for rhodanese-mediated cyanide biotransformation to thiocyanate. The mechanism of nitrite is less

clear. Traditional rationale relies on the ability of nitrite to generate methemoglobin. Because cyanide has a higher affinity for methemoglobin than for cytochrome a_3, cytochrome oxidase function is restored. However, improved hepatic blood flow and nitric oxide formation are alternate explanations (Antidotes in Depth: Sodium and Amyl Nitrites, Sodium Thiosulfate and Hydroxocobalamin).

Amyl nitrite is contained within glass pearls that are crushed and intermittently inhaled or intermittently introduced into the ventilator system to initiate methemoglobin formation. The amyl nitrite pearls are reserved for cases where intravenous access is delayed or not possible. Intravenous sodium nitrite is preferred and is supplied as a 10-mL volume of 3% solution (300 mg). The outdated goal of intravenous nitrite therapy is to achieve a methemoglobin level of 20â€“30%. This level is not based on cyanide treatment data but represents the maximum tolerated concentration without adverse symptoms from methemoglobinemia in a healthy individual. Clinical response is reported at lower methemoglobin levels of 3.6â€“9.2%. These reports are not conclusive because levels typically are not drawn serially, and peak levels may be misrepresented. Also, methemoglobin levels do not include cyanomethemoglobin. Therefore, lower than expected methemoglobin levels may represent indirect evidence of cyanide poisoning.

Adverse effects of nitrites include excessive methemoglobin formation and, because of potent vasodilation, hypotension and tachycardia. Avoiding rapid infusion, monitoring blood pressure, and adhering to dosing guidelines will limit adverse effects. Because of excessive methemoglobinemia during nitrite treatment, pediatric dosing guidelines are available.[15] Based on the premise that nitrite oxidizes hemoglobin on a mole-for-mole basis, doses were calculated for various hemoglobin concentrations (Table 121-2). These values are useful if the patient is known to be anemic. However, when giving nitrite empirically, treatment is based on a presumed 12-g hemoglobin concentration. Do not delay treatment

while awaiting a hemoglobin measurement. Amyl nitrite pearls are aromatic and should be used with caution in closed spaces because persons administrating them can become hypotensive and dizzy.

TABLE 121-2. Cyanide Management: Pediatric Nitrite Guidelines[a]

Hemoglobin (g)	$NaNO_2$ (mg/kg)	3% $NaNO_2$ solution (mL/kg)
7.0	5.8	0.19
8.0	6.6	0.22
9.0	7.5	0.25

[a]Pediatric thiosulfate dose: 1.65 mL/kg of 25% solution.
Adapted, with permission, from Berlin CM: The treatment of cyanide poisoning in children. Pediatrics 1976;46:793â€“796.

Sodium thiosulfate is the second component of the cyanide antidote kit. It is supplied as 50 mL of 25% solution (12.5 g). It is a substrate for the reaction catalyzed by rhodanese that is essentially irreversible, converting a highly toxic entity to a relatively harmless compound. However, thiocyanate does, have its own toxicity in the presence of renal failure, including abdominal pain, vomiting, rash, and CNS dysfunction (Chap. 60).[45] Thiosulfate itself is not associated with significant adverse reactions. The pediatric dose of thiosulfate is adjusted for weight.

Patients who do not survive cyanide poisoning are suitable organ donors. Heart, liver, kidney, pancreas, cornea, skin, and bone were successfully transplanted following cyanide poisoning.[33,69,149] (See Special Considerations, SC-1.)

Other Therapies

Although the cyanide kit is the mainstay of antidotal therapy in the United States, other treatments are used abroad. In Europe, 4-dimethylaminophenol (4-DMAP), rather than sodium nitrite, is the methemoglobin-inducing agent of choice. It generates methemoglobin more rapidly than sodium nitrite, with peak methemoglobin concentrations at 5 minutes after 4-DMAP rather than 30 minutes after sodium nitrite. The dose of 4-DMAP is 3 mg/kg and is coadministered with thiosulfate. As with sodium nitrite, its major adverse effect is excessive methemoglobin formation and potential for hypotension.

Hydroxocobalamin, a vitamin B_{12} precursor, is used for acute and chronic cyanide poisoning in Europe.[22] Hydroxocobalamin is a metalloprotein with a central cobalt atom that complexes cyanide, forming cyanocobalamin (vitamin B_{12}). Cyanocobalamin is eliminated in the urine or releases the cyanide moiety at a rate sufficient to allow detoxification by rhodanese. For this reason, thiosulfate is coadministered with hydroxocobalamin. One molecule

of hydroxocobalamin binds one molecule of cyanide, yielding a molecular weight binding ratio of 50:1. The standard initial dose of hydroxocobalamin is 4 g which is expected to bind 200 mg cyanide. The dose can be repeated in cases of massive poisoning. Hydroxocobalamin has few adverse effects, which include allergic reaction and a transient reddish discoloration of the skin, mucous membranes, and urine.[32,68] No hemodynamic adverse effects other than a potential mild transient rise of blood pressure are observed.[14,131] (See Antidotes in Depth: Hydroxocobalamin.)

Cobalt in the form of dicobalt edetate has been used as a cyanide chelator, but its usefulness is limited by serious adverse effects such as hypotension, cardiac dysrhythmias, decreased cerebral blood flow, and angioedema.[30,105]

Stroma-free methemoglobin, oxidized hemoglobin from which the cell membrane has been removed, is an investigational agent. It attenuates lethality and prevents hemodynamic changes in animal models.[29,150] The advantage to this treatment lies in providing exogenous methemoglobin to bind cyanide without compromising the oxygen-carrying capacity of native hemoglobin and removal of the cell membrane eliminates antigenicity.

Dihydroxyacetone (DHA) is an investigational antidote that restores mitochondrial respiration inhibited by cyanide in isolated rat hepatocytes.[108] It also diminishes cyanide lethality in animal models and has synergistic effects with thiosulfate.[107,109] DHA binds readily to cyanide to form a cyanohydrin, but this binding is reversible and cyanide's clinical effects reappear between 1 and 24 hours without readministration.[107]

Î±-Ketoglutarate is another investigational antidote. It rapidly complexes cyanide to form a cyanohydrin.[103] Pretreatment with Î±-ketoglutarate reduced lethality and increased sodium thiosulfate efficacy in animal studies.[19,50,74,110] The advantage of Î± ketoglutarate is direct binding of cyanide without generation of

methemoglobin. Preliminary evidence demonstrates that Î±-ketoglutarate at a dose offering maximum antidotal efficacy is nontoxic and potentially safe for treatment of cyanide poisoning.[18]

In animal models, antioxidant vitamins (eg, vitamins A, C, and E) diminish the extent of tissue damage caused by subacute cyanide intoxication.[111] This is especially important in the tropics, where the majority of dietary staples are cyanophoric crops such as cassava.

Hyperbaric oxygen (HBO) has been used for cyanide treatment, often with dramatic clinical improvement.[47,54,62,133,137,153] However, the patients received multiple therapies during resuscitation, so improvement cannot be attributed to HBO alone. Experimental data regarding HBO are contradictory. In a murine model, survival increased with 100% oxygen at 2 ATA compared to normobaric oxygen. However, combined HBO and nitrite/thiosulfate did not confer additional protection compared to normobaric oxygen and nitrite/thiosulfate. Currently, the Undersea and Hyperbaric Medical Society supports hyperbaric therapy for cases of cyanide poisoning complicated by coincident carbon monoxide toxicity.[166] Until further studies clearly demonstrate the efficacy of hyperbaric therapy for isolated cyanide poisoning, it should not supplant the combination of normobaric oxygen, nitrite, and thiosulfate.

Hydrogen Sulfide Poisoning

Case 2

A 23-year-old man entered an empty petroleum storage tank to perform repairs. He rapidly collapsed and fell unconscious. Two coworkers attempted a rescue, but both collapsed immediately after they entered the tank. Firefighters wearing self-contained breathing apparatus (SCBA) entered the tank and removed all 3 victims. Both of the would-be rescuers regained consciousness after they were removed from the tank. The first worker to collapse was removed

and noted to be cyanotic, with minimal respiratory effort. When paramedics arrived on the scene, the worker was immediately intubated.

When the worker arrived in the emergency department, he was intubated and receiving 100% oxygen by assisted ventilation. He had shallow spontaneous respirations and responded only to deep painful stimuli. Vital signs were: blood pressure, 110/72 mm Hg; pulse, 140 beats/min; respiratory rate, 34 breaths/min; rectal temperature 102Â°F (38.4Â°C). Pertinent findings on physical examination included dilated pupils, marked conjunctival injection, and diffuse crackles in both lung fields.

Laboratory data with arterial blood gas (ABG) analysis revealed: pH, 7.21; PCO_2, 30 mm Hg; PO_2, 48 mm Hg; bicarbonate, 11 mEq/L. The carboxyhemoglobin level was 1.5%, and the lactate concentration from ABG was 10.5 mEq/L. The electrocardiogram showed sinus tachycardia with normal intervals and axis. Chest radiograph showed diffuse alveolar infiltrates and a normal-sized heart.

The patient was attached to a ventilator with 100% oxygen and positive end-expiratory pressure of 10 cm H_2O. Over the next hour, his oxygenation improved, and his PO_2 was 335 mm Hg. He rapidly required less ventilatory support. The metabolic acidosis resolved over the next 8 hours. His neurologic status slowly improved over the next 20 hours, at which point he appeared alert and would follow commands. Following extubation, a repeat neurologic examination was normal. Followup 1 week later did not show any adverse effects. Air samples from the tank, taken the day after the exposure, revealed hydrogen sulfide, 880 ppm; methane, 420 ppm; carbon, dioxide 400 ppm; carbon monoxide, 50 ppm; oxygen, 18%.

History and Epidemiology

Hydrogen sulfide (H_2S) toxicity is not common. The American

Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) reported only 1336 exposures in 2003 (Chap. 130). Only 325 of these exposures required evaluation at a healthcare facility, fewer than 150 reported moderate or major effects, and only 4 deaths occurred. From 1983â€“1992, 5563 exposures and 29 deaths attributed to hydrogen sulfide were reported.[145] US Occupational Safety and Health Administration (OSHA) records show 80 occupationally related fatalities between 1984 and 1994.[56] Between 1990 and 1999, hydrogen sulfide poisoning was associated with the deaths of 18% of US construction workers killed by toxic inhalation.[49] Many died while working in confined spaces.

Hydrogen sulfide's rapid and deadly onset of clinical effects have been termed the *slaughterhouse sledgehammer effect.* Poisoned workers are â€œknocked down,â€• most frequently in an agricultural or industrial event. Numerous case reports describe multiple victims in these events. Would-be rescuers often themselves become victims when they attempt a rescue in an environment having high concentrations of hydrogen sulfide.[41,46,85,115,145] In the OSHA data, 25% of fatalities involved rescuers.[56]

Hydrogen sulfide is implicated in environmental disasters. In 1950, 22 people died and 320 were hospitalized in Poza Rica, Mexico, when a local natural gas facility inadvertently released hydrogen sulfide into the air.[96] Hydrogen sulfide claimed nine lives when a sour gas well failed, releasing a cloud of the poisonous gas into the Denver City, Texas community in 1975.[104] In 2003, a gas drilling incident in southwest China released natural gas and a cloud of hydrogen sulfide into a populated mountainous area. More than 200 people died, 9000 were treated for injuries, and more than 40,000 were evacuated.[165]

Hydrogen sulfide is produced naturally by bacterial decomposition of proteins and is used or produced in many industrial activities.

Industrial sources of hydrogen sulfide include pulp paper mills, heavy-water production, the leather industry, roofing asphalt tanks, vulcanizing of rubber, viscose rayon production, and coke manufacturing from coal.[35,72,115,143,158] It is a major industrial hazard in oil and gas production, particularly in sour gas fields (natural gas containing sulfur). Decay of sulfur-containing products (eg, fish, sewage, and manure) also produces hydrogen sulfide. Several farm workers and rescuers have died from exposure to hydrogen sulfide generated in liquid manure pits.[101,115] An adolescent laboratory worker lost consciousness while cleaning a reoxygenation tank in a fish hatchery, and a sailor died from exposure to sewage and hydrogen sulfide fumes while repairing an on-board sewage collection system.[97,106] Natural

sources are volcanoes, caves, sulfur springs, and underground deposits of natural gas.[46,72,127]

Pharmacology

Hydrogen sulfide is a colorless gas, more dense than air, with an irritating odor of â€œrotten eggs.â€• It is highly lipid soluble, a property that allows easy penetration of biologic membranes. Systemic absorption usually occurs through inhalation, and it is rapidly distributed to tissues.[127] The tissues most sensitive to hydrogen sulfide are those with high oxygen demand. Hydrogen sulfide's systemic toxicity results from its potent inhibition of cytochrome oxidase, thereby interrupting oxidative phosphorylation.[144] Hydrogen sulfide binds to the ferric (Fe^{3+}) moiety of cytochrome a_3 oxidase complex with a higher affinity than does cyanide (Figure 121-2). The resulting inhibition of oxidative phosphorylation produces cellular hypoxia and anaerobic metabolism.[141] In addition to cytochrome oxidase inhibition, hepatocyte studies suggest H_2S toxicity involves opening the mitochondrial permeability transition pore, generating reactive oxygen species and compromising glycolysis.[51,152] Besides

producing cellular hypoxia, hydrogen sulfide causes potassium channelâ€“mediated hyperpolarization of neurons and potentiates other neuronal inhibitory mechanisms. It also alters brain neurotransmitter content and release.[1,127] A proposed mechanism of death is poisoning of the brainstem respiratory center through selective uptake by lipophilic white matter in this region.[162]

In addition to systemic effects, hydrogen sulfide produces intense dermal irritation. It reacts with the moisture on the surface of mucous membranes to form sodium sulfide, which produces the irritant chemical effect. Despite skin irritation, it has little dermal absorption.

Toxicokinetics

The major pathways of hydrogen sulfide detoxification are enzymatic and nonenzymatic oxidation of sulfides and sulfur to thiosulfate and polysulfides.[23] Other pathways, such as methylation to dimethyl sulfide and conversion to sulfite or sulfate by oxidized glutathione, also may play a role in detoxification and elimination.[12] Hydrogen sulfide binds to metalloproteins such as heme proteins. It is a detoxification pathway when it binds to endogenously produced methemoglobin to form sulfmethemoglobin. However, binding to heme proteins such as cytochrome oxidase is its major mechanism of toxicity. Only small amounts of sulfide are excreted in urine or exhaled into the air. Sulfhemoglobin is not found in significant concentrations in the blood of animals or fatally poisoned humans.[143]

Clinical Manifestations

Acute Manifestations

Hydrogen sulfide poisoning should be suspected whenever a person is found unconscious in an enclosed space, especially if the odor of

rotten eggs is noted. The primary target organs of hydrogen sulfide poisoning are those of the CNS and respiratory system. The clinical findings reported in two large series are listed in Table 121-3.[7,35] The intensity of exposure likely accounts for the diverse clinical findings in the reports. A distinct dose response to hydrogen sulfide is identified. The odor threshold is between 0.02 and 0.13 ppm, and a strong intense odor is noted at 20â€“30 ppm. Mild mucous membrane irritation occurs at 50â€“100 ppm, and olfactory fatigue occurs at 100â€“150 ppm. Thus, the ability to perceive the odor is rapidly extinguished because of olfactory nerve paralysis at higher levels. Prolonged exposure can occur when the extinction of odor recognition is misinterpreted as dissipation of the gas. Strong irritation of the upper respiratory tract and eyes and ALI occur at 200â€“300 ppm. At >500 ppm, H_2S produces systemic effects. Rapid unconsciousness and cardiopulmonary arrest occur at concentrations >700 ppm.[12,127]

Mucous membrane irritation of the eye produces keratoconjunctivitis. If exposure persists, damage to the epithelial cells produces reversible corneal ulcerations (â€œgas eyeâ€•) and, rarely, irreversible corneal scarring.[99] The irritant effects on the respiratory tract include rhinitis, bronchitis, and ALI.[7,35]

Neurologic manifestations are common and may be severe. In a series, 75% of 221 patients with acute hydrogen sulfide exposure lost consciousness at the time of exposure.[35] In acute, massive exposures, rapid loss of consciousness (â€œknockdownâ€•) results from loss of central respiratory drive.[100,144] If the patient is rapidly removed from the exposure, recovery may be prompt and complete. Secondary neurologic effects can result from hypoxia secondary to respiratory compromise.[12,127] Neurologic outcome can be quite variable, ranging from no neurologic impairment to permanent sequelae. Delayed neuropsychiatric sequelae may occur after acute exposures.[35,37,72,84,145,148,154,155,163] Most evidence suggests that the early rapid CNS effects are direct neurotoxic effects of hydrogen sulfide, whereas the permanent neurologic sequelae result from

hypoxia secondary to respiratory insufficiency.[12,99,100,127] Reported neuropsychiatric changes include memory failure (amnestic syndrome), lack of insight, disorientation, delirium, and dementia.[163] Neurosensory abnormalities include transient hearing impairment, vision loss, and anosmia. Motor symptoms likely are caused by injury to the basal ganglia and result in ataxia, position/intention tremor, and muscle rigidity.[154] Common neuropathologic findings observed on CT scan and at autopsy are subcortical white matter demyelination and globus pallidus degeneration.[57,155]

Acute exposures affect other organ systems. Myocardial hypoxia or direct toxic effects of hydrogen sulfide on cardiac tissue may cause cardiac dysrhythmias, myocardial ischemia, or myocardial infarction.[64] Because unresponsiveness is rapid, trauma from falls should not be overlooked.[7] In a report, 7% of patients experiencing a â€œknockdownâ€• had associated traumatic injuries.[7]

Chronic Manifestations

Most data about chronic, low-level exposures to hydrogen sulfide come from oil and gas industry workers.

Mucous membrane irritation seems to be the most prominent problem in patients with low-level exposures. Workers report nasal, pharyngeal, and eye irritation, fatigue, headache, dizziness, and poor memory with low-level, chronic exposures. One third of viscous rayon workers left their jobs because of persistent eye irritation (spinner's eye). The chronic irritating effects of hydrogen sulfide were thought to be the cause of reduced lung volumes observed in sewer workers.[129] Volunteer studies have not demonstrated significant cardiovascular effects at low-level exposures (<10 ppm).[16] The liver, kidneys, and endocrine system are unaffected. No studies demonstrate increased incidences of cancer with low-level exposures.[44]

TABLE 121-3. Hydrogen Sulfide Poisoning

When to suspect hydrogen sulfide poisoning
Person rapidly loses consciousness (â€œknocked downâ€•)
Rotten eggs odor
Rescue from enclosed space, such as sewer or manure pit
Multiple victims with sudden death syndrome
Collapse of a previously healthy worker at work site
Clinical Manifestations

System	Signs and Symptoms
Cardiovascular	Chest pain, bradycardia
Central nervous	Headache, weakness, dysequilibrium, convulsions, coma
Gastrointestinal	Pharyngitis, nausea, vomiting
Ophthalmic	Conjunctivitis
Pulmonary	Dyspnea, cyanosis, hemoptysis, crackles

Rapid loss of consciousness after a high-level exposure was a well known and, amazingly, accepted part of the workplace in the gas and oil industry for many years.[70] Some workers experienced repeated â€œknockdowns,â€• and these workers reported an increased incidence of respiratory diseases and cognitive deficits. Clearly, single or repeated high-level exposures resulting in

unconsciousness can cause serious cognitive dysfunction. Case series suggest that protracted low-level exposures cause subtle changes that can be measured by only the most sensitive neuropsychiatric tests.[37,83]

Epidemiologic data regarding the effects of low-level environmental exposures to hydrogen sulfide are clouded in populations exposed to complex mixtures of pollutants. Other malodorous sulfur compounds (eg, methyl mercaptan and methyl sulfide) are generated as byproducts of pulp mills. Study populations exposed to this complex mixture of pollutants demonstrate a dose-related increase in nasal symptoms, cough, nausea, and vomiting.[44]

Hydrogen sulfide's strong odor at low concentrations can magnify irritant effects by triggering a strong psychological response.[101] Hydrogen sulfide has been the alleged source of mass psychogenic illness cases.[57,101] Clinical, epidemiologic, and toxicologic analyses suggested that 943 cases of illness in Jerusalem were caused by the odor of low concentrations of hydrogen sulfide gas. The most frequent associated symptoms are headaches, faintness, dizziness, nausea, chest tightness, difficulty breathing (hyperventilation), irritation of eyes, nose, and throat, weakness, and extremity numbness.[27] Mild-to-moderate hydrogen sulfide toxicity produces nonspecific signs and symptoms that could closely mimic psychogenic illness. Attempting to identify true toxicity from a powerful emotional reaction can be extremely difficult.[58] Therefore, symptomatic patients must be assessed for toxicity even when mass psychogenic illness is suspected (Chap. 124).

Diagnostic Testing

Because no available rapid method of detection is of clinical diagnostic use, management decisions must be made based on history, clinical presentation, and diagnostic tests that infer hydrogen sulfide's presence. Circumstances surrounding the patient's illness often will provide the best evidence for hydrogen

sulfide poisoning (Table 121-3). At the bedside, the smell of rotten eggs on clothing or emanating from the blood, exhaled air, or gastric secretions suggests hydrogen sulfide exposure.[73] In addition, darkening of jewelry is a clue to exposure. Paper impregnated with lead acetate changes color when exposed to hydrogen sulfide and is used to detect its presence in the patient's exhaled air but is not rapidly available.[44]

Specific tests for confirming hydrogen sulfide exposure are not readily available in clinical laboratories. Therefore, the presence of hydrogen sulfide is best confirmed by directly measuring the gas in the environment. It can be detected in atmospheric air samples by monitoring devices such as colorimetric tubes or toxin-specific air sampling devices. Many emergency response teams investigate the toxic environment of a hazardous materials incident with detection devices that measure hydrogen sulfide by electrochemical sensors.

In acute poisoning, readily available diagnostic tests that are biomarkers of hydrogen sulfide poisoning may be useful but are nonspecific. ABG analysis demonstrating metabolic acidosis with an associated elevated serum lactate concentration is expected, and oxygen saturation should be normal unless ALI is present. Hydrogen sulfide, like cyanide, decreases oxygen consumption and is reflected as an elevated mixed venous oxygen measurement. Because sulfhemoglobin typically is not generated in patients with hydrogen sulfide poisoning, an oxygen saturation gap is not expected.[143]

After serious injury from hydrogen sulfide, diagnostic testing for neurologic structure and function may show abnormalities for weeks or months. Brain MRI and head CT studies demonstrate structural changes such as globus pallidus degeneration and subcortical white matter demyelination. Neuropsychological testing after serious hydrogen sulfide poisoning demonstrates specific abnormalities in cortical functions, such as concentration, attention, verbal abstraction, and short-term retention. Single-photon emission computed tomography (SPECT)/PET brain scans define neurotoxin-

induced lesions that correlate well with clinical neuropsychological testing.[37]

Clinical laboratory tests may be useful for confirming exposure but are not readily available for clinical decision making in an acute exposure. Whole-blood sulfide concentrations >0.05 mg/L are considered abnormal. Reliable measurements are ensured only if the concentration is obtained within 2 hours after the exposure and analyzed immediately.[127] In acute exposures, blood and urine thiosulfate concentrations may be reflective of exposure, and urinary thiosulfate excretion is used to monitor chronic low-level exposure in the workplace.[80]

Sulfide concentrations obtained in postmortem investigations may be useful, but their use requires rapid sample collection because sulfide concentrations rise with tissue decomposition.[127] In addition to blood sulfide concentrations, sulfide and thiosulfate concentrations are at their highest in lung and brain.[76,99] At autopsy, a greenish discoloration of the gray matter, viscera, and bronchial secretions may be noted.[79,80]

Management

The initial treatment (Table 121-4) is immediate removal of the victim from the contaminated area into a fresh-air environment. Administer high-flow oxygen as soon as possible. Optimal supportive care has the greatest influence on the patient's outcome. Because death from inhalation of hydrogen sulfide is rapid, limited human cases reaching the hospital for treatment are reported in the literature. Most patients experience significant delays before receiving treatment. Therefore, specific treatments and antidotal therapies do not show definitive improvement in patient outcome.

Most animal studies and human case reports suggest that oxygen therapy is beneficial for hydrogen sulfide poisoning.[13,23,126,143] In rats, HBO was more effective than normobaric oxygen, nitrite, or

sham treatment in preventing mortality from sulfide poisoning.[23] Studies showing benefit of HBO for cyanide toxicity have led to the use of HBO in hydrogen sulfide poisoning. Case reports suggest that HBO is beneficial, although use of HBO may be impractical in most cases.[140,168] No studies evaluating the role of HBO for preventing delayed neurologic sequelae are available.

Proposed mechanisms for oxygen's beneficial effects are competitive reactivation of oxidative phosphorylation by inhibiting hydrogen sulfideâ€“cytochrome binding, enhanced detoxification by catalyzing oxidation of sulfides and sulfur, and improved oxygenation in the presence of ALI.[13,140] All patients suspected of hydrogen sulfide poisoning should receive supplemental oxygen. Patients with persistent neurologic or cardiovascular effect may benefit from HBO therapy. Consider using HBO if it is immediately available, but because data on the efficacy of HBO are limited, it is not necessary to transfer the patient solely for HBO therapy.

TABLE 121-4. Hydrogen Sulfide Poisoning: Emergency Management

Supportive care
Prehospital
Attempt rescue only if using SCBA
Move victim to fresh air
Administer 100% oxygen
During extrication, consider traumatic injuries from falls
Apply ACLS protocols as indicated
Emergency department
Maximize ventilation and oxygenation
Consider PEEP for ALI
Treat acidosis based on arterial pH and serum bicarbonate analysis

Administer crystalloid and vasopressors for hypotension

Antidote

Give sodium nitrite (3% $NaNO_2$) IV over 2â€“4 minutes

Adult dose: 10 mL (300 mg)

Pediatric dose: see Table 121-2

Caution:

Monitor blood pressure frequently

Obtain methemoglobin level 30 minutes after dose

Consider HBO if immediately available

The similarities in the toxic mechanism between hydrogen sulfide and cyanide created an interest in the use of nitrite-induced methemoglobin as an antidote. Methemoglobin protects animals from toxicity of hydrogen sulfide poisoning in both pretreatment and postexposure models.[141,142,144] Nitrite-generated methemoglobin acts as a scavenger of sulfide. Hydrogen sulfide's affinity for methemoglobin is greater than that for cytochrome oxidase.[141] When hydrogen sulfide binds to methemoglobin, it forms sulfmethemoglobin.[13] Because hydrogen sulfide poisoning is rare, no studies have evaluated the clinical outcomes of patients treated with sodium nitrite. Animal studies suggest that nitrite must be given within minutes of exposure to ensure effectiveness.[13] However, several human case reports showed rapid return of normal sensorium when nitrites were administered soon after exposure.[72,119,148] Patients with suspected hydrogen sulfide poisoning who have altered mental status, coma, hypotension, or dysrhythmias probably should receive sodium nitrite by slow infusion at the same dose given for cyanide poisoning. Sodium thiosulfate is of no benefit in the treatment of hydrogen sulfide.

Treatment of patients with hydrogen sulfide poisoning requires optimal supportive care. Treatments and antidotes beyond supportive care are not of proven clinical benefit. Because hydrogen sulfide toxicity is severe and case reports suggest the occurrence of

delayed sequelae, the potential benefits of nitrite therapy and HBO should be considered for seriously ill patients exposed to hydrogen sulfide. These therapies should be initiated after optimum supportive care has been ensured.

Summary

Both cyanide and hydrogen sulfide are high-risk industrial agents. Industrial precautions are essential to limit worker risk. Cyanide is of great concern with regard to homicide and suicide. There are particular metabolic risks and concerns with regard to exposure to both agents because they bind specifically to the ferric moiety of the cytochrome a_3 oxidase complex. Odor recognition is unreliable and is not a definitive approach to diagnosis. The laboratory evaluation usually is not timely for diagnostic purposes. Decontamination, removal from the site of exposure, and oxygen are essential. The controversies over the ideal therapeutic modalities for these agents are substantial, and extensive research continues.

Antidotes in Depth

Sodium and Amyl Nitrites

Mary Ann Howland

Amyl and sodium nitrite are effective cyanide antidotes when they are administered in timely fashion. Amyl nitrite is volatile and available in ampules that can be broken and administered by inhalation until sodium nitrite can be administered intravenously. Although the exact mechanism of action of the nitrites is unclear, the production of methemoglobin is both therapeutic and potentially life threatening if nitrites are administered to a patient with impaired oxygen-carrying capacity, such as lung injury from smoke inhalation, or elevated carboxyhemoglobin or methemoglobin from any cause. In the latter cases, sodium thiosulfate can be administered intravenously with impunity. Hydroxocobalamin, currently available elsewhere in the world and soon to be available in the United States, also has this advantage.

History

Expanding on earlier work that demonstrated the limited role of

methylene blue and the efficacy of sodium nitrite in cyanide-poisoned animals, inhaled amyl nitrite was used successfully in dogs.[2] Amyl nitrite administered by inhalation protected dogs from up to 4 minimum lethal doses of sodium cyanide (24 mg/kg subcutaneously). In the regimen used, therapy started within 5 to 7 minutes of exposure and continued for several hours. The frequency of inhalations was based on clinical response. Inhalation of amyl nitrite prevented and protected against cyanide-induced seizures and muscular rigidity.[2] The results of these experiments were so convincing that use of inhaled amyl nitrite was justified in patients poisoned by cyanide. Later that year, the same authors discovered that intravenous (IV) use of sodium thiosulfate alone protected against 3 minimum lethal doses of cyanide in dogs and that the combination of sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite protected against 10 and 13â€“18 minimum lethal doses, respectively.[3,4] This finding confirmed the synergistic effects of a nitrite and sodium thiosulfate administered together.[3] Chen[4] credits Pedigo in 1888 with first noting the antidotal effect of amyl nitrite on cyanide poisoning, Lang in 1895 with demonstrating the beneficial effects of sodium thiosulfate, and Mota in 1933 with first using sodium nitrite in a patient. The first case series of combined antidotal therapy with nitrites and thiosulfate was reported in 1949.

Chemistry

The chemical formula for sodium nitrite is $NaNO_2$ and for amyl nitrite is $C_5H_{11}NO_2$. Sodium nitrite has a molecular weight of 69 daltons and amyl nitrite 117 daltons. Amyl nitrite is volatile even at low temperatures, and it is highly flammable.

Mechanism of Action

Cyanide quickly and reversibly binds to the ferric iron in cytochrome oxidase, inhibiting effective energy production

throughout the body. The ferric iron in methemoglobin preferentially combines with cyanide, producing cyanomethemoglobin. This drives the reaction toward cyanomethemoglobin and liberates cyanide from cytochrome oxidase. Stroma-free methemoglobin is effective against 4 minimum lethal doses of cyanide in rats.[16] Nitrites oxidize the iron in hemoglobin to produce methemoglobin. Because nitrites are accepted antidotes for cyanide poisoning, for many years methemoglobin formation was assumed to be their sole antidotal mechanism of action of nitrites.[12,20] Other, faster methemoglobin inducers, such as 4-dimethyaminophenol and hydroxylamine, also are effective as cyanide antidotes.[12,18] The benefits of sodium nitrite are maximal in experiments when sodium nitrite is given prophylactically, but the benefits still are evident when sodium nitrite is administered following cyanide poisoning. The production of methemoglobin by nitrite is slow, but when methylene blue is administered to prevent methemoglobin formation, nitrite still is an effective antidote.[12,20] Reasoning that nitrite-induced vasodilation might be part of the mechanism of action, the antidotal actions of other vasodilators were investigated. Only the Î±-adrenergic antagonists and ganglionic blockers demonstrate antidotal activity, and only when they are administered with sodium thiosulfate.[20] It is possible that the benefits of nitrites given shortly after cyanide result from reversal of cyanide-induced circulatory effects rather than reversal of the effects of cyanide on cytochrome oxidase.[17] Evidence in experimental heart and organ damage induced by hypoxia or hypotension suggest that the benefits of nitrite may be related to its ability to be converted to nitric oxide, a potent vasodilator. The conversion to nitric oxide appears to occur only in tissues or blood with the lowest oxygen concentrations.[5,13] Regardless of the exact mechanism of action, sodium nitrite clearly is effective soon after administration, even when methemoglobin levels are low. Thus a target methemoglobin level should not be used to determine the correct dose of sodium

nitrite, although care must be taken to avoid excessive methemoglobinemia.[10]

Administration of sodium nitrite should always be followed by sodium thiosulfate. Sodium thiosulfate donates a sulfur, which with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfurtransferase, carries sulfane sulfur to bind to cyanide, producing thiocyanate. Thiocyanate is a much less toxic substance than cyanide and is renally eliminated.[2]

Pharmacokinetics and Pharmacodynamics

The pharmacokinetics of sodium nitrite are not established. Most studies have been directed at measuring methemoglobin levels rather than nitrite levels.[18]

Sodium nitrite administered intramuscularly to dogs is not effective as a cyanide antidote unless atropine is given as pretreatment.[19] Most likely the rapid reversal of cyanide-induced bradycardia by

atropine allows sufficiently rapid absorption of sodium nitrite, which then can be effective.[19]

Clinical Use

As early as 1952, 16 patients were reported who had either ingested a cyanide salt or been exposed to hydrocyanic acid as a fumigant and survived with administration of nitrites and sodium thiosulfate.[4] Even patients who were unconscious or apneic have survived when given timely cardiopulmonary resuscitation and antidotal therapy.[4] Case reports attest to the ability of amyl nitrite, sodium nitrite, and sodium thiosulfate to reverse the effects of cyanide if they are administered in a timely fashion.[8,21] A 34-year-old man who ingested 1 g potassium cyanide became

comatose within 45 minutes. One hour after ingestion, he arrived in the emergency department, became apneic, and was intubated. His blood pressure was 134/84 mm Hg and pulse 84 beats/min; his pupils were dilated. At 1 hour 15 minutes, he was given 300 mg sodium nitrite intravenously over 20 minutes, followed by 12.5 g sodium thiosulfate. Seizure activity that began just prior to sodium nitrite infusion resolved rapidly, and by the time the sodium thiosulfate had finished infusing, his pupils were reactive and spontaneous respirations had returned.[8]

In another case, a 4-year-old child ingested twelve 50-mg tablets of laetrile (amygdalin), became unresponsive, and developed seizures within 90 minutes.[7] Upon arrival at a second hospital, the patient required intubation, he had no blood pressure, and his pupils were dilated and minimally responsive. Arterial blood gas analysis revealed: pH, 6.85; PCO_2 15 mm Hg; PO_2 169 mm Hg on 100% oxygen. The anion gap was 26. The patient's vital signs improved with intermittent inhalation of amyl nitrite pearls. Six hours after ingestion (and 1 hour 45 minutes after amyl nitrite administration), sodium nitrite and sodium thiosulfate obtained from another hospital were administered. Within 30 minutes of completion of 5 mL (0.33 mL/kg) 3% sodium nitrite solution by IV infusion, spontaneous respirations returned, and his blood pressure and pulse normalized. Over the next 3 hours, the patient's mental status and acidâ€“base balance improved. By 15 hours after ingestion, he was alert, oriented, and extubated. Elevated whole blood cyanide concentrations verified the ingestion.

Adverse Effects

Sodium nitrite works by inducing methemoglobinemia, but too much methemoglobinemia is potentially lethal. Therefore, nitrite dosages must be carefully calculated and nitrites administered to avoid excessive methemoglobinemia, especially in cases where other coexisting conditions, such as carboxyhemoglobin,

sulfhemoglobin, and anemia, might compromise hemoglobin oxygen saturation.[9,14] Children are particularly at risk for medication errors because of dosage miscalculations. The first reported death from methemoglobinemia was caused by the administration of an adult dose of sodium nitrite to a 17-month-old child suspected of ingesting a toxic amount of cyanide.[1]

In healthy adults, 300 mg IV sodium nitrite can produce peak methemoglobin concentrations of 10â€“18%.[4] Inhalation of crushed amyl nitrite ampules in human volunteers produces insignificant amounts of methemoglobin but does cause headache, fatigue, dizziness, and hypotension.[11]

Nitrites are potent vasodilators, so transient hypotension may occur. Other adverse effects include headache, nausea and vomiting.[4]

Administration and Dosing

Cyanide

Adults

Sodium nitrite 300 mg (10 mL of 3% solution) should be injected intravenously at a rate of 2.5â€“5 mL/min. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[15]

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[6,15] Inhalation of amyl nitrite should be discontinued prior to sodium nitrite administration. The healthcare provider should not inhale the amyl nitrite.

Immediately following sodium nitrite infusion, 12.5 g (50 mL of 25% solution) sodium thiosulfate should be infused intravenously. The same needle and vein can be used. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[6,15]

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire, the nitrite can be withheld and only the sodium thiosulfate administered, or, if hydroxocobalamin is available, sodium thiosulfate can be administered following the hydroxocobalamin.

Children

Intravenously inject 6â€“8 mL/m^2 (~0.2 mL/kg) of 3% sodium nitrite solution, not to exceed 10 mL or 300 mg.[15] A 0.2 mL/kg dose of 3% sodium nitrite solution is 6 mg/kg sodium nitrite. Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/100 mL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin or sulfhemoglobin.[1] The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours after the first dose as prophylaxis (see Table 121-2).[15]

As for adults, amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break 1 amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[6,15] Inhalation of amyl nitrite should be discontinued prior to sodium nitrite administration. Immediately following sodium nitrite infusion, 7 g/m^2 or 0.5 g/kg (2 mL/kg) of 25% solution of sodium thiosulfate, not to exceed the adult dose of 12.5 g (50 mL of 25% solution) sodium thiosulfate, should be infused intravenously. The same needle and vein can be used. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear

or at 2 hours as prophylaxis.[6,15]

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire in which other toxic gases may coexist, the nitrite can be withheld and only the sodium thiosulfate administered, or, if hydroxocobalamin is available, sodium thiosulfate can be administered following the hydroxocobalamin.

Availability

Sodium nitrite is available in ampules containing 300 mg in 10 mL (3% concentration) water for injection (USP). It contains no additives

or preservatives. It also is available in a kit containing 2 ampules of sodium nitrite (300 mg in 10 mL) with 12 ampules of amyl nitrite inhalants (0.3 mL) and 2 vials of sodium thiosulfate 12.5 g in 50 mL water for injection (USP), with boric acid or sodium hydroxide added to adjust the pH.[6]

Antidotes in Depth

Sodium Thiosulfate

Mary Ann Howland

Sodium thiosulfate is an effective, relatively nontoxic antidote that detoxifies cyanide by donating a sulfur moiety to form thiocyanate. Thiocyanate is a much less toxic substance than cyanide and is renally eliminated. Sodium thiosulfate works synergistically with nitrites and hydroxocobalamin in the detoxification of cyanide. Because sodium thiosulfate does not compromise hemoglobin oxygen saturation, it can be used without nitrites in circumstances where the formation of methemoglobin would be detrimental, as in patients with smoke inhalation from fires who have elevated carboxyhemoglobin or preexistent methemoglobinemia.

History

In 1933 Chen et al.[2] noted that intravenous (IV) sodium thiosulfate was able to protect against 3 minimum lethal doses of sodium cyanide in dogs. Even more remarkable was the synergistic effects of combining sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite, which protected the dogs against

10â€“18 minimum lethal doses of cyanide.[2,3]

Chemistry

The chemical formula of sodium thiosulfate is $Na_2S_2O_3$. The molecular weight of sodium thiosulfate is 248 daltons. It is a pentahydrate that is highly water soluble. Sodium hyposulfite is a synonym.

Mechanism of Action

The sulfur provided by sodium thiosulfate binds to cyanide with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfur transferase.[2,19,20] This sulfur, a sulfane sulfur (a divalent sulfur bound to one other sulfur), is the only type of sulfur that reacts with cyanide. Thiocyanate, a minimally toxic substance, is renally eliminated. In many different animal models, sodium thiosulfate protects against several minimum lethal doses of cyanide.[9,12] The addition of rhodanese increases the efficacy of sodium thiosulfate, but its use is impractical in the clinical setting.[12,21] The cationic site on rhodanese is crucial to cleaving the sulfurâ€“sulfur bond of thiosulfate and forming a sulfurâ€–rhodanese complex that readily reacts with cyanide.[20]

Rhodanese likely is not solely responsible for sulfurâ€–sulfur bond cleavage, as rhodanese is largely a mitochondrial enzyme found in the liver and skeletal muscle, and sodium thiosulfate is a divalent ion that poorly crosses membranes.[6,12,16,19,20] An additional theory proposes that both mercaptopyruvate sulfurtransferase and rhodanese are involved in the formation of sulfane sulfur in the liver from sodium thiosulfate and that serum albumin then carries the sulfane sulfur from the liver to other organs. When cyanide is present, albumin delivers this sulfur to cyanide, forming thiocyanate.[10,19,20,21]

Pharmacokinetics and Pharmacodynamics

Animal Studies

Sodium thiosulfate is a large divalent anion. Canine studies suggest that sodium thiosulfate rapidly distributes into the extracellular space and then slowly into the cell, perhaps with a carrier facilitating entry into the mitochondria.[16] When administered prior to cyanide, thiosulfate was able to convert >50% of the cyanide to thiocyanate within 3 minutes and increased the endogenous conversion rate more than 30 times.[18] Thiosulfate is filtered in the kidney and then secreted. At low plasma concentrations, thiosulfate is largely reabsorbed. At high plasma concentrations, filtration and secretion predominate.[7,16]

Human Volunteers

A volunteer study examined the pharmacokinetics of sodium thiosulfate and the fate of thiosulfate.[9,16] After injection of 150 mg/kg, Vd was 0.15 L/kg, distribution half-life was 23 minutes, and elimination half-life was 3 hours. The peak plasma thiosulfate concentration rose 100-fold. Approximately 50% of the drug was eliminated in 18 hours, mostly within 3 hours. Baseline thiosulfate concentrations were higher in starved patients and children, presumably because of their higher protein utilization and metabolism to thiosulfate.[9] Normally the kidney actively reabsorbs thiosulfate, but this study found that with exogenous administration, thiosulfate clearance equaled creatinine clearance.[9]

Another report researching the effects of thiosulfate as a cisplatin neutralizer found that thiosulfate had a half-life of 80 minutes, and that renal clearance accounted for only 30% of the total clearance.[17] Oral sodium thiosulfate is poorly absorbed and acts as

a laxative.[16]

Clinical Use

Cyanide

As early as 1952, 16 patients were reported who had either ingested a cyanide salt or been exposed to hydrocyanic acid as a fumigant and survived with administration of nitrites and sodium thiosulfate.[3] Even patients who were unconscious or apneic survived when given timely cardiopulmonary resuscitation and antidotal therapy.[3]

Case reports attest to the ability of sodium nitrite and sodium thiosulfate to reverse the effects of cyanide if they are administered in timely fashion.[4,15,16]

In the few reported cases where cyanide was ingested and sodium thiosulfate alone was used, all patients had favorable outcomes.[16] We advocate the use of amyl or sodium nitrite, or hydroxocobalamin if available, prior to sodium thiosulfate unless the

methemoglobin produced by administration of sodium nitrite is already at a potentially dangerous level, as occurs in patients with smoke inhalation from a fire who have elevated carboxyhemoglobin or methemoglobin levels.

Nitroprusside

Canine experiments reveal that when the nitroprusside infusion rate is >0.5 mg/kg/h, cyanide concentrations in the blood begin to rise. Coadministration of sodium thiosulfate with sodium nitroprusside in a 5:1 molar ratio (because nitroprusside contains 5 cyanide ions) prevents the rise in cyanide concentration.[16]

Adverse Effects

The toxicity of sodium thiosulfate is low. The LD_{50} for animals is approximately 3â€“4 g/kg, with death attributed to metabolic acidosis, elevated sodium concentration, and decreased blood pressure and PO_2.[12] Sodium thiosulfate delivers a significant sodium load and is hyperosmolar. Administering the infusion over 10â€“30 minutes attenuates some of these adverse effects.[16]

Adverse effects associated with therapeutic dosing include hypotension, nausea, and vomiting. The osmotic and diuretic effects presumably result from both the formation of thiocyanate and the intrinsic osmotic properties of the drug.[16]

Administration and Dosing

Cyanide

Adults

In a patient with presumed cyanide poisoning, the adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) administered intravenously either as a bolus injection or infused over 10â€“30 minutes, depending on the severity of the situation.[5] The dose of sodium thiosulfate can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[5]

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 300 mg sodium nitrite (10 mL of 3% solution) at a rate of 2.5â€“5 mL/min prior to administration of sodium thiosulfate. The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[5]

Amyl nitrite can be used prior to IV administration of sodium

nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.[5] Inhalation of amyl nitrite should be discontinued prior to administration of sodium nitrite.

Immediately following sodium nitrite infusion, 12.5 g (50 mL of 25% solution) of sodium thiosulfate should be infused intravenously. The same needle and vein can be used. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[5]

In situations where the additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire in which carboxyhemoglobin or methemoglobin may be present, the nitrite can be withheld and only the sodium thiosulfate administered.

When hydroxocobalamin becomes available in the United States, combined therapy of hydroxocobalamin with sodium thiosulfate, which is synergistic, would be ideal. When the formation of methemoglobin would not be detrimental, a combination of hydroxocobalamin, sodium nitrite, and sodium thiosulfate should be studied to determine if it is advantageous.[11]

Children

The dose of sodium thiosulfate in children is 7 g/m^2, up to the adult dose[5] or 0.5 g/kg (2 mL/kg of 25% solution) up to the adult dose of 12.5 g (50 mL of 25% solution).[16] The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[5]

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 3% sodium nitrite solution at 6â€“8 mL/m^2 (~0.2 mL/kg), not to exceed 10 mL or 300 mg, prior to administration of sodium thiosulfate.[5] A 0.2

mL/kg dose of 3% sodium nitrite solution is approximately 6 mg/kg sodium nitrite. Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/100 mL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin, methemoglobin, or sulfhemoglobinemia.[1] The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours after the first dose as prophylaxis.[5]

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Break one amyl nitrite ampule and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off. Amyl nitrite inhalation should be discontinued prior to administration of sodium nitrite. The healthcare provider should not inhale the amyl nitrite.

Immediately following sodium nitrite infusion, sodium thiosulfate should be administered intravenously at a dose of 7 g/m^2 of 25% solution or 0.5 g/kg (2 mL/kg of 25% solution), up to the adult dose of 12.5 g (50 mL of 25% solution).[16] The same needle and vein can be used. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis.[5]

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire, the nitrite can be withheld and only the sodium thiosulfate administered.

Nitroprusside

The usual dosage of sodium nitroprusside is 3 Âµg/kg/min (range 0.25â€“10 Âµg/kg/min).[13] Each mole of nitroprusside contains 5 cyanide ions. Prolonged infusion or doses in excess of the body's detoxifying capability may lead to thiocyanate or cyanide toxicity.

Some authors recommend adding 0.5 g sodium thiosulfate to each 50 mg of nitroprusside.[14] This dose of sodium thiosulfate usually is sufficient to prevent cyanide toxicity from nitroprusside; however, thiocyanate may accumulate, especially in patients with renal insufficiency. Thiocyanate is relatively nontoxic compared to cyanide but may produce dose-dependent tinnitus, miosis, hyperreflexia, and hypothyroidism, especially at serum concentrations >60 Âµg/mL,[13] and thiocyanate is hemodialyzable. Nitroprusside-induced cyanide toxicity should be treated like cyanide toxicity from any other cause: stop the nitroprusside dosage and administer sodium thiosulfate, sodium nitrite, or hydroxocobalamin (if available) according to the doses and precautions listed.

Availability

Sodium thiosulfate is available in 50-mL vials containing 12.5 g in water for injection (USP), with boric acid or sodium hydroxide

added to adjust the pH. It also is available in a kit containing 2 ampules of sodium nitrite (300 mg in 10 mL water for injection) with 12 ampules of amyl nitrite inhalants (0.3 mL) and 2 vials of sodium thiosulfate 12.5 g in 50 mL water for injection, with boric acid or sodium hydroxide added to adjust the pH.[5]

Antidotes in Depth

Hydroxocobalamin

Mary Ann Howland

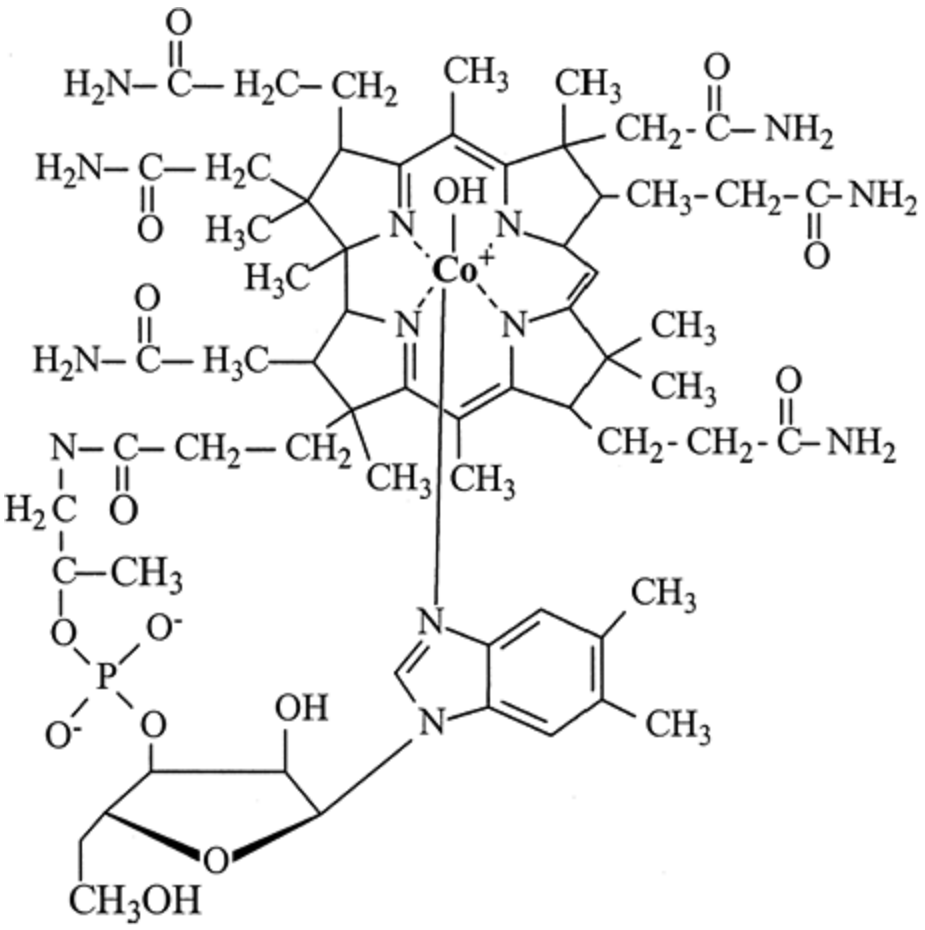

Figure. No Caption Available.

Hydroxocobalamin has been used as a cyanide antidote in France for many agent and then in combination with sodium thiosulfate.[14] This combination FDA as an orphan drug in 1985, and two US manufacturers are in the pro commercially available.

History

The antidotal actions of cobalt as a chelator of cyanide were recognized a Muschett is attributed with first using the cobalt-containing compound hy antidote to cyanide in mice.[21] Hydroxocobalamin subsequently was shown protecting against several minimum lethal doses of cyanide as long as an hydroxocobalamin to cyanide was used.[21 , 22 , 27]

Chemistry

The chemical formula for hydroxocobalamin is $C_{62}H_{89}CoN_{13}O_{15}P$. Its r 1346.47 daltons. It is a vitamin B_{12} precursor often referred to as vitamir difference between cyanocobalamin (vitamin B_{12}) and hydroxocobalamin CN group with an OH group. In vitro studies demonstrate that cyanide dis hydroxocobalamin to form cyanocobalamin.[20, 24] Hydroxocobalamin is a solubility of 1 part in 50 parts of water.[24]

Mechanism of Action

The cobalt in hydroxocobalamin combines with cyanide to form the relati cyanocobalamin.[21, 22] An ex vivo study using human skin fibroblasts de hydroxocobalamin penetrates intracellularly to form cyanocobalamin.[3] Oth as dicobalt ethylenediaminetetraacetic acid (EDTA), have been used both clinically in other countries, but their therapeutic index is narrow, especia cyanide. Additionally, idiosyncratic adverse effects make these compound [28] One mole of hydroxocobalamin binds 1 mole of CN. Given the molecula requires 52 g of hydroxocobalamin to bind 1 g of cyanide.[14] Use of hydr thiosulfate is synergistic and comparable to the sequential use of sodium thiosulfate.[14, 27]

Pharmacokinetics and Pharmacodynamics

Under an FDA Investigational New Drug Permit, the first pharmacokinetic hydroxocobalamin was performed in the United States and published in 1 who were heavy smokers were intravenously administered 5 g hydroxoco been obtained from a French manufacturer. The first four patients receive over 20 minutes. They then received 12.5 g (50 mL of 25% solution) of intravenously infused over 20 minutes. The next eleven patients received hydroxocobalamin but diluted with 100 mL water for injection (USP) and The serum and urine sampling of hydroxocobalamin differed in the two p somewhat different half-lives (4 hours vs. 1.27 hours). The alpha distribu hours in the group 1 patients. Peak hydroxocobalamin concentration aver Âµmol/L), and Vd averaged 0.38 L/kg. A mean dose of 62% was recovered

hours. Whole-blood cyanide concentrations significantly decreased in all hydroxocobalamin. A problem with this study was the short collection time plasma hydroxocobalamin concentrations making the pharmacokinetic an

A second pharmacokinetic study performed in adult victims of smoke inha dramatically different results.[18] This finding is not unexpected given the populations.[1, 19] These patients were administered hydroxocobalamin 5 g over 30 minutes, starting within 30 minutes of their removal from the fir half-life of hydroxocobalamin was 1.86 hours, elimination half-life was 26. sampling up to 6 days, and Vd was 0.45 L/kg. The peak plasma cyanoco 212 Âµmol/L. In the one patient who subsequently was determined not to cyanide, the hydroxocobalamin elimination half-life was 13.6 hours and Vd clearance of hydroxocobalamin was 37% in the cyanide-exposed patients unexposed patient.

A study of 12 fire victims in France who were suspected of having cyanid conducted.[16] These patients received intravenous hydroxocobalamin 5 g in (USP) over 30 minutes, and pretreatment and posttreatment cyanide cor cyanocobalamin concentrations were analyzed. In patients with cyanide Âµmol/L, a linear relationship existed between the blood cyanide concent of cyanocobalamin. In the 3 patients with blood cyanide levels >40 Âµmo cyanocobalamin reached a plateau, implying that all of the hydroxocobala the one patient with a blood cyanide level >40 Âµmol/L who received a s hydroxocobalamin, the cyanocobalamin concentration subsequently rose.[2

The protein binding and tissue distribution of cyanide, hydroxocobalamin, likely are different.[17] In addition, hydroxocobalamin probably causes redi the intracellular to the intravascular space.[17]

Clinical Use

Many case reports in France document the efficacy of hydroxocobalamin thiosulfate for treatment of cyanide toxicity.[7, 15] In one study, 69 patie were administered a mean dose of 8 g hydroxocobalamin by IV infusion Two thirds of the patients with documented cyanide levels >39 Âµmol/L,

considered a fatal concentration, survived.

Hydroxocobalamin was also able to prevent the rise in cyanide concentra nitroprusside infusion in patients who received hydroxocobalamin compare not.[8]

Most animal studies demonstrate a synergistic effect of hydroxocobalamir

Adverse Effects

Hydroxocobalamin has a large therapeutic index and appears to be well doses have been administered to animals, with no adverse effects.[22, 25] g/kg.

Red discoloration of mucous membranes, plasma, and urine may occur and days after therapy.[6] Rarely, allergic reactions are reported.[24] Prior chroni hydroxocobalamin or cyanocobalamin for treatment of vitamin B_{12} deficie with development of anaphylaxis.[14]

The hydroxocobalamin solution should not be administered through the sa same time as the thiosulfate solution[10] because sodium thiosulfate binds renders it inactive.[23]

An in vitro study found statistically significant alterations in serum conce aminotransferase (AST), total bilirubin, creatinine, magnesium, and iron administration.[9] Colorimetric assays are most likely to be adversely affec hydroxocobalamin and cyanocobalamin have an intensely red color.

Administration and Dosing

Cyanide

A dose of 70 mg/kg (not to exceed 5 g initially) administered intravenous recommended. This dose can be administered as an IV push in cases of arrest.[6, 7] The dose can be repeated (not to exceed a total dose of 15 g The second and subsequent doses are to be infused intravenously over a hours), except in refractory cardiac arrest or collapse.[6]

The World Health Organization has recommended 10 mL (4g) of 40% sol intravenously over 20 minutes.[29]

The adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) a intravenously as either a bolus injection or infused over 10 to 30 minutes severity of the situation. The dose of sodium thiosulfate can be repeated manifestations of cyanide toxicity reappear or at 2 hours as prophylaxis. methemoglobin would not be detrimental, a combination of hydroxocobala sodium thiosulfate may be considered.[14 , 27]

Nitroprusside

When nitroprusside is administered, use of concomitant hydroxocobalamir accumulation and toxicity in both animal models and in humans.[7 , 8 , 30]

Availability

The FDA designated hydroxocobalamin as an orphan product on Septembe is Orphan Medical in Minnesota, and the trade name will be CYANOKIT.[12]

Hydroxocobalamin is available in France under the trade name Cyanokit 2 a 2.5-g vial of lyophilized powder by LIPHA SA-Le Pressoir Vert. The solu reconstituted by diluting one 2.5-g vial of lyophilizate in 100 mL sterile, chloride solution for injection.[10]

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 122
Methemoglobin Inducers

Dennis Price

A 27-year-old man was brought to the emergency department (ED) by a with a complaint of shortness of breath. The patient had a history of acq immunodeficiency syndrome (AIDS), complicated by *Candida* esophagitis episodes of *Pneumocystis carinii* pneumonia. His medical regimen include zidovudine and dapsone. He recently had become depressed over the deat close friend and had taken â€œall of his medicationsâ€• in a suicide atte hours before arrival at the ED. He had vomited once at home and began short of breath approximately 2â€“3 hours later.

On physical examination, the patient appeared cachectic, cyanotic, and sh breath. He appeared less short of breath than his level of cyanosis sugge vital signs were: blood pressure, 90/40 mm Hg; pulse, 140 beats/min; r rate, 40 breaths/min; rectal temperature, 100.2Â°F (37.9Â°C). A pulse o revealed 88% oxygen saturation on room air. The skin was diaphoretic wi track marks. Examination was remarkable for perioral cyanosis. His neck supple and without jugular venous distension. The chest was clear to aus with good airflow. Cardiac examination revealed a tachycardia with norma S_2 heart sounds and a grade 1/6 systolic ejection murmur heard best at t

lower sternal border. The abdomen was nontender with good bowel sound hepatomegaly. Examination of the extremities revealed no clubbing or ed the nail beds were markedly cyanotic. His neurologic examination was no 100% non-rebreather oxygen mask was applied, and the patient was atta cardiac monitor. An intravenous (IV) line was inserted, and blood sample obtained for a complete blood count, electrolytes, blood urea nitrogen (B glucose, and acetaminophen concentration. After a few minutes of oxyge the patient's heart rate decreased to 128 beats/min, but he was still cya tachypneic. The pulse oximeter continued to read 86â€“88% oxygen sat Arterial blood gas analysis was obtained while the patient was receiving supplemental oxygen, but the house officer thought that the specimen m venous because it was darkly colored. The results were: pH, 7.34: PCO_2 Hg; PO_2 , 400 mm Hg; calculated oxygen saturation, 99%. The patient w 60 g activated charcoal in a slurry of water.

The electrocardiogram (ECG) showed a sinus tachycardia with normal axi intervals, ST segments, and T waves. The chest radiograph was normal. acetaminophen concentration was zero. All other laboratory test results unremarkable. Cooximetry of an arterial specimen revealed total hemoglo g/dL; oxyhemoglobin, 64%; methemoglobin, 33%; deoxyhemoglobin, 1% carboxyhemoglobin, 2%.

The patient received 60 mg methylene blue (0.1 mL/kg of 1% solution) intravenously over 20 minutes. Pulse oximetry dropped to 73â€“75% for minutes with no change in his clinical symptoms. Approximately 40 minu methylene blue infusion, the patient was less cyanotic, and a repeat methemoglobin level was 6%. Three hours later, he was again short of b cyanotic, and his methemoglobin level had risen to 24%. Another 60 mg methylene blue was infused and led to improvement in his color and tac within 20 minutes. His repeat methemoglobin level was 4%.

Over the first 24 hours, the patient required a total of 3 doses of methyl therapy. His hemoglobin subsequently fell to 6.2 g/dL, resulting in a tran 2 units of packed red blood cells. While in the hospital, he was evaluated psychiatrist and enrolled in an AIDS support group. The patient was disc days after admission with a hemoglobin of 9.7 g/dL and normal cooximet

Introduction

Biologic systems constantly use endogenous mechanisms to protect them from oxidants to survive. Cellular components such as enzyme systems a structural elements are spontaneously oxidized and have increased rates oxidation when exposed to exogenous oxidants. Methemoglobin occurs wh iron atom in hemoglobin loses 1 electron to an oxidant, and the ferrous (state of iron is transformed into the ferric (Fe^{3+}) state. Although methe is always present at low levels in the body, methemoglobinemia is define as an abnormal elevation of methemoglobin level.

Reduced hemoglobin functions reliably as an oxygen transporter because protected heme pocket it shares an outer valence electron with the oxyge transports. Normally it releases this oxygen without giving up an electron occasionally this electron is lost to the departing oxygen in the process o autooxidation. Oxidation is increased in the presence of some hereditary conditions such as hemoglobin M disease. However, oxidizing xenobiotics produce methemoglobin by direct interaction with the Fe^{2+} moiety. These exogenous products are the major source of oxidant stress to the individu the most frequent cause of methemoglobinemia. Although typically not lif threatening, methemoglobinemia may produce symptoms of cellular hypo should be considered in the differential diagnosis of the

cyanotic patient who has no apparent cardiovascular cause. In the cases methemoglobinemia and sulfhemoglobinemia, cyanosis is not caused by deoxyhemoglobin but rather by the color imparted to the skin as a result oxidized hemoglobin. Methylene blue, an exogenous electron carrier, red oxidized hemoglobin in patients with methemoglobinemia.

History and Epidemiology

Methemoglobin was first described by Felix Hoppe-Seyler in 1864.[32] In 18 case of transient drug-induced methemoglobinemia was described.[68] In t 1930s, methemoglobinemia was recognized as a predictable adverse effec sulfanilamide use, and methylene blue was recommended for treatment o

ensuing cyanosis.[44] Some authors recommended concurrent use of methy when sulfanilamides were used.[106] In 1948, an enzyme defect was report twin brothers. The defect caused cyanosis in the absence of cardiopulmor disease that responded to ascorbic acid therapy.[34]

Methemoglobinemia can be hereditary or acquired. The hereditary types a with only several hundred cases reported in the literature.[8, 23, 46, 62, The frequency with which xenobiotic-induced methemoglobinemia occurs unknown. The American Association of Poison Control Centers (AAPCC) a Toxic Exposure Surveillance System (TESS) data show approximately 100 methylene blue as an antidote. However, these data certainly underestim incidence of this poisoning because Poison Control Centers are not notifie cases.

Cooximetry data were collected at two teaching hospitals and a significan of elevated methemoglobin levels were found. A total of 5248 cooximetry were performed over 28 months on 1267 patients. Six hundred sixty test revealed methemoglobin levels >1.5% in 414 patients (some patients had than one test). Thus, 12.5% of all tests and 19.1% of all patients who u cooximetry had an abnormal methemoglobin level. One hundred thirty-ei patients with peak methemoglobin levels >2% were identified. The mean methemoglobin level was 8.4% (range 2.1â€“60.1%), and patients ranged from 4 days to 86 years.

Benzocaine spray accounted for the most seriously poisoned patients (n = a mean peak methemoglobin of 43.8% (range 19.1â€“60.1%). Dapsone for the largest number of cases (n = 58), with a mean peak of 7.6% (ran 2.1â€“34.1%). Thirty three of 35 patients who had methemoglobin levels were considered to have signs and symptoms consistent with acquired methemoglobinemia and 12 received methylene blue. There was 1 fatality near fatalities that were directly attributed to methemoglobinemia. These likely represent an underestimation of the true number of cases of methemoglobinemia at these institutions because cooximetry was perform upon physician orders (the physician suspected a dyshemoglobinemia), ar fourth of cases with levels >2% were found incidentally when cooximetry performed in the catheterization laboratory to provide data on oxyhemog

deoxyhemoglobin. In addition, not all patients taking dapsone were teste Extrapolating these data throughout the country suggests underreporting substantial underrecognition of this entity with its potential danger.

The incidence of methemoglobinemia induced in the workplace is poorly documented. Two reports, one in 1964 and another in 1986, document s hundred cases of chemically induced cyanosis resulting from methemoglc Several more workplace exposures are documented as case reports. Underreporting and underrecognition associated with minimal symptoms by low levels may account for this phenomenon.[14 , 95]

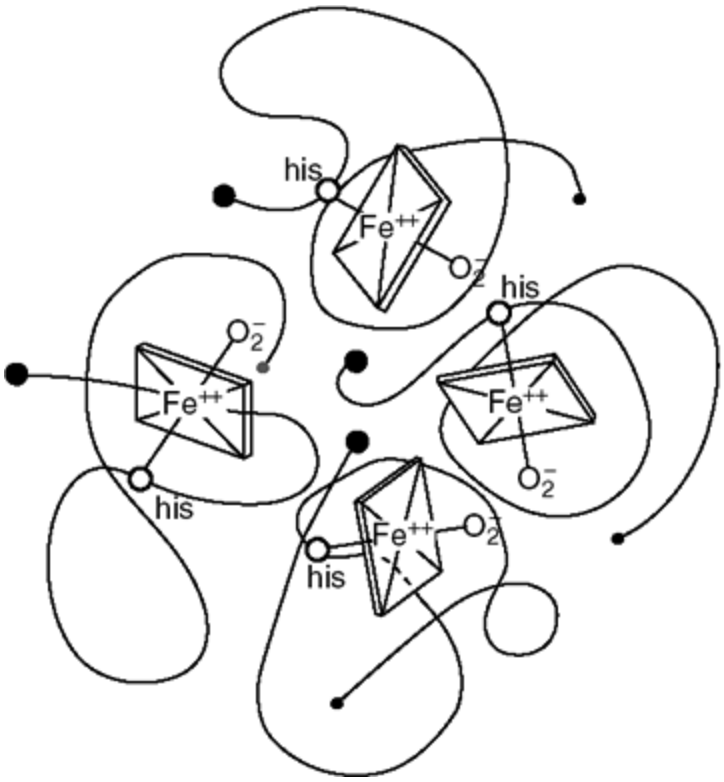

Figure 122-1. Hemoglobin molecule symbolically represented with its he center surrounded by the globin portion of the molecule.

his = histidine

Hemoglobin Physiology

Hemoglobin consists of 4 polypeptide chains noncovalently attracted to o another. Each of these subunits carries 1 heme molecule deep within the structure. The polypeptide chain protects the iron moiety of the heme m from inappropriate oxidation (Figure 122-1).

The iron is held in position by 6 coordination bonds. Four of these bonds between iron and the nitrogen atoms of the protoporphyrin ring; the fifth bond sites lie above and below the protoporphyrin plane. The fifth site is by histidine of the polypeptide chain. Changes in the amino acid sequence polypeptide chain, as occur in hemoglobin M, influence this protective â€œpocket,â€• allowing easier iron oxidation (Figure 122-2).

This process is referred to as *hemoglobin autooxidation.* The sixth coord site is where most of the activity within hemoglobin occurs. Oxygen trans occurs here, and this site is involved with formation of methemoglobin or monoxide poisoning (Figure 122-3). It is at this site that an electron is l oxidant xenobiotics, transforming iron from its ferrous to its ferric form, producing oxidized hemoglobin or methemoglobin.

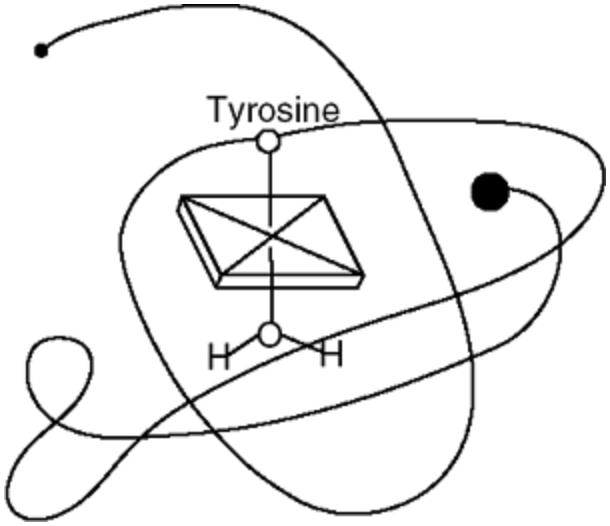

Figure 122-2. Hemoglobin M occurs when histidine is replaced by tyrosin amino acid sequence of the polypeptide chain. Hemoglobin M is more eas autooxidized (as shown) to methemoglobin.

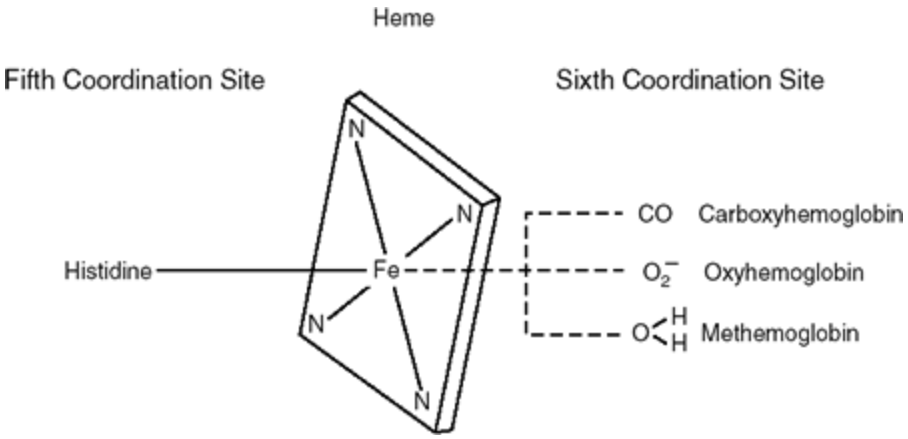

Figure 122-3. Heme molecule depicted with its bonding sites. Oxyhemo carboxyhemoglobin, and methemoglobin all involve the sixth coordination site of iron.

Hemoglobin transports an oxygen molecule only when its iron atom is in reduced ferrous state (Fe^{2+}). During oxygen transport, the iron atom ac transfers an electron to oxygen, thus transporting oxygen as a superoxid particle $Fe^{3+}\ O_2^{-}$. When oxygen is released, the ferrous state is restore hemoglobin is ready to accept another oxygen molecule. Interestingly, a percentage of oxygen is released from hemoglobin with its shared electro (forming superoxide $\hat{A}\cdot O_2$), leaving iron oxidized. This sixth coordination becomes occupied by a water molecule. This abnormal unloading of oxyg contributes to the steady-state level of approximately 1% methemoglobin normal individuals. In summary, the differences between hemoglobin and methemoglobin are subtle and involve only a small part of the hemoglobi molecule but make hemoglobin incapable of oxygen transport.

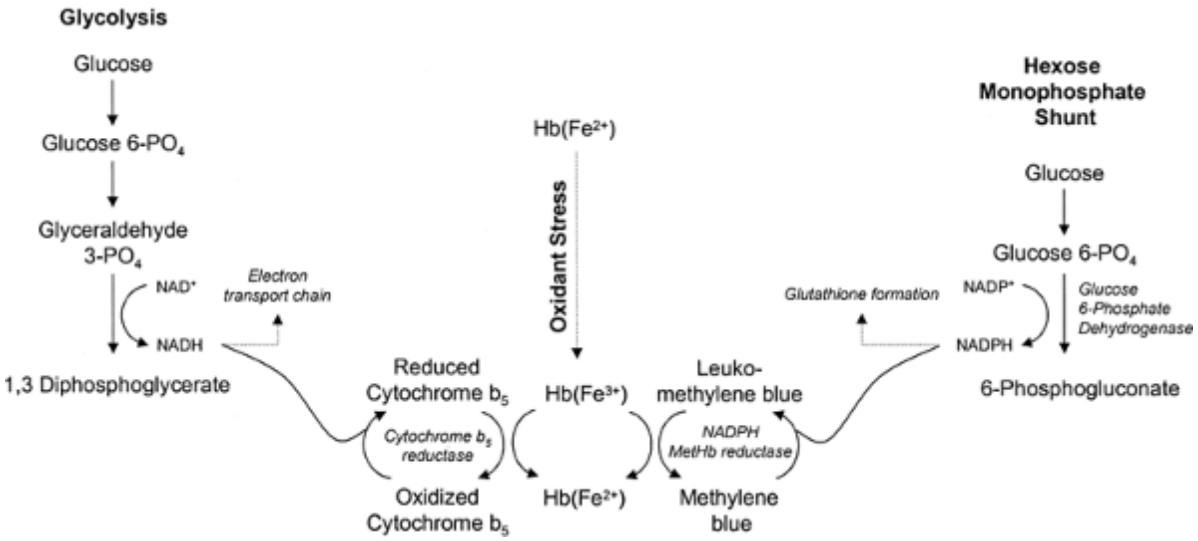

Figure 122-4. Role of glycolysis in the Embden-Meyerhof pathway and th methylene blue in the reduction of methemoglobin.

Methemoglobin Physiology and Kinetics

Because of the spontaneous and xenobiotic-induced oxidation of hemoglo erythrocyte has developed multiple mechanisms to maintain the normal le methemoglobin at <1%.[11] All of these systems donate an electron to the iron atom. The half-life of methemoglobin acutely formed as a result of e to oxidants is between 1 and 3 hours.[50 , 67] With continuous exposure to oxidant, the half-life of methemoglobin appears prolonged.

Quantitatively the most important reductive system requires nicotinamide dinucleotide (NADH), which is generated in the Embden-Meyerhof glycoly pathway (Figure 122-4). NADH serves as an electron donor, and along w enzyme NADH methemoglobin reductase, reduces the oxidized ferric (Fe^{3} to the more functionally favorable ferrous (Fe^{2+}) iron state. There are r cases of hereditary deficiencies of the enzyme NADH methemoglobin red [63] Individuals who are homozygotes for this enzyme deficiency usually ha methemoglobin levels of 10â€“50% under normal conditions without any xenobiotic stressors. Individuals who are heterozygotes do not ordinarily demonstrate methemoglobinemia except when they are subject to oxidan stresses. Additionally, because this enzyme system lacks full activity unti

approximately 4 months of age, infants are more susceptible than adults oxidizing stresses.[73, 109]

Oxidized iron can be reduced nonenzymatically using ascorbic acid and r glutathione as electron donors, but this method is much slower and quar less important under normal circumstances.

Within the red cell is another enzyme system for reducing oxidized iron th dependent on the nicotinamide adenine dinucleotide phosphate (NADPH) in the hexose monophosphate shunt pathway (Figure 122-4). NADPH red a small percentage of methemoglobin under normal circumstances. Becaus relatively minor role in methemoglobin reduction, patients with a deficien NADPH methemoglobin reductase do not exhibit methemoglobinemia unde circumstances.[94]

When the NADPH methemoglobin reductase system is provided with an e electron carrier such as methylene blue, this system is accelerated and ca in the reduction of oxidized hemoglobin.[30] (Methylene blue is reduced to leukomethylene blue by NADPH-dependent methemoglobin reductase, usi NADPH as the electron donor; leukomethylene blue directly reduces the h [Antidotes in Depth: Methylene Blue]).

Etiologies

Nitrates and nitrites are powerful oxidizing agents that are 2 of the most methemoglobin-forming compounds. Sources of nitrates and nitrites inclu water, food, industrial compounds, and pharmaceuticals. The contaminatio drinking water occurs mainly with nitrates because nitrites are easily oxid the highly soluble nitrates in the environment. When water containing ni based fertilizers and nitrogenous waste from animal and human sources i to run off fields, it easily contaminates shallow rural wells. Foods such as cauliflower, carrots, spinach, and broccoli have high nitrate content, and enter the food chain as preservatives in meat products such as hot dogs sausage.[4, 5, 18]

The oxidation reaction of nitrates that occurs both in vivo and in vitro is

and poorly understood. Ingested nitrates are reduced to nitrites by bacter gastrointestinal tract (especially in infants) and then can be absorbed, u leading to methemoglobin production. This conversion is not essential, h because nitrates themselves can oxidize hemoglobin.[30 , 42 , 98] Some qu whether well water consumption alone can cause serious methemoglobine the absence of comorbid disease.[26]

In the past, nitrates were a too common cause for well water contaminati infant fatalities were associated with methemoglobinemia.[20 , 59 , 66] A nu reports from the midwest United States demonstrated the problems of pc constructed shallow wells that permit contamination by surface waters c chemicals, pesticides, fertilizers, and microorganisms.[69] In several South studies, 20â€“50% of wells contained both coliform bacteria and water th exceeded the Environmental Protection Agency (EPA) standards for perm quantities of nitrogen as nitrates (10 ppm or 10 mg/L).[51] In New York St wells from rural farms demonstrated elevated concentrations of nitrogen compounds, and 15.7% were found to have nitrate concentrations >10 m

Nitroglycerin (glyceryl trinitrate) and organic nitrates are more effectivel absorbed through mucous membranes and intact skin than from the gastrointestinal (GI) tract. Their onset of action is more rapid, and the to is much greater, when mucous membrane or cutaneous absorption occurs [82] Aromatic amino and nitro compounds may indirectly produce methemo These agents do not form methemoglobin in vitro; therefore, they are ass do so by in vivo metabolic chemical conversion to some active intermedia [55 , 99]

Elevated methemoglobin and carboxyhemoglobin concentrations are found victims of fires and automobile exhaust fume poisoning.[10 , 49 , 52 , 60] He induced hemoglobin denaturation in burn patients and the inhalation oxid nitrogen from combustion are suggested to be causative factors for methemoglobin formation.

Topical anesthetics are widely used to facilitate multiple procedures and l implicated in the most serious of toxic methemoglobin cases.[1 , 40 , 56 , 75] Cetacaine spray (14% benzocaine, 2% tetracaine, 2% butylaminobenzoat Hurricaine spray (20% benzocaine) are the agents most commonly associ

production of methemoglobin. The dosing recommendations are difficult t comprehend (eg, 0.5-second spray repeat once) and often are ignored. O showed that the dose is dependent on the residual volume in the canister physical orientation of the canister as the spray is being applied.[57]

A review of 52 months of data from the FDA's Adverse Event Reporting S demonstrated 132 cases of benzocaine-induced methemoglobinemia. Ben spray was implicated in 107 severe adverse events and 2 deaths. In 123 the product was a spray. In 69 cases where the dose was specified, 37 p received a single spray.[70]

This FDA effort is exclusively based on self-reporting and probably greatl underestimates the extent of the problem.[38] The FDA itself has estimated approximately 10% of serious events are reported and that some studies â‰¤1% serious event reporting.[70]

Nitric oxide delivered by inhalation is used to treat persistent pulmonary hypertension of the newborn and other cardiopulmonary diseases associa pulmonary hypertension because it is a potent vasodilator.[90] Although nit is a potent oxidant, limited methemoglobin production with minimal clinic significance occurs when nitric oxide doses <40 ppm are used. Most patie maintain methemoglobin levels <4%.[47 , 105] Some cases of serious toxici occurred because of excessive dosing or unintentional overdose. Patients nitric oxide therapy, particularly at higher doses, who develop unexplaine cyanosis or a fall in oxygen saturation by pulse oximetry should be evalu methemoglobinemia.

Dapsone is increasingly implicated as a cause of methemoglobinemia beca its frequent use by patients with AIDS. Cases of prolonged methemoglob from dapsone ingestion are related to the long half-life of dapsone and th conversion to its methemoglobin-forming metabolites.[25] Patients receivin dapsone should be carefully monitored for methemoglobinemia.[108]

The bladder anesthetic phenazopyridine is among the most commonly re causes of methemoglobinemia.[19 , 28 , 35 , 37 , 72 , 96] For this reason its u limited today. Other causes of methemoglobinemia are listed in Table 12

Clinical Manifestations

The clinical manifestations of methemoglobinemia are related to impaired carrying capacity and delivery to the tissue. The clinical manifestations o methemoglobinemia usually are more severe than those produced by a corresponding degree of anemia. This discordance occurs because methe not only decreases the available oxygen-carrying capacity but also increa affinity of the unaltered hemoglobin for oxygen. This shifts the oxygen h dissociation curve to the left, which further impairs oxygen delivery (Chap This effect is attributed to the formation of heme compounds intermediat between normal reduced hemoglobin (all 4 iron atoms are ferrous) and methemoglobin, in which one or more of the iron moieties are in the ferr , [22] The degree to which this high oxygen affinity hemoglobin reduces ox delivery to the tissue from arterial blood is unclear, but is clinically signi

Because the symptomatology associated with methemoglobinemia is relate impaired oxygen delivery to the tissue, concurrent diseases such as anen congestive heart failure, chronic obstructive pulmonary disease, and pne may greatly increase the

clinical effects of methemoglobinemia (Figure 122-5). Predictions of sym and recommendations for therapy are based on methemoglobin concentra previously healthy individuals with normal total hemoglobin concentration

Hereditary

- Hemoglobin M
- Cytochrome b_5 reductase deficiency (homozygote and heterozygote)

Acquired

A. Medications

- Amyl nitrite
- Benzocaine
- Dapsone
- Lidocaine
- Nitric oxide
- Nitroglycerin

Nitroprusside
Phenacetin
Phenazopyridine
Prilocaine (local anesthetic)
Quinones (chloroquine, primaquine)
Sulfonamides (sulfanilamide, sulfathiazide, sulfapyridine, sulfamet

B. Other xenobiotics

Aniline dye derivatives (shoe dyes, marking inks)
Butyl nitrite
Chlorobenzene
Fires (heat-induced denaturation)
Food adulterated with nitrites
Food high in nitrates
Isobutyl nitrite
Naphthalene
Nitrates
Nitrites
Nitrophenol
Nitrous gases (seen in arc welders)
Silver nitrate
Trinitrotoluene
Well water (nitrates)

Pediatric

Reduced NADH methemoglobin reductase activity in infants (<4 months

Associated with low birth weight, prematurity, dehydration, acidosis, c and hyperchloremia.

TABLE 122-1. Common Etiologies of Methemoglobinemia

Cyanosis is a consistent physical finding in patients with substantial methemoglobinemia due to the deeply pigmented color of methemoglobin Cyanosis typically occurs when just 1.5 g/dL of methemoglobin is present represents only 10% conversion of hemoglobin to methemoglobin if the hemoglobin is 15 g/dL. In contrast, 5 g/dL deoxyhemoglobin (representing

hemoglobin) in the deoxygenated form is needed to produce the same de cyanosis.

In previously healthy individuals, methemoglobin concentrations of 10â€' usually result in cyanosis without apparent adverse clinical manifestations 20â€“50% methemoglobin levels, dizziness, fatigue, headache, and exer dyspnea may develop. At approximately 50% methemoglobin, lethargy ar usually appear. The lethal concentration probably is >70% (Table 122-2).

The cyanosis associated with methemoglobinemia is generalized, being b peripheral and central. Patients often appear in less distress or less ill th patients with cyanosis secondary to cardiopulmonary causes. A wide rang pigment levels produce the same degree of cyanosis.

Some patients may have a mixed etiology for their cyanosis, such as cardiopulmonary-induced hypoxia in addition to methemoglobinemia. The oxygen-carrying capacity in such situations may be drastically reduced (F 122-5 ; O_2 content of blood is discussed in Chap. 22).

Symptomatology of methemoglobinemia is determined not only by the ab concentration of methemoglobin but also by its rates of formation and e Levels of methemoglobin that may be clinically benign when caused by h defects or maintained chronically, likely will produce more severe signs w acutely acquired. Healthy subjects lack the compensatory mechanisms th develop over a lifetime in individuals with hereditary compromise, such a erythrocytosis and increased 2,3-diphosphoglyceric acid.

Certain xenobiotics characteristically produce prolonged methemoglobinem instance, dapsone has a very long half-life.[24 , 25] In the presence of rena drugs such as phenazopyridine are eliminated slowly and cause prolonged methemoglobinemia.

Some compounds producing oxidant stress may have associated toxicities unrelated to the development of methemoglobinemia, such as seizures ca benzocaine and lidocaine or hypotension caused by nitrates.[77]

Diagnostic Testing

For individuals in whom methemoglobinemia is suspected, a source for th stress should be sought. Arterial blood gas sampling may reveal blood wit characteristic chocolate brown color. (See ILMETHB in the Image Library http://www.goldfrankstoxicology.com) (In patients with known methemoglobinemia, a venous blood gas will

be accurate in demonstrating the degree of methemoglobinemia.) Arterial should be normal, reflecting the adequacy of pulmonary function to deliv dissolved oxygen to the blood. However, arterial PO_2 does not measure t important physiologic parameter, the hemoglobin oxygen saturation (SaO oxygen content of the blood. When the partial pressure of oxygen is know oxyhemoglobin and deoxyhemoglobin are the only species of hemoglobin, saturation can be calculated accurately from the arterial blood gas. Howe other hemoglobins are present (eg, methemoglobin, sulfhemoglobin, or carboxyhemoglobin), then the fractional saturation of the hemoglobin mus determined by the cooximeter.

TABLE 122-2. Signs and Symptoms Typically Associated wit Methemoglobin Concentrations in Healthy Patients with Nor Hemoglobin Concentrations

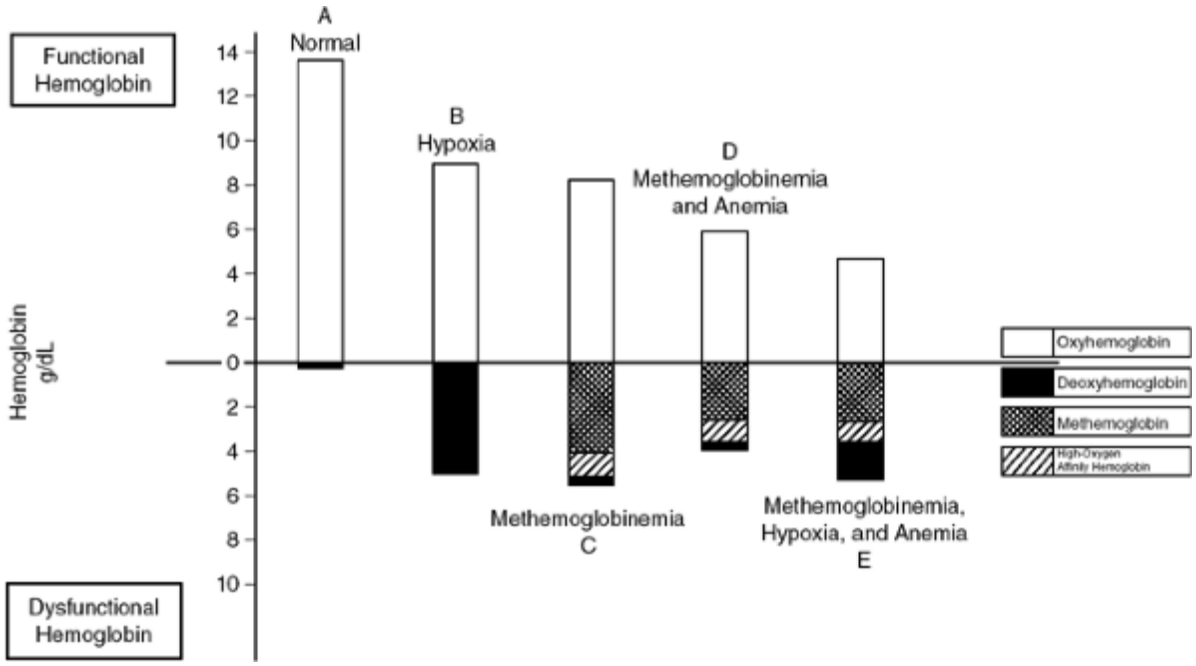

Figure 122-5. Clinical manifestations of methemoglobinemia depend on of methemoglobin and on host factors such as preexisting disease, anemi hypoxemia. Five examples of arterial blood gas and cooximeter analyses presented. A. Blood gas from a normal individual with 14 g/dL of hemogl Almost all hemoglobin is saturated with oxygen. B. Blood gas from a pati

cardiopulmonary disease producing cyanosis in which only 9 g/dL of hemo capable of oxygen transport. C. Methemoglobin level of 28% in an otherv normal individual will reduce hemoglobin available for oxygen transport to (approximately 4 g/dL of methemoglobin and 1.3 g/dL of high-oxygen-af hemoglobin because of the left shift of the oxyhemoglobin dissociation cu Same degree of methemoglobin as in C but in a patient with a hemoglobir g/dL. Only 6 g/dL of hemoglobin would be capable of oxygen transport. E Methemoglobinemia and anemia to the same degree as D but in a hypoxi

The cooximeter is a spectrophotometer that identifies the absorptive characteristics of several hemoglobin species at different wavelengths. B oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobi have different absorptions at the different measuring points of the cooxi their proportions and concentrations can be determined. Some newer ins have an expanded spectrum of detection and are able to identify fetal he and sulfhemoglobin.[29 , 111]

The pulse oximeter applied to a patient's finger at the bedside was develo estimate oxygen saturation trends in critically ill patients. The device tak advantage of the unique absorptive characteristics of oxyhemoglobin and deoxyhemoglobin and the different concentrations of these 2 hemoglobin during different phases of the pulse. Each manufacturer has calibrated its using volunteers breathing progressively increasingly hypoxic gas mixtures absence of a dyshemoglobin.[86 , 97 , 104] In other words, the oxygen satu values displayed on the pulse oximeter are derived independently by eacl manufacturer, who develops a formula using their own hardware and sens manufacturer then compares this value to a set of validation data derived experimental population.

Methemoglobin interferes with pulse oximetry in a complicated fashion. N manufacturer provides any validation data for situations where any dysh is present. All manufacturers disclaim accuracy under such circumstances. similar fashion to the cooximeter, the pulse oximeter reads absorbance of wavelengths of 660 and 940 nm, which are selected to efficiently separat oxyhemoglobin and deoxyhemoglobin. However, methemoglobin absorptio

these wavelengths is greater than that of either oxyhemoglobin or deoxyhemoglobin.[6, 76] Therefore, when methemoglobin is present, the r become inaccurate. The degree of inaccuracy is unique for each brand of instrument and may be influenced by signal quality, skin temperature, re error induced by blood cells and other factors, such as finger thickness ar perfusion.[88]

In the dog model, the pulse oximeter oxygen saturation (SpO_2) values d increasing methemoglobin levels. This fall in SpO_2 is not exactly proportio the fraction of methemoglobin, however, as the pulse oximeter overestim level of actual oxygen saturation. For example, in a case where the methemoglobin

level measured in the blood using a cooximeter was 20%, the pulse oxim indicated an SpO_2 of 90%. However, as the methemoglobin concentration approached 30%, the pulse oximeter saturation values decreased to abou and then leveled off, regardless of how much higher the methemoglobin became.[6, 103]

Blood gas analyzer
Blood
Partial pressure of dissolved oxygen in whole blood
PO_2
Also gives information about pH and PCO_2
Calculates SaO_2 from the partial pressure of oxygen in plasma; inaccurate of Hb other than OxyHb and DeoxyHb are present
An abnormal Hb form may exist if gap exists between ABG and pulse oxi
Cooximeter
Blood
Directly measures absorptive characteristics of oxyhemoglobin, deoxyhe methemoglobin, carboxyhemoglobin at different wavelength bands in who
SaO_2 % MethHb, %CoHb, %OxyHb, %DeoxyHb
Measures hemoglobin species directly
Provides data on hemoglobin only; most instruments will not measure sulfhemoglobin, HbM, and some other forms of Hb

Measuring Device	Source	What is Measured?	How Are Data Expressed?	Benefits	Pitfalls
Most accurate method to determine oxygen content of blood					
Pulse oximeter					
Monitor Sensor on patient					
Absorptive characteristics of oxyhemoglobin in pulsatile blood assuming t presence of only OxyHb and DeoxyHb in vivo					
SpO_2					
Moment-to-moment bedside data					
Inaccurate data, if interfering substances are present: methemoglobin, sulfhemoglobin, carboxyhemoglobin, methylene blue					
Maximum depression 75â€“85%, regardless of how much methemoglobin present					

TABLE 122-3. Hemoglobin Oxygenation Analysis

From our experience and that of others, levels of oxygen saturation (SpO lower than 85% in humans can be indicated by pulse oximetry when methemoglobin levels rise above 30%.[39, 56, 87, 92, 102] These differenc from variations in the way different model pulse oximeters deal with methemoglobin interference.[87, 88] Therefore, the clinician must (1) und how the particular pulse oximeter measures oxygen saturation when methemoglobin levels are elevated and (2) recognize that cooximetry determination is needed when methemoglobinemia is suspected.

Although the pulse oximeter reading in patients with methemoglobinemia be as accurate as desired, it may, nevertheless, be helpful when it is cor with that of the arterial blood gas. If there is a difference between the *m* oxyhemoglobin saturation of the pulse oximeter (SpO_2) and the *calculate* oxyhemoglobin saturation of the arterial blood gas (PO_2), then a â€œsa gapâ€• exists. The calculated SpO_2 will be greater than the measured Sp methemoglobin is present (Table 122-3). Hyperlipidemia may also interf accurate cooximetry determinations.[71, 100]

Acquired Methemoglobinemia and Infancy

Infants are more susceptible to methemoglobinemia than adults. The NAD methemoglobin reductase of an infant is not fully active until age 4â€“6 Infants who are bottle-fed may be exposed to nitrates and nitrites in well Additionally, infants have a relatively large body surface area, making al of oxidants via the skin more of a threat to them than to adults.

Methemoglobinemia of unknown origin is often reported in infants,[53 , 78 110] who are usually ill for other reasons, such as dehydration, acidosis, a diarrhea.[41] These infants can have methemoglobin levels in the 20â€“67% with severe consequences.[48]

Methemoglobinemia and Hemolysis

The enzyme defect responsible for most instances of oxidant-induced her glucose-6-phosphate dehydrogenase (G6PD) deficiency. A review of hem addressed the confusion regarding the relationship between hemolysis an methemoglobinemia.[9 , 31]

Confusion persists today for a number of reasons. Both hemolysis and methemoglobinemia are caused by oxidant stress, and hemolysis can occ following episodes of methemoglobinemia. Certain protective mechanisms oxidants (NADPH production) are the same in both disorders. Excessive blue treatment of methemoglobin reportedly produces hemolysis.[36 , 45]

However, oxidants damage the erythrocyte at different locations in the tw disorders. Hemolysis occurs when oxidants damage the hemoglobin chain directly as electron acceptors or through the formation of hydrogen perox other oxidizing free radicals. Oxidants forming irreversible bonds with su groups of hemoglobin cause denaturation and precipitation of the protein precipitates are quantitatively sufficient to form

Heinz bodies within the erythrocyte. Cells with large numbers of Heinz bo removed by the reticuloendothelial system, producing hemolysis. Alterna some oxidants can destroy the erythrocyte membrane directly, causing

nonâ€“Heinz body hemolysis. Methemoglobinemia does not necessarily pr hemolysis if untreated.

Numerous cases describe the occurrence of hemolysis following methemoglobinemia, although most poisonings with oxidant compounds d manifest both types of toxicity. The combined occurrence is reported with dapsone,[24 , 25 , 74] phenazopyridine,[19 , 28 , 37 , 72 , 96] amyl nitrite,[15] an aniline.[43 , 51 , 65] These instances of combined occurrences may represen incidental toxicity of an oxidizing agent or the depletion of all cellular de against oxidants. Currently, it is not possible to predict with any level of when hemolysis will follow methemoglobinemia, but clearly there is an ir incremental risk.

Another source of confusion concerning hemolysis and methemoglobinemia reduced glutathione (GSH) is required to protect against both toxic man Erythrocytes can withstand hemolytic oxidant damage as long as they car maintain adequate levels of reduced glutathione, the principal cellular ar Glutathione is maintained in its reduced form by using NADPH as its redu agent. Thus, cells with reduced capacity to produce NADPH (ie, erythrocy patients with G6PD deficiency, or cells with depleted reduced glutathione are susceptible to hemolysis. In the presence of methemoglobinemia, red glutathione plays a minor role as a reducing agent, but NADPH is necessa successful antidotal therapy with methylene blue. This codependence on reducing power of NADPH links the two disorders. Competition for NADPH oxidized glutathione and exogenously administered methylene blue is po to be the cause of methylene blue-induced hemolysis, that is, competitive inhibition of glutathione reduction. Methylene blue itself is an oxidant, but assessment of the hemolytic potency of varied drugs, methylene blue in d 390â€“780 mg proved to be only a moderate hemolytic agent.[54] The clin importance of this phenomenon is uncertain. It may be easier to consider hemolysis and methemoglobin formation as subclasses of disorders of ox stress. They should be considered separate clinical entities that share lim characteristics.

Management

For most patients with mild methemoglobinemia, no therapy is necessary than withdrawal of the offending xenobiotic, as reduction of the methem will occur by intact normal reconversion mechanisms (NADH methemoglo reductase). However, even small elevations of methemoglobin levels shou considered problematic because they suggest the individual is at a point further oxidant stress may cause methemoglobin levels to rise. An indivic receiving dapsone with a small elevation of methemoglobin level may be susceptible to clinically significant methemoglobinemia if challenged with benzocaine-containing anesthetic or an increase in dapsone dose. In the setting, continued absorption, prolonged half-life, and toxic intermediate metabolites may prolong methemoglobinemia. Patients should be examin carefully for signs of physiologic stress related to decreased oxygen deliv the tissue (Figure 122-6). Obviously, changes in mental status or ischem pain necessitates immediate treatment, but subtle changes in behavior or inattentiveness may be signs of global hypoxia and should be treated. Ab vital signs (eg, tachycardia and tachypnea) or lactic acidosis thought to b by tissue hypoxia or the functional anemia of methemoglobinemia should treated aggressively. A methemoglobin level alone generally is not an ad indication of need for therapy, although many recommend empiric therapy patients with methemoglobin concentrations above 25%.

The most widely accepted treatment of methemoglobinemia is administrat methylene blue 1â€“2 mg/kg body weight infused intravenously over 5 m (0.1â€“0.2 mL/kg of 1% solution). Use of a slow 5-minute infusion helps painful local responses from rapid infusion. When a painful reaction occurs be minimized by flushing the IV rapidly with at least 15â€“30 mL of fluid the infusion. Clinical improvement should be noted within 1 hour of meth blue administration if an elevated methemoglobin level is etiologic. If cya does not disappear within 1 hour of the infusion, a second dose should be while other factors are considered. Methylene blue causes a transient dec the pulse oximetry reading because of its blue color and excellent absorp 660 mm.[58 , 61 , 107]

Use of methylene blue in patients with G6PD deficiency is controversial. G deficient patients have been excluded from most treatment protocols bec methylene blue is a mild oxidant and case reports suggest methylene blu

An estimated 200 million people worldwide have this enzyme deficiency a incidence in the United States is highest among African Americans (11%) However, because of the lack of immediate availability of the test for G6F deficiency, most patients who need treatment

receive methylene blue therapy before their G6PD status is known. Althou patients with G6PD deficiency undoubtedly have been treated unknowingl case reports of toxicity are described.

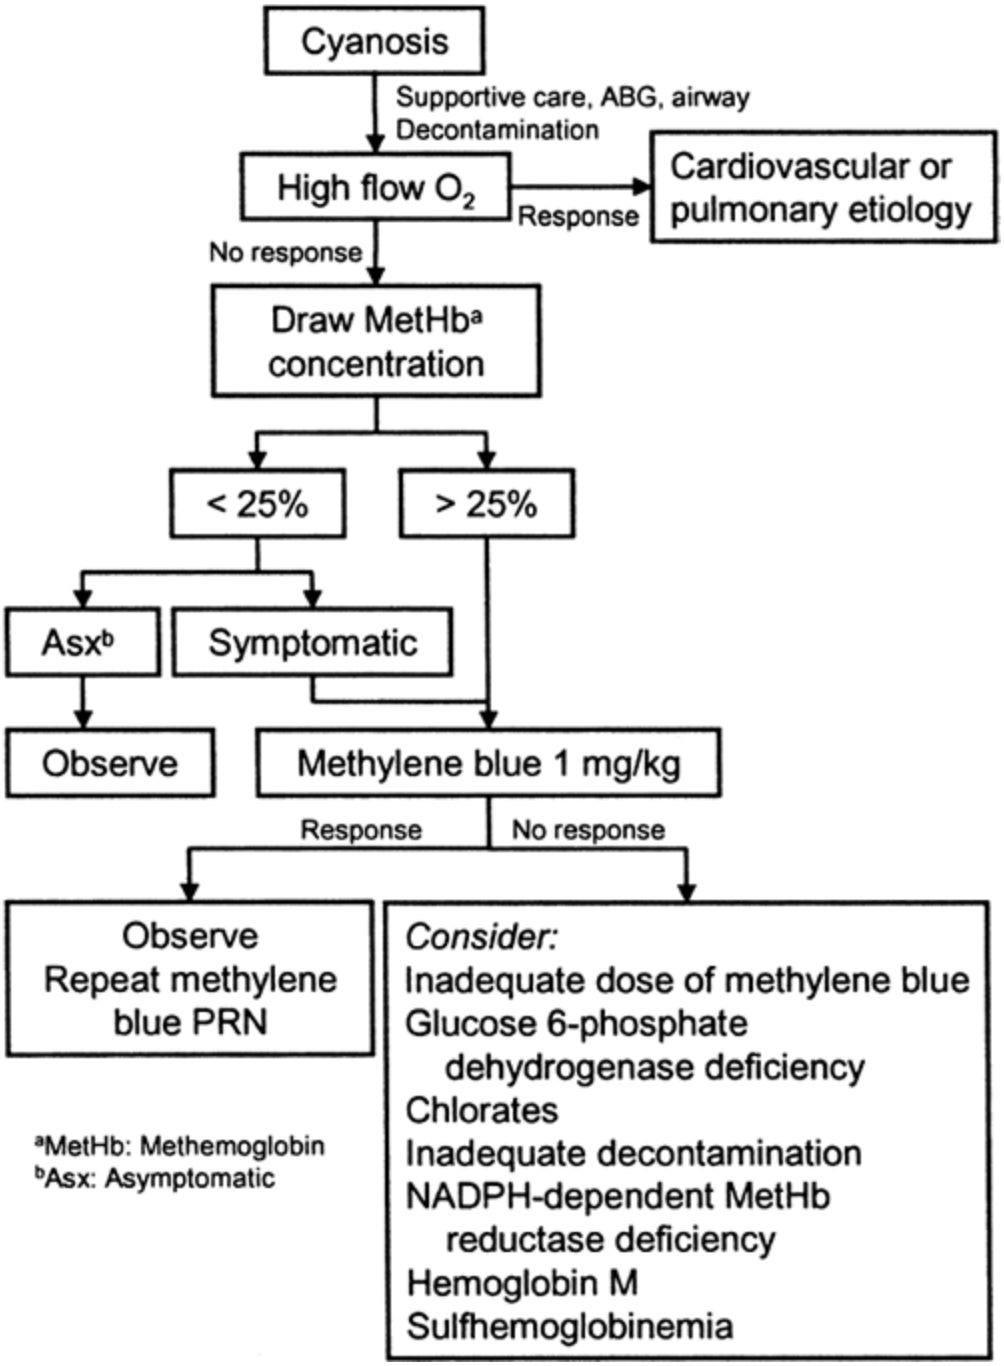

Figure 122-6. Toxicologic assessment of the cyanotic patient.

Even the authors of the review most frequently cited as a rationale for w methylene blue treatment were unsure whether the methylene blue given G6PD-deficient patient produced hemolysis.[91] The dose of methylene blue

the patient under study was small, and the patient had taken other xeno capable of producing hemolysis. The enzyme activity in patients with G6P deficiency is variable and they manifest different levels of disease in resp oxidant stress. For all of these reasons, the judicious use of methylene bl warranted in most patients with G6PD deficiency and symptomatic methemoglobinemia.

If methylene blue treatment fails to significantly relieve the methemoglob number of possibilities should be considered. The cause of the oxidant str not have been identified and adequately removed, allowing for continuing oxidation. In such situations, decontamination of the gut and skin cleansi be assured. Additional doses of methylene blue are also indicated. Patient have sulfhemoglobinemia, or are deficient in NADPH methemoglobin redu have severe G6PD deficiency, may not improve following methylene blue

Theoretically, exchange transfusion or hyperbaric oxygen may be benefici methylene blue is ineffective. Both interventions are time consuming and but hyperbaric oxygen allows the dissolved oxygen time to protect the pa while endogenous methemoglobin reduction occurs. Ascorbic acid is not in the management of acquired methemoglobinemia because the rate at w ascorbic acid reduces methemoglobin is considerably slower than the rate normal intrinsic mechanisms.[12] Methylene blue has no therapeutic effect sulfhemoglobinemia.[83]

Specific Management for Dapsone-Induced Methemoglobinemia

Treatment of dapsone deserves special consideration because of the freq with which it occurs and its tendency to produce prolonged methemoglob -hydroxylation of dapsone to its hydroxylamine metabolite by a cytochrom mediated reaction is partly responsible for methemoglobin formation in b therapeutic and overdose situations. Both the parent compound and it m are oxidants with long half-lives. Cimetidine is an inhibitor of this metabo pathway and reduces methemoglobin levels during therapeutic dosing.[89] overdose situations, cimetidine may exert some protective effects and sh

used with methylene blue. When dapsone is therapeutically indicated but levels of methemoglobin are found, cimetidine should be considered as a for reducing oxidant stress.

Sulfhemoglobin

Sulfhemoglobin is a hemoglobin variant in which a sulfur atom is incorpo the heme molecule, but is not attached to iron. The exact location of the atom in the porphyrin ring is unclear. Sulfhemoglobin is a darker pigment methemoglobin, producing cyanosis when only 0.5 g/dL of blood is affect cyanosis produced is similar to that produced by methemoglobinemia. Sulfhemoglobin also produces a drop in pulse oximetry readings.[2 , 79] In laboratory, sulfhemoglobin is characterized by its spectrophotometric ap and its lack of reaction when cyanide is added to the mixture. In contrast methemoglobin absorption peak is eliminated by the addition of cyanide. this reading is not routinely done in clinical laboratory practice, and the often is made based upon the patient's failure to improve with methylene [16 , 64 , 79 , 80] In the laboratory, isoelectric focusing techniques allow for delineation.

Sulfhemoglobin is an extremely stable compound that is eliminated only v blood cells are removed naturally from circulation. Although the oxygen-capacity of hemoglobin is reduced by sulfhemoglobinemia, unlike methemoglobinemia there is a decreased affinity for oxygen in the remai â€œunalteredâ€• hemoglobin. The oxyhemoglobin dissociation curve is s the right (see Figure 22-2), making oxygen more available to the tissues phenomenon reduces the clinical effect of sulfhemoglobin at the tissue le

Sulfhemoglobin can be produced experimentally in vitro by the action of sulfide on hemoglobin and was produced in dogs fed elemental sulfur.[62] A of drugs induce sulfhemoglobin in humans, including acetanilid, phenacet nitrates, trinitrotoluene, and sulfur compounds. Most of the drugs that pr methemoglobinemia have been reported to produce

sulfhemoglobinemia in various degrees. Sulfhemoglobinemia is recognized individuals with chronic constipation and in those who abuse laxatives.[62]

122-4 lists some differences between methemoglobin and sulfhemoglobin

Definition
Commonly accepted: hemoglobin with an oxidized heme moiety
Less well understood: hemoglobin with sulfur attached through an oxidat reaction
Clinical appearance
Cyanosis, may appear ill
Cyanosis, appears less ill at a comparable concentration
Spectrophotometric characteristics
Peak absorption at 570 and 620 mm
Peak absorption at 520 and 626 mm
Reversible by antidote
Yes
No
Level necessary to detect cyanosis
1.5 g/dL
0.5 g/dL
Etiologies
See Table 122-1
Similar to methemoglobin, an oxidant and a source of sulfur needed to p sulfhemoglobin
Diagnosis
Cooximetry
Cyanide added to blood in laboratory will completely eliminate methemog not sulfhemoglobin; some newer cooximeters measure directly
Effects on oxyhemoglobin dissociation curve
Decreased oxygen-carrying capacity, shifts curve to left with impaired O_2 to tissues
Decreased oxygen-carrying capacity, shifts curve to right, improving O_2 tissue
Response to methylene blue
Very good
Eliminated only with RBC natural turnover, no specific treatment

Methemoglobin Sulfhemoglobin

TABLE 122-4. Differences Between Methemoglobin and Sulfhemo

Sulfhemoglobinemia usually requires no therapy other than withdrawal of offending xenobiotic. It appears that patients with sulfhemoglobinemia co the attention of clinicians earlier because sulfhemoglobinemia produces r cyanosis than methemoglobinemia at a lower sulfhemoglobin level. There antidote for sulfhemoglobinemia because it results from an irreversible c bond that occurs within the hemoglobin molecule. Exchange transfusion sulfhemoglobin levels, but this approach usually is not necessary.

Summary

Oxidation of hemoglobin is a rare but treatable etiology of cyanosis. In th absence of findings of cardiopulmonary disease, cyanosis from methemo is likely. The diagnosis is confirmed by evaluation of blood by cooximetry treatment is clinically indicated, methylene blue is the treatment of choic source of oxidant stress should be sought and eliminated. Patients with lo methemoglobin levels should be considered to be under oxidant stress an for more serious methemoglobinemia if oxidant stressors persist.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Antidotes in Depth

Methylene Blue

Mary Ann Howland

Methylene blue is an extremely effective antidote for acquired methemoglobinemia. Methylene blue also has other actions, including inhibition of nitric oxide synthase and guanylyl cyclase and inhibition of the generation of oxygen free radicals. These effects are used to explain the beneficial effects of methylene blue in the hepatopulmonary syndrome,[39] treatment of priapism, modulation of streptozocin-induced insulin deficiency, prevention and treatment of ifosfamide-induced encephalopathy, and reduction of development of postsurgical peritoneal adhesions.[14,15,19,22,32,39,45]

History

Methylene blue was initially recommended for use as an intestinal and urinary antiseptic and subsequently recognized as a weak antimalarial agent.[18] In 1933, Williams and Challis successfully used methylene blue for treatment of aniline-induced methemoglobinemia.[49]

Pharmacology

Methylene blue is tetramethylthionine chloride,[18] a basic thiazin dye. Methylene blue is an oxidizing agent, which, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH methemoglobin reductase, is reduced to leukomethylene blue (see Figure 122-5). Leukomethylene blue then becomes available to reduce methemoglobin to hemoglobin.[10,18,46] Reduction of methemoglobin via this NADPH pathway is limited under normal circumstances. However, in the presence of methylene blue, the role of the NADPH pathway is dramatically increased (4â€“5 times in dogs) and becomes the most efficient means of methemoglobin reduction. This property makes methylene blue the treatment of choice for methemoglobinemia.

Pharmacokinetics

The pharmacokinetics of methylene blue were studied in animals and now volunteers following IV and oral administration of 100 mg.[10,11,12,33] Methylene blue exhibits complex pharmacokinetics consistent with extensive distribution into deep compartments, followed by a slower terminal elimination with a half-life of 5.25 hours. Peak concentrations after oral administration were reached in 1â€“2 hours, but were approximately 80â€“90 nmol/L, as opposed to 8000â€“9000 nmol/L following IV administration. Based on the human data in conjunction with the data obtained in rats, extensive first-pass distribution following oral administration is responsible for the substantial differences in whole-blood concentrations achieved by the routes of administration.[33] Total urinary excretion at 24 hours accounts for 28.6% after IV administration versus 18.5% after oral administration. In both cases, one third was in the leukomethylene blue form.

Adverse Effects

Reports of the apparent paradoxical ability of methylene blue to induce methemoglobinemia suggest an equilibrium between the ability of methylene blue to oxidize hemoglobin directly to methemoglobin and the ability of methylene blue (through the NADPH and NADPH methemoglobin reductase pathway and leukomethylene blue production) to reduce methemoglobin to hemoglobin.[5,6] Methylene blue does not produce methemoglobin at doses of 1â€“2 mg/kg. The equilibrium seems to favor the reducing properties of methylene blue, unless excessively large doses of methylene blue are administered[4,17,48] or the NADPH methemoglobin reductase system is abnormal. This equilibrium constant may vary substantially, as 20 mg/kg IV in dogs and 65 mg/kg intraperitoneally in rats failed to produce methemoglobinemia.[42] In the earliest studies, 50â€“100 mL of a 1% concentration (500â€“1000 mg) of methylene blue was used intravenously in volunteers[29] and to treat patients with aniline dye-induced methemoglobinemia.[49] In these studies, methemoglobin levels, measured when symptoms were most pronounced, were approximately 1.0 g/dL (0.4â€“8.3% of total hemoglobin), and unlikely to be solely responsible for the adverse effects demonstrated. Other consequential adverse effects included shortness of breath, tachypnea, chest discomfort, burning sensation of the mouth and stomach, initial bluish-tinged skin and mucous membranes, paresthesias, restlessness, apprehension, tremors, nausea and vomiting, dysuria, and excitation. Urine and vomitus had a blue color. These studies with limited evidence led to the recommendation to avoid doses >7 mg/kg.

In high doses, methylene blue can induce an acute hemolytic anemia independent of the presence of methemoglobinemia.[17,27] In doseâ€“response studies in glucose-6-phosphate dehydrogenase (G6PD)-deficient homozygous African American men, daily doses of 390â€“780 mg (5.5â€“11 mg/kg) of methylene blue produced hemolysis,[26] which was comparable to the results following exposure to 15 mg of primaquine base.[26] Because of the

sensitivity of neonates (hemoglobin F [HbF] and diminished NADH reductase) to these risks, the smallest effective dose of methylene blue should be used.[21,25] Because oxidizing agents can independently result in chemical-induced Heinz body hemolytic anemia, the contribution of methylene blue often is difficult to elucidate.[25]

Methylene blue is a dye. It will alter pulse oximeter readings.[7] Large doses may interfere with the ability to detect a clinical decrease in cyanosis; therefore, repeat cooximeter measurements and arterial blood gas analysis should be used in conjunction with clinical findings.

Intraamniotic injection of methylene blue may result in a number of adverse effects, including infants born with skin dyed blue (with resultant inaccurate pulse oximetry readings), methemoglobin, hemolysis, phototoxic skin reactions, or intestinal obstruction.[7,9,24,27,28,30,36,44] One infant exposed in utero at 5.5 weeks was normal at birth.[24] Enteral methylene blue in an excessive dose with subsequent leakage into the peritoneum of a premature neonate most likely resulted in a hemolytic anemia appearing 3 days later.[1]

Methylene blue leads to a bluish-green discoloration of the urine and may cause dysuria.[35] Intravenous methylene blue is irritating

and exceedingly painful. It may cause local tissue damage even in the absence of extravasation.[36] Subcutaneous and intrathecal administration are contraindicated.[36]

Xenobiotic-Induced Methemoglobinemia

Methylene blue doses of 1â€“2 mg/kg intravenously or 65 to 130 mg orally every 4 hours reversed sulfanilamide-induced methemoglobinemia.[20,47] With these regimens, a very rapid fall in

methemoglobin occurred accompanied by disappearance of cyanosis. Subsequent investigations confirmed the effectiveness and safety of IV doses of 1â€“2 mg/kg methylene blue in reversing the methemoglobinemia produced by sulfanilamide,[47] aniline dye,[13] and silver nitrate, among other xenobiotics.[43]

Use in Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Methylene blue is suggested to be ineffective in reversing methemoglobinemia in patients with G6PD deficiency[38] because G6PD is essential for generation of NADPH (Chap. 24). Without NADPH, methylene blue cannot act in the reduction of methemoglobin. However, G6PD deficiency is an X-linked hereditary deficiency with more than 400 variants. The red cells containing the more common G6PD A^- variant found in 11% of African Americans retain 10% residual activity, mostly in younger erythrocytes and reticulocytes. In contrast, the enzyme is barely detectable in those of Mediterranean descent who have inherited the defect. Therefore, it is impossible to predict before the use of methylene blue who will or will not respond, and to what extent. Currently, it appears that most individuals have adequate G6PD and express deficiency states in relative terms. This variable expression of their deficiency allows an effective response to most oxidant stresses.

Theoretically, normal cells might convert methylene blue to leukomethylene blue, and the leukomethylene blue might diffuse into G6PD-deficient cells and effectively reduce methemoglobin to hemoglobin.[3] Before it is assumed that G6PD deficiency is responsible for continued methemoglobin levels despite administration of methylene blue, continued toxin absorption and/or continued methemoglobin production must always be excluded. However, when therapeutic doses of methylene blue fail to have an impact on the methemoglobin level, the possibility of

G6PD deficiency should be considered, further doses of methylene blue should not be administered and because of the risk for methylene blue-induced hemolysis. In these cases, exchange transfusion and hyperbaric oxygen are potential alternatives (Chap. 122).

Dosing

Methylene blue is indicated in patients with symptomatic methemoglobinemia. This usually occurs at methemoglobin levels >20%, but may occur at lower levels in anemic patients or those with cardiovascular, pulmonary, or central nervous system compromise.

In most cases, doses of 1â€“2 mg/kg given intravenously over 5 minutes, followed immediately by a fluid flush of 15â€“30 mL to minimize local pain, is both effective and relatively safe. In neonates, 0.3â€“1 mg/kg doses often are effective.[23] The onset of action is rapid, and effects usually occur within 30 minutes.

Repetitive dosing of methylene blue may be required in conjunction with efforts to decontaminate the GI tract when there is continued absorption or slow elimination of the xenobiotic producing the methemoglobinemia, such as with dapsone.[41] Additionally, cimetidine is indicated to prevent further formation of the methemoglobin-inducing metabolite of dapsone.[8,37]

A continuous IV infusion of methylene blue at 0.1 mg/kg/h or 3â€“7 mg/h (in a concentration of 0.05% in 0.9% sodium chloride solution) also has been used.[2,41] However, this method of administration is not adequately studied.

Intraosseous administration of 0.3 mL of 1% solution (1 mg/kg) of methylene blue over 3â€“5 minutes into the anterior tibia of a 6-week-old infant was well tolerated.[21,31] Methylene blue is ineffective in treating other entities such as sulfhemoglobinemia (Chap. 122).

Availability

Methylene blue is available in 10-mL 1% ampules containing 10 mg/mL.

Summary

Methylene blue is an effective reducing agent for patients with acquired induced methemoglobinemia. When used in the proper dose, its onset of action is rapid and adverse reactions are limited. Repeat doses often are required when methemoglobin-producing drugs with a long duration of effect such as dapsone are ingested.

Chapter 123
Smoke Inhalation

Christopher P. Holstege
Mark A. Kirk

Firefighters discovered an unresponsive 39-year-old man in a smoke-filled room at an apartment building fire. At the scene, his initial vital signs were: palpable blood pressure, 70 mm Hg; pulse, 160 beats/min; respiratory rate, 0/min. A large amount of soot was noted in the patient's upper airway during endotracheal intubation in the field. He was placed on 100% oxygen during transport. On arrival at the emergency department (ED), he was unresponsive to painful stimuli and had a palpable systolic blood pressure of 100 mm Hg. No evidence of head trauma or skin burns was noted. Pupils were equal and reactive to light; conjunctival irritation and corneal burns were noted. He had singed nasal hairs and soot in his oropharynx, and carbonaceous material was suctioned from his endotracheal tube. Diffuse wheezing was present in all lung fields. He was attached to a ventilator with 100% oxygen, and aerosolized albuterol was administered. His blood pressure improved with intravenous (IV) fluid therapy. He did no respond to IV naloxone (2 mg), thiamine (100 mg), or dextrose (25 g).

His initial electrocardiogram (ECG) revealed sinus tachycardia at 160 beats/min without evidence of ischemic changes. Initial laboratory data revealed: white blood cell count, 14,000 cells/mm^3; hemoglobin, 11.3 g/dL; sodium, 141 mEq/L; potassium, 3.5 mEq/L; chloride, 111 mEq/L; bicarbonate, 12 mEq/L; BUN, 27 mg/dL; creatinine, 0.7 mg/dL; blood glucose, 80 mg/dL. Blood lactate concentration was 14 mEq/L. Arterial blood gas analysis on 100% oxygen revealed pH, 7.17; PCO_2, 30 mm Hg; PO_2, 150 mm Hg. Cooximeter measured a carboxyhemoglobin concentration of 38% and a methemoglobin concentration of 0.8%. Blood ethanol concentration was 179 mg/dL. A chest radiograph was unremarkable.

Because of his critical condition, the presence of metabolic acidosis, and his exposure to a fire environment, the possibility of cyanide poisoning was entertained, and 12.5 g of sodium thiosulfate was given intravenously. The patient was transferred to the intensive care unit, where mechanical ventilation and fluid resuscitation continued. He had no further significant hemodynamic instability. Within 4 hours of admission, he received hyperbaric oxygen therapy. He had progressive improvement in mental status and was awake 6 hours after admission. The patient had complete recovery with no neurologic deficits. An admission whole-blood cyanide concentration of 1.80 Âµg/mL (<1 Âµg/mL normal) was reported 12 hours later.

Introduction

Smoke inhalation is the leading cause of death from fires. Smoke contains numerous toxins that are generated during combustion. Combustion, or pyrolysis, is the rapid decomposition or oxidation of a substance (fuel) by heat. Smoke is a complex mixture of heated air, suspended solid and liquid particles, gases, fumes, aerosols, and vapors. Combustion products resulting from a fire are difficult to predict; in fact, even the composition of smoke is quite variable within the same fire environment.[10,37,112] The chemical composition of the fuel, oxygen availability, and temperature determine the

combustion products found in smoke (Table 123-1).[10,30,42,50,61,101,112,118,119,137] The extensive variety of materials used in our environment contributes to the broad spectrum of combustion products present in typical smoke.[30]

The association of smoke inhalation with burns produces a more serious systemic illness.[41,130,135,141,158] Burn victims with smoke inhalation injury have higher morbidity and mortality than those with burns only; the incidence of acute respiratory failure is 61% in burn victims with smoke inhalation injury versus 12% in those with burns only.[8,29,143,156,159] In addition, burn edema is accentuated and nonburned tissue has increased vascular permeability when associated with smoke inhalation injuries.[40]

History and Epidemiology

Disastrous fires are frequent reminders of the role of inhalation injuries in fire deaths.[37,79] In the United States, a fire department responds to a fire every 20 seconds.[73] In 2003, the National Fire Protection Agency reported 1,584,500 fire incidents in the United States, with 3925 fire deaths and 18,125 fire injuries.[73] Compared with other countries, the United States has one of the highest fire death rates in the world.[90] An estimated 50â€“80% of these fire deaths result from smoke inhalation injuries, rather than dermal burns or trauma.[16,62,101,160] More than 30% of patients hospitalized in burn units develop concomitant pulmonary complications, and 75% of these patient die.[65,136] World Health Organization data show that smoke from solid fuel is one of the four most common causes of death and disease in developing countries.[15]

Fire injuries can result from an array of inhaled toxic xenobiotics and/or thermal burns. Prior to 1942, toxic inhalation from dwelling fires was considered unusual. However, in that year, a fire at the Cocoanut Grove Night Club in Boston proved that toxic gases can be generated in typical dwelling fires.[111] From 1955â€“1972, death from smoke inhalation injury increased 3-fold and was attributed to

abundant use of newer synthetic materials for building and furnishings.[16] Despite improved firefighting resources, mass casualties from smoke inhalation continue. On November 11, 2000, 170 deaths occurred when a cable train carrying skiers caught fire in a

tunnel in Austria. Most of the victims apparently managed to escape the burning train but were killed by â€œacrid smokeâ€• as they tried to flee.[3] On February 20, 2003, a fire in a crowded Rhode Island nightclub killed 100 people and injured more than 200 people, with the majority suffering from smoke inhalation.[36] On December 31, 2004, a fire at an Argentina night club killed 175 people and injured more than 700. Most of the victims died of smoke inhalation.[4]

TABLE 123-1. Common Materials and Their Combustion Products

Products	Combustion Products
Wool	Carbon monoxide, hydrogen chloride, phosgene, chlorine, cyanide
Silk	Sulfur dioxide, hydrogen sulfide, ammonia, cyanide
Nylon	Ammonia, cyanide
Wood, cotton, paper	Carbon monoxide, acrolein, acetaldehyde, formaldehyde, acetic acid, formic acid, methane

Petroleum products	Carbon monoxide, acrolein, acetic acid, formic acid
Polystyrene	Styrene
Acrylic	Acrolein, hydrogen chloride, carbon monoxide
Plastics	Cyanide, hydrogen chloride, aldehydes, ammonia, nitrogen oxides, phosgene, chlorine
Polyvinyl chloride	Carbon monoxide, hydrogen chloride, phosgene, chlorine
Polyurethane	Cyanide, isocyanates
Melamine resins	Ammonia, cyanide
Rubber	Hydrogen sulfide, sulfur dioxide
Sulfur-containing material	Sulfur dioxide
Nitrogen-containing material	Cyanide, isocyanates, oxides of nitrogen
Fluorinated resins	Hydrogen fluoride

Fire-retardant materials	Hydrogen chloride, hydrogen bromide

Pathophysiology

Toxic combustion products are classified into three categories: simple asphyxiants, irritant toxins, and chemical asphyxiants (Table 123-2). Simple asphyxiants such as carbon dioxide exert a space-occupying effect; they simply displace oxygen.[37,42,133,158] In addition, combustion utilizes oxygen, potentially resulting in an oxygen-deprived environment (Chap. 119).[37]

TABLE 123-2. Toxic Combustion Products

Simple Asphyxiants Carbon dioxide	Irritants High water solubility (upper airway injury)
Chemical Asphyxiants Carbon monoxide Hydrogen cyanide Hydrogen sulfide Oxides of nitrogen (methemoglobinemia)	Acrolein Sulfur dioxide Ammonia Hydrogen chloride Intermediate water solubility (upper and lower respiratory tract injury) Chlorine Isocyanates Low water solubility (pulmonary parenchymal injury)

	Oxides of nitrogen Phosgene

Irritant xenobiotics are chemically reactive compounds that exert a local effect on the respiratory tract (Chap. 119). For example, high concentrations of acrolein are measured in air samples from fire environments and in the blood of fire victims.[2,86,150] Acrolein penetrates cell membranes easily because it is lipid soluble, injuring cells by denaturing intracellular proteins and nucleic acids.[51,160] Ammonia is generated when wool, silk, nylon, or synthetic resins are burned. It reacts with the mucosal moisture to produce the alkaline agent ammonium hydroxide.[31,81] Sulfur dioxide, an oxidation product of sulfur-containing material, is found in >50% of air samples from fires.[23] Sulfurous acid forms when sulfur dioxide reacts with the water of the respiratory mucosa. Hydrogen chloride, chlorine, and phosgene are formed from the oxidation of polyvinyl chloride (PVC), a plastic widely used in home and office furnishings, floor coverings, and electrical insulation.[17,20,37,42,88] In the presence of mucosal water, these combustion products generate damaging hydrogen chloride and reactive oxygen species.[38] Phosgene produces delayed alveolar injury.[21] Isocyanates, combustion products generated from upholstery, cause intense irritation of the upper and lower respiratory tracts.[115]

Combustion of organic material produces finely divided carbonaceous particulate matter (soot) suspended in hot air and gases. Inhalation of soot particles and aerosols enhances exposure to irritant xenobiotics in a fire environment. These particles are not just composed of carbon; organic acids, aldehydes, and reactive chemicals such as sulfur dioxide, hydrogen chloride, chlorine, and phosgene are adsorbed to their surfaces.[23,42,66,88,133,158] Soot adheres to the mucosa of the airways, allowing adsorbed irritant xenobiotics to react with the mucosal surface moisture. The deposition of these particles in the respiratory tract depends on their

size, with particles of 1â€“3 Âµm reaching the alveoli.[94] Experimental animals have markedly decreased lung injury when they are exposed to smoke that was filtered to remove particulates.[76] Irritant gases can â€œpiggybackâ€• on aerosol droplets and alter the site of gas deposition.[63]

Water solubility is the most important chemical characteristic in determining the timing and anatomic level of respiratory tract injury. Injury from water-soluble xenobiotics occurs in the upper airway and results in damage to mucosal cells with release of mediators of inflammation and/or reactive oxygen species.[22,82,95,118] The rapidity with which this process occurs provides a warning that the environment is unsafe and prompts escape. Following more than a trivial exposure, the intense inflammatory response increases microvascular permeability and allows movement of fluid from the intravascular space into the tissues of the upper airway. The loosely attached underlying tissue of the supraglottic larynx can become markedly edematous, causing upper airway obstruction within minutes to hours.[69] The obstruction can progress such that the upper airway is completely occluded.[124] Xenobiotics with low water solubility react with the upper respiratory mucosa very slowly and do not elicit an escape response. These xenobiotics reach the distal lung parenchyma, where they react slowly to create a delayed toxic effect. In addition to water solubility, factors such as concentration of the substance inhaled, duration of exposure, particle size, respiratory rate, absence of protective reflexes, and preexisting disease influence the region of respiratory tract injury.

Tracheobronchial injuries result from inhaled particulates and toxic gases, which cause increased airway resistance from intraluminal debris, airway mucosal edema, inspissated secretions, and brochospasm.[29,87,144] Damaged cells release chemotactic factors

that stimulate production of an exudate rich in protein and inflammatory cells.[152] This reaction eventually results in sloughing of the mucosa, which combines with the exudate to create casts of the

airways. In victims of smoke inhalation, casts block major airways, increasing airway resistance and mechanically preventing passage of oxygen to the alveoli.[29,33,99,144,152] Increased tracheobronchial vascular permeability leads to interstitial edema of the airways and increased airway resistance. Bronchoconstriction and subsequent wheezing are caused by a response to mediators of inflammation, a reflex response to toxic mucosal injury.[58,148]

Toxic xenobiotics that reach the alveoli injure the lung parenchyma.[105] Caustics, proteolytic enzymes, reactive free radicals, and mediators of inflammation all contribute to acute lung injury (ALI).[75,78,114,148,158] Pathophysiologic changes of ALI decrease lung compliance and bacterial defenses and lead to ventilationâ€“perfusion mismatch with intrapulmonary shunting, increased extravascular lung water, and microvascular permeability.[29,52,148,152,155] Decreased lung compliance from atelectasis is produced when toxic chemicals deactivate pulmonary surfactant.[29,105,113,152] In animals, patchy atelectasis occurs rapidly after smoke is inspired.[29,105,152] In addition, ventilationâ€“perfusion mismatch occurs when pulmonary blood flow is diverted by hypoxia and vasoactive mediators of inflammation.[83,84,104,148] Xenobiotics cause further injury by impairing mucociliary clearance, altering alveolar macrophage function, and impairing phagocytosis of bacteria, which all contribute to development of pulmonary infections and sepsis.[12,13,47,64,123] The combination of delayed toxic effects of some inhaled xenobiotics and slowly developing inflammatory response may explain the limited initial manifestations of parenchymal injury during the first 24 hours after smoke exposure.

Chemical asphyxiants exert their toxic effects at extrapulmonary sites. Incomplete combustion of organic materials generates carbon monoxide, which is considered the most common serious acute hazard to victims of smoke inhalation injury (Chap. 120).[1,14,37,150,160] Carbon monoxide prevents oxygen from binding to hemoglobin, creating a functional anemia. It also hinders the release of oxygen at the tissues by shifting the oxyhemoglobin

dissociation curve to the left. Other mechanisms, such as lipid peroxidation, contribute to the toxicity of carbon monoxide (Chap. 120).[139] Cyanide is produced from combustion of organic nitrogen-containing products such as plastics, melamine resins, polyurethanes, wool, silk, nylon, nitrocellulose, polyacrylonitriles, synthetic rubber, and paper.[112] High concentrations of cyanide are measured in air samples from fires and elevated blood cyanide concentrations occur in both fire survivors and fire fatalities.[5,9,10,27,37,60,72,128,129,134,154] Cyanide has at least an additive, if not synergistic, effect with carbon monoxide in smoke inhalation toxicity (Chap. 121).[9,93,108,117,119] Nitrogen-containing materials generate oxides of nitrogen, which are irritants and methemoglobin inducers (Chap. 122).

Smoke inhalation associated with burns results in an elevation of systemic nitric oxide because of the increased activity of inducible nitric oxide synthase.[44,45 and 46,131] The elevation of nitric oxide may result in myocardial contractile dysfunction with subsequent hypotension.[131] Nitric oxide can combine with superoxides to form the highly reactive peroxynitrite $ONOO^-$, which may lead to further alveolar capillary membrane damage and subsequent ALI.[44]

Depending on the fuel, other combustion products are aerosolized and act by local irritation or systemic toxicity. Metal oxides, hydrocarbons, hydrogen fluoride, and hydrogen bromide may contribute to toxicity. Antimony, bromine, cadmium, chromium, cobalt, gold, iron, lead, and zinc often are recovered from air samples taken during fires and from soot removed from the surface of the trachea and bronchi of fire victims.[14,37] Unusual fires at industrial sites, clandestine drug laboratories, transportation incidents, or natural disasters such as erupting volcanoes produce additional toxic inhalants.

Clinical Manifestations

The primary clinical problem in smoke inhalation victims is

respiratory compromise. The patients may have voice changes, and their speech may progressively worsen as the airway becomes increasingly edematous. Stridor and acute respiratory arrest may develop. Patients may have difficulty managing airway secretions, with expectoration of copious quantities of soot containing sputum. Visualization of the vocal cords by direct laryngoscopy may be difficult because of soot accumulation, secretions, or edema.

Auscultation of the chest may demonstrate rhonchi, crackles, and wheezing suggestive of ALI.[56] ALI is defined as diffuse alveolar filling of acute onset with hypoxemia but without left atrial hypertension.[11] The most severe manifestation of ALI is the acute respiratory distress syndrome (ARDS), which is defined based on the patient's ability to oxygenate (Chaps. 22 and 119). Bronchospasm may occur, particularly in patients with underlying reactive airway disease. Breath sounds, including wheezing, may be virtually inaudible in patients with severe bronchospasm.

Tachycardia and tachypnea may be pronounced and hypotension may occur, with faint or no peripheral pulses noted.[131] Smoke inhalation victims may develop an altered mental status, including agitation, confusion, or coma. Conjunctival injection, corneal ulcerations, marked lacrimation, and blepharospasm may be noted on ophthalmologic examination.

Diagnostic Testing

Because smoke inhalation injury causes pulmonary and airway damage, diagnostic studies should focus on assessing oxygenation and ventilation. Therefore, arterial blood gas (ABG) analysis, carboxyhemoglobin and methemoglobin concentrations, and chest radiography are the most important tests to obtain.

ABG analysis assesses both pulmonary function and blood pH. The presence of metabolic acidosis may be an early clue to tissue hypoxia. Serial measurements of arterial oxygenation and alveolar

ventilation are helpful in identifying hypoxemia or ventilatory failure. The accuracy of oxygen saturation measurement depends on the method used. Oxygen saturation calculated from ABG analysis may be unreliable in the setting of carbon monoxide poisoning, but measured oxygen saturation determined by cooximeter accurately reflects the percent saturation of hemoglobin. Transcutaneous measurement of oxygen saturation by pulse oximetry is unreliable in the patient with smoke inhalation because it overestimates oxygen saturation in the presence of carboxyhemoglobin.[7,43,107,151]

A carboxyhemoglobin concentration should be obtained for all smoke inhalation victims.[28,159] Either arterial or venous samples can be used to accurately measure carboxyhemoglobin concentrations.[85,147] The carboxyhemoglobin concentration alone is a poor predictor of the severity of smoke inhalation because a low or nondetectable concentration does not exclude the possibility of developing inhalation injury.[92,132] Because elevated methemoglobin concentrations are rarely reported in fire victims, methemoglobin

concentrations should also be obtained in the initial laboratory evaluation.[67,127] Blood cyanide analysis is of little clinical use because results of analysis are not available for hours, and therapy should never await laboratory confirmation of the presence of cyanide. Accurate measurement depends on acquiring the sample soon after exposure because cyanide is rapidly eliminated from the blood following smoke inhalation.[9,74]

A chest radiograph obtained early in the course of smoke inhalation is an insensitive indicator of pulmonary injury.[28,56,116,157] The most frequent abnormal findings on initial chest radiograph are diffuse alveolar and interstitial changes found in 34% of patients, followed by focal abnormalities in 12%.[56] In one series, no significant differences in the duration of either ventilation or stay in the intensive care unit were observed between smoke inhalation victims who exhibited abnormal findings on the first chest radiographic examination and those without any abnormalities.[56] Subtle findings

within 24 hours of exposure include perivascular haziness, peribronchial cuffing, bronchial wall thickening, and subglottic edema.[80,136] Serial chest radiographs following a baseline study are helpful in detecting pulmonary disease following smoke inhalation.[58] Widespread airway disease usually occurs more than 24 hours after inhalation injury and may represent ALI, aspiration, volume overload, infection, or cardiogenic pulmonary edema.[136]

Nuclear imaging and pulmonary function testing, although not readily available for initial evaluation, can detect pulmonary injury after smoke inhalation. Xenon ventilation studies can detect small airway and alveolar injuries before changes are seen radiographically.[58,96] Abnormal flow volume curves can indicate early upper airway obstruction.[57] Abnormal spirometry, especially forced expiratory volume at 1 second (FEV_1), detects early obstructive pulmonary defects of smoke inhalation, which may precede abnormalities of ABGs or radiography.[58,98]

Management

Critical airway compromise may be present upon the patient's arrival at the hospital, or it may develop subsequently.[34,57,124] A major pitfall in managing a patient with smoke inhalation is failing to appreciate the possibility of rapid deterioration. The history and physical findings help to determine significant smoke exposure and the potential for clinical deterioration. The clinical effects of smoke exposure and their appropriate treatment are described in Figure 123-1. Upper airway patency must be rapidly established. When obvious oropharyngeal burns are observed, upper airway injury almost certainly is present, even if overt injuries are not seen, and distal injury may be present and underestimated.[57] Direct evaluation of the upper airway, preferably with fiberoptic endoscopy, is essential for assessing patients at high risk for inhalation airway injury.[34,57,58,69] When evidence of upper airway injury exists, early endotracheal intubation should be performed under controlled

circumstances. Other indications for early intubation include coma, stridor, and full-thickness circumferential neck burns.[8,57,58,124] Massive fluid resuscitation of the burned patient contributes to upper airway edema.[57,58,100,124] Therefore, early intubation may be necessary in the patient with dermal burns undergoing aggressive fluid management.[57]

Although inhaled Î²$_2$-adrenergic agonists are effective and considered first-line therapy for acute reversible bronchoconstriction resulting from asthma or chronic obstructive pulmonary disease, their efficacy in patients with smoke inhalation is unknown.[18,89] However, pathophysiologic changes induced by irritant toxins in smoke are partially reversible, suggesting that Î²$_2$-adrenergic agonists improve airflow obstruction.[71,91] The benefits of corticosteroids given for treatment of smoke inhalation injury are not demonstrated in either clinical or animal studies.[103,125]

Pathophysiologic changes in the lung may cause progressive hypoxia over hours to days. Treatment of progressive respiratory failure includes mechanical ventilation, continuous positive airway pressure, positive end-expiratory pressure, and vigorous clearing of pulmonary secretions.[102] Frequent airway suctioning, chest physiotherapy, and therapeutic bronchoscopy can clear inspissated secretions, plugs, and casts.[33,99] Inhalation injury can progress to ALI or ARDS. Experimental treatment has examined high-frequency ventilation, percutaneous arteriovenous carbon dioxide removal, perfluorocarbons, inhaled nitric oxide, extracorporeal membrane oxygenation, instillation of natural surfactant into the lung, continuous IV infusion of heparin, and deferoxamineâ€“hetastarch complex for improving inhalation injury.[26,32,39,59,70,77,97,106,109,110,120,121] However, none of these modalities has been definitively proven to improve outcome.

Treatment of carbon monoxide poisoning consists of supplemental oxygen therapy, administered by a high-flow, tight-fitting mask, endotracheal tube, or hyperbaric oxygen therapy, depending on the

circumstances. Studies suggest that hyperbaric oxygen is superior to normobaric 100% oxygen in correcting toxicity and preventing delayed neurologic sequelae.[138,142,145,153] If readily available, hyperbaric oxygen should be considered in patients with smoke inhalation and a history of loss of consciousness, confusion, coma, headache, malaise, forgetfulness, fatigue, dizziness, visual disturbances, nausea, vomiting, cardiac ischemia, focal neurologic findings, or pregnancy.[140,153] Hyperbaric oxygen should be administered to patients only after life-threatening conditions such as associated trauma or hemodynamic instability are treated and the patient's condition has stabilized (Chap. 120 and Antidotes in Depth: Hyperbaric Oxygen).

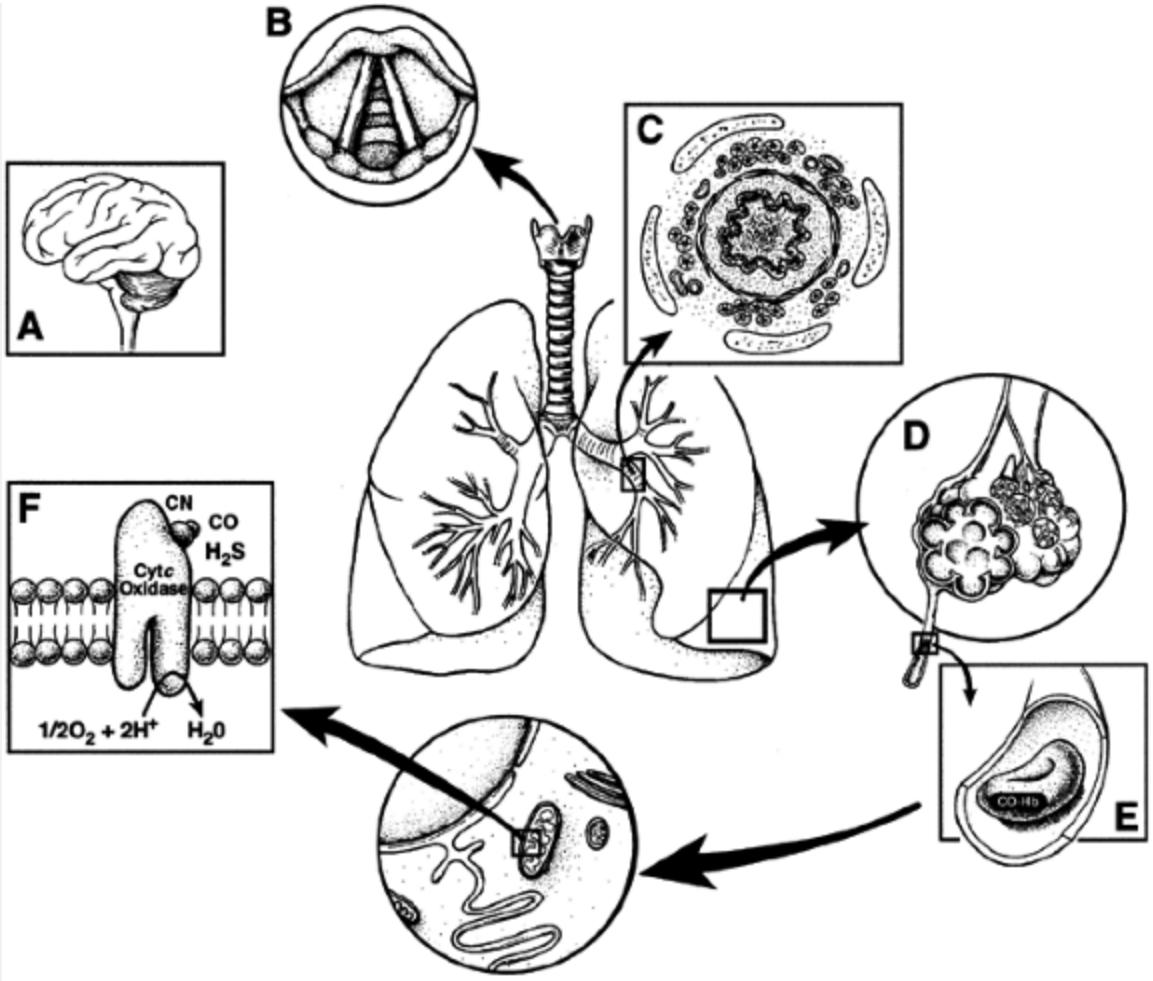
Cyanide poisoning should be suspected in seriously ill patients with smoke inhalation and metabolic acidosis.[48,122] Plasma lactate concentrations at the time of hospital admission correlate closely with blood cyanide concentrations, with plasma lactate concentrations >10 mmol/L reported to be a sensitive indicator of cyanide toxicity.[9] Treatment of cyanide toxicity should be considered while other life support measures, including 100% oxygen therapy, are instituted.[9,93,108,117,118,129] Treatment options include supportive care alone, administration of all or part of the cyanide antidote kit, and hyperbaric oxygen therapy. Patients have survived potentially lethal cyanide concentrations with simply oxygen therapy and supportive care.[19,126] Hyperbaric oxygen has been suggested to improve the outcome of cyanide toxicity, although the data supporting its use alone are not convincing.[49,60,149] Currently, hyperbaric oxygen therapy is considered only an adjunct treatment of cyanide poisoning in the presence of concomitant carbon monoxide poisoning.[146]

The cyanide antidote kit (amyl nitrite, sodium nitrite, and sodium thiosulfate) is the only antidote for cyanide poisoning available in the United States. Amyl nitrite and sodium nitrite produce methemoglobinemia. Detoxification occurs when methemoglobin binds cyanide to form cyanomethemoglobin, but alternate

mechanisms to methemoglobin formation are proposed. Sodium thiosulfate donates sulfur to the enzyme rhodanese, which converts cyanide to thiocyanate. Nitrite-induced methemoglobin and

sodium thiosulfate work synergistically to detoxify cyanide.[24,25] Unfortunately, methemoglobin is a dysfunctional hemoglobin that is unable to carry oxygen; in addition, its presence increases the affinity of the remaining hemoglobin for oxygen, which prevents its release to the tissues.[35] Impairing oxygen-carrying capacity and oxygen delivery to tissues with nitrite-induced methemoglobinemia is a valid concern in the presence of tissue hypoxia from carboxyhemoglobinemia and other factors. In a small series of fire victims treated with sodium nitrite, methemoglobin concentrations peaked at 7.8â€“13.4% between 35 and 70 minutes after slow IV infusion.[74] Corresponding carboxyhemoglobin concentrations decreased before peak methemoglobin concentrations had been reached. To the contrary, a case of hypotension and prolonged impairment of oxygen-carrying capacity was reported in a smoke inhalation victim following rapid infusion of sodium nitrite.[53] Because the safety of nitrites has not been studied in a large population of concomitant cyanide and carbon monoxide poisoning and the effect of cyanomethemoglobin on oxygen-carrying capacity is not well understood, initial treatment with thiosulfate alone is reasonable, with use of nitrite reserved for refractory cases or those patients with documented low carboxyhemoglobin concentrations. Sodium thiosulfate has few adverse side effects and can be safely administered to all patients seriously ill from smoke inhalation. When hyperbaric oxygen therapy is available, sodium nitrite can be administered just before the patient enters the hyperbaric chamber, if still clinically indicated, with less concern for impairing oxygen-carrying capacity.[54] Hydroxocobalamin chelates cyanide and is a safe and effective antidote.[9,48,55,68] Because of its apparent safety and efficacy, it can be given empirically to patients seriously ill from

smoke inhalation, thus eliminating the need for nitrites.[9,55] Hydroxocobalamin is designated but not yet approved for use in the United States (Chap. 121 and Antidotes in Depth: Amyl and Sodium Nitrites, Sodium Thiosulfate, and Hydroxocobalamin).



Pathophysiology	Signs and Symptoms	Management
A) Direct CNS toxic effects	Coma Hypoventilation	Oxygen; Secure unprotected airway
B) Upper airway edema	Hypoxemia; Respiratory distress Stridor Hoarse voice	Oxygen Direct visualization of vocal cords Endotracheal intubation
C) Bronchiolar airway obstruction Mucosal edema Intraluminal debris and casts Inspissated secretions Bronchospasm	Respiratory distress Hypoxemia Wheezes Cough Increased peak airway pressures	Oxygen Removal of debris and secretions Chest physiotherapy Frequent airway suctioning Therapeutic bronchoscopy Inhaled β-adrenergic agonists
D) Atelectasis Surfactant destruction Acute Lung Injury (ALI)	Respiratory distress Hypoxemia Crackles Chest radiographic changes	Oxygen Continuous positive airway pressure Mechanical ventilation Positive end–expiratory pressure
E) Impaired oxygen–carrying capacity (carbon monoxide or methemoglobinemia)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Consider hyperbaric oxygen Consider methylene blue
F) Impaired oxygen use at tissues (cyanide, hydrogen sulfide, or carbon monoxide)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Assure adequate tissue perfusion Consider treating suspected cyanide toxicity with sodium thiosulfate Consider hyperbaric oxygen

Figure 123-1. The final common pathway from all pathophysiologic changes that occur in smoke inhalation is hypoxia. All treatments should be focused on improving oxygen delivery and oxygen utilization.

Although rarely reported in fire victims, methemoglobinemia can result from inhalation of certain toxic combustion products.[67,127] Elevated methemoglobin concentrations in the presence of elevated carboxyhemoglobin concentrations increase tissue hypoxia. Oxygen therapy alone should be effective for most cases, and the need for methylene blue therapy is rarely clinically indicated following smoke inhalation (Chap. 122 and Antidotes in Depth: Methylene Blue).

Respiratory compromise and other conditions may not result from smoke inhalation, but rather from trauma or underlying medical problems. Trauma from falls or explosions must be suspected and treatment started simultaneously with treatment of burns and inhalation injury. Comatose patients should be considered to have other etiologies for their injuries and should receive naloxone, thiamine, and hypertonic dextrose as indicated. Inhaled xenobiotics, such as carbon monoxide, can directly cause altered mental status, but drug and ethanol intoxication contribute significantly to adult fire fatalities and injuries. Blood ethanol concentrations correlate with elevated concentrations of carbon monoxide and cyanide, implying that intoxication impairs escape and prolongs toxic smoke exposure.[6,14,101] Intracranial pathology should be considered and CT scans obtained as indicated.

Xenobiotics may injure the skin or mucous membranes in addition to the respiratory mucosa.[31] The duration of contact of a xenobiotic with tissue is an important factor in determining the extent of chemical injury to the skin and eyes. Rapid removal of soot from skin or eyes may prevent continued injury. The eyes should be evaluated for corneal burns caused by thermal or irritant chemical injury. The eyes of patients with signs of ocular irritation should be irrigated.

Dermal decontamination should be considered to prevent dermal burns from toxin-laden soot adherent to the skin.

Summary

Smoke inhalation continues to contribute significantly to the morbidity and mortality of fire victims. Clinicians caring for these patients must have a basic knowledge of the pathophysiology of smoke inhalation injury. A spectrum of events is possible, ranging from rapid upper airway occlusion to delayed ALI and ARDS. There are controversies regarding the care of these patients and further research is warranted. However, definitive therapies are available and should be considered.

Chapter 124

Risk Assessment and Risk Communication

Charles McKay

Cases

- A mother called the poison center (PC) with a question about her 6-year-old child who had head lice (*pediculosis capitis*). She followed instructions listed on a topical pyrethroid shampoo yesterday, but was concerned that the infestation persisted. She wanted to know if it was safe to re-treat; today she also asked about treating the 1-year-old sibling because she had seen him â€œtugging at his ears.â€•

  Focusing on the mother's implied concern that â€œlice are everywhere,â€• the PC provided some practical advice regarding washing of bedclothes and reemphasized the importance of removing nits from the 6-year-old's hair. She was instructed to thoroughly examine the younger child's hair

and contact the pediatrician for follow-up. The residual effects following active treatment and the potential risk of repeated treatments or treatments of those without indications were also communicated. This combination of practical action steps and information on possible risks of excessive treatment was well-received and the mother thanked the PC specialist for her/his assistance.

- A worker came to the toxicology clinic concerned that she was being poisoned by her work environment. She worked in a stressful office setting with little privacy. Many of her co-workers try to grow potted plants in the area and have applied a variety of fertilizers and insecticides. She identified one of the products as containing pyrethrins and piperonyl butoxide. The patient noted intermittent headaches, burning eyes, stuffy nose, and â€œcloudy thinking.â€• She did not have any gastrointestinal symptoms, rash, breathing difficulties, or tremors. She asked if these symptoms were related to exposure to the insecticide in her office area.

  The patient was asked if others in the office area were experiencing similar symptoms. As they were not and there had been no large spill or other significant exposure, she was told that the symptoms she described were not likely to result from a toxic exposure to these compounds. She was told that the major effect that usually occurs with casual exposure to pyrethrins would be allergic symptoms in susceptible individuals. As some of her symptoms could be allergic in nature, a history of past and current atopic symptoms or seasonal allergy was sought. Examination of the upper airways and mucosal surfaces was normal. A site visit and industrial hygiene evaluation were arranged, although the patient expressed some concern about â€œstirring up trouble.â€• Most of the patient's workday was spent sitting at a computer terminal where the lighting seemed suboptimal. The insecticide was verified to be a pyrethroid/piperonyl butoxide

product. No other substances of note were identified in the workplace. The industrial hygienist found moderate changes in such â€œcomfort featuresâ€• as temperature, humidity, ambient CO_2 as a measure of air exchanges, particulates, and general assessment of cleanliness. During a follow-up visit, these results were discussed with the patient, along with a discussion of individual discomfort levels and a possible contribution of workplace stress and job routine. Some recommendations were made regarding varying her routine to decrease monotony. A follow-up was suggested for persistent symptoms, including the possibility of arranging for skin-prick allergen testing. The potential costs and possible nonspecific nature of this test were discussed. The worker was appreciative of the information, although she was still convinced that her workplace was making her ill, particularly because â€œwe are all being poisoned by this stuff all around us.â€•

- A homeowner called the PC, expressing concern about symptoms in himself and his family. He noted that they all had â€œsick headachesâ€• that day with vomiting and that they felt awful. He noted that they recently had work performed on the house, and wondered if everyone was feeling ill from the paint and wood stain vapors from the remodeling.

  Concerned that these symptoms may represent carbon monoxide poisoning, rather than low-level hydrocarbon exposure, the PC recommended that all family members leave the house

  immediately and activate 911 for evaluation and oxygen therapy. The fire department was contacted and found ambient air CO determinations of 100â€“300 ppm, along with a blocked chimney flue. Other volatile organic compounds were near background readings. Consultation by a medical toxicologist in the emergency department (ED) identified no mental status or

neurological symptoms, and all family members had normal mini-mental status examinations. All symptoms resolved with evacuation from the house and high flow oxygen therapy. Initial carboxyhemoglobin (COHb) measurements ranged from 7â€“15%; no one was pregnant or had any chronic cardiac disease. The toxicologist discussed the varying effects of carbon monoxide as a function of duration and amount of exposure and arranged follow-up visits with the primary care physicians 2 weeks later to evaluate for delayed neurological sequelae. The importance of a carbon monoxide alarm was discussed and the family was discharged to a nearby family's home until their chimney could be repaired.

The Certified Specialist in Poison Information (CSPI) and the medical toxicologist are often tasked with formidable challenges. Responding to an anxious parent with questions about his/her child's potentially toxic exposure or dealing with an urgent consultation for a critically ill patient in the ED or ICU. Under these difficult conditions the PC healthcare specialist must establish rapport and provide information, instructions, and when appropriate, reassurance over the telephone. For the PC, attribution of the patient's complaints to one or more potential exposures, and ascertaining the true reason or concern behind a call are also difficult given the limited information and time and lack of visual clues usually available in a clinical evaluation. The good reputation and ready availability of PCs within the United States provides the basis for authority and credibility, as does the advanced clinical training of the medical toxicologist. Nonetheless, the healthcare provider must be capable of a knowledgeable, compassionate, and well-reasoned response. This chapter focuses on two particular components of this response: risk assessment and risk communication. These principles are the same and can be applied to either an individual poison center call or to interactions with the public or medical professionals in educational outreaches,

occupational and environmental exposure evaluations, and supportive roles with other public health agencies, such as bioterrorism preparedness or environmental public health tracking, and research.

Risk Assessment

Risk assessment is the process of determining the likelihood of toxicity for an individual or group following a perceived exposure. It involves determining the nature and extent of the exposure (xenobiotic, dose, duration, route) and its specific clinical effects, defining an exposure pathway of, and assessing the likelihood of effects from, the exposure. Although it is generally true that a published body of knowledge can be applied to the risk characterization or assessment, this assessment is often based on incomplete (eg, exact dose) or unpredictable (eg, host factors that would modify a response) information. The emotional response to being â€œpoisonedâ€• makes this task even more difficult.

A good example of the practical difficulties involved in a risk assessment is evident from a description of mass psychogenic illness.[10] Many individuals in a school complained of odor-triggered symptoms that spread in a so-called â€œline of sightâ€• transmission. Extensive testing identified no toxic exposure, but demonstrated the possibility of potential exposures, such as dry floor drain traps. The extent of investigation of these events can vary, highlighting our technological abilities, but our ability to assess a â€œno-riskâ€• situation is limited, as can be seen in the letters to the editor criticizing the methods or conclusions in this event and â€œsubsequent and comparableâ€• outbreaks.[2,8,15] Those doing a risk assessment are affected by their own biases and assumptions in the interpretation of their results, as are the people to whom a risk assessment is communicated.

The response of individuals to uncertainty correlates with their affinity for one component of the negative data paradigm: â€œthe

absence of evidence of harmâ€• or â€œevidence of absence of harm.â€• Both of these positions have at their core the continued evaluation of evidence as it becomes available, with subsequent refinement of a resulting risk assessment. Unfortunately, these converging points on a spectrum of knowledge and research have been polarized into vilified caricatures of the Robert Kehoe and Precautionary Principles. The former is best summarized as â€œprove something is harmful before excluding a product with known benefits because of concern about potential, unproven future adverse effects.â€• This position has been misused in the past, for example to minimize known risks attributable to environmental lead pollution to delay removal of lead additives from gasoline.[17] Its detractors have opined that waiting for evidence of harm from a substance results in costly or irreparable damage. The alternative position of the â€œPrecautionary Principleâ€• is often summarized as â€œwhere there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent component of the principle, complaining that devotees stifle economic growth and prosperity with unfounded fears, rather than reasoned consideration of known data. This is often seen in such statements as: â€œHow could it be safe, when there are thousands of new chemicals brought into production every year?â€• Although these principles originated as policy approaches to public health issues, each individual responds similarly in his/her own personal risk assessment or tolerance. The response to uncertain situations is derived from one's framing of belief systems and assumptions about life, justice, and eternity.[1,5,7] These underlying world views should be explicitly recognized and addressed in a formal risk assessment. Table 124-1 lists components of a risk assessment.

TABLE 124-1. Components of a Risk Assessment

Hazard Identification
What is the name and amount of the suspected xenobiotic?
In the absence of a specific xenobiotic, what general or use category is suspected?
Exposure Pathway
What is the proposed route of exposure?
Is the route of exposure consistent with the nature of the xenobiotic?
Modifying Factors
Are there environmental factors that influence the systemic availability of the xenobiotic?
Are there underlying host susceptibility or resistance factors to consider?
Chronic medical conditions?
Possible xenobiotic-drug or other interactions?
Genetic polymorphisms in hepatic or other metabolic pathways?
Toxicity Assessment
What organ effects are expected from the identified xenobiotic?
Are existing symptoms consistent with known effects of the presumed xenobiotic?

Differentiating Public Health from Individual Risk Assessment

It is often difficult to translate public health risk assessment done for populations by entities such as the Environmental Protection Agency (EPA) to the individual level. Simplistically, the iterative process of adjusting known noncancer adverse exposure outcome limits in an animal model (eg, lowest observed adverse effect level [LOAEL], or no observed adverse effect level [NOAEL]) to a safe level of exposure for all humans (including so-called â€œsensitive subpopulationsâ€•) has been arbitrarily set at multiplicative factors of 10. These â€œuncertainty factorsâ€• are actually safety factors that can lower exposure limits to amounts as small as 0.001 times the amount demonstrated to cause an adverse effect of interest. Thus when an individual exceeds these limits, they are encroaching into very robust safety factors, not exposing themselves to a defined harm. An example of this would be the dietary guidelines (also known as â€œfish health advisoriesâ€•) for fish consumption based on concern about methylmercury and polychlorinated biphenyls (PCB) exposure. The dietary recommendations are based on epidemiological studies that suggest subtle neuropsychiatric abnormalities in maternal-fetal pairs (in at least some populations) from levels of consumption 10â€“100 times that of the â€œusualâ€• American diet. Clinical mercury toxicity requires still higher levels of consumption. Although it is reasonable for pregnant women to limit their intake of certain high mercury-containing fish species, it would be inappropriate to avoid fish and the nutrients contained therein because of a misplaced fear of mercury exposure. These risk assessments do not apply to nonpregnant woman, children, or men.[22]

The public health modeling concept for cancer health effects risk assessment is even more often misunderstood. In this setting, modeling assumes a linear, no-threshold effect. Cancer risk from

small exposures is extrapolated from data in cancer-prone animal models with exposures so large that they are only possible in the experimental setting, ignoring potential metabolic and self-repair mechanisms in the human. The â€œacceptable riskâ€• in this setting is then taken as â€œone excess cancer in a population of 1,000,000 exposed individuals.â€• Although a limitation of this model is explicit in the statement that this represents â€œa plausible upper bound estimate of risk at low dose where true risk may be lower, including zero,â€•[6] this important caveat is rarely communicated, resulting in the common response by individuals that â€œan extra cancer may be acceptable for you, but not when it is my child.â€• Risk assessment is often imprecise. Risk characterization for the individual best avoids arbitrary numbers, aiming instead to communicate the likelihood of significant risk for the exposure actually experienced.

TABLE 124-2. Principles of Poison Center Risk Communication

	Principles	Applications
1	Accept and involve the public as a partner.	The caller must be involved to obtain the best information possible.
2	Plan carefully and evaluate your efforts.	There is a very short time to establish rapport with the caller; do not increase anxiety by asking irrelevant questions or arguing. Monitor your tone; ask for repetition of key information or

		recommendations.
3	Listen to the public's specific concerns.	Why did the person call? Was it for information, treatment recommendations, or reassurance? Make sure the underlying reason has been addressed.
4	Be honest, frank, and open.	If there is uncertainty or there are unknowns, indicate that, while providing a workable plan.
5	Work with other credible sources.	Involve medical toxicology back-up and other consultants, particularly for questions regarding chronic exposure/effects.
6	Meet the needs of the media.	If calls involve media notification or contact, make sure the critical information is stated frequently, provide a human context, and avoid sensationalism.
7	Speak clearly and with compassion.	Remember that the caller was concerned enough to initiate the contact; make sure the call is completed with a clear plan; provide follow-up appropriate to the situation.

Modified from Covello V, Allen F: *Seven Cardinal Rules of Risk Communication.* Washington, DC: US Environmental

Protection Agency, Office of Policy Analysis, 1988.

Risk Communication

Risk communication is an exchange of facts and opinions to allow an individual or group to make an informed decision regarding a course of action or treatment. Practically, risk communication is a way of translating incomplete knowledge into a form that will allow for informed decision-making. During a one-on-one interaction with a poisoned individual and his/her family or a caller to the PC, there is a need to gain the fullest attention or cooperation of the individual. Once this has occurred, the discussion is usually focused on risks and benefits of various treatment options (eg, gastrointestinal decontamination) or possible diagnostic modalities (eg, observation vs. neuroimaging vs. antidote administration). The group dynamics of environmental exposure risk communication at a public meeting are very different. Federal agencies that interact with communities in â€œSuperfundâ€• sites (eg, the EPA and the Agency for Toxic Substance and Disease Registry (ATSDR) have promulgated principles and practical recommendations for risk communication in this setting. Table 124-2 summaries general principles of risk communication.

Although some of these recommendations are more applicable to longer-term deliberations and interactions, much of the individual communication done by the PC and medical toxicologists succeed or fail based on these same principles (see second column in Table 124-2). Lacking the opportunity for repeated interactions over time to identify and discuss assumptions and biases, the toxicologist needs to establish credibility, listen to concerns and respond empathetically, admit areas of insufficient knowledge, and commit to follow-up, to effectively convey a risk characterization for an individual, based on available knowledge and experience. The scientific terms, rationale and any extrapolation from

modeling (such as animal data or case series) should be conveyed in an understandable manner to show that appropriate safety factors are incorporated into areas of uncertainty as a risk-diminishing step. The individual should leave the interaction with a clear understanding of the difference between a short-term risk of symptoms that will resolve or result in serious illness, and the degree of certainty about the potential for a long-term consequence.

The example of the 1976 industrial dioxin release in Seveso, Italy is one example of a failure in risk communication. Based on extrapolation from animal models and case reports, many dioxin-exposed pregnant women were counseled to have abortions following exposure to this â€œmost toxic industrial chemical.â€• An evaluation of birth defects did not identify an increased incidence of teratogenicity based on graded dioxin exposure amount or comparison with other unaffected regions in those who carried their pregnancies to term.[21] The question â€œis it safe? â€• and the meaning of â€œsafeâ€• lies at the heart of risk communication.[11,19]

Effective risk communication must therefore address several questions. Once the best information is obtained about the identification of the xenobiotic and the nature of the exposure, we must convey:

- The likely magnitude of the risk. This would include information on dose-response, such as â€œdoes the reported exposure to a toxic compound approach exposure amounts reported to cause symptoms?â€•
- The urgency of the risk must also be conveyed, along with recommendations to decrease toxicity or ongoing exposure.
- The applicability of a risk characterization might also need to be addressed: Is the animal data applicable to humans? Is the

exposure something of concern for an individual?

- Uncertainties of the risk assessment. This could include a â€œworst-case scenarioâ€• approach to unknown exposures or uncertainties in the quantity of an absorbed dose. The need for continued observation or follow-up for clinical changes would be expressed here. Individual risk tolerance may vary greatly. The same information may be interpreted differently by risk-averse contrasted with risk-tolerant people. A variety of comparisons or communication techniques may be used to provide an adequate characterization of risk.
- Options for management. In addition to follow-up and repeated evaluations by a medical toxicologist the range of choices, along with their relative benefits or risks, would be presented to the individual or group, along with a summary recommendation or opinion from the presenter. This last step is important to avoid the impression that â€œno one knows what is going on or what we should do.â€•

Application of Risk Assessment and Communication Principles to Acute Care Toxicology

Although it has long been recognized that many home-initiated poison center calls concern nontoxic or minimally toxic xenobiotics ingested by children,[16] the frequent lack of documented ingestion raises the possibility of the Pollyanna Phenomenon. If the patient actually took none of the xenobiotic, the individual will not experience adverse effects from that xenobiotic. It is generally assumed that the sheer volume of calls provides some reassurance regarding the accuracy of our risk assessment of these xenobiotics, but we should remain cautious in our interpretation of poison center data[9,18] (Chap. 130). Moreover, even calls about

nontoxic xenobiotics require communication between the caller and CSPI beyond simple substance identification. The importance of risk assessment and communication principles can be seen in the joint position statement on the prehospital management of â€œminimally toxic substancesâ€• supported by the American Association of Poison Control Centers (AAPCC), American Academy of Clinical Toxicology (AACT), and the American College of Medical Toxicology (ACMT). According to the position statement, in order for a CSPI to make a risk assessment that an exposure is benign or minimally toxic, the following characteristics must be true:

- â€œThe information specialist has confidence in the accuracy of the history obtained and the ability to communicate effectively with the caller.
- The information specialist has confidence in the identity of the product(s) or substance(s) and a reasonable estimation of the maximum amount involved in the exposure.
- The risks of adverse reactions or expected effects are acceptable to both the information specialist and the caller based on available medical literature and clinical experience.
- The exposure does not require a healthcare referral because the potential effects are benign and self-limited.â€• [14]

The position statement further notes that patient disposition decisions can be altered by many additional factors, including intent, environment, presence or absence of symptoms, and ongoing review of current recommendations in the face of more data. These points emphasize both the dependence of the CSPI on information derived from the caller, and his or her confidence in the level of comprehension of the caller. The caller should understand that their exposed child is safe; the conversation with the toxicology experts should alleviate concern as the nature of the assessment process is explained to whatever degree is

necessitated by the caller's risk tolerance.

In the case of a symptomatic patient or a hospital- or physician-initiated contact to a poison center and/or medical toxicologist, the caller expects more than the provision of information; but also the individual expects knowledge and expertise that will provide reassurance or direction for improved patient health. Relaying information regarding diagnosis, course, and predicted outcome is insufficient, however. There is usually another, underlying reason for the call. This could be anxiety, uncertainty, or misinformation built on a person's previous experiences or knowledge base. A sense of guilt may underlie a parent's call for an inadvertent exposure occurring when a child was unsupervised. A physician may have had a bad experience with a previous overdose. If these issues are not addressed, the caller may continue seeking reassurance by repeated calls to the PC or by seeking additional input from other sources, such as family, friends, primary physicians, or other healthcare providers. Variance in the information obtained will be considered inconsistencies between supposed experts, rather than differences in emphasis of the same information, leading to further uncertainty for the caller. Table 124-3 lists some barriers to effective risk assessment and communication.

TABLE 124-3. Factors Affecting Appropriate Risk Assessment and Effective Risk Communication

Nature of previous encounters with poison center or healthcare field
Lack of prior patient-healthcare worker relationship
Incomplete data to answer a question
Providing information contrary to â€œpopular understandingâ€• or media representation
Loss of credibility
Individual or cultural differences in perception of risk or applicability of data
Poor comprehension of scientific or statistical principles

Interpreting Public Health Concerns for the Individual

The CSPI and medical toxicologists frequently encounter callers or individuals at community events, or interact with the media regarding public healthâ€“related issues, such as heavy metal contaminants involving mercury, lead, or arsenic, or concerns for â€œmold toxicityâ€• and other environmental xenobiotics. Often these people are concerned that their symptoms or future health or family health may be adversely impacted by such exposures. Such supposed exposures are usually poorly documented, sometimes also driven by popular media depictions or litigation, and the risk to a caller is virtually impossible to ascertain during a short telephone or personal interaction. In these situations, the individual is best served by referral to a primary care physician with toxicology consultation or directly to a medical toxicology clinic. In such a setting, the data and perceptions can be reviewed completely, and a more appropriate risk assessment communicated. These interactions are very difficult, as they are often emotionally and politically charged.

In general, the communication of and response to information is dependant on a preexisting world view and prevailing circumstances. The same possible outcome will be perceived as more or less severe depending on several factors other than the nature of the outcome itself. Several authors have characterized the perceived tolerance to different risks, stratified by features such as familiarity and personal control[5,19] (Table 124-4). The emotional response of individuals confronted with these risks is sometimes characterized as â€œoutrage.â€• The greater the degree of familiarity with the particular exposure situation and the greater the voluntary nature of the exposure, the less fear or outrage will be expressed for a given adverse outcome. Although risk communicators can use analogies to place exposures in context, one must be careful to avoid equating voluntary and involuntary risk assumption, or equating those exposures or risks assumed by one segment of the population unequally. An example of this would be the presentation of a smoking risk analogy to a nonsmoker.

Risk communication has become very important in the setting of preparedness for terrorism. Although a great deal of attention and money has been directed to improvement of public health infrastructure, reporting and surveillance mechanisms, and response to perceived and actual terrorist acts, less attention has been directed to the process of communicating risk to the individual.[4,12] Although some countries practice public health emergency drills regularly, the United States has concentrated on preparation of organizational structures. Maintaining a readiness for catastrophic terrorist events (or natural occurrences such as pandemic influenza) should use the same risk assessment and communication techniques as are appropriate for other urgent public health matters. Unfortunately, there are many factors that affect the characterization of risk other than the facts, as exemplified by these two composite articles describing the same events:

- An unknown assailant (or assailants) has infiltrated the mail delivery system, resulting in severe illness and death throughout the country. Victims have included children, healthy adults, and older adults. Initial symptoms can be nonspecific, but rapidly progress. If treatment is not begun early, death is a likely result. Anyone who receives regular mail may be at risk. The government has no system in place to detect this threat and the medical community routinely fails to diagnose the conditions early. The long-ignored public health system is not prepared to deal with the huge burden of preventing illness in those who may have been or will be exposed. Tens of thousands of our citizens are taking prophylactic antibiotics â€œjust in case.â€• If you receive any unusual packages or see collections of powder that don't have an obvious explanation, call the police. If you develop a fever, cough, chest pain, or unusual rashâ€”which may not be painful, seek medical attention at once. Tune in to your local news station for more information on this burgeoning threat to our nation's security.
- A small number of individuals in isolated exposure settings have developed illnesses following bioterrorism events. Although the most severe form of this disease was previously thought to have a very high mortality rate, most people have survived these exposures, particularly with early and proper medical care. For the general population, it is estimated that the risk of exposure is about 1 in 200,000,000. The government has developed a case definition and medical experts have disseminated information to assist the medical community and public in the early recognition of symptoms and signs that are consistent with this exposure. Prophylactic treatment within days of exposure of those in high-risk professions, such as mail handlers at major postal sorting facilities, prevents illness. Unfortunately, there have been a

large number of hoaxes and false alarms about possible terrorist events, and a lot of understandable fear in the community about nonspecific symptoms. For additional information, contact your state health department at 211 or go to http://www.bt.cdc.gov/agent/anthrax/needtoknow.asp.

TABLE 124-4. Factors that Alter the Acceptability of Perceived Risk

More Acceptable	Less Acceptable
Natural	Man-made
Associated with a trusted source	Not associated with a trusted source
Familiar	Exotic
Voluntary	Involuntary
Potentially beneficial	Limited or absent potential benefit
Statistical (low harm likelihood)	Catastrophic (high harm likelihood)
Fairly distributed or shared by all	Unfairly distributed (injustice)

Affects adults	Affects children

Modified from Fischhoff B, Lichtenstein S, Slovic P, Derby SL, Keeney RL: *Acceptable Risk.* Cambridge, MA: Cambridge University Press, 1981.

Both of these paragraphs describe the 2001 anthrax bioterrorism events within the United States where a total of 22 people sickened or died from anthrax exposure. The first communication suggests that everyone is at risk and the situation is dire; the communication in the second paragraph is that the risk is isolated (a single individual died who was not in what was recognized as an at-risk setting) and there is a plan and process being developed to respond to the threat. The first is sensationalistic, imparting a helpless, victim role to the reader, although the second provides a framework in which to assess one's personal risk and access to sources of reliable information. Both types of reports were prevalent following the 2001 anthrax attacks. Which report seems more complete, accurate, or useful is determined by the assumptions and perspectives of the reader, in addition to the message the author wishes to deliver or response desired. Some would say that communicating a high degree of risk is important to gain the attention of the reader and to ensure that no one ignores a warning. However, the lack of a risk perspective prevents the reader from

placing this information in context with the myriad other risk communication messages conveyed on a daily basis. In general, those risk communication messages that do not provide a context or comparison to generally familiar activities or risks, are more prone to misinterpretation or misapplication. As biopreparedness moves from infrastructure and surveillance improvement to planning and response drills, appropriate message development

and risk communication to the public become increasingly important.

Summary

High-quality risk assessment and effective risk communication are the hallmarks of a successful interaction between the public and the PC, and between the toxicologist and an individual patient, the media, or the public health community. Adherence to general principles include obtaining the best information possible regarding potential exposures, and conveying as complete as possible a risk characterization of the hazard, likelihood of a completed exposure pathway, possible effects, and treatment options, in an understandable fashion. It is important to clarify the difference between public health standards and individual exposure risks, with an understanding of the many psychosocial issues that influence perception. Information should be provided in a context that allows the individual to prioritize his/her response based on a factual and balanced presentation.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 125
Hazmat Incident Response

Frank G. Walter

Hazmat Incident Response

A hazardous material (hazmat) can be defined as any xenobiotic capable of harming people, property, or the environment; therefore, the list of hazardous materials is understandably large.[26, 27]

A hazardous materials' emergency is an uncontrolled or unexpected release of a hazardous material. Hazmat incident response is an area of special expertise within the field of medical toxicology. In general, hazmat incident response focuses on the care of patients exposed to xenobiotics in the prehospital setting, prepares for multicasualty incidents, and emphasizes patient decontamination while at the same time trying to prevent contamination of healthcare providers. The general principles of toxicology apply regardless of whether a patient is at a hazmat incident, in a prehospital setting, or in a hospital setting. Although patient-care resources vary among these treatment settings, the fundamental principles of patient care remain the same.

Because the number of hazardous materials is so large, it is efficient to group hazardous materials according to their toxicological characteristics. Various classification systems have been devised. The International Hazard Classification System (IHCS) is the most commonly used (Table 125-1).[106 , 110] Individual hazmat studies commonly use their own classification systems, emphasizing the toxicodynamic effects of hazardous materials such as systemic asphyxiants or highlighting individual chemicals such as ammonia or chlorine or general classes of chemicals such as acids, bases, or volatile organic compounds.[26 , 27]

Epidemiology

Although the concepts regarding hazardous materials toxicology are centuries old, the systematic study of hazmat epidemiology only began in recent decades. Because the United States Department of Transportation (DOT) regulates transportation of hazardous materials, it has been collecting data on hazmat incidents since 1971. Recent data, spanning a decade, indicate that in the United States the number of transportation incidents has decreased somewhat from 16,105 in 1994 to 15,220 in 2003, although the number of deaths has remained relatively low: 11 in 1994 and 14 in 2003.[105]

For decades, the vast majority of hazmat incidents were thought to occur during transportation because the DOT collected, published, and promulgated data regarding hazmat incidents that occur only during transportation. In the late 1980s, medical science began to focus on the epidemiology of hazmat incidents. There are a limited number of hazmat epidemiology articles in peer-reviewed medical journals.[15 , 16 , 17 , 18 , 19 , 20 and 21 , 26 , 27 and 28 , 30 , 31 and 32 , 34 , 35 , 37 , 38 , 43 , 44 , 45 and 46 , 49 , 53 , 54 , 55 and 56 , 58 , 59 , 60 , 61 , 62 and 63 , 67 , 68 , 69 , 70 and 71 , 73 , 81 , 82 , 92 , 93 , 95 , 98 , 100 , 101 , 109 , 110 , 111 , 112 , 113 and 114 , 117 , 118]

Nevertheless, data from these articles and other US government

sources indicate that the majority of hazmat incidents actually occur at fixed facilities rather than during transportation.[1,2,3,4,5,6,7,8,9,10 and 11,104]

The substances most commonly encountered at hazmat incidents vary from one locale to another and are predominately determined by the major industries in a particular area.[109,110] For example, pesticides are the most commonly encountered class of hazardous materials in Fresno County, whose major industry is agribusiness.[109] Although most hazmat incidents involve only one hazardous material, more than one hazardous material can be encountered at a given incident. One study described 107 hazmat incidents involving a total of 156 materials.[109]

The vast majority of consequential hazmat incidents are caused by gases, vapors, or aerosols. In one study, 4 of the 5 most commonly encountered individual chemicals were ammonia, phosphine, sulfur oxides, and hydrogen sulfide.[27] The important implication for decontamination is that gases do not usually contaminate people secondarily because they do not adhere to patients. Therefore, patients exposed only to gases generally do not require skin decontamination to prevent secondary contamination, and much greater efficiency is possible in patient care at gas, vapor, and aerosol hazmat incidents. Inhalation is the most common route of exposure at hazmat incidents and was the route of exposure at 73% of the hazmat incidents, accounting for 76% of the exposed patients described in one study.[26,27]

The vast majority of hazmat incidents do not result in patient injury. Of 53,142 hazmat incidents, only 4,413 incidents (8%) resulted in patients injury.[62] Most patient-producing hazmat incidents are multicasualty incidents. For example, the 4,413 patient-producing incidents resulted in 17,743 patients.[10,62] Most hazmat patients do not require hospital admission. Of the 8,126 total patients in one study, 51% were transported to and treated at a hospital but were not admitted; 24% were treated on scene but

were not transported; 3% were transported to a hospital and only needed observation; 8% were transported and subsequently admitted to a hospital; and 6% were seen at their physicians' offices within 24 hours of the hazmat incident.[11]

Hazmat incidents can result in fatalities and injuries. Of the 17,743 patients from the 4,413 patient-producing hazmat incidents, 244 (1%) died. One study reported that 63 deaths were caused by

hazardous materials released in 36 fatal hazmat incidents. The majority of these fatal hazmat incidents, 26 of 36 (72%) occurred at fixed-facilities, with 10 of 36 (28%) being transportation-related.[92] Among the 63 total fatalities, 6% were rescue personnel responding to the hazmat incident. Explosions killed 16 of 63 victims (25%).[92] Rescue personnel and healthcare providers must focus on the whole patient and not just poisoning because hazmat victims can also have injuries caused by vehicular crashes, explosions, or thermal burns.[92]

Class 1: Explosives
- Division 1.1: Mass explosion hazard
- Division 1.2: Projection hazard
- Division 1.3: Predominantly a fire hazard
- Division 1.4: No significant blast hazard
- Division 1.5: Very insensitive explosives
- Division 1.6: Extremely insensitive detonating articles

Class 2: Gases
- Division 2.1: Flammable gases
- Division 2.2: Nonflammable compressed gases
- Division 2.3: Poisonous gases
- Division 2.4: Corrosive gases (Canada)

Class 3: Flammable/combustible liquids

Class 4: Flammable solids
- Division 4.1: Flammable solid
- Division 4.2: Spontaneously combustible materials

Division 4.3: Dangerous when wet materials
Class 5: Oxidizers and organic peroxides
Division 5.1: Oxidizers
Division 5.2: Organic peroxides
Class 6: Poisonous materials and infectious substances
Division 6.1: Poison materials
Division 6.2: Infectious substances
Class 7: Radioactive substances
Class 8: Corrosive materials
Class 9: Miscellaneous hazardous materials

TABLE 125-1. International Hazard Classification System

Emergency personnel and equipment can become contaminated at hazmat incidents.[35,70,71,73,109,110,117] For example, in one study, contamination occurred to one ambulance that drove through a puddle of liquid organic phosphorus pesticides that had spilled from a crashed exterminator truck. This ambulance was responding to a call for a â€œmotor vehicle crash.â€•[109]

Hazardous Materials and Hazmat Response

Chemical Names and Numbers

Chemical compounds may be known by several names, including the chemical, common, generic, or brand (proprietary) name.[22,23] A chemical may be the sole substance in a given hazardous material or one of several compounds in a mixture.

The Chemical Abstracts Service (CAS) of the American Chemical Society (ACS) numbers chemicals to overcome the confusion regarding multiple names for a single chemical. The CAS assigns a unique CAS registry number (CAS#) to atoms, molecules, and

mixtures. For example, the CAS# of methanol is 67â€“56â€“1.[88, 89] These numbers provide a unique identification for chemicals and a means for crosschecking chemical names. Identifying a chemical by name and CAS# is critical because one must be as specific as possible about the hazardous material in question. Trade or brand names can be misleading. The material safety data sheet (MSDS) describing a product usually lists the chemical name, the CAS#, and the brand name.[83]

Vehicular Placarding: UN Numbers, NA Numbers, and PIN

Substances in each hazard class of the IHCS (Table 125-1) are assigned 4-digit identification numbers, which are known as United Nations (UN), North American (NA), or Product Identification Numbers (PIN) and are displayed on characteristic vehicular placards. This system is used by the US DOT in the Emergency Response Guidebook.[106] The IHCS assigns a chemical to a hazard class based on its most dangerous physical characteristic, such as, explosiveness or flammability. Other potential hazards of an agent, such as its ability to cause cancer or birth defects, are not considered. This system provides very little guidance in treating poisonings caused by hazardous materials.

National Fire Protection Association 704 System for Fixed Facility Placarding

Fixed facilities such as hospitals or laboratories use a placarding system that is different from the vehicular placarding system. The National Fire Protection Association (NFPA) 704 system is used at most fixed facilities.[84] The NFPA system uses a diamond-shaped sign that is divided into 4 color-coded quadrants; red, yellow, white, and blue. This system gives hazmat responders information about the flammability, reactivity, health effects, and also other

information, such as the water reactivity, oxidizing activity, or radioactivity.

The red quadrant on top indicates flammability; the blue quadrant on the left indicates health hazard; the yellow quadrant on the right indicates reactivity; and the white quadrant on the bottom is for other information, such as OXY for an oxidizing product, W for a product that has unusual reactivity with water, and the standard radioactive symbol for radioactive substances.

Numbers in the red, blue, and yellow quadrants indicate the degree of hazard: numbers range from 0, which is minimal, to 4, which is severe and indicate specific levels of hazard.

Like all placarding systems, this one also has limitations. It does not name the specific hazardous substances in the facility and gives no information about the quantities or locations of the materials.

Substance Identification

Once a hazardous materials emergency has been recognized, responders must know what the material is and its potential health effects. Obviously, exact identification is desirable but not always possible. Information regarding the site of the hazmat incident, the type of business, laboratory, or vehicle,

involved allows hazmat responders to safely search for and identify essential placards or documents. Fixed facility placards, vehicular placards, MSDSs, bills of lading, shipping documents, inventory sheets, verbal information from employees and management, are potential sources of information.

CHEMTREC is a service of the Chemical Manufacturers Association. It has information about shippers, products, and manufacturers. CHEMTREC can be reached at 1â€“800â€“424â€“9300.[39] The internet address for CHEMTREC is http://www.chemtrec.org . CHEMTREC provides information at no charge, 24 hours a day.

Details of an incident are relayed to the shipper's or manufacturer's 24-hour emergency contact, and they, in turn, are linked to hazmat incident responders. Technical data are available on handling the substance(s) involved, including the physical characteristics, transportation, and disposal.

A regional poison center (PC) is another valuable source of information. Other information sources include local and state health departments, the American Conference of Governmental and Industrial Hygienists (ACGIH), the Occupational Safety and Health Administration (OSHA), National Institutes of Occupational Safety and Health (NIOSH), Agency for Toxic Substances and Disease Registry (ASTDR), and the Centers for Disease Control and Prevention (CDC).[1,13,14,88,89,94] If the name of the substance is known before arrival at the scene, then research can begin en route with reviews of the physical, chemical, and toxicologic properties of the material. If the chemical is not known before arrival at the scene, efforts to obtain this information should begin as soon as safely possible. Responder safety is a priority.

Even if the exact identity of the toxic material is not known, hazmat responders may be able to classify the hazardous material into one of several major toxicologic classes by identifying a hazmat toxidrome that allows them to reasonably treat the patient and protect themselves and others; for example, do patients have irritation of the mucous membranes and upper airway caused by a highly water-soluble irritant gas? Do the patients exhibit signs of asphyxia with major central nervous system and/or cardiopulmonary signs and symptoms? Do patients exhibit signs of cholinergic excess caused by organic phosphorus compounds or carbamate poisoning? Do patients exhibit chemical burns compatible with corrosives? Do patients have the odor of solvents with signs of CNS depression and cardiac irritability, compatible with exposure to hydrocarbons or halogenated hydrocarbons? Also, even when the exact identity of the hazardous material is not known, what is usually known is the physical state of the material, that is: solid, liquid, or gas. Airborne

xenobiotics potentially mean many more victims. Airborne xenobiotics include not only gases and vapors, but also the liquid suspensions, fog and mists, and the solid suspensions, smoke, fumes, and dusts.

State

The physical state of a material determines how it will spread through the environment and gives clues to the potential route(s) of exposure for the material.

Unless moved by physical means such as wind, ventilation systems, or people, solids will usually stay in one area. Solids can cause exposures by inhalation of dusts, by ingestion, or rarely by absorption through skin and mucous membranes. Solids that undergo sublimation, changing directly from a solid into a gas without passing through the liquid state, can give off vapors that can cause airborne exposure. Only two commonly encountered solids sublime, dry ice and naphthalene. A vapor is defined as a gaseous dispersion of the molecules of a substance that is normally a liquid or a solid at standard temperature and pressure (STP), that is, 32Â°F (0Â°C = 273Â°K) and 1 atm (760 torr = 760 mm Hg = 14.7 psi). Uncontained liquids will spread over surfaces and flow downhill. Liquids can evaporate, creating a vapor hazard.

Primary and Secondary Contamination

The state of matter will also help healthcare providers determine whether the hazardous material presents a significant risk of secondary contamination and whether decontamination of the skin and mucous membranes is necessary.

Primary contamination is defined as contamination of people or equipment caused by direct contact with the initial release of a hazardous material by direct contact at its source of release. Primary contamination can occur whether the hazardous material is

a solid, a liquid, or a gas.

Secondary contamination is defined as contamination of healthcare personnel or equipment caused by direct contact with a patient or equipment covered with adherent solids or liquids that have been removed from the source of the hazardous material spill. Secondary contamination generally occurs only with solids or liquids. In general, patients or equipment covered with adherent solid or liquid hazardous materials, including chemical, biological, or radiological agents, should be decontaminated before transportation, to prevent downstream contamination of healthcare providers and equipment. An exception to the principles of limited need for cutaneous decontamination for those exposed to gas is the patient whose sweaty skin was exposed to a highly water-soluble irritant gas such as ammonia that dissolves in sweat to produce corrosive ammonium hydroxide. In this case, the primary purpose of decontamination is to prevent or treat the patient's chemical burns caused by the caustic action of aqueous ammonium hydroxide on perspiring skin, rather than preventing secondary contamination of rescuers.

Aerosols are airborne xenobiotics that are not gases. Aerosols are suspensions of solids or liquids in air, such as solid dusts or liquid mists, that can cover victims with these adherent solids or liquids, which can effect secondary contamination. These patients do require decontamination to prevent secondary contamination.

Water Solubility

The water solubility of a hazardous material determines whether water alone is sufficient for skin decontamination or whether a detergent must also be used. The general rule regarding solubility is that â€œlike dissolves like.â€• In other words, a polar solvent, such as water, will dissolve polar substances such as salts. For example, the herbicide paraquat is actually a salt, paraquat dichloride, that is miscible in water. Therefore, if a patient's skin is contaminated with paraquat, copious water irrigation is sufficient for

skin decontamination. A mild liquid detergent is acceptable but is not necessary. On the other hand, a nonpolar solvent, such as toluene, is not water-soluble and is immiscible.[88, 89] Therefore, if a patient's skin is contaminated with toluene, water irrigation alone may be insufficient for decontamination, and a mild liquid detergent is also necessary.[88, 89]

Vapor Pressure

The vapor pressure (VP) is useful to estimate whether enough of a solid or liquid will be released in the gaseous state to pose an inhalation risk. VP is defined essentially as the quantity of the gaseous state overlying an evaporating liquid or a subliming solid. The lower the VP, the less likely the xenobiotics will volatilize and generate a respirable gas. Conversely, the higher

the VP of a chemical, the more likely it will volatilize or generate a respirable gas. Water has a VP of approximately 20 mm Hg at 70Â°F (21Â°C), and acetone has a VP of 250 mm Hg at the same temperature. Therefore, acetone evaporates more rapidly than water and poses more of an inhalation risk. Standard reference texts (*NIOSH Pocket Guide to Chemical Hazards Merck Index*) list vapor pressures for commonly encountered chemicals.[88, 89, 106]

Temperature Terminology System[a]	Color Terminology System	Explanatory Terminology System

TABLE 125-2. The Nomenclatures of the Hazmat Control Zones

Hazmat Scene Control Zones

Scene management is a fundamental feature at a hazmat incident. It is almost always necessary to isolate the scene, deny access to the public and the media, and limit access to emergency response personnel to prevent needless contamination. Three control zones are established around a scene and are described either by â€œtemperature,â€• â€œcolor,â€• or â€œexplanatory terminologyâ€• (Table 125-2 and Figure 125-1). NIOSH, the US Environmental Protection Agency (EPA), and most US prehospital and hospital healthcare professionals use the temperature terminology system.[88]

The hot zone is the area immediately surrounding a hazardous materials incident. It extends far enough to prevent the primary contamination of people and materials outside this zone. Primary contamination can occur to those who enter this zone. In general, evacuation, but no decontamination or patient care, is carried out in this zone, except for opening the airway and placing the patient on a backboard with spine precautions. This is because rescuers are generally hazmat technicians who wear level A or B suits that severely limit visibility and dexterity.

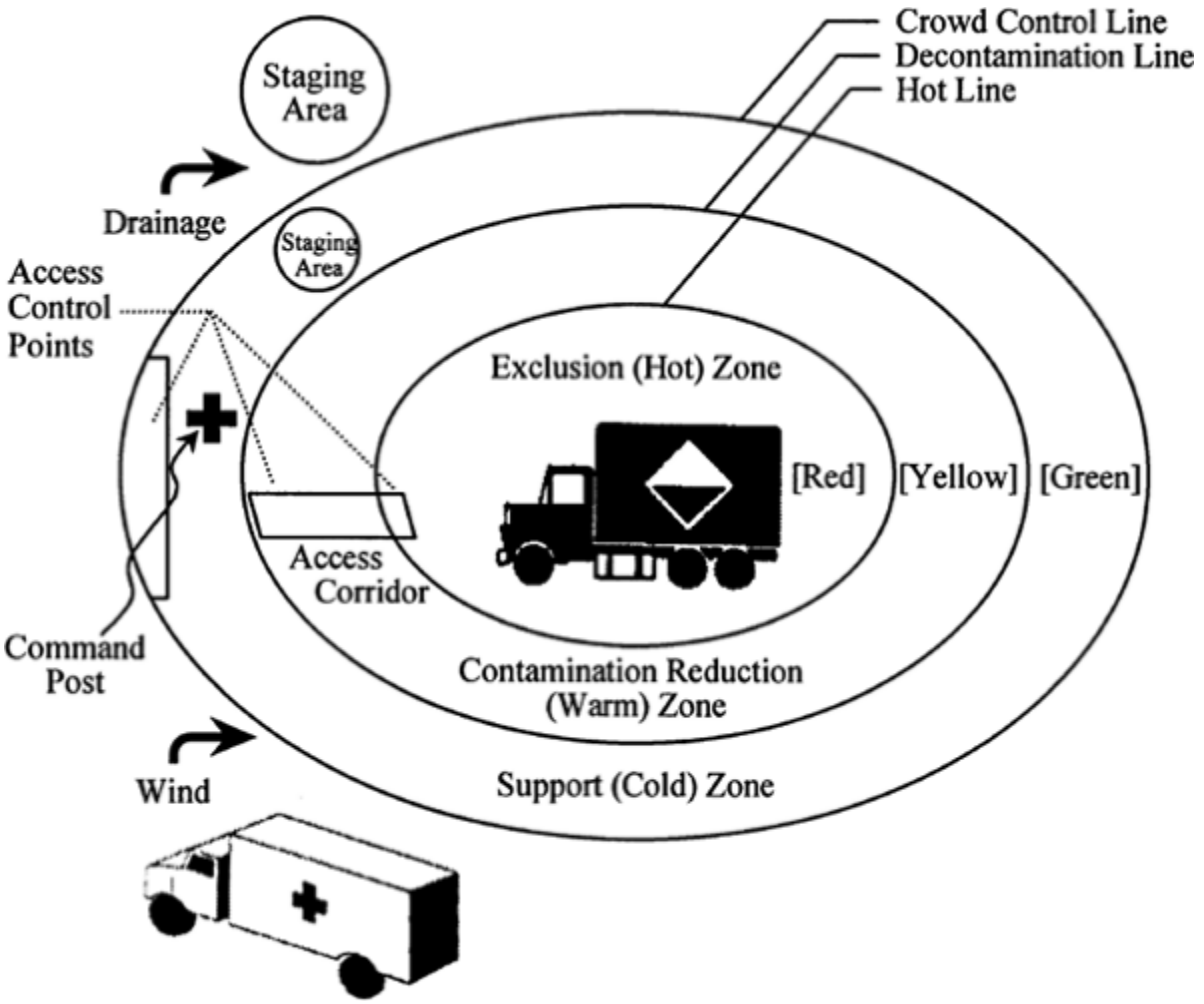

Figure 125-1. NIOSH/OSHA recommended control zones. *(Modified from ATSDR guidelines.) Modified with permission from The Advanced Hazmat Life Support Provider Manual, 3rd ed. Tucson, Az, Arizona Board of Regents, 2003.*

The warm zone is the area surrounding the hot zone and contains the decontamination or access corridor, where victims, the hazmat entry team members, and their equipment are decontaminated. It includes two control points for the access corridor. Many consider initiating therapy at this stage, particularly for chemical weapons events where multiple casualties are involved.

The cold zone is the area beyond the warm zone. Contaminated

victims and hazmat responders should be decontaminated before entering this area from the warm zone. Equipment and personnel are not expected to become contaminated in this zone. This is the area in which resources are assembled to support the hazmat emergency response. The incident command center is usually located in the cold zone, and definitive patient care is conducted here. This zone includes the primary survey and resuscitation with management of airway (with cervical spine control), breathing, circulation, disability, and exposure with evaluation for toxicity and trauma (ABCDE). Definitive care also includes antidotal treatment for specific poisonings.

Personal Protective Equipment

A critical goal of hazmat emergency responders is protecting themselves and the public. Safeguarding hazmat responders includes wearing appropriate personal protective equipment (PPE) to (1) prevent exposure to the hazard and (2) prevent injury to the wearer from incorrect use of or malfunction of the PPE equipment.[77, 90]

Personal protective equipment can create significant health hazards, including loss of cooling by evaporation, heat stress, physical stress, psychological stress, impaired vision, impaired mobility, and impaired communication. Because of these risks, individuals involved in hazmat emergency response must be trained regarding the appropriate use, decontamination, maintenance, and storage of PPE. This training includes instruction regarding the

risk of permeation, penetration, and degradation of PPE. PPE with a self-contained breathing apparatus (SCBA) has a fixed supply of air that significantly limits the amount of time the wearer can operate in the hot zone, usually about 20 minutes.

TABLE 125-3. Personal Protective Equipment

Levels of Protection

The EPA defines four levels of protection for PPE, levels A (highest) through D (lowest). The different levels of PPE are designed to provide a choice of PPE, depending on the hazards at a specific hazmat incident (Table 125-3).

Level A provides the highest level of both respiratory and skin (clothing) protection and provides vapor protection to the respiratory tract, mucous membranes, and the skin. This level of PPE is airtight, and the breathing apparatus must be worn under the suit.

Level B provides the highest level of respiratory protection but less skin protection. Level B provides skin splash protection by using chemical-resistant clothing. It does not provide skin vapor protection but does provide respiratory tract vapor protection. Some hospitals have specially trained healthcare professionals who wear level B PPE when decontaminating contaminated patients presenting to the hospital, prior to decontamination. However, the majority of hospitals are training their frontline, emergency department (ED) healthcare professionals to wear level C PPE when decontaminating contaminated patients who present to the hospital, prior to decontamination.

Level C protection should be used when the type of airborne substance is known, when its concentration can be measured, when the criteria for using air-purifying respirators are met, and when skin and eye exposures are unlikely. Level C provides skin splash protection, the same as level B; however, level C has a lower level of respiratory protection than either level A or B.

Level D is basically a regular work uniform. It should not be worn

when significant chemical respiratory or skin hazards exist. It provides no respiratory protection and minimal skin protection. Level D was specifically developed to show *what not to wear* for chemical protection.

PPE Respiratory Protection

Personnel must be fit-tested before using any respirator. A tiny space between the edge of the respirator and the face of the hazmat responder could permit exposure to an airborne hazard. Contact lenses cannot be worn with any respiratory protective equipment. Corrective eyeglass lenses must be mounted inside the face mask of the PPE. The only exception to these general rules are the use of hooded level C powered air purifying respirators (PAPRs) that do not require fit testing and allow individuals to wear their own eyeglasses within the hooded PAPR. This is the reason that the majority of US hospitals prefer hooded PAPRs for their ED personnel who must decontaminate contaminated patients who present directly to the ED.

Level A PPE mandates use of a self-contained breathing apparatus. A SCBA is composed of a face piece connected by a hose to a compressed air source. An open-circuit, positive-pressure SCBA, is used most often in emergency response, and provides clean air from a cylinder to the face piece of the wearer, who exhales into the atmosphere. Thus, a higher air pressure is maintained inside the face piece than outside. This affords the SCBA wearer the highest level of protection against airborne hazards, because any leakage will force air out of the face piece and not allow airborne hazards to enter against the higher pressure within the face piece. Disadvantages of SCBA include its bulkiness, heaviness, and a limited time period of respiratory protection because of the limited amount of air in the tank.

A supplied-air respirator (SAR) may be used in level B PPE and differs from SCBA in that air is supplied through a line that is

connected to a source located away from the contaminated area. Only positive-pressure SARs are recommended for hazmat use. One major advantage of SARs over SCBA is that they allow an individual to work for a longer period. However, a hazmat worker must stay connected to the SAR and cannot leave the contaminated area by a different exit.

An air-purifying respirator (APR) may be used in level C PPE and allows breathing of ambient air after inhalation through a specific purifying canister or filter. There are three basic types of APRs: chemical cartridge, disposable, and powered-air (PAPR). Although APRs afford the wearer increased mobility, they can be used only where there is sufficient oxygen in the ambient air. The chemical cartridges/canisters purify the air by filtration, adsorption, and/or absorption. Filters may also be used in combination with cartridges to provide increased protection from particulates such as asbestos.

Hazmat Incident Response Rules and Standards

OSHA and NFPA have developed, respectively, rules and guidelines regarding hazmat incident response.[75 , 84 , 85 , 86 and 87 , 97 , 107] OSHA rules are mandated as law and must be followed.[75 , 97 , 107] Meeting NFPA guidelines will ensure OSHA compliance.[75 , 84 , 85 , 86 and 87 , 97]

The Superfund Amendments and Reauthorization Act of 1986, known as SARA, required OSHA to develop and implement standards to protect employees responding to hazardous materials emergencies. This resulted in the â€œHazardous Waste Operations and Emergency Responseâ€• standard, 29 CFR 1910.120, or HAZWOPER.[107]

NFPA 471, â€œRecommended Practice for Responding to Hazardous Materials Incidents,â€• outlines the following tactical objectives: incident response planning, communication procedures, response

levels, site safety, control zones, personal protective equipment, incident mitigation, decontamination, and medical monitoring.[85]

NFPA 472, â€œStandard on Professional Competence of Responders to Hazardous Materials Incidents,â€• helps define the minimum skills, knowledge, and standards for training outlined in HAZWOPER for 3 types of responders.[86]

Prehospital Hazmat Emergency Response Team Composition, Organization, and Responsibilities

First Responder at the Awareness Level

First responders at the awareness level could be first on the scene at an emergency incident involving hazardous material. They are expected to recognize the presence of hazardous materials, protect themselves, secure the area, and call for better trained personnel. They must take a safe position and keep other people from entering the area. They must recognize that the level of mitigation exceeds their training and call for a hazmat response team. Most emergency medical technician (EMT) basic curricula include this level of first responder training.

First Responder at the Operational Level

These individuals are trained in all competencies of the awareness level and are additionally trained to protect nearby persons, the environment, or exposed property from the effects of hazmat releases. Operational level certified individuals are expected to assume a defensive posture, to control the release from a safe distance, and to keep the hazardous material from spreading. Operational level individuals are trained to perform absorption of

liquids, containment of the spill, vapor suppression, and vapor dispersion. They do not operate within the hot zone.

Hazardous Materials Technician

Hazardous materials technicians respond to hazmat releases, or potential releases, for the purpose of controlling the release. They are trained in the use of chemical-resistant suits, air-monitoring equipment, mitigation techniques, and the interpretation of physical properties of hazardous materials. Technicians are capable of containing an incident, making safe entry into a hazardous environment, determining the appropriate course of action, victim rescue, and cleaning up or neutralizing the incident to return the property to a safe and usable status, if possible. These individuals are trained to operate within the hot zone to mitigate the incident. This certification level includes knowledge of hazardous material chemistry, air-monitoring equipment, tools used within the hot zone, and more.

Advanced Hazmat Components

Advanced Hazmat Providers

Paramedics should be trained in the recognition of signs and symptoms caused by exposure to hazardous materials, and the delivery of antidotal therapy to victims of hazmat poisonings.[75]

The inclusion of such training into a department's hazmat response team is beneficial, not only for the needs of the public but also to protect hazmat technicians who make entry into hazardous atmospheres.[75] Ideally, hazmat technician entry into hazardous atmospheres should not be performed, unless appropriately trained paramedics are standing by, on scene, with resuscitative equipment in place, including a drug box containing essential antidotes for specific hazardous materials.[75]

Medical Control

Obtaining medical control should begin early in the development of the hazmat team. Incidents involving hazardous materials can have far-reaching community implications. The ideal medical director for a hazardous materials team should be a medical toxicologist familiar with the operations and logistics of functioning in the prehospital environment.[75] This physician should be consulted in all aspects of planning for a hazmat response. In addition to developing training curricula and treatment plans for toxic exposures, this physician can work with emergency responders and hospitals to help integrate emergency personnel into the incident command structure and assist with the logistics of decontamination and hospital preparedness for victims of hazmat incidents.[75]

Online, direct medical control plays an important role in caring for hazmat victims.[75] Contact with medical control should be established as soon as possible after deciding that hot zone entry is necessary. This prealert notification allows the physician and hospital staff to be prepared to institute contingency plans when patients are identified who may require transport to a receiving facility.

Medical control should also include consultation with a regional PC, if possible. Field personnel should be familiar with how to access information through the PC. Similarly, the PC should be familiar with the level of training of responding emergency medical services (EMS) personnel.

Patient Care Responsibilities of the Prehospital Decontamination Team and the Hazmat Entry Team

Hazmat responders should identify the entry and exit areas by controlling points for the access corridor (decontamination corridor)

from the hot zone, through the warm zone, to the cold zone (Figure 125-1). This corridor should be upwind, uphill, and upstream from the hot zone, if possible. Hazmat technician entry team members should remove victims from the contaminated hot zone and deliver patients to the inner control point of the access (decontamination) corridor.[33 , 42 , 66 , 72 , 75 , 79 , 80 , 102] Hazmat decontamination team members decontaminate patients in the decontamination (access) corridor of the contamination reduction (warm) zone.[33 , 42 , 66 , 72 , 75 , 79 , 80 , 102] After decontamination, hazmat responders deliver patients to paramedics in the cold zone.[33 , 42 , 66 , 72 , 75 , 79 , 80 , 102]

The primary responsibility of the prehospital hazmat medical sector is the protection of the hazmat entry team personnel. This is accomplished by researching and recording clinically pertinent information about the hazardous material (Table 125-4), remaining available on scene for medical treatment, (Table 125-5) and assessing individuals before entry into, and on exit from, a hazardous environment.[75] Documentation of each assessment should be recorded on a prepared form and compared to the exclusion criteria defined by NFPA 471.[75 , 85] A position in the hazmat medical sector should be held by advanced hazmat trained individuals, preferably with operational level responder competency and ideally with hazmat technician level competency.[86 , 87]

Patient Care Responsibilities of EMS Paramedics at Hazmat Incidents

EMS paramedics who are not part of the hazmat team should report to the incident staging area and await direction from the incident commander. They should approach the site from upwind, uphill, and upstream, if possible.

EMS paramedics should remain in the cold zone until properly protected hazmat incident responders arrive, decontaminate, and deliver patients to them for further triage. Then, EMS paramedics

should evaluate each patient, direct patients without complaints to the

occupant staging area, and take patients with complaints to the patient staging area. An EMS paramedic should stay with the patients in the occupant staging area to continually reevaluate these asymptomatic victims and transfer them to the patient staging area if they do become symptomatic. Patients leaving the occupant staging area should receive instructions regarding potential signs and symptoms that may develop and necessitate their subsequent evaluation at a healthcare facility.

- ❑ Research hazardous material information (use 3 references) and contact poison center
- ❑ Contact most appropriate base hospital
- ❑ Preentry medical evaluation on entry team and backup teams
- ❑ Brief entry and backup teams on signs and symptoms of exposure
- ❑ During entry, be available for immediate treatment and/or transport, following emergency decontamination.
- ❑ Postentry medical evaluation (immediate and 10 minutes postentry, if possible)
- ❑ After incident, update hospital on incident termination

TABLE 125-4. Hazmat Incident Response Paramedic Worksheet

Under most circumstances EMS patient care takes place in the patient staging area of the cold zone, including medical management of hazmat victims except under certain mass casuality scenarios. Decontamination should not be necessary because EMS paramedics in the cold zone should care only for decontaminated

patients or patients who did not have skin contamination.

Transportation of patients from the hazmat incident is ultimately under the control of the incident commander but is usually delegated to the prehospital hazmat medical sector and EMS paramedics in consultation with a base hospital physician. In general, no victim with skin contamination should be transported from the hazmat site without being properly decontaminated. Before transportation, EMS should notify the base hospital of the number of victims being transported, and their toxicologic history, patient assessments, and treatment rendered. The base hospital physician may have additional orders, either before or after consultation with the PC and/or a medical toxicologist. If a patient is to be transported to a hospital other than the base hospital, the receiving hospital should be contacted.

Atropine
Î²-Adrenergic antagonist, calcium channel blocker, and cardioactive steroids overdoses; muscarinic mushroom (*Clitocybe, Inocybe*) poisoning; organic phosphorus and carbamate insecticide poisoning
Benzodiazepines
Stimulants, organic phosphorus poisoning
Calcium chloride
Calcium channel blocker overdose, hydrofluoric acid
Diphenhydramine
Extrapyramidal reactions from antipsychotics or antiemetics, organic phosphorus poisoning
Glucagon
Î²-Adrenergic antagonists, calcium channel blocker overdoses, hypoglycemia
Oxygen
Carbon monoxide, cyanide, hydrogen sulfide poisoning, organic phosphorus poisoning
Sodium bicarbonate
(1) Cyanide, methanol, ethylene glycol (reversal of metabolic

acidosis)
(2) Salicylates, chlorpropamide, phenobarbital, formic acid, chlorphenoxyherbicides (enhanced elimination)
(3) Cyclic antidepressants, quinine, carbamazepine, type IA and IC antidysrhythmics, cocaine, some phenothiazines (reversal of type IA ECG effects)
[a] Use of medications outside of protocols may not be permissible in some areas, even with on-line medical control.
[b] Table does not include medications such as D_{50} W, thiamine and naloxone primarily intended to be used as standard component of overdose management antidotes for an altered level of consciousness.

Medication Antidotal Use

TABLE 125-5. Antidotes Commonly Employed by Paramedics[a, b]

Emergency Department Responsibilities for Hazmat Victims

Since 2001 many, but not all, hospitals and EDs have dramatically improved their decontamination equipment, fit testing, and training in the safe use of personal protective equipment.[12, 24, 47, 52, 64] It is critical that hospitals be involved with community hazmat planning to ensure that as many hazmat victims as possible are decontaminated in the field before delivery to the hospital.[25, 29, 36, 40, 41, 48, 74, 91] The hospital must have a preestablished protocol by which hospital response teams will decontaminate patients who arrive at the hospital if not previously decontaminated.[25, 51, 57, 65, 74, 76, 96, 99, 103, 108, 115, 116] Hazmat patients who require skin decontamination should be denied entry to the ED until decontaminated by an appropriately trained

and equipped hazmat response team. The emergency physician will determine when the patient is safe to enter the ED after carefully assessing the risks and benefits to the decontaminated patient, the other patients in the ED, and the ED healthcare personnel.

Decontamination

Decontamination has two important functions: altering absorption for the patient and preventing secondary contamination of others. Primary goals at any hazmat incident are protecting emergency responders, preventing secondary contamination, and decreasing morbidity and mortality of hazmat victims.[29, 33, 50, 66, 76, 78, 79, 102, 108] Prompt, adequate skin decontamination is the most important determinant to improve patient outcome with chemical burns.[78]

Exposure solely to gases, such as simple asphyxiants, generally requires no skin or mucous membrane decontamination to prevent secondary contamination of others. However, exposure to highly water-soluble irritant gases, such as anhydrous ammonia, can cause skin and mucous membrane irritation and chemical burns; these are treated with copious amounts of water irrigation. This primarily treats the patient, rather than primarily preventing secondary contamination of healthcare providers.

When indicated by the presence of adherent solids or liquids on a patient, skin decontamination should be performed in the field, in the decontamination zone, if at all possible. If this is not done, these patients must be decontaminated at the hospital, prior to entering the hospital. Decontamination is a 2-step procedure. First remove all clothing, jewelry, and shoes. Bag and tag these possessions. The patient's possessions should be left at the scene, stored, and may need to be disposed of as hazardous waste. Any adherent solid particles should be brushed away from the patient. Gently blot away any obvious adherent liquid. Step two is meticulous washing with large quantities of water. Use a mild liquid

detergent if the adherent solids or liquids are not water-soluble or if the identity of the material is unknown. Most decontamination solutions are made for equipment, not people.[50] Do not use these potentially irritating solutions on people.[50] Pay close attention to all exposed skin and, in particular, the skin folds, the axillae, the genital area, and the feet. Use lukewarm water with gentle water pressure to reduce the risk of hypothermia. Apply water systematically from head to toe, protecting the patient's airway.

Exposed, symptomatic eyes should be continuously irrigated with water throughout the patient contact, including transport, if possible. Remember to check for and remove contact lenses. Use of therapeutic lenses is the most efficient method to decontaminate a patient's eyes, but this requires using an ocular topical anesthetic such as proparacaine.

Role of the Emergency Physician in Collaboration with the Emergency Department Nursing Staff and Hospital Safety Officer

- Provide prehospital medical control as the base hospital emergency physician, if possible.
- Activate the hospital's disaster plan, initiating the Hospital Incident Command, if indicated.
- Contact the PC and/or medical toxicologist or, alternatively, call the hospital's chemical spill coordinator or the hospital's radiation control personnel, if the substance is believed to be radioactive.
- Decide what procedures should be used in the field for decontamination in conjunction with the PC and/or medical toxicologist.

- Advise prehospital EMS personnel on precautions and adequate decontamination procedures.
- Decide if field decontamination procedures are adequate with the help of the PC and/or medical toxicologist.
- Meet the ambulance and decontaminated patients outside of the ED, and reassess for the adequacy of decontamination before patient entry into the ED.
- Deny ED entry to any physician or patient with skin contamination who has not been decontaminated before arrival in the ED, and if necessary, contact dispatch to send a hazmat response team to the ED while the patient waits outside the ED in an area of limited patient traffic.
- Notify hospital security to provide ED security and deny entry of contaminated patients unless the attending emergency physician makes a conscious decision to allow entry after considering the risks and benefits.

- Decide if and how a decontamination room should be used, when necessary, and when available.
- Decide if an additional decontamination area should be prepared outside the ED and, if so, establish the external unit.[25 , 29 , 40 , 41 and 42 , 51 , 57 , 65 , 74 , 96 , 99 , 103]
- Review current ED status and staffing and assign personnel to care for all ED patients.
- Call an appropriate level trauma alert, if the patient has physical injuries.

Summary

Hazmat incident response is an integrated, interdisciplinary approach involving prehospital, hospital, PC, and public health

professionals. Most patients at hazmat incidents are exposed through inhalation of a gas, or a solid or liquid aerosol. Prehospital and hospital healthcare professionals must use appropriate personal protective equipment when caring for patients who have not been decontaminated. Decontamination is critical to alter absorption for the patient and to prevent secondary contamination of downstream healthcare providers and equipment.

The general principles of toxicology apply regardless of whether a patient is at a hazmat incident in a prehospital or hospital setting. Although patient-care resources vary among these treatment settings, the fundamental principles of patient care remain the same: All patients should receive a primary survey and resuscitation, emphasizing airway, breathing, circulation, etc. Additionally, in hazmat patients, goals will include altering absorption of xenobiotics by decontamination; administering antidotes if possible; changing the catabolism of xenobiotics and, also if possible, creating less toxic or nontoxic metabolite; distributing the xenobiotics differently within the body, particularly away from active binding sites, if possible; and enhancing the elimination of xenobiotics from the body, if possible.

Chapter 126
Chemical Weapons

Jeffrey R. Suchard

On March 20, 1995, during peak morning commuter traffic, a religiously motivated terrorist cult released sarin in the Tokyo subway system. Cult members concealed the nerve agent in plastic bags wrapped in newspape which they placed on 5 subway car floors and punctured with umbrellas l leaving the trains. Fifteen subway stations were filled with a noxious sub resulting in a mass casualty event.[63,67,68] Initial reports suggested an explosion with consequent toxic gas release, and preparations were made receive victims with burns, blast and inhalation injuries, and carbon mon exposure. The first ambulatory victims reached local hospitals 30 minutes the chemical release with complaints of eye pain and dim vision. Ambula began arriving 15 minutes later. Victims denied any explosion, and repor instead that people abruptly began collapsing in the subway stations.[67] S Luke's International Hospital received the largest number of victims, abou patients within the first hour, mostly arriving by private vehicle or on foo [67] Nearly 2 hours after the event, the fire department reported that the causative material was acetonitrile and that victims were suffering from toxicity.[67] Medical teams noted, instead, symptoms more consistent with cholinergic toxicity. Mildly affected victims had ocular complaints related

miosis, rhinorrhea, and mild headache. Moderately ill victims also had dy vomiting, muscle fasciculations, and weakness. The most critical victims seizures, coma, and respiratory or cardiac arrest.[63] Serum cholinesterase were severely depressed in the sickest patients, leading to suspicion of c phosphorus compound poisoning. Sarin was confirmed as the causative ag hours after its release.[67] A total of 5510 people sought medical attention more than 200 hospitals and clinics in the Tokyo area.[84] The majority of patients were either minimally affected, and were discharged home after observation period, or had no demonstrable toxicity. One thousand fifty were at least moderately ill. Eight fatalities occurred the first day, later increasing to 12.[105] Some healthcare workers were symptomatic from se exposure, particularly when the victims were taken directly to poorly ver areas. A survey conducted 4 years after the terrorist attack revealed that majority of victim respondents had persistent physical and psychologic complaints.[103]

Recent years have witnessed an enormous resurgence of interest in chem and biological weapons (CBW). Although â€œunconventionalâ€• warfare chemical and biological agents has been practiced since antiquity, it was until the 20th century that such weapons have been manufactured and us a mass scale. In addition to battlefield use, chemical weapons may appea terrorist groups, in that the technology and financial outlay required to p them is much less than for nuclear weapons, although the potential morb and mortality remain high (Table 126-1).

Chemical weapons clearly fall within the purview of medical toxicology. I unlike the many drugs and chemicals widely studied by toxicologists that incidentally cause poisonings, these compounds were specifically designed kill, incapacitate, or injure. Some agents generally considered nonlethal, tear gas and pepper spray, are therefore also considered chemical weapo Biological warfare agents share many characteristics with chemical agent (Table 126-2) and are covered in Chap. 127 , although the issues commo both chemical and biological weapons are discussed in this chapter.

History

The first well-documented intentional use of chemicals as weapons occurr 429 B.C. when Spartans besieging Athenian cities burned pitch-soaked wo brimstone to produce sulfurous clouds.[28] Chemical weapons were sporad used, or their use considered, up through the 19th century, and in 1854 British Lord Playfair even suggested that asphyxiating enemy soldiers wit poison gases was more humane than killing them with conventional weap

Large-scale chemical warfare began in World War I. On April 22, 1915, th Germans released chlorine from compressed gas cylinders near Ypres, Be A cloud of chlorine gas drifted over Allied lines, killing hundreds and forc 15,000 troops to retreat. The Germans had not anticipated such impressi effectiveness and were unable to fully exploit their tactical advantage.[28] Both sides rapidly escalated the use of toxic gases, released from cylinde by artillery shells, including various pulmonary irritants, lacrimators, ars and cyanides.

The Germans first used sulfur mustard on July 12, 1917, again near Ypres first mustard attack alone caused over 20,000 deaths or injuries and pre new problems.[28 , 53 , 90] Unlike prior war gases, mustard was persistent i environment and vesicated the skin in addition to injuring the lungs and membranes. The Allies soon responded in kind. Sulfur mustard was unequ its ability to incapacitate opponents.[10] Injuries far outweighed fatalities, up manpower and resources to care for the wounded. Although only abou 2â€“3% of 120,000 British sulfur mustard casualties died, only 30% of th survivors could be released from the hospital within 30 days.[54]

Only one major chemical weapon event occurred during World War II. On December 2, 1943, German planes bombed American ships in Bari, Italy. John Harvey was destroyed, releasing the contents of 2000 mustard bom causing over 600 Allied military and an unknown number of civilian casu , 53 , 90

Chemical warfare

Intentional use of weapons designed to kill, injure, or incapacitate on the of toxic or noxious chemical properties

Biologic warfare
Intentional use of microorganisms or toxins derived from living organisms cause death, disability, or damage in humans, animals, or plants
Terrorism
The unlawful use of force against persons or property to intimidate or coe government, the civilian population, or any segment thereof, in furtheran political or social objectives
CW
Chemical warfare or chemical weapon
BW
Biological warfare or biologic weapon
CBW
Chemical and/or biologic warfare, or weapons
NBC
Nuclear, biologic and/or chemical; usually in reference to weapons
WMD
Weapons of mass destruction; nuclear, radiologic, chemical, and/or biolo weapons intended to produce mass casualties

TABLE 126-1. Unconventional Weapons: Definitions and Acronyms

Germany began producing nerve agents just before World War II. Tabun developed in 1936 by Gerhard Schrader when conducting insecticide rese for IG Farbenindustrie.[32 , 87] Tabun was abandoned as an insecticide beca its overwhelming human toxicity, and was instead reported to the govern as mandated for all discoveries of potential military importance. Sarin wa synthesized in 1938, named after its developers: Schrader, Ambrose, Ru and Van der Linde.[32] Between 10,000â€“30,000 tons of tabun and 5â€“10 of sarin were produced during World War II. Soman was synthesized in 1 but no large-scale production facilities were developed. When the Allies discovered these nerve agents at the end of the war, code names were designated based on the order of their development. Tabun was called GA letter G standing for German), sarin was GB, and soman was GD.[32]

- Agents most effectively dispersed in aerosol or vapor forms
- Delivery systems frequently similar
- Movement of agents highly subject to wind and weather conditions
- Appropriate personal protective equipment prevents illness

â€¢

Rate at which attack results in illness

Rapid, usually minutes to hours

Delayed, usually days to weeks

â€¢

Identifying release

Easier because of:

- Rapid effects
- Possible chemical odor
- Commercially available chemical detectors

Harder because of:

- Delayed effects
- Lack of color, odor, or taste
- Limited development of real-time detectors

â€¢

Agent persistence

Variable

- Liquids semipersistent to persistent
- Gases nonpersistent

Generally nonpersistent; most BW degraded by sunlight, heat, desiccatio
(exception, anthrax spores)

â€¢

Victim distribution

Near and downwind from release point

Victims may be widely dispersed by time disease is apparent

â€¢

First responders

EMTs, hazmat teams, firefighters, law enforcement officers

Emergency physicians and nurses, primary care practitioners, infectious
physicians, epidemiologists, public health officials, hospital administrator

laboratory experts (but may be same as CW if release is identified imme
â€¢
Decontamination
Critically important in most cases
Not needed in delayed presentations; less important for acute exposures
â€¢
Medical treatment
Chemical antidotes, supportive care
Vaccines, antibiotics, supportive care
â€¢
Patient isolation
Unnecessary after adequate decontamination
Crucial for easily communicable diseases (eg, smallpox, pneumonic plagu
however, many BW agents are not easily transmissible

Contrast

In 1952, the British synthesized an even more potent nerve agent while
searching for a dichlorodiphenyltrichloroethane (DDT) replacement. This
substance was given to the United States for military development, and w
named VX, with the letter V presumably standing for venom. A VX leak k
6000 sheep near a military base in Skull Valley, Utah in 1968.[32, 49, 87] I
is believed to have used riot-control agents, mustard, and possibly nerve
in the Yemen War of 1963â€“1967. The United States used defoliants and
control agents in Vietnam and Laos, claiming that these were not forbidde
the Geneva Protocol, which the United States finally ratified in 1975. Iraq
sulfur mustard, tabun, and soman during its war with Iran, and may have
used cyanide against the Kurds.[36, 47, 53, 90]

More recently, terrorist groups have begun to employ chemical weapons. was released twice by the Aum Shinrikyo cult in Japan. The first release occurred in Matsumoto in 1994, killing 7 and injuring over 600.[56, 64] A r highly publicized sarin attack occurred in the Tokyo subway system in 19 killing 12 and resulting in over 5000 persons seeking medical attention.[84] members have also used VX in assassinations.[55, 60]

General Considerations

Nerve Gas, Mustard Gas, Poison Gas

The term â€œwar gasâ€• is generally a misnomer. Sulfur mustard and n agents are liquids at normal temperatures and pressures, and many riot- agents are solids. These weapons are most efficiently dispersed as aeros Some chemical weapon agents (eg, chlorine, phosgene, hydrogen cyanide truly gases, although these agents are generally considered obsolete for battlefield use; they might still be used as improvisational agents, especi terrorist attacks.

Liquid chemical weapons have a certain degree of volatility and may eva into poisonous vapors. Volatility is inversely related to persistence, the t to remain in the environment. Persistent agents, such as mustard or VX c contaminate an area for prolonged periods, denying the enemy free mov and use of material. The toxic hazard from semipersistent agents like sari nonpersistent agents like hydrogen cyanide dissipate more rapidly.

Chemical or biological agent aerosols and chemical weapon gases and va are highly subject to local atmospheric conditions. Less dispersion occurs inversion layers and in the absence of wind, as typically occurs at night o early morning. Enclosed spaces also prevent wind dispersion and even si dilution. Except for hydrogen cyanide, CBW gases and vapors are all more than air and will pool in low-lying areas.

Chemical weapons dispersion in enclosed, low-lying spaces was used in th Tokyo subway sarin attack. The number of fatalities could have been muc

higher had the nerve agent been effectively aerosolized instead of simply allowed to evaporate. Photos from the attack show severely affected or deceased victims in very close proximity to mildly affected, ambulatory individuals. Presumably, sarin concentrations decreased with distance fror source, and only a few victims, if any, were actually contaminated with li After removal from high-concentration areas, the victims' bodies posed le threat to bystanders because of dilution and improved ventilation. Even s some healthcare providers were secondarily exposed, as the victims were even disrobed prior to entering the hospitals. Up to 46% of hospital staff areas with poor ventilation reported symptoms consistent with mild acute poisoning, although cholinesterase levels were not reported.[61, 63, 67] Ab one third of rescue workers in the 1994 Matsumoto sarin incident also de mild toxicity. Rescuers arriving at the scene later were less likely to deve symptoms.[57]

Preparation for CBW Incidents

A rational medical response to CBW events differs from the common resp isolated toxicologic incidents. Healthcare providers must learn new inforr related to unconventional weapons. Fortunately, a multimillion-dollar Do Preparedness Program was funded in 1996 by the Nunn-Lugar-Domenici initiative for weapons of mass destruction (WMD) defense.[62] Medical pro in 120 major US cities are receiving training in the recognition and treatn chemical and biologic casualties.[19, 21]

Healthcare providers must protect themselves and their facilities first, or ultimately no one will receive care. New medicolegal and ethical consider will arise in CBW mass-casualty events that are otherwise infrequently se greatest good for the greatest number of victims may preclude heroic interventions in a few critical patients. Charges of negligence may later a regarding delays in treatment or failure to diagnose subtle signs of disea even if such actions were unavoidable at the time.[19]

The responses to chemical and biological agents will also differ.[30] Chemic weapons, like conventional explosives, generally produce clinical effects seconds to hours, making a â€œsceneâ€• or â€œhot zoneâ€• evident. T

responders for a chemical event will be fire and police authorities, hazma teams, and emergency medical services (EMS). Patients will be brought t area healthcare facilities and the disease process, although perhaps not t specific diagnosis, will be recognized. With biologic agents, the victims wi all present for care at the same time in the same place. First responders local and distant emergency departments (EDs) and primary care offices, highlighting in these specialties the need for further training of healthcar personnel. Currently, there is no standard curriculum for the training of emergency and other physicians about the health hazards related to nucl biological, chemical (NBC) weapons, although progress in this regard is underway.[21, 71] Anesthesiologists and critical care specialists, too, are recognizing their lack of formalized training in preparing for chemical ma casualty incidents.[7, 44]

In preparation for the 1996 Olympic Games in Atlanta, a multidisciplinary force was assembled to detect, identify, and respond to any CBW threat c release of toxic industrial chemicals.[82] Efforts included stockpiling antibi and antidotes, training first-responders, enhancing surveillance, and aug clinical capabilities. The group correctly suspected that the most likely te event was use of conventional explosives; nevertheless, samples from th Centennial Park explosion were rapidly obtained to exclude dissemination CBW agent. Such an intense response to the threat of CBW terrorism wou difficult to maintain for extended periods.

Recommendations for more sustained healthcare facility domestic prepar include, improved training to promptly recognize CBW mass casualty eve efforts to protect healthcare providers, and establishing decontamination triage protocols.[48] Table 126-3 lists specific recommendations. Several fa the response to a CBW event are still being refined, such as the optimal of personal protective equipment, determining who needs decontaminatio by what means, and what is to be done with wastewater produced by mas decontamination.[48]

Communication is always a key issue in disaster management. Preestabli lines of communication and command should be implemented.[150] Outside agencies should also be alerted to CBW incidents, which in the United Sta

should include, at a minimum, the Federal Bureau of Investigation (FBI) a Centers for Disease Control and Prevention (CDC) (Table 126-4).[40] On a level, communication can be severely impaired by personal protective ge which points out the need for loudspeakers or some other form of public address.[48 , 100]

Decontamination

Decontamination serves two functions: (1) to prevent further absorption spread of a noxious substance on a given casualty and (2) to prevent spr other persons. Decontamination is critical for some chemical weapons exposures, but is less crucial for biologic agents. Victims of an occult bio weapon agent release

will not present for medical care until they become symptomatic, usually days later when decontamination will make no difference. Also, chemical agents can be dispersed as liquids, which are more amenable to decontamination than gases or aerosols, and are more likely to spread on person or between persons. Decontamination issues specific to biological weapon agents are discussed in the following chapter.

- Immediate access to personal protective equipment (PPE) for healthc providers
- Decontamination facilities that can be made operational within 2 to 3 minutes
- Triage of victims into those able to decontaminate themselves (decre the workload for healthcare providers) and those requiring assistance
- Decontamination facilities permitting simultaneous use by multiple pe and providing some measure of visual privacy.
- A brief sign-in process where patients are assigned numbers and give identically numbered plastic bags to contain their clothing and valuab
- Provision of food, water, and psychological support for staff, who may required to perform for extended periods
- Secondary triage to separate persons requiring immediate medical tr

from those with minor or no apparent injuries who are sent to a holdi for observation
- Providing victims with written information regarding the agent involv potential short- and long-term effects, recommended treatment, stres reactions, and possible avenues for further assistance
- Careful handling of information released to the media to prevent con or erroneous reports
- Instituting postexposure surveillance studies

TABLE 126-3. Recommendations for Healthcare Facility Respons CBW Incidents

Xenobiotics that are exclusively gases at normal temperatures and press (eg, chlorine, phosgene, or hydrogen cyanide) require only removing the from the area of exposure. Isolated vapor exposures, as from volatilized agents or sulfur mustard, are also terminated by leaving the area and ma require no skin decontamination of victims.[53,85] Japanese experience w sarin suggests that clothing should be removed from victims of nerve age vapor exposure and placed in airtight receptacles, such as plastic bags. S the secondary exposures to sarin were thought to have occurred as nerve that had condensed on the victims' clothing revaporized into the ambient and this caution probably holds true also for sulfur mustard vapor exposu

Chemical weapons dispersed as liquids present the greatest need for decontamination. Because nerve agents are highly potent and have rapid of effects, some victims with significant dermal contamination may not s to reach medical care.[85] Liquid-contaminated clothing must be removed, a able, victims should remove their own clothing to prevent cross-contami

Decontamination should be done as soon as practicable, to prevent prog of disease, and outside of healthcare facilities, to prevent contamination working environment and secondary casualties. Decontamination near the incident scene would be ideal in terms of timeliness, although this will no logistically be possible in many situations. The more likely scenario is tha victims may arrive independently at a decontamination center in proximity

healthcare facility. In mass-casualty incidents, decontamination efforts m benefit from separating victims into those who can remove their own clot and shower themselves with minimal direction and assistance, and the m seriously affected who will require full assistance. The degree of protectiv required by the decontamination personnel cannot be predicted in advanc may not be easy to objectively determine at the time of the incident. Lev gear may be adequate for persons assisting the â€œwalking wounded,â€ although level A gear is appropriate for those decontaminating the most seriously affected (and presumably most seriously contaminated) victims Chemically contaminated victims presenting to a healthcare facility shoulc possible, be denied entrance until decontaminated. Patients who have alı entered a healthcare facility and are only later determined to be a contamination hazard present a more difficult problem. If the situation a such patients should be taken outside for decontamination before returnir the previous care area cordoned off until any remaining safety hazard has eliminated. In a mass-casualty disaster, however, such efforts at remedi may not be practical.

Nerve agents are hydrolyzed and inactivated by solutions that release ch such as household bleach or solutions that are sufficiently alkaline. To av potential dermal and mucous membrane injury, a 1:10 dilution of househ bleach in water (producing a 0.5% sodium hypochlorite solution) has bee recommended, not only for nerve agents, but also for sulfur mustard and biological agents.[48 , 51 , 87] Alternatives include regular soap and water c copious water alone. Rapid washing is more important than the solution u because 15â€“20 minutes is necessary for hypochlorite solutions to inact chemical agents.[48] Care should be taken to clean the hair, intertriginous axillae, and groin.[87]

Decontamination after sulfur mustard exposure is more problematic than nerve agents. First, it is more likely that significantly contaminated victim survive to reach medical care, and they may remain asymptomatic for se hours. Also, the biochemical damage becomes irreversible long before sy develop.

Decontamination within 1â€“2 minutes is the only effective means of limi

tissue damage from mustard.[89] The actual means of mustard decontamir however, are identical to those for nerve agents. Victims must be disrobe thoroughly showered. Dilute hypochlorite solutions (eg, 0.5% sodium hypochlorite, a 1:10 dilution of household bleach) have been advocated t inactivate mustard, but copious water irrigation will also suffice.[53] Sympt victims of mustard exposure should still be decontaminated, even though unlikely to benefit that particular casualty, to prevent the spread of agent others.[89] Lewisite and phosgene oxime must also be decontaminated qui although they produce immediate symptoms, making it more likely that will present promptly when decontamination is most effective.

TABLE 126-4. CBW Phone Numbers/Contacts

Water irrigation is generally recommended for riot control agent exposure because hypochlorite solutions may exacerbate skin lesions.[53] Inadequate decontaminated patients exposed to lacrimator agents can produce secon cases among healthcare providers, so any contaminated clothing should b removed and bagged.

Significant issues remain regarding decontamination measures. The numb people potentially requiring decontamination may easily outstrip capacity. simulation of sarin and sulfur mustard decontamination, the maximum ca was 16 patients per hour.[98] Incidents with hundreds or thousands of vict may need to rely on communal showers and/or selective decontamination Decontamination wastewater should ideally be contained and treated, but facilities have the capability or funds to do this. Wastewater may, howeve minor issue. In biological weapon incidents there is only a temporary risk because of rapid environmental degradation, and in large-scale chemical events the wastewater poses only a small percentage of the total enviro impact.[48]

Risk of Exposure

The actual release of CBW agents can be characterized as a low-probabili high-consequence event.[9,73] Potential sources for civilian exposure incl terrorist attacks, inadvertent releases from domestic stockpiles, direct m attacks, and industrial events. Terrorist may sabotage military or industr stockpiles or directly attack the populace. Experience has shown that ph are much more likely to encounter hoaxes,[13] isolated cases,[77] or limited incidents with a modest number of casualties.[1,99] Riot control agents ar exceptions, in that treating riot control agent and pepper spray victims is routine occurrence in many urban emergency departments.

Technical and organizational obstacles decrease the chance of major CBW terrorist events. Obtaining or producing chemical or biological weapons, although simpler than for nuclear weapons, is only part of the process. E dissemination is difficult if the goal is to maximize casualties. Proper milli biologic agents to produce stable, respirable aerosols requires technical sophistication probably only attainable with governmental research suppo Illustrating this point is the ineffectiveness of the Aum Shinrikyo's biolog weapon releases and the limited number of sarin fatalities, despite large amounts of funds available to support these attacks.[69] Low-technology a such as food contamination, poisoning of livestock, and enclosed-space v dispersal appear more likely to occur than attacks resulting in hundreds, thousands, or millions of casualties.[92] Smaller attacks, or merely threate use of CBW agents, may be equally consequential from a terrorist's pers if they exert the same political influence.

Nevertheless, even inefficiently dispersed agents of sufficient toxicity can produce multiple casualties and terrorize the populace, as occurred in the Matsumoto and Tokyo sarin attacks. Impact estimates of efficiently dispe biological weapons are alarming. Fifty kilograms of anthrax spores disser along a 2-km line upwind of 500,000 people would be expected to kill 95 and incapacitate another 125,000 people: nearly a 50% casualty rate.[20] societal economic impact of bioterrorist attacks range from $477.7 million 100,000 persons exposed for brucellosis to $26.2 billion per 100,000 exp for anthrax.[38]

The chemicals most likely to be used militarily appear to be sulfur mustar the nerve agents. A â€œlow-techâ€• terrorist attack could involve the r of industrial chemicals, such as chlorine, phosgene, or ammonia gas. Alth the list of potential biological weapon agents is long, only a handful of pathogens have credible risk of producing public health disasters by overwhelming healthcare resources and causing high mortality, widespre panic, and massive disruption of commerce.[14] Topping this list are anthra smallpox, and plague, followed by botulinum toxin, hemorrhagic fever vi and tularemia.

Psychological Effects

Either the threat or the actual use of CBW presents unique psychologic stressors. Even among trained persons, a CBW-contaminated environment produce high stress through the necessity of wearing protective gear, po exposure to agents, high workload intensity, and interactions with the dea dying. About 10â€“20% of participants in military training exercises, in w chance of actual exposure exists, experience moderate to severe psycho symptoms.[25] Disorders of mood, cognition, and behavior will be common exposed or potentially exposed victims as a result of the uncertainty, fear panic that may accompany a CBW incident, even a hoax. The psychologic casualties will probably outnumber victims requiring medical treatment. without training, including some healthcare providers, are likely to confus somatic symptoms with true exposure. Medical resources may easily be overwhelmed unless triage can identify those who will benefit most from appropriate counseling, education, and psychologic support. Psychiatrists be enlisted in plans to manage CBW incidents for their expertise in treati anxiety, fear, panic, somatization, and grief.[16]

Experience with actual or threatened exposures to CBW agents have born these concerns. In Israel during the Gulf War, anxiety-related somatic re to missile attacks were reported in 18â€“38% of persons surveyed,[11] and 500 people sought medical attention in emergency departments for anxie Among 5510 people seeking medical attention after the Tokyo subway sa release, only about 25% were hospitalized.[84] Some of the â€œvictimsâ€• presented days or even weeks after the incident,[63, 68] apparently feeling unwell and thinking they had been exposed.[105]

Uncontrolled release of information may compound terror and increase psychologic casualties. Imagine the influx of patients resulting from a new report suggesting that anyone with dizziness or nausea be checked for ne agent toxicity, or that fever and cough indicate infection with anthrax.

The Israeli Experience During the Gulf War

Israel as a country is probably best prepared for CBW disasters. In late 1

the civilian population was supplied with rubber

gas masks, atropine syringes, and Fuller earth decontamination powder.[7
Israeli hospitals conduct chemical practice drills every 3â€“5 years.[100] Th
drills identify several key lessons, including designating specific hospitals
chemical casualties, blocking hospital access to a single guarded entrance
prevent internal contamination, and extending nurses' authority to initiat
treatment by established protocols. The Israeli plan provides two tiers of
The first triage occurs outside of the hospital by protected medical perso
who perform only life-saving interventions, such as intubation, hemorrha
control, and antidotal therapy. Patients are then decontaminated and ente
hospital. Afterwards, patients are triaged again according to severity of i
into separate areas in which dedicated healthcare teams provide the app
interventions.[79 , 100]

Thirty-nine ballistic missiles with conventional warheads were launched a
Israel from Iraq in early 1991, with only 6 missiles causing direct casualt
Many more â€œinjuriesâ€• resulted from CBW defensive measures and
psychologic stress than from physical trauma. Out of 1060 injuries report
from EDs during this time period, 234 persons were directly wounded in
explosions (most injuries were minor), and there were only 2 fatalities fr
trauma.[37 , 74] Over 200 people presented for medical evaluation after sel
injection of atropine, a few requiring admission to the hospital.[4 , 37 , 74] A
540 people sought care for acute anxiety reactions. Some suffocated from
improperly used gas masks, fell and injured themselves when rushing to
sealed against CBW agents, or were poisoned by carbon monoxide in thes
airtight rooms.[2 , 37 , 74] Increased rates of myocardial infarction and
cerebrovascular accidents were also observed.[74] A survey of hospital staf
members found that only 42% would report for duty following a chemical
weapon attack.[80]

Special Populations

Pregnancy does not appear to be a significant factor in the treatment of
victims of chemical weapons. In the Tokyo subway sarin attack, 5 victims

identified at one hospital as being pregnant. These women were only mild affected and were admitted for observation. All had healthy babies, the fi born 3 weeks after the incident.[63 , 65 , 68] In Israel, no obstetric complic occurred among women wearing gas masks during labor and delivery.[22 ,

Children have important differences from adults regarding chemical weap effects and decontamination efforts. Perhaps the most obvious differences that children breathe at a lower elevation above the ground and at a high than adults. Because nearly all chemical weapon gases and vapors are he than air, children will be exposed to higher concentrations than adults in same exposure setting.[76 , 108] Children may also be more susceptible to vesicants and nerve agents than adults with equivalent exposures.[75 , 108] Children have thinner and more delicate skin, allowing for more systemic absorption and more rapid onset of injury with sulfur mustard. The pedia bloodâ€“brain barrier may also be less resistant than in adults and the a of endogenous detoxifying enzymes, such as paraoxonase, is less, allowin greater toxicity with nerve agents. Additionally, children with organic phosphorus compound poisoning less frequently exhibit a muscarinic toxic syndrome than adults, and often present with isolated CNS depression.[75]

The decontamination of children is another feature that requires an age approach. Children have a larger surface area-to-mass ratio and may be likely to carry a toxic or fatal dose of a chemical weapon on their skin. M children will need assistance and supervision during decontamination procedures; keeping a mother or other adult guardian with a child should with both decontamination and thermoregulation.[76] Neonatal incubators been suggested as improvised chemical weapon protective devices for ve young children in the hospital setting.[23] This suggestion from Israel make tacit assumption, however, that the hospital would be experiencing a pot chemical weapon attack, which is more applicable to a warfare scenario th a response to events occurring outside the hospital.

Nerve Agents

Physical Characteristics and Toxicity

Nerve agents (Figure 126-1) are extremely potent organic phosphorus compound cholinesterase inhibitors, and are the most toxic of the known chemical weapons.[53] For example, sarin is 1000-fold more potent in vitro the pesticide parathion.[85] Aerosol doses causing 50% human mortality (L range from 400 mg-min/m^3 for tabun down to 10 mg-min/m^3 for VX, con to 2500â€“5000 mg-min/m^3 for hydrogen cyanide. Dermal exposure LD_{50} nerve agents range from 1700 mg for sarin down to only 6â€“10 mg for V [85] Pure nerve agents are clear and colorless. Tabun has a faint fruity odo soman has been variably described as smelling sweet, musty, fruity, spic nutty, or like camphor. Most subjects exposed to sarin and VX are unable describe the odor.[49 , 85] The G-agents tabun (GA), sarin (GB), and soman are volatile and present a significant vapor hazard. Sarin is the most vola only slightly less so than water. VX is an oily liquid with low volatility and environmental persistence.[49 , 53 , 85] Other G- and V-agents have been developed but are not discussed here in detail, because the clinical effect treatment options are essentially identical.

Pathophysiology

The pathophysiology of nerve agents is essentially identical to that from phosphorus compound insecticides (Chap. 109), differing only in terms o potency and physical characteristics of the toxins. The resultant toxic syn includes muscarinic (salivation, lacrimation, urination, defecation, GI cra emesis, or SLUDGE syndrome) and nicotinic (muscle fasciculation, weakn paralysis) signs, and central effects (loss of consciousness, seizures, res depression).[32 , 83 , 87]

Clinical Effects

Nerve agent vapor exposures produce rapid effects, within seconds to mi whereas the effects from liquid exposure may be delayed as the agent is absorbed through the skin.[51 , 85] Vapor or aerosol exposures have histor been more common, whether through experiments or from unintentional releases in the laboratory[83] or in terrorist attacks.[56 , 68] Aerosol or vapo exposure initially affects the eyes, nose, and respiratory tract. Miosis is

common, resulting from direct contact of nerve agent with the eye, and r persist for several weeks.[83, 87] Other ocular effects include conjunctival injection and blurring and dimming of the vision. Dim vision is often ascri pupillary constriction, but central neural mechanisms also play a role.[85] C spasm produces ocular pain, headache, nausea, and vomiting, often exac by near-vision accomodation.[32] Rhinorrhea, airway secretions, bronchoconstriction, and dyspnea occur with increasing exposures. With a vapor exposure, 1 or 2 breaths may produce loss of consciousness within seconds, followed by seizures, paralysis, and apnea within minutes.[51]

Military Designation	Common Name	Proper Name	Chemical Formula
GA	Tabun	Ethyl-*N,N*-dimethylphosphoramidocyanidate	GB	Sarin	Isopropyl-methylphosphonofluoridate	GD	Soman	Pinacolyl-methylphoshonofluoridate	VX	-	*O*-Ethyl-*S*-[2-(diisopropylamino)ethyl]-methylphosphonothiolate	
Figure 126-1. Nerve agents.

In the 1995 Tokyo subway sarin incident ocular effects were most commc sarin vapor exposure, with miosis (89â€“99% of symptomatic victims), ey dim vision, and decreased visual acuity.[32, 68] Other common complaints cough, throat tightness, nausea, headache, dizziness, chest discomfort, a abdominal cramping.[50, 94] Among 111 patients admitted to one hospital,

most common presenting signs and symptoms were miosis (99%), heada (74.8%), dyspnea (63.1%), nausea (60.4%), eye pain (45%), blurred vis (39.6%), dim vision (37.8%), and weakness (36.9%).[63, 68] Excessive secretions were less common, with rhinorrhea seen in about one quarter patients admitted at one hospital,[68] and in none of 58 patients at anothe Secondary exposures occurred among emergency medical technicians (EM and hospital personnel in both the Tokyo[50, 61, 63] and Matsumoto[56, 57] terrorist sarin releases, apparently from evaporation of nerve agent that condensed on the primary victims' clothing.

Liquid nerve agents can permeate ordinary clothing, allowing for percuta absorption and rendering patients as potential hazards to healthcare per prior to proper decontamination.[27] Mild dermal exposure produces localiz sweating and muscle fasciculations after an asymptomatic period lasting u 18 hours. Moderate skin exposure produces systemic effects with nausea, vomiting, diarrhea, and generalized weakness. Substantial dermal contar will produce earlier and more severe symptoms, often with abrupt onset. toxicity from any route of exposure causes loss of consciousness, seizure generalized fasciculations, flaccid paralysis, apnea, and/or incontinence.[5, 87] Cardiovascular effects are less predictable, as either bradycardia (mu or tachycardia (nicotinic) may occur.[51] In the Tokyo sarin event, tachyca and hypertension were more common than bradycardia.[59, 94] Subtle CNS effects may continue for weeks, but typically resolve if no anoxic brain ir occurred. Neither delayed peripheral neuropathy nor the intermediate sy have been described in humans exposed to nerve agents.[87, 88] Followup have shown persistent neurologic, neurobehavioral, and electrocardiogra changes,[78, 107] although these studies are limited by small numbers and potential for introducing bias. Psychological sequelae included acute stres reactions in one third of admitted patients[68] and posttraumatic stress disorder.[103, 107]

Treatment of Nerve Agent Exposure

Decontamination

In critically ill patients, antidotal treatment may be necessary before or c the decontamination process; but generally, decontamination should occu before other treatment is instituted.

Atropine

Atropine is the standard anticholinergic antidote for the muscarinic effects nerve agents.[18] Atropine does not reverse nicotinic effects but does have central effects and may thus assist in halting seizure activity.[32 , 49 , 85]

Atropine is administered parenterally, either by the intravenous (IV) or intramuscular (IM) route, and the dose is determined by titration to effec standard adult dose determined by the American military is 2 mg, an am expected to produce substantial benefit in reversing nerve agent toxicity that should be tolerated by an unpoisoned adult unintentionally receiving drug.[85] Current recommendations place the minimum initial dose of atrop adults at 2 mg; dosing in children begins at 0.02 mg/kg, with a minimum mg. Severely poisoned adult patients receive an initial dose of 5â€“6 mg. Repeat doses are given every 2â€“5 minutes until resolution of muscarini of toxicity. Therapeutic endpoints are, drying of respiratory secretions

and resolution of bronchoconstriction, bradycardia, and/or seizures (if in present). Reversal of miosis or development of tachycardia are not reliab markers to guide atropine therapy.[32] The total amount of atropine necess treat nerve agent poisoning is often much less than required for organic phosphorus compound insecticide toxicity of similar degree. Typically, less 20 mg is required in the first 24 hours, even in severe cases.[32 , 85 , 87] F than 20% of moderately ill patients admitted to one hospital for sarin po in Tokyo required more than 2 mg atropine.[68]

American troops in the Gulf War were issued 3 MARK I kits for immediate treatment of nerve agent poisoning. Each kit contains two autoinjectors: AtroPen containing 2 mg of atropine in 0.7 mL diluent, and a ComboPen containing 600 mg of 2-PAM in 2 mL diluent (Survival Technology, Rockv MD).[85] These autoinjectors permit rapid IM injections of antidote through protective clothing and are given in the lateral thigh.[18] Treatment algorit

guided the number of MARK I kits to administer. In general, conscious ca not in severe distress self-administer 1 kit (2 mg atropine), moderate to cases receive 3 kits (6 mg atropine) initially, and all receive additional do necessary, every 5â€“10 minutes.[18,53,85]

In a nerve agent mass casualty incident, a hospital's intravenous atropine supplies may be rapidly depleted. Alternative sources include atropine fro ambulances, ophthalmic and veterinary preparations, or substituting alte antimuscarinic agents, such as glycopyrrolate.[32] Atropine might also be s as a bulk powder formulation and rapidly reconstituted for injection when needed.[26,43]

Oximes

Oximes are nucleophilic compounds that reactivate organic phosphorus compound-inhibited cholinesterase enzymes by removing the dialkylphos moiety. The only oxime approved in the Unites States by the FDA is prali (pyridine-2-aldoxime) chloride, or 2-PAM, a monopyridinium compound. O pralidoxime salts are used elsewhere, such as the methanesulfonate salt pralidoxime (P2S) in the United Kingdom and 2-PAM methiodide in Japan. oximes include the bispyridinium compounds trimedoxime (TMB4) and ob (Toxogenin) used in other European countries.[49,68,85] Oximes should b given in conjunction with atropine, as they are not particularly effective i reversing muscarinic effects when given alone. Oximes are the only nerve antidotes that can reverse the neuromuscular nicotinic effects of fascicul weakness, and flaccid paralysis.

Oximes are effective only if administered before irreversible dealkylation, â€œaging,â€• of the organic phosphorus compound-cholinesterase comp occurs. Soman (GD) has an aging half-life of 2â€“6 minutes in humans.[17] unlikely that soman-poisoned victims will reach medical care early enough oxime therapy to be of great benefit. For comparison, tabun (GA) has an half-life of about 14 hours, sarin (GB) 3â€“5 hours, and VX 48 hours.[17] Pralidoxime is effective against sarin and VX in animal studies but not ag tabun because of ineffective nucleophilic attack against that particular ag and not because of aging issues. Obidoxime also is effective against sarin

not against tabun.[49]

The bispyridinium Hagedorn (H-series) oximes, particularly HI-6 and HLÃ have also been studied in the context of nerve agent toxicity.[49] HI-6 app beneficial against soman poisoning (possibly through direct pharmacologi action and/or reactivation of aged soman-inhibited ChE) but is not very against tabun. HLÃ¶-7 has reactivating activity for both soman- and tabu inhibited ChE and may thus represent a universal oxime antidote for nerv agents. Administration of HI-6 and HLÃ¶-7 by autoinjector is difficult bec they are not stable in aqueous solution.

For more details about pralidoxime administration, dosing, and side effec Antidotes in Depth: Pralidoxime . The ComboPen autoinjector in MARK I k contains 600 mg pralidoxime, which produces a therapeutic maximal plas concentration of 6.5 Âµg/mL in average human subjects.[85] When possible however, pralidoxime is optimally administered IV. Repeat pralidoxime do continuous infusions are less likely to be needed for nerve agents than fo organic phosphorus compound insecticides because severe effects are sh lived in properly decontaminated patients.[32]

Anticonvulsants

Severe human nerve agent toxicity rapidly induces convulsions, which pe a few minutes until the onset of flaccid paralysis. Diazepam has beneficia effects beyond other anticonvulsants and simple Î³-aminobutyric acid (GA channel agonism, including effects on choline transport across the blood barrier and acetylcholine turnover.[49] Current American military doctrine is administer 10 mg diazepam IM by autoinjector at the onset of severe tox whether seizures are present or not. Thus, whenever 3 MARK I kits are u victim is given diazepam as well. Additional autoinjectors are given by m personnel as necessary for seizures.[53] The reason for the IM route of dia suggested above is mostly because of issues of timely administration und conditions. If intravenous access is feasible, IV diazepam in 5-mg doses every 15 minutes (up to 15 mg) is recommended.[49] Although diazepam is most well-studied benzodiazepine in the treatment of nerve agent toxicity medications in the same class (eg, lorazepam, midazolam) should have s

beneficial effects.

Pyridostigmine Pretreatment

The first large-scale use of pyridostigmine as a pretreatment for nerve ag toxicity occurred during Operation Desert Storm.[39] Pyridostigmine is a carbamate acetylcholinesterase inhibitor that is freely and spontaneously reversible, whereas nerve agent inhibition is permanent once â€œagingâ€ occurs. Toxicity from rapidly aging nerve agents such as soman (GD) can probably not be reversed by standard oxime therapy in realistic clinical situations. Almost paradoxically, then, a carbamate can occupy cholinest blocking access of nerve agent to the active site, and thereby protect the enzyme from permanent inhibition. Following nerve agent exposure, pyridostigmine is rapidly hydrolyzed from acetylcholinesterase and can als easily displaced by oximes, regenerating functional enzyme. Between 20% 40% cholinesterase inhibition is desired to protect against nerve agents.[1] milligram doses of pyridostigmine bromide reduces cholinesterase activity 28.4% in healthy individuals. Asthmatics taking 30 mg doses had a mean reduction in cholinesterase activity without significant reductions in resp function or in response to inhaled atropine.[72] In animal studies, pyridost confers a benefit against soman and tabun, but not against sarin or VX.[18] it must be recognized that pyridostigmine is not an antidote, but is instea pretreatment adjunct that greatly enhances the efficacy of atropine and therapy.[27 , 87]

American troops in the Gulf War took 30 mg pyridostigmine bromide orall 8 hours when under threat of nerve agent attack. Cholinergic side effects mostly gastrointestinal, were common but rarely required treatment or discontinuing therapy.[39] Israeli soldiers taking the same dose also report range of

mostly cholinergic symptoms but also a high incidence (71.4%) of dry m which may be more related to environmental and psychological stressors. Israeli patients were hospitalized during the Gulf War for acute intentiona pyridostigmine overdoses.[3] All patients recovered fully, including one pat

who self-treated with atropine autoinjectors and presented with anticholi toxicity and another who suffered cardiac arrest, apparently from coinges 4000 mg propranolol.

Military Designation	Common Name	Proper Name	Chemical Formula
H, HD	Sulfur mustard	Bis-(2-Chloroethyl) sulfide 2,2'-Dichloroethyl sulfide	L	Lewisite	2-Chlorovinyldichloroarsine β-Chlorovinyldichloroarsine	CX	Phosgene oxime	Dichloroformoxime	
Figure 126-2. Vesicants.

Vesicants

Vesicants are agents that cause blistering of skin and mucous membranes (Figure 126-2).

Sulfur Mustard

Sulfur mustard is bis(2-chloroethyl) sulfide, a vesicant alkylating compou similar to nitrogen mustards used in chemotherapy. Nineteenth-century scientists described the compound as smelling like mustard, tasting like and causing blistering of the skin on contact. The Allies of World War I ca Hun Stoffe (German Stuff), abbreviated as HS and later as just H. Distille nearly pure mustard is designated HD. The French called it Yperite, after site where it was first used, and the Germans called it LOST after the two chemists who suggested its use as a chemical weapon, Lommel and Stein was also called â€œyellow crossâ€• after the markings on German artille shells filled with mustard.[10 , 15 , 54 , 89] Sulfur mustard was used by the and Japanese in the 1930s, by Egypt in the 1960s, and by Iraq in the 19

Some Iranian mustard casualties were evacuated to Europe, resulting in a number of recent reports on treatment.[58, 97] Non-battlefield exposures l also occurred among Baltic Sea fishermen while recovering corroding she dumped after WWII[1, 97] and to persons unearthing shells from old battlefields.[77, 89]

Physical Characteristics

Sulfur mustard is a yellow to brown oily liquid with an odor resembling n garlic, or horseradish. Mustard has relatively low volatility and high environmental persistence. Nonetheless, most historical mustard injuries occurred from vapor exposure, a danger that increases in warmer climate Mustard vapor is 5.4 times denser than air. Mustard freezes at 57Â°F (1 so it is sometimes mixed with other substances, including such chemical agents like chloropicrin or Lewisite, to lower the freezing point and permi dispersion as a liquid.[15, 53, 89]

Pathophysiology

Sulfur mustard toxicity occurs through several mechanisms. First, mustard alkylating agent. Mustard spontaneously undergoes intramolecular cycliza form a highly reactive sulfonium ion that alkylates sulfhydryl (-SH) and a NH_2) groups (Figure 126-3).[10, 15, 53, 89] The most important acute manifestation is indirect inhibition of glycolysis. Sulfur mustard rapidly a and crosslinks purine bases in nucleic acids. DNA repair mechanisms are activated, depleting NAD^+ , which in turn inhibits glycolysis, and ultimate leads to cellular necrosis from adenosine triphosphate (ATP) depletion.[10] Mustard also depletes glutathione, leading to loss of protection against o stress, dysregulation of calcium homeostasis, and further inactivation of sulfhydryl-containing enzymes.[89] Sulfur mustard is also a weak cholinerg agonist.[53, 89]

Clinical Effects

The organs most commonly affected by mustard are the eyes, skin, and respiratory tract. During WWI, 80â€“90% of American mustard casualties

cutaneous lesions, 86% had ocular involvement, and 75% had airway inj
Iranian soldiers treated in Europe had more airway (95%) and ocular inju
(92%), and 83% had cutaneous lesions, probably because of the more e
vaporization occurring in the warmer environment.[10 , 89] Incapacitation m
severe in terms of number of lost man-days, time for

lesions to heal, and increased risk of infection. In contrast, mortality is r
low. In WWI, only 2â€“3% of British mustard casualties and fewer than 2
American casualties died. Fatality rates of 3â€“4% were reported from th
Iraq War.[10 , 54] Most deaths occur several days after exposure, either fro
respiratory failure, secondary bacterial pneumonia, or bone marrow supp

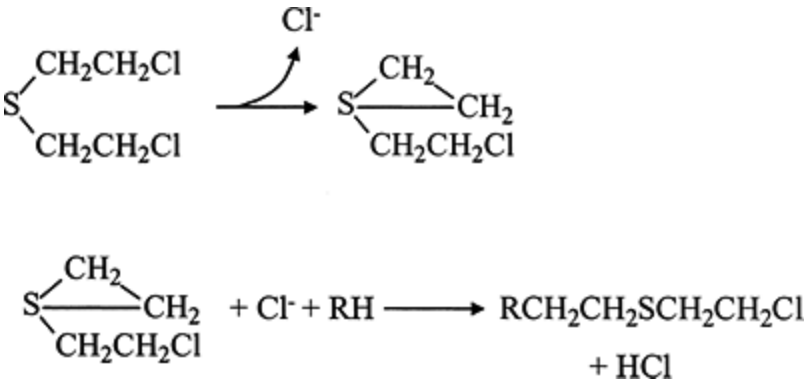

Figure 126-3. Mechanism of sulfur mustard toxicity.

Dermal exposure produces dose-related injury. After a latent period of 4
hours, victims develop erythema that may progress to vesicle and/or bull
formation and skin necrosis. Warm, moist, and thin skin is at increased ri
mustard injury, in particular the perineum, scrotum, axillae, antecubital
and neck. The vesicle fluid does not contain mustard because all chemica
reactions are complete within a few minutes.[54] If decontamination is not
performed immediately after exposure, injury can not be prevented. Late
decontamination may, however, limit the severity of lesions and further
of the agent. Skin exposure to vapor typically results in first- or second-
burns, although liquid exposure may result in full-thickness burns.[89] Mus
easily penetrates normal clothing and uniforms, and many soldiers receiv
gluteal, perineal, and scrotal burns from sitting on contaminated objects.

dermal effects include changes in pigmentation, increased incidence of melanocytic nevi and cherry angiomas, and the development of chronic neuropathic symptoms in mustard burned areas.[15, 24, 89, 97]

Latency of several hours also occurs following ocular and respiratory trac exposures. Ocular effects include pain, miosis, photophobia, lacrimation, vision, blepharospasm, and corneal damage. Permanent blindness is rare, recovery generally occurring within a few weeks. Inhalation of mustard r in a chemical tracheobronchitis. Hoarseness, cough, sore throat, and ches pressure are common initial complaints. Bronchospasm and obstruction fr sloughed membranes occur in more serious cases, but lung parenchymal damage only occurs in the most severe inhalational exposures. Productive associated with fever and leukocytosis is common 12â€“24 hours after exposure, and represents a sterile bronchitis or pneumonitis. Nausea and vomiting are common within the first few hours. High-dose exposures ma cause bone marrow suppression.[10, 15, 53, 89]

Various long-term sequelae have been associated with sulfur mustard. Fa workers chronically exposed to mustard have increased risk of respiratory carcinomas, although no clear association is demonstrated for battlefield exposures.[88] Chronic respiratory sequelae include chronic bronchitis, bronchiectasis, pulmonary fibrosis, interstitial lung disease, emphysema, bronchiolitis obliterans.[5, 96] A delayed keratitis may also occur, sometim many years after ocular exposure, along with the skin changes noted abo Among the approximately 34,000 Iranians with confirmed exposure to su mustard during the war with Iraq, chronic pulmonary sequelae were noted 42.5%, ocular lesions in 39.3%, and dermatologic lesions in 24.5%.[42]

Treatment

Decontamination is essential in treating the sulfur mustard exposures, ev among asymptomatic victims. In addition to previously described decontamination regimens, animal data suggests that topical iodine prep (eg, povidone-iodine ointment) may be beneficial in decontaminating the from sulfur mustard,[106] although human clinical experience is currently l

Further treatment is largely supportive and symptomatic. Military

recommendations are to keep skin lesions clean and to treat with topical antibiotics. Small blisters (<1 cm) need not be dÃ©brided, but larger bul should be unroofed. Fluid losses tend to be less than from thermal burns. healing can take weeks to months, although skin grafting is rarely neces Ophthalmic injuries usually heal completely with routine chemical burn ca Victims may become blinded because of a combination of blepharospasm corneal edema, which completely resolves in most cases; patients should informed that this condition is very likely temporary.[34] Severe eye injurie require topical mydriatics, anesthetics, and petroleum jelly to prevent fo of lid synechiae. Respiratory tract injuries are treated with antitussives, bronchodilators, mucolytics, and oxygen supplementation as needed. An should be reserved until there is confirmation of a bacterial pathogen. Ea intubation should be considered for severe airway involvement to assist i ventilation, provide positive airway pressures, and facilitate bronchoscop removal of pseudomembranes and debris.[10 , 53 , 89] Several antiinflamma and sulfhydryl-scavenging agents have shown benefit in animals as prop therapy (or if given immediately after exposure), but there are no data to support their use after injury has occurred.[89] Mustard-induced neutropenia be treated with granulocyte colony-stimulating factor.[52]

Lewisite

Lewisite (2-chlorovinyldichloroarsine) was developed to avoid some shortcomings in the use of sulfur mustard in World War I. It was difficult stage attacks across mustard-contaminated ground, and a less persistent alternative was desired. US Army Captain W. L. Lewis isolated this chemic pure form in 1918. Lewisite was never used in combat because the first shipment was en route to Europe when the war ended, and it was intenti destroyed at sea. British anti-Lewisite (BAL, dimercaprol) was developed a specific antidotal agent and remains in use for chelation of arsenic and o heavy metals.[49 , 89]

Pure Lewisite is an oily, colorless liquid. Impure preparations are colored amber to blue-black to black and have the odor of geraniums. Lewisite is volatile than mustard and is easily hydrolyzed by water and by alkaline a

solutions such as sodium hypochlorite. These properties increase safety f offensive battlefield use, but make maintaining a potent vapor concentra difficult.

Lewisite toxicity is similar to that of sulfur mustard, resulting in dermal a mucous membrane damage, with conjunctivitis, airway injury, and vesicu An important clinical distinction is that Lewisite is immediately painful, w initial contact with mustard is not. Other differences are faster onset of inflammatory response and healing of lesions from Lewisite, less seconda infection of Lewisite lesions, and less subsequent pigmentation changes.[8] mechanisms of Lewisite toxicity are not completely known, but appear to glutathione depletion and arsenical interaction with enzyme sulfhydryl gr Nevertheless, Lewisite toxicity is qualitatively and quantitatively different the arsenic it contains. Treatment consists of decontamination with copio water and/or dilute hypochlorite solution, supportive care, and BAL. BAL parenterally for systemic toxicity and is also used topically for dermal or ophthalmic injuries. Alternative heavy metal chelators that may be used a Lewisite antidotes include dimercaptopropane sulfonate (DMPS) and succ (2,3-dimercaptosuccinic acid).[49]

Phosgene Oxime

Although classified as a vesicant, phosgene oxime (dichloroformoxime, or does not cause vesiculation of the skin. CX is more properly an urticant o â€œnettleâ€• agent, in that it produces erythema, wheals, and urticaria to stinging

nettles. Phosgene oxime produces immediate irritation of the skin and m membranes. CX has never been used in battle, and little is known about mechanism or effects on humans.[53 , 89]

Cyanides (Blood Agents)

Several cyanides have been used as chemical weapons. During World War French used hydrogen cyanide (HCN) and cyanogen chloride (CNCl), desi as agents AC and CK respectively, without great success; the Austrians

introduced cyanogen bromide (CNBr). Cyanide weapons are relatively in
because of rapid dispersion and their â€œall or nothingâ€• biological ac
An exposed individual either rapidly succumbs to cyanide toxicity, or will
recover with minimal sequelae. Mass casualty events from cyanide CW ag
have been reported during the Iran-Iraq War and from Iraq's suppression
Kurds.[6 , 53]

The cyanides have been called â€œblood agentsâ€• based on the under
early in the 20th century that they were carried in the blood to exert sys
toxicity, whereas the other known chemical weapon agents produced loca
effects. This term is now antiquated because sulfur mustard and nerve a
can be carried in the blood and because the target of cyanide toxicity is
respiration in the mitochondria. The clinical effects and treatment of cyan
toxicity are covered elsewhere (Chap. 121) and do not differ significantly
used as a weapon. Hydrocyanic acid gas persists for only a few minutes i
atmosphere, because it is lighter than air and rapidly disperses. Cyanoge
chloride additionally causes ophthalmic and respiratory tract irritation and
produce delayed acute lung injury in victims who are not rapidly killed.[6 ,

Pulmonary Agents

Both chlorine (agent CL) and phosgene (agent CG) were used as war gase
World War I. Chlorine, phosgene, various organohalides, and nitrogen ox
belong to a group of toxic chemicals designated â€œpulmonary agentsâ€
because they can all induce delayed pulmonary edema from increased al
capillary membrane permeability.[49 , 53 , 101] Although pulmonary agents
not been used militarily since 1918, the risk of chlorine and phosgene ex
remains because of their extensive use in industry, or possibly as a terro
weapon. See Chap. 119 for clinical details, as the remainder of this sectio
highlights mass-casualty issues regarding these agents.

When released on the battlefield, chlorine forms a yellow-green cloud with
distinct pungent odor detectable at levels that are not immediately dange
Phosgene is either colorless or seen as a white cloud as a result of atmos
hydrolysis. Phosgene is reported to smell like grass, sweet newly mown h
corn, or like moldy hay. Although sulfur mustard was known as the â€œki

war gases,â€• [10] phosgene accounted for about 85% of all WWI deaths attributed to chemical weapons.[49] Phosgene produces injury by hydrolysis lungs to hydrochloric acid and by forming diamides that cross-link cell components (Figure 126-4). Battlefield exposure triggers cough, chest discomfort, dyspnea, lacrimation, and the peculiar complaint that smokin tobacco produces an objectionable taste. WWI phosgene fatalities were n develop a mushroom-shaped efflux of pink foam at their mouths from pu edema fluid. Prolonged observation after phosgene exposure is the rule, some casualties have initially appeared well and have been discharged, o return in severe respiratory distress a few hours later.[49 , 53 , 101]

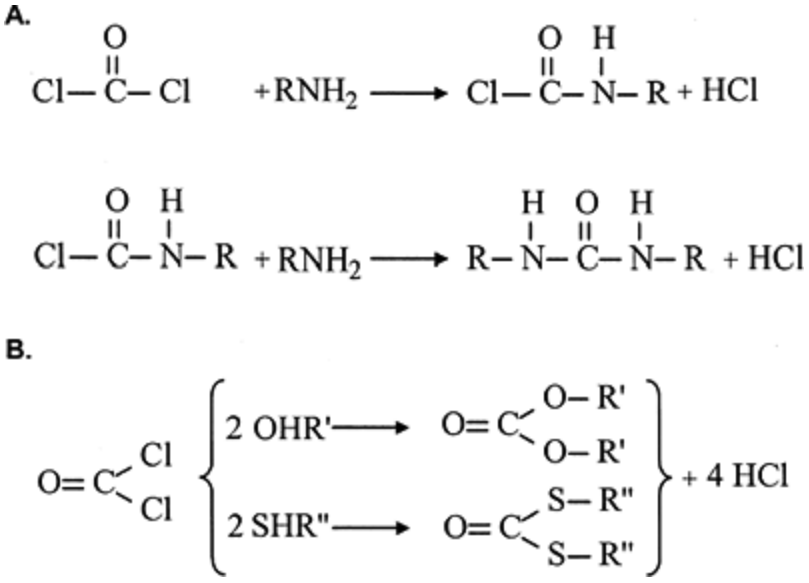

Figure 126-4. Proposed mechanisms of phosgene toxicity. A . Phosgene crosslinks two amine equivalents, forming a diamide and HCI. B . Similar crosslinking reactions occur with hydroxyl and thiol groups.

Riot Control Agents

Riot control agents (Figure 126-5) are intentionally nonlethal xenobiotics temporarily disable exposed individuals through intense irritation of expo mucous membranes and skin. These xenobiotics are also known as lacrin irritants, harassing agents, human repellents, and tear gas.[33] They are s

normal temperatures and pressures, but are typically dispersed as aeroso as small solid particles in liquid sprays. Common characteristics include r onset of effects within seconds to minutes, relatively brief duration once exposure has ceased and the victim is decontaminated, and a high safety (lethal dose vs. effective dose).[49 , 53 , 86]

CN (chloroacetophenone) has been widely used since WWI. CN is the acti ingredient in the Chemical Mace brand nonlethal weapon originally produc 1965 by the General Ordinance Equipment Company, later a division of S Wesson.[93] CS (o-chlorobenzilidene malononitrile) has largely replaced CN because of its higher potency, lower toxicity, and improved chemical stal [, 45 , 86] When used for crowd control, both CN and CS are disseminated a aerosols or as smoke from incendiary devices. Exposed persons develop irritation of the eyes, progressing to conjunctival injection, lacrimation, photophobia, and blepharospasm. Mucous membranes of the upper aero tracts can also be involved. Inhalation causes chest tightness, cough, sn and increased secretions. Dermal exposure may cause a burning sensatio erythema, or vesiculation, depending on the dose. Victims generally rem themselves from the offensive environment and recover within 15â€“30 Deaths are rare from riot control agents, and typically occur from respira tract complications in closed-space exposures where exiting the area is impossible.[49 , 53 , 86]

Personal protective devices dispensing lacrimator substances also cause chemical injuries in the absence of war or civil unrest. Law enforcement agencies and private citizens may have access to products containing CS, and/or OC (oleoresin capsicum, or pepper spray). OC is the essential oil from pepper plants (*Capsicum anuum* species) which contains capsaicin (8-methyl-N-vanillyl-6-noneamide), a naturally occurring lacrimator. Caps activates heat-dependent nociceptors, explaining why exposures are experienced as â€œhot.â€• [12] Severe respiratory tract injuries and fatali occasionally reported from exposures to these devices.[91 , 102]

Chloropicrin (trichloronitromethane or nitrochloroform) is another lacrima previously used as a CW agent that occasionally causes human toxicity by

use as a fumigant and soil insecticide.[95] DM (10-chloro-5,10-dihydrodiphenarsazine, or diphenylaminearsine) is a vomiting agent. Clin effects are delayed for several minutes after exposure, by which time the may have absorbed a significant amount. In addition to upper respiratory ocular irritation, DM causes more prolonged systemic effects with headac malaise, nausea, and vomiting.[53 , 86]

Military Designation	Common Name	Proper Name	Chemical Formula
CN	Chemical mace	1-Chloroacetophenone 2-Chloroacetophenone 2-Chloro-1-phenylethanone	CS	Tear gas	O-Chlorobenzylidene malonitrile 2-Chlorobenzalmalonitrile	DM	Adamsite	10-Chloro-5,10-dihydrophenarsazine Diphenylaminechlorarsine	OC	Pepper spray, capsaicin	*trans*-8-Methyl-*N*-vanillyl-6-noneamide Oleoresin capsicum	
Figure 126-5. Riot control agents.

The primary treatment for all riot control agents is removal from exposur Contaminated clothing should be removed and placed in airtight bags to secondary exposures.[45] Skin irrigation with copious cold water is used fo significant dermal exposures.[8 , 45 , 46] Symptomatic treatments, such as topical ophthalmic anesthetics, nebulized bronchodilators, or oral antihis and corticosteroids, are indicated as appropriate in more severely affecte victims.[8] Capsaicin-induced dermatitis has been treated variably with im in water or oil, vinegar, bleach, lidocaine gel, and topical antacid suspen [, 35 , 93] Cold water produces earlier symptomatic relief, but oil immersion longer-lasting benefit.[35]

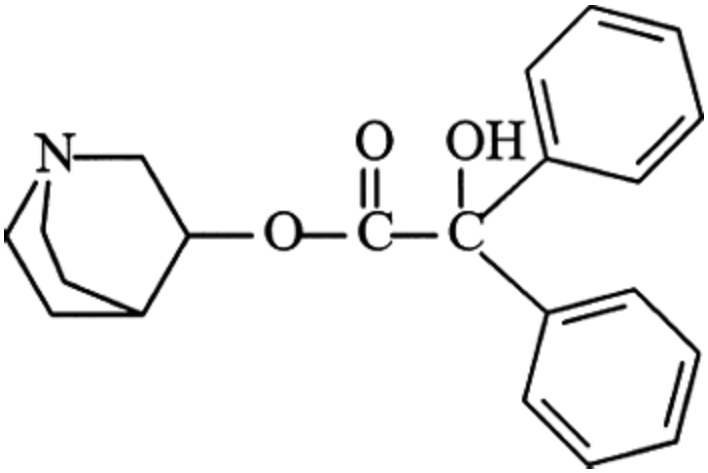

Figure 126-6. Incapacitating agent BZ (3-Quinuclidinyl benzilate, QNB).

Incapacitating Agents

3-Quinuclidinyl benzilate (BZ or QNB; Figure 126-6) is an antimuscarinic compound that has been developed as an incapacitating CW agent. BZ is more potent centrally than atropine, with an ID_{50} (dose that incapacitates of those exposed) of about 0.5 mg. Clinical effects are characteristic for anticholinergics, with drowsiness, poor coordination, and slowing of thou processes progressing to delirium. BZ takes at least an hour to produce manifestations, peaks at 8 hours, continues to incapacitate for 24 hours, takes 2â€“3 days to fully resolve.[41] During the recent Balkan wars, alleg were made that Bosnian Serbs used BZ against civilians, who reported hallucinations associated with attacks by artillery shells emitting smoke.[2]

Ultra-potent opioids may also be used as incapacitating CW agents. In 20 Russian security forces used a fentanyl derivative (possibly carfentanil or remifentanil) to end a 3-day standoff with terrorists in a Moscow theater which Chechen rebels held more than 800 hostages.[104] A â€œgasâ€• wa introduced into the theater ventilation system, which quickly subdued the occupants. Over 650 of the hostages were hospitalized, and 128 died. In news reports suggested the use of BZ, although the clinical findings were consistent with a CNS depressant. Within a few days, Russian officials sta that the agent used was a fentanyl derivative and was not expected to ca

fatalities. The relatively high case fatality rate could be because of multip factors, including variability in dose, displacement of oxygen by rapid introduction of gas into the building, failure to adequately notify healthca teams and supply them with antidotes, and poor physical condition of the hostages.

Lysergic acid diethylamide (LSD) has also been investigated as an incapa agent.[41] Table 126-5 describes the various toxic syndromes that may be from use of CW agents.

Summary

Unconventional weapons of mass destruction continue to pose a threat to safety. Chemical and biologic weapons releases are considered more likely occur than thermonuclear weapons incidents, as CBW agents use resourc subject to less governmental control and requires less sophisticated tech and financial outlay than nuclear weapons. CBW agents are appealing to terrorist groups because the impact in terms of death, disability, econom losses, and panic remain high. The psychological impact of CBW terrorism well exceed that for conventional or nuclear weapons. Although the prob of incidents resulting in widespread public health disasters appears low, t consequences are high, and substantial preparations must be made in ad Smaller CBW incidents, unintentional releases, and hoaxes have occurred will probably continue to occur. Toxicologists and associated healthcare professionals occupy a unique position to impact preparedness and respo through familiarity with chemical hazards and biologic toxins.

Nerve Agents
Tabun (GA),

Sarin (GB) Soman (GD), VX

â€¢
Aerosol/vapor (Mild/moderate exposure)
Rapid (sec-mins)
Miosis, eye pain, dim or blurred vision
Rhinorrhea, â†‘secretions
Dyspnea, cough, wheezing, bronchorrhea
â€”
Headache
Nausea, vomiting, abdominal cramps
â€”
â€¢
Dermal exposure (Mild/moderate exposure)
Delayed (min-hrs)
â€”
â€”
â€”
Localized sweating
â€”
Nausea, vomiting, diarrhea, cramping
Subjective weakness local muscle fasciculations
â€¢
Severe exposure (Any route)
As above (by route)
Miosis
â†‘Secretions
Apnea
â€”
Sudden collapse, seizures
Incontinence
generalized fasciculations, weakness, flaccid paralysis
Vesicants
Sulfur Mustard (H, HD)
Delayed (hrs)
Conjunctivitis, pain, blurred vision, blindness (temporary)

Irritation, hoarseness barky cough, sinus tenderness tracheobronchitis
(More severe exposures) Productive cough, pseudomembrane formation, obstruction
Erythema, vesicles, bullae, necrosis
â€”
Nausea, vomiting
Bone marrow suppression (in severe exposures)
Lewisite (L)
Immediate irritation Delayed vesication
Pain, blepharospasm conjunctivitis, lid edema
(Same as Sulfur Mustard)
(Same as Sulfur Mustard)
Erythema, vesicles
â€”
â€”
Shock (in severe exposures)
Phosgene Oxime (CX)
Immediate irritation Delayed urtication
Pain, corneal damage
Irritation
Acute lung injury
Pain blanching, erythema, urticaria Necrosis
â€”
â€”
â€”
Pulmonary Agents
Phosgene (CG), Chlorine (CL)
Immediate Irritation Delayed ALI
Irritation
Irritation stridor (Chlorine)
Dyspnea, cough Acute lung injury
â€”
â€”
â€”

Chlorine effects more rapid than phosgene
Cyanides
Hydrogen Cyanide (AC)
Rapid (sec-mins)
â€”
â€”
Hyperpnea then apnea
â€”
Anxiety, agitation, sudden collapse, seizures
â€”
â€”
Cyanogen Chloride (CK)
Rapid (sec-mins)
Irritation
Irritation
Hyperpnea then apnea
â€”
Anxiety, agitation, sudden collapse, seizures
â€”
â€”
Riot Control Agents
Lacrimators (CN, CS) Capsaicin (OC)
Immediate
Pain, lacrimation, blepharospasm conjunctivitis
Irritation
Cough, chest pain
Burning pain, erythema Vesiculation severe exposures
â€”
Nausea, retching (may occur with CN/CS)
â€”
Adamsite (DM)
Rapid (min)
Irritation
Irritation, sneezing

Cough, chest pain
â€”
Headache
Nausea, vomiting, abdominal cramps
â€”
Incapacitating Agent
3-quinuclidinyl benzilate (BZ)
Delayed (hrs)
Mydriasis
Dry mouth
â€”
â€”
Anticholinergic delirium
â€”
â€”
Ultra-potent opioids
Rapid (sec-min)
Miosis
â€”
Hypoventilation
â€”
CNS depression

Chapter 127
Biological Weapons

Jeffrey R. Suchard

On March 10, 1998, when employees at a collection agency in Phoenix, A opened an envelope containing a payment for $53.99, some granular ma and a threatening note were found. The letter read, â€œYou S.O.B.!!!! Yo just been exposed to anthrax spores prepare to die â€¦ you better have a ready â€¦ Also a standard pestelence [sic] has been put on you and your â€¦.â€•[86] After a 911 call, police and a fire department hazmat team re to the scene. Little useful information was immediately available regardin kind of decontamination or treatment would be necessary, leading the potentially exposed employees to believe they were destined to develop a rapidly fatal illness. Nine employees and one police officer were quarantir several nearby businesses were evacuated while a decontamination showe constructed at the scene.[87] The victims were transported to a local hospi emergency department (ED), where they were examined, advised to retur they developed influenza-like symptoms, and given prescriptions for ciprofloxacin. However, their clothes, wallets, and purses were still in quarantine, making it difficult for the victims to fill these potentially life- prescriptions. The perpetrator was identified and apprehended from retur address information accompanying the payment. He was indicted 2 days

charges of mailing threatening communications and threatening to use w of mass destruction. Within 4 days, bacteriologic testing of the envelope letter excluded the presence of *Bacillus anthracis* ; the granular material believed to be salt and pepper.[53 , 86]

Expertise in dealing with biological weapons requires specific knowledge the fields of infectious disease, epidemiology, toxicology, and public heal Biological and chemical warfare agents share many characteristics in com including intent of use, some dispersion methods, and initial defense base adequate personal protective equipment and decontamination (see Tables and 126-2). Key differences between biological and chemical weapons h involve a greater delay in onset of clinical symptoms after exposure, that incubation period for biological warfare (CBW) agents is greater than the period for chemical warfare agents, and that decontamination is less cruc victims exposed to BW agents than to CW agents. Additionally, a few BW can reproduce in the human host and cause secondary casualties, and di following exposure to several of these agents can be prevented by the ti administration of prophylactic medications.

Biological weapons may be bacteria, viruses, or toxins derived from microorganisms. Some fungi are listed as potential BW agents, although t none are known to have been developed into weapons.[96] Because toxin w do not contain living organisms, some authorities classify them as chemi rather than biological, weapons. For the purposes of discussion in this ch toxin weapons derived from microorganisms will be considered biological weapons. Of note to toxicologists, most of the bacterial BW agents exert effects through toxins they elaborate.

Most of the diseases caused by biological weapons are either infrequently encountered in modern clinical medicine, such as anthrax and plague, or longer occur naturally, such as smallpox. Physicians and other healthcare personnel therefore require specific training in the recognition and mana of biological warfare victims. Potential BW agents have been categorized risk of mass-casualty outbreaks resulting from deployment and exposure. high-risk agents are easily disseminated or transmitted and may cause hi mortality and potentially a public health disaster; these agents include s

anthrax, plague, botulism, tularemia, and several hemorrhagic fever viru The moderate-risk agents include Q fever, brucellosis, the equine encepl viruses, ricin, and staphylococcal enterotoxin B, all of which are discussed this chapter.

History

Biological warfare has ancient roots. Missile-type weapons poisoned with toxins were used as early as 18,000 years ago (Chap. 1). Recent excava an Egyptian tomb, from about 2100 BC, yielded arrows coated with cardi steroids and paralytic toxins.[68] Around 600 BC, the Athenians used helle and the Assyrians used ergot alkaloids, to poison enemy water supplies.[6] 200 BC, the Carthaginian general Maharbal tainted wine consumed by Af rebel forces with the anticholinergic herb mandragora and then ambushed intoxicated troops. In 184 B.C., Hannibal ordered earthen pots filled with â€œserpents of every kindâ€• hurled onto enemy ships, thereby winning naval battle of Eurymedon against King Eumenes of Pergamon.[28 , 49 , 83] B.C., King Mithridates VI of Pontus was retreating from the Roman Gener Pompey near Trebizond, modern northeast Turkey. At the advice of a ph counselor, Mithridates maneuvered Pompey's troops into a region where honey was contaminated with grayanotoxins from rhododendron nectar. Romans ate the poisoned honey and were effectively ambushed.[52]

From 1344 to 1346 AD, the Tartars besieged the Genoan trade city of Kaf the Black Sea coast. When the Tartars began to die

of bubonic plague, the dead bodies were hurled over the battlements. Wi city, plague forced the Genoans to flee, and they then disseminated the to other trade ports and eventually to the rest of Europe, causing the Bla Death.[98] In 1763, Sir Jeffrey Amherst, the commander of British forces d the French and Indian War, instituted a policy of spreading smallpox to N Americans by giving them contaminated blankets and handkerchiefs.[22 , 7]

During World War I, Germany was the only combatant nation with an acti program. German agents infected Allied livestock with anthrax and gland Eighty years after the capture of a German device used to disseminate a

viable spores were recovered.[75]

Shiro Ishii, a Japanese army doctor, headed an active BW program throu Japan's war with China and World War II.[38] Several centers were founded most famous being Unit 731 in Manchuria, where human experiments on prisoners-of-war and imprisoned civilians occurred. Several field trials wi bubonic plague were performed on Chinese civilians and Russian troops. Soviets Union, Germany, France, Britain, and Canada all started BW rese facilities in the period between the World Wars.

BW research program in the United States was founded at Camp Detrick, Maryland in 1942. Fort Detrick, as it is now known, remains the home of United States Army Medical Research Institute of Infectious Diseases (USAMRIID). Anthrax and botulinum toxin were the foci of weapons deve during WWII; it is estimated that the United States could have manufactu 1,000,000 anthrax bombs and 275,000 botulinum bombs by 1945 had fu production been implemented.[4]

The British BW program was established in 1940 at Porton Down, but mos the field testing of anthrax occurred on Gruinard Island off the northern c Scotland.[66] In 1979, the soil was still found to be contaminated with viab anthrax spores.[54] The island was decontaminated with 5% formaldehyde water, and was deemed safe by the British government in 1988.[1]

During the Cold War, the US military maintained active research into bio weapons, including field trials with bacterial simulants. In 1950, ships in Francisco harbor released aerosols of *Serratia marcesans* and other simu which resulted in a minor outbreak of Serratia sepsis. In 1966, light bulb with *Bacillus subtilis* var *globigii* were shattered in the New York City sub system, confirming the hypothesis that the piston-like action of the subw trains could rapidly disperse the bacterial aerosol throughout the city.[22] , , 78

In London, in 1978, the Bulgarian exile Georgi Markov was assassinated b tiny metal pellet fired from a gun designed to appear like an umbrella. He thought to have died from sepsis until the pellet was found at autopsy.[23] After the fall of the Soviet Union, government officials confirmed that the

used umbrella guns firing ricin pellets to assassinate Markov and others.

In 1979, an outbreak of human anthrax caused at least 66 fatalities in th Russian city of Sverdlovsk. Soviet officials first blamed the outbreak on gastrointestinal anthrax from a shipment of contaminated meat.[55] Autops however, revealed that the deaths were from inhalational anthrax, and epidemiologic investigation demonstrated that almost all of the cases occ downwind from a military facility. These data are consistent only with a of aerosolized anthrax, which has since been confirmed by Russian autho

In the late 1970s and early 1980s, many reports came from Southeast As Afghanistan that Soviet-supported troops were using a biological weapon as Yellow Rain.[39] Some samples of Yellow Rain were found to contain trichothecene mycotoxins, although controversy remains regarding wheth finding represents intentional biological warfare or a naturally occurring phenomenon.[70]

During the 1990s there was a great deal of concern about the use and po stockpiling of weapons of mass destruction by Saddam Hussein in Iraq.[51] part of the WMD program, Iraq had a very active BW research program, investigating at least 5 bacteria, 1 fungus, 5 viruses, 4 toxins, simulants, variety of dispersion methods.[81 , 99] Thousands of liters of anthrax spore botulinum toxin, and aflatoxin were produced and weaponized into bombs payloads for SCUD missiles.

Biological terrorism and the threat of bioterrorism are now recognized as worldwide, growing public health concerns.[40] In the US in 1984, a large outbreak of salmonellosis was traced to intentional contamination of rest salad bars by the Rajneeshee cult in Oregon.[91] The Aum Shinrikyo cult ba Japan investigated the use of cholera and Q fever, unsuccessfully release anthrax spores and botulinum toxin, and even sent members to Africa to the Ebola virus.[71 , 89] The mere threat of biologic agent release can terro city. At the end of the 1990s, there was a huge increase in false anthrax threats, which paralyzed Los Angeles and cities in Indiana, Kentucky, and Tennessee among many others.[11] Because of heightened concern for bioterrorism, even naturally occurring disease outbreaks have raised sus of biological terrorism. In 1999, an outbreak of West Nile-like virus ence

in New York and a case of brucellosis in New Hampshire acquired under suspicious circumstances were investigated as potential BW agent release[76] Similarly, a 1999â€“2000 epidemic of tularemia in war-torn Kosovo wa scrutinized as the potential result of an intentional BW agent release.[37]

General Considerations

Differences Between BW Incidents and Naturally Occurring Outbreaks

Because the clinical effects of bioweapons are delayed, as may be the symptoms, it can be difficult to differentiate occult BW releases from nat occurring disease outbreaks. Several epidemiologic criteria are proposed t in such determinations,[69] at least several of which should be identifiable i incident (Table 127-1).

To avoid early detection, terrorists might choose to release an endemic infection, or a disease that mimics an endemic infection, during its seasor peak incidence. In some areas of the United States, for example, a few ca bubonic plague would not attract notice; that is, until dozens or hundreds cases were identified. An outbreak of inhalational anthrax during the infl season may similarly be hidden amongst patients with identical early syn until an unusually high mortality was evident.[20] By the time the BW outb recognized for what it truly is, the perpetrators could dispose of any phys evidence and flee the area. On the other hand, even a single case of sma (anywhere in the world), Ebola virus infection, or Congo-Crimean hemorr fever (in nonendemic areas) would immediately raise suspicion of a BW a

Preparation

Many BW agents initially produce nonspecific symptoms of diseases, rarely ever seen in clinical practice. Inhalational anthrax

and pneumonic plague, for example, could easily be misdiagnosed as infl or acute bronchitis. Providers in EDs and primary care medicine must be

educated to recognize the signs, symptoms, and clinical progression of d caused by BW agents.[77 , 94] Clear identification, isolation, and aggressive treatment early after exposure within the first 24â€“48 hours are the bes only means of reducing mortality and, in the case of smallpox or plague, preventing secondary or tertiary cases.[27] However, even with increasing awareness and educational efforts, many physicians remain inadequately prepared. As recently as 1999, only 53% of surveyed emergency medicin residencies included formal training in BW issues, with more than 70% of residency directors rating themselves as less than adequate or very poor recognizing BW casualties.[72]

- Large epidemic with unusually high morbidity and/or mortality
- Epidemic curve (number of cases versus time) showing an â€œexplos of cases, reflecting a point source in time rather than insidious onset
- Tight geographic localization of cases, especially downwind of potenti release site
- Predominance of respiratory tract symptoms because most BW agents contracted by aerosol inhalation
- Simultaneous outbreaks of multiple unusual diseases
- Immunosuppressed and elderly persons more susceptible
- Nonendemic infection (â€œimpossible epidemiologyâ€•)
- Unseasonal time for endemic infection
- Organisms with unusual antimicrobial resistance patterns, reflecting E genetic engineering
- Animal casualties from same disease outbreak
- Absence of normal zoonotic disease host
- Low attack rates among persons incidentally working in areas with fil air supplies or closed ventilation systems, using HEPA masks, or rem indoors during outdoor exposures
- Delivery vehicle or munitions discovered
- Law enforcement or military intelligence information
- Claim of BW release by belligerent force

TABLE 127-1. Epidemiologic Clues Suggesting Bioweapons Releas

Decontamination

Biological warfare agents are most effective when dispersed by aerosol. after a known or suspected release of bioaerosols, decontamination is a relatively minor concern, because aerosols sized to reach the lower resp tract (<5 Âµm particles) produce little surface contamination. However, s removal of clothing will eliminate a high proportion of deposited particles, subsequent showering with soap and water will probably remove 99.99% remaining organisms on the skin.[48] Thus, decontamination after BW aero exposure, when needed, is achieved through disrobing and showering wit and water, which can be done on-site or in the victims' homes and away healthcare facilities, thereby reducing strain on disaster response manpov material in multiple-victim exposures.[27 , 40 , 48 , 77] When there is gross, evidence of skin exposure to biological agents, the patient should be decontaminated by thorough irrigation, and, if available, sterilizing the sk a sporicidal/bactericidal solution (eg, 0.5% sodium hypochlorite), and a f water rinse.[48 , 77] After occult bioweapons releases, victims are identified after exposure; decontamination will obviously not be helpful and may or serve to delay care.

Biological Warfare Agents

Bacteria

Anthrax

Anthrax is caused by *Bacillus anthracis* , a Gram-positive spore-forming found in soil worldwide. *B. anthracis* causes disease primarily in herbivor animals. Human anthrax cases generally occur in farmers, ranchers, and workers handling contaminated animal carcasses, hides, wool, hair, and bones.[35] Details regarding the 2001 bioterrorist anthrax outbreak in the

States are given below.

Clinical Manifestations

A few clinically distinct forms of anthrax may occur, depending on the rou exposure. Cutaneous anthrax results from direct inoculation of spores into skin via abrasions or other wounds and accounts for about 95% of endem (naturally occurring) human cases. Patients develop a painless red macule vesiculates, ulcerates, and forms a 1â€“5-cm brown-black eschar surroun edema.[58] The eschar color gave rise to the name anthrax, from the Greek *anthrakos* meaning â€œcoal.â€• Most skin lesions heal spontaneously, a 10â€“20% of untreated patients progress to septicemia and death. Cutan anthrax fatalities are uncommon when treated with antibiotic therapy.

Gastrointestinal anthrax results from ingesting insufficiently cooked meat infected animals. Patients develop nausea, vomiting, fever, abdominal pai mucosal ulcers, which can cause GI hemorrhage, perforation, and sepsis. Mortality from gastrointestinal anthrax is at least 50%, even with antibio treatment.[35 , 62]

Inhalational anthrax results from exposure to aerosolized *B. anthracis* sp Although this form of anthrax is very rare, it is so closely associated with occupational exposures that it has been called â€œwoolsorter's disease.â Inhalational anthrax is also likely to be the form that occurs in a BW atta because the anthrax spores would be most effectively disseminated by a After an incubation period of 1â€“6 days, the patient develops fever, ma fatigue, nonproductive cough, and mild chest discomfort, which may be e mistaken for community acquired pneumonia.[18] The initial symptoms may improve for 2â€“3 days or the patient may abruptly progress to severe respiratory distress with dyspnea, diaphoresis, stridor, and cyanosis. Bacteremia, shock, metastatic infection such as meningitis, which occurs about 50% of cases, and death may follow within 24â€“36 hours. Prior to 2001 bioterrorist outbreak, mortality from inhalational anthrax was expec be nearly 100%, even with antibiotics, once symptoms develop.[31 , 35 , 62] Currently, with appropriate antibiotic therapy and supportive care, 5 of 1 patients with inhalational anthrax died, albeit a high mortality rate, but l

than previously predicted.[44]

Pathophysiology

Inhalational anthrax causes a mediastinitis. Diagnostic imaging typically mediastinal widening from enlarged hilar lymph nodes and pleural effusic although pulmonary parenchymal infiltrates may also be seen.[44] Inhaled are taken up into the lymphatic system where they germinate and the ba reproduce. *B. anthracis* produces three toxins: protective antigen, edema and lethal factor. Protective antigen (PA) is so named because antibodies against it protect the subject from the effects of the other 2 toxins. PA fo heptamer that inserts into plasma membranes, facilitating endocytosis of other two toxins into target cells.[73] Edema factor is a calmodulin-depend adenylate cyclase. Increased intracellular cyclic adenosine monophosphat (AMP) upsets water homeostasis, leading to massive edema and impaired

neutrophil function. Lethal factor is a zinc metalloprotease that stimulate macrophages to release tumor necrosis factor Î± and interleukin-1Î², contributing to death in systemic anthrax infections (see Figure 127-1).[2]

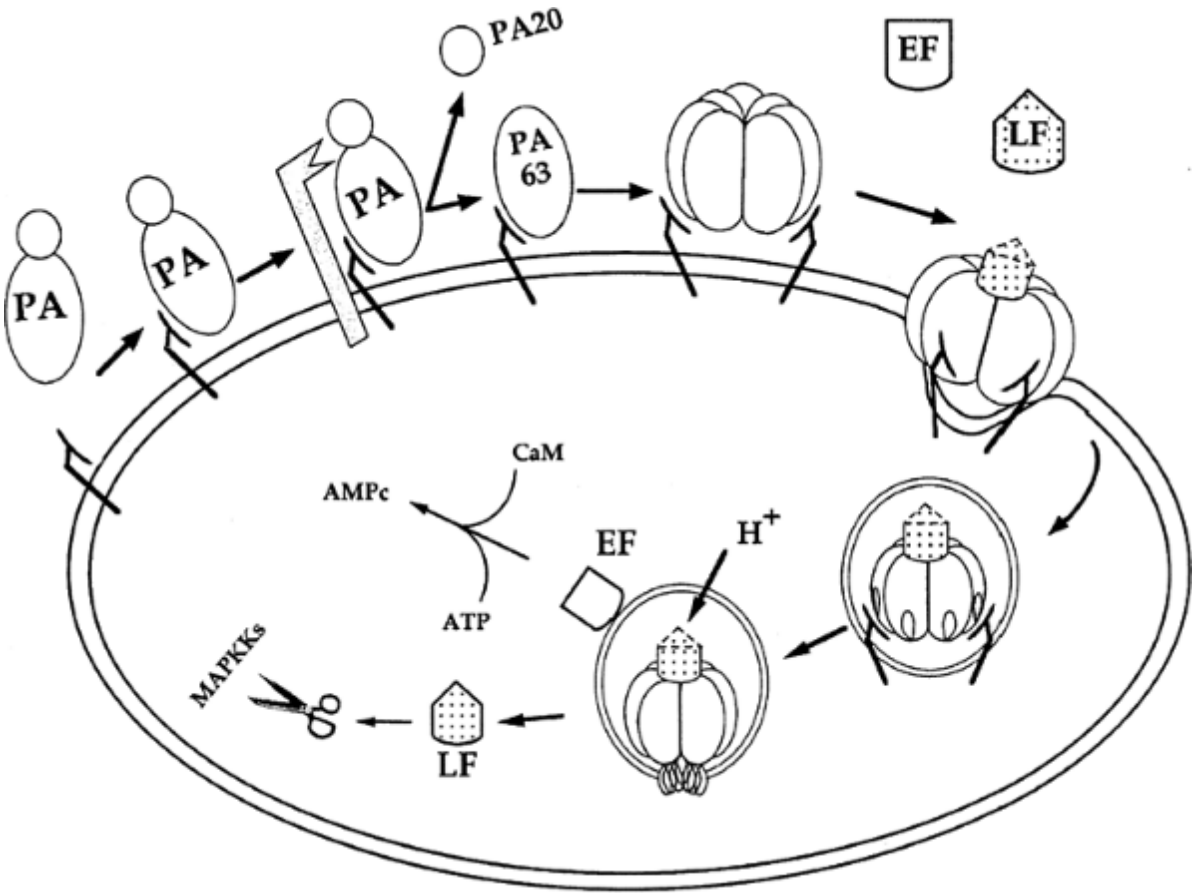

Figure 127-1. Model of action of anthrax toxins. PA = Protective antigen; Edema factor; LF = Lethal factor; CaM = Calmodulin; MAPKKs = Mitogen-activated protein kinases. *(Reprinted with permission from Brossier F, Mo Toxins of Bacillus anthracis. Toxicon 2001;39:1747â€“1755.)*

Treatment

The primary antibiotics recommended to treat anthrax are ciprofloxacin a doxycycline. Although other fluoroquinolones would be expected to have activity against anthrax, only the manufacturer of ciprofloxacin applied fo received a Food and Drug Administration (FDA)-approved indication for us this infection. In a mass-casualty setting or for postexposure prophylaxis should be treated with ciprofloxacin 500 mg PO every 12 hours. Alternate therapies are doxycycline 100 mg PO every 12 hours, or amoxicillin 500 r every 8 hours, if the anthrax strain is proven susceptible.[44] The recomm

duration of therapy is 60 days, stemming from case experience in Sverdl where some patients developed disease several (6â€“7) weeks after the release.[63] Children can also be treated with ciprofloxacin (15 mg/kg; ma 500 mg/dose) or amoxicillin (80 mg/kg/d divided every 8 hours; maximu mg/dose). The relative pediatric contraindication to fluoroquinolones is outweighed by the risk of potentially fatal disease. Cutaneous anthrax is with the same drugs and doses as for postexposure prophylaxis.

Inhalational anthrax should be treated initially with intravenous antibiotic Adults should receive ciprofloxacin 400 mg IV or doxycycline 100 mg IV 12 hours, along with 1 or 2 additional antibiotics with in vitro activity ag anthrax (eg, rifampin, vancomycin, penicillin, ampicillin, chloramphenicol imipenem, clindamycin, clarithromycin). Children should be given ciproflo 10 mg/kg IV (max 400 mg/dose), or doxycycline 2.2 mg/kg IV (max 100 mg/dose), and additional antibiotics as above.[44] In a true mass-casualty however, when resources are strained and inpatient care is not available every victim, oral therapy, as described above, may be instituted. When clinically appropriate, oral antibiotic therapy can be substituted for IV, wi total treatment duration of 60 days. Some patients in the 2001 outbreak specifically treated with antibiotics that inhibit protein synthesis in attem reduce bacterial production of toxins.

Anthrax Vaccine

An effective vaccine against anthrax is available.[36, 60, 61, 79, 100] In th United States, the Bioport Corporation (formerly Michigan Biologic Produc Institute) is licensed by the FDA to produce anthrax vaccine adsorbed (A FDA advisory panel review in 1985 found the vaccine to be safe and effe The vaccine consists of a membrane-sterilized culture filtrate of *B. anthr* V770-NP1-R, an avirulent, nonencapsulated strain that produces protecti antigen, adsorbed to aluminum hydroxide, formulated with benzethonium chloride (preservative) and formaldehyde (stabilizer).[100] In human and a experiments, the vaccine is highly effective in preventing all forms of an (including inhalational), and the vaccine is recommended for workers in h risk occupations. As with any vaccine, local reactions to AVA occur in som

recipients (up to 20% with mild, local reactions), and self-limited system reactions occur more rarely (<1.5%). Serious adverse events are very ra only 22 potentially related cases of serious adverse events from over 1 r doses administered to US armed forces.[36] The dosage schedule for AVA is mL subcutaneously at 0, 2, and 4 weeks and 6, 12, and 18 months, follov yearly boosters.

Undue concern has arisen regarding the safety of anthrax vaccination, an several members of the armed service have been punished or discharged refusing to accept vaccinations.[67]

The 2001 Bioterrorist Anthrax Outbreak

Starting on September 27, 2001 a 63-year-old Florida man developed ma fatigue, fever, chills, anorexia, and diaphoresis. He was admitted to a loc hospital on October 2, after presenting with additional complaints

of nausea, vomiting, and confusion. Chest radiography showed cardiomeg left perihilar infiltrate, small left pleural effusion, and a prominent superi mediastinum. Lumbar puncture revealed hemorrhagic meningitis with ma Gram-positive bacilli. *Bacillus anthracis* was isolated from the cerebrospir after only a 7-hour incubation and from blood cultures within 24 hours. T patient had progressive clinical deterioration and died on hospital day nu 4.[46]

On October 4, the Centers for Disease Control and Prevention (CDC) relea public health message regarding this case, which initially appeared to be isolated, perhaps naturally occurring sporadic event; another case of ant was reported in Texas earlier the same year.[14] Nevertheless, the rarity o inhalational anthrax especially outside of a high-risk occupation, combine increased suspicion in the wake of events on September 11, 2001, led to investigation of a potential bioterrorist event. Within days, epidemiologic investigation suggested workplace exposure to anthrax spores, and perso working in the same building were started on prophylactic ciprofloxacin.[15] October 12, a case of cutaneous anthrax was reported in New York City associated with a suspicious letter opened on September 25.[16] Anthrax c

and environmental contamination were also soon detected in Washington, and in a New Jersey postal facility. The public response to the reports of serious and fatal cases included misuse and hoarding of antibiotics, purc gas masks (often with inappropriate filtering mechanisms for biological weapons), reporting numerous miscellaneous powdery substances, and perpetrating or reporting copycat hoaxes.

By November 7, 2001, a total of 22 cases of anthrax were reported: 10 inhalational and 12 cutaneous.[17] One additional death from inhalational occurred on November 21, 2001,[3] and a case of cutaneous anthrax also occurred in a laboratory worker analyzing samples obtained during the investigation.[19] In two of the fatal cases, no contact with contaminated l could be established.[3, 31, 65] One infant hospitalized in New York City w cutaneous anthrax was initially misdiagnosed as suffering from a brown r spider envenomation.[33] The total number of medical victims of anthrax in Fall of 2001 was 23: 11 cases of inhalational anthrax (with 5 fatalities), a cases of cutaneous anthrax (8 confirmed and 4 suspected).[19]

Although the overall morbidity and mortality from this bioterrorist event relatively low, the psychosocial-economic impact was high. Several hundr postal and other facilities were tested for *B. anthracis* spore contaminatio public health authorities recommended antibiotic prophylaxis be initiated approximately 32,000 persons.[17] Additional indirect costs and effects are difficult to quantify, including the number of persons self-initiating antibi treatment without an evident indication, lost production and wages, environmental and biologic sample testing, decontamination efforts, and international sense of unease.

Published estimates of tens of thousands of deaths from a military-style attack[47] depend on efficient BW agent dispersion. The technically easier letter has clearly proven itself to be a â€œWeapon of Mass Disruption.â€ predicted, the psychological impact far exceeded the actual medical eme and events with a modest number of medical patients are probably more than true mass-casualty BW incidents. On the other hand, prior assumpti regarding the clinical aspects of anthrax were not as reliable. The mortali among the 11 cases of inhalational anthrax was 45%, considerably lower

expected and probably because of earlier diagnosis, improved supportive measures, and a wider choice of antibiotics, compared to historical contr Presentation with fulminant illness, such as sepsis, still appears to be pr of a fatal outcome, yet the initial phase of illness does not necessarily lea death, if treated with appropriate antibiotics.[5 , 46 , 56] Pleural effusions w the most common radiographic abnormality, rather than a widened medi and pulmonary parenchymal infiltrates were seen in 7 patients, whereas teaching had been that pneumonia does not commonly occur with inhalat anthrax.[35 , 46 , 62]

Plague

Yersinia pestis is a Gram-negative bacillus responsible for over 200 millio human deaths and 3 major pandemics in recorded history.[58 , 59] Naturall occurring plague is transmitted by flea vectors from rodent hosts, or by respiratory droplets from infected animals or humans. Plague is a particu frightening BW agent because it can be released as an aerosol to cause a fulminant communicable form of the disease for which no effective vaccin exists. Antibiotics must be initiated early after exposure because once sy develop, mortality is extremely high.

Clinical Presentation

Plague occurs in three clinical forms: bubonic, septicemic, and pneumonic Bubonic plague has an incubation period of 2â€“10 days followed by feve malaise, and painful, enlarged regional lymph nodes called buboes. The i nodes are most commonly affected, because the legs are more prone to f bites.[62] In the United States, 85â€“90% of human plague patients have t bubonic form, 10â€“15% have a primary septicemic form without lymphadenopathy, and about 1% present with pneumonic plague. Secondc septicemia occurs in 23% of patients presenting with bubonic plague.[59] V skin lesions at the site of inoculation (pustules, vesicles, eschars, or pap occur in some patients, although the petechiae and ecchymoses that occu advanced cases may resemble meningococcemia.[58 , 62] Distal gangrene f small artery thrombosis may occur, explaining why plague pandemics are

sometimes called â€œThe Black Death.â€• If left untreated, bubonic pla carries a 60% mortality rate.[58] Bubonic plague could result from an inter release of plague-infested fleas.

Pneumonic plague is an infection of the lungs with *Y. pestis* . Between 5% 15% of bubonic plague patients develop secondary pneumonic plague thr septicemic spread of the organism.[59] Primary pneumonic plague occurs fr inhalation of infected respiratory droplets or an intentionally disseminated aerosol. The incubation period of pneumonic plague after inhalation is 2â days. The onset of disease is acute and often fulminant. Patients develop malaise, and cough productive of bloody sputum, rapidly progressing to dyspnea, stridor, cyanosis, and cardiorespiratory collapse. Plague pneumo almost always fatal unless treatment is begun with 24 hours of symptom onset.[32 , 62]

Diagnosis and Treatment

Plague can be diagnosed by various staining techniques, immunologic stu by culturing the organism from blood, sputum, or lymph node aspirates. gram stained, *Y. pestis* appears as a Gram-positive â€œsafety-pinâ€•-sh bipolar coccobacillus.[31] Chest radiographs in pneumonic plague reveal pa consolidated bronchopneumonia. Leukocytosis with a left shift is common, markers of low-grade disseminated intravascular coagulation (DIC) and elevations of unconjugated bilirubin and hepatic aminotransferases.[32]

Antibiotic treatment options are similar to those for anthrax. In a mass-c setting or for postexposure prophylaxis, adults are

treated with doxycycline 100 mg PO twice daily or ciprofloxacin 500 mg P daily. Children receive doxycycline 2.2 mg/kg or ciprofloxacin 20 mg/kg, u maximum of the adult doses. Chloramphenicol 25 mg/kg PO four times da an alternative. The duration of treatment is 7 days for postexposure prophylaxis, and 10 days for mass-casualty incidents. Patients with pneu plague need to be isolated to prevent secondary cases. Respiratory dropl precautions are necessary in pneumonic plague until the patient has rece antibiotics for three days.[32] In a contained-casualty setting, pneumonic

is treated with parenteral streptomycin or gentamicin; alternative antibic include doxycycline, ciprofloxacin, and chloramphenicol.[43] A killed whole- vaccine effective against bubonic plague is available, but does not reliabl protect against pneumonic plague in animal studies.[58, 61]

Tularemia

Francisella tularensis is a small, aerobic, Gram-negative coccobacillus weaponized by the United States and probably other countries as well. T occurs naturally as a zoonotic disease spread by bloodsucking arthropods direct contact with infected animal material. Tularemia in humans may oc ulceroglandular or typhoidal forms, depending on the route of exposure. Ulceroglandular tularemia is more common, occurring after skin or mucou membrane exposure to infected animal blood or tissues. Patients develop ulcer with associated lymphadenopathy, fever, chills, headache, and mal Typhoidal tularemia presents with fever, prostration, and weight loss wit adenopathy. Exposure to aerosolized bacteria, as employed in BW, will m likely result in typhoidal tularemia with prominent respiratory symptoms s a nonproductive cough and substernal chest discomfort. Diagnosing tulare often difficult, as the organism is hard to isolate by culture and the symp are nonspecific. Chest radiography may demonstrate infiltrates, mediasti lymphadenopathy, or pleural effusions.[24, 29, 31, 61, 62]

Antibiotic treatment options are again similar to those for anthrax and pl In mass-casualty settings, or for postexposure prophylaxis, adults are tr with doxycycline 100 mg twice daily or ciprofloxacin 500 mg orally twice for 14 days; pediatric dosing for doxycycline is 2.2 mg/kg or ciprofloxacin mg/kg (maximum = adult dose) twice daily. When dealing with a limited of casualties, the preferred antibiotics are streptomycin 1 g IM twice daily gentamicin 5 mg/kg IM/IV once daily. Alternatives include parenteral doxycycline, chloramphenicol, and ciprofloxacin.[24]

Brucellosis

Brucellosis could potentially be used as an incapacitating BW agent, becau causes disease with low mortality but significant morbidity. Brucellae (*Bru*

melitensis , *abortus* , *suis* , and *canis*) are small, aerobic, Gram-negative coccobacilli that generally cause disease in ruminant livestock. Humans c brucellosis by ingesting contaminated meat and dairy products or by aero transmission from infected animals. The United States weaponized *B. suis* other countries are also believed to have developed brucella bioweapons. Brucellosis commonly presents with nonspecific symptoms such as fever, and malaise, with either an acute or insidious onset. Because brucellae a facultative intracellular parasites that localize in the lung, spleen, liver, C bone marrow, and synovium, organ-specific signs and symptoms may occ Diagnosis is made by serologic methods or culture. Because single-drug treatment often results in relapse, combined therapy is indicated. Treatm choice (adult doses) are doxycycline 200 mg/d orally, plus rifampin 600â mg/d orally for 6 weeks, or doxycycline 200 mg/d orally for 6 weeks with streptomycin 15 mg/kg twice daily IM or gentamicin 1.5 mg/kg IM q8h fo first 10 days.[31 , 42 , 61 , 62]

Q Fever

Q fever was first described by Edward Derrick in 1937, and was given its nameâ€”Q for â€œqueryâ€•â€”because the causative organism was not known. Q fever occurs naturally as a self-limited febrile, zoonotic disease contracted from domestic livestock. Q fever is now known to be caused b *Coxiella burnetti* , a unique rickettsia-like organism that can persist on inanimate objects for weeks to months and can cause clinical disease with inhalation of only a single organism. These features are of obvious benefi use as a potential BW agent. After a 10â€“40-day incubation period, Q fe manifests as an undifferentiated febrile illness, with headache, fatigue, a myalgias. Patchy pulmonary infiltrates on chest radiography that resembl or atypical bacterial pneumonia, occur in 50% of cases, although only hal patients have cough and even fewer have pleuritic chest pain. Uncommon complications include hepatitis, endocarditis, meningitis, encephalitis, an osteomyelitis. Patients are generally not critically ill, and the disease can long as 2 weeks. Treatment with antibiotics will shorten the course of acu fever and can prevent clinically evident disease when given during the incubation period. Tetracyclines are the mainstay of therapy, and either

tetracycline 500 mg PO q6h or doxycycline 100 mg PO q12h should be giv 5â€“7 days.[9 , 31 , 62]

Viruses

Smallpox

Smallpox is caused by the variola virus, a large DNA orthopoxvirus with a range limited to humans. Prior to global World Health Organization (WHO efforts to eradicate naturally occurring smallpox by immunization, recurre epidemics were common and the disease carried roughly a 30% fatality ra unvaccinated populations.[41 , 57] Smallpox is highly contagious. Outbreaks the 1960s and 1970s in Europe often resulted in 10â€“20 secondary cases index case. One German smallpox patient with a cough, isolated in a sing room, infected persons on three floors of a hospital.[41] The overwhelming majority of secondary infections, however, occur among close family con especially those sleeping in the same room or even in the same bed.[26]

In 1980, the United Nations' WHO certified that smallpox had been eradi from the world, and recommended ceasing vaccinations and either destro transferring remaining stocks of variola virus to one of two designated b level 4 facilities: the CDC in Atlanta, or the Russian State Research Cente Virology and Biotechnology (VECTOR).[7] All remaining known variola stock scheduled for destruction in 1999; however, before this was done, a WHO resolution called for a delay based on an Institute of Medicine report con that live virus should be retained to develop new antiviral agents or vacci protect against any potential future release of smallpox.[82] The Soviet Uni known to have weaponized smallpox, and other countries are believed to maintain stocks of variola virus. Until very recently, worldwide stocks of smallpox vaccine were considered inadequate for mass inoculations, if necessary. However, in addition to the known stockpiles of smallpox vacc millions of stored doses were discovered in the United States, and experi have determined that the administration of diluted vaccine successfully immunizes recipients.[34] Additionally, new methodologies for smallpox va production are being developed. Smallpox vaccination

for military personnel was reinstated in 2002 and was made available for civilians in 2003.[20 , 21]

Pathophysiology

Transmission of smallpox typically occurs through inhalation of droplets o aerosols, but may also occur through contaminated fomites. The infectiou is not known, but is probably only a few virions. After a 12â€“14-day inc period, the patient develops fever, malaise, and prostration with headach backache. Oropharyngeal lesions appear, shedding virus into the saliva. T three days after the onset of fever, a papular rash develops on the face a spreads to the extremities. The fever continues while the rash becomes vesicular and then pustular. Scabs form from the pustules and eventually separate, leaving pitted and hypopigmented scars. Deaths usually occur the second week of the illness. Vaccination before exposure, or within 2â days after exposure, provides almost complete protection against smallpo disease most likely to be confused with smallpox is chickenpox (varicella) Although the individual lesions of smallpox and varicella are physically indistinguishable, the person infected with smallpox may still be differen clinically. The lesions of smallpox should all appear at the same stage of development, whereas chickenpox lesions occur at varying stages. Small lesions tend to be found in a centrifugal distribution (face and distal extremities), whereas chickenpox lesions are more centripetal and tend t appear first on the trunk.

Two antiviral drugs commercially available in the United States, cidofovir ribavirin, are effective in vitro against variola.[61] Current evidence sugges however, that although cidofovir may prevent smallpox when given within days of exposure, it is unlikely to be effective once symptoms develop.[41] single case of smallpox should be considered a potential international hea emergency and immediately reported to the appropriate public health authorities.

Smallpox Vaccination

Rapid postexposure vaccination confers excellent protection against smal
The smallpox vaccine employs a live vaccinia virus (derived from cowpox
vaccine) rather than the actual variola virus that causes smallpox. Althou
contracting smallpox from the vaccine is therefore impossible, other adve
reactions may occur. The two most serious reactions are postvaccinal
encephalitis and progressive vaccinia. Postvaccinal encephalitis occurs in
3 cases per million primary vaccinees. Forty percent of cases are fatal, a
some survivors are left with permanent neurologic sequelae. Progressive
vaccinia can occur in immunosuppressed individuals and is treated with v
immune globulin (VIG). Because smallpox was eradicated before the eme
of HIV, there is limited clinical experience with smallpox vaccination in A
patients, who theoretically are at increased risk of progressive vaccinia.[4
However, among 10 individuals with undiagnosed HIV at the time of rece
smallpox vaccination, none developed complications.[90] Routine vaccinatio
contraindicated in the immunosuppressed, persons with a history or evide
eczema and other chronic dermatitis, close household or sexual contacts
patients with these contraindications, and during pregnancy. Because the
vaccine is a live virus, it can be transmitted from the vaccinee to close c
Thirty secondary and tertiary cases of vaccinia were reported resulting fr
recent US military vaccinations.[20] The number of serious adverse events
modern smallpox vaccination is very low.[21] However, two confirmed and
suspected cases of myopericarditis occurred among over 450,000 vaccine
After a true exposure to variola, most authorities would agree that the o
absolute contraindication to smallpox vaccination is significant impairment
systemic immunity. Concomitant administration of VIG would be recomm
for pregnant women and persons with eczema.[57]

Viral Hemorrhagic Fevers

Several taxonomically diverse RNA viruses produce acute febrile illnesses
characterized by malaise, prostration, and increased vascular permeability
can result in bleeding manifestations in the more severely affected patie
Viral hemorrhagic fevers (VHF) are all highly infectious by the aerosol ro
making them candidates for use as BW agents. These agents include the
causing Lassa fever, dengue, yellow fever, Crimean-Congo hemorrhagic f

and the Marburg, Ebola, and Hanta viruses. Clinical features, such as the of renal, hepatic, and hematologic involvement, vary according to the in agent, but they all carry the risk of secondary infection through droplet aerosols. Ribavirin has been used for some VHFs, but supportive care is t mainstay of therapy.[6 , 31 , 45]

Viral Encephalitides

Three antigenically related alpha viruses of the *Togaviridae* family pose r BW agents: western equine encephalitis (WEE), eastern equine encephali (EEE), and Venezuelan equine encephalitis (VEE). Birds are the natural r of these viruses, and natural outbreaks occur among equines and humans mosquito transmission. Eastern equine encephalitis infections are the mo severe in humans, with a 50â€“70% fatality rate and high incidence of neurologic sequelae among survivors. WEE is less neurologically invasive, severe encephalitis from VEE is rare, except in children. Adults infected w usually develop an acute, febrile, incapacitating disease with prolonged recovery. The equine encephalitides have many properties helpful for weaponization, in that they can be produced in large quantities, they are relatively stable and highly infectious to humans as aerosols, and a choice available between lethal or incapacitating infections.[84]

Venezuelan equine encephalitis is considered the most likely BW threat a the viral encephalitides. After a 1â€“5-day incubation period, victims exp the sudden onset of malaise, myalgias, prostration, spiking fevers, rigors severe headache, and photophobia. Nausea, vomiting, cough, sore throat, diarrhea may follow. This acute phase lasts 24â€“72 hours. Between 0.5% 4% of cases develop overt encephalitis, with meningismus, seizures, com paralysis, which carries up to a 20% fatality rate. The diagnosis is usually established clinically, although the virus can sometimes be isolated from or from throat swabs, and serologic tests are available. The white blood c count often shows a striking leukopenia and lymphopenia. Treatment is supportive. Person-to-person transmission can theoretically occur from c nuclei. Recovery takes 1â€“2 weeks.[31 , 62 , 84]

Toxins

Several toxins derived from bacteria, plants, fungi, and algae could theo be used as BW agents, if produced in sufficient quantities. Because of the potency, only small amounts of these agents would be needed to kill or incapacitate exposed victims. Fortunately, obstacles in manufacturing weaponizable amounts limits the number of toxins that are practical for u biological weapons. Discussion here is limited to those toxins known or h suspected to have been weaponized. Toxins themselves are not living or and therefore can not reproduce; for this

reason, they are arguably equivalent to chemical weapons. But because t weapons are derived from living organisms, they are categorized here as biological weapons.

Botulinum Toxin

Botulinum toxin has been developed as a biological weapon in the United and other countries.[2 , 71 , 81 , 99] The two most likely means of employin botulism as a BW agent are by food contamination or by aerosol. Either r would result in the clinical syndrome of botulism (Chap. 46), characterize multiple bulbar nerve palsies and a symmetric descending paralysis, endir death from respiratory failure. Inhalation botulism from laboratory incider occurred rarely in humans and has also been investigated in animal experiments.[64] Onset of symptoms of botulism can occur as early as 24â hours, or may take several days. The mainstay of therapy is supportive c with ventilation if necessary. Serotype-specific antitoxin should halt prog of disease, but does not reverse established neurologic deficits. In the U States, the CDC produces and distributes antitoxin against the botulism serotypes commonly found in food poisoning, either a bivalent equine an against types A and B or a trivalent antitoxin against serotypes A, B, and US Army maintains a â€œdespeciatedâ€• equine heptavalent antitoxin a serotypes A through G. In animal experiments, these $F(abâ€²)_2$ fragments protective against inhalation botulism if given prior to onset of symptoms Prophylaxis for persons at high risk, usually laboratory personnel, is

accomplished by vaccination with a pentavalent toxoid for botulinum serc Aâ€“E. This toxoid was given to approximately 8,000 service members du the Gulf War and caused self-limited, local symptoms similar to tetanus immunization.[62 , 64]

Ricin

Ricin, one of the most toxic and easily produced plant toxins, derived fror castor bean plant, *Ricinus communis* . Although ricin has never been used battle, it has attracted the attention of domestic extremists and terrorists has been used in politically motivated assassinations.[23 , 30 , 50] Ricin inh protein synthesis at the ribosome. Clinical toxicity will vary depending on dose and route of exposure. Inhalation of aerosolized ricin results in incr alveolar-capillary permeability and airway necrosis following a latent phas 4â€“8 hours. Ingestion causes gastrointestinal hemorrhage with necrosis liver, spleen, and kidney. Intramuscular administration produces severe necrosis with extension into the lymphatics. In the absence of specific immunologic testing, differentiating ricin poisoning from sepsis may be c because of the presence of leukocytosis and fever. Vaccination of laborat animals with an investigational toxoid is protective.[30 , 62]

Staphylococcal Enterotoxin B

Staphylococcal enterotoxin B (SEB) is 1 of 7 enterotoxins produced by *Staphylococcus aureus* . SEB is recognized as a â€œsuperantigen,â€• be of its profound activation of the immune system on exposure to even to quantities. As a BW agent, SEB could be ingested through contaminated f water, resulting in acute gastroenteritis identical to classic staphylococcal poisoning. If inhaled as an aerosol, SEB produces fever, myalgias, and a pneumonitis after a 3â€“12-hour latent period. SEB inhalation can be fata more often would simply be incapacitating for several days to weeks. Tre is supportive.[62 , 93]

Trichothecene Mycotoxins

The trichothecene mycotoxins are low molecular weight (250â€“500 dalto

nonvolatile compounds produced by filamentous fungi (molds) of various
including *Fusarium* , *Myrotecium* , *Trichoderma* , and *Stachybotrys* .
Trichothecene mycotoxins are unusual among potential BW agents in that
toxicity can occur with exposure to intact skin. Naturally occurring tricho
toxicity results from ingesting contaminated grains or by inhaling toxin
aerosolized from contaminated hay or cotton. Outbreaks of ingested
trichothecene toxins result in a clinical syndrome called alimentary toxic
characterized by gastroenteritis, fevers, chills, bone marrow suppression
granulocytopenia, and secondary sepsisâ€”a syndrome similar to acute r
poisoning. Survival beyond this stage is characterized by the development
and upper airway ulceration, and intradermal and mucosal hemorrhage.
Trichothecene toxins are potent inhibitors of protein synthesis in eukaryo
cells, producing widespread cytotoxicity, particularly in rapidly proliferati
tissues. Exposure to any mucosal surface results in severe irritation. Der
exposure can produce inflammatory lesions lasting for 1â€“2 weeks,
vesiculation, and, in higher doses, death.[62 , 85 , 95]

Several reports from the 1970s and 1980s suggested that Soviet support
forces were using trichothecene mycotoxins, particularly the toxin T-2 (Fi
127-2), as BW agents. Aerosol and droplet clouds called â€œYellow Rain
were associated with mass casualty incidents in Afghanistan, Laos, and
Kampuchea.[39 , 95] Yellow Rain attacks have also been reported in the Ira
War.[77] Such attacks would involve multiple routes of exposure, with skin
deposition likely being the major site. Early symptoms included nausea,
vomiting, weakness, dizziness, and ataxia. Diarrhea would then ensue, at
watery and then becoming bloody. Within 3â€“12 hours victims would de
dyspnea, cough, chest pain, sore mouths, bleeding gums, epistaxis, and
hematemesis. Exposed skin areas would become intensely inflamed, with
appearance of vesicles, bullae, petechiae, ecchymoses, and frank necrosi

Nonetheless, evidence that trichothecene mycotoxins were used as BW a
was mostly circumstantial. Although T-2 toxin was found in victims' blood
urine, it was also found in samples from unexposed individuals, probably
baseline ingestion of contaminated foods. Environmental samples contain
Yellow Rain droplets were inconsistently found to contain mycotoxins.
Eyewitness accounts of Yellow Rain attacks varied widely (including

various descriptions of the alleged agent's color), and, despite the large of such attacks, no contaminated ordinance or dispersal device was ever recovered.[80] It was also discovered that Yellow Rain droplets were comp mostly of pollen grains. Supporters of the Yellow Rain as BW theory reto that pollen grains would be an ideal carrier for biotoxins, given that their ideal for aerosolization. However, the pollen in Yellow Rain samples did n contain protein, similar to pollen that has been digested by bees. Further distribution of pollen species found in Yellow Rain was indistinguishable fr contents of feces of the Asian honeybee, and mass bee defecation resulti showers of yellow droplets has been observed.[70 , 80] The Yellow Rain as feces theory assumes that any mass casualty incidents were from endem disease outbreaks, other CBW agents not yet identified, or a combination both. Whether Yellow Rain was intentional biological warfare or a comple natural phenomenon, trichothecene mycotoxins remain a potentially effe dermally active BW agent.

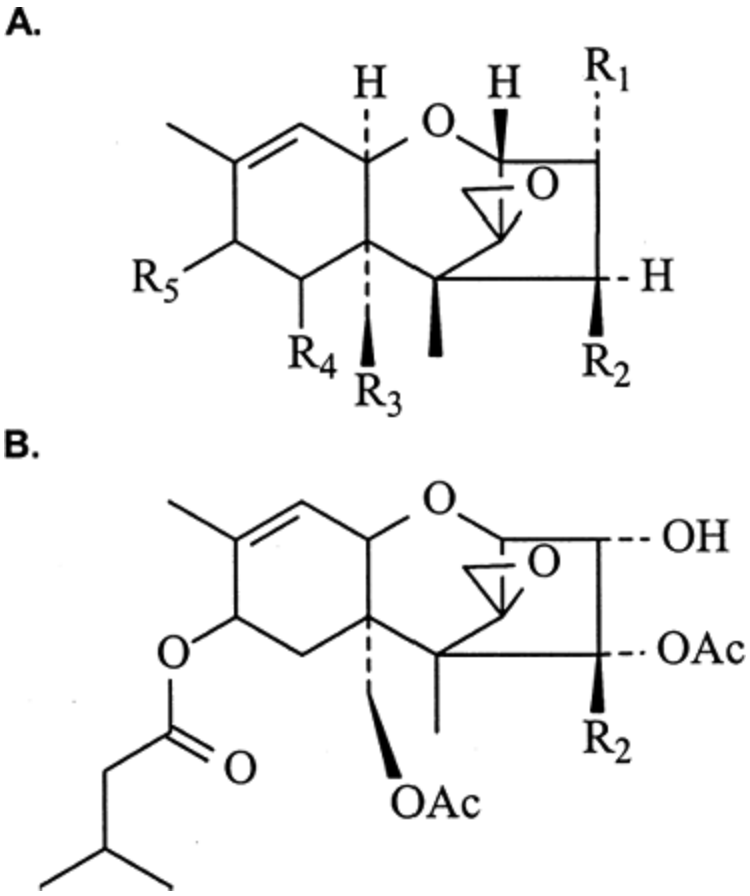

Figure 127-2. Trichothecene mycotoxins. A. Tetracyclic trichothecene n
B. T-2 toxin.

Summary

Although biological weapons have been used intermittently for centuries,
recently has their danger in potentially causing mass casualties been con
recognized. Even with multinational bans against their development and u
threat of biological weapons remains because the financial outlay in deve
biological weapons is low compared to other weapons of mass destruction
because even the threat of their use may aid some parties in furthering t
political goals. Currently, the risk of a medical catastrophe from BW agen
producing thousands or millions of victims appears low, with inhalational
or smallpox being the most likely agents in such a scenario. Nevertheless
incidents with limited numbers of casualties, or just threats of employing

agents, can have significant social impact.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 128
Radiation

Joseph Rella

A 16-year-old boy broke open an illuminated exit sign, when the liquid contents spilled onto his clothing. He then discovered a radioactive caution sticker on the back of the frame, told his parents who were concerned about potential radioactivity, and called 911. On arrival to the emergency department (ED), the radiation safety officer was notified. The patient was disrobed, his skin was washed with lukewarm water and soap, and his clothing was placed in a sealed plastic bag. The patient's vital signs and clinical examination were normal. A portable dosimeter measured 28 ÂµCi of radioactivity in his urine sample from the isotope tritium (^{3}H), the radioactive source in the exit sign. Intravenous crystalloid fluids were administered to increase urine output, and the patient remained asymptomatic. He was discharged from the hospital the next day. Routine blood work remained normal several days later.

Over the last century, radiation injuries and the nature of radiation itself have been vigorously studied as a result of its expanding role in our society. Today, radionuclides are used for a wide variety of

medical and nonmedical purposes ranging from detecting smoke to diagnostic testing to powering spacecraft. Although useful, radionuclides can present a danger to humans both through their metallic nature and through the process of radioactive decay. This ionizing radiation may cause injury to multiple cellular structures and critical molecules, such as DNA, resulting in mutations, neoplasms, or cell death. The particles of radiation, their sources, and the mechanisms by which they pose a health risk are the subjects of the following discussion.

Historical Exposures

Radiation became a concern for scientists as a toxin only a year following the discovery of x-rays by Wilhelm Roentgen in 1895.[87] Soon after, Thomas Edison reported corneal injuries in several of his workers conducting experiments using his newly invented x-ray generator. Eight years later, Clarence Dally, one of Edison's most dependable assistants, became the first radiation-related death in the United States.[29] Fortunately, the medical community recognized the utility of Edison's fluoroscope and began to use x-ray machines to help diagnose various illnesses. For example, the British army developed and used mobile x-ray machines to find bullets and shrapnel in wounded soldiers in Sudan in the early 1900s.

Over the next 10â€“15 years, radioactive substances also found their way into society as objects of fascination and as a means of alternative medical therapies. Aggressively marketed as cure-alls, advertisements for products such as the Revigator and Radithor enticed people to drink water â€œchargedâ€• with radon or radium. These products ushered in 20 years of â€œhealthâ€• products containing radioactive materials.[57,58]

In 1915, the British Roentgen Society, recognizing the potential hazards of radiation, proposed standards for radiation protection of workers, which included shielding, restricted work hours, and medical examinations. However, no dose limits were implemented because

dose quantitation was unavailable.

The opening of the Radium Luminous Materials Corporation in Orange, New Jersey in 1917 represented the first of several companies to profit from the novelty and popularity of radium's bluish glow. In an industry that employed over 4000 workers at its peak, nearly all of whom were female, the radium was hand-painted onto watch and instrument dials. These young women were instructed to obtain a fine tip on their paintbrushes using a technique called â€œlip pointing,â€• which meant using their lips and tongues to shape their paintbrushes. Unaware of the danger, some of these women also painted their nails, lips, and eyelids with the radioactive paint. By 1927, about 100 of them died from osteosarcoma of the jaw, brain tumors, and developed other noncancerous lesions of the mouth, all related to radium exposure.[60,72]

The only occasion a nuclear bomb was used against a human population occurred in August 1945 when the United States dropped a bomb on Hiroshima and on Nagasaki, Japan.[27] One contained a uranium core and liberated energy equivalent to 12,500 tons of TNT. The other contained a plutonium core and liberated an energy equivalent to 20,000 tons of TNT. Estimates of dead and injured for both cities are well over 200,000.[35] Most of the deaths were from the bomb blast, but many thousands died from acute radiation syndrome (ARS) and subsequently from radiation-induced cancers. In addition to the people of those cities who were victims of the bombs, at least 20,000 men and women from Britain, Australia, New Zealand, and India who formed the British Commonwealth Occupation Forces (BCOF) were also exposed to residual radiation as they were involved in security and clean-up tasks. Published memoirs even include photographs of Australian soldiers playing football on the flattened hypocenter of Hiroshima. Data concerning the health effects of the BCOF in postwar Japan are less well known than those reported by the British Nuclear Tests Veterans Association (BNTVA). The BNTVA is a group of 20,000 men who were required to attend United Kingdom nuclear weapons tests in Australia and at Christmas

Island between 1952 and 1963. Over two thirds of this cohort died of neoplasms at ages of 50â€“65 years, irrespective

of the individual's age at the time of the witnessed explosion.[79,80] Since that time there have been thousands of nuclear bomb tests around the world in the atmosphere, underground, and underwater.

With the beginning of the nuclear age also came unintentional criticality events of varying kinds in which individuals were exposed to large amounts of radiation. Criticality refers to the chain reaction of fissionable atoms that results in the release of energy. It is the basic operating principle behind fission bombs and nuclear reactors and is an efficient means of generating energy. Two criticality events occurred in Los Alamos in the 1940s during experiments in which scientists performed what was called â€œtickling the dragon.â€• In that era, determining the amount of fissionable material necessary to precipitate a chain reaction was not precisely defined mathematically. Harry Daghlian and Louis Slotin, two scientists involved in the development of the first atomic bomb, were to bring subcritical amounts of fissionable material together to see if a reaction would occur. Both men died of first use acute radiation sickness (ARS) following exposure to high levels of radiation released during these experiments. Since 1945, there have been numerous criticality events, the most recent occurring in Tokaimura, Japan in 1999. In that instance, workers making fuel for nuclear reactors allowed excess uranium to enter the reaction container. The criticality event that resulted killed one worker and caused the evacuation of all the people living within 350 meters of the manufacturing plant.

During the late 1920s, radiologists used a thorium-containing contrast agent called Thorotrast. During that time when imaging modalities were limited, this opacifying agent, provided intravascularly in a colloidal suspension, provided essential medical information during the early development of angiography. Unfortunately, physicians did not appreciate the dangers of this

agent and only later discovered its very slow elimination rate and propensity to accumulate in hepatic tissue. Because of emission of Î± particles, cases of thorium-induced hepatic carcinomas and angiosarcomas, led to its eventual discontinuance in 1952.

Although many nuclear reactor incidents have occured around the world, the most serious occurred at Chernobyl in the Ukraine in 1986. In this instance, a series of errors led to a fire at the reactor core, several explosions, and a meltdown of the reactor. Over the first 10 days following the incident, a cloud carrying radioactive material (predominantly ^{131}I and ^{137}Cs) spread to the Baltic States, Scandinavia, and Europe. In addition to the 31 people who died of ARS in the first few weeks following the event, nearly 250 others in the surrounding area were hospitalized, and an unknown number suffered other long-term sequelae.[28,33,45]

Not all radiation events occur at nuclear facilities. In September 1987 in GoiÃ¢nia, Brazil, two men scavenged the contents of an abandoned medical clinic and unwittingly handled a source of ^{137}Cs. As in the early part of the century with radium, the fascinating bluish glow contributed to many radiation exposures, some of them quite extensive. In the end, the government monitored approximately 113,000 individuals and found nearly 250 contaminated individuals. Forty-six patients were treated with a chelating agent, 19 were found to have localized radiation burns, and 4 died in the month following the initial exposure with another dying several years afterward from radiation-induced injuries.[67]

The Principles of Radioactivity

Dating from the 15th century, radiation is defined as energy sent out in the form of waves or particles. Although considered by physicists as incomplete, the particle-wave theory remains a useful model by which to understand the toxic aspects of radiation. Despite the strong nuclear force that holds the basic building blocks of atoms together, many isotopes are unstable. Several other forces, most

notably the electroweak force, may tip the balance toward instability and an isotope will transform. This process may be intentional, as with the criticality events in a nuclear reactor or nuclear bomb, but mainly occurs spontaneously in nature as the process called radioactive decay.

Radioactive Decay

In 1900, Marie Curie discovered that unstable nuclei decay or transform into more stable nuclei (daughters) via the emission of various particles or energy. Radioactive decay occurs through five mechanisms: emission of Î³ rays, Î± particles, Î² particles, positrons, or capture of an electron. It is the emission of these various particles that makes radioactive decay dangerous because these particles form ionizing radiation. These emitted particles are released with specific decay energies depending on the isotope undergoing the process.

The terminal half-life ($t_{1/2}$), a term first used by Ernest Rutherford in 1904, is the period of time it takes for a radioisotope to lose half of its radioactivity. Every radioisotope has a characteristic half-life. Some isotopes exist for millionths of a second, whereas others last billions of years. In every case, the activities of radioactive isotopes diminish exponentially with time. The equation $R = R_0e^{-Âμ}$ describes radioactive decay, in which R is the activity, R_0 is initial activity, t is time, and Î» is the decay constant. Each radioisotope has its own decay constant (Table 128-1).

Photons are massless particles that travel at the speed of light and mediate electromagnetic radiation. Depending on the energy of the particles, and therefore their wavelength, the radiation has different names. Radiation having the lowest energy and the longest wavelength are called radio waves. As photons become more energetic and have shorter wavelengths, they are called, sequentially, microwaves, heat or infrared, visible light, and ultraviolet rays. Î³ Rays and x-rays have greater energy than ultraviolet rays and can penetrate deeply into the body, which makes

them both deadly and beneficial as radiation therapy.

TABLE 128-1. Physical Properties of Common Radioisotopes

Isotope	Half-Life	Mode of Decay	Decay Energy (MeV)[1]
^{47}Ca	4.53 days	Î²-	1.979
^{14}C	5730 yrs	Î²-	0.156
^{137}Cs	30.23 yrs	Î²-	1.176
^{51}Cr	27.8 days	electron capture	0.752
^{57}Co	270 days	electron capture	0.837
^{67}Cu	61.8 hrs	Î²-	0.576
^{3}H	12.26 yrs	Î²-	0.02
^{123}I	13.3 hrs	electron capture	1.4
^{131}I	8 days	Î²-	0.970
^{40}K	1.28 Ã— 10^{9} yrs	Î²-/Î²+ electron capture	1.35/1.505
^{32}P	14.3 days	Î²-	1.710

^{222}Rn	3.8 days	Î±	5.587
^{85}Sr	64 days	electron capture	1.11
^{201}TI	73 hrs	electron capture	0.41
^{238}U	4.51 Ã— 10^{9} yrs	Î±	4.268
^{133}Xe	5.27 days	Î²-	0.427
^{1}MeV = mega-electron volts			

Î³ Rays and x-rays are essentially the same and are only distinguishable by their source. Î³ Radiation is emitted by unstable atomic nuclei in the process of radioactive decay. A given Î³ ray will have a fixed wavelength depending on the energy that formed it; the greater the energy of the decay, the smaller the wavelength of the Î³ radiation. X-rays come from atomic processes outside the nucleus. For example, an x-ray machine generates x-rays by accelerating electrons through a large voltage and colliding them into a heavy metal target. The rapid deceleration of electrons in the target generates x-rays. In general, the higher the voltage, the greater the energy of the x-rays generated along a spectrum of wavelengths. X-rays and Î³ rays may have the same energy. Once an x-ray and Î³ ray of the same energy leave their respective sources they cannot be distinguished from one another. They behave in exactly the same way, including the types of biological effects they may cause. Because of their nature, high-energy Î³ and x-rays can penetrate several feet of insulating concrete.

Î²--*Particles* are also called electrons. They are emitted during Î²-decay from an unstable radionuclide, which is an atom that disintegrates by emitting a particle, electromagnetic radiation or both. Positrons, positively charged electrons, may also be emitted during decay processes. Because of their mass, electrons have less penetration than Î³ radiation but may still pass several centimeters into human skin.[86] For this reason, Î² particles cause health problems chiefly through incorporation into living organisms, which occurs when a radionuclide is inhaled, ingested, or deposited on a wound.[5]

Î±-*Particles* are helium nuclei (2 protons and 2 neutrons) stripped of their electrons. These relatively massive particles are emitted during Î± decay. These particles are the most easily shielded of the emitted particles mentioned and are stopped by a piece of paper, skin, or clothing. Like Î² particles, Î± particles principally cause health effects only when they are incorporated.

Neutrons are primarily released from nuclear fission, although high-energy photon beams used in radiotherapy may also produce them. The natural decay of radionuclides does not include emission of neutrons. This is mainly a health hazard for workers in a nuclear power facility or victims of a nuclear explosion. Unique among the particles of radioactivity, when neutrons are stopped or captured they can cause a previously stable atom to become radioactive.

Cosmic rays complete the group of various kinds of radiation to which an individual may be exposed. Cosmic rays are streams of electrons, protons, and Î± particles thought to emanate from stars and supernovas. They rain down on the earth from all directions only to give up their energy as they strike the nuclei of oxygen and nitrogen in the upper reaches of the earth's atmosphere. By the time it reaches the earth, the energy of cosmic radiation is reduced by several orders of magnitude. Traveling or living at altitude where the atmosphere shields relatively less cosmic radiation naturally means greater exposure to cosmic rays but in general is not considered a

toxic threat to humans.

Ionizing Radiation Versus Nonionizing Radiation

Ionizing radiation refers to any radiation with sufficient energy to disrupt an atom or molecule with which it impacts. In this interaction, an electron is removed or some other decay process occurs, leaving behind a changed atom. Depending on the specifics of the interaction, these atoms may now be ionized or highly-reactive free radicals. Hydroxyl free radicals, formed by ionizing water, are responsible for biochemical lesions that are the foundation of radiation toxicity.

The space between collisions of ionizing radiation and their target molecules varies with the particle type and its energy. A heavy charged particle, such as an Î± particle, loses kinetic energy through a series of small energy transfers to other atomic electrons in the target medium, such as tissues. Most of the energy deposition occurs in the infratrack, a narrow region around the particle track extending about 10 atomic distances. The energy loss per unit length of particle track is called the linear energy transfer (LET), which is expressed in kiloelectron volts per micrometer (keV/Âµm; see Table 128-1). Heavy charged particles, such as Î± particles, are referred to as high LET radiation, whereas x-rays, Î³ rays, and fast electrons are low LET radiation.

Because of its large size, collisions along the path of an Î± particle are clustered together, limiting its ability to penetrate tissue. By comparison, collisions along the path of Î³ rays are spread out, increasing their ability to penetrate tissue. It is this ability to penetrate tissue and transfer energy that accounts for the relative dangers of the forms of radiation and tissue susceptibility.

For a source of radiation to pose a threat to tissue, the ionizing particle must be placed in close proximity to vital components of

tissue that can sustain damage. High-energy photons penetrate deeply and so pose a similar risk whether they come from an external source or from an incorporated source. As noted above, Î± and Î² particles have much more limited tissue penetration and thus radionuclides that radiate these particles must first be incorporated to pose a threat to tissue.

Nonionizing radiation spans a wide spectrum of electromagnetic radiation frequencies. Generally, nonionizing radiation consists of relatively low-energy photons and is used safely in cell phone and television signal transmission, radar, microwaves, and magnetic fields that emanate from high-voltage electricity and metal detectors. Although these are all considered radiation in that they are all energies released from a source, these photons lack the necessary energy required to cause ionization and cellular damage.

Radiation Units of Measure

The amount of radiation to which an object is exposed, that is, the amount emitted from a source that falls on an object, is given in units called roentgens (R). A roentgen is a unit for measuring the quantity of Î³ or x-radiation by measuring the amount of ionization produced in air. It may be loosely defined as the amount of x-radiation that produces 1 electrostatic unit of charge in 1 cubic centimeter of air at standard temperature and pressure. As an example, an individual standing at a given distance from the x-rayâ€“generating tube of a particular x-ray machine is exposed, on the skin, to a particular number of roentgens of x-rays (Figure 128-1).

Not all roentgens to which an individual is exposed pose a risk for cellular damage. Much of the radiation passes through the body and does not cause harm. Only the fraction is absorbed by the tissue has a probability of causing cellular damage. The unit that describes absorbed radiation is the rad (radiation absorbed dose), which corresponds to an absorption of energy in any medium of 100 ergs/g.

The units of the International System (SI), first introduced in the 1970s, have largely replaced the older units. The gray (Gy) is the corresponding SI unit to the rad and is equivalent to 100 rads.

Not all radiations produce the same effects at the tissue level. For example, a given number of Gy of x-rays produce less cellular damage than the same number of Gy of Î± particles when all other conditions are equal. To predict the degree of damage that radiation of any type may cause, other units of measure are needed to normalize the different potencies in terms of their risk. The rem (roentgen equivalent

man) and the Sv (sievert, in SI) are the units that allow these calculations. These units are useful for comparing the effects of different radiations or evaluating the danger of a mixture of radiations, such as in radioactive decay, in which some isotopes emit more than one kind of radiation at a time (eg, Î² and Î³). In defining rem, x-rays are the standard radiation for comparison. One rem may be defined as the dose of radiation that produces damage equivalent to one rad of x-rays (or 0.01 Sv). Thus, for x-rays, one Sv is equivalent to 100 rem. To perform the normalization, the dose in grays is multiplied by a relative biologic effectiveness-dependent quality factor (Q). This factor Q multiplies the amount of radiation by 1 for x-rays, Î³ rays, and Î² particles, 2 for Î± particles, and by 5 or more for neutron radiation. Thus, 1 Sv is equivalent to 1 Gy of x-rays. As a very coarse reference point, a regular chest radiograph imparts about 20â€“40 mrem or 0.2â€“0.4 mSv to an individual, but it must be remembered that this radiation dose is delivered very quickly to a limited portion of the body and is quite different from a similar amount delivered over a longer period of time to a worker through an occupational exposure.

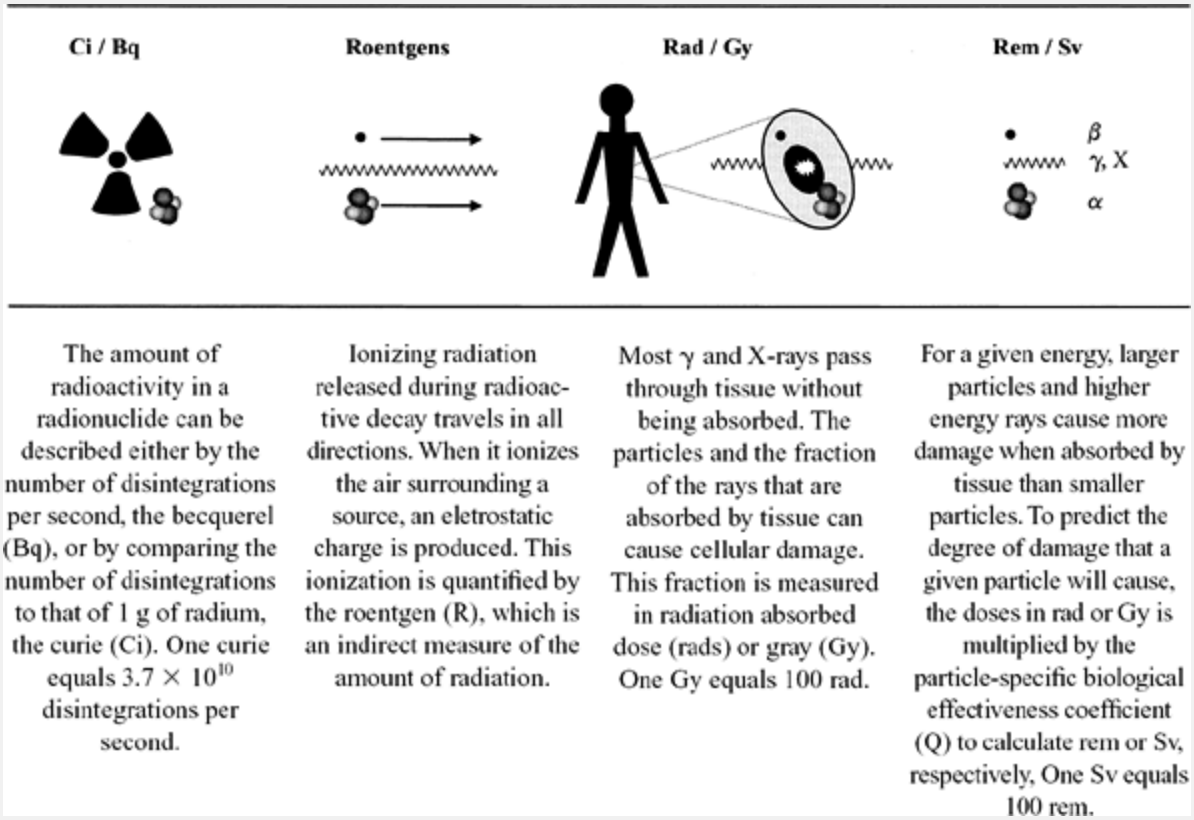

Figure 128-1. The definitions associated with radiation. Both curie and bequerel describe a quantity of radionuclide in terms of the number of disintegrations rather than mass. Roentgens describes the amount of air ionized by either gamma (Î³) or x-rays, which indirectly quantifies the amount of radiation in the air around a source. Rad and gray describe the fraction of radiation that actually interacts with cellular material and potentially causes injury. Roentgen equivalent man (Rem) and sievert (Sv) calculate the effective dose taking into account the different particles. For example, a 100 keV alpha (Î±) particle causes more damage to cellular material than a 100 keV beta particle (Î²).

In 1910, the curie (Ci) became the unit defining the activity of

radioactive decay, although it does not give information regarding what is released or the risk of exposure. One curie equals 3.7 Ã— 10^{10} disintegrations per second, based on the decay of 1 g of radium. The SI unit is the becquerel (Bq), named for Antoine Henri Becquerel, who in 1896 first reported invisible emanations from naturally occurring minerals that fogged photographic plates. One becquerel is equivalent to 1 disintegration per second. Thus, 1 Ci is equivalent to 3.7 Ã— 10^{10} Bq. This number corresponds to an amount of radioactivity in a source. For example, following the Chernobyl incident, 1.2 Ã— 10^{7} TBq (terabecquerel, 1.2 Ã— 10^{19} disintegrations per second) of radioactive material was released into the atmosphere. By comparison, the men who removed the source of ^{137}Cs in GoiÃ¢nia found 50.9 TBq (50.9 Ã— 10^{12} Bq or 13.7 Ã— 10^{5} mCi) of cesium. A thallium stress test uses 111 Ã— 10^{6} Bq (3 mCi) of ^{201}Tl, and the average indoor concentration of ^{222}Rn in the United States is 55 Bq/m^3 (14.8 Ã— 10^{-6} mCi). To illustrate further, a stress test's dose of ^{201}Tl provides a dose of 0.018 Gy (1.8 rad) and 0.018 Sv (1.8 rem).

Irradiation, Contamination, and Incorporation

An object that is irradiated is exposed to ionizing radiation. This type of exposure includes handling radioactive isotopes, medical diagnostic imaging modalities such as x-ray machines and CT scanners, and rare exposures to criticality events. These sources of ionizing radiation can generate high-energy photons, which penetrate tissue well and cause tissue damage. A whole-body irradiation is one in which the entire body is exposed at once, whereas more commonly shielding devices, such as lead aprons, and collimation techniques used in radiotherapy limit the amount of exposed tissue to the intended target. The risk of tissue damage depends on the total amount of radiation and the tissue type because different tissue types have their own intrinsic resistance to radiation damage. An

irradiated object does not become radioactive itself, unless exposed to neutrons.

The Food and Drug Administration (FDA) approved irradiation of wheat and flour in 1963. They have concluded from 40 years of study that irradiation is a safe and effective process for many foods to control bacteria such as *Escherichia coli*, *Salmonella*, and *Campylobacter*. The FDA states that irradiation does not make food radioactive, compromise nutritional quality, or noticeably change the taste, texture, or appearance of food, as long as it is applied properly to a suitable product. Organizations that support irradiation of food include the American Medical Association (AMA), the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO).

Contamination occurs when a radioactive substance covers an object completely or in part. Several examples include a laboratory or industrial worker who unintentionally spills a radioactive nuclide on clothing or skin or a victim of a radiologic dispersing device, a â€œdirty bomb,â€• in which a radioisotope is packaged with a conventional explosive and the resultant explosion disperses the radionuclide. In these similar cases, the source of radiation is the nuclide undergoing its normal decay process, and the individual is exposed to particles such as those mentioned in Table 128-1. The risk for tissue damage from the radiation particles is usually quite low, assuming that the contamination is detected and appropriate measures for decontamination are instituted.

Incorporation occurs when a radionuclide assimilates into a patient's body tissue. It generally follows exposure via the inhalational, enteral, or parenteral route, but may occur via any route that permits a radionuclide to enter the body. This principle is used in many diagnostic and therapeutic procedures such as a thallium stress test, bone scan, gallium scan, liver and spleen scan, and ^{89}strontium therapy. Depending on the dose and type of radionuclide,

incorporation may lead to tissue damage, as was the situation for many people following the event at Chernobyl. In this instance, inhalation and subsequent absorption of ^{131}I allowed this radionuclide access to the thyroid, resulting in an increase in thyroid cancer among children and adolescents in the most contaminated regions of Ukraine and Belarus.[9,43,92]

Regulation and Reporting

The Nuclear Regulatory Commission (NRC), the Environmental Protection Agency (EPA), and many state governments share the responsibility of licensing and regulating radioisotopes in the United States. The individual states regulate radioactive substances that occur naturally or are produced by machines, such as linear accelerators or cyclotrons. The FDA regulates the manufacture and use of linear accelerators, but the states regulate their operation. The NRC regulates medical, academic, and industrial uses of nuclear materials generated by or from a nuclear reactor.

The Oak Ridge Institute for Science and Education's (ORISE) Radiation Emergency Assistance Center/Training Site and the International Atomic Energy Agency (IAEA) both maintain radiation incident registries that track US and foreign radiation incidents. However, recognizing that both these registries are limited in their data collection regarding individual patients' clinical conditions and their therapy, the Moscow Ulm Radiation Accident Clinical History Database (MURAD) was formed in 1990. The International Computer Database for Radiation Exposure Case Histories (ICDREC) succeeded MURAD and seeks to gather as many cases of ARS as possible to develop research and management strategies for the scientific community.[15]

Exposures to man-made sources of radiation are not required to be reported to poison centers and in general do not result in significant morbidity. However, the American Association of Poison Control Centers Toxic Exposure Surveillance System (AAPCC-TESS) reported

a total of 2636 exposures to radioactive isotopes over the last 10 years, increasing from 166 in 1993 to 320 in 2003. This increase in reported exposures was commensurate with the overall increase in reports to poison centers. Of the 2003 reported cases, 287 (90%) were unintentional, and 26 (8%) involved children younger than 6 years of age. There were no deaths reported to poison centers from exposure to radioisotopes over the last 10 years (Chap. 130).

Epidemiology

Everyone is exposed to radiation in one form or another each day (Table 128-2). There are naturally occurring sources of radiation in the earth's crust that make the largest annual contribution to man's radiation exposure, and man-made sources of radiation, which make a relatively smaller contribution to our average annual exposure.

Natural Sources of Radiation

A wide variety of natural sources expose humans on a daily basis to ionizing radiation. In the United States the estimated annual dose equivalent of radiation is 3.6 mSv, and natural sources contribute about 80% of that annual dose.[12,29] Terrestrial sources of radiation originate from radionuclides in the earth's crust that move into the air and water. These primordial radionuclides, so named because their physical half-lives are comparable to the age of the earth, include uranium, actinium, and thorium. Geographic areas vary regarding the content of these radionuclides.

Radon, a radioactive noble gas, accounts for most of the human exposure to radiation from natural sources. This gas, a natural decay product of uranium and thorium, enters homes and other buildings from the building materials themselves or through microscopic cracks in the building's structures. With a relatively short half-life of 3.82 days, ^{222}Rn poses a health risk if decay occurs while in the

respiratory space and deposits on respiratory tissue as one of its daughter isotopes, which are solids. These radon daughters emit Î± particles as they decay and are the principle causes in the associated increased incidence of lung cancer in those exposed to radon.[74]

TABLE 128-2. Average Effective Annual Ionizing Radiation Dose Equivalent in the United States

Source	Dose[1] mSv[2]	%
Natural		
Cosmic	0.27	8
Internal	0.39	11
Radon[3]	2.0	55
Terrestrial	0.28	8
Subtotal	2.94	82
Man-Made		
Consumer products	0.10	3
Nuclear medicine	0.14	4

Occupational	<0.01	<0.3
X-ray diagnostic imaging	0.39	11
Subtotal	0.63	18
Total	3.6	100

[1]All doses are averages and contain some variability within the measurement.
[2]mSv = millisieverts
[3]Average effective dose to bronchial epithelium

Additionally, radon daughters are charged and can attach to larger aerosols to be inhaled primarily. Radon daughters can also remain unattached to aerosols and form smaller sized aggregates, enabling them to penetrate to smaller airspaces. There is a complex relationship between exposure to radon progeny and dose to target cells. Influencing physiologic factors include tidal volume, minute ventilation, mucus thickness, and mucociliary clearance.

The risk of lung cancer is increased in heavy smokers who additionally expose their lungs to 200 mSv from ^{210}Po (a radon daughter) that is naturally found in tobacco smoke. Areas of New York, New Jersey, and Pennsylvania, called the Reading Prong, have particularly high levels of radon as a result of a richer concentration in the earth's crust of primordial radionuclides that liberate radon. The EPA has recommended household level intervention when ambient radon levels exceed 147 Bq/m^3 (4 pCi/L). Individuals can test their own homes for radon with either short-term (less than 90 days) or long-term (greater than 90 days) commercially available measurement devices.

The second largest natural source of radiation originates from ingested radionuclides, of which ^{40}K, a naturally occurring isotope, is the most abundant. Together with other primordial radionuclides in our diet, this source of internal radiation accounts for about 12% of the annual dose of absorbed radiation.

Man-Made Sources

As mentioned earlier, man-made sources of radiation can be found in many consumer products and in many different types of industry (Table 128-3). The National Council on Radiation Protection and Measurements (NCRP) estimates the annual number of workers occupationally exposed to radiation to be nearly a million.[29] On average, those occupations with the highest exposures (about 12 mSv/yr) are uranium miners, nuclear power operators, and sailors in close proximity to nuclear reactors. Those with lesser additional exposures (about 1â€“2 mSv/yr) include physicians, x-ray technologists, nuclear fuel processing workers, and workers in other industries that use radionuclides.

Medical occupational exposure principally includes physicians, nurses, and x-ray technologists, who receive an additional annual effective dose of about 1 mSv. This dose can range up to 17 mSv with certain techniques such as fluoroscopy but are only partial body exposures because of the appropriate use of lead aprons and other protective barriers. Medical procedures also account for substantial annual exposure to man-made radiation for patients. In 1989, the NCRP estimated the annual number of various diagnostic procedures involving radiation in the United States to exceed 250 million, although the number has increased quite rapidly over the last decade. Medical sources of exposure to patients account for about 0.5 mSv or 15% of the average annual exposure.

Exposures have been studied in emergency physicians, orthopedists, and interventional cardiologists.[30,42,95,100] Each of these fields uses different modalities of radiation, which pose different risks to the

individual performing the procedure. Two studies examining exposure to physicians assisting in cervical spine radiographs found the calculated whole-body exposure ranged up to 0.027 mSv per procedure, or 0.75% of the estimated annual dose equivalent of radiation in the United States.[42,100] This exposure annualized over a year neared the NCRP upper limits of safety, which might be exceeded if the number of procedures were to increase. Two other studies examined physician exposure to radiation by fluoroscopy used in interventional cardiology and orthopedic procedures. These doses ranged from 0.05â€“0.3 mSv per procedure. In each of these four studies, appropriate shielding was used, and dosimeters measured individual areas of exposed body parts such as extremities and the head. Radiation was undetectable beneath a lead apron. Estimated whole-body exposures to these procedures were considered not to exceed the limits established by OSHA of 50 mSv per year. Although the likelihood of exceeding established radiation limits is low regardless of the procedure, and even assuming a reasonable increase in the number of procedures performed, appropriate shielding and safety training are emphasized to minimize the risk of exposure.

TABLE 128-3. Uses of Radioisotopes

^{241}Americium:	Used in smoke detectors, to measure lead levels in paint, steel, and paper production
^{109}Cadmium:	Analyze metal alloys
^{47}Calcium:	Biomedical research of cell function and bone formation

^{252}Californium:	Inspect luggage for explosives, gauge moisture content of soil and silo materials
^{14}Carbon:	Pharmaceutical research, radiometric dating
^{137}Cesium:	Measure dosages of radioactive pharmaceuticals, oil industry to measure flow in pipelines
^{51}Chromium:	Red blood cell survival studies
^{57}Cobalt:	Nuclear medicine
^{67}Copper:	Chemotherapy
^{244}Curium:	Mining industry
^{123}Iodine:	Diagnosis of thyroid disorders
^{129}Iodine:	Used to check some radioactivity counters in vitro diagnostic testing
^{131}Iodine:	Treatment of thyroid disorders
^{192}Iridium:	Test the integrity of pipeline welds, boilers, and aircraft parts
^{55}Iron:	Analyze electroplating solutions

^{85}Krypton:	Indicator lights, textile industry
^{63}Nickel:	Detect explosives, voltage regulators, surge protectors
^{32}Phosphorus:	Molecular biology and genetics research
^{238}Plutonium:	Power source for NASA spacecraft
^{210}Polonium:	Photographic film production
^{147}Promethium:	Thermostats, textile industry
^{226}Radium:	Lightning rods
^{75}Selenium:	Protein studies
^{24}Sodium:	Industrial pipelines integrity
^{85}Strontium:	Study bone formation and metabolism
^{99}Technetium:	Nuclear medicine
^{201}Thallium:	Cardiac imaging
^{232Th}Thoriated tungsten:	Electric arc welding

^{229}Thorium:	Fluorescent lights
^{230}Thorium:	Coloring and fluorescence in colored glazes and glassware
^{3H}Tritium:	Basic science and pharmaceutical studies, for self-luminous signs, luminous dials, gauges and wrist watches, luminous paint
^{234}Uranium:	Dental fixtures
^{235}Uranium:	Fuel for nuclear power plants and naval nuclear propulsion systems, fluorescent glassware, colored glazes, and wall tiles
^{133}Xenon:	Nuclear medicine

Various medical scans use radioactive nuclides to study various disease processes (Table 128-4). Other radionuclides used in

medical diagnostics include ^{111}In, ^{67}Ga, and ^{51}Cr. Other scientific research uses tritium (^{3}H) and ^{32}P. These nuclides decay through Î²-particle capture or emission. In general, unintentional topical exposure to these radionuclides in this setting is not considered hazardous because skin and clothing provide adequate barriers against the poorly penetrating particles emitted. In the case of unintentional incorporation, it is highly unlikely that the amount infused will be sufficient to cause a serious health risk.

TABLE 128-4. Diagnostic Imaging Procedures: The Type and Amount of Radionuclide or Radiation

Test	Radionuclide	Amount
Whole Body Bone Scan	^{99}Tc	25mCi(9.25 Ã— 10^8Bq)
Radionuclide Cerebral Angiogram	^{99}Tc-DTPA	15mCi(5.55 Ã— 10^8Bq)
Cardiac Ejection Scan (MUGA)	$^{99}TcO_4$	20mCi(7.4 Ã— 10^8Bq)
DISIDA/Hepatobiliary Scan	^{99}Tc-DISIDA	5mCi(18.5 Ã— 10^7Bq)
Ventilation/Perfusion Scan	^{133}Xe	10mCi(37 Ã— 10^7Bq)
	^{99}Tc	4mCi(14.8 Ã— 10^7Bq)
Thyroid Scan	^{123}I	0.2mCi(0.74 Ã— 10^7Bq)
Myocardial Perfusion Scan (Exercise)	^{201}TI	3mCi(11.1 Ã— 10^7Bq)

	^{99}Tc	20mCi(7.4 Ã— 10^8Bq)
Strontium Therapy	^{89}Sr	4mCi(14.8 Ã— 10^7Bq)
Venogram	^{99}Tc	20mCi(7.4 Ã— 10^8Bq)
Chest radiograph	60 mrad or 0.06 mGy in a collimated field[1]	
Abdominal radiograph	100â€“1500 mrad or 1â€“5 mGy in a collimated field	
CT-Head	1â€“2 rads or 0.01â€“0.02 Gy per slice[2]	
CT-Body	1 rad or 0.01 Gy per slice[2]	
[1]Collimation is the act of restricting the size of the useful x-ray field to the region of clinical interest. These skin-entry doses are approximations dependent on equipment and technique. [2]The dose per each examination is about the same as the dose per slice and not the sum of the slices.		

Depleted uranium (DU) is used by the United States military and by several other governments as an armor piercing alloy ammunition. Munitions made of this material are favored because it is pyrophoric, sharpens on impact, has a high density (about 1.7 times that of

lead), and is less expensive than tungsten, which was used for this purpose until 1973. DU can be obtained from the enrichment process of natural uranium in the development of nuclear fuel, the reprocessing of spent nuclear fuel, or developed directly for military purposes. DU is mainly ^{238}U, but contains approximately 0.2% of other isotopes of uranium and several other transuranic elements as well depending on its origin. Consequently, DU's Î± and Î² activity is about 40% less radioactive than naturally occurring uranium. When DU munitions strike a hard target, it is dispersed as an aerosol and contaminates a limited area. Radiation exposure is derived from incorporation of the aerosolized material.[31] Thus, as a radiation hazard, exposure to solid ^{238}U is considered to be negligible although currently many studies are investigating the potential link between DU and the incidence of leukemias, other cancers, and birth defects.[4,11,18,24,41,62,63,69,70,73] One study examined a cohort of over 50,000 service personnel from the United Kingdom who served in the Gulf War but found no increase in the incidence of any cancers over 6 years following the end of the war.[56]

Exposure Limits

The various agencies involved in regulating radiation exposures to both workers and the public include OSHA, the NRC, and the Department of Transportation (DOT). The NRC has established â€œStandards for Protection against Radiation,â€• which regulates radiation exposures using a 2-fold system of dose limitation: doses to individuals shall not exceed limits established by the NRC, and all exposures shall be kept as low as reasonably achievable (ALARA). The total effective dose equivalent may not exceed 50 mSv/yr to reduce the risk of stochastic effects (see Stochastic Versus Deterministic Effects of Radiation). The dose to the fetus of a pregnant radiation worker may not exceed 5 mSv over 9 months and should not substantially exceed 0.5 mSv in any one month, although this amount is not carefully defined.[40,82]

Pathophysiology

Ionizing radiation causes damage to tissue by several mechanisms depending on its energy. Radiation with high LET predominantly causes direct damage, which is when incoming radiation impacts a target molecule directly. This occurs because high LET radiation, such as an Î± particle, has a high statistical probability of impacting an important molecule, such as DNA.[29] If this occurs, a mutation may arise, which may then result in alteration of a germ line, development of a neoplasm, or cell death. The risk of these consequences overall, however, is low because of the relative paucity of DNA within a cell and the even smaller percentage of active DNA within a given cell.

Low LET radiation, x-rays, Î³ rays, and fast electrons, predominantly cause indirect damage. The likelihood that radiation will cause cell damage is a function of its LET and reaches a peak at about 100 keV/Âµm. At this energy, the average separation between ionization events coincides with the diameter of the DNA helix and allows for the greatest probability of double-strand breaks, which is the basis for most biologic effects. Greater or lesser energies correlate to a lower probability of DNA impacts, and so the rest of the cell media becomes the energy absorber.[37]

Indirectly, radiation impacts a molecule and creates a reactive species, which then chemically reacts with organic molecules in cells, altering their structure or function. These radiation-induced ions are quite unstable, however, and usually convert to free radicals. Most importantly, radiation may impact a water molecule, which is in great abundance, to generate a hydroxyl radical (OHÂ·).[29] The hydroxyl radical diffuses only a short distance through the cell because of its highly reactive nature and itself causes molecular damage.

The bystander effect refers to cellular damage in unirradiated cells that neighbor irradiated cells. As early as the 1940s, there were reports of inactivation of cells by ionization of the surrounding

medium. Today, with the use of a single-particle microbeam, a device that can fire a predefined exact number of Î± particles through a particular cell nucleus, cultured cells that were not hit by radiation have increased chromosome damage, rearrangement, and rate of death. The bystander effect is demonstrated using proton beams and x-rays, and in cells cultured with DU.[64,75] Communication from cell to cell via gap junctions is an important factor in cell death and mutations, which are observed in these experiments. In one experiment, when 10% of cells on a dish were exposed to two or more Î± particles, the resulting frequency of induced oncogenic transformation was indistinguishable from that when all the cells on the dish were exposed to the same number of Î± particles.[84]

Genomic instability is when a gene responsible for the stability of the genome and the consistency of replication is altered, resulting in a cascade of other mutations and the subsequent development of

a neoplasm. Several studies demonstrate that, in addition to direct radiation damage to genetic material, radiation causes perturbations in intracellular oxidation-reduction reactions and far outlast radiation-generated hydroxyl radicals, which exist only for fractions of a second. These changes in oxidation-reduction reactions in turn cause other changes in signaling pathways leading to apoptosis, transformation, and other bystander effects that manifest as delayed or lethal mutations and chromosomal instability. Studies are ongoing that investigate specific causes of cellular injury and the precise mechanisms that may be responsible.[37,55]

Although any molecule may be damaged in a variety of ways that may lead to cell injury of varying severity, double-stranded breaks in DNA are the type of damage most likely to cause chromosomal aberrations or cell death. The cell's radiosensitivity is directly related to its rate of proliferation and inversely related to its degree of differentiation.[44,78] Thousands of these types of lesions occur daily in the human body from natural environmental radiation.

For this reason, there are several mechanisms that protect and repair damage that may result from either direct or indirect means of radiation damage. It is estimated that up to 90% of all chromosomal breaks heal by adhesion in a process known as â€œrestitution.â€• All that is required for DNA to heal is oxygen and time, which forms the basis for fractionated radiation therapy. This therapy takes advantage of the inefficient repair mechanisms of cancerous cells compared to normal cells. Thus, by giving the radiation dose over several sessions, radiation damage will accumulate in cancer cells during radiation therapy, and more cancer cells are killed. Sulfhydryl-containing molecules, such as glutathione, and other scavengers provide protection against free radicals. These molecules react with free radicals and inactivate them quickly, thus limiting the damage they can cause. Following a large radiation exposure, however, both restitution and the protection provided by free radical scavengers may be overwhelmed, and damage may occur.

Stochastic Versus Deterministic Effects of Radiation

The radiation damage just described has two consequential results: it kills cells or it alters cells and causes cancer. Injuries that do not require a threshold limit to be exceeded include mutagenic and carcinogenic changes to individual cells where DNA is the critical and ultimate target. This is the stochastic effect of radiation. Theoretically, there is no dose of radiation too small to have the potential of causing cancer in an exposed individual.[13] Theories suggesting that a single dose of radiation can cause a change in the genome that potentially alters the structure of a protooncogene, control of an oncogene, or activates oncogenic viruses in hosts are supported by a growing body of work investigating bystander effects and genomic instability.[34] These effects may take several months to years to manifest, as happened with Japanese survivors of the nuclear bombs who suffered a spectrum of malignancies many years

after the event.

Whereas the stochastic effects of radiation may follow less severe exposures, such as prolonged exposure to low-level radon gas, the deterministic effects of radiation usually follow a large whole-body exposure, such as a Chernobyl- or Tokaimura-type event. In terms of cell death, a relatively large number of cells of an organ system must be killed before an effect becomes clinically evident. This number of killed cells constitutes a threshold limit that must be exceeded, and this is what is known as the deterministic or nonstochastic effects of radiation.

To illustrate the differences between stochastic and nonstochastic effects consider a single alpha particle from ^{210}Po incorporated in a radon-contaminated household may impact an active segment of DNA in a patient's respiratory tract, ultimately giving rise to a cancerâ€”the stochastic effect. In Tokaimura, the most severely injured worker received 17 Sv of neutron and Î³ radiation and experienced so much cell death across so many systems in his body that he died well before any injured yet surviving cells could develop into a cancerâ€”the deterministic effect.

Acute Radiation Syndrome

The Army Medical Corps first described ARS in 1946 when victims of the explosions at Hiroshima and Nagasaki were admitted for treatment at Osaka University Hospital.[47] Understanding the features of ARS is essential for managing a patient who is exposed to massive whole-body irradiation, generally considered to be 1 Gy (250 times the average annual exposure) or more. In many cases, a reliable estimate of the radiation dose is difficult, thus making it more practical to focus on the clinical features of radiation injury and their prognostic utility.

The acute radiation syndrome involves a sequence of events that varies with the severity of the exposure.[26,93,99] Generally, more

severe exposures lead to more rapid onset of symptoms and more severe clinical features. There are four classic clinical stages described, which begin with the early prodromal stage of nausea and vomiting. These symptoms begin anywhere from hours to days postexposure. Although the time to onset postexposure is inversely proportional to the dose received, the duration of the prodromal phase is directly proportional to the dose. That is, the greater the dose received, the more rapid the onset of symptoms, and the longer their duration, except in cases in which death follows rapidly.[78] The latent period follows next as an apparent improvement of symptoms during which time the patient appears to have recovered and has no clinically apparent difficulties. The duration of this stage is inversely related to dose and may last from several days to several weeks. The third stage usually begins in the third to fifth week after exposure and consists of manifest illness described below. If one survives this stage, recovery, the fourth stage, is likely, but may take weeks to months before it is completed. Those exposed to supralethal amounts of radiation may experience all the phases in a few hours prior to a rapid death.

These four stages describe the clinical manifestations that may be observed as a result of massive exposure, but the various systems of the body manifest their own injuries, which constitute several subsyndromes.[26,99] These subsyndromes are not mutually exclusive of one another and may overlap as cell death or damage progresses.

The cerebrovascular syndrome describes the manifestations of injury to the central nervous system following massive irradiation. This syndrome, following exposure to doses of about 15â€“20 Gy or greater, is characterized by rapid or immediate onset of pyrexia, ataxia, loss of motor control, apathy, lethargy, cardiovascular shock, and seizures. The mechanism of this injury may be a combination of radiation-induced vascular lesions and free radicalâ€“induced neuronal death and cerebral edema.

Despite autopsy evidence of some radiation-induced inflammatory

changes to the heart, animal experiments show this organ to

be relatively resistant to high doses of radiation. Cardiovascular shock is more likely because of systemic vascular damage, which may later compound shock resulting from other subsyndromes should the patient survive to that point. A â€œvascular radiation subsyndromeâ€• might be considered to help explain the changes in hemodynamics a patient experiences following a massive dose of radiation. Once these subsyndromes are manifest, they may never resolve.[20,26,78,83]

The gastrointestinal syndrome begins following an exposure to about 6 Gy or more where there is gastrointestinal mucosal cell injury and death. Symptoms include anorexia, nausea, vomiting, and diarrhea. As the mucosal lining is sloughed, there is persistent bloody diarrhea, hypersecretion of cellular fluids into the lumen, and a loss of peristalsis, which may progress to abdominal distension and dehydration. Destruction of the mucosal lining allows for colonization by enteric organisms with ensuing sepsis.

The hematologic changes that occur following an exposure to about 1 Gy or greater are called the hematopoietic syndrome. Hematopoietic stem cells are highly radiosensitive, in contrast to the more mature erythrocytes and platelets. Lymphocytes are also radiosensitive and can die quickly from cell lysis following an exposure. This contrasts with granulocytes, which endure radiation better. In addition to stem cell death and white cell depletion with immunodeficiency, platelets are consumed in gingival and gastrointestinal microhemorrhages. The main effect of radiation-induced hematopoietic syndrome is pancytopenia leading to death from sepsis complicated by hemorrhage. A lymphocyte nadir typically occurs 8â€“30 days postexposure, with higher doses achieving earlier nadir.[14,25]

The pulmonary system is not spared injury from irradiation. Pneumonitis may occur within 1â€“3 months following a dose of 6â€“10 Gy. This may lead to respiratory failure, pulmonary fibrosis,

or cor pulmonale months to years later.

Dose Estimation

Determining the dose received by an individual who was irradiated is important in providing appropriate therapy and establishing a prognosis. However, estimating the dose received is difficult for a number of reasons, such as the absence of a radiation-monitoring device, exposure to radiation of mixed form (such as Î³ and neutron radiation), and partial shielding of various body parts.[83]

In cases of whole-body irradiation, it is the ARS itself that allows for an estimate of the radiation dose received. The Biological Assessment Tool available at the Armed Forces Radiobiology Research Institute's web site, and guidelines from the International Atomic Energy Agency (IAEA), use clinical signs and symptoms, including the time to onset of vomiting after an exposure to radiation, to calculate the exposure dose and may be the clinician's best dosimeter.[78] Use of this kind of timing may be limited, however, because most exposures can not be perceived by human senses.

As previously mentioned, the component of the hematopoietic syndrome that manifests as lymphopenia is common following an exposure to 1 Gy or more. The observed predictability of this lymphopenia has led to the development of several models for biodosimetry. It is important to note that dosimetry models account for changes in lymphocyte count because of other reasons, such as trauma and burns, and have been validated. However, discrepancies between the models suggest that more than one element of dosimetry be used whenever possible.[99]

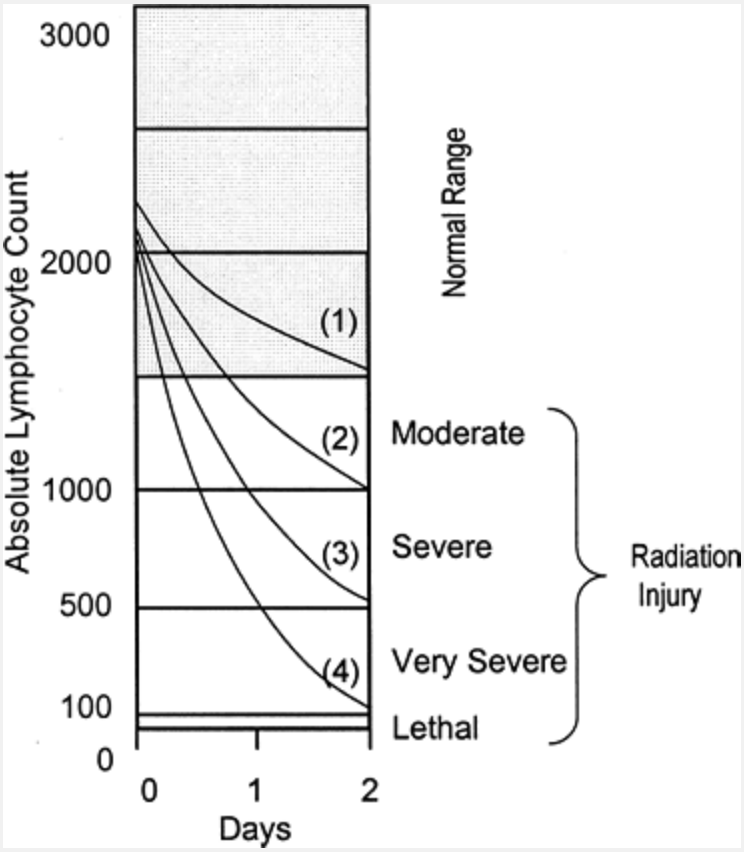

Figure 128-2. Classic Andrews lymphocyte depletion curves with accompanying clinical severity curves. Curves 1â€“4 correspond to whole body exposures of 3.1, 4.4, 5.6, and 7.1 Gy, respectively. *(From Goans RE, Holloway EC, Berger ME, Ricks RC: Early dose assessment following severe radiation accidents. Health Phys 1997:72:513â€“518.*

The broad ranges of radiation dose that correlate with lymphocyte count are described in the classic Andrews nomogram of 1965 (Figure 128-2). Using historical data from exposed patients, one author calculated a lymphocyte depletion constant using the equation:

$$L(t) = L_0 e^{-K(D)\ t}$$

in which L(t) is the lymphocyte count at time t, L_0 is the lymphocyte count prior to the exposureâ€”the population mean taken as 2.45 Ã— 10^9 cells/L, K(D) is the rate constant for a given dose of radiation, and D is the dose of radiation. Solving for K(D) will allow for an accurate estimate of a rapidly delivered, whole body exposure[32] (Table 128-5).

The standard criterion for biodosimetry are chromosome aberration bioassays. Introduced in 1966, this technique analyzes the number of dicentric chromosomes that occur following an exposure to radiation. An exposure to radiation can cause breakage of

the DNA molecule in two nonhomologous chromosomes and produce â€œsticky endsâ€• that recombine end-to-end. In metaphase, these appear as a single chromosome with two centromeres and are called dicentric. The number of dicentrics in lymphocytes correlates reliably with a given dose of radiation. Additionally, if the number of dicentric chromosomes follow a Poisson distribution, a uniform exposure can be assumed (see Table 128-5).[1,50,76]

TABLE 128-5. Biodosimetry Tools[99]

Dose Estimate (Gy)	Time to Onset of Vomiting (Hours)	Rate Constant for Lymphocyte Depletion	Dicentric Chromosomes in Human Peripheral Blood Lymphocytes (per 1000 Cells)
0	n/a	â€”	1â€“2
1	>24	0.126	88

2	4.5	0.252	234
3	2.5	0.378	439
4	1.75	0.5	703
5	1.25	0.63	1024

Even though there is no currently accepted standard for performance, analysis of dicentric chromosomes in peripheral blood lymphocytes is the only method routinely used in biodosimetry. However, because proliferative death of cells containing aberrant chromosomes reduce the number of such cells available for analysis over time, and the migration of lymphocytes into tissue and the lymphatic system, there is a limited period available to use this test to perform dose calculations retrospectively.[46,49] A recent development in molecular biology, the fluorescence in situ hybridization (FISH) chromosome-painting technique, has opened the possibility for accurate recognition of translocations and thus retrospective determination of dose. Unlike dicentrics, complete translocations persist in cell division and enable dose estimation over years following exposure.[48] In fact, this technique was employed to evaluate the radiation dose experienced by clean-up workers at Chernobyl. These authors concluded that it is likely that recorded doses for these cleanup workers overestimate their average bone marrow doses, perhaps substantially.[52] Unfortunately, these techniques are not widely available, require incubation times of 48â€“72 hours, and can not assess for doses greater than 5 Gy, although new methods for high-exposure assessments are being developed.

Prognosis

The prognosis of those exposed to radiation will vary with the amount of the exposure, the type of medical care received, and the number of casualties in a given exposure scenario. Survival is inversely proportional to the radiation dose absorbed, and even the relatively radioresistant cell types can be killed by high amounts of radiation. For these reasons, an acute dose of 20 Gy or more is considered supralethal.[86] Historically, those who were exposed to greater than 10 Gy died despite care. This includes one worker at Tokaimura who was exposed to 17 Gy who died 3 months postexposure, and 20 of 21 workers who were exposed to radiation in the 6â€“16-Gy range at Chernobyl. Some authors suggest that those exposed to 10 Gy or greater be given supportive and comfort care only because their survival is considered to be unlikely.[99]

Within the group exposed to 5â€“10 Gy, depending on the dose received, there may be milder forms of CNS and cardiovascular syndromes that last for a longer time. A severe GI syndrome in which high fever and persistent hematochezia are present suggests a poor prognosis. This syndrome may overlap with a severe form of the hematopoietic syndrome in which damage to bone marrow stem cells is so severe that bone marrow function may not recover for weeks or months. These patients will likely require bone marrow transplantation and multiple transfusions of platelets and red blood cells, optimal supportive care, and infection control to survive.

Patients exposed to radiation in the range of 2â€“5 Gy will likely survive with medical care. Although the median lethal dose of radiation for humans is estimated to be 4.5 Gy, the manifestations of ARS will be similar to those noted above but will likely be delayed and less severe. Many patients will survive without bone marrow transplantation if supportive care optimizes fluid and electrolyte replacement and controls bleeding and infection.

Survival is expected for those patients acutely exposed to less than 2

Gy with little medical intervention necessary. Mild forms of GI and hematopoietic syndromes may occur in delayed fashion compared to more severe exposures.

Carcinogenesis

There are good data to support that radiation increases the incidence of specific cancers in humans. One of the most important sources of these data is life-span studies of atomic bomb survivors in Japan.[19] This group of people is extensively studied over the last half-century, and although the relative risks assigned to specific cancers are modified over the years and subject to interpretation, there is a general agreement that the incidences of leukemia (except chronic lymphocytic leukemia, CLL), female breast carcinoma, and thyroid cancer increase following a sufficient exposure. This risk is largely extrapolated from models of high-dose exposures, but is also supported by data for persons exposed to radon.[19] These cancers usually do not appear until years after the exposure. Because of technical and logistic difficulties in performing appropriate epidemiological studies, there is difficulty in quantifying the cancer risk from exposure to low-dose (less than 10 mSv) radiation.[7] For those exposed while they are young, the excess incidence of cancer occurs only when they are at the age when those cancers otherwise appear in the unirradiated population, as was discussed earlier with the British Nuclear Tests Veterans Association (BNTVA) group.[29,80]

Pulmonary exposure to radon has been studied extensively in the last few years. Both uranium miners and household residents in areas with high ambient radon concentrations, such as New Jersey and Sweden are at increased risk for developing lung cancer from exposure to radon gas. A cohort of nonsmoking uranium miners showed a 12-fold increased risk of lung cancer over controls, which is similar to the estimates of the increased risk of lung cancer caused by radiation exposure in atomic bomb survivors.[12,81] The increased risk of lung cancer from exposure to radon gas is modified by

concurrent cigarette smoking, which may have a multiplicative effect rather than an additive effect.[71]

Commonly Encountered Radionuclides

Most exposures that come to medical attention are not large, whole-body irradiations but are rather small spills in the laboratory or inadvertent exposures from one of many products that are commercially available. With the notable exception of a well-known case of massive americium contamination in Oak Ridge, Tennessee and the cesium exposure in GoiÃ¢nia, Brazil, the vast majority of these types of cases are not reported in the medical literature.[25,91]

Americium (symbol Am, atomic number 95, and atomic weight 243) was discovered in 1946 in Chicago during the Manhattan Project. Its most stable isotope, ^{243}Am, has a half-life of over 7500 years, although ^{241}Am, with a half-life of 470 years, was the first isotope to be isolated. It decays by Î± activity and Î³ emissions and will accumulate in bone if incorporated.[53] It is used to test machinery integrity, glass thickness, and in smoke detectors, where

it ionizes the air between 2 electrodes and generates an electric current that soot may impede. Î±- Particles from these detectors are easily absorbed within a few centimeters of the surrounding air and pose little risk. One g of americium dioxide provides enough americium for more than 5000 smoke detectors. Useful chelators include diethylenetriaminepentaacetic acid (DTPA, now FDA-approved) and linear tetrahydroxypyridinone (LIHOPO). In 1976, a worker at the Hanford Plutonium Finishing Plant, suffered a large ^{241}Am contamination in an explosion at the site. One hundred g (500,000 smoke detectors worth) of ^{241}Am was involved, contaminating the victim's face with 70MBq, but there was likely some inhalational exposure as well. He was treated with long-term DTPA, and despite some leukopenia from the radiation, he survived for 11 years before dying from unrelated cardiac disease.[91]

Cesium (symbol Cs, atomic number 55, and atomic weight 132): Bunsen discovered Cs spectroscopically in 1860. It decays by Î² activity and Î³ emissions and tends to follow the potassium cycle in nature, providing a whole-body dose if incorporated. It is used as a radiation source in radiation therapy and as a radionuclide source for atomic clocks. Cesium, the nuclide of the GoiÃ¢nia incident, comes in the form of a powder, which would make dispersal relatively easy if used in a dirty bomb. Insoluble Prussian blue was recently approved by the FDA as a chelator for patients contaminated with cesium (see Antidotes In Depth: Prussian Blue).[17,51]

Cobalt (symbol Co, atomic number 27, and atomic weight 58.9) was discovered in 1735 by Brandt. ^{60}Co is an artificially made isotope and is an important source of Î³ rays for radiotherapy, and detecting weld seam integrity. ^{60}Co was the source of a significant radiation incident that took place in North America in 1983.[59] A radiotherapy source containing 16.65 (10^{12}Bq (450 Ci) of ^{60}Co in the form of thousands of millimeter-sized pellets was opened and spilled onto a truck in a junk yard in Juarez, Mexico. At least 200 people were exposed to the contaminated truck and the materials subsequently made from the contaminated scrap metal in the junk yard.

Iodine (symbol I, atomic number 53, and atomic weight 126.9): Courtois discovered iodine in 1811. There are 23 isotopes of iodine; ^{127}I is the only one that is stable. ^{125}I is used in thyroid studies and decays by Î³ emissions. ^{131}I is used in metastatic thyroid surveys and decays by Î² activity and Î³ emissions. ^{129}I and ^{131}I are also products of fission in nuclear reactors that may be released into the environment during an event. These isotopes will accumulate in thyroid tissue if incorporated and can cause local damage to thyroid tissue. It is this potential for incorporation that prophylaxis with potassium iodide (KI) is indicated in the event of a large exposure.

Phosphorus (symbol P, atomic number 15, and atomic weight 30) was discovered in 1669 by Brand. ^{32}P has a half-life of 14 days and decays by Î² activity. The maximum range of decay particles in air is

20 feet, and in tissue, 1/3 inch. For soluble ^{32}P compounds, bone receives approximately 20% of the dose following ingestion or inhalation. Shielding for ^{32}P and other Î² emitters should be made of material with atomic numbers of less than 13 (aluminum) to reduce the generation of x-rays, electromagnetic radiation produced by the rapid change of velocity of a fast moving particle as it approaches an atomic nucleus and is deflected.

Radon (symbol Rn, atomic number 86, and atomic weights range from 204 to 224) was discovered in 1900 by Dorn, and was first called *radium emanation*, then *niton*, and finally radon in 1923. Radon is the heaviest noble gas. Radon is also a decay product of radium and a decay product of thorium and actinium, where it is also called thoron and actinon, respectively. ^{222}Rn decays by Î± activity and Î³ emissions. Exposure of radon gas to the pulmonary epithelium is associated with an increased incidence of lung cancer in both uranium miners and in those who dwell in residences with increased levels of radon. Damage to bronchial epithelium results from radon's Î± emissions and radiation from radon daughters that precipitate as solids and remain in the lungs. Good enclosed space ventilation, abstinence from cigarette smoking, and monitoring of radon levels will help to minimize this risk.

Technetium (symbol Tc, atomic number 43, and atomic weight 98.9) was discovered in 1937, and it was the first element to be produced artificially. Tc does not exist in terrestrial materials but does seem to exist literally among the stars. ^{99}Tc is used in testicular, bone, and thyroid scans and has a half-life of 6 days. Tc decays by Î² activity and Î³ emission. Chelation may be accomplished with DTPA.

Thallium (symbol Tl, atomic number 81, and atomic weight 204): Crookes discovered thallium spectroscopically in 1861. ^{201}Tl is used for cardiac imaging, has a half-life of 73 hours, and decays by electron capture and Î³ emission. Chelation can be accomplished with Prussian blue (see Antidotes in Depth: Prussian Blue).

Tritium is an isotope of hydrogen whose nucleus contains 1 proton

and 2 neutrons, and its symbol is ^{3}H.[98] Tritium decays by Î² activity and is used in basic science research as a radioactive label, and for luminous dials. Tritium has a half-life of 12.25 years. When ingested as tritiated water, tritium tends to follow the water cycle in humans, providing a whole-body dose if incorporated. However, its biological half-life is 10â€“12 days, which can be decreased by increasing urine output, greatly limiting its potential toxicity.

Xenon (symbol Xe, atomic number 54, and atomic weight 131): Ramsay and Travers discovered Xe in 1898. There are 31 isotopes of Xe, 22 of which are unstable. ^{133}Xe is used in ventilation/perfusion scans. Its half-life is 5.27 days, and it decays by Î² activity and Î³ emission.

Management

Initial Assessment

The initial management of patients exposed to radiation will obviously depend on a number of different factors, including the amount of radiation in the exposure and the number of casualties in the event. These important factors will describe to a great extent the amount of resources, such as hospital beds or relatively rarely used medications, that will be required in managing those who were exposed. In a mass-casualty event, established prehospital plans should be followed to best manage the large numbers of variously injured given that the radiation exposure may also be accompanied by an explosion of potentially catastrophic size.

All patients should have stabilization of their airway, breathing, and circulation. Field triage protocols, according to the kind of event, will designate patients as minor, delayed, immediate, or deceased depending on their burns or physical trauma and will not be altered because of their radiation exposure. Decontamination should proceed in the field taking care not to contaminate prehospital providers or

equipment. Prehospital personnel should use personal protective equipment and Geiger counters.

Initial Emergency Department Management

When one or more patients who have been exposed to massive irradiation present to the ED, attention must first be paid to the more conventional injuries that may also be present.[78,93,99] Many times

radiation exposures occur with fires or explosions, and patients may have burns, smoke inhalation injuries, or traumatic injuries. This scenario would be the same for the explosion of the â€œdirty bomb,â€• a conventional explosive designed to disperse a radionuclide. Most survivable radiation injuries require prompt treatment but are not life threatening in the first few hours postevent. Thus, there is time to determine if the nature of the exposure was an irradiation or contamination by a radionuclide. Routine considerations of airway, breathing, and circulation take priority for these patients as with all others. If a patient should require surgery, the Armed Forces Radiobiology Research Institute (AFRRI) recommends that surgery proceed immediately because of the delayed and impaired wound healing associated with irradiated tissue.

For large-scale radiation incidents, it is likely that a number of individuals will be involved in developing the best management plan for the casualties. Locally, the radiation safety officer, the medical toxicologist, and the medical oncologist will lend their expertise to the emergency physician to determine the risk of the contaminant, begin appropriate testing to determine the biological effect, and lastly to initiate medical therapy if warranted. Additionally, the local or regional Department of Health should be notified. Larger or complex exposures may require the expertise of the Radiation

Emergency Assistance Center based in Oak Ridge, Tennessee (865-576-3131 Mondayâ€“Friday 8amâ€“4:30pm EST, after hours call 865-576-1005), which can provide valuable support.

Smaller-scale exposures to radiation still require at least a brief evaluation for burns and trauma, depending on the circumstances surrounding the nature of the exposure. Calls to the poison center from a residence require referral to emergency services for an expert evaluation of the level of contamination of the site and appropriate decontamination measures. Exposures in the laboratory or nuclear medicine suites require referral to the radiation safety officer in the building for a similar evaluation.

Decontamination

Patients exposed to radionuclides may be contaminated with radioactive material either externally or internally or both. Historically no medical personnel have ever developed ARS through exposure to a contaminated patient, although caution must be exercised when performing decontamination to minimize exposure to care providers. Unless there is active ongoing radiation, many authors recommend decontamination at the site of exposure to minimize the spread of radioactive materials.[78] All clothing should be removed, and patients should be thoroughly washed with soap and water. In the past, green soap, phosphate-based detergents, and chelating agents such as ethylenediaminetetraacetic acid (EDTA) and DTPA were used.[83] This can remove up to 95% of radioactive material from the patient. Open wounds should be carefully scrubbed to minimize the risk of internal contamination. A portable dosimeter may assist in external decontamination. If the patient was exposed to neutron radiation such as from a nuclear reactor, blood samples testing for induced ^{24}Na by $\hat{I}^3$-spectrophotometric analysis may help as an additional indicator of total dose received. Collected emesis and feces may also be analyzed, if desired, to help estimate total body dose. All clothing and liquid used to decontaminate must be

collected and be clearly marked as radioactive waste. Obviously, there should be no eating, drinking, or smoking at the scene of decontamination.

For patients with smaller exposures to radionuclides, such as laboratory workers, decontamination is often the only management technique required to limit injury. Portable dosimeters will identify contaminated areas, which may be sealed off to limit spread of exposure, especially if the radionuclide is in gaseous form. As with larger exposures, contaminated clothing must be removed and collected. Contaminated skin must be washed with lukewarm soap and water, repeatedly if needed, with care taken not to abrade intact skin and risk inadvertent incorporation. Washing may also be guided by a portable dosimeter. The cesium-exposed patients in GoiÃ¢nia received repeated baths in warm water and neutral soap over the first 2 days of their hospitalization, as did the Hanford americium patient.[91] If the patient is still contaminated after repeated washing, it is recommended to use a cream hand cleaner that contains no abrasives. Some of the GoiÃ¢nia patients habitually walked barefoot and had developed hyperkeratosis. The palms and soles that were heavily contaminated were treated with titanium dioxide mixed with hydrated lanolin. The paste was rubbed into the contaminated area and then gently abraded to try to remove more cesium.[67]

In evaluating an area in which a spill of radioactive material has occurred, a judgment must be made regarding the severity of the incident so that appropriate steps are taken. If a major incident has occurred involving large amounts of radioactive material, a large contaminated area, airborne radioactivity, or spread of radiation outside an authorized area, evacuation, notification of the radiation safety officer in an institutional setting, and calling local or regional emergency response are recommended. Minor incidents involve small amounts of radioactive material where the individual knows how to clean the site, has appropriate decontamination material on hand, and can clean the area in a reasonably short time. Several different decontaminating agents are commercially available from general

stores and many scientific suppliers. These agents come in the form of concentrated detergents or foaming sprays where a small spill is quickly wiped clean and disposed of in an appropriate container.

Triage

It is critical for patients exposed to a large dose of radiation to be triaged according to the dose so that a management plan can be created for them. There are many proposed stages of the various subsyndromes of ARS to help with this dosimetry, but in general we may consider three groups: exposure to less than 2 Gy, 2â€“4 Gy, and greater than 4 Gy. Those exposed to less than 2 Gy may experience some of the hematopoietic syndrome, but may be followed as an outpatient with or without cytokine therapy. Between 2 and 4 Gy, the hematopoietic syndrome is likely and may be severe, but at this dose the GI syndrome is not likely to be a major complication. Hospitalization is recommended at least initially for more accurate dosimetry and supportive care, including the early initiation of cytokine therapy. Exposure to greater than 4 Gy will mean a severe hematopoietic syndrome and likely a severe GI syndrome as well. These patients will likely require an intensive care setting and substantial supportive care for their survival.

Medical Management

In the ED, after airway and breathing have been managed appropriately, intravenous access should be established. As with thermal burns, peripheral IVs are more prone to infection, and central venous access is recommended. Fluid replacement may begin with crystalloid solution where the rate will be modified by recorded inputs and outputs and assessment of surface area burns if any.

Emergency management of emesis and pain may be difficult in those patients who received a high dose of radiation. Many types of

antiemetics are used to control an irradiated patient's vomiting. The 5-HT_3 antagonists, ondansetron and granisetron, are particularly effective in this setting. Mild pain may be managed with acetaminophen, but nonsteroidal antiinflammatory medications are not recommended, as they may exacerbate gastric bleeding in a patient for whom bleeding may soon become difficult to control. Morphine is recommended for the management of more severe pain, which may develop within a few hours after the injury from burns, mucositis, and other complications. As with burn patients, prophylactic use of antibiotics is not recommended.

In the ED it is important to obtain a complete blood count as soon as possible after exposure to begin biodosimetry estimation, and for blood typing. The timing of prodromal signs, such as vomiting, and calculation of the rate constant for lymphocyte depletion help to estimate the dose of radiation to which the patient was exposed. Ideally, a CBC is obtained 3 times a day for the first 2â€“3 days following exposure. Some authors recommend initiation of cytokine therapy as soon as possible if the estimated exposure dose is 3 Gy or greater. A threshold of 2 Gy may be used for children younger than 12 years and adults older than 60 years since these patients may be relatively more sensitive to the toxic effects of radiation. Blood typing early is important because the patient may require transfusions of red blood cells and platelets. Use of irradiated cells is recommended to avoid graft-versus-host disease.

For patients who survive the acute period, sepsis is the leading cause of death. To maximize survival, patients with a severe radiation exposure should be treated as other severely burned or immunocompromised patients regarding their risk of infection. Rigorous attention must be paid to the proper use of H_2 antagonists, antibiotics, antifungals, antivirals, and cultures of body fluids.

Special Management Techniques

Some patients may require supportive measures to boost their

immune system and decrease the risk of infection.[78,99] The colony-stimulating factors, granulocyte colony-stimulating factor, and granulocyte macrophage colony-stimulating factor prime neutrophil microbicidal activity and accelerate neutrophil recovery. Spared hematopoietic stem cells in patients with significant whole body or partial radiation exposures can be stimulated to proliferate in this manner. Although these cytokines only have approval by the FDA for treatment of myelosuppression resulting from cancer treatments, the rationale for their use in the setting of radiation-induced myelosuppression is based on positive results obtained in treating cancer patients and a small number of radiation incident victims and experiments with nonhuman primates.[21,22,99] Colony-stimulating factors were used successfully at GoiÃ¢nia and decreased the period of leukocyte depression while raising the nadir. Although there is no conclusive evidence that early administration is critical for best outcome for these patients, colony-stimulating factor therapy should be initiated as early as possible following the diagnosis of a 3 Gy exposure or greater. These factors should be continued until the absolute neutrophil count exceeds 1000 cells/mm^3. However, in the setting of a mass casualty event, it may be prudent to withhold these resources from those with large dose exposures or those with significant concurrent traumatic injuries.

Following Chernobyl, 13 patients received bone marrow transplantation for hematopoietic support until their irradiated bone marrow could recover.[1,78] Unlike patients who undergo bone marrow suppression for clinical reasons, patients involved in a radiation exposure may have incomplete exposure and are usually partially shielded, which may allow for survival of some stem cells. Eleven of these bone marrow transplantation patients at Chernobyl died, complicating the interpretation of the efficacy of transplantation. Bone marrow transplantation does not change the mortality risk from the other subsyndromes of ARS. The ability of bone marrow transplantation to improve the clinical course of an irradiated patient depends on how likely the patient was to die from hematopoietic

syndrome alone. Some authors consider that there is limited indication for stem cell transplantation when there is also severe radiation injury to organ systems other than the hematopoietic system.[15] This remains a controversial mode of treatment for irradiated patients.

Probiotics is the introduction of selective nonpathogenic strains of *Lactobacillus* and *Bifidobacteria* into the gastrointestinal tract to suppress the number of pathogens.[78,94] Experimentally, this technique increases survival in canine and rodent models. Probiotics was also used in Chernobyl on 3 men whose survival time was prolonged, although it was not statistically significant when compared respectively to case controls.

Incorporation of radionuclides presents a challenge to the treating physicians in which the goal is removal of an internal store of the radioactive material. Beginning in 1966, experiments with beagle dogs treated with DTPA showed decreased incidences of bone cancer when exposed to ^{241}Am.[53,54] Both Ca-DTPA and Zn-DTPA were approved in August 2004 by the FDA for human use for decontamination of plutonium, americium, and curium, although both are also considered useful in the elimination of soluble uranium salts (nitrates and chlorides not oxides) as well. The FDA recommends Ca-DTPA to be given first, ideally within 6 hours of exposure. Because its potency as a chelator is greater than its zinc counterpart, it poses a greater risk in long-term treatment because of loss of essential minerals. For this reason the FDA recommends using Zn-DTPA if treatment is to continue past 24 hours postexposure.[18] Zn-DTPA is poorly absorbed via the gastrointestinal tract. Both drugs may be administered intramuscularly, intravenously, or via nebulizer if a pulmonary exposure is suspected. Currently, Oak Ridge Associated Universities (ORAU) distributes DTPA under contract with the US Department of Energy (DOE). Additionally, rat experiments with LIHOPO demonstrate decreased retention of plutonium and uranium even after incorporation into bone.[18,97]

Prussian blue, ferric hexacyanoferrate, has been used for many years to treat thallium poisoning. Because it absorbs cesium ions, it is used in fission product recovery and is therefore useful in chelation therapy for patients contaminated with cesium. The two forms of Prussian blue, soluble and insoluble, have been used somewhat interchangeably as antidotes for thallium. However, it is the insoluble form that has the advantage when increasing elimination of cesium from the body (see Antidotes in Depth: Prussian Blue).[17,90,96]

As was mentioned earlier, ^{131}I is one of the key fission products that may be released from a nuclear power facility in an accident such as happened at Chernobyl. Additionally, much discussion is currently devoted to the potential for a terrorist attack either on a nuclear power facility or using a radiological dispersal device (a.k.a. â€œdirty bombâ€•) in which there could be environmental dispersal of radioactive iodine, although the 8-day half-life of ^{131}I theoretically limits its utility as an effective environmental contaminant. The increase of thyroid cancer observed in atomic bomb survivors and in those contaminated from the Chernobyl event prompted

the International Atomic Energy Agency (IAEA) to establish intervention criteria for a radiation emergency of an effective dose equivalent of 100 mSv.

TABLE 128-6. Potassium Iodide Regimen

Age	Dosage
>18â€“40 years	130 mg
3â€“18 years	65 mg
1 monthâ€“3 years	32 mg
Newbornâ€“1 month	16 mg

For children 18 years and younger, when there is prolonged risk for inhaled radioactive iodine, it is recommended that the indicated dose be repeated daily until the risk is considered past. This recommendation applies to lactating mothers.
For adults younger than 40 years, repeated dosing is not indicated in favor of controlling food intake, eg, abstention from drinking milk during the time of contamination.
For adults older than 40 years, the risk of radiation-induced cancer is so low that iodide prophylaxis is not indicated, unless the radiation amount is on the order of 5 Gy, but this is unlikely.

Supplying stable iodide to the thyroid, which acts as a blocking agent, reduces the uptake of ^{131}I.[89] This treatment, which should begin as soon as the environmental contamination has occurred, will limit the deterministic and stochastic effects of radioactive iodine uptake in thyroid tissue, particularly in children. The WHO, the CDC, the NRC, and the FDA all recommend similar dosing regimens based

on age for the prophylactic use of KI if an iodine-involving radiation incident threatens a population. KI is FDA-approved as a nonprescription drug and is available as 130-mg tablets that can be either split or dissolved in liquid for the smaller doses (Table 128-6). Several studies have also demonstrated that iodine can be absorbed transdermally when applied as tincture of iodine and povidone iodine to block thyroid uptake of radioiodine.[65,66]

Pregnancy and Radiation

In the normal course of events, uncertainty exists regarding the normal viability of the fertilized ovum, and there is a naturally high rate of embryo loss during the early weeks of pregnancy. When exposure to radiation via medical examination is possible, pregnant women and physicians have exhibited extreme concern over its potential teratogenic effects, even though maternal exposures to less than 0.05 Gy (5 rad) is considered not to be teratogenic.[3,36,77] Additionally, risk of direct harm to the fetus from cosmic radiation during casual airline travel is thought to be negligible.[2] Unfortunately, there is little direct information concerning the effects of radiation in early human pregnancy. Experimental data using rats and mice show increased mortality rates both in vitro and in vivo following irradiation and a dose-response curve that depicts incremental increases in radiation dose corresponding to increasingly greater effects in causing malformations.[88] Experimental human data from the 1930s show increased lethality and induction of abortion when pregnant women were exposed to 3.6 Gy and 5 Gy for a therapeutic abortion by x-ray.[39,61]

The most important sources of information concerning the teratogenic effects of fetal irradiation are the survivors of the nuclear bomb blasts of World War II. The three principal risks to a fetus following radiation exposure are congenital abnormalities, severe mental retardation, and the late development of a neoplasm. The embryo is at particular risk because of its rapid development,

and there are several periods of particular sensitivity so that irradiation at specific times is associated with increased risk of specific problems. Roughly speaking, uterine absorption of 0.1â€“0.15 Sv during the first 2 weeks postconception risks fetal lethality. During the third to seventh weeks postconception, uterine doses of 0.05â€“0.5 Sv risks congenital abnormalities, growth retardation, and small head size that may be accompanied by mental retardation. During the time between weeks 8 and 25 postconception, the risk is severe mental retardation, that decreases at the 16th week.[23,85,88]

Accurate specification of the risks from fetal doses is difficult especially at doses less than 0.2 Sv. Different models consider dose-response relationships for developmental complications and cancer development as linear or linear-quadratic, and with or without a threshold limit. A risk of congenital abnormalities of 5% following exposure to 0.2 Sv compares to a widely accepted average incidence for congenital abnormality of 6% for newborns throughout the world.[88] Patients receiving various diagnostic procedures in the hospital may be exposed to these doses.[38] Clearly, pregnant women who are exposed to radiation are at some risk for a fetal complication, although that risk may be difficult to quantify at the low doses expected with routine radiologic procedures.[10] That low-level intrauterine exposure to radiation increases subsequent cancer risk is not the question, but rather the etiologic significance of the radiation. For many years, studies have been plagued with incomplete data, biological implausibility, and other problems that confound an explanation.[6] Consideration should always be given to the potential maternal benefit of the radiologic procedure and the potential risk to the fetus.[82] However, the vast majority of routine diagnostic imaging procedures imparts less than 0.05 Sv to the fetus and so is considered to be of negligible risk.

Pediatrics and Radiation

The use of CT scanning in children has markedly increased over the last 20 years. One hospital's survey showed a 92% increase in abdominal and pelvic CT examinations from 1996 to 1999 for children younger than 15 years old. Although it is difficult to estimate the increased incidence of cancer rates because of LET radiation, there are reports that attribute a greater lifetime risk for cancer mortality resulting from CT examination in children. This risk is compounded by the tendency not to adjust the radiation dose given to a child during a CT examination from the amount given to adults. Together, these trends may mean increased radiation-induced mortality over the lifetime of the patient resulting from medical evaluation.[8,16,68]

Summary

The danger of ionizing radiation to humans is through the disruption of cellular structure and function. Cell death and mutagenesis are the destructive consequences of an exposure to radiation. Fortunately, large exposures of radiation to the general population are rare outside of the setting of an armed conflict, and most contaminations that occur are small and easily controlled.

In general, recognition of the exposure and thorough decontamination are the critical steps to minimizing the potential toxicity of an exposure. Careful attention to storage of radioactive waste and contaminated materials and good supportive care are usually all that are required to care for most patients.

Chapter 129
Poison Prevention and Education

Lauren Schwartz

Preventing poisonings and improved access to poison center (PC) services are both national public health issues. Healthy People 2010 is a federal document that presents health goals for the nation. This document reflects the input of public health individuals and organizations and consists of 28 areas with objectives to reach two main goalsâ€”increasing quality and years of healthy life and eliminating health disparities. Two objectives in the Injury and Violence Prevention section relate to poison prevention. Objective 15-7 is to reduce nonfatal poisonings and Objective 15-8 is to reduce deaths caused by poisoning. Objective 1-12 in Access to Quality Health Services focuses on national access to PCs and recommends establishing a single toll-free telephone number for access to PCs on a 24-hour basis throughout the United States.[18] This objective was achieved in 2002. Community-based public education programs at PCs are designed to help meet these public health objectives.

Legislation and Poison Prevention

As discussed in Chap. 1, because the first PC was established in 1953, a number of legislative events have improved poison prevention and awareness efforts and reduced the number of unintentional poisonings in children. Public education programs at PCs have been influenced by these federal measures.

National Poison Prevention Week

In 1961, President John F. Kennedy signed Public Law 87-319, designating the third week of March as National Poison Prevention Week (PPW) to raise awareness of the dangers of unintentional poisonings. During PPW, PCs and other organizations around the country organize events and activities to promote poison prevention. The American Association of Poison Control Centers (AAPCC) (http://www.aapcc.org) publicizes PPW nationally through joint efforts with the Poison Prevention Week Council and the Consumer Product Safety Commission (CPSC).

Child-Resistant Packaging Act

In 1970, the Poison Prevention Packaging Act was passed. This law requires that the CPSC mandate the use of child-resistant containers for toxic household substances. In 1974, oral prescription medications were included in this requirement. A review of mortality data in children younger than age five shows a significant decrease in deaths after enforcement of the child-resistant packaging legislation.[44,53]

Toll-Free Access to Poison Centers

In 2000, the Poison Control Center Enhancement and Awareness Act was enacted with a goal of nationwide access to PCs. A toll-free number (1-800-222-1222) was established access for all US

PCs. Callers are connected to a regional PC based on the area code and telephone number exchange. The AAPCC operates the toll-free number through a Cooperative Agreement with the Centers for Disease Control and Prevention (CDC) and Health Resources Services Administration (HRSA).[5] Figure 129-1 displays the national logo incorporated into educational efforts to support and promote the new national number for US PCs.

The Role of Public Educators in Poison Centers

Nationally, PCs employ approximately 100 public educators; 40% of whom are full-time.[20] Educators encompass a range of educational background including nurses, pharmacists, health educators, and teachers. The primary goals of public education programs at PCs are to teach poison prevention techniques (primary prevention) and to raise awareness about available services should a poisoning occur (secondary prevention).[8,20,31] Public educators at PCs provide community-based programs by developing print materials, videos, and awareness campaigns through public service advertising using radio, television, print, and mass transit venues. Additionally, the use of the Internet has provided a new medium for educators to

provide information and materials that can be downloaded without cost. Educators participate in community health coalitions, work in conjunction with other injury prevention groups such as National Safe Kids coalitions, and collaborate with a wide range of community health agencies. Caregivers of children younger than age six are often deemed the most important group to reach with education programs. Educators often work with national programs for families including Women, Infant and Children (WIC), Head Start, and the Red Cross. Additionally, programs for seniors and grandparents offer an educational opportunity to reach this large

high-risk population. Collaborative programs with American Association of Retired Persons (AARP), senior centers, and Department for the Aging offer an opportunity to provide programs focused on medication safety and poison prevention for older adults.

Figure 129-1. National toll-free number logo.

The membership of the AAPCC's Public Education Committee (PEC) includes the educators from PCs across the United States and Canada. A Chair, Co-Chair, Secretary, and seven Steering Committee members represent the leadership of the committee. The mission of the PEC is to provide poison prevention awareness programs, in an effort to reduce morbidity and mortality associated with poisoning.[4] The PEC provides education sessions at the North American Congress of Clinical Toxicology each year. PEC workshops focus on program development, evaluation, grant writing, strategic planning, and other topics of interest to PC educators.[20]

Needs Assessments

To develop successful poison education programs, educators must analyze demographic data, call volume rates, cultural issues, language, and barriers to calling a PC. Geographic information systems (GIS) software offers a way for PCs to visually map demographic data. The use of this type of software is increasing in public health and can be applied to PC efforts. The coordination of data retrieval from various data entry programs and the use of GIS software by PC staff provides access to call rates by zip codes, counties, census tracts, or congressional districts to be used for planning programs. Health and social services for the targeted community may also be presented using GIS maps. Using GIS for population-based programs is recommended for developing social marketing campaigns, health education programs, outreach efforts, and coalition building.[43] The study of geographic areas with low call rates enhances the potential for educational targeted programs.

Focus groups provide a useful qualitative method for PC educators to identify caregivers' and seniors' perceptions about calling the PC. Barriers frequently cited by low-income English- and Spanish-speaking mothers include: preference for calling 911 rather than the PC, fear of being reported to child welfare agencies, confidentiality issues, language difficulties, lack of direct contact with health providers, low self-efficacy, and concerns regarding cost for the call are identified as issues regarding PC utilization.[1,7,9,22,47] In one study, 51% of caregivers interviewed in a low-income urban pediatric clinic said that they would immediately take their child to the emergency department (ED) after a possible poisoning exposure.[45] Each of these barriers must be considered when planning new programs for reaching caregivers of young children.

Focus groups conducted with seniors show that the majority does not perceive the PC as a service appropriate for their concerns; rather as a service for children and parents. Additionally, the participants expressed a very narrow view of what was considered

a poison such as bleach and household products. Similar to caregivers of children, seniors repeatedly state that they would call 911 in an emergency.[10]

Follow-up surveys are an additional way to analyze factors related to PC access. English- and Spanish-speaking caregivers in Texas were contacted after an ED visit related to a child's poisoning exposure. Findings showed that more than half had spoken to PC staff prior to the hospital visit. Of those who did not call the PC, 68% claimed prior knowledge of the PC, yet failed to use it. Significant demographic variables associated with a failure to call the PC were Hispanic (schooled in Mexico) and African American.[24] Findings from an ethnographic study of 50 Mexican mothers with children younger than five years demonstrated that none had the PC number in their home.[35]

Poison Education Programs

Of the two million annual calls to PCs nationally, more than one million involve children younger than age six.[54] As a result, programs to teach caregivers about primary and secondary prevention techniques have been the focus of education efforts. Typically, these programs focus on teaching poison prevention tips (Table 129-1) and raising awareness of PC services. Historically, seniors have not been a priority population for PC education resources. However, this group represents the majority of fatalities reported nationally to PCs.[20,54] Poison education programs designed to reach individuals (caregivers, pediatricians, children, and seniors) through community-wide interventions are reported in the literature. Interventions have reported an increase in knowledge about PC messages and poison prevention.[23,30] Those programs that targeted communities using mass mailing[6,27,57] were shown to be less

effective in raising awareness than programs that combined

mailing with media campaigns.[1,50]

TABLE 129-1. Poison Prevention Tips

[check mark]Identify poisons inside and outside the home
[check mark]Keep poisons out of reach in a locked cabinet
[check mark]Keep products in their original containers
[check mark]Never keep food and nonfood items together
[check mark]Install carbon monoxide detectors in sleeping areas
[check mark]Keep plants out of reach of children and pets
[check mark]Use child-resistant containers
[check mark]Post the poison center number on all telephones

Interventions Targeting Health Behavior

Unintentional poisonings frequently happen when children are left unattended for a brief period of time (<5 minutes) and a toxic product in use or recently purchased is left within reach of the unattended child.[37] Retention of knowledge and change in behavior measured through telephone surveys after a poison prevention intervention revealed that caregivers are more likely to have the PC number posted in the home.[23,55]

Interventions may be conducted with caregivers after a potential poisoning exposure occurs. The ED presents an opportunity for poison education programs to work with families to prevent further exposure situations.[14] An injury prevention program provided to caregivers of young children after a home injury was shown to be effective, particularly regarding poison prevention information and

the use of safety devices.[39]

The effectiveness of a poison prevention education for families that called the PC following a potential exposure in a young child was also studied. Poison prevention instructions, telephone stickers, a cabinet lock, and a coupon for syrup of ipecac were sent to the family one week after the initial call. Follow-up telephone interviews showed that intervention group recipients reported a higher use of the cabinet lock (59%) and were significantly more likely to post the telephone number for the PC (78%) than those in the control group who did not receive any poison prevention materials within two weeks of the incident. However, families receiving the intervention were not more likely to store syrup of ipecac in the home.[55] Similar results were found during follow-up telephone calls made to WIC participants receiving a free cabinet lock and telephone stickers after an educational workshop.[46]

Poison education programs developed to address caregiver barriers have also been evaluated. To address barriers, a video targeting low-income and Spanish-speaking mothers was developed and evaluated. Results showed increased knowledge about the services, staff, and appropriate use of the PC compared with a control group that attended the regularly scheduled WIC class. After the intervention, changes in attitudes about calling the PC and an increase in the number of participants with the PC number posted at home were reported.[23]

Instructor training programs have been designed by a number of PCs to reach leaders or educators of community-based organizations to incorporate poison education into their roles for the general population. Working with community-based services such as WIC presents an opportunity to reach the target population. Pre- and posttests administered to WIC staff and public health nurses showed increased understanding about poison prevention and increased awareness of PC services.[40]

Focus group participants identified pediatricians as a trusted source of health information for parents.[47] The American Academy of Pediatrics (AAP) includes a poison prevention counseling recommendation as part of The Injury Prevention Program (TIPP). TIPP is a safety education program for parents of children newborn through age 12. The TIPP Age-Related Safety Sheets includes poison prevention advice for parents of children 6â€“12 month olds, 1â€“2 years, and 2â€“4 years.[3] In each, parents are encouraged to call the toll-free number for PCs if the child ingests a potentially poisonous product. It is important that the AAP continues its support for efforts by PCs to prevent childhood poisonings.[31] In another study, family practitioners and pediatricians were surveyed with respect to poison prevention counseling for parents. Although more than 80% of both groups reported that this was an important topic, family practitioners were less likely to provide poison information during a visit.[17]

Education programs are designed for school-age curricula. The effectiveness of MORE HEALTH, a program to teach kindergarten and third-grade students about poison prevention was studied.[30] Posttests administered 1â€“2 weeks after the intervention, showed increased knowledge in the intervention group of children. Parents of children in the intervention group also reported their homes were more likely to be â€œpoison-proofed.â€• The population at highest risk for poisoning fatalities is older adults. As mentioned previously, there is a paucity of poison education programs targeting this group. Recommendations have been made to educate older adults about potential problems with medication use, storage of products, and the services of the PC.[20,29,49] Efforts to teach nursing home staff about potential poisoning exposures is also recommended.[29] There has been a shift in the priority of poison education programs to address this target population. An ED study of patients older than 65 years old showed that seniors had poor knowledge of their current medications. Patients taking more medications were less likely to know the proper dose, name,

and purpose.[12] An evaluation of the effectiveness of PC education programs is necessary to measure changes in knowledge, attitudes, and behavior as a result of interventions with seniors.

Community-Wide Interventions

In a recent review of pediatric literature focusing on community-based poisoning prevention programs, only four studies could be found using poisoning rates as the outcome measure. There is a need for more studies to measure community-based poison prevention efforts.[36]

Mass mailing campaigns have been evaluated as a relatively inexpensive way to raise awareness and increase PC call volume. In most instances, this technique has not been found to be effective.[16,27] On follow-up surveys, only 50% of mailing recipients remembered ever receiving PC materials.[16] When compared with the prior year, a mass mailing effort did not result in increased call volume for exposure or information calls.[27] Likewise, a distribution of textbook covers with the national logo and PC information to elementary and secondary schools in low utilization counties was also not an effective method for increasing PC call volume.[57] However, overall call volume increased by 11.2% after more than one million pieces of literature containing the toll-free number were distributed in a mass mailing effort.[26]

An increased number of information calls to the PC was attributed to a campaign developed to raise community awareness.[50] Media provide a venue for conducting educational activities. Direct mail, radio, television, newspapers, and magazines were incorporated into a media campaign developed to raise awareness in a particular Latino community. A telephone survey conducted with families of children younger than 6 years old in the targeted area showed an increase in awareness about the PC.[1] Developing this type of program is often costly compared with other education efforts, however the potential audience is extensive. Mass media

campaigns are powerful tools used in health promotion and disease prevention efforts. Research shows that media campaigns combined with community-based interventions are successful at changing health behaviors and raising awareness. Creating a supportive

environment for the action required is essential for short- and long-term behavioral changes.[41] News stations often provide a way to broadcast poison prevention messages through the media during PPW and during periods associated with perceived increased risks to a community. Free and confidential services at poison control centers provide caregivers with access to general information or a response to emergencies.

Multilingual Populations

Language and culture must be addressed when planning community-based programs. Quantitative and qualitative research examining Latino communities and calls to the PC have been conducted. Two studies examined the call rates in communities with significantly Latino populations. These areas had lower call rates than comparable areas with high Caucasian populations.[13,52] Furthermore, a number of studies demonstrate that Spanish speaking caregivers are less likely to call the PC because of concerns including confidentiality and language barriers.[1,7,13,22,35] In a study conducted with 100 Mexican mothers of children younger than age five, 32% reported that a doctor or nurse would be the initial contact for health advice. Other sources include friends and family (29%), mother, grandmother, mother-in-law (21%), and spouses (17%). The majority of mothers (81%) acknowledged the use of home remedies to treat their children's illnesses.[33] Caution should be used when planning programs based on census data for demographic information as this may not reflect the specific component under study in community-based programs. If ethnicity information is not collected when callers contact the

PC, there are severe limitations to the value of the data.[13,48]

Qualitative research can help to identify cultural issues when planning targeted education efforts. Monolingual Spanish mothers were more likely to report poor storage of household products and plants.[1] Mexican-born mothers of children younger than five were interviewed in their homes about poison prevention techniques. Safe storage was clearly a problem in these homes with 64% of homes (32/50) having bleach stored within reach of children. Housing made up of multiple families living in the same home further impedes safe storage practices. In this study, families stored all personal products including medications and cleaners with them in their bedroom rather than common areas such as the bathroom.[35]

It is important to consider employment of bilingual staff as public educators when trying to expand public awareness. The benefits include the ability to provide programs directly to the audience and eliminate the need for a translator. A lack of bilingual providers was the most significant barrier identified for Latina women interviewed about injury prevention techniques.[19] Health education programs including mass media campaigns, designed to accurately reflect the cultural identityâ€”language, beliefs, rolesâ€”of the targeted population are more likely to be accepted. Field testing concepts and materials is important for the development and distribution of appropriate information for multicultural populations. Further work is needed to examine cultural beliefs related to poison prevention and an individual's use of and access to the PC. It is important to address cultural beliefs related to use of herbal medicine and complementary medicine use.[33] New education programs are needed to reach targeted populations including Latino and Asian communities across the country. Programs may be more successful if individuals trust and view a source as credible, particularly when cultural attitudes and beliefs closely resemble their own.[28]

Literacy/Health Literacy

Literacy is another area of consideration when designing poison education programs. Health literacy is defined as â€œthe degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.â€• [42] This encompasses the ability to read, understand, and discuss medical information.[38] It is estimated that approximately 90 million Americansâ€”half the adult populationâ€”have limited literacy skills and are often unable to understand health information and complete the tasks required by the healthcare system. Older adults, minority groups, immigrants, and low-income individuals are at highest risk for low health literacy.[25] People with low functional health literacy abilities are less likely to understand written and verbal health information, medicine labels, and appointment information.[56] This type of health information is often written at reading levels of at least 10th grade or higher.[15] Inability to read labels because of eyesight or the inability to read English often contributes to unintentional poisoning exposures associated with dosing errors for prescription and nonprescription medications. Identification of products may rely on brand recognition along with label reading.[34] Older adults are at particularly high risk because of their extensive use of medications.[49] The inability to read warning labels in English presents a literacy issue for those who are not native English speakers regardless of age.[35] Improvements for labels of both nonprescription and prescription medications are needed to address the actual reading abilities of the adult population. When designing written health materials, the recommended reading level is sixth grade. The majority of Americans are able to understand medical information at this level.[15] In addition to reading level, use of graphics, font style, color, type size, and layout are important components when developing print material. Recommendations for nonprint methods for communicating health information include audiotapes, visuals (posters, fotonovelas,

pictographs), action-oriented activities (role-play, theater, story telling), and audiovisuals (videos, CDs).[2,15,38,56]

Applying Health Education Principles to Poison Education Programs

Health education involves planning, implementing and evaluating programs based on theories and models. These models offer direction for educators with health promotion planning.[32] There is a need to increase the number of poison educational programs incorporating health education principles. This includes education efforts designed to reach individuals through community-based programs and media campaigns.

Both the Health Belief Model (HBM) and Social Cognitive Theory (SCT) incorporate the concept of self-efficacy and are applicable when designing poison prevention interventions and mass media campaigns. Self-efficacy is the individual's belief that he or she will be able to accomplish the task requested.[6,15,21] It is often believed that self-efficacy is necessary for changing health behaviors. The SCT suggests that individuals, the environment, and behavior are intimately and inextricably interrelated.[6] The HBM suggests that individuals are more likely to make health behavior changes based on perceived risk susceptibility, severity, potential barriers, and self-efficacy. Again, decisions are made when actions are seen as potentially more beneficial to the individual than the perceived risks associated with surmounting the current barriers.[21]

One project to conduct focus groups used the HBM approach as a framework for poison prevention and for the assessment of barriers to PC use. Questions for participants were developed based on the principles of HBMâ€”that is perceived susceptibility, severity, benefits, barriers, and self-efficacy related to the health

action requested. The majority of mothers viewed poisoning as an emergency and felt it was a health concern for their children. Cues to action are also a component of the model and involve discussions about poison prevention or related information. Participants recommended using community-based venues and culturally appropriate information to expand awareness about poison prevention and the poison control center.[9]

The HBM and SCT approaches were used to develop the questions for focus groups in both English and Spanish. These questions addressed issues related to poison prevention (severity and susceptibility), the services of the PC (including barriers), and suggestions for education. Focus group participants suggested the use of modeling to reinforce real-life scenarios in which a mother handles the poisoning emergency with the staff at the PC with a positive outcome.[22] As a result, a video was developed addressing these ideas. Two poisoning situations in which a mother calls the center are depicted. One involves home management (ingestion of bleach) and the second involves taking the child to the emergency department (swallowing grandmother's antihypertensive pill). The video is available in English and Spanish along with teaching guides.[23]

A Spanish-language instrument was developed and tested that addresses home safety beliefs using the HBM framework. Low-income monolingual Spanish-speaking mothers of children younger than 4 years of age were interviewed about perceived susceptibility, severity, barriers, and self-efficacy factors affecting unintentional home injuries including poison prevention measures. Barriers identified include literacy skills and access to bilingual health information. Additionally, it is important to develop questionnaires that will be accepted and understood by the target population.[19]

The HBM supports the idea that a â€œteachable momentâ€• may be the right opportunity to present poison prevention

interventions.[39] People may be more open to health information after experiencing a traumatic experience.[11] Events, such as an unintentional poisoning exposure, may motivate individuals to behavioral change. Applying HBM principles suggests that individuals will make changes in terms of poison prevention when or if they view the severity and susceptibility of a poisoning to be high in the home.

Summary

Poison center public education efforts encompass needs assessments, program development, implementation, and evaluation. Two populations, children younger than six years and the elderly, are at highest risk for unintentional poisoning exposures. Focus groups with caregivers of young children conducted across the country have consistently identified barriers to calling poison control centers. These include calling 911, fear of being reported to child welfare agencies, and lack of confidence in handling poisoning emergencies. Using health education theories and models, programs should be developed that address these barriers and encourage caregivers to use the services of the PC appropriately. Education programs focusing on the needs of seniors addressing multigenerational living conditions should be designed. Cultural, health literacy, and language needs of target populations are important considerations when planning poison education programs.

Chapter 130

Poison Information Centers and Poison Epidemiology

Robert S. Hoffman

History

In 1950, the American Academy of Pediatrics (AAP) created a Committee on Accident Prevention to explore methods to reduce injuries in young children. A subsequent survey by that committee demonstrated that injuries resulting from unintentional poisoning were a significant cause of childhood morbidity. Simultaneously came the realizations that a source of reliable information on the active ingredients of common household xenobiotics was lacking and that there were few accepted methods for treating poisoned patients. In response to this void, the first poison center (PC) was created in Chicago in 1953.[64] Although initially designed to provide information to healthcare providers, both the popularity and the success of this center stimulated a PC movement, which rapidly spread across the country. The myriad of new PCs not only offered product content information to healthcare providers but also began to offer first aid

and prevention information to members of the community.

Approximately 50 years have passed, and in that short time, countless achievements have been realized by a relatively small group of remarkably altruistic individuals. Throughout this time, poison services have remained free to the public, highlighting their essential role in the American public health system. Many of these legislative and educational accomplishments, which are chronicled in Chap. 1, have directly reduced the incidence and severity of poisoning in children.[63,67,71] Concurrently, the number, configuration, and specific role of PCs has shifted in response to public and professional needs.[26,78] Regional centers are staffed by highly trained and certified health professionals who are assisted by extensive information systems. Support is provided by 24-hour access to board-certified medical toxicologists and consultants from all disciplines of medicine and from industry.

The PC of today is charged with many of the same mandates as the original centers. These responsibilities include maintaining a database, providing information to public and health professionals, collecting epidemiologic data on the incidence and severity of poisoning, preventing unnecessary hospitalizations following exposure, and educating healthcare professionals on the diagnosis and treatment of poisoning. However, a crucial test of the utility of PCs will be their ability to demonstrate a reduction in poison related mortality. Although this is an idealistic analysis, surrogates such as ICU admissions, length of stay in hospitals, and total healthcare expenditures might serve as additional indicators of PC success. This chapter explores some of these critical roles and offers a vision of the future.

Maintaining a Database on Product Contents and Poison Management

The first toxicology database created in the United States was a set of

cumbersome 5 Ã— 8 inch index cards produced in the 1950s by the US National Clearinghouse of Poison Control Centers.[64] When it grew to include more than 16,000 cards, the sheer volume of space required to store this information, and the extensive time necessary to manually search these cards, created the necessity of a central repository, such as a PC. As available information grew, a rapid expansion of information technology occurred, and the unwieldy index card database was privatized and transformed into microfiche. Although this resource was physically smaller, specialized equipment was required, and a search was still time-consuming. Numerous encyclopedic and clinical textbooks were written to supplement the database and provide resources for the office or the bedside. With the growth of the computer age and the Internet, the product known as POISINDEX was established as the major source of data on the contents of innumerable household and industrial products, drugs, and plant and animal xenobiotics. POISINDEX also provides uniform management strategies for many potentially toxic exposures.

With this evolution of information technology, PCs are no longer perceived as the sole guardians of toxicology information. Although these services are still essential for the public at large, and those professionals away from their computers, a predictable decline in PC utilization has paralleled this growth in availability of information. A 1991 study in Utah demonstrated that 82.6% of emergency physicians who had POISINDEX available in their institutions no longer routinely consulted the PC.[12] A similar 1994 New York State study suggested that 76% of physicians who had POISINDEX in their emergency departments (EDs) perceived that this decreased their own use of their PC.[76]

An initial analysis might suggest that this is an acceptable trend in that it both allows physicians to respond more rapidly to patient needs and for PCs to be more available to those individuals who do not have access to this information system. However, this practice of â€œnot callingâ€• not only undermines the efforts of PCs to gather

epidemiologic data (see below), it also creates an understanding gap. In other words, the interpretation of the data may be more essential than the data itself. For example, some commonly used sources of toxicology information such as the Physicians' Desk Reference (PDR) and material safety data sheets (MSDS) occasionally provide information that is frankly inaccurate, potentially misleading, or significantly limited.[30,59] Likewise, two recent reviews of drug interaction programs designed for personal digital assistant devices demonstrate significant variability between individual programs.[4,62] Although POISINDEX routinely provides more accurate information regarding overdose, it fails to adapt to ongoing epidemiological trends (such as regional variations in substance use) and is only updated periodically. Essential new information can only be obtained from skilled professionals who specialize in poisoning. Also, because most databases are designed to provide information about known entities, they perform poorly when dealing with unknown and unclear scenarios. For example, consider the case of a clinician caring for a lethargic child whose only medication is Zantac syrup. After the other causes of altered mental status have been excluded, the clinician considers drug toxicity. Consultation with standard references suggests that altered consciousness would not be expected with use of this medication. However, a certified poison information specialist at a regional PC recognized the potential for drug error and had the physician review the syrup bottle in question and call the pharmacy where the drug was provided. Although the prescription was written for Zantac (ranitidine), the bottle actually contained Zyrtec syrup (cetirizine) which could account for the child's symptoms.

Thus, although originally designed as providers of information, PCs must now be considered valued consultants, with staff who not only provide content information but also interpret clinical material and link both to appropriate management strategies. This goal is achieved only through rigorous training and certification criteria designed to provide a valued interaction with healthcare professionals.[2] Access to computer programs cannot be considered a substitute for a thoughtful

human analysis. Computers do not recognize anxiety, inappropriate questions, and other subtle issues that can only be appreciated with a human interface. Another illustrative example of the value of PCs can be drawn from the use of flumazenil for benzodiazepine overdose (Chap. 72). Although it may easily be determined by anyone capable of using an index that flumazenil is an antidote for benzodiazepine overdoses, many subtle characteristics of the patient or the overdose often contraindicate its use. A prospective study determined that when flumazenil was used before consultation with the PC, contraindications were present in 10/14 (71%) cases, resulting in one serious adverse event.[11] In the study mentioned earlier, although physicians with access to Poisindex were less likely to call the PC, 86.7% still felt that using the PC to gain access to a physician toxicologist was a valued resource.[12] Many PCs are linked with centers for poison treatment (CPT), which are healthcare facilities that can provide both bedside consultation and unique diagnostic and therapeutic interventions for a subset of patients with severe or complex poisoning.[1] Preliminary data suggest that direct bedside consultation and care help reduce length of hospital stay and healthcare costs.[20]

Collecting Poison Epidemiology Data

Recent data demonstrate that poisoning is the third leading cause of injury-related fatalities, ranking behind motor vehicle crash and firearm use.[27] Understanding the evolving trends in poisoning is essential to the development of enhanced surveillance, prevention, and education programs designed to reduce unintentional poisoning. Although data can be analyzed from numerous sources such as death certificates, hospital discharge coding records, and PCs, it is essential to recognize the biases that are inherent in each of these reports. Because not all significant poisoning results in either hospitalization or fatality, data from PCs appear to offer a unique perspective.

Unfortunately, the term â€œpoisoningâ€• is often defined differently

and therefore may be confusing. For the purposes of this text, â€œpoisoningâ€• is any exposure to any xenobiotic (drug, toxin, chemical, or naturally occurring substance) that results in injury. Yet the data collected and disseminated by PCs is defined by the term â€œexposures.â€• [47,48,49,50,51,52 and 53,72,73 and 74] Many exposures are of no consequence because of the properties of the xenobiotic involved, the magnitude or duration of the exposure, or uncertainty regarding whether an actual exposure has occurred; therefore, data collected by PCs represent a limited and ill defined measure of poisoning.

The situation is further confounded by multiple biases that are introduced by the actual reporting process, which first and foremost is voluntary and passive. Because the majority of calls concern self-reported data that come from the home and are never subsequently confirmed, a significant percentage of existing data may actually represent potential or possible exposures, with the potential for resultant large statistical errors introduced into the database. Also, current events, hoaxes, and media awareness campaigns all may influence self-reporting rates.[54] Furthermore, to report, a caller must have a telephone and probably speak English. Although telecommunications devices for the hearing impaired and translation services exist, they are rarely used. Enhancement of technology to facilitate the accurate exchange of information between poison information specialists and either hearing impaired callers or those who do not speak English is essential to the future success of PCs. Another would be to entertain more active reporting systems automatically triggered by hospital laboratory values.

Under the present passive system, when hospitals report to the PC, a comparison of the hospital chart with the PC record shows good agreement, demonstrating an accurate exchange of information.[35] Unfortunately, a reporting bias similar to that described above is well recognized regarding professional utilization of poison information centers and has been called the â€œPollyanna phenomenon.â€• [31] For example, in the spring of 1995, PCs in the northeast United States

began to receive numerous reports of severe psychomotor agitation and other manifestations of anticholinergic syndrome in heroin users. In the initial phase of the epidemic, most of the callers requested assistance in establishing a diagnosis, determining possible etiologic agents, and raised questions regarding treatment with physostigmine.[32] Although the epidemic continued for many months, once the media announced that the heroin supply was tainted with scopolamine, and clinicians became familiar with the indications and administration of physostigmine, call volume decreased. Stated simply, healthcare professionals are less likely to call the PC regarding

issues with which they are familiar, are of little clinical consequence, or are not recognized as being related to a poison. Thus, a bias is introduced that results in overreporting of new and serious events and underreporting of the familiar or very common, the extremely rare or unrecognized poisoning, and those exposures or poisonings that are apparently inconsequential. Numerous comparisons support this contention. Thus, investigators who rely on published data from PCs as a sole source of epidemiological information demonstrate a failure to understand the complexity of poisoning data and the aforementioned consequential limitations of PC-derived data.

Fatal Poisoning

A 4-year study compared deaths from poisoning reported to the Rhode Island medical examiner with those reported to the area PC.[46] Not surprisingly, the medical examiner reported many more deaths: 369 compared to 45 reported by the PC. Although the majority of the cases not reported to the PC were victims who died at home, were pronounced dead on arrival to the hospital, or those in whom poisoning was not suspected until the postmortem analysis, 79 patients who subsequently became unreported fatalities were actually admitted to the hospital with a suspected poisoning. In 10 of these cases, the authors concluded that a toxicology consultation might have altered the outcome. Examples of interventions that, if

recommended and performed, might have resulted in a more favorable outcome included the proper use of antidotes such as naloxone, *N*-acetylcysteine for acetaminophen poisoning, the cyanide antidote kit, sodium bicarbonate for a tricyclic antidepressant overdose, and hyperbaric oxygen for carbon monoxide poisoning and hemoperfusion for a theophylline overdose and hemodialysis for a lithium overdose. Likewise, when medical examiner data were analyzed in Massachusetts, over 47% of poison fatalities had not been reported to the PC.[66] A California study evaluating 358 poisoning fatalities reported to the medical examiner showed that only 10 PC fatalities had been reported over a similar time period, demonstrating a comparable reporting gap.[6] Once again in this study, whereas the majority of underreporting was with respect to prehospital deaths (68%), only 5 of 113 hospitalized patients who ultimately died were reported to the PC. Additionally, a cross-sectional comparison of national mortality data with PC data for agricultural chemical poisoning demonstrated a similar trend of underreporting to PCs of seriously poisoned admitted patients who became fatalities.[42] Furthermore, when data for an entire year from the National Center for Health Statistics (NCHS) were compared to the same year of data from the American Association of Poison Control Centers Toxic Exposure Surveillance System (AAPCC-TESS), it was apparent that TESS captured only about 5% of annual poison fatalities.[34] More recent analyses have highlighted a remarkably frightening trend. When 11 states evaluated trends in poison related mortality from 1990â€“2001, an average increase of 145% was noted.[13] A more comprehensive investigation of the Centers for Disease Control and Prevention's (CDC) Web-based Injury Statistics Query and Reporting System (WISQAR) database, demonstrated at 28% reduction in death rates from suicidal poisoning, but confirmed the above noted increase in fatalities from unintentional poisoning. Overall, poisoning fatalities have increased by 56%.[36] In fact, only fatality rates in small children (younger than 9 years old) and older adults (older than 70 years old) have decreased. Focusing on PC data alone would produce the

erroneous assumption that poisoning-related fatalities were not a significant public health concern. In actuality, poisoning is a significant concern in that other programs designed to reduce deaths from motor vehicle crashes and firearms have been largely successful.

It is logical to assume that similar disparities exist regarding reporting of nonfatal poisonings. The resultant gap in public health needs to be addressed through improved definitions, epidemiology, reporting, and analysis of poison-related data systems. This inequity has developed through a long-standing tradition of PCs to focus attention and concentrate on the largely benign exposures in children. The emphasis needs to be redirected toward seriously ill poisoning, ICU utilization, and other markers of actual poisoning rather than healthcare utilization for benign events.

Nonfatal Poisoning

An outreach study in Massachusetts determined that hospitals geographically close to a PC reported their cases almost twice as often as hospitals remotely located (46% vs. 27% of total cases).[14] Additionally, the authors noted that private physicians were less likely to report cases than residents in training. A 1-year retrospective review demonstrated that only 26% (123/470) of poisoned patients who were treated in a particular ED were reported to the PC.[33] Interestingly, only 3% of inhalational exposures were reported, compared with 95% of cyclic antidepressant ingestions. The authors also noted, as suggested above, that reporting decreased when comparable exposures occurred over a short period of time. Finally, in the physician survey study cited earlier, physicians reported that they would â€œalmost neverâ€• contact the PC for asymptomatic exposures (62.9%), chronic toxicity (50.4%), or simply to assist in establishing a reliable database (90.2%).[12]

Occupational Exposures

Xenobiotic exposure occurs commonly in the workplace. As a result of the long-recognized association between occupational exposure and illness, a number of federal and state government-funded agencies, such as the National Institute for Occupational Safety and Health (NIOSH), Occupational Safety and Health Act (OSHA), and the Agency for Toxic Substances and Disease Registry (ATSDR), exist to prevent occupational illness, to educate the public, and to collect data on exposures to occupational xenobiotics. Legislation provides for mandatory reporting in some instances and offers workers job protection for voluntary reporting. PCs also provide information on occupational exposures and collect data. Once again, there are discrepancies between poison information data and the data collected by governmental agencies. A 6-month survey in California noted that only 15.9% of the occupational cases reported to the PC were captured by a state reporting system.[8] These cases tended to underrepresent dermatitis, the most common occupational toxicologic illness. A follow-up study by the same authors demonstrated that over a third of calls came directly from the individual worker, 70% of whom were unaware of the link between their occupation and their symptoms.[7] Although these data suggest that PCs can provide substantial assistance following occupational exposures, one author expressed concern, noting in a followup study that the PC failed to provide an adequate epidemiological assessment in that it did not identify an average of 12 other people per workplace who were also potentially exposed in addition to the index case.[10] A 1999 survey of PCs concluded that PCs' â€œresponses to work-related calls are inadequate,â€• and suggested that written protocols might be helpful.[9]

Adverse Drug Events and Medication Errors

Although the actual numbers are a source of controversy, data

suggest that a striking number of adverse drug events (ADEs) occur each year in the United States, with many resulting in death.[17,45] The ease of 24-hour telephone access, combined with the ability to consult with a health professional, make PCs ideal resources for reporting of ADEs.[18] Yet, over 76% of physicians surveyed stated that they would â€œalmost neverâ€• contact the PC regarding adverse drug events.[12] Moreover, 30/56 (53.6%) PCs surveyed stated that they had not submitted any of their ADE data to the FDA's MedWatch program.[16] Many of the other centers reported only partial compliance with the MedWatch system.[68]

Prescription drug errors are another area of potential poisoning. Retrospective review of PC data suggest that many of these errors are reported. In one report, the PC provided valuable feedback to pharmacists and physicians about these errors. Ideally, reporting to the state board of pharmacy would ensure that proper surveillance and counseling continue. The PC seems to be an ideal institution to perform this function.[65]

Drugs of Abuse

PCs also collect data on exposures to drugs of abuse and misuse. These data consist largely of calls for information from the concerned public and reports of overdose requiring healthcare intervention. Although ethanol, tobacco, and caffeine are the most common xenobiotics used in society, these cases are rarely reflected in poison information data, with the exception of unintentional exposures in children. In fact, because most substance abuse does not result in immediate interactions with the healthcare system, other databases such as the National Institute of Drug Abuse (NIDA) Household Survey (now referred to as the Monitoring the Future Study) might better reflect substance abuse trends.[22] Yet even this database has significant limitations.[5,29] However, because PCs are more focused on immediate healthcare effects of exposures, it could be argued that only those cases in which healthcare interaction is required are of

value in the database. Whereas PC data is collected passively, the Drug Abuse Warning Network (DAWN) provides an active surveillance system of a sample of hospital visits and deaths that relate to substance abuse. Unfortunately, because DAWN data uses hospital chart â€œmentions,â€• which are infrequently validated, the data have been significantly criticized.[69] As such, it is clear that none of these three systems accurately encompasses the scope of the substance abuse problem.

Grossly Underreported Xenobiotics

As discussed above, there is little doubt that alcohol and tobacco are the most common xenobiotics intentionally used and misused in our society. Although their toxicologic manifestations can be acute and severe, chronic subclinical poisoning often goes unnoticed for many years. Similarly, more than one million American children have lead levels above 10 mcg/dL and elevated levels of polychlorinated biphenyls (PCBs) can be found in countless adults and children. We must remain cognizant of these facts when we read that plants, cleaning products, and cosmetics comprise the most common exposures to xenobiotics.[72] These are the most common â€œreportedâ€• exposures.

Using the Existing Data

With the current limitations of the TESS data, it should be clear that neither the numerator nor the denominator of poisoning can be easily appreciated. Analysis of these data for trends may be more useful because the inherent biases involved in TESS reporting are probably consistent over many years. Efforts should be directed to encourage reporting by such enhanced access methods as web-based forms for passive reporting, a direct interface between laboratory and hospital databases that actively transmit data to PCs. Additional resources should be directed at improved case definitions (distinguishing asymptomatic exposure from poisoning) and integration with other

essential databases such as MedWatch and the National Center for Health Statistics (NCHS).

Despite its limitations, TESS data have significant utility. It is often an exposure rather than an actual poisoning that provides the impetus for contact with healthcare. For those exposures that are unlikely to be consequential, the PC can intervene to prevent potentially harmful attempts at home decontamination and costly unnecessary visits to healthcare providers. Interactions with parents at a time of perceived crisis also provides a â€œteachable momentâ€• (Chap. 129) that may help prevent a more consequential exposure in the future. For those exposures that may result in poisoning, the period of time immediately following exposure is an ideal moment to initiate first aid measures designed to prevent or lessen the severity of poisoning. Thus, the cost, benefits, and efficacy of PCs especially regarding home calls must be measured in terms of exposures and not poisonings.

Preventing Unnecessary Hospitalizations Following Exposure

When visits to pediatric EDs for acute poisoning were analyzed, one study demonstrated that 95% of parents had not contacted the PC before coming to the hospital.[15] Sixty-four percent of those children required no hospital services. In contrast, when parents called the PC first, fewer than 1% sought emergency services. When 589 callers to one PC were surveyed, 464 (79%) stated that they would have used the emergency care system if the PC was unavailable.[39] TESS data confirm that approximately 75% of exposures that originate outside of healthcare facilities can be safely managed on site with limited telephone follow-up (TESS). Suggesting simple techniques or reassurance can successfully reduce hospital visits for patients in the TESS population, which as defined, may only represent a potential exposure. Unfortunately, this approach is less applicable to adults and the population as a whole. Many barriers prevent a person from calling a PC, including a lack of familiarity, intellectual and cultural

factors, language difficulties, and confidentiality concerns.[19,40] Epidemiological studies demonstrate that areas of increased population density with high percentages of minority inhabitants have lower utilization of PC services.[70] Also, a recent survey demonstrated additional barriers such as the absence of caregiver comfort with the hands-on contact provided by the healthcare system and a concern regarding implications of child abuse or neglect when reporting to agencies such as PC, many of which have governmental ties.[54] Although it is clear that the institution of a single nationwide toll-free access number has increased calls to PC,[44] it has yet to be determined if this has altered the patterns of use.

The national average cost to the PC for a single human exposure call is less than $35.[78] A federally funded study concluded that in one year, PCs reduced the number of patients who were treated and not hospitalized by 350,000 and reduced hospitalizations by an additional 40,000 patients.[58] Each call to a PC prevented at least $175 in

subsequent medical costs, providing strong theoretical evidence to support the cost efficacy of PCs. In fact, two natural experiments support these calculations: In 1988, Louisiana closed its state-sponsored PC. During the year that followed, the cost of emergency medical services for poisoning in Louisiana increased by more than $1.4 million. This additional expenditure represented a greater than 3-fold increase above the operating cost of that center.[41] Similarly, because of financial disputes in California, direct access to the San Francisco PC was electronically restricted for one major county, with a recording referring callers instead to the 911 system for assistance.[61] The result of each blocked call was to increase healthcare costs by approximately $33. Moreover, these calculations can not account for the unmeasured benefits to society from PC interventions that reduce waiting times for ambulances and hospital treatments because of lower volumes, money saved by the prevention or reduction of injury from early intervention, or lives saved by enhancing access to or utilization of the healthcare system for seriously poisoned patients.

Providing Education for the Public and Health Professionals

PC staff work closely with physicians, community health educators, community support groups, and parent-teacher associations to develop poison prevention activities.[55] Table 130-1 lists common strategies advocated to prevent poisoning. PCs are also actively involved in enhancing training programs for paramedics,[25] medical students,[38] pharmacy students,[21] and resident physicians[21,60] and form an integral part of postgraduate training programs in medical toxicology fellowships.

As stated previously, there is an inherent risk in both enhanced public and professional education programs. Currently, decreased telephone utilization of a PC could equally be the result of a decrease in the incidence of exposure or poisoning or an enhanced understanding of the prevention, diagnosis, and treatment of poisoning. Although education should never be viewed as detrimental, programs must include an emphasis on the continued use of poison information centers to ensure access to current information in a rapidly changing discipline. In actuality, as a result of the ongoing analysis of incoming calls, the knowledge base has the potential to change as rapidly as the calls are reported. Thus, additional emphasis should be applied to routine utilization of the PC as a public health tool to improve the accuracy of epidemiological data. Reporting of rare or suspected events can serve as sentinel efforts that help identify consequential adverse drug opportunities long before normal postmarketing surveillance tools identify areas of concern.

TABLE 130-1. Common Strategies Advocated to Help Prevent Poisoning

All xenobiotics should be kept in their original containers. Food and drink containers should never be used for the excess of a xenobiotic.
Never store xenobiotics in unlocked cabinets under the sink.
Apply locks to medicine cabinets that are within the reach of a child.
In the absence of a lock, the more toxic xenobiotics should be stored on the highest shelves.
Xenobiotics should never be left in the glove compartment of the family car.
Parents should buy or accept medication only if it is in a child-resistant container.
Medication should be considered as medicine, not a plaything and certainly not candy.
Adults should not take their medications in front of children: This will limit exposure to drug-taking role models that may become objects of imitative behavior.
Unused portions of prescription medications should be discarded by flushing the excess down the toilet at the completion of drug therapy. Activated charcoal should be readily available in the home for use if directed by a poison information specialist or clinician. Since it should be anticipated that about 10% of children who have ingested a poison will do so again within a year, these children should receive an enhanced level of supervision.

However, outreach programs that advise the public to access free services for inconsequential events have the ability to overwhelm the already stressed ability to respond to incoming calls in an appropriate

time frame. Public education and public health must cooperate to assure that PCs are staffed with the appropriate number of skilled individuals to respond not only to daily events, but also to address surges in calls that might result from true epidemics or media awareness. Increasing calls to demonstrate increased utilization offers no public health advantage if the utilization is inappropriate or if seriously ill or potentially ill callers lose access to timely responses.

Development of Public Health Initiatives

The initial public health efforts of poison information centers focused on attempts to alter product concentration and to enhance product labeling and packaging. These clearly beneficial endeavors should continue and must evolve. However, current events have also increased PC activities in preparedness for disasters resulting from radiologic, biologic, and chemical terrorism.[28,43] Additional links with governmental agencies such as the CDC and ATSDR will expand the role of medical toxicology in community health.[75] The need for 24-hour rapid access to centralized information, existing data entry and retrieval systems, and links to experts in medical toxicology and emergency medicine helps to place PCs in critical roles in both local and national initiatives. Recent contributions have included development of triage and treatment protocols and assessments of antidote supplies.[23,24]

Summary

Poison centers provide unique benefits to society. Public education efforts help reduce the likelihood of exposure. Provision of first aid advice helps to diminish the consequences of a poisoning once an exposure has occurred. Reassurance and proper first aid help to curtail unnecessary utilization of expensive healthcare. Interactions with healthcare professionals streamline the care of poisoned patients and improve access to toxicologically specific antidotes and the services of medical toxicologists. Data on exposures are used

effectively to create legislation to further limit poisoning by altering contents or improving packaging or labeling.

Recent successes include the establishment of a single nationwide toll-free number to assure easy access to poison services, the development of near real-time surveillance system, and the creation of a stable stream of federal funding. Goals for the continued success of PCs must involve maintaining a uniformly high quality of service, and working to improve the accuracy of the TESS database, a shift in emphasis toward active reporting, reduction of critical services such as ICU admissions, prevention of fatal poisoning,

and prevention of medical error. Many experts believe that part of this success will be through development of uniform practice guidelines, which has already begun.[3,56,57,77] Poison information centers must publicize the need for reporting all poisonings including ADEs and strive to improve systems of active surveillance. Barriers to utilization and reporting must be identified and overcome. TESS reporting must be integrated with other databases so that the true numerators and denominators of poisoning can be understood and so that a concerted response to poisoning and poison prevention can be made. Finally, the causes of the dramatic rise in poison-related deaths must be identified and addressed. Table 130-2 summarizes these and other initiatives, which are also discussed extensively in a recent report from the Institute of Medicine.[37]

TABLE 130-2. Goals for Improving Poisoning Epidemiology Data

Identify and remove barriers to reporting
Create multiple methods of reporting:
Telephone, Facsimile, Internet based or e-mail
Simplify communications devices for the hearing impaired

Allow rapid access to translation services
Enhance awareness of the public health role of PCs
Enhance education of caregivers and healthcare professionals
Establish public health legislation requiring professional reporting of exposures
Distinguish possible exposures from actual exposures to improve the integrity of the database
Create a category for unconfirmed exposures in the database and encourage its use
Divide confirmed exposures by certainty:
  Confirmed by history
  Confirmed by physical examination
  Confirmed by quantitative and qualitative laboratory analysis
Integrate TESS with other databases (such as the ICD and â€œEâ€• code systems) and utilize a standardized data collection instrument
Automatically interact with hospital and commercial laboratories
Uplink pharmacy ADE reports, hospital discharges, public health department reports (similarly available with lead screening programs), fire departments and hazardous materials responders, industry workplace exposures, death certificates, and drug abuse monitoring systems
Provide real-time analysis of incoming data
Enhance the speed of data collection and reporting
Analyze data as it is reported to identify emerging trends
Mandate the use of accepted epidemiological and statistical analyses of data
Provide rapid and regular feedback to primary reporters
Issue timely analyses and reports

Acknowledgment

Chapter 131

International Perspectives in Medical Toxicology

Aaron Hexdall

Michael Eddleston

Poisoning is a worldwide problem. The goal of this chapter is to describe what is known about the epidemiology of acute poisoning globally and some of the international efforts that aim to address these problems. The mortality and morbidity attributable to chronic environmental or occupational exposure to xenobiotics in the developing world is beyond the scope of this chapter. Detailed clinical information about individual xenobiotics can be found in the corresponding chapters of this textbook.

Major trends in poisoning epidemiology are highlighted in Table 131-1, which compares poisoning patterns between one hospital in the industrialized world (Bellevue Hospital Center, New York City, United States), and two hospitals in the developing world (Anuradhapura and Polonnaruwa, North Central Province, Sri Lanka). Although these data were not specifically collected to compare poisonings in New York and rural Sri Lanka, major trends in poisoning patterns can be

appreciated (Chap. 130). Utilizing different data sets and rough approximations, the incidence of poisoning is similar in rural Sri Lanka (0.97%) and New York City (0.96%). The most important contrasts between these two environments, are in terms of the classes of xenobiotics that are most common, the overall number of poison-related deaths and the differences in case fatality rates. In Sri Lanka, pesticides account for 50% of all cases of poisoning and are responsible for 75% of poisoning deaths. At Bellevue Hospital in New York City, pesticides are not responsible for any deaths and exposure is uncommon. At Bellevue Hospital, pharmaceutical products account for about 70% of all reported poisoning cases and 95% of poisoning deaths, whereas in Sri Lanka, pharmaceuticals account for about 70% of poisoning cases and only 1.4% of poisoning deaths. Botanical products, yellow oleander in particular, account for about one third of all poisoning cases and nearly 1 in 5 poisoning deaths in Sri Lanka. Botanicals did not cause any deaths at Bellevue Hospital over the same time period. There were 8 poisoning deaths at Bellevue Hospital in New York City, whereas there were more than 30 times the number, 252, in two rural hospitals in Sri Lanka. Finally, in rural Sri Lanka the case fatality rate is 8.1%, which is approximately 10 times more than that at Bellevue Hospital (0.87%). The contrast in poisoning mortality observed in developing versus industrialized countries is not explained by differences in the types of poisons ingested alone, but also reflects profound disparities in healthcare resources. Much of the mortality in Sri Lanka could be dramatically reduced with adequate antidote availability, increased access to intensive care facilities, and public education campaigns.

The 1993 World Development Report divided the world into industrialized and developing countries. The developing world was defined as those countries that were neither recognized to have an established market economy nor are part of the former socialist economies of Europe (eg, the former Soviet Union and its immediate neighbors).[290] This definition is inadequate to describe global poisoning patterns and assumes that healthcare delivery systems and

economies develop in parallel. In fact, while many countries with market economies have rudimentary healthcare delivery systems, there are resource poor countries that provide universal healthcare.

More importantly, variations in poisoning patterns within any given country may be significant, especially when comparing wealthier urban centers with agrarian, often poorer, rural areas. Although the majority of healthcare and academic resources are concentrated in urban centers, it is in the countryside in which much of the mortality from acute poisoning occurs. The accessibility of pesticides to rural people, and their lethality, has a profound influence on global poisoning patterns. This chapter focuses on acute poisoning patterns in countries outside of the United States, Canada, Australia, and Western Europe.

Throughout the world access to evidence-based information is limited, either because of a lack of educational opportunities or because such information simply does not exist.[42] Public health education about poisons and laws limiting access to the most highly toxic chemicals are practically absent in much of the world. Rudimentary public health infrastructures often make the western model of a toxicology consult service impractical. Treatment guidelines designed for poisonings in the industrialized world are often prohibitively resource intensive in healthcare systems that are already overburdened. Many rural healthcare facilities have little in the way of resources beyond the individual physician and a limited pharmacopoeia. Life-saving, yet basic, resources such as mechanical ventilation, antidotes, and antivenoms in are in particularly short supply.[213,271,285] Cultural factors also contribute to the patterns of acute poisonings in individual countries such that countries that are geographically adjacent or linguistically similar may have

very different poisoning patterns. Finally, poisoning patterns change over time and are influenced by the spectrum of available xenobiotics, trends in popular culture and the general level of awareness of the dangers of poisons. It is important to develop a

flexible and dynamic approach to local poison control efforts to ensure that the few resources that are available are used most effectively.

TABLE 131-1. Comparison of Poisoning Patterns Between Bellevue Hospital* (USA) and Anuradhapura and Polonnaruwa Hospitals** (Sri Lanka) 2004

Hospital	Bellevue*	Anuradhapura and Polonnaruwa**
Location	New York City	North Central Province
	Urban	Rural
Annual Census	95,000	320,000
Poisoned Patients	916 (0.96%)	3115 (0.97%)
(% annual census)		
Male (%)	65%	â€“
Adults (>12 years)	93%	â€“
Pharmaceuticals***	70%	10%

Nonpharmaceuticals	30%	90%
Pesticides	0%	50%
Botanicals	0%	31%
Other xenobiotics	â€“	9%
Total Deaths (%)	8 (0.87%)	252 (8.1%)
Pharmaceuticals	75%	1.5%
Nonpharmaceuticals	25%	98.5%
Pesticides	0%	75%
Botanicals	0%	18%
Other xenobiotics	25%	5.5%

*Bellevue Hospital data is abstracted from the AAPCC-Toxic Exposure Surveillance System (TESS) 2004 and represents voluntarily reported cases.

**No emergency department per se exists in these hospitals. Census data represents all hospital admissions in 2004.
***Percentages are approximate, (â€“) indicates that complete data is not available

The PC model, which has been so widely accepted in the industrialized world, has yet to be fully embraced throughout the developing world. Such centers collect and analyze epidemiologic data, provide clinical and public policy consultation, and train indigenous experts. Additionally, PCs may reduce unnecessary emergency department (ED) visits by providing reliable and expert telephone consultation to the public.[192] Although the various functions of a PC may be disseminated throughout the public health system, for the poisoned patient to receive timely and effective care it is necessary that these responsibilities be integrated into a cohesive unit. Much debate exists, however, regarding the utility of a PC within healthcare systems that lack the resources to act on its recommendations. Many of the resources which are integral to the functioning of a PC, such as phone lines and the Internet, are not reliable in the rural areas of the world in which the majority of acute poisoning deaths occur. Furthermore, inpatient care of poisoned patients is not as financially demanding as it is in the United States and other industrialized nations. Hence, reducing ED admissions may not be a compelling argument in favor of PCs in the developing world. A 20-year review of the medical literature found only 7 developing-world countries that had published PC data, perhaps reflecting the difficulties of creating and maintaining PCs[96] (Chap. 130).

The challenges of treating acute poisoning are complex and will require a coordinated effort between governments, academic centers, and individual toxicologists. In countries in which one of these elements is not functional, efforts should be directed toward supporting the existing infrastructure pending the development of other key resources. In particular, treatment guidelines should be evidence based whenever possible. When this is not possible, guidelines should be designed with local experiences and resources in mind. Ultimately, indigenously trained toxicologists will form the foundation for any sustainable poison control program.

Numerous governmental and nongovernmental organizations support

initiatives to provide toxicology information, education, and training internationally. The world wide web has facilitated levels of communication and access to information that were previously not possible.[87,151,161,168,218,229,234] Thus, highly sophisticated and technical information may be easily obtained in many urban centers throughout the world, and clinicians may consult with toxicology experts in academic and governmental centers with a speed and economy that was heretofore unimaginable. Unfortunately, it is unlikely that this technology will become available to rural practitioners in the near future and it remains to be seen if advances in information technology will translate into improved patient care in urban areas. In most cases the challenges faced by practitioners in the developing world are not diagnostic in nature, but relate to the availability of evidence-based treatment guidelines and resources, such as antidotes and ICU facilities. Hence, information alone is unlikely to significantly impact patient care in the developing world.

The Global Health Burden of Poisonings

Although a number of large population poisonings have been widely publicized, the scope of toxicological problems worldwide remains largely unknown. In 1984 in Bhopal, India an industrial error released a cloud of methyl isocyanate, resulting in thousands of deaths [93,127,243,279] More recently, mass arsenic poisoning secondary to contaminated drinking water in rural Bangladesh has been widely reported.[13,120,199,237,248,257] Although these cases of mass poisoning raise public awareness, defining the true burden of disease attributable to mass poisonings is difficult. What is certain is that the mortality attributable to deliberate self-poisoning is extremely high in the developing world: In 1990 the results of several small studies were extrapolated to suggest that there were 2 million episodes of deliberate self-poisoning with pesticides annually in the Asia-Pacific region alone and that the mortality rate was 10%, thus producing 200,000 deaths annually.[143] In the industrialized world, reported mortality rates from intentional ingestions range from

0.5â€“1.0%.[142,226] Occupational or unintentional exposure to pesticides in the same region was estimated to effect 1 million people acutely, and as many as 25 million subacutely. Only 20,000 annual deaths, however, were attributed to unintentional pesticide exposure (mortality rate: 0.8â€“2.0%).[144]

The Global Burden of Disease (GBD) project, administered by the World Health Organization (WHO), attempts to estimate global trends in mortality by cause. Data is divided by region, age of the deceased, and by primary cause of death. Injuries are subdivided into

unintentional injuries, which include poisonings, and intentional injuries, which include intentional self-harm and suicide.[202] The GBD study estimated that at least 75% of world-wide deaths attributed to deliberate self-harm occurred in the developing world: In 1990, 786,000 such deaths were recorded, placing self-harm as the 12th leading cause of death worldwide. The GBD study authors also used several statistical models to project global mortality through 2020: In this study self-inflicted injuries rose to the 10th leading cause of death in 2020, placing them above malaria (29th), perinatal disorders (16th), cirrhosis (12th), measles (27th), and war (15th).[200] In 2000, WHO statistics placed poisoning within the top 15 causes of death worldwide for persons age 5â€“44 years old.[216] Unfortunately, injury surveillance systems are in their infancy in most parts of the world. Global and regional injury statistics are frequently estimates based on data from a minority of countries and tend to overrepresent the experiences of a relatively small group of investigators, potentially introducing significant observer bias into these data.[166]

When examining fatal poisonings alone, some authors have reported that 99% of all worldwide deaths occur in the developing world.[27] In China suicide is now the fifth leading cause of death, where it accounts for 3.58% of all deaths, slightly less than pneumonias.[223] In women aged 15â€“44, self-harm (primarily pesticide ingestions) accounted for nearly 1 in 4 deaths.[201] Whether these data represent a newly emerging epidemic of self-poisoning, or simply reflect

increased reporting of such deaths is unclear. A study of 28,998 injury-related deaths in Bangladeshi women between the ages of 10 and 50 years old found that 60% of injury-related deaths were attributed to poisoning (14% of all deaths in this age group). The majority of these events were intentional ingestions of pesticides, which compares to 2% of all deaths that were attributed to traffic crashes. Married women under the age of 30 were at highest risk for death from self-harm (unadjusted mortality rate: 15 per 100,000).[297]

Unfortunately, self-poisoning is not limited to adults. A 20-year retrospective case series from Northern India examined 217 poisonings in children 0â€“15 years old: 50 of 62 ingestions by children 11â€“15 years of age were intentional, and intentional ingestions accounted for 78% of 27 deaths.[255] Another study of 1188 poisonings in children younger than age 18 from Turkey found that the 12.8% of ingestions were intentional.[131] The intentional ingestion of a xenobiotic should be considered in all children above 6â€“8 years of age.

The terms deliberate self-poisoning or intentional ingestion are preferable to suicidal gesture, as numerous studies have documented that these patients frequently do not actually wish to die nor are they depressed (in this chapter the terms â€œself-poisoningâ€• and â€œintentional ingestion of poisonsâ€• are used synonymously).[96,130,220] Patients in the industrialized world who fatally harm themselves are likely to be male, depressed, middle-aged, or older adult.[43] They are also socially isolated and frequently have alcoholism as a prominent comorbidity. In contrast, patients who complete a fatal self-poisoning in the developing world are more likely to be married or within a family structure, live in a rural area, and be young adults. Depression is present in a minority of patients and alcohol is not frequently cited as a contributing factor.[6,27,41,102,143,183,184 and 185,224] Anecdotal experience, however, suggests that alcohol contributes to despondency and impulsivity, especially in men. This demographic pattern is similar to

that of nonfatal self-poisoners in the industrialized world, where female sex, youth and impulsivity, or personality disorders are risk factors. The main distinction is in terms of mortality, which is low in the industrial world because self-poisoners ingest substances that are less lethal. Thus, assessment tools for depression are unlikely to be useful in the developing world and it is difficult to identify patients at risk for self-poisoning within the general population.

TABLE 131-2. Major Themes in Poisoning in the Developing World

1. Deliberate self-poisoning is a major cause of mortality
2. Pesticides are the most common poisons used in fatal self-poisonings
3. Young, otherwise healthy, people are at high risk for self-poisoning
4. Healthcare resources are frequently inaccessible to rural peoples
5. Lack of healthcare resources, especially intensive care, contributes to higher case fatality rates in the developing world
6. Lack of specific antidotes and antivenoms in the developing world is of major concern

The reasons why intentional ingestion of poisons in the developing world is becoming a public health emergency are multifactorial (Table 131-2). The single most important factor contributing to the high case fatality rate associated with self-poisoning in the developing world is the easy availability of highly toxic xenobiotics in the home. Inadequate pesticide storage practices, unclear labeling and the intrinsic lethality of these compounds are also contributory factors. The reasons that young people intentionally ingest poisons are likely

similar to those found in the industrialized world: Impulsivity and emotional distress combined with economic hardship are commonly cited as the reasons for the ingestion.[129,130] A study of 268 self-poisoners in Sri Lanka found that more than 50% of patients ingested the poison within 30 minutes of deciding to harm themselves, emphasizing the importance of impulsivity in acts of self-poisoning.[104] In contrast to violent means of self-harm, such as jumping from height, hanging, or self-immolation (setting oneself on fire), the danger of intentional ingestion of pesticides may be poorly understood by the public. In a study of 97 self-poisoned patients in Sri Lanka, less than half of the patients were aware of the potential lethality of the pesticide they had ingested.[129] Other cultural factors, such as disputes over dowry and women's roles in society are also important.[145]

Epidemiology of Acute Poisoning Globally

Pesticides: (Chaps. 104,105,106,107,108,109,110,111,112)

Recent work shows that pesticides are the most commonly used poisons in fatal intentional ingestions in the Asia-Pacific region, and that such ingestions have reached epidemic proportions. Although many classes of pesticides are implicated in fatal self-poisonings, organic phosphorus (OP) compounds are responsible for the majority of pesticide-related deaths (Table 131-3).[96,102] In particular, reports from Sri Lanka and India have highlighted this public health emergency.[7,121,128] China also is an area in which this phenomenon is also increasingly reported.[146,223,231] Although many case series come

from the Asia-Pacific region, pesticide ingestion is hardly an

exclusively Asian phenomenon. Case series have also been reported from South America,[79,83,90] Central America,[23,186,281,282,284] the Caribbean,[204] Africa,[95,152,158,287] and the Middle East.[2,4,176,193]

TABLE 131-3. Pesticide Classes Commonly Used in Self-Poisoning in the Developing World

1. Organic phosphorus compounds
2. Organic chlorine compounds
3. Carbamate compounds
4. Paraquat and diquat compounds

Deliberate self-poisoning with OP pesticides puts a high cost on the healthcare system. In a study examining the experience in Sri Lanka, OP pesticide poisoning was responsible for 943 of 2559 (36%) hospital admissions for poisoning. The mortality rate for OP poisoning was 21%, and pesticide-poisoned patients occupied 41% of all medical intensive care beds.[102] In another study of 187 consecutive pesticide poisoned patients in Taiwan the mortality rate was 23%.[249] In all likelihood, such studies underestimate the mortality associated with intentional pesticide ingestion as they are hospital-based and do not include patients who die prior to arrival.

In contrast, a 40-year retrospective study of poisoning in England and Wales found that OP pesticides were responsible for only 68 of 87,385 deaths (0.0007%).[48] Similarly, although more than 80,000 exposures to OP or carbamate pesticides were recorded by the American Association of Poison Control Centers (AAPCC) between 1998 and 2002, an average of only 8 deaths occurred annually

(Chap. 130). The dramatic differences between mortality rates documented in the industrialized world, where pesticide exposures are relatively rare events and primarily unintentional, and the developing world, where massive intentional ingestion is commonplace, highlight the profound differences in terms of epidemiology and resources between these environments.

Factors that contribute to the high mortality in self-poisoning with pesticides in the developing world include the intrinsic lethality of many pesticides and healthcare systems that are poorly prepared to handle such critically ill patients (Table 131-4). Pesticides are easily available, and in highly concentrated preparations, in rural communities throughout the developing world. Inadequate pesticide storage systems are an issue, particularly in unintentional ingestions in children. The ease of drinking liquid pesticides is also a factor facilitating massive intentional ingestions. The extraordinarily high human, economic, and social costs of pesticide-related mortality in the developing world reinforce the importance of developing strategies specifically designed to care for acutely poisoned patients in resource-poor environments. Treatment protocols, such as one recently instituted in Sri Lanka, should be simple, economical, and evidence-based.[98]

The organic chlorine insecticides, such as endosulfan and endrin, are widely reported in South Asia,[50,74,242,252,259] and in Sri Lanka.[240] Although organic chlorine compounds are metabolized rapidly and most patients with minor exposures are expected to do well with supportive care, significant mortality is reported. One report from rural India, where old pesticide containers were used to store food, describes an epidemic of new onset seizures. Thirty-five people were affected, and three children died, before the cause was discovered.[92] Deliberate self-poisoning with organic chlorine pesticides results in significant mortality.[241]

TABLE 131-4. Factors Contributing to High Mortality from Self-Poisoning with Pesticides in the Developing World

1. Ease of access in rural, agrarian households
2. Poor storage practices
3. Inadequate labeling of lethal products
4. High potency
5. Lack of evidence-based practice guidelines appropriate for resource poor areas
6. Lack of clear treatment guidelines

Aluminum phosphide is converted to phosphine gas when it comes in contact with water.[75,170] The product is sold in 3-g tablets, thus facilitating easy ingestion by adults and children. Aluminum phosphide has emerged as a major cause of death in Northern India, where it is reported to be the most common fatal ingestion: Of the 720 cases presented in 4 studies, 439 people died (case fatality rate 61%).[1,15,26,122,157] In a study of 217 poisoned children in Northern India, 58% of all aluminum phosphide patients died and this agent accounted for 62% of all deaths.[255]

Thallium poisoning is reported in the developing world, primarily secondary to homicidal acts using thallium-containing rodenticides, and deliberate self-harm. Reports of poisoning with thallium-containing products is reported in Asia, Africa, the Caribbean, and throughout Latin America.[20,22,113,132,134,178,180,182,196,219,246,277] In a case series of 50 patients reported from Mexico, one patient died after developing pneumonia, whereas another suffered optic nerve atrophy.[236]

Dipyridyl herbicides, such as paraquat and diquat, are used in agricultural regions throughout the world (Chap. 111). These

herbicides are classically characterized by being relatively benign when used as directed, as they rapidly become inert after contact with soil microbes, but extremely toxic when ingested or when massive dermal exposure occurs. Thousands of deaths have been attributed to intentional ingestion of 20% paraquat and diquat concentrates since the introduction of these agents in the early 1960s: Fatalities attributed to these agents have been reported from virtually every country where they are available.[114] Mortality is reported to be greater than 70% in cases of intentional ingestion in the developing world.[128,221] This compares to a 20% mortality rate for paraquat ingestions reported in the United Kingdom, although the amount and formulation of paraquat ingested may have differed in these studies.[215] Because there is no specific antidote to paraquat, and supportive care has little impact on patient outcome, the amount and the concentration of paraquat ingested are the primary predictors of mortality.[114]

In particular, high rates of fatal paraquat poisoning are reported in the Caribbean, the South Pacific, and Korea.[10,19,37,138,221] In Trinidad and Tobago, for example, paraquat ingestion was reported to be the most frequent cause of poison-related death in 1992, although this phenomenon appears to be waning.[137] A Korean study of 154 patients presenting to the Institute of Pesticide Poisoning found that the majority of ingestions were intentional (>75%) and the mortality was greater than 50%.[138] Other sources of fatal exposure include unintentional ingestion, massive dermal exposure, and prolonged occupational spraying.[283]

Ingestion of glyphosphate-surfactant herbicide has been reported in case series from Taiwan. Despite the fact that the mechanism of action of glyphosphate is ostensibly plant-specific, toxicity and death are reported in humans. In a Taiwanese study describing 93 patients who ingested glyphosphate-surfactant herbicide the majority of patients had minor symptoms. The mortality rate in cases of deliberate self-poisoning, however, remained significant at approximately 10%.[270,273]

Recently propanol pesticide self-poisoning, which produces methemoglobinemia and hemolytic anemia, has been recognized in Sri Lanka. In a 4-year retrospective study of 16 severely poisoned patients, 9 deaths were reported. Interviews with local doctors suggested that the case fatality rate was 5â€“10%.[101]

Caustics (Chap. 100)

Caustic chemical compounds (Chap. 100) are common in the developing world in both industry and in the home. Caustic chemical poisoning is distinct from other common poisonings in two respects:

- Gastric lavage and administration of activated charcoal (AC), mainstays of the basic management that may be available in the developing world, are generally contraindicated because of direct damage to the oropharynx, esophagus, and stomach.
- Unlike most xenobiotics, if the acute phase of caustic poisoning is survived, there is a high rate of late complications, primarily esophageal strictures. Late complications may require surgical intervention, balloon dilatation of the esophagus (bougienage), or feeding tube placement. These treatments are expensive, require significant hospital resources and also have inherent morbidity and mortality. A study of 110 caustic poisoned patients from Sri Lanka found that all patients required either bowel resection, reanastomosis surgery, or bougienage. Four patients died during the acute phase of poisoning, however an additional 7 patients died as a result of complication from surgery or bougienage.[96]

In Taiwan, self-poisoning with hydrochloric and sulfuric acid is a major problem. In two reports that describe the experience of 274 patients, the mortality rate was 12%. The majority of these cases resulted from deliberate self-harm (>75%) and more than half of the patients ingested HCl. All severely ill patients who were treated

conservatively and 19 of 27 severely ill patients who went to the operating theater died.[169,262] Another Taiwanese study of 325 caustic poisoned patients, primarily deliberate HCl acid ingestion, reported only 5 deaths in 28 patients who required operative management. Unfortunately, the number of patients too ill to go to surgery was not reported.[292] In contrast, no deaths were reported in a retrospective study of late complications in 75 caustic poisoned patients. This Taiwanese group described outcome as â€œgoodâ€• in 90% of cases. All caustic ingestions in adults (62 patients) were intentional.[291]

Formic and acetic acids are used in the manufacture of rubber, and case series are reported from areas surrounding rubber factories in India and Sri Lanka.[96,235] Because these acids are highly concentrated when used industrially, mortality may be significant. Of 53 formic acid poisoned patients presenting to Trivandum hospital in southern India, there were 15 deaths (28%).[235]

Concentrated acetic acid is also sold for dilution to make vinegar. In Surinam, it was an important means of self-harm prior to 1980 when its sale was banned.[88] In Curacao, 112 cases of acetic acid poisoning were reported during a 4-year period in the 1970s.[235] â€œRubnigneâ€• is a domestic cleaning product commonly found in households in the Caribbean that contains hydrofluoric acid and ammonium diflouride. In 23 cases admitted to the hospital over 3 years in Cayenne, the case fatality rate was 21%.[136]

Ingestion of acid from car batteries is reported in Africa, Papua New Guinea, and the Caribbean. Fatalities have been reported and late complications such as esophageal stricture formation were common in survivors.[85,222,225,289] In a case series of 27 patients reported from South Africa, the majority of patients stated that they ingested the car battery acid because they were aware of its potential harm and the car batteries were easily accessible in unelectrified homes where they are used to provide power.[289] Although no patients died, four required surgical intervention.

Industrial Xenobiotics

Although many toxic xenobiotics are used in industrial processes, a complete review of such xenobiotics or occupational exposures is beyond the scope of this chapter. However, several products commonly used in self-poisoning require mention. Copper sulfate causes direct damage to the GI tract, hepatorenal failure, and hemolysis. It was widely used for self-poisoning in South Asia, especially in the 1960s and 1970s.[77,250,254,255] More recently, in Bangladesh there has been a resurgence in self-poisoning with copper sulfate. In a report of 123 patients seen over six years in the Rajshahi region of southern Bangladesh there were 31 deaths.[11]

Cases of fatal cyanide self-poisoning have been reported in Korea, Taiwan, and India.[35,172,295] In a 4-year autopsy case series from Korea, 121 fatalities were attributed to cyanide poisoning, accounting for 61% of the cases reported.[174] Another autopsy study that compared cause of death in Koreans between the 1930s and the 1960s did not report any cases of cyanide poisoning, suggesting that this is a recent phenomenon.[173] Case reports of self-poisoning with industrial chemicals have been reported from throughout the world including turpentine,[217] chromic acid,[179,275] ethylene dibromide,[227,244,253] ethylene chloride,[67] sodium hypochlorite,[177] ferric chloride, and xylene.[3] As the world becomes increasingly more industrialized, particularly in countries that are considered developing, laws to regulate access to industrial chemicals and ensure safe labeling of xenobiotics have lagged behind the expansion of exposure to these agents. Furthermore, industrial factories are often placed in urban areas, or the areas around factories are rapidly urbanized, placing large numbers of people at risk of poisoning from industrial errors and facilitating easy access to poisons in cases of intentional ingestion.

Domestic Xenobiotics (Chaps. 98 *and*

102)

Domestic products include kerosene used for lighting, household cleaning agents such as chloroxylenol (Dettol), bleach, NaOH-containing cleaners, and strong acids such as HCl used for drain cleaning. Patterns of self-harm using domestic products appear to have significant country to country variability. In one large case series from Zimbabwe, the majority of exposures were unintentional ingestions in children younger than age 6 (61% of all cases). Self-harm was cited in just 19% of cases: kerosene was the most frequently used xenobiotic, followed by rodenticides, bleach, and oven cleaners containing NaOH.[208] Another prospective study from Jordan reported on unintentional ingestion of kerosene in 120 children. Only one patient died, whereas the remaining patients were discharged without complications. Poor storage of kerosene, typically in soda or water containers, and in easily accessible locations was cited as a major factor.[5] Paraffin oils is reported to be a cause of morbidity in Africa.[108] Both kerosene and paraffin cause harm through aspiration and subsequent pulmonary insufficiency.

In contrast, in Hong Kong significant morbidity is associated with self-poisoning with domestic products. â€œDettolâ€• products contain 4.8% chloroxylenol, pine oil, and isopropyl alcohol. When large quantities are ingested, coma and cardiopulmonary depression may occur.[64,148] The risk of pulmonary aspiration is reported to be 8%.[63] Renal failure and direct GI damage are also reported, but appear to be rare.[58,64] Upper airway obstruction is also reported.[150] In one case series of 187 patients from Hong Kong, 95% of ingestions were intentional self-harm, primarily of Dettol-type products. Two deaths were associated with aspiration of Dettol or other detergent solutions; inadequate airway protection and gastric

lavage were identified as risk factors.[60,63] In another Hong Kong study of adolescents, Dettol or detergent products such as cetrimide were cited in more than 50% of cases.[53,76]

Another domestic cleaning product, potassium permanganate, is reported in Hong Kong.[214,296] Death results from hepatorenal insufficiency. Domestic cleaning products containing NaOH are reported to be a common method of self-harm in Malaysia.[24] In Korea, NaOH was reported to be the most common method of self-poisoning in the 1930s and 1960s, although it has now been replaced by other agents such as paraquat and cyanide.[24,172]

Although cosmetics are not cited as a major source of poisoning in the developing world, there are numerous case reports from the Middle East, Africa, and India of hair dye (paraphenylenediamine) poisoning.[191,260,294] During the 1990s, hair dye was reported to be the leading cause of poisoning deaths in Morocco.[29] Forty-six cases of hair dye poisoning were reported from Khartoum and Casablanca. Acutely, patients presented with severe facial and neck edema and depressed level of consciousness. Because of airway compromise and the risk of aspiration, tracheotomy was frequently required. In severe poisoning, multiple organ failure ensued, leading to death (case fatality rate 18%).[38,107,293,294] Barium sulfide, arsenic sulfide, and calcium oxide are contained in many traditional hair removal preparations (darou or nefazat). Ingestion of hair removal products is reported in India and Iran, where it became a popular and dangerous method of self-poisoning after a widely publicized suicide.[9,96]

Animal Envenomations (Chaps. 115,116,117)

Snakebites and envenomations by other animals represent a significant cause of morbidity and mortality in the developing world. Venomous snakes are found on all continents, with the exception of Antarctica, although the majority of species are found in equatorial, tropical, or sub-tropical environments. The health impact of snakebites is determined by the species of snake in a given area, the lethality of venom from these species, snake behavior and human activities. Snakebites from members of the Elapidae and Viperidae

families are responsible for the vast majority of deaths, although several other families are medically important (Colubridae and Atractaspididae species, in particular).[285]

In the United States, snakebite victims are frequently curious children, intoxicated young males, reptile collectors, and snake handlers. In contrast, snakebite may be considered an occupational hazard of working in the rural tropics. Victims are just as likely to be women as men, reflecting rural farming practices. Working in large plantations and subsistence farms places rural people in frequent contact with venomous snakes. With simultaneous changes in global climate and expansion of human settlements, it is likely that the range of venomous snakes will enlarge to include urban areas and regions previously considered too temperate to support them.[133,207]

Few countries mandate the reporting of animal bites, making it difficult to estimate snakebite incidence, severity, and outcome. Because the majority of rural people in many parts of the developing world first consult traditional healers, hospital based studies of mortality and morbidity associated with snakebites may underestimate the scope of the problem.[72,258] A study of rural Philippine rice farmers found that only 8% of cobra (*N. naja philippinensis*) bite victims reached a hospital.[278] The World Health Organization (WHO) estimates that there are 5 million snakebites each year, about half of which result in potential envenomation. Although some disagreement among experts exists, poisonous snakebites are responsible for at least 125,000 deaths annually.[71] In contrast, less than 100 snakebite deaths per year are estimated to occur in Europe, the United States, Canada, and Australia combined.[71] In Australia, an area where venomous snakes are endemic, only 18 deaths were reported over a 10-year period and in the United States, a 20-year retrospective review identified only 97 deaths associated with reptile envenomations.[197,265]

The majority of worldwide deaths from snakebite occur in the Asia-Pacific region, where an estimated 100,000 deaths occur annually.

The incidence of snakebite ranges from 3 per 100,000 in temperate areas of Australia to 526 per 100,000 in Papua New Guinea.[71,82] It is important to understand local trends in snakebite epidemiology because species-specific antivenom should be used whenever possible. There is considerable variation between Asian-Pacific countries in terms of the predominant species responsible for human deaths. In Sri Lanka Russell's viper (*V. russelli*) and the common cobra (*N. naja*) are responsible for 75% of deaths. In Malaysia more than half of hospitalized patients are bitten by the Malayan Pit Viper (*C. rhodostoma*). In India, the case fatality rate is reported to reach 20%, primarily from the carpet viper (*E. carinatus*), Russell's viper (*V. russelli*), and the common cobra (*N. naja*).[71] In Mayanmar, Russell's viper (*V. russelli*) accounts for 70% of venomous snake bites, although this may simply reflect the impact of mandatory reporting laws.

Throughout Africa, snakebites are a source of considerable morbidity and mortality: The incidence of snakebite ranges from 48â€“603 envenomations per 100,000 inhabitants and the case fatality rate ranges from 1â€“28%.[71] The burden of poisonous snakebites on local resources is substantial. During the rainy season in Benin, snakebites account for up to 20% of all hospital admissions. The mortality rate is estimated to be 3.1â€“5.9%. In this region, the incidence of snake bites ranges from 200 annual envenomations per 100,000 in rural villagers to 1,300 envenomations per 100,000 in sugar cane plantation workers (average of 440 envenomations per 100,000 inhabitants).[72] One study conducted in Nigeria in the late 1970s noted an incidence of 497 per 100,000 and a 12.2% mortality rate (primarily because of envenomations by the carpet viper, *E. carinatus*).[232] In another study from rural Kenya, snake bite was estimated to be responsible for 0.7% of all deaths annually.[258] A slightly different pattern emerged in studies of 1069 cases of snakebite in Zimbabwe: the majority of snakebites occurred at night and were not specifically work-related. Although the mortality was relatively low (1.8%), the cost of caring for these patients was

substantial ($225 USD per day, not including the cost of antivenom).[153,209] In Central and South America *Crotalus* spp. are responsible for the majority of deaths. In Brazil, approximately 20,000 snakebites are reported annually. In the tropical Amazon region, the case fatality rate is 1.3%, compared to 1% in more urban areas of the country.[71] In Mexico approximately 4,000 snake bites are reported annually, primarily from *Crotalus* spp.[49]

Several diagnostic and treatment approaches have been developed for snakebites.[34,70,82,165,285] The mainstay of effective therapy is antivenom: Antivenoms must be safe, effective, economical, and widely available.[73] The currently available antivenoms are either prohibitively expensive, ineffective, or have a high rate of adverse reactions. Equally important, many antivenoms must be refrigerated making them impractical therapies in the developing world. The most important challenge to treating snakebites is the lack antivenom availability. Critical evaluation of existing antivenoms and development of new products are desperately needed.[28,171,271,285]

After snakebites, the second most common cause of mortality and morbidity from venomous animals is scorpion stings. Medically important scorpion species are widely distributed throughout the

tropics, being particularly common causes of morbidity in North Africa, Mexico and Brazil.[30,89,105,116,118,238] The total number of medically significant scorpion stings that occur annually is unknown. In Mexico, for example, 240,124 scorpion stings and no deaths were reported for 2003, although antivenom therapy is standard of care throughout the country.[49,89] Mortality rate was reported to reach 8% in areas of the Middle East prior to widespread use of antivenom.[106,139] The majority of these deaths occur in older adults and infants in rural areas where access to healthcare and antivenom is limited. The role of antivenom therapy is widely accepted in many countries, although evidence for its efficacy is scant and there is some debate among experts.[119,140] In reports of 20,000 scorpion stings treated with primarily with antivenom in Saudi Arabia, the rate

of adverse drug reactions was low (1.7â€“13.9%), there were no cases of anaphylaxis and only one death.[139,141]

Other venomous insects, such as Arachnida (spiders) and Hymenoptera (bees, ants, and wasps) are rarely sources of significant mortality on a global level. Most deaths are associated with anaphylactic reactions to Hymenoptera venom. There is morbidity associated with venomous insects, in particular necrotic arachnidism caused by *Loxosceles* ssp. (recluse spiders), which are common throughout the Americas (Chap. 115). Effective antivenom is available to widow spiders (*Lactrodectus* spp), the Brazilian banana or armed spider (*Phoneutria* spp), and the Australian funnel spider (*Atrax robustus*).[285]

Medications

Poisoning with pharmaceutical products is reported throughout the world. In general, the use of pharmaceuticals is more common in urban areas in which access is easier and there are more people with the financial means to buy medications. The pharmacopeia available in the developing world is smaller than in the industrialized world, with the exception of drugs to treat tropical diseases that may indigenous to a particular area. Overall, medications with CNS activity are the most common medications used in self-poisoning in the developing world: This pattern, however, largely reflects the urban experience.[8,55,155,175] In rural areas, pesticides remain the most important cause of poisoning fatalities. In the 1970s, barbiturates were a very common means of self-poisoning and several large case series exist.[83,123,167] Recently, benzodiazepines have grown in popularity, presumably because of their increased availability and a perception amongst lay people that they are dangerous in overdose.[155] Case series also cite tricyclic antidepressants and anticonvulsants, such as carbamazepine.[59,124,193,254,266]

Overdoses of analgesic preparations, such as acetaminophen and

aspirin, are reported from many countries.[40,55,62,286] Intentional overdoses are rare, however, and may reflect that the potential toxicity of these medications is not as widely recognized as in the industrialized world, where such intoxications are commonplace. The majority of these reports are from urban center in which analgesics were less common than either barbiturates or benzodiazepines.[12,52,54,56,57,59,68,69,193,195,261]

Important exceptions to this trend are the antimalarial drugs, chloroquine in particular, which are widely available throughout the developing world and more commonly prescribed in rural areas in which malaria is more prevalent.[78,117,190] A retrospective review of poisoning with pharmaceuticals at 8 referral hospitals in Zimbabwe found that antimalarials accounted for 53.1% of admissions, with chloroquine accounting for 96% of these cases.[25] Fatalities from chloroquine self-poisoning are reported from Africa, Asia, and the Pacific region.[25,81,91,163,181,187,194,205,206,211,230,233,239,247,251,276,288] A report of 29 cases of chloroquine poisoning from Zimbabwe found that 11 patients had at least 1 episode of cardiac arrest and that the fatality rate was 20%.[187] In a more recent study from Zimbabwe the fatality rate was lower, 5.7%. The authors noted that chloroquine self-poisoning was significantly associated with pregnancy, suggesting that it is used as an abortifacient.[25] Self-poisoning with other antimalarial drugs such as quinine is also reported.[45,80,115,164,210,228]

Dapsone is a second-line therapy for *pneumocystis carini* pneumonia in the industrialized world, but a first-line agent for leprosy in the developing world. A review of the medical literature from 1950â€“1993 found just 32 cases of poisoning worldwide.[274] Isoniazid, used to treat tuberculosis, is also reported, although it does not appear to be a common method of self-poisoning nor a major cause of mortality.[263,269]

Herbal and Traditional Medicines (Chaps. 43 *and* 114)

Much is known about the use or the potential toxicity of traditional medicines in the developing world. Large schools of traditional medical theory and practice exist throughout China and India (Ayurvedic medicine). In other countries, traditional medical theory is learned through an apprenticeship process. In Mexico, for example, the National Ethnobotanical herbarium catalogues more than 14,000 different plants used in traditional medical practices.

Although traditional medicinal preparations have been tested by generations of practitioners and the concentrations of active ingredients are generally low, both intentional and unintentional poisonings are common.[65,159,160,267] Because traditional medicines are frequently used by immigrants from the developing world, it is reasonable to ask all immigrant patients if they take any non-physicianâ€“prescribed remedies. As general rule, immigrants should be assumed to have full access to the traditional pharmacopeia of their country of origin.

Toxicity from traditional Chinese medicines is increasingly reported, although the reasons for this phenomenon are not clear (increased use, increased reporting, or increased use in Western cultures). A review of traditional Chinese medicines found 2788 reports of adverse drug reactions, representing 40% of all products (herbs and pharmaceuticals). The most commonly reported agents were *Aconitum* spp, followed by *Triperygium wilfordihoo f.*, and *Isatis tinctoria L.*[160] Adulterants are also common in traditional Chinese medicines, particularly synthetic pharmaceuticals and heavy metals.[61] A Taiwanese study of 2609 samples found that 23% were adulterated with pharmaceutical products (primarily caffeine, nonsteroidal antiinflammatory drugs [NSAIDS], acetaminophen, and diuretics).[135] The seeds of Cycas species contain cyanogenic glycosides and are used in traditional Chinese medicine. A report of

21 symptomatic cases of poisoning in Taiwan noted elevated cyanide level, although not in the toxic range.[66]

Plants (Chaps. 43 *and* 114)

Poisonous plants have been used therapeutically and for harm throughout human history. Typically, they are used to induce abortion, for recreational intoxication, in homicidal acts, or for self-harm. Plants have also been the source of unintentional poisoning, either through direct toxicity or because of a toxic contaminant. This section highlights toxic plants that are commonly used in self-poisoning or have caused epidemic poisoning in the developing world.

Yellow oleander (*Thevetia peruviana*) grows throughout the tropics and contains cardioactive steroids in its sap, leaves, and seeds.[100] Yellow oleander has been used for abortion, homicide, and suicide throughout India. In Sri Lanka, thousands of cases intentional ingestion occur each year.[97,245] A recent report, which did not include patients treated with anti-digoxin Fab, noted that 43% of patients presented with severe dysrhythmias and 6% died.[97] In Latin America, yellow oleander is widely used as an appetite suppressant. Sporadic cases of fatal poisoning are reported throughout Latin America, although most of these cases appear to be unintentional.

Oduvan (*Clistanthus collinus*) leaf contains the glycosides clistanthin A and B, which produce severe hypokalemia and cardiac dysrhythmias.[18,110] Over 500 cases were reported in a series from Tamil Nadu, India.[17] Mortality is significant: in two Indian case series of 77 patients, 24 deaths were reported (case fatality rate of 31%).[264,272]

Ackee tree fruit (*Blighia saphia*), which contains hypoglycin when unripe, is widely consumed as a food source. Epidemics of unripe Ackee fruit poisoning are reported throughout the Caribbean and in Africa.[51,109,189,198] In a report from Jamaica, the mortality was 25%.

In Burkina Faso, the deaths of 29 preschool children over a 5-month period were attributed to consumption of unripe Ackee.[188]

The Superb lily (*Gloriosa superba*) and Meadow saffron (*Colchicum autumnale*) contain colchicine alkaloids. Cases of deliberate self-poisoning are reported from India and Sri Lanka.[14,16,147] It is likely that colchicine-specific Fab would be effective therapy, although no studies are currently available.

Numerous plant species contain atropine-like alkaloids, causing an anticholinergic syndrome when ingested. Most often jimsonweed or thorn apple (*Datura stramonium*) or Peruvian apple (*Datura sanguinea*) are ingested. Reports of intentional ingestion of Datura species have been reported throughout Africa, in Asia, and in Latin America.[36,94,125,156,212,268] Most commonly, the seeds are ingested as a recreational drug for their hallucinatory effects, or as part of traditional medical preparations, where it is often used to treat asthma.

Ingestion of *Karwinskia humboldtiana* (buckthorn, coyotillo in Mexico, wild cherry, or tullidora) causes a demyelinating polyneuropathy, clinically similar to Guillain-BarrÃ© syndrome.[32] The plant grows wild in semi-arid areas throughout the United States, Central and South America, and the Caribbean; poisonings are reported throughout its range.[33,44,46,47] The berries of this shrub are attractive, especially to children, and unintentional ingestions are common. Epidemic poisoning are reported in Central America and Mexico.[21,47] One report from Mexico describes a family that ate the fruit: all patients that ate buckthorn berries developed symptoms, and 3 of 11 patients died.[31]

Castor beans (*Ricinus communis*) are commonly used as purgative agents for weight loss in Mexico, Central and South America. Poisoning by castor beans, or other lectin-containing plants such as Jatropha ssp. (African purging nut), is also reported in Africa and South Asia.[112,126,149] These small, mottled, beans are attractive and widely available. Ricin, the toxic component, produces cytotoxicity

with prominent gastrointestinal symptoms. A few masticated beans contain enough ricin to cause death, although it is rare because GI absorption is poor.[39,280]

Reducing Poisoning Mortality Globally

Recognition of the fact that self-poisoning with pesticides is responsible for the majority of poisoning deaths worldwide compels us to act to reduce the mortality associated with these xenobiotics. Ironically, some programs to remove the most environmentally persistent and toxic chemicals have inadvertently replaced them with chemicals that are highly toxic to humans; for example, the replacement of persistent organic chlorine compounds with carbamates in malaria control programs. The opposite has also occurred when pyrethroids replaced organic phosphorus pesticides in an effort to reduce human toxicity.[162] Strategies to reduce the health effects of pesticides should take into account concerns regarding both environmental and human toxicity, and anticipate which pesticides will replace the most highly toxic chemicals as they are phased out of use. A strategy based on industrial hygiene models of hierarchy of controls has been proposed by several authors (Table 131-5).[241] Although this approach is appealing, it does not specifically address how to reduce intentional ingestions or how to improve hospital care for the individual poisoned patient.

TABLE 131-5. Hierarchical Strategies to Reduce Pesticide Poisoning Mortality in the Developing world

Most Effective

1. Eliminate the most highly toxic compounds
2. Substitute with less toxic, equally effective alternatives
3. Reduce use through improved equipment
4. Isolate people from the hazard
5. Label products and train applicators in safe handling practices
6. Promote use of personal protection equipment
7. Institute administrative controls

Least Effective

Adapted from Roberts DM, Karunarathna A, Buckley NA, et al. Influence of pesticide regulation on acute poisoning deaths in Sri Lanka. Bull World Health Organ 2003;81:789â€“798.

Four basic strategies have been proposed to limit the health impact of the most hazardous chemicals worldwide (Table 131-6).[162] Voluntary interventions include international policy statements and industrial pesticide initiatives. In 1985, the Food and Agriculture Organization (FAO) of the United Nations issued a strongly worded document, the Code of Conduct on the Distribution and Use of Pesticides.[111] The pesticide industry has also worked in cooperation with the FAO to remove or destroy large stockpiles of obsolete or banned pesticides in the developing world. CropLife International is an industry sponsored initiative that claims to reduce the health burden of pesticide poisoning through Safe Use and Integrated Pest Management (IPM) programs (http://www.croplife.org/default/aspx, 2005). The cost effectiveness of industry sponsored Safe Use of

Pesticides programs, however, is questionable.[203] Voluntary initiatives, unfortunately, suffer from a lack of resources, a shortage of political will, and nonexistent enforcement mechanisms.[162]

Integrated Pest Management Programs (IPM) increase productivity and profitability of farms, reduce or eliminate pesticide reliance

and reduce exposure of farmers to pesticides.[154,256] Restricting access to pesticides, however, is the key step in reducing the number of cases and the mortality of intentional ingestions. National programs that remove specific WHO class I and class II pesticides demonstrate this effect on mortality.[86] In Somoa, for example, suicide rates climbed after the introduction of paraquat; when paraquat became less available because of financial constraints, combined with a public education campaign, poisoning case fatality rates returned to previous levels.[37] Similarly, when parathion was recognized to be responsible for more than 90% of pesticide deaths in Jordan, it was banned, resulting in a dramatic reduction in poisoning deaths.[4]

TABLE 131-6. Strategies to Reduce Pesticide Availability in the Developing World

1. Voluntary guidelines, safe use initiatives, and international policy instruments;
2. Changing farming practices: integrated pest management (IPM) and plant biotechnology
3. Direct restriction of pesticide use
4. A minimum pesticide list

Adapted from Konradsen F, van der Hoek W, Cole DC, et al: Reducing acute poisoning in developing countiresâ€"options for restricting the availability of pesticides. Toxicology 2003;192:249â€“261.

A minimum pesticide list, based on the WHO essential drug list initiative, has been proposed.[99] Such a list would provide policy makers and small farmers with a source of unbiased information, and remove the most dangerous and obsolete pesticides from everyday use. Programs to restrict the availability of pesticides reduce mortality, although careful consideration of alternative self-harm agents is necessary to prevent the public from simply switching to another, equally deadly, agent.[4,241]

International Resources

Through the collaboration of the Society of Toxicology (USA) and the European Society of Toxicology, the International Union of Toxicology (IUTOX) was established in 1980 with the goal of fostering international cooperation in the field of toxicology. The IUTOX, which was initially formed by 8 national toxicology organizations, now includes more than 40 member societies from around the world. The IUTOX is a membership organization of toxicology professionals and functions to facilitate cooperation between toxicology societies. In addition to organizing the International Congress on Toxicology every 3 years, IUTOX has also sponsored the Congress of Toxicology in

Developing Countries, which provides opportunities for collaboration between the organizations and individuals in the developing world and their counterparts in industrialized nations.

The International Programme for Chemical Safety (IPCS) provides extensive information via the world wide web and numerous publications. The IPCS is supported by the WHO, the International Labor Organisation, and the United Nations Environment Programme, with many national organizations contributing useful information and resources. The Poisons Information Monographs provide extensive peer-reviewed information on chemicals, pharmaceuticals, poisonous plants, and poisonous and venomous animals. Although this information is not specifically evidence-based, this internationally reviewed document represents consensus opinion from poison control centers around the world. The IPCS materials are available in French, English, Spanish, and Portuguese.

The World Federation of Associations of Poisons Centres and Clinical Toxicology Centres produces a directory of poison centers, called YellowTox, which is a listing based on country. This resource identifies both organizations and individuals with recognized expertise in toxicology (Table 131-7 lists public access web sites that provide toxicology information).

Outside of the United States, numerous governments directly support toxicology information services. The benefit of such programs is that they may provide language appropriate information that is not available from Anglo-American sources.

Summary

Poisoning is a common cause of death throughout the developing world. Although many different xenobiotics exist in the developing world, pesticides are the most important source of mortality. In particular, paraquat, organic phosphorous compounds and aluminum phosphide are responsible for a disproportionate number of deaths. Conservative estimates suggest that at least three million cases of pesticide poisoning occur annually, resulting in at least 220,000 deaths.[143] The majority of deaths occur in the context of acts of deliberate self-poisoning. It is estimated that at least five million snakebites occur annually, producing at least 125,000 additional

deaths.[71]

Deliberate self-poisoning is a phenomenon that is increasingly reported in the developing world. Although the majority of these patients do not actually wish to die, the availability of highly lethal compounds in homes throughout the developing world leads to the remarkably high case fatality rates. Restricting access to the most dangerous compounds has been shown to reduce mortality, and implementing safe storage programs may further reduce the opportunities for impulsive acts of self-harm.

Epidemiologic information about regional and local poisoning patterns is needed to guide public health interventions. At present, poisoning epidemiology represents estimates derived from a minority of developing world countries. Assumptions regarding the generalizability of these data may not be true. Efforts to develop epidemiologic surveillance systems and establish harmonized definitions of poisonings will yield a more complete picture of global poisonings.

Lack of evidence to support many treatment interventions hinders public health policy in the developing world. Randomized controlled trials need to be conducted to critically evaluate accepted toxicology dogma, especially in the area of pesticide poisoning.[42] Economic analysis must also be conducted prior to recommending expensive, yet unproven, therapies.[103] Pending the implementation of such studies proven therapies, such as atropine for organic phosphorus pesticide poisoning and snake antivenoms, should be made available and affordable. In the case of pesticide poisoning, a coordinated international effort to restrict access to the most lethal agents is of paramount importance.[99]

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 132

Principles of Epidemiology and Research Design

Kevin C. Osterhoudt

In 1963, Reye and Johnson described a series of patients with encephalopathy and fatty degeneration of the liver.[25,37] Further anecdotal observation of similar patients allowed the development of a hypothesis that aspirin may be an etiologic factor in Reye syndrome (RS).[15] Given such a common exposure as salicylate therapy and such a rare disease as RS, how would researchers investigate whether an association between salicylate and RS truly exists?

In 1976, a case series suggested that enteral erythromycin given to neonates might predispose to infantile hypertrophic pyloric stenosis.[38] How might this association be confirmed given that pyloric stenosis typically occurs in approximately 1 of every 500 infants, but intake of erythromycin is unusual among this group? Gastric emptying has a long tradition as a method of gastrointestinal decontamination to treat patients after acute oral overdose. Hyperbaric oxygen therapy (HBO) is considered as a

therapy to prevent delayed neurologic sequelae from carbon monoxide (CO) poisoning. How can it be determined if these treatments actually offer a patient benefit? Advances in clinical medicine are usually achieved through a typical scientific method. First, astute clinicians make interesting observations. These observations lead to the generation of hypotheses. Research questions are analyzed with epidemiologic investigation, and initial studies are examined with methodologic scrutiny. Initial analytic techniques are improved, and confirmatory studies are performed. Ultimately, models relating cause to effect are formulated.

The field of medical toxicology is rapidly transitioning from a descriptive discipline to one of rigorous scientific exploration. New associations between toxic xenobiotics and diseases are being explored every year. Recent high-profile associations include those between thimerosal vaccine preservatives and childhood neurodevelopmental disorders, and insecticide exposures and childhood cancers and Parkinson disease. An understanding of basic principles of research design and epidemiology is required to interpret published studies and to lay the groundwork for future investigation in toxicology.

Epidemiologic Techniques Available to Investigate Clinical Problems

Table 132-1 lists different study formats.

Observational Design: Descriptive

A staggering array of xenobiotics are able to injure people, necessitating reliance of toxicologists on good descriptive data regarding toxic outcomes. The Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers (AAPCC) now has a database of over 36 million human poison exposure cases.[45] Descriptive case reporting serves a valuable

purpose in describing the characteristics of a medical condition or procedure and remains a fundamental tool of epidemiologic investigation. A case report is a clinical description of a single patient or procedure with respect to a situation. Case reports are most useful for hypothesis generation. However, single case reports are not generalizable, as the reported situation may be atypical. A number of case reports can be grouped, on the basis of similarities, into a case series. Case series can be used to characterize an illness or syndrome, but without a control group they are severely limited in proving cause and effect. In the now classic paper, Reye described 21 children with encephalopathy and fatty degeneration of the liver that characterized the syndrome that now bears his name.[37] Further descriptive data collection suggested that use of aspirin might be associated with RS,[15] but analytic study would be required to support that hypothesis. Published annual reports of TESS data state that their descriptive data are meant to â€œidentify hazards early, focus prevention education, guide clinical research, and direct training.â€•[45] In these roles, descriptive data are often underappreciated.

Cross-sectional studies assess a population for the presence or absence of an exposure and condition simultaneously. Such data often provide estimates of prevalenceâ€”the fraction of individuals in a population sharing a characteristic or condition at a point in time. These studies, particularly helpful in public health planning, have been extremely useful in monitoring common environmental exposures, such as childhood lead poisoning, or population-wide drug use, such as occurs with tobacco, marijuana, and alcohol. The US National Health and Nutrition Examination Survey investigations demonstrated that the percentage of children with blood lead levels >10 Âµg/dL decreased from 88.2% to 4.4% between 1976 and 1991, with the highest rates of plumbism among African American, low-income, or urban children.[5] An *analysis of secular trends* is a study type that compares changes in illness over time or geography to changes in risk factors. These

analyses often lend

circumstantial support to a hypothesis; however, because of the ecological nature of their design, individual data on risk factors are not available to allow exclusion of alternative hypotheses also consistent with the data. A prime example of an analysis of secular trends is Arrowsmith's finding that reports of RS declined between 1980 and 1985, coincident with a fall in sales of, or physician recommendations of, children's aspirin products.[3] This investigation added further confirmation to the etiologic role of aspirin in the development of RS but could not exclude alternative hypotheses such as a change in viral epidemic patterns.

[a]Study designs are listed in descending order from the design that offers the best epidemiologic evidence for association to that which offers the least.

Observational Design: Analytical

Hypotheses generated by theoretical reasoning or anecdotal association require analytic testing. Case-control studies and cohort studies are analytic techniques that use observational data, and each technique has its own advantages and disadvantages (Table 132-2). *Case-control studies* compare affected, treated, or diseased patients (cases) to nonaffected patients (controls) and look for a difference in prior risk factors or exposures (Figure 132-1A). Because subjects are recruited into the study based on prior presence or absence of a particular outcome, case-control studies

are always retrospective in nature. They are especially useful when the outcome being studied is rare, and they enable the investigation of any number of potential etiologies for a single disease.

RS is an illness well suited to case-control study. The incidence of RS peaked in the United States in the mid-1970s, and clustered together with viral epidemics of influenza A, influenza B, and varicella. Based on anecdotal observations in a series of patients, a hypothesis was formulated that salicylate may be an etiologic factor in RS.[15] Other putative contributory factors were also proposed, including viral infections, aflatoxin, pesticides, antiemetic drugs, and valproic acid. Exposures to salicylates were common in the 1970s, but the incidence of RS was less than 10 cases per million persons younger than age 18. In the epidemiologic investigation that served as a foundation for decades of research to follow, seven children diagnosed with RS were compared to 16 control children who were matched on the basis of age, gender, time, and viral symptoms.[40] Families were interviewed regarding the types and quantities of medications taken by the children. Salicylates were the only exposure found to be statistically different between cases and controls, and this became the first case-control study to identify increased odds of developing RS after aspirin therapy. Larger subsequent case control studies added confirmatory evidence to the association between salicylate use and RS.[17,23,44]

TABLE 132-2. Advantages of Case-Control versus Cohort Study Designs

Case-control study
Smaller sample required when outcome is rare
Reduced bias in outcome data
Can study many exposures simultaneously
Allows estimation of relative risk
May obviate need for long followup period
Cohort study
Provides more robust evidence of association
Reduced bias in exposure data
Can study many outcomes simultaneously
Allows direct calculation of incidence
Allows direct calculation of relative risk

Cohort studies compare patients with certain risk factors or exposures to those patients without the exposure, then follow these cohorts to see which subjects develop the outcome of interest (see Figure 132-1B). In this respect, they allow the comparison of *incidence* (the number of new outcomes occurring within a population initially free of disease over a period of time) between populations who share an exposure and populations who do not. They may be retrospective or prospective and enable the study of any number of outcomes from a single exposure. They are particularly well-suited to investigations in which the outcome of interest is relatively common. In circumstances when an outcome of interest is very uncommon, such as the case with RS, the large number of study subjects required might make a cohort study impractical. A suggested association between oral erythromycin administration to newborn infants and increased risk of idiopathic hypertrophic pyloric stenosis, which typically affects up to 3

individuals per 1000 live births, remained unstudied until a 1999 cohort study. Investigators analyzed a patient population in which 157 out of 282 infants born at a hospital in a 2-month period were treated with erythromycin prophylaxis because of a pertussis exposure.[20] Investigators separated

these patients into cohorts based on exposure to erythromycin and looked at the differences of pyloric stenosis rates between the 2 groups. Neonates treated with erythromycin were found to be at significantly greater risk of pyloric stenosis than untreated controls. Perhaps the most famous and ambitious cohort study was the Framingham Heart Study in which 5209 residents of Framingham, MA, ages 30â€“62 years have been followed for over 50 years. This study provided a useful tool for studying the incidence of lung cancer, stroke, and cardiovascular disease in those exposed to cigarette smoke[13] and other hazardous agents.

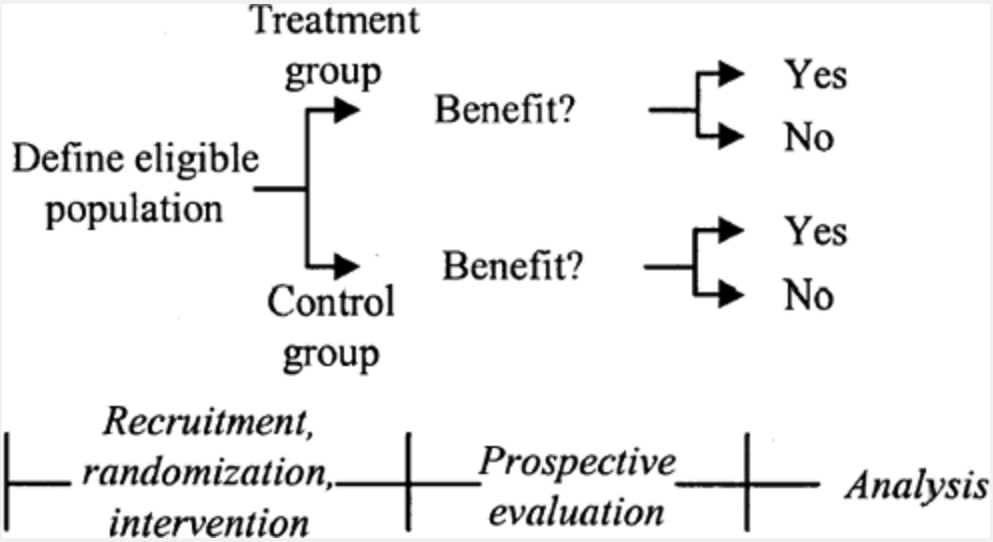

Figure 132-2. Schematic representation of the design of a randomized clinical trial.

Experimental Design

Experimental studies are those in which the treatment, risk factor, or exposure of interest can be controlled by the investigator to study differences in outcome between the groups (Figure 132-2). The prototype is the randomized, blinded, controlled clinical trial. Among epidemiologic study types, these provide the most convincing demonstration of causality. Clinical trials are used to measure the *efficacy* (the treatment effect within a controlled experimental setting) of treatment regimens and to draw inferences about the *effectiveness* of a treatment applied to the general population. Unfortunately, interventional studies are the most complex to perform, and several questions must be addressed by investigators before performing a clinical trial (Table 132-3). Human clinical trials have been especially difficult to apply to the practice of toxicology. Indeed, between 1992 and 1996, one author found only three such randomized clinical trials.[41] Table 132-4 lists characteristics of poisoned patients, which hamper attempts at clinical trials. Volunteer studies, using nontoxic drugs or subtoxic drug doses, are often used to circumvent many of the problems in controlling human poisoning studies; but it is typically difficult to apply results from these studies to the actual physiology of toxic overdose.

TABLE 132-3. Considerations in Designing a Clinical Trial

What is the question of interest?
What is the target patient population?
How will the safety of subjects be assured?
What is a suitable control group?
How will outcomes be measured?
What difference in outcomes between groups is considered important?
What is the analysis plan?
How many subjects will be required?
How will randomization and blinding be achieved and maintained?
How long a followup period will be required?
How will loss of study subjects be handled?
How will treatment compliance be evaluated?

TABLE 132-4. Difficulties in Applying Clinical Trials to Human Poisoning

It is unethical to intentionally â€œpoisonâ€• subjects.
Poisoned patients represent a broad spectrum of demographic patterns.
A wide variety of poisons exist.
Exposures to any single poison are usually limited.
A limited number of poisoned patients are available at any one study site.
Uncertainty often exists as to type, quantity, and timing of most poison exposures.
Poisoning typically results in a relatively short course of illness.

Perhaps the best way to demonstrate an etiologic association between salicylate use and RS would be to perform a randomized, double-blinded, controlled clinical trial. Patients with influenza and fever could be randomly treated with salicylate or placebo, and the incidence of RS in both treatment groups could be determined. However, with such a strong association noted from case-control studies, and with suitable alternative antipyretic medications available, such a study would be unethical. As toxicologists strive to find evidence for, or against, the traditions of clinical practice, several important clinical trials have been published. Among them are many important examples and lessons in epidemiologic study design.

One trial attempted to evaluate whether or not corticosteroids might be beneficial in preventing esophageal strictures secondary to circumferential caustic injury of the esophagus.[2] Because of the inherent difficulty in recruiting eligible patients from a single institution, only 60 patients with esophageal injury were recruited over an 18-year period. These patients were randomized to therapy with or without corticosteroids and followed for the development of stricture. Ten of the 31 patients treated with

corticosteroids developed strictures in comparison to 11 of 29 control patients. The authors concluded that there was no apparent benefit from the use of corticosteroids to treat children who have ingested a caustic substance. A second study challenged our notions of gastrointestinal decontamination and randomized 876 acutely poisoned patients with respect to gastric emptying procedures.[35] Outcomes measured were clinical course, length of hospital stay, and complications. The investigators concluded that routine use of gastric emptying did not provide additional therapeutic benefit beyond that offered by the use of the antidote, activated charcoal. A third representative study demonstrated benefit from HBO therapy regarding the prevention of delayed neurologic sequelae after CO poisoning.[42] Sixty patients with acute CO poisoning were randomized to either ambient pressure or HBO, then followed for the occurrence of neurologic dysfunction. The conclusions of each of the three aforementioned studies have encountered tremendous academic dissection and debate. Certain concerns with the methodology and analysis of these studies are examined later in this chapter to illustrate epidemiologic concepts. Additionally, each of these studies is described in more detail in the relevant chapters of this text (Chaps. 100, 8, and 120).

Measures Used to Quantify the Strength of an Epidemiologic Association

The objective of analytic studies is to define and quantify the degree of statistical dependence between an exposure and an

outcome. Such associations are ideally represented by the relative risk of developing an outcome if exposed in comparison to being unexposed. Thus, the *relative risk* can be defined as the incidence of outcome in exposed individuals compared to the incidence of outcome in unexposed individuals. The relative risk can be

calculated directly from cohort or interventional studies. However, in a case-control study, an investigator chooses the numbers of cases and controls to be studied, so true incidence data are not obtained. In case-control studies an *odds ratio* can be calculated, and the odds ratio will provide an estimate for relative risk in situations in which the outcome is rare, such as when the outcome occurs in fewer than 10% of exposed individuals. Figure 132-3 demonstrates the calculation of relative risk or odds ratio from analytic studies.

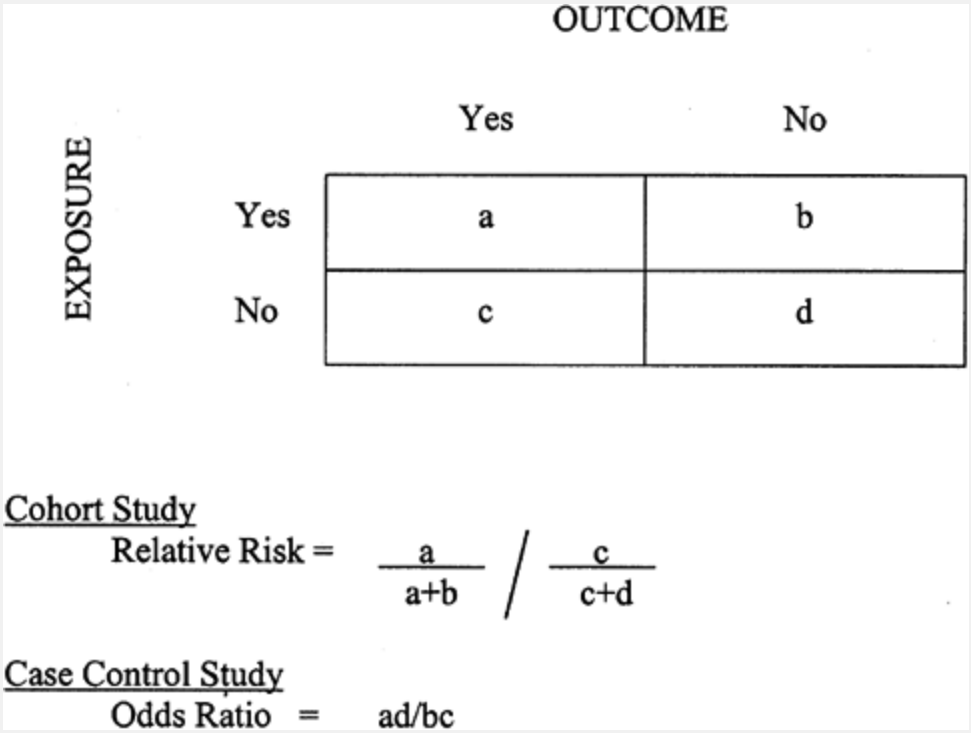

Figure 132-3. Use of a 2 Ã— 2 table to calculate or estimate relative risk from analytic studies. In cohort studies, study subjects are selected on the basis of exposure. In case-control studies, subjects are selected on the basis of outcome. The letters a, b, c, and d represent the number of subjects either exposed or unexposed to a â€œrisk factorâ€• or treatment, with or without the outcome of interest. The odds ratio

estimates the relative risk if the outcome of interest is rare.

A relative risk of 1.0 signifies that an outcome is equally likely to occur whether an individual is exposed or not and implies that no association exists between the exposure and the outcome. A relative risk approaching 0 suggests that an exposure is a marker of protection regarding the outcome, and a relative risk approaching infinity suggests the exposure predicts a tendency toward the outcome. In the previously described case-control investigation of the link between salicylate use and RS, all of the 7 case subjects had used aspirin compared to only 8 of 16 controls.[40] The odds ratio calculated from these data approaches infinity and suggests a strong association between exposure and outcome. In the described clinical trial of therapeutic corticosteroids (the â€œexposureâ€•) in the prevention of esophageal strictures (the â€œoutcomeâ€•), 10 of 31 treated patients developed strictures compared to 11 of 29 untreated patients.[2] This relative risk calculation approximates 1 and seemingly demonstrates little benefit from corticosteroid therapy.

Measures Used to Quantify the Significance of an Epidemiologic Association

Analytic studies are performed to test hypotheses, typically that an exposure is associated with an outcome. The presence of such association in any given study has a number of possible explanations, as detailed in Table 132-5. The goal of statistical analysis is to determine the degree to which chance can be excluded as the true reason the results of the study were obtained. By convention, statistical analysis typically tests the *null hypothesis*â€”the hypothesis that there is no association between exposure and outcome.

Because analytic studies involve only a sample of the total population, they contain two types of inherent error. *Type I error*, also referred to as alpha (Î±) error, is the likelihood that an investigator may conclude that an association exists when none truly does. *Type II error*, or beta (Î²) error, is the possibility that an investigator will be unable to find an association when one is really present. The most commonly reported measures of type I error in published toxicology studies are the *p*-value and the confidence interval (CI). Statistical significance has customarily, but not necessarily, been defined as having less than a 1 in 20 chance of conducting a false-positive study. Therefore, a type I error of less than 5%, which corresponds to a *p*-value of less than 0.05, is usually deemed â€œstatistically significant.â€•

Perhaps a more informative description of the significance of an association is provided through the CI. The CI not only provides a test of statistical significance, it also offers information pertaining to the degree (and possible range) of differences observed. In an unbiased study, the 95% CI provides a range between which, if the study could be repeated an infinite number of times, the observed magnitude of effect would lie 95% of the time. One study reported that no toddlers ingesting 1 or 2 calcium channel antagonists became seriously ill, but a subsequent analysis of the CI around this small set of data demonstrated

that the true incidence could be as high as 18%.[32] A CI around a relative risk or odds ratio is not statistically significant if it includes 1.0, and the narrower the CI the more precise the estimate of the magnitude of effect.

TABLE 132-5. Types of Associations between Exposures and Outcomes That May Be Found with a Clinical Study

No Association	The outcome is independent of exposure.
Artifactual Association	
Chance	The association demonstrated by the study resulted from random error.
Bias	Systematic error in the study led to the noted association.
Indirect Association	The association is real, but not truly cause and effect (confounding).
Causal Association	The outcome is dependent on the exposure.

TABLE 132-6. Considerations in Choice of Sample Size

	Sample Size	
	Large	Small
Pros	• Able to detect associations of small magnitude • Less susceptible to some biases • More robust analysis	• Less work • Less cost
Cons	• More work and more cost	• Might not detect associations of small magnitude • More susceptible to biases associated with patient differences

The likelihood that a study will find a difference if one truly exists is termed statistical *power* and relates to the likelihood of a false-negative study (type II error). Power is usually artificially set by an investigator before a study is performed and is typically set at 80% or 90% to practically limit the number of study subjects needed. Table 132-6 lists considerations applicable to choice of sample size. The sample size of a study is determined by the frequency of the exposure and outcome within the study population, the strength of association deemed clinically relevant, and the amount of error deemed acceptable in the study. Because

power is often set relatively low, it is difficult to state that an association does not exist. It is more appropriate to state that a study was unable to reject the null hypothesis to find an association. In the ongoing controversy regarding the utility of HBO in the treatment of acute CO poisoning, three early randomized studies had alleged benefit,[11,28,42] and two had no benefit.[36,39] Conventional parameters for statistical significance suggest that, if unbiased, the positive studies met a greater burden of evidence than did the negative studies. A more recent multicentered clinical trial found HBO to protect against CO induced cognitive sequelae at 6 weeks (odds ratio 0.45 [95% CI: 0.22â€“0.92]), and at 12 months.[46]

Differentiation Between Clinical Significance and Statistical Significance

The finding of a low *p*-value indicates a statistically high level of confidence that a difference between study groups exists but offers no indication that the difference is clinically important. The interpretation of statistical versus clinical significance is often facilitated through calculation of confidence intervals. Small actual differences between two groups can become statistically significant if large numbers of subjects are studied. Likewise, impressive associations of cause and effect can seem trivial if few subjects are in a study. The clinical significance of an association is left to the judgment of the individual interpreting a study. Ideally, a working definition of clinical significance is developed before a study is performed.

In the noted study of corticosteroids and corrosive injury of the esophagus, 64% of control subjects required esophageal replacement versus 40% of treated subjects.[2] The investigators' calculation of the *p*-value for this comparison is greater than 0.05.

Many would interpret a reduction in esophageal replacement by approximately one-third to be potentially clinically important, yet it is unlikely that this study had statistical power to find such an association. Likewise, in a study suggesting no benefit from gastric emptying after acute overdose, when patients presenting within 1 hour of overdose were examined, 15% of treated patients showed improvement versus 4% of controls.[35] Again, statistical significance was not achieved, but the clinical significance of these data is subject to speculation.

Methodologic Problems Found Within Clinical Studies

Calculation of a *p*-value or confidence interval does nothing to assess the adequacy of study design. These measures are used to quantify the influence of random error, or chance, on research findings. Clinical research involving patients is particularly susceptible to *bias*, which can be defined as systematic error in the collection or interpretation of data. Because such error can lead to an inappropriate estimate of the association between an exposure and an outcome, careful evaluation of potential biases affecting a clinical study is of paramount importance.

Selection bias refers to error introduced into a study by the manner in which subjects are selected for inclusion in the study. This type of bias is most problematic for retrospective studies in which exposures and outcomes have both occurred at the time of subject recruitment. Selection bias may be introduced into a prospective clinical study if the study fails to enroll potential subjects, or if potential subjects refuse to participate, on a systematic basis. Selection bias may even influence the results of clinical trials. In the 1995 trial that found no difference in outcome between acutely poisoned patients treated with gastric emptying and patients from whom gastric emptying was withheld, all patients presenting to the emergency department (ED) after acute

overdose were enrolled.[35] Because most patients with poisoning exposure are likely to do well with minimal support,[45] selection of patients on this basis might be expected to bias this study to find no effect. Reasoning suggests that the patients most likely to benefit from gastric emptying are those with life-threatening toxic ingestion presenting within the first hour after overdose. As mentioned previously, subgroup review of the results of this paper suggests clinical benefit within this group of patients, but without conclusive power.

Information bias refers to error introduced into a study as a result of systematic differences in the quality of data obtained between exposed and unexposed groups, or between those with and without the outcome of interest. Several distinct types of information bias may exist. Affected and nonaffected individuals may have differential memories regarding exposures, so recall bias is a concern in retrospective studies. The potential for *recall bias* is frequently cited as criticism of early retrospective case-control studies of aspirin as an etiologic factor for RS, in which families were asked to recollect their children's aspirin use history. Critics suggest that the parents of children affected by RS might be more vigorous in their recall of exposures than the parents of unaffected children. Similarly, *interviewer bias* may occur if study personnel differ in how they solicit, record, or interpret information as a result of knowledge of the subjects' status regarding exposures or outcomes.

Prospective studies may be troubled by loss to follow-up, especially if subjects are lost from the study for reasons relating to either exposure or outcome such as when subjects withdraw from a study because they are feeling better, or are â€œlostâ€• because they die. *Misclassification bias* occurs when investigators incorrectly categorize subjects with respect to exposure or outcome. In a retrospective study of 378 children regarding the predictability of caustic esophageal injury from clinical signs and

symptoms, it was found that 11 of 80 asymptomatic children had significant burns.[14] There is a possibility that this â€œasymptomaticâ€• child was misclassified because of lack of rigorous written documentation of symptoms or signs within the medical charts.

Bias is best minimized through careful study design. It is important to precisely define the study question and the population at risk and to carefully define rigorous inclusion and exclusion criteria. The outcome should also be defined precisely. During data acquisition the best way to reduce bias may be to keep study personnel gathering exposure data blinded to outcome, and vice versa. Often, it may also be advisable to keep study subjects unaware of their status within a study to the extent that it is ethical (thus, â€œdouble-blindedâ€•â€”neither investigators nor subjects are aware of the subjects' status within a study). Use of placebos or â€œsham treatmentsâ€• is a way to facilitate blinding. One of the strongest criticisms of a 1995 trial of HBO for the prevention of delayed neurologic syndromes after CO poisoning[39] has been the failure to blind patients and investigators to the treatment in question,[30] a flaw that was corrected in a follow-up study published in 2002.[46] It is inevitable that some degree of potential bias will be present in any clinical study. Such bias should be reviewed in analysis, and estimations of its magnitude and direction (bias toward or away from rejection of the null hypothesis) should be considered.

Unlike selection and information biases, which are errors introduced into studies primarily by the investigators or subjects, confounding is a special type of problem that may occur within a study as a result of interrelationships between the exposure of interest and another exposure. *Confounding* is a bias wherein an observed association is not a product of cause and effect but instead results from linking of the exposure of interest to another associated exposure. Studies pertaining to adverse effects of drugs of abuse are especially prone to confounding by variables

such as concomitant caffeine use, alcohol use, tobacco use, nutritional deficiency, and/or psychiatric illness. Analytic studies may restrict characteristics of enrolled subjects or match subject characteristics between comparison groups in an effort to reduce confounding. Accordingly, it has been suggested that future studies on delayed neuropsychiatric manifestations following CO poisoning control for potential confounding from depression and cyanide exposure.[27] Randomization is an important method to assure that unsuspected confounding factors are equally distributed between treatment groups within interventional studies. During data analysis, confounding can often be controlled through stratification of data into subgroups or through multivariate analysis techniques.

Biases Inherent in Studies Using the American Association of Poison Control Centers Database

The TESS database of the AAPCC is an ambitious effort to catalog and describe the epidemiology of poisoning in the United States and Canada. These data serve to help identify new poisoning epidemics, focus prevention and education efforts, guide demographic and economic poisoning analyses, and guide implementation of public health policies. It is a desirable goal to use this database in defining the scope of toxicity for particular xenobiotics and as a clinical research tool. In this regard, it is important to understand the biases inherent in the current database.

It has been suggested that selection bias might exist within poison center (PC) data if poisoning is unrecognized as a cause of illness or if a caregiver has no questions pertaining to the management of a recognized poisoning.[18] Indeed, a survey of 170 emergency physicians in Utah found that 53% admitted to using a PC for

symptomatic acute overdoses, and only 10% contacted PC for the purposes of reporting cases to the national database.[9] Such selection might result in a bias of PC data toward more severe cases. On the other end of the spectrum, investigation has found selection bias in PC data suggesting that fatal poisonings may be severely underrepresented.[21] It is interesting to note that in a 2004 report of the Institute of Medicine,[24] the estimated range of annual fatal poisonings in the United States was from approximately 1000, derived from AAPCC data, to over 30,000, derived from other databases. A study of potential spectrum bias in PC utilization found that one ED reported 95% of cyclic antidepressant overdoses, 33% of venomous snakebites, and only 3% of inhalation exposures.[19] Further complicating the interpretation of PC data are the findings that such data may also be biased regarding geographic distribution of callers,[1] age,[34] ethnicity,[1,10,34,43] and socioeconomic status.[43]

Knowledge of information bias within TESS data is less well-characterized. Phone interviews of callers, many under duress, by PC personnel is certain to be subject to recall and interviewer bias. A comparison of rural hospital chart data to the TESS database demonstrated deficiencies in PC reporting and in clinical information transfer to the TESS database.[22] Loss to follow-up remains a problem for many PC, and misclassification of poisonings by healthcare providers inadequately trained in medical toxicology remains too common.

Despite the large volume of descriptive poisoning data available, it has proven difficult to derive valid, clinically useful conclusions from either the TESS database or from published case reports.[6] One suggested means through which to minimize information bias in descriptive toxicology is through the use of improved data collection charts.[7] Other researchers have found it useful in clinical studies to transform PC data collection from a passive to an active process through use of specific research instruments.[29] Further efforts are required to reduce and to quantify the impact

of selection, interviewer, recall, misclassification, and information biases within PC data to optimize the value of this important resource.

Evidentiary Criteria Used to Link Cause and Effect

As was illustrated in Table 132-5, association of an exposure to an illness does not necessarily equate to cause and effect. In assessing causation it must be determined if bias is present in the selection or measurement of exposure or outcome. If a study is unbiased, the role of chance in the occurrence of the observed association must be explored. If an association is unbiased, unlikely to result from random error, and is not subject to confounding, then assumptions

regarding to causation can be derived. Table 132-7 provides a list of evidentiary criteria that are often used to support causation.

TABLE 132-7. Criteria Supporting Causation

Study design	Was the association demonstrated in a well-designed study?
Temporality	Does the cause precede the effect?
Strength	What degree of relative risk was demonstrated in the analysis?
Dose response	Does an increased presence of risk factor correlate togreater or more frequent

	effect?
Consistency	Does the cause and effect hold true in different studies, locations, and populations?
Plausibility	Is the association in accordance with current scientific knowledge?
Specificity	Does the effect occur without the cause in question, orvice versa?

Many toxicologists deem clinical trials indicating a lack of benefit from gastric emptying, or indicating a therapeutic benefit of HBO therapy for CO intoxication, unconvincing because of the degree of bias present in all relevant published clinical trials. Study design flaws such as bias and confounding are problematic for any epidemiologic study, and after decades of investigation, they still raise skepticism regarding the causative role of salicylates in RS. A wealth of evidence exists to support an etiologic relationship for salicylates regarding RS. Salicylate administration in the prodromal phase of a viral illness was temporally related to the development of RS. The strength of association, as measured by the odds ratio from case-control studies, was enormous in epidemiologic terms. A study by a US Public Health Service Task Force determined that the adjusted odds ratio for an increased risk for RS if exposed to salicylate in the prodromal illness was 40.[23] Because of the rare nature of RS, this measure approximates that salicylate-exposed individuals were at 40 times greater risk of developing RS than those not exposed to salicylate. Concerns of bias in early analytic studies were addressed in further studies,[12] and the association between salicylate use and RS was consistent in refined analysis. Data from a number of studies suggested a

dose-response correlation between salicylate use and RS.[23,40] Finally, the association was consistent throughout different studies performed in different populations. After reviewing the strong epidemiologic evidence linking salicylate use to RS, in 1986 the US Food and Drug Administration (FDA) required labeling of aspirin warning of the possible association. Further evidence supporting the results of earlier case-control studies was the observation that the incidence of RS has fallen dramatically in apparent parallel to a decline in salicylate use.[4,16]

However, in medical toxicology it is virtually impossible to prove causal relationships beyond any doubt. The goal is to build empiric evidence so that associations can be confirmed or refuted with conviction. To some physicians the link between salicylate therapy and RS remains a matter of debate. A recent review of 49 cases of diagnosed RS in Australia found that most of the cases were able to be reclassified as other medical conditions such as inborn errors of metabolism.[31] Advances in medical technology, and a lack of absolute diagnostic criteria that could be applied to all possible RS patients, suggest that significant misclassification bias exists in most of the early RS research. Additionally, it has been suggested that antigenic shift within influenza B and varicella viruses may be an uncontrolled confounding variable in RS research.[26] Despite these dissenting views, the overwhelming majority of evidence suggests that the association between salicylate therapy and development of RS is an important one. Of note, aspirin was taken by millions, and yet the peak incidence of RS was less than 10 cases per million. It remains unsolved whether salicylate use can cause RS in physiologically normal children with viral illness or, perhaps, whether there exists an unidentified metabolic abnormality that may place a specialized population at risk.

Evaluation of Diagnostic Tests and Criteria

In clinical practice it is often useful to have a test, which may be a laboratory result or clinical paradigm, to help arrive at a diagnosis or predict an outcome. For instance, historical questionnaires, capillary blood lead levels, and venous blood lead levels might all be used to identify children at risk of neurocognitive injury from plumbism.[8] However, each of these approaches is likely to have certain disadvantages in terms of effort, cost, discomfort, and/or accuracy. Targeting lead evaluation and therapy at children on the basis of exposure history is expected to be easy and inexpensive, but may not identify some children with significant poisoning; thus, the test may be susceptible to being falsely negative. Capillary blood testing is more costly and uncomfortable and may be susceptible to false-positive test results because of environmental lead dust present on fingertips. The possibility of false-positive or false-negative results must be considered with any diagnostic test (Figure 132-4).

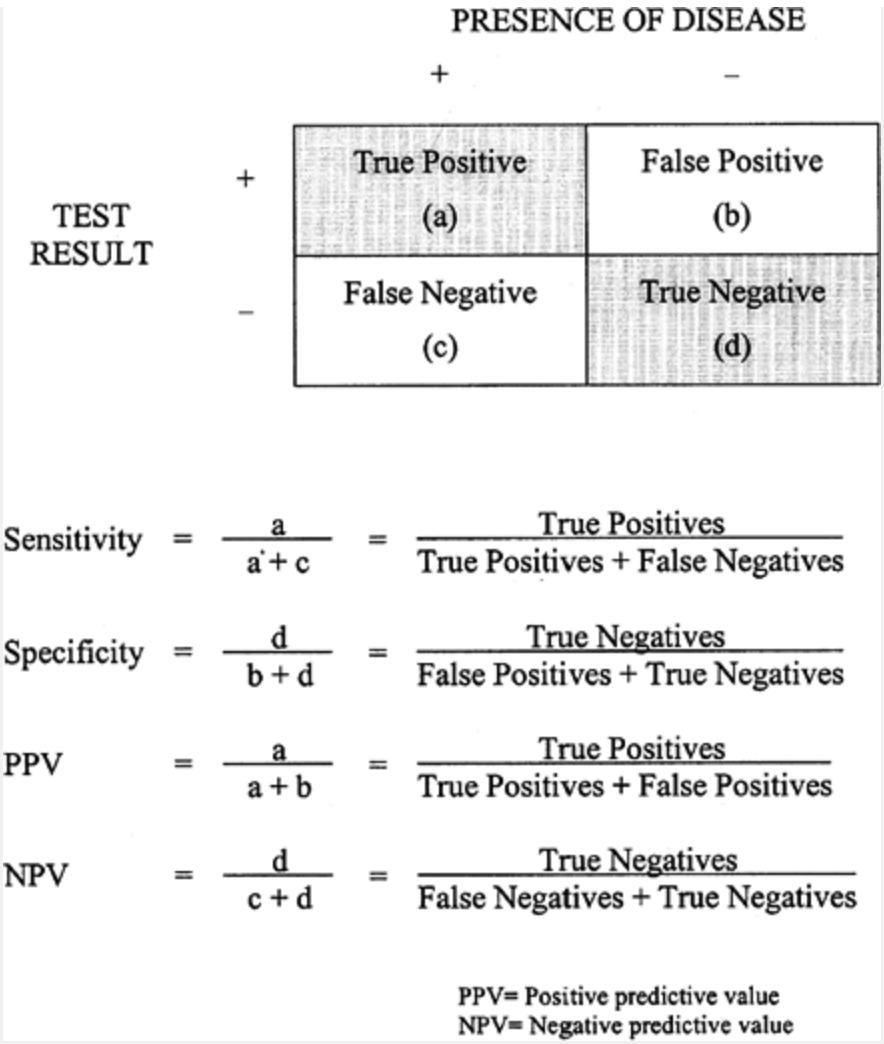

Figure 132-4. Possible results of diagnostic testing and the statistical characteristics used to describe the utility of diagnostic tests. The letters a, b, c, and d represent the numbers of tested individuals with or without the disease of interest.

The utility of diagnostic testing is often described in terms of sensitivity, specificity, predictive value of a positive test (PPV), and predictive value of a negative test (NPV). A cross-sectional

design is often used to study diagnostic tests, as we seek to determine the prevalence of positive tests among the diseased (*sensitivity*), and the prevalence of negative tests among the healthy (*specificity*). A perfect test would be highly sensitive and specific, but this is seldom possible in medical toxicology. A highly sensitive test is often used in screening programs because they rarely lead to false-negative diagnoses. Specific tests are typically used to â€œrule-inâ€• a diagnosis, as they rarely yield false-positive results. Whereas sensitivity and specificity are inherent properties of a diagnostic test applied to a given population; the probability of disease, based on the results of a test, is highly dependent on the prevalence of disease within the population being tested. The PPV is the probability of having disease in a patient with a positive test; the NPV is the probability of not having disease when the test result is negative. A number of studies have tried to examine the utility of vomiting, leukocytosis, hyperglycemia, total iron-binding capacity, and radiographic findings in predicting toxicity after acute iron overdose. In a retrospective assessment of 40 adults with oral iron overdose, vomiting was found to predict a serum iron level above 300 Âµg/dL with a sensitivity of 84%, specificity of 50%, NPV of 44%, and PPV of 87%.[33] This suggested that the presence of vomiting should raise concern for iron toxicity but that the lack of vomiting was not particularly reassuring. Figure 132-4 illustrates the calculation of the sensitivity, specificity, PPV, and NPV. It is important to remember that these calculations, too, are subject to bias and that these calculations are best presented with confidence intervals.

Summary

Medical toxicology has embraced the vision of incorporating â€œevidence-based, or literature-based, medicineâ€• into practice. Randomized clinical trials, although a noble goal, are rare and have proven difficult to perform within the discipline. As toxicologists move beyond descriptive data reporting, there

remains great potential for scientific advancement in the field of toxicology via observational, hypothesis-testing, clinical research. Clinical investigators are charged with the imperative to perform studies based on sound epidemiologic principles. All studies, by nature of population sampling, are at the mercy of chance, but such random error can be quantified using statistical techniques. Systematic error (bias) can be limited, but not entirely excluded, through careful study design. Clinicians interpreting published toxicologic research need to thoroughly evaluate a study's research objectives, design, data acquisition, analysis, and conclusions before applying the results to patient care (Table 132-8). Future epidemiologic investigation should allow more valid conclusions to be drawn regarding the associations between exposures and outcomes, or regarding the value of treatments for poisonings, discussed in the preceding chapters of this text.

Galen, an influential physician from the second century, remarked of his clinical trial, â€œAll who drink of this remedy recover in a short time, except those whom it does not help, who all die. Therefore, it is obvious that it fails only in incurable cases.â€• Unfortunately, error in contemporary clinical investigation of poisoning tends to be more insidious than the error in logic in Galen's conclusion, and skillful scrutiny of published research remains an important endeavor.

TABLE 132-8. Questions to Consider when Evaluating a Study

Research objectives
What is the study question?
What is the studied population?
Study design
What type of study was performed?
How were subjects recruited and enrolled?
Why were subjects excluded?
What was the nature of the comparison group?
Data accrual
How were the data collected?
Are the exposures and outcomes clearly defined?
Are the observations reliable and reproducible?
Was randomization and/or blinding used?
Were subjects lost to followup?
Analysis
Are the results statistically significant?
Are the results clinically significant?
Are potential confounding variables controlled?
Was the study powered to detect important differences?
Conclusions
Are the conclusions justified by data?

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 133

Adverse Drug Events and Postmarketing Surveillance

Louis R. Cantilena Jr.

A 57-year-old man was brought to the emergency department (ED) by ambulance with a history of 3â€“4 days of progressive weakness, sore muscles, and 1 day of dark colored urine. The patient had been well until the onset of these symptoms. There was no history of illicit drug use, recent surgery or infection, or significant exercise or trauma. His past medical history was significant for mild hypertension, hypercholesterolemia, and smoking. The patient was treated with lovastatin for hypercholesterolemia for 2 years and was switched 9 days earlier from hydrochlorothiazide to mibefradil for hypertension during a routine office visit to his physician. Physical examination revealed a slightly lethargic, well developed male in no distress, blood pressure 110/65 mm Hg, pulse 53 beats/min, respirations 20 breaths/min, and temperature 100.4Â°F (38.0Â°C). Laboratory evaluation showed the CBC to be within normal limits, potassium 6.1 mEq/L, serum bicarbonate 13 mEq/L, BUN 22 mg/dL, and creatinine 5.2 mg/dL. A serum CPK returned

elevated at 65,100 IU. The urine analysis was positive for myoglobin.

A working diagnosis of probable drug-induced rhabdomyolysis was established, all medications discontinued, and the patient was admitted for further treatment of acute renal failure associated with rhabdomyolysis. The Î²-hydroxy-Î²-methylglutaryl-coenzyme A (HMG CoA) reductase inhibitor lovastatin, one of several statin drugs available for the treatment of hypercholesterolemia was suspected as the offending agent as this adverse drug event (ADE) had been previously associated with the statins. What puzzled treating physicians at the time of admission however was the fact that the patient had been treated with the same dosage of lovastatin for 2 years without prior evidence of adverse effects. Attention turned toward the newly started medication, mibefradil, a calcium channel blocker (CCB) approved as an antihypertensive agent by the Food and Drug Administration (FDA) in August 2001. With the assistance of a clinical pharmacology and medical toxicology consultation service, a working hypothesis was developed that mibefradil interfered with the metabolism of lovastatin, raising the serum lovastatin concentration leading to â€œstatin-inducedâ€• rhabdomyolysis. Since the inhibition of cytochrome oxidase by mibefradil was described in its FDA approval, a specific warning regarding a potentially serious metabolism-based drug interaction with certain statins was added to the mibefradil drug label.

This case demonstrates an ADE associated with a specific drug that was not fully appreciated at the time of drug approval and marketing and was not identified until approximately 4 months following the drug's approval. In fact, numerous case reports of suspected drug-drug interaction problems were reported to the FDA within a few months of the initiation of marketing of the agent. The mibefradil drug label was modified and â€œDear Doctorâ€• letters were sent out to warn of these newly discovered drug interactions.[10] The list of known drug interactions for mibefradil grew rapidly to well over 30 agents in a short period of time. Because of this expanding list of potentially serious drug interactions and the availability of alternative therapies for the cardiovascular indications of the agent, mibefradil was withdrawn from the market less than 1 year

after approval.

This chapter focuses on drug-induced disease resulting from adverse drug events (ADEs) caused by both inherent drug toxic effects and as a consequence of unintentional drug interactions. The topics covered in this chapter include a discussion about the diagnosis of drug-induced disease, an overview of the FDA process for drug approval, postmarketing surveillance of ADEs, and the role of the medical toxicologist in the discovery, reporting, and prevention of ADEs.

ADEs are defined as an untoward effect or outcome associated with use of a drug. In this chapter, the word â€œdrugâ€• will be used for a pharmaceutical product and includes prescription and nonprescription products, and dietary supplements.

In the United States, all prescription and nonprescription products must be approved by the Food and Drug Administration (FDA) prior to marketing and sale. For complex reasons, dietary supplements fall outside of this legal requirement. Regulation of these products is discussed later in this chapter and in Chap. 43 .

History of the United States Drug Approval Process

Today in the United States, approvals of new therapeutic agents are occurring at an unprecedented rate. The evolution of the system that currently exists for review of drug applications and approval of new therapeutic agents is the result of relatively recent changes in the US drug approval law. The US drug approval law was closely linked to a series of medical product disasters that occurred during the 20th century in the United States. Before 1900, there was no legal requirement for a company to test a product for safety or efficacy or even to

make valid claims in the drug label. Products such as aspirin-containing heroin were sold as cough syrup. Wine with cocaine was marketed to enhance sales of the alcoholic beverage. Further, there was no legal

requirement for systematic testing of products to determine content or the presence of possible adulterants in product formulations. The Food and Drug Act of 1906 required pharmaceutical manufacturers to meet a standard for the concentration and purity of the drugs they marketed. However, the burden of proof was on the FDA to show that the drug was incorrectly labeled or that the advertising or label was false or misleading.

The Food, Drug and Cosmetic Act of 1938 resulted from a tragedy in which more than 100 patients (mostly children) died from poisoning by a excipient of an oral solution of sulfanilamide. A pharmaceutical company, in an attempt to improve the palatability of a sulfanilamide product for pediatric formulations, introduced the solvent diethylene glycol into the formulation. Diethylene glycol is a sweet-tasting but nephrotoxic hydrocarbon. Only after almost a full year of marketing were cases of renal failure and death reported in sufficient numbers to alert authorities to the extremely toxic nature of the product. The Food Drug and Cosmeti Act of 1938 accomplished the following:

- Required companies to list the ingredients of the product on the product label.
- Required companies to provide the known risks concerning use of the product to physicians or pharmacists.
- Made illegal the misbranding of food or medical products.
- For the first time required companies to test their products for safety before being sold.

Drugs already marketed before 1938 were exempt from the requirement (Chap. 1).

An application in the early 1960s for the approval of Î±-*N* - phthalylglutaramide (Thalidomide), a sedative that had already been marketed in Europe, was submitted to the FDA. The sedative drug had a rapid onset and short duration of action, did not affect ventilation, did no

cause a morning-after effect, and was inexpensive. A medical officer at the FDA (Dr. F. Kelsey) delayed approval by asking the sponsor to clarify several issues in the reportedly poorly organized new drug application (NDA). In the interim, an unusual teratogenic effect, phocomelia, or limb misdevelopment, was linked in Europe to the use of thalidomide. Congressional hearings resulted in the Kefauver-Harris Act of 1968, whicl required a drug manufacturer or sponsor to do the following:

- File an investigational new drug application (IND) before beginning a clinical study with a drug in humans.
- Demonstrate that the drug was effective for the condition that it was being marketed to treat.
- Provide adequate directions for safe usage of the drug.

Once again, the act did not exempt drugs that were already on the market.

Subsequent US laws that affect the FDA's review and approval of product include the following:

- The Orphan Drug Act of 1983, which provides financial incentives to drug manufacturers to develop drugs for the treatment of rare diseases and conditions (see http://www.fda.gov/orphan/designat/recent.htm for a list of drugs that have been approved under the Orphan Drug Act.).
- The Prescription Drug User Fee Act (PDUFA) of 1992, which required manufacturers to pay user fees to the FDA for NDAs and supplements to enable the FDA to hire additional reviewers and accelerate the review process.
- The Dietary Supplement Health and Education Act (DSHEA amendment) of 1994, which removed from FDA the authority to require proof of safety or efficacy prior to marketing of products considered dietary supplements (including herbal remedies). Only

when a specific health claim is made by the product's manufacturer does the FDA have premarketing approval authority. Furthermore, rather than placing on the manufacturers the burden of proof for safety and efficacy of a product, the FDA is required to determine tha a product is unsafe to prevent sale and distribution in the United States.

- Section 112 of the FDA Modernization Act of 1997, allowed for an accelerated drug approval process for agents to treat life-threatening illnesses such as AIDS and cancer if the agent has the potential to address medical needs unmet by currently available drugs. Many of the accelerated drug approvals rely on efficacy results derived from surrogate markers linked to the ultimate indication for the drug. For example, the protease inhibitors were approved on the accelerated track for the treatment of AIDs because of their ability to reduce HIV viral load.
- The Pediatric Research Equity Act of 2003 requires manufacturers to study the pediatric population drugs being submitted for approval for a claimed indication. As a result more data from children is being provided to guide therapeutic use of medication in this patient group.

A complete listing of the laws and statues enforced by the FDA is found on the FDA web site.[12]

A current area of controversy is whether or not changes to FDA law resulting in shorter review times for NDAs have led to an increase in the need to withdraw unsafe medications.[13 , 27 , 33] Recent drug product withdrawals of cyclooxygenase-2 (COX-2) inhibitor antiinflammatory agents have resulted in congressional hearings on the review practices and monitoring of drug safety by the FDA. Depending on the safety signa generated and the specific nature of the ADE, it is possible that in some cases there may be as much as a 10â€“15-year lag in the postmarketing surveillance system, particularly for rare or difficult to diagnose ADEs. Figure 133-1

shows data summarized to 2003, which thus far does not indicate an increase in the percentage of drug withdrawals after PDUFA implementation. The next several years will likely determine whether or not there is an association between the increased rate for drug approval and the rate of safety-related drug withdrawals.

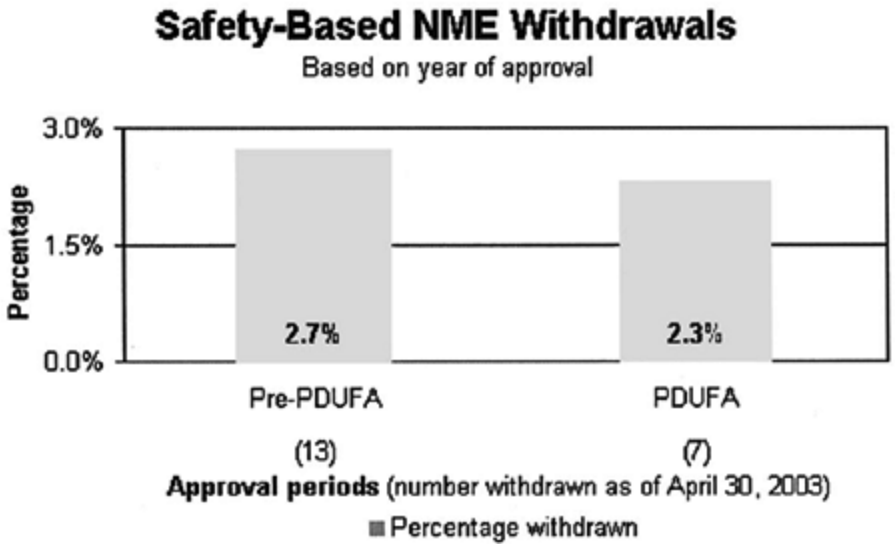

Figure 133-1. Rate of safety based new molecular entity (NME) withdrawals from before and after (to 2003) implementation of the Prescription Drug User Fee Act (PDUFA). (From http://www.fda.gov)

The Drug Development Process

Figure 133-2 shows a schematic overview of the process for drug development of a new molecular entity (NME). The process begins with the preclinical evaluation of the candidate drug. During this evaluation, toxicologic testing is performed in more than one animal species and other testing including stability of the product, manufacturing methods, purity, and initiation of testing for possible carcinogenicity. Dose-response relationships in animal models and in vitro receptor binding or surrogate marker effects are often determined at this time in the program. Also, this is the time when many manufacturers determine the drug's metabolism in animal and in vitro human systems. Following this

preclinical testing, the sponsor submits an IND application to the FDA for approval to initiate human testing. This application contains all relevant data concerning animal and in vitro toxicology testing, product manufacturing and purity, and a protocol for using the drug in initial human investigation. Within 30 days, the FDA must review the IND application and either allow the proposed human study to proceed or inform the sponsor that additional data or preclinical work is required before clinical testing of the candidate drug can begin.

The clinical study of new medications is divided into four basic phases. Phase 1 clinical testing involves a relatively small number of subjects wit the primary aim of determining the safety and toxicity of the drug. Many phase 1 studies will also determine the human pharmacokinetics and metabolism of the drug. Phase 1 studies are normally conducted in 20â€“100 healthy volunteer subjects with the notable exception of phase 1 studies for cancer chemotherapeutic agents, which only enroll patients with cancer.

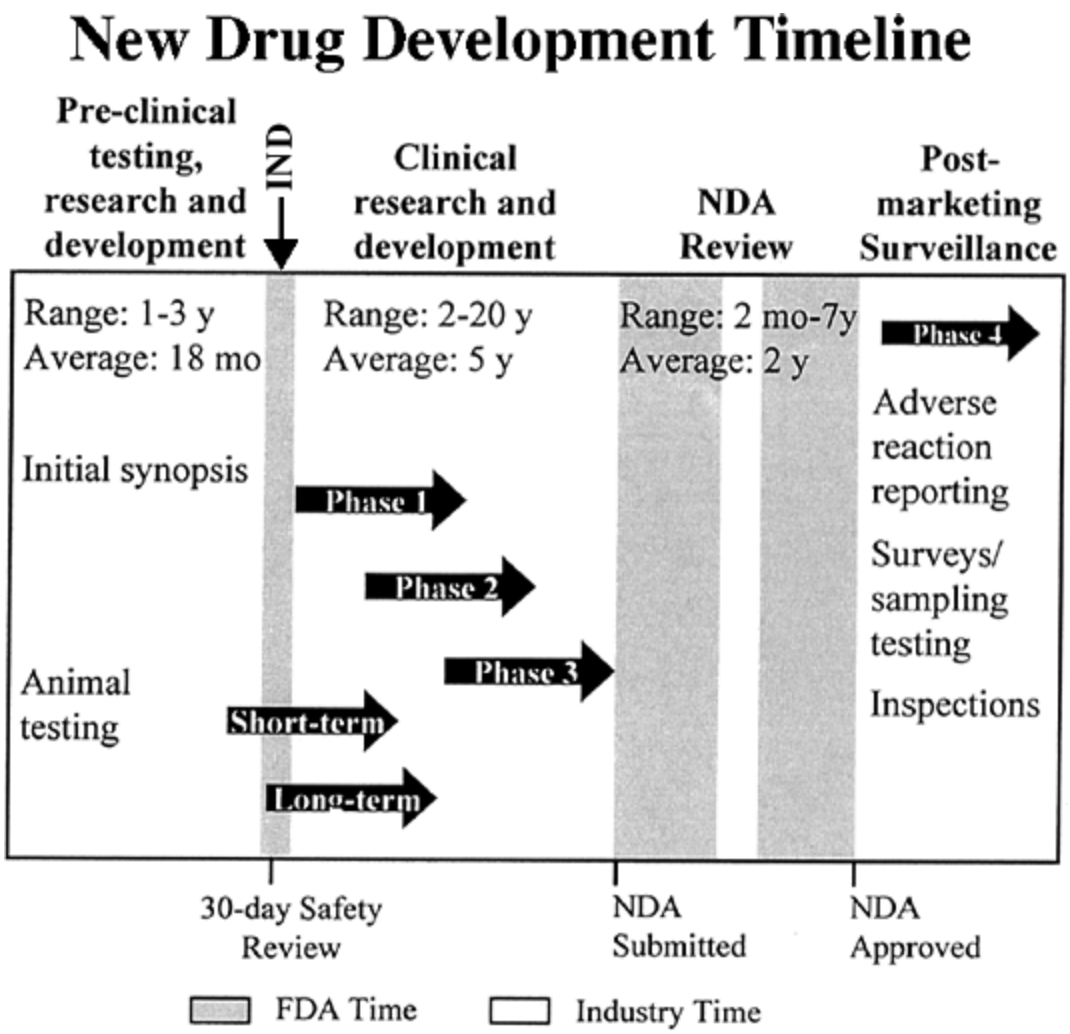

Figure 133-2. Schematic representation of new drug development. (Fror http://www.fda.gov .) NDA = New Drug Application.

Phase 2 clinical testing is designed to determine the potential efficacy of the drug product in humans and sometimes explores the range of effective drug dosages. In this phase, approximately 100â€“300 subjects are usually studied. In phase 2 clinical trials, subjects generally have the diseases for which the drug is intended or are capable of demonstrating the appropriate, validated, biologic surrogate marker to indicate response to the drug.

Phase 3 clinical drug studies usually involve large-scale clinical trials in the actual population for which the drug is intended to be used. Typically

this phase of a drug's development will involve testing a treatment cohor of several hundred to several thousand patients who have the target disease, depending on both the prevalence of the disease and effectiveness of the drug. The primary goal of phase 3 studies is to determine the safety and efficacy of the candidate drug in the actual patient population it will be used in, under conditions close to the anticipated medical use. A candidate drug completing phase 1, 2, and 3 can thus be approved for marketing after study in only 2000â€“4000 patients. In the setting of a fast-track approval or under the Orphan Drug regulations, substantially fewer patients will receive the drug before its approval for marketing. The next phase of drug development is discussed separately below.

Phase 4 Drug Development: Postmarketing Surveillance

The approval of every drug or medical device for marketing always carrie with it some potential risk.[7] If society required that only â€œcompletelyâ€• safe drug products were allowed to be marketed, the drug approval process would likely take decades and fewer drugs would be made available. The FDA and the drug industry therefore significantly relies on postmarketing surveillance for further safety data regarding the toxicity of a drug after approval. There are systems in place to monitor post approval drug safety that are intended to detect instances in which the safety profile of an approved agent may appear to be different after marketing. These systems fall under the category of post marketing surveillance. Individual pharmaceutical manufacturers are responsible for monitoring the safety of their products and reporting to the FDA, on a regular basis, any ADEs that were reported to them. The FDA's postmarketing surveillance (MedWatch Program) for all medical products is a parallel system in place to monitor drug and medical device safety. Because manufacturers are required by law to report ADEs associated with use of their products to FDA, eventually the FDA database contains one complete data set called the Adverse Event Reporting System (AERS

database). These reporting systems are passive in nature. The reports are sent in spontaneously and not actively obtained or pursued by the FDA or manufacturers. Health professionals contribute the majority of reports to the ongoing passive surveillance of drug safety.

Phase 4 clinical studies are sometimes conducted and may include marketing-type studies comparing the new drug to a competitor or studies to evaluate potential safety issues with a drug. The enhancement of safety information is the primary goal of most phase 4 studies. The methods by which phase 4 safety studies are conducted are primarily observational and epidemiologic studies. Main sources of data for the pos approval monitoring of the safety of a drug are the spontaneous reports gathered by both the pharmaceutical manufacturer and FDA. The fields of pharmacovigilance

and pharmacoepidemiology are typically employed in the conduct of phase 4 studies.[21] Until 1993, the FDA used the spontaneous reporting system (SRS) to gather information regarding ADEs occurring in patients using the approved drug. In 1993, this system was renamed and promoted as the MedWatch system.[17] This system relies on spontaneous reports by healthcare professionals or patients regarding the occurrence of deleterious effects associated with the use of a medical product. The primary goals of the MedWatch system are the following:

- To increase awareness of drug- and device-induced disease.
- To clarify what should (and should not) be reported to the agency.
- To make it easier to report adverse effects by creating a single system for health professionals to use in reporting ADEs and product problems to the agency. (4) To provide regular feedback to the healthcare community about safety issues involving medical products.[20]

Currently, the MedWatch program is supported by over 140 organizations representing health professionals and industry, that have agreed to be

MedWatch Partners to help achieve these goals.

Medical product manufacturers that are regulated by the FDA are required to report ADEs occurring in association with the use of their products. Healthcare professionals are encouraged (but not required) to report ADEs. An adverse event is any undesirable experience associated with the use of a medical product in a patient. The MedWatch system has tried to make reporting by healthcare providers easier. A MedWatch report can be made by either facsimile, telephone, mail, or Internet. Establishing causality for a specific medical product is not required before submission of a MedWatch report. The FDA is primarily interested in the report of a serious adverse event, or an ADE previously not associated with the drug being administered, whether or not a causal relationship is established. An event is serious and should be reported when the patient outcome is one of the following:

- Death, and the death is suspected to be a direct result of the adverse event.
- Life-threatening, if the patient was considered to be at substantial risk of dying at the time of the adverse event or the use or continued use of the product would result in the patient's death. (Examples include gastrointestinal hemorrhage, bone marrow suppression, pacemaker failure, and infusion pump failure that permits uncontrolled free flow and results in excessive drug dosing.)
- Hospitalization (initial or prolonged) if admission to the hospital or prolongation of a hospital stay resulted from the adverse event. (Examples include anaphylaxis, pseudomembranous colitis, or bleeding causing or prolonging hospitalization.)
- Disability, if the adverse event resulted in a significant, persistent, or permanent change, impairment, damage, or disruption in the patient's body function/structure, physical activities, or quality of life. (Examples include cerebrovascular accident caused by drug-induced coagulopathy, toxicity, and peripheral neuropathy.)

- Congenital anomaly, if there are suspicions that exposure to a medical product before conception or during pregnancy resulted in an adverse effect on the child. (Examples include vaginal cancer in female offspring from exposure to diethylstilbestrol during pregnancy or limb malformations in the offspring from thalidomide use during pregnancy.)
- Requires intervention to prevent permanent impairment or damage if use of a medical product is suspected to result in a condition requiring medical or surgical intervention to preclude permanent impairment or damage to a patient. (Examples include acetaminophen overdose-induced hepatotoxicity requiring treatment with *N* -acetylcysteine to prevent permanent damage, burns from radiation equipment requiring drug therapy, or breakage of an orthopedic screw requiring replacement of hardware to prevent malunion of a fractured long bone.[20])

Physician reports are given priority for review by the FDA in the MedWatch system. A well-documented case of a serious adverse event is a significant and useful contribution to the MedWatch system.

Reports of serious ADEs to the FDA or to the manufacturer can evolve into an epidemiologically detectable signal that can catalyze subsequent, more detailed investigations (examples of cases where this has occurred are provided later in this chapter). On occasion serious ADEs detected in the AERS database have led to the withdrawal of products from the US market without conducting additional studies.

Reporting serious ADEs has periodically been encouraged by various healthcare groups in conjunction with the FDA. With the introduction of the MedWatch system and MedWatch partner programs, medical societies and organizations such as the American Medical Association (AMA), the American College of Medical Toxicology (ACMT), and the American Academy of Pediatrics (AAP) have encouraged their members to report to the MedWatch system. As a requirement for hospital accreditation, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO)

mandates hospitals to collect, analyze, and report significant and unexpected ADEs to the FDA.

The primary limitation of the MedWatch system is the exclusive reliance on spontaneous reporting of ADEs. Significant underreporting is known to occur in such systems. Current estimates are that fewer than 10% of ADEs are reported.[14, 23, 26] The true incidence of the reported ADE is almost never obtainable because the denominator, which is the number o actual exposures to the drug, is rarely accurately known. Despite these limitations, the MedWatch system is capable of detecting significant ADEs The relatively small number of patients or subjects exposed to the drug before approval (phases 1â€“3) is one reason why relatively uncommon ADEs are frequently not detected until the post approval marketing phase. For example, to detect an uncommon ADE occurring in approximately 1 of 5,000 individuals exposed to a drug with 95% probability that the ADE resulted from exposure to that drug, approximately 15,000 patients would have to be exposed to the drug.[11] In a balanced (equal numbers of drug and placebo recipients) placebo-controlled clinical trial, 30,000 subjects would need to be enrolled. Premarketing clinical studies (phase 1, 2, and 3) may not be able to detect rare ADEs, ADEs that are incorrectly diagnosed, or ADEs that result from a drug interaction that may not have been tested in the development program. An example of a rare ADE not detected until postmarketing involves the drug felbamate, which was approved by the FDA in September 1993 and subsequently found to be associated with aplastic anemia during postmarketing surveillance. Felbamate-induced aplastic anemia had not been detected during the drug development program for the

agent. By July 1994, 9 cases had been reported from an estimated 100,000 patients exposed to felbamate in the United States. Most of the aplastic anemia cases occurred in patients who had taken the drug for less than 1 year. The 9 cases represented an approximate 50-fold increase in aplastic anemia over the expected rate in the population with the very low background rate of 2â€“5 cases per million per previous

year[1 , 29] allowing the FDA to attribute this rare condition to exposure to felbamate.

A primary role of the MedWatch system is to generate a â€œhypothesisâ€• for a potential association of an ADE with a specific drug. Attributing a serious ADE to a drug solely from MedWatch reports does occur but less commonly than does the AERS database producing a signal suggesting a possible drug-related safety problem. An example of this â€œhypothesis generationâ€• function of MedWatch is the question of whether phenylpropanolamine (PPA) causes hemorrhagic stroke in patients using nonprescription diet suppressants or cough and cold preparations containing PPA. In the early 1990s, the Spontaneous Reporting System (SRS, now AERS) detected a potential association of hemorrhagic stroke and nonprescription use of PPA. An industry-sponsored prospective, case-controlled study resulted, to determine if such an association existed. The multicenter study demonstrated that an association did exist, especially for women ages 18â€“49. The Nonprescription Drug Advisory Committee (NDAC) of FDA reviewed this study and the associated MedWatch data in the fall of 2000 and decided that the evidence supported such an association. The committee advised the FDA to remove PPA from the market, which occurred a short time later. Although the entire process of signal identification from MedWatch to presentation of results from the prospective epidemiologic study required nearly a decade for PPA, the process demonstrates the value of the hypothesis-generating ability of the MedWatch system.

1. Was the timing of the adverse event appropriate relative to the exposure to the drug?
2. Has the effect noted, which is the suspected ADE, been reported before?
3. Is there evidence of excessive exposure to the drug?
4. Are there other more likely etiologies responsible for the condition suspected as being an ADE?
5. What is the patient's response to dechallenge?
6. What is the patient's response to rechallenge?

TABLE 133-1. Questions to Consider When Establishing the Diagnosis of an Adverse Drug Event

Establishing the Diagnosis of Drug-Induced Disease

The recognition and diagnosis of a drug-induced disease, or an ADE, is an essential skill for practitioners, including medical toxicologists and clinical pharmacologists. The diagnosis of an ADE is typically established as a result of a systematic medical evaluation. One approach to establishing the diagnosis of drug-induced disease involves consideration of six related questions concerning the patient's clinical presentation and available medical data, as shown in Table 133-1 .

The first question concerns the timing of the onset of the adverse event in relationship to the reported exposure to the drug. Perhaps because of publicity or word of mouth, ADEs are sometimes reported to the FDA MedWatch system even when the onset of the adverse event occurs before the first exposure to the suspect drug. A careful reconstruction of the time course of drug exposure and onset of adverse effects is extremely important in assessing causality. The time course differs considerably for different adverse clinical events. An anaphylactic reaction to a drug occurs within minutes of exposure, whereas renal insufficiency caused by a drug is not likely to be clinically detectable for up to several days after the exposure. A drug that causes cancer (a carcinogen) may not produce a clinically detectable effect for decades. Establishing a time course is an essential first step in the process of making the diagnosis of drug-induced disease.

The second question is whether or not this adverse effect has been reported previously for the suspect drug. An adverse drug effect that occurs commonly is likely to be known before the approval of the drug and is therefore usually found on the initial drug label. For example,

respiratory depression and mental status changes were well known before the approval of fentanyl, an opioid agonist. Less common ADEs for drugs that have been on the market for a period of time are sometimes reported in the literature, included in various medical databases, and in some cases will appear in a revised drug label for the medical product. Previous reports linking the observed adverse effect to drug exposure are very helpful to the physician trying to establish a significant level of probability for causality in the setting of an ADE.

However, in the setting of a newly approved drug or a previously unreported possible ADE, neither previous reports, the medical literature nor the drug label will help establish causality. In this setting, the clinician must rely more on what is known of the pharmacology, the pharmacokinetics, and the anticipated pharmacodynamics of the suspect drug and the timing of the appearance and observed time course of the adverse event. It is important to put â€œdrug-induced diseaseâ€• in the differential diagnosis for most patients presenting for medical care. Someone has to be the first to report what is ultimately recognized as an adverse effect for every xenobiotic. Appropriate vigilance for the possibility of a new ADE significantly increases the probability that a finding can be made early after introduction of a new drug to prevent more widespread drug-induced morbidity or mortality.

The next question to consider is: â€œIs there evidence of excess exposure to the drug?â€• The majority of ADEs that occur are predictable on the basis of the known pharmacology of the specific drug. Such ADEs are referred to as â€œtype Aâ€• ADEs.[3] For example, antihistamines such as diphenhydramine are known to cause significant anticholinergic effects. When a patient presents with mental status changes and clinical findings consistent with the anticholinergic toxidrome after significant exposure to an antihistamine-containing product, the observed effects are consistent with an ADE attributable to the antihistamine. Occasionally, proof of drug excess can come from measurement of the drug in plasma. In the case of the patient with a history of manic-depressive illness, who exhibits hyperreflexia and tremors, the measurement of an elevated lithium plasma concentration

supports the diagnosis of lithium toxicity or an ADE attributable to lithium. In either case, knowing the pharmacology of the drug is important for establishing the diagnosis of an ADE.

When an ADE is caused by an allergic mechanism or another mechanism unrelated to dose of the drug, ie, a â€œtype Bâ€• ADE, evidence of drug excess usually does not contribute to the diagnosis. In this setting, other factors such as allergy history or pharmacogenetic background are weighed more heavily to support the diagnosis of an ADE.

The next issue to address in considering possible causality is whether there are other more likely etiologies that could be responsible for the observed effects. Although it is important to be appropriately vigilant for possible ADEs, it is equally important not to miss an alternative cause for the patient's condition. There are certain clinical settings in which establishing an ADE becomes a diagnosis by exclusion. For example, in the case of persistent fever, the assignment of the diagnosis â€œdrug feverâ€• should not be made until a complete search for infectious causes has excluded this etiology.

Another factor to consider in contemplating a diagnosis of ADE is â€œWhat is the patient's response to cessation of a suspect drug (dechallenge)?â€• In this case, the pharmacokinetics of the drug and the timing of resolution of the specific condition must be carefully considered. In some instances, the resolution of a â€œtype Aâ€• ADE closely follows the pharmacokinetics of the suspect drug. For example, in the case of acute ethanol intoxication, central nervous system effects resolve in association with decreasing plasma concentrations of ethanol. However, confounding this approach is the case of a penicillin rash, which may develop within 1 or 2 days of starting the medication but may take several days to weeks to completely resolve. In this case of a â€œtype Bâ€• ADE, the resolution of the condition (rash) occurs over a much longer time period than would be predicted by the pharmacokinetics of the drug. When a suspected ADE resolves after discontinuation of exposure to the offending drug, along a predictable time course, then the

result of this â€œdechallengeâ€• would support the diagnosis of ADE.

Last, the clinician may have the opportunity or need to rechallenge the patient with the suspect agent. If the rechallenge results in the identical response or effect, then this would be considered strong evidence to support a causal relationship for the suspect agent and the adverse event. In the setting of a serious or life-threatening adverse event, it is too dangerous to perform a rechallenge with the suspect drug, in which case the response to rechallenge will not be known. In this setting, the weight of evidence previously discussed will then be the only factors available to assign the probability of causality.

Examples of FDA Regulatory Action Because of Safety Concerns for Drugs on the United States Market

When new information about a marketed drug raises concern for the safety associated with its use, the FDA has several options to exercise to either attempt to improve the safety of the drug or terminate the availability of the drug on the market. A frequently employed option is fo the FDA to modify the label of the drug. These modifications can include restrictions on who should receive the drug, what doses should be given for which indications, what type of monitoring should be performed durin therapy and how long should treatment be administered. When potentiall life-threatening safety information comes to light, and if the FDA believes that the risk-benefit relationship still favors availability of the drug, the FDA can require that a â€œblack boxâ€• warning be carried in the label. A â€œblack boxâ€• warning is the most serious warning placed in the label of a prescription medication. Additionally, once a drug's label contains a black box warning, advertisements that serve to remind healthcare professionals of a product's availability are not permitted for that specific product at any time. Additionally, the manufacturer is required in most cases to send a â€œDear Doctorâ€• letter to potential prescribers informing them of the black box warning. Dear Doctor letters

are sent to prescribers to notify them about a significant change in the drug label and not just the addition of a â€œblack boxâ€• warning. An example of current medications with recently added black box warnings include the antidepressant medications which now must warn about the increased risk of suicidality in children and adolescents who receive these agents. Another example is the recent inclusion of a black box warning on the label of COX-2 inhibitors and other nonsteroidal antiinflammatory drugs (NSAIDs) that addresses the increased risk of serious cardiovascular events such as heart attack or stroke. A third example is the 2001 black box addition to the droperidol label intended to increase the prescriber's awareness of and assessment for the potential for cardia dysrhythmias during drug administration, and to encourage that consideration be given to the use of alternative medications for patients at risk for cardiac dysrhythmias.

Another option sometimes employed by FDA is to permit continued availability of a drug for marketing but with specified restrictions. For example, use of the drug isotretinoin (Accutane) requires compliance with a multiple component risk management program including informed consent, prescriber and dispensing pharmacy registration, serial pregnancy testing if applicable, documentation of patient education, and completion of risk management programs by patients who will receive the medication.[8]

When the FDA believes that a drug can no longer be safely used despite implementation of labeling changes, that is, the regulatory threshold is reached when an acceptable riskâ€“benefit relationship for continued availability of a drug product is not possible, the FDA begins a defined process to remove the drug from the market. Table 117-2 in the Seventh edition of *Goldfrank's Toxicologic Emergencies* contains a compilation of products that were withdrawn or removed from the market in the United States for reasons of safety or efficacy. Some recent additions to that list of drugs include valdecoxib (marketed as Bextra) and rofecoxib (marketed as Vioxx), withdrawn because of recognition of elevated cardiovascular risk associated with their use.[13] In the case of the COX-2 inhibitor withdrawals the precipitating factor for withdrawal was the

findings of a strong safety signal for excess cardiovascular mortality and morbidity during the conduct of efficacy studies for other potential therapeutic indications for these agents. The postmarketing surveillance system did not serve as the initial, precipitating data set for regulatory action in this instance.[4,18,24,25] The manufacturers voluntarily withdrew these COX-2 inhibitors and the majority of the drugs listed in Table 117-2 of the Seventh edition of *Goldfrank's Toxicologic Emergencie* from the United States market. In many cases, the manufacturer removes the drug from the market after notification by the FDA that regulatory action is being initiated to remove their drug from the market. Only very rarely has the FDA itself actually removed a drug from the market. One example where the FDA did implement removal is the drug phenformin, which was removed by the FDA after due process was completed. In the case of ephedra containing dietary supplements, the FDA removed these products from the market based on their analysis of safety data obtained from the medical literature and from analysis of cases reported to the MedWatch system. In some cases, the pharmaceutical manufacturers file suit against the FDA to fight or delay the planned regulatory action against the product.

The manufacturer's legal action generally prolongs the time the product remains on the market because the drug usually continues to be sold while the legal proceedings and appeals proceed through the courts.

In addition to the recent COX-2 withdrawals, where an elevated risk of cardiovascular ADEs was cited, the past several years have seen drug withdrawals from the US market because of postmarketing recognition of ADEs in 3 general areas:

- Prolongation of the QTc interval
- Significant drug-drug interactions
- Hepatotoxicity

Prolongation of the QTc Interval

Three significant drug withdrawals in the mid- to-late 1990s exemplified a serious drug safety issue with an agent found to prolong the QTc interval when administered alone or as the result of increasing plasma concentrations of the drug as a result of inhibition of its metabolism by other medications. The three examples in this category are terfenadine (Seldane), astemizole (Hismanal), and cisapride (Propulsid). Numerous deaths were reported to the MedWatch system for patients taking these medications. The FDA funded small prospective clinical studies to confirm a previously unrecognized ability of terfenadine to dramatically alter cardiac repolarization, which can lead to torsades de pointes. The drug was marketed in 1985, cardiac toxicity detected in clinical use in 1990,[22] the FDA funded clinical cardiac safety research performed in 1991[16] and ultimately the drug was withdrawn from the market in 1998. Astemizole (Hismanal), another antihistamine, with similar propensity to alter cardia repolarization was first marketed in 1988. In the early 1990s, the FDA SRS pointed to signals of altered cardiac conduction and prolongation of the QT interval similar to those associated with terfenadine. These reports lead to a â€œblack boxâ€• warning for the potential to prolong the QT interval that could produce torsades de pointes and sudden death In June 1999, the FDA announced that the sponsor was voluntarily withdrawing astemizole from the market.[5] There are substantial parallels between terfenadine and astemizole. Both drugs are nonsedating antihistamines that are metabolized by cytochrome P450 (CYP3A); both parent compounds alter cardiac repolarization to produce prolongation of the QT interval, leading to cardiac dysrhythmias and its complications, and inhibition of CYP3A4 by erythromycin raised serum concentrations of the parent compound leading to dysrhythmia.

Another similar example involves the GI motility drug cisapride (Propulsid). By December 31, 1999, cisapride was associated with 341 reports of cardiac dysrhythmias including 80 fatalities. The mechanism fo the prodysrhythmic effect was similar to astemizole and terfenadine, (potassium channel inhibition), and inhibition of cisapride metabolism

increased the risk for dysrhythmia and death. Administration of cisapride with inhibitors of CYP3A such as clarithromycin results in prolongation of the QTc (QT interval corrected for heart rate) interval on the surface electrocardiogram.[28] Despite several modifications in the drug label to enhance the warnings for the product, reports of significant cardiotoxicity continued. In March 2000, the manufacturer agreed to stop marketing this agent as of July 2000.[6] Unlike the voluntary withdrawals of astemizole and terfenadine, the sponsor was able to retain the ability to make cisapride available to patients who meet specific clinical eligibility criteria for a limited-access protocol. It is unclear at this point whether or not this drug will eventually be completely withdrawn from the US market.

In addition to the drug-drug interactions that lead to accumulation of toxic cardiac parent drugs as in the case of terfenadine, astemizole and cisapride, drugs shown to inhibit multiple metabolic pathways, especially of drugs with narrow therapeutic indices, have been removed from the market.

Significant Drug-Drug Interactions

The case example of mibefradil (Posicor) presented at the beginning of this chapter is a prime example of drug withdrawn from the US market because of postmarketing discovery of a plethora of drug-drug interactions. Mibefradil, a pharmacologically unique calcium channel blocker was approved by the FDA for the treatment of patients with hypertension and chronic stable angina. The FDA approved mibefradil for marketing in 1997 and at that time information regarding its inhibition of hepatic CYP isozymes were known and printed on the drug label. The initial labeling for mibefradil specifically listed three drug-drug interactions: astemizole, cisapride, and terfenadine. During the one year that mibefradil was marketed, information accumulated regarding drug-drug interactions with many other drugs as well. As the in vitro and in vivo drug interaction data continued to accumulate for mibefradil, the FDA made labeling changes and issued a public warning for these

potential drug interactions within 5 months of its initial approval. Additionally, the sponsor distributed a letter to healthcare professionals warning of drug-drug interactions. In the face of a growing and significan list of drug-drug interactions, and a 3-year international study demonstrating no clinical benefit of mibefradil over placebo for congestiv heart failure, the FDA initiated regulatory action. In an unprecedented step for a drug with numerous drug interactions, the FDA requested approximately 1 year after it was approved that it be withdrawn from the market. The FDA felt that the diversity of drug-drug interactions could no be addressed by standard drug label instructions and additional public warnings.[7]

Drug-Induced Hepatotoxicity

Another category of ADE of recent concern is those drugs that cause hepatotoxicity. In June 1998, the manufacturer of the NSAID bromfenac sodium (Duract) withdrew this agent from the US market. The NDA was submitted for review to the FDA in 1994 and after 28 months of review was approved. The drug was withdrawn approximately 11 months later after postmarketing discovery of significant hepatotoxicity. Although no cases of serious liver injury were reported during premarketing clinical trials, after introduction to the market a higher incidence of liver enzyme elevation was found in patients who were being treated with the drug. Post approval exposure of patients to bromfenac generally resulted in longer periods of treatment than that of the subjects in the clinical trials. Because of a pre approval concern by the FDA that long-term exposure to bromfenac could cause hepatotoxicity, bromfenac labeling specified that the product was to be used for 10 days or less. This dosing limitation appeared to be in conflict and inconsistent logically, with the initial approved drug indication for treatment of a chronic condition (eg, osteoarthritis). Information concerning elevated hepatic enzymes was actually included in the original product labeling. The postmarketing surveillance of this product identified rare cases of hepatitis and liver failure, including some patients who required liver transplantation, among those using the drug for more than the 10 days specified on the

label. In February 1998, approximately 6 months after approval for marketing, the FDA amended the drug label for bromfenac sodium with a special â€œblack boxâ€• warning indicating that the drug should not be taken for more than 10 days and emphasizing the risk of severe hepatitis and liver failure. The label change was done in conjunction with a required â€œDear Doctorâ€• letter to prescribers informing them of this labeling change. Nonetheless, severe injury and death from long-term us of bromfenac sodium continued to be reported, and ultimately, the sponsor agreed to voluntarily withdraw bromfenac sodium from the market. The withdrawal of bromfenac sodium raised several important questions concerning interpretation of â€œsafety laboratories,â€• such as liver enzymes during the drug development program, and also raised questions concerning the effectiveness of drug labeling.

Another example of a drug withdrawn for safety concerns related to hepatotoxicity is the oral antidiabetic agent troglitazone (Rezulin). It was approved in the mid-1990s and severe liver toxicity was detected by postmarketing surveillance in 1997. Increasingly serious labeling changes and warnings to prescribers recommending close monitoring of liver function tests in patients taking troglitazone were issued over the next 2 years. In March 1999, an FDA advisory committee reviewed the status of troglitazone and its risk of liver toxicity and recommended continued marketing of this drug in patients with type II diabetes who were not wel controlled by other drugs. When two newer agents for type II diabetes, rosiglitazone and pioglitazone, became available, the FDA concluded that the risk profile for troglitazone was significantly worse than these newer agents and asked the manufacturer to remove troglitazone from the market.[15] Analogous to the example with mibefradil, this FDA-initiated drug withdrawal was based on a change in the risk-benefit profile for the specific agent in light of new safety information discovered during the post approval phase for the drug.

A recent example of post marketing discovery of hepatotoxicity occurred with interferon Î²-1b (marketed as Betaseron), a drug used to treat multiple sclerosis. The manufacturer recently sent a â€œDear Doctorâ€•

letter to prescribers to remind them of the need to check hepatic enzymes periodically while administering this agent. If reminders such as these are ineffective in limiting the reported rate of hepatic ADEs, the usual next step is a â€œblack boxâ€• warning and if the problem persists, the potential for drug removal from the market becomes increasingly more likely.[15]

Other Examples of Postmarketing Safety Problems Leading to Drug Withdrawal

One voluntary withdrawal of 2 separate drugs used in combination serves as an example of the discovery and publicizing of an unusual adverse event occurring years after individual drug approval but after a significan increase in the prescription use of the combination product. The drug fenfluramine was approved in 1973 after an FDA review period of 75 months. Clinical investigation of a similar agent, dexfenfluramine, began in 1991 in the United States with approval of its IND. The new drug application for this product was filed in 1993, and after 35 months of review the drug was approved for marketing in 1996. A significant increase in prescription use of a combination product of fenfluramine with phentermine (referred to as â€œfen-phenâ€•) began to occur in the 1990s when clinical data suggested that this drug combination was effective in a weight loss program.[30,31,32] Dexfenfluramine was approved for weight loss as a single agent for up to 1 year of use. Use of the fen-phen drug combination, however, was never fully approved by the FDA and was therefore considered an â€œoff-label usageâ€• of the product. The number of prescriptions for the drug combination soared in the mid-1990s. In July 1997, research from the Mayo Clinic reported 24 cases[2] of an unusual form of cardiac valvular disease causing aortic and mitral regurgitation in patients using the fen-phen combination. The publicity surrounding the potential linkage of this drug combination to an unusual adverse event led to a significant increase in reports of possible adverse events associated with this drug combination. The FDA issued a public health advisory and initiated further epidemiologic studies to

ascertain its prevalence. The FDA also encouraged echocardiographic studies of valvular diseases in patients taking fenfluramine or dexfenfluramine either alone or in combination with phentermine. Although at the onset neither the FDA, the product manufacturers, nor the medical community expected valvular lesions to be associated with either fenfluramine or dexfenfluramine, the epidemiologic evidence suggested a possible association, leading the FDA to conclude that these agents should be removed from the US market. The potential association of valvular heart disease with these agents is an example of the use of a case-control study to explore a possible causal relationship between drug exposure and an ADE. In this case, it is unclear what the strength of the MedWatch signal was for the possible association of cardiac valvular disease with exposure to the fen-phen combination. If the association between cardiac valvular lesions and exposure to the drug combination o components of the combination is ultimately proven to be true, however, this would serve as an example of elucidation of a rare, unexpected ADE as the result of a dramatic increase in the number of exposed patients using a product.

The Role of the Toxicologist in the Detection and Prevention of Adverse Drug Events

Toxicologists can have significant beneficial impact in ADE diagnosis and prevention. These areas include patient care, education, and administrative functions. In patient care, it is common for the medical toxicologist to be the first medical specialist to be consulted for a patient with a potential ADE. As a result, medical toxicology occupies an important position as sentinel for drug-induced disease. Maintenance of clinical skills and appropriate continuing education is essential, especially in the area of newly approved therapeutic agents or newly recognized ADEs caused by older approved therapeutic agents. Maintenance of a current knowledge base in the area of therapeutics enhances the ability of the medical toxicologist to diagnose drug-induced disease. Perhaps

more than any other medical specialty, medical toxicologists are likely to include a thorough medication history that also includes nonprescription products and dietary supplements. As stated previously, obtaining a history for drug exposure is an essential component in attributing an observed adverse medical event to a specific drug product. The medical toxicologist's active involvement in the clinical arena, especially in settings in which the initial diagnosis of ADEs can be made, serves to provide an important role model: the medical toxicologist is an educator in the specialty to promote the detection and prevention of ADEs.

Medical toxicologists occupy many different roles in clinical practice in the United States. An obvious role for the medical

toxicologist is as educator in the academic setting of a medical school and affiliated teaching hospitals. Here, the academic toxicologist can champion the inclusion of education in therapeutics in the curriculum for medical students and house officers and take an active role in the implementation of the instruction. Assuring that the curriculum in therapeutics includes recognition and prevention of ADEs and medical errors that lead to ADEs could have a significant beneficial impact on the ultimate outcome of the education process toward reduction of preventable ADEs. In addition to making sure that quality information is presented in the curriculum for trainees, the medical toxicologist can often create a special teaching opportunity for this type of education by establishing an elective or, in some cases, required experience in the curriculum for training in therapeutics. Participation in a quality learning experience can significantly impact on the graduates' knowledge of and attitudes toward therapeutics and risk reduction in the practice of medicine. Although a recent Institute of Medicine report on medical errors[19] did not focus on education initiatives in its main recommendations for reduction of medical errors in United States, it seems logical that education be considered a useful tool to improve medication use and prevent ADEs and medical errors with therapeutic agents.

In the private practice setting, the medical toxicologist sometimes has an

opportunity to educate fellows in training in the medical specialty and peers who call on them for consultations. In these settings, a consistent approach to the patient that includes the listing of drug-induced disease, drug excess, or potential drug-drug interactions in the differential diagnosis to explain an unexpected drug response can provide an exampl for medical colleagues.

The administrative functions that the toxicologist can perform could also beneficially impact on enhancing detection and prevention of ADEs. The main administrative functions that fall into this category include the reporting of ADEs and serving on hospital or health organization committees that oversee therapeutics (eg, the pharmacy and therapeutics committee).

ADEs are known to be significantly underreported in the United States.[14] [23] , [26] Reporting ADEs at the local (hospital) and national level (MedWatch) has been a priority and has been made less difficult administratively. Despite efforts to encourage filing of ADE reports, the overall reporting rates do not appear to have changed significantly. A well-documented, complete report to MedWatch made by a healthcare professional is given priority review by the FDA. The MedWatch system encourages reporting of serious adverse events by all practitioners. The toxicologist is likely to encounter a significant number of drug-induced disease cases from a diagnostic and management standpoint, therefore practitioners of the specialty can make a significant impact on ADE reporting. Toxicologists and their trainees should always submit an adverse event report locally for appropriate cases they encounter. Hospitals generally do not mandate or request that the reported event be â€œseriousâ€• as a requirement. The FDA's MedWatch system asks that reported events be serious in nature or not previously associated with the medication involved. Manual review of reports and database checks are performed by FDA, and duplicative reporting is accounted for when noted In addition to reporting of the ADE, the toxicologist should promote publication of case reports of all new adverse events or adverse events occurring with newly approved products. Such publication often stimulates appropriate reporting of ADEs from other practitioners.

Service on hospital or healthcare organization committees is another important opportunity for toxicologists to impact on the drug-induced disease problem. Whenever possible, toxicologists should participate in the local hospital pharmacy and therapeutics committee. Often these committees have ADE-monitoring or medication safety committees where the expertise of the medical toxicologist in diagnosing drug-induced disease could prove beneficial to the organization. These committees systematically analyze trends in ADEs and occasionally recommend various interventions for the medical, pharmacy, or nursing staff to reduce the potential risk for ADEs. These interventions include a targeted educational program, system modifications to reduce error risk, or limitation of a specific drug usage by certain components of the organization. Another committee where the toxicologist can have an impact on ADEs and medical error prevention is the quality assurance committee of the hospital or healthcare organization. Careful analysis of medical errors or ADE reports brought to the quality assurance committee can often reveal significant trends that are sometimes amenable to educational initiatives or systematic improvements in process. The medical toxicologist is ideally suited to play an important role on the committee as a practitioner of clinical medicine with specialized expertise in the potentially harmful effects of drugs.

Summary

Drug-induced disease is common in both inpatient and outpatient settings in the practice of medicine. Despite significant advances in medical science applied to drug development and regulation, ADEs continue to occur. These ADEs have a significant impact on patient mortality and morbidity in addition to producing a significant burden on the healthcare system. ADEs caused by newly approved drugs and ADEs resulting from a previously unrecognized association with therapeutic agents with a long marketing history continue to be a significant cause of mortality and morbidity. The specialty of medical toxicology is well-positioned to have a beneficial impact toward recognition and prevention of ADEs. Early

recognition of drug-induced disease by the medical toxicologist can benefit the individual patient in many cases and may lead to prevention of further patient harm by prompt ADE reporting to local authorities and, if appropriate, to the FDA. The rapidly expanding number of approved therapeutic agents requires that the medical toxicologist and other practitioners have a strong continuing education commitment to reduce the risk for ADEs in medical practice. Local and national-level involvemen by the specialty of medical toxicology to design and implement programs and activities aimed at decreasing the occurrence of preventable ADEs should benefit patients and, by extension, society.

Chapter 134
Medications, Errors, and Patient Saf

Pat Croskerry

In the summer of 2004, a group of Americans and Canadians that include minister, and students, set out to climb Mount Kilimanjaro in Tanzania. Th more challenging ascent routes that would take about 10 days. Since leav had incurred a variety of mishaps, but by day 7 had arrived reasonably s injury at the Lava Tower camp, a small plateau below the Western Breach about 15,500 feet and the temperature is below freezing. There remained steep wall of the breach, to the final crater camp. Everyone was suffering altitude sickness that had started at about 12,000 feet. Some had very r one of the students, a 19-year-old, had an oxygen saturation measured b low sixty percents. Other symptoms included headache, fatigue, nausea, palpitations, and mild confusion. Each of the three physicians had brough medications for the climb. These included antibiotics, antiemetics, aceta and benzodiazepines.

Some had taken medications for altitude sickness, others had not. The m completing the ascent without medication, had begun to show significant sickness. One of the physicians, an internist, became concerned and advis complete the climb if he didn't relieve his symptoms with medication, sp

dexamethasone. Being so close to the summit, he reluctantly agreed. He and began the ascent with the group. About 20 minutes later, the internist mg tablet of dexamethasone and realized, to his horror, that the one he smaller and must have been the 10-mg diazepam tablet. He immediately and gave him 4-mg dexamethasone.

The breach climb is steep but not technically difficult. It is mostly up pat slopes, with occasional rock-climbing sections. About an hour after taking minister became increasingly light-headed, disoriented, and unsteady. The could not be reversed and they could not stay exposed on the breach unt retrace their path back down would have been more hazardous than cont not appear to be any option but to continue. They did so by boxing in the climbers to assist him and prevent his falling, and slowly made their way done, and the minister successfully climbed the breach. He went on to su Kilimanjaro (19,340 ft) the next day.

In the summer of the previous year, a 65-year-old man presented to the department (ED) of a teaching hospital where one of the Kilimanjaro phys major complaint was left-sided weakness, which started about 2 hours ea of mild holocranial headache and nausea, both of which started at the sar He had no other neurological symptoms and had never had similar sympto history included lung cancer for which he was currently undergoing chem mellitus, and hypertension. He had no allergies. Medications included de metoprolol, and ranitidine.

Vital signs at triage were: blood pressure 170/96 mm Hg; pulse 130 bea breaths/min; and O_2 saturation of 95% on room air. His bedside rapid re mg/dL. His speech was normal and he had no cranial nerve abnormalities abdomen were unremarkable. Marked weakness and increased reflexes we side. Sensory examination was normal. A noncontrast CT scan was compl A neurologist was consulted, describing the stable condition of the patient nonhemorrhagic cerebrovascular accident. The physician then gave a verb â€œ10mg Maxeran IVâ€• for nausea and headache.

The physician was called to his bedside 10 minutes later as the patient h with a respiratory rate of 8. A discussion followed with his family, in whicl apparently deteriorating condition was discussed. A decision was made to

CT scan, and reassess him at that time. However, a second nurse noticed medication vial attached to his IV bag was not Maxeran (metoclopramide) immediately given the benzodiazepine antagonist, flumazenil IV, following appeared to recover to his baseline condition.[24]

Both these incidents involve medication errors. Although both medications the therapeutic range, and without apparent interaction with other medic that might have led to a catastrophic outcome. This is an important distin medications and patient safety. The first issue is whether or not a medica second concerns the conditions under which a safe medication is adminis review both issues, with a focus mostly on factors that compromise the s

Although both errors occurred in markedly different settings, they share 134-1). In the Kilimanjaro incident, the tablets were green, the route of the dose-range was similar, both medication names begin with the same stored together in a backpack. In the emergency department (ED) incide in brown glass vials, both had a white label with black print, there was ar midazolam vial and a lighter orange marking on the Maxeran vial, both v the dose range was similar, both began with the same letter, and they w other in the same drawer.

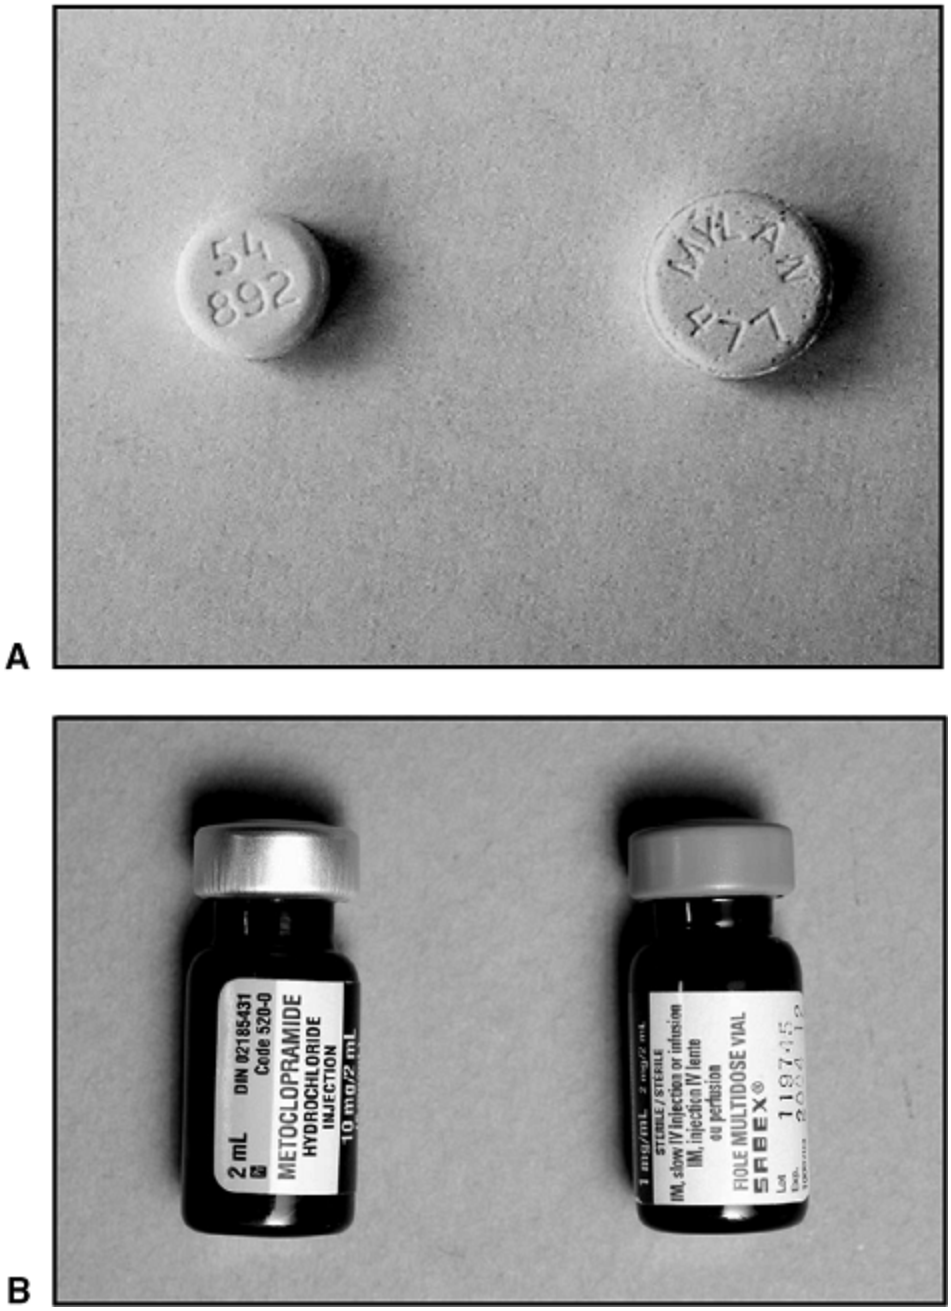

Figure 134-1. Examples of look-alike medicationsâ€”side-by-side photos two examples in the text. A: Dexamethasone (4 mg) and Diazepam (10 r and Midazolam.

It is estimated that 25% of medication errors reported to national report confusion with look-alike and sound-alike drug names.[48] Lists of such dru

potential harm to patients have been developed by the Joint Council on Organizations (JCAHO) for specific healthcare settings, together with rec preventing medication errors. Also, individual health organizations have d supplementing these recommendations.[64] Medication name suffixes are al confusion.[16] The suffixes of one medication alone, diltiazem, include CD, I suffixes used are ER, ES, S, XL, and CR. A number of errors have arisen Additionally, a variety of problems associated with color-coding of medica described.[49]

There are other common factors that predispose to adverse drug events described above. Firstly, in neither case was the medication dispensed by are the only professional group to be formally trained in dispensing medi surprisingly, their presence is associated with a lower medication-dispens and other restraints, pharmacists cannot be assigned to every area in wh or even those in which tightly coupled dangerous medication use is high su Tight coupling[78] refers to the administration of time-dependent, potent m rapid and significant onset of action, and may not be easily reversed; ex and those used in rapid sequence intubation.[24] In one ICU study, the pre pharmacist's input at rounds was estimated to save $270,000 annually in because of ADEs.[63]

Secondly, in both incidents, ambient conditions were less than favorable performance. The internist was probably distracted by the cold, fatigue, a altitude sickness, prominent among which is insomnia. The ED nurses we busy and hurried conditions in a workplace that has been described as pr Additionally, they worked 12-hour high-acuity shifts and were scheduled and nights, which compromise performance through their effects on sleep In a study of intern's performance following a traditional schedule with ex hours or more) serious medication errors occurred 17% more frequently in which the maximum number of consecutive hours worked was limited t of serious medical errors was with medications at nearly 1 for every 5 pa other error-producing conditions and violation-producing factors have bee with human performance.[82, 27, 103] Table 134-1 lists some of the more errors often manifest as a simple slip of action, or execution failure, arisi attentional capture by something other than the task at hand.[81] Vigilance individuals who are well-rested and working without interruption or distra

environment. It was recognized more than a decade ago that fewer medi optimally designed environments.[62]

TABLE 134-1. Common Factors That May Affect Human Performan

The Production of Safe Medications

There is probably a widely held view among the general public that medi approval through the Food and Drug Administration (FDA) are generally sa maintains close ongoing surveillance of drugs that are approved. The first the second unrealistic. Prior to 1900 in the United States, there was no l manufacturers to establish the safety of their products through testing, ar restrictions on the therapeutic benefit claims that could be made. The firs came with the Food and Drugs Act (1906) under which medications were for strength and purity. Throughout its first century of existence the FDA stringent requirements for the safe introduction of new drugs.

There are a number of factors that influence the development of a new d

consideration is that pharmaceutical manufacturers are commercial concerr effectively compete in the market place and satisfy their shareholders. F is often the prime motivator in deciding whether to target research and d medication to a particular therapeutic area. Once these initial decisions ha research phase will develop potential candidate medications to undergo p purity, carcinogenicity, toxicology, and other properties of the medication testing on animals. The safety of selection of first-time dose in humans ca variety of approaches, eg, using interspecies scaling of clearance of the subsequently files an investigational new drug application (IND) with the testing the medication on humans. If it is approved, the clinical testing o proceeds in 4 phases, successively approximating it to its intended clinical

The Medicating Process

Five stages in the sequence of ordering a medication to its delivery are transcription â†' dispensing â†' administration â†' monitoring.[4] In a stud errors, 39% were found to occur at the prescribing stage, 12% at transc and 38% at administration.[62] Despite medication errors being the most co patients, only a relatively small proportion actually cause patient harm wit injury or ADE. Nevertheless, the incidence of ADEs in hospitalized patients from a little over 2â€“20% or higher,[14] and about 7000 deaths are attrib annually in the U.S.[57] The rate of medication errors will depend on the in methods of surveillance. In a study using a comprehensive method, the ra medication orders in general medical units, including an ICU, over a 51-da errors resulted in an ADE, and all were considered preventable. Thus, the written was 0.05%. The greatest number of errors resulting in preventable prescribing stage.[5] In a study of prescribing errors in 17,808 inpatient an only 342 (0.5%) were found to be clinically significant.[11] Although no dire made between studies, it appears that prescribing errors may have more errors at later stages of the process.

The more steps there are in any process, the greater the likelihood of err correctly 99.5% of the time, there will be a 5% probability of failure in a probability proportionately increasing with an increased number of steps in there are 25 steps, excluding fatigue and other factors that affect perfor

error will have reached 12%.[46] Although the medicating process has only multiple steps within each stage and so the potential for error is high. An been added to describe errors that may arise in follow-up after medicati Figure 134-2 describes typical errors that occur at each stage in the proc strategies.

Communication issues are very important at all stages in this process. All in writing, printed, speech, or by other means, must be transmitted in a timely fashion. Physician's handwriting is still an important issue. In its 2 Goals, JCAHO developed a minimum list of 5 sets of dangerous abbreviat symbols that should not be used, and proposed preferred terms.[52] The In Practices (ISMP) has also published a comprehensive list.[50] Communicatior important between physicians and patients. In a study of 661 patients in practices, patient reports of medication side effects to their physicians led 76% of cases. A failure to identify medication-related symptoms resulted 2% preventable ADEs. Ameliorable ADEs were defined as those in which could have been reduced substantially had different actions been taken.â the point that the first error of a preventable ADE is compounded by the identify it.

Monitoring is another very important stage in the process and has receiv The sixth stage was added to emphasize the final part of the medication drawing attention to considerations that should be made for patients afte hospital, ED, or physician's office.[24 , 33] Monitoring needs to be seen as a begins at the time the patient receives the medication, wherever they ma system, and continues for as long as they are on the medication. In the such as in the hospital or ED, the process is especially important and rec between the pharmacy, laboratory, and physician,[88] but it continues thro system. In the primary care setting, 17 separate tasks were identified fro order a laboratory test through to getting the result to the patient.[44] In undertaken by 40 Massachusetts hospitals, 9 safe practice recommendatic improve communication of critical test results.[41]

Adverse Drug Events, Adverse Drug Reactio Related Morbidity

Thus far, most of the emphasis in improving medication safety has been preventability of ADEs, which (in contrast to adverse drug reactions [ADR errors. The National Coordinating Council for Medication Error Reporting a defines a medication error as â€œâ€¦ any preventable event that may ca medication use or patient harm while the medication is in the control of t professional, patient, or consumer. Such events may be

related to professional practice, health care products, procedures, and s prescribing; order communication; product labeling, packaging, and nom dispensing; distribution; administration; education, monitoring and use.â morbidities (MRMs) is a more encompassing term that describes the failur achieve its intended therapeutic outcome, but also may include biosocial related problems such as noncompliance, undertreatment, and others.[42]

Stage	*Error Producing Conditions*	*Medication Error Reducing Strategies*
Prescribing	Incomplete knowledge of medication	Readily available medication reference systems
	Incomplete knowledge of patient	Increased pharmacist availability
		Take a thorough medication/medical/allergy history
		Physician order entry
		Computerized decision support
		Pediatric patients:
		Determine accurate weight in kilograms
		Be alert for calculation/decimal point errors
		Caution with 'off-label' prescribing
		Geriatric patients:
		Consider co-morbidities and drug-drug interactions in particular
		Consider possibility of falls with new medications
		Consider renal, hepatic and thyroid function
		Follow Beers criteria[8,9]
		Potentially pregnant patients:
		Rule out pregnancy
		Careful evaluation of risk:benefit
Transcribing	Verbal orders	Avoid verbal orders except in emergencies
	Poor penmanship	Write legibly; print if necessary
	Abbreviations, symbols	Avoid acronyms or prohibited abbreviations
		Electronic order transcription
		Team communication errors
		Indicate decimal point clearly
		No trailing zeros
		Avoid apothecary terms
		Include physician phone number/pager

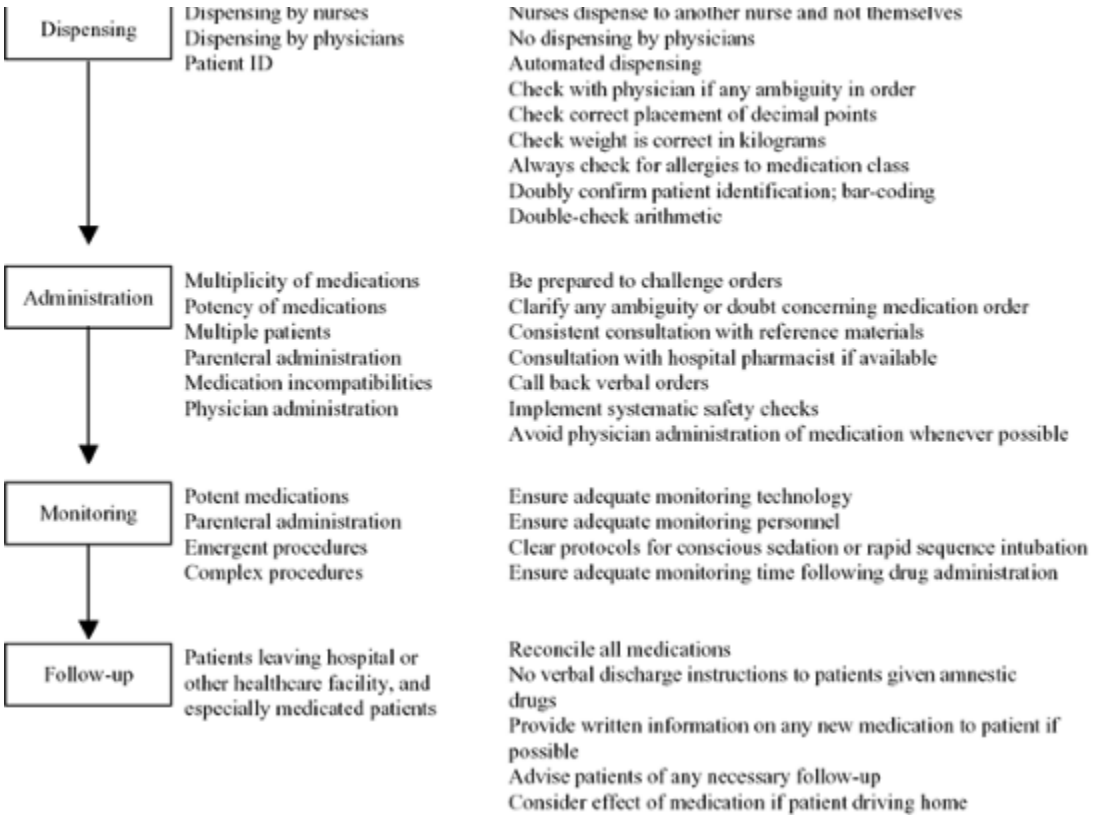

Figure 134-2. Stages in the ordering and delivery of a medication, and with each stage.

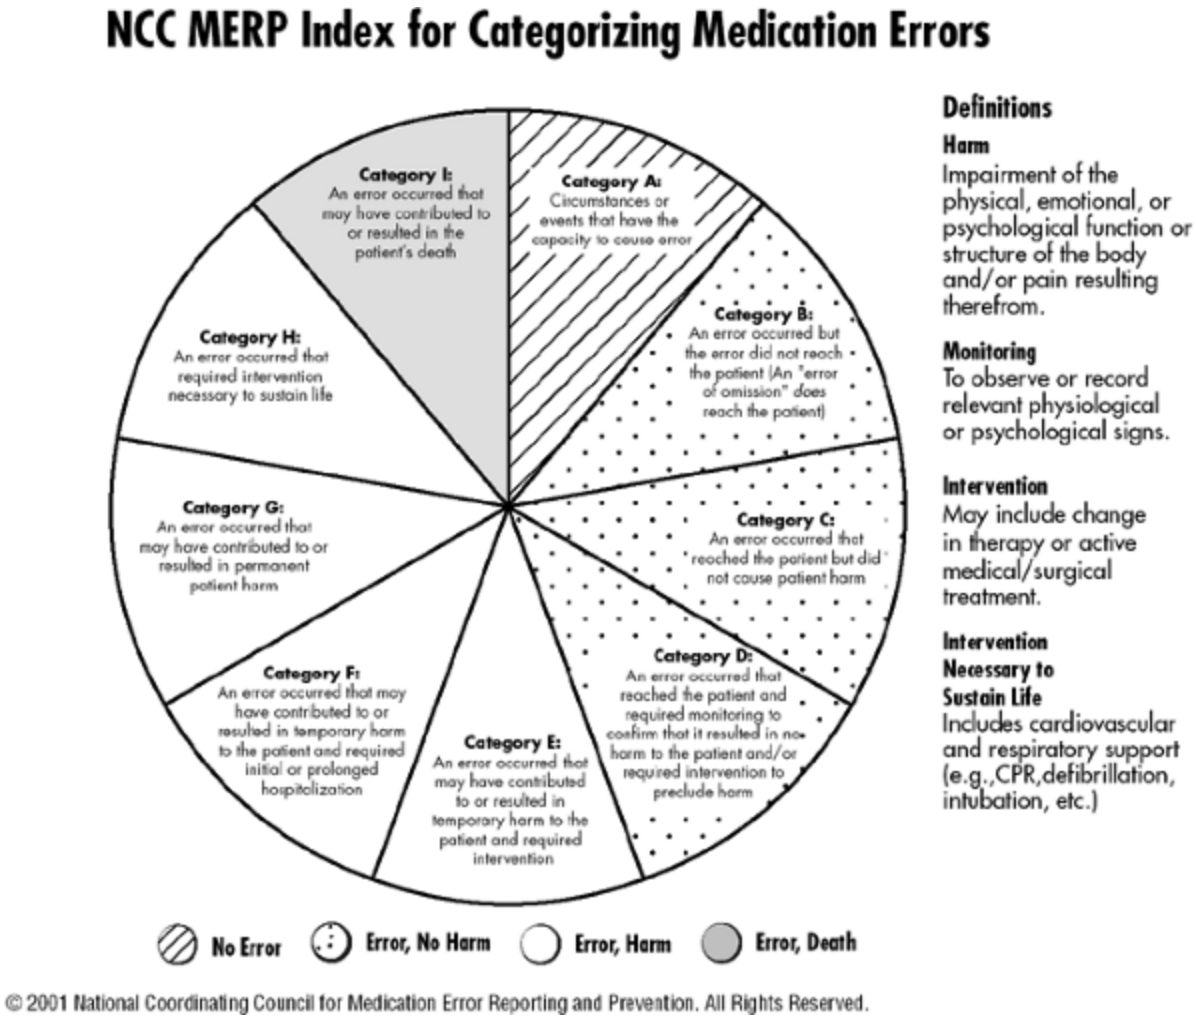

Figure 134-3. Pie diagram showing NCC MERP categories of medication to errors with no impact on patient care.

An ADR is not a medication error. For example, if a patient with no known medication and subsequently develops a reaction to it, an ADR has occurr foreseeable or preventable with the information available. The World Hea generally defines an ADR as any noxious, unintended, and undesired effec occurs at doses used in humans for prophylaxis, diagnosis, or therapy, e failures, intentional and unintentional poisoning, and medication abuse, a events because of medication administration errors, or noncompliance.[104] hospitalized patients from 1966â€“1996 estimated the overall incidence of and fatal ADRs at 0.32%. In 1994, 106,000 deaths were attributed to AD

A useful medication error taxonomy developed by the NCC MERP, classifi according to severity (Figure 134-3).[73] Importantly, the categories of lea describe circumstances or events in which the potential to cause error ex but does not reach the patient. These â€œnear missesâ€• or â€œnear hi critical source of information and learning about medication error, but ar and underappreciated. MEDMARX, a national database for medication erro United States Pharmacopeia (USP) in 1998. It is an Internet-accessible r program, using multiple reporting methodologies, that is confidential, de (importantly) anonymous. The results of a 3-year review (1999â€“2001) submitted to MEDMARX from hospitals and health systems found the majo total), followed by B (32%), A (10%), D (13%), E (2%), F (0.4%), H (0.(There were 19 errors in category I, contributing to or resulting in patient The top 4 types of error were

omission (30%), improper dose/quantity (21%), unauthorized medication prescribing (12%).[87]

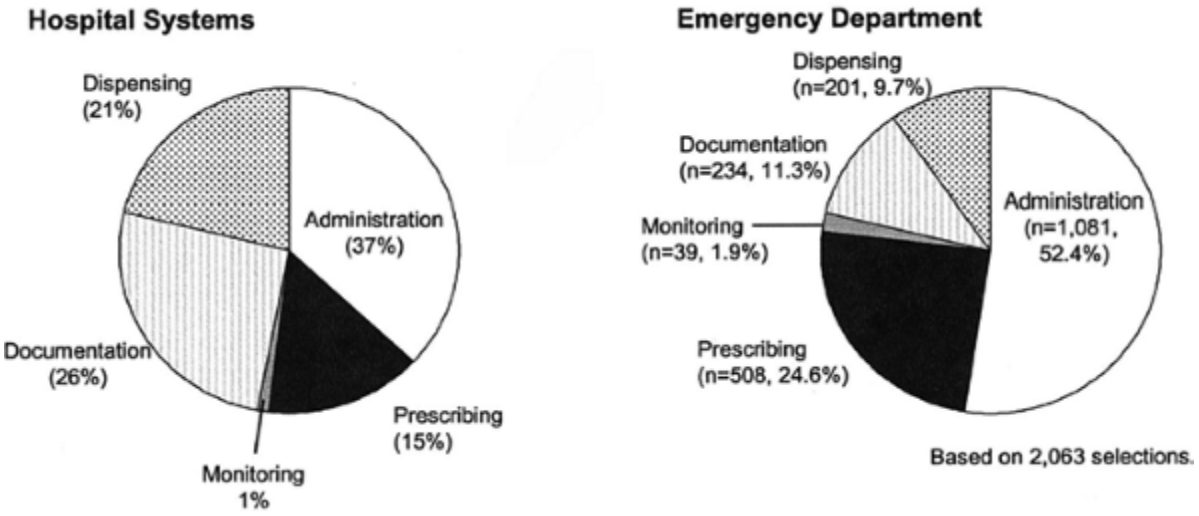

Figure 134-4. Pie diagrams showing MEDMARX data for (A) hospital syst one settingâ€”the ED. Adapted from United States Pharmacopeial Conve

The origin of errors was identified in Categories Bâ€“I (Figure 134-4A), the most frequently reported at 37%. The monitoring category at 1% is underreported because of its lower visibility. The pattern of errors will var

healthcare delivery. In contrast to these data for hospital systems overal specific data for a particular site, the ED. The differences reflect the ope ED[24 , 79] that lead to fewer dispensing and documenting errors, but more administering errors.

The most frequently reported cause of error in each of the 3 years of stu at 43%â€”more than double the next most frequent cause *procedure/proto* performance deficit means that the individual making the error had the avoid the error but failed to do so. As noted above, there are numerous contribute to performance deficit, including many ergonomic issues such resource limitations, staff shortages, and others. *Documentation* was thir *knowledge deficit* was fourth at 10%.

In 2001, the most frequently cited medications associated with harmful e morphine (3%), heparin (3%), potassium chloride (3%), warfarin (2%), the 2003 data, the same products remained in the top five.[45]

These data are subject to various forms of reporting bias. There are a va documentation and reporting of medication errors may be discouraged, ar underreported. Nevertheless, they do provide an overall picture of chara errors that is helpful.

There are significant costs associated with an ADE. In 1997, excluding the or malpractice costs, the cost of one ADE was estimated at $2000â€“2500 almost double that.[6 , 15] Nearly 10 years ago, other studies estimated the medication-related morbidity and mortality to be over $77 billion in the $2 billion in hospitals,[6 , 15] and $4 billion in nursing home settings.[13] The cost was estimated to have more than doubled to $177 billion by the yea not take account of legal or psychological cost to the patient, and to thei

The Impact of Age

There are important medication safety issues for children and older adults underrepresented or excluded from clinical trials. It is estimated, for exam the medications used to treat children have been adequately tested in th concerns apply to medications used in older adults.[47] It is important to n studies on medication error has been on preventability. Errors associated

inappropriate prescribing of antibiotics) or underuse (eg, failure to prescr such as a cholesterol-lowering agent) are typically not captured and rem

Children

Adverse exposure to medications may occur during pregnancy and lactat may occur in all settings: the home, in ambulatory care, the ED, hospita care unit (PICU), and neonatal intensive care unit (NICU) (Chap. 31). Er home environment with nonprescription medications, but the true incidenc survey, the inaccuracy of home antipyretic use was estimated at almost 5 typically one of underdosing, this may periodically be beneficial in avoidir antipyretics that lead to liver failure from dosing at levels greater than t dose.[85] In the ambulatory setting, the incidence is again unknown but or â€œnumerousâ€• errors in prescription writing in a pediatric clinic.[99] In rate was estimated at 10% of all charts,[59] and the sources of some of th The incidence for medication errors of hospitalized patients is estimated a written, about 20% of which were classified as potentially

harmful; the majority (74%) occurred at the ordering stage.[34] Generally, care unit appear to be at higher risk for errors, presumably reflecting the disease and the medications used.[56] The most commonly reported produc medication errors in children are intravenous fluids.[28] A number of errors also found in discharge instructions from the hospital.[54]

Children are vulnerable to medication errors for a variety of reasons. Firs communication difficulties. Before language has developed fully, children m articulate their symptoms, cannot report whether or not they have taken or how much they have taken in an overdose situation, and other proble only infer what has happened. The patient does not play an active role in process, and the child is entirely dependent on adults. This dependency i exposure to medications during pregnancy and lactation. Secondly, confu the child's weight. Children may be weighed in either kilograms or pounds information is usually in kilograms, an additional calculation may be requ kilograms. Thirdly, their lower weights make them vulnerable for several adults, weight-based dosing is necessary, which introduces an additional a

process. Also, there is often a requirement for dilution of stock medicatio dose, usually without the input of a pharmacist. Erroneously calculated d make incorrect dosing the most commonly reported error. Fourthly, there vulnerability of critically ill children to injury from medication, especially i systems are immature; children are three times more likely to suffer harm medication error compared with adults. As noted above, the majority of have not been studied sufficiently to provide safe labeling information,[83] literature, there is clear evidence that publication bias has undermined s medication errors and their causes in the pediatric setting, and a compre recommendations is provided in the 2003 policy statement of the America (AAP).[18]

Older Adults

As in the case of children, medication errors in older adults occur in all s ambulatory care, in nursing homes, in the assisted living setting, and in t The incidence of medication error at home with nonprescription medicatio reasons outlined below, would be expected to exceed that of the younger ambulatory care setting, using a variety of methodologies, ADEs were eva period in a multispeciality practice in a cohort of 27,617 Medicare enrolle 30,000 person-years of observation. Extrapolating their findings to all Me or older), estimated to number 38 million, would predict nearly 2 million >25% would be considered preventable. About 180,000 fatal or life-threa predicted.[40]

There are more than 1.5 million nursing home residents in the United St uses six different medications, and 20% use ten or more.[10] Extrapolating study of 18 community-based homes in Massachusetts over a one-year p 350,000 ADEs annually, more than half of which would be preventable.[39] ADEs would represent 20,000 of these predicted events of which 80% wo Approximately one million other seniors live in assisted-living facilities, ar medication errors from a variety of reasons including: inadequate physic trained staff, and staffing shortages.

Addressing these issues is becoming increasingly important as the US Ce increase of 62 million in the number of Americans 65 years or older by th

represents a 78% increase in the number of older adults in 2001. Over th population of 85 or older will increase by 7.4 million, an increase of 68%.

Advancing age brings with it several important considerations from the pc safety:

- There is an increasing morbidity with age, and therefore an increasing medication. In the US, people over age 65 comprise 15% of the total one third of prescribed medications.[94] Comorbidities and disease chro of concurrent medications, and therefore the number of potential int the relative efficacy of medication with increasing age have made sor treat aggressively. The use of thrombolysis in acute coronary syndrom counter-therapeutic after the age of 75 and actually present a disadv have argued that this may constitute underuse of therapy: neither re nor the serious complication rates should negate the therapeutic bene is very good evidence to the contrary less attention should be paid to Given the preponderance of women among older adults, there should, emphasis on female geriatric pharmacotherapy.[93]
- Frailty and cognitive decline in older adults may result in errors in s require the assistance of family members or others for proper medica
- The majority of medications are developed and tested on healthy you adults are underrepresented the slowing of metabolism, renal functior variety of other changes that result in altered pharmacokinetics are considered (Chap. 9). Alterations in medication absorption, metaboli elimination may all affect the efficacy of the medication.

Recognizing the special problems that medications pose for older adults, both the US[8 , 9] and Canada[72] to determine appropriateness of medicatio home residents. The authors identified 48 medications, or classes of med medications to avoid in the presence of 20 diseases/conditions.[32] In a re 750,000 patients 65 years or older over, 21% had filled a prescription fo that should have been avoided, psychotropic medications accounting for a cases.[29] The prevalence of inappropriate medication use in older adults ha be estimated in the range 12â€“40%.[90] Both the medication effect and th

implications should be considered. Older adult patients medicated with b example, have a 4-fold increase in falls. Significant differences within the were found: the risk of injury associated with benzodiazepine use genera

be independent of half-life; there was no increase associated with long-ac was there a dose-effect, whereas there was an associated risk with the u oxazepam. Flurazepam and chlordiazepoxide (both long-acting) were asso increase in risk of injury.[92] An alternate approach has been taken to dev indicators of preventable medication-related morbidity (PMRM) in older ad technique, the four unique elements of a PMRMâ€"that it be recognizabl and controllableâ€"were used to develop an expert consensus on 52 clini follow-up study, the top seven indicators were found to account for almos technique has the potential to prospectively identify patients at risk for a optimize medication use in this age group.

Solutions

Although the importance of medication safety issues has long been recog emergence of a commitment to patient safety has brought them into cons refreshing number of new initiatives have emerged in recent years. The fo US in 1994 was an important step. It is an independent, nonprofit organi funding from the pharmaceutical industry. It provides a number of useful newsletter with individualized editions to acute care, community/ambulato sectors. ISMPs have now been established in Canada and in Spain.

The last decade has seen a significant number of publications on medicat data has been made available from reporting systems. Although reported selective and subject to various biases, those gathered by the USP throug programs provide a useful overview of trends that might guide research s Long-standing issues have been addressed, such as the confusion over a and look-alike and sound-alike medications. Attention has also been direct concern. In some, a useful consensus has evolved resulting in the publica such as that of the AAP on the prevention of medication errors in the pe number of innovative approaches toward prevention have been proposed. their early stages of development and all will continue to undergo furthe

Response to Medication Error

The leading cause of medication errors is human performance deficit. Inva precede the ADE, and this temporal contiguity of action and consequence tendency to blame someone; this will usually be the last person to have h patient. In recent years, however, a consensus has emerged that blaming counterproductive. The number of ADEs that result from truly egregious b more often than not the explanation will be found within the system. Roo term originally used to investigate major industrial events, is a technique structured, process-oriented analysis of sentinel events. Its use was mand accredited hospitals in 1997. It is a time-consuming process requiring m specialized training, and is subject to various biases and methodological judiciously conducted RCA may provide insights into systemic failures und identify areas that require change. An alternative approach that more eff off the individual and onto the system is a clinical incident analysis proto It uses a framework of seven factors to map out the ground to be covere organizations have developed a hybrid combining these two approaches. B incident analysis are conducted retrospectively, and therefore subject to alternative approach is failure mode and effect analysis (FMEA), which pr identify errors that might occur, to implement preventative measures. On 1993,[17] it is now a requirement under the JCAHO Patient Safety Standard ISMP.[51]

Human Factors Approach

That human performance deficit is the primary cause of medication errors in a medical environment that is extremely complex. This environment is enriched by many properties inherited from its historical past. Human fac draws on a variety of disciplines including industrial engineering, industr psychology, information technology, and others. There is much that can b interface between humans and the work environment and to ensure that efficiently. As a general principle, it would be preferable if the dominant medical devices and processes was that they fit human users, and not th

A particularly important goal is the reduction of cognitive load. Many me

from cognitive failings because of interruptions, distractions, inexperience overloadingâ€”referred to as performance deficit. Further effort needs to reduce cognitive failure. The adoption of some very simple strategies bas engineering principles will reduce error, such as simplification of the num reducing reliance on memory, applying cognitive forcing strategies,[23] and particularly useful aid is the color coded Broselow-Luten system, which ca medication dosing.[65] This approach has the potential for further developm of nonprescription medications and other potentially dangerous products us universal standard color-coding drug labeling system has been proposed i between-class medication errors.[1 , 76]

Information Technology Innovations

Information technology (IT) in healthcare has been ponderously slow to c use in other organizations, but it is now gathering momentum and has o patient safety.[7] Although considerable gains may be made, new technolog introduce new types of error. USP announced in 2004 that nearly 20% o reported to MEDMARX involved computerization or automation.[87] One stu computerized physician order entry (CPOE) in one tertiary care hospital fo actually facilitated a wide variety of medication error risks.[43] Another stu types of failures associated with CPOE but suggested that many could be particular by concentrating on organizational factors.[58] This part of the c technology is sometimes referred

to as â€œtransitional instability,â€• when â€œturbulence and chaos often harbingers of new forms of order.â€•[106] Recently, more detailed insights why process-supporting information technology systems fail.[100] Much of t medication area is relatively simple and straightforward, amenable to rap and cross-checking, and it would be expected that, in time, CPOE and oth ultimately prove very effective at reducing medication error rates.

Drug Selection

- Laboratory findings contraindicates drug

â€“ Pregnancy test â€“ ACE inhibitor

â†‘BUN/Cr-metformin
Prevents prescription writing or dispensing

- Laboratory finding suggests indication for drug

â†‘TSH-levothyroxine
â†‘Cholesterol-lipid-lowering treatment
Generates timely reminders, tracking intervention
Dosing

- Laboratory finding affects drug dose

â†‘Creatinine-digoxin, aminoglycosides
Performs dose calculations based on age, sex, value, weight

- Drug requires laboratory measure for titration

Warfarin sodium-PT/INR
Anticonvulsants-drug levels
Statistical process control dosing adjustment charts
Monitoring

- Abnormal laboratory value signals toxicity

Liver enzymes-isoniazid, glitazones
â†“ HCT, WBC-chloramphenicol
Triggers alert, assesses likelihood

- Drug warrants laboratory value monitoring for toxicity

Clozapine-WBC
Amphotericin B â€“ creatinine
Oversees scheduling of both baseline and serial monitoring tests
Laboratory Interpretation

- Drug influences or interferes with laboratory finding

Carbamazepine-free thyroxine
Quinolones-false-positive urine opiates
Warns against/interprets false-positives and false-negatives

- Drug impacts on response to laboratory finding

Insulin-â†“or â†‘glucose
Penicillin â€“RPR
Resets alarm threshold for treated patients
Improvement

- Drug toxicity/effects survelliance

Detects signals of previously undocumented reaction (eg. hepatotoxicity)
Data mining of laboratory and drug data to generate new hypotheses of

- Quality oversight

Treatment delay after abnormal results
(â†‘TSH, â†‘K^+ , +blood culture) and initiation of appropriate treatment.

identification (RFID) microchip that is implanted subdermally,[21] a technol
the livestock industry. Bar code technology reduces administration errors
errors. Bedside bar-coding, in particular, has considerable potential for r
medication administration errors by nurses. Computerized medication ad
achieve significant reductions in administration and transcription errors. Fu
by improvements of the interface between the laboratory and the pharma
critical values can be transmitted simultaneously to the attending physici
specific examples. Software applications can also be developed to track th
medications or antidotes that might have been used in the treatment of a
a continuous quality monitoring strategy. Computerized links between the
office, and pharmacies can improve the safety of patients being discharged
healthcare facility (stage 6 in Figure 134-2).

Ward-Based Clinical Pharmacists

Pharmacist participation at the clinical interface reduces medication errors
involvement of a clinical pharmacist in work rounds of an adult ICU reduc
66%,[63] and in the PICU reduced the serious medication error rate to one
rate.[55] However, fiscal restrictions will inevitably mitigate against the exp
professionals and cost-benefit arguments will be applied. An unintended co
clinical pharmacist is present, nurses, residents, and attending physicians
them and spend less time developing and maintaining their own skills for
such help may not be available.

Improving the Workplace

Working long hours, experiencing sleep deprivation, and incurring sleep de
compromise cognitive and psychomotor performance[12] and are, undoubte

medication errors. The reduction of residency work hours to 80 hours

per week (still double the industry standard) has met with concern that p deteriorate as care is being transferred more frequently.[80] This is probabl dissuade us from efforts to reduce the impact of circadian disruption, sle debt. Whereas errors because of hand-overs probably increase in a fairly successive hand-overs, those associated with fatigue and sleep loss prob Thus, the goal should be to find the optimum shift length for safe patient effort in improving the quality of hand-offs. More work needs to be done that optimize both healthcare worker safety and patient safety.[26] Like tru to be regulated for the total number of clinical hours they work each wee

Education

The prevailing emphasis in physician training is on knowledge acquisition. inculcating critical thinking skills and teaching reasoning, the assumption passively acquired during the process of training. Although this is partially opportunities to improve these cognitive faculties by direct intervention.[2] reasoning can be improved and expertise cultivated by specific teaching variety of other strategies have been proposed to reduce predictable cog the beginning of the medicating process improved clinical judgment has t patient safety. For example, errors of omission or undertreating are often commission, but may have equal or greater impact.

Many aspects of the medicating process are not formally taught during u training. There is little explicit medical school training for students in the dosing, weight-based calculations, medication interactions, and so on. Ver in how to achieve medication safety or in how to pursue multidisciplinary these goals. A study of medication dose calculation in emergency medicin this appeared to be a discrete skill, responsive to a relatively brief educa in the short term.[74] Generally, there appears to be a tacit assumption tha acquired during clinical training, but this study suggested that they might independently and that specific training is indicated.

Importantly, communication theory should receive more emphasis in trai skills both within and between disciplines, and especially between practiti

will limit errors. As patients are admitted, transferred within, and discha facilities there is an ongoing imperative to communicate exactly what me doses they are receiving, and ensure that any changes are accurately rec of medication reconciliation and has been adopted by JCAHO in 2005 as c Safety Goals. It is an important communication strategy to ensure safe co other aspects of patient safety, these issues should be formally introduce curriculum. Improving the training of health professionals is two of only there is evidence of efficacy.[84]

Improved Accountability of Medication Ma

There are many ways in which pharmaceutical companies might improve Initiatives are already underway to insure the appropriate naming and pr minimize confusion.

The entire structure of pharmaceutically funded clinical research must be to be a number of changes in the way in which research is conducted. Id to have an independent body, publicly funded, that would evaluate new d efficacy and safety with that which is currently available. The National Ce Technology, established in 1978 was such a body, but expired after only pressure. Other efforts along these lines have met a similar fate. It remai greater proportion of pharmaceutical research independent of industry an sources, but until that balance is redressed clear standards have to be e pharmaceutical companies' research to the accepted rigor and scrutiny of method. A recent agreement among editors of a number of leading journa pharmaceutical companies to register any trial begun after July 1, 2005 in all trials that have been done on a particular drug will be known and pre data.

Throughout the pharmaceutical, nursing, and medical professions, there is awareness regarding the marketing practices of pharmaceutical companie need to be taken. In 1992, the McMaster University Department of Medic that restricted contact of trainees with pharmaceutical company represen in posttraining found they had less contact with these representatives. C from another medical school that had no such restrictions the McMaster pharmaceutical company representatives to be less helpful.[70] Restrictions

companies' activities, and especially restricting contact with medical stude now been adopted by many institutions.

Another pharmaceutical practice that undermines safety and efficacy of m distribution by physicians of drug samples. Despite some obvious immedi benefits of this practice, it has a variety of inherent flaws and violates fu drug safety that have been described.[37] Several recommendations for cha improve safety have been proposed.[66]

Finally, advertising of pharmaceutical products is another area that should two areas of concern. The first is advertising to the medical profession. A the availability of references and sponsorship of original research cited i advertisements in medical journals for the year 1999.[19] Approximately 30 medical claims contained no references. Of those with references, about on file. When the authors tried to access this data from the pharmaceutic unavailable 80% of the timeâ€"in contravention of the WHO policy on eth drug promotion.[104] They also found that 58% of original research cited had authors affiliated with the same pharmaceutical company. The second legalized approach of direct-to-consumer marketing for prescription medic clearly aimed at inducing the public to pressure their physicians for newer expensive drugs. The practice is illegal in many countries. The rationale this is an educational process and is about choice is unacceptable. There educating about disease and raising awareness

without using direct consumer advertising. Because even physicians are n research that have been perpetrated by industry, it seems unlikely that t meaningfully evaluate the claims made by drug advertisers, and choose t themselves.

The variety of ethically questionable behaviors of industry has attracted recent years and will need constant monitoring. The confidence of the sc communities, and the general public has been seriously undermined by r a growing and disquieting awareness that the problems are more wide re believed.

Summary

Medications are the principal commerce of modern medicine, and medicati importance to healthcare systems. With the emergence of the new indust safety, renewed attention and energy has been directed at the problem. safely to patients is a more complex process than originally imagined. It but creates special problems at the extremes of age, in the children and components, the development of safe medications, and their safe use, re and vigilance. The multiplicity of stages in the delivery process results in preventable errors, some of which may be fatal. Many innovations, especia information technology, hold promise for significant improvement.

The process can no longer be perceived as a simple 3-way relationship b physician, and pharmacist. Patient safety requires a collaborative effort p medication manufacturer, but also federal regulation authorities, indepen organizations, error theorists, hospital administrators and managers, inf nurses, cognitive psychologists, human factors ergonomists, geneticists, this new multidisciplinary approach, there is considerable potential for re This appears to be one area in patient safety in which tangible and measu

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 135

Risk Management and Legal Principles

Barbara M. Kirrane

Dainius A. Drukteinis

The use of emergency services has increased dramatically since the early 1970s, and along with it the number of toxicologic emergencies has increased steadily and continues to rise today. This chapter is concerned primarily with the medical-legal management of patients who present to an emergency department (ED) with an organic impairment, that is, a relatively recent deterioration in the level of cognitive or behavioral function caused by the effects of xenobiotics or alcohol. A secondary component of this chapter addresses the legal dilemmas associated with the social and ethical issues that emergency practitioners routinely face.

Patients who are experiencing toxicologic emergencies require immediate care yet are often unable to give consent because their impaired consciousness prevents them from making decisions. Treating patients who present with an acute organic impairment

manifested by confusion and irrational, or even dangerous, behavior is extremely difficult. Emergency physicians must recognize the medical-legal problems created when the impaired patient refuses treatment or admission to the hospital and insists on leaving against medical advice. No clear guidelines are available to the physician confronted with such a toxicologic emergency. There is no nationally recognized standard of law relating to these issues; instead, the relevant laws vary from state to state. The emergency physician must become familiar with the legal requirements of informed consent and the essential management necessary to avoid liability for negligence and abandonment. Of particular concern are the risk management and liability issues that relate to the patient who attempts to leave the ED while impaired. The legal requirements of informed consent in emergency settings, the duty to treat, medical malpractice, battery, and negligence are examined here, and guidelines based on generally accepted common law principles, and New York State case law and statutes, are suggested for developing appropriate patient care plans and departmental policies.

Informed Consent

Patient 1 An 18-year-old college student was brought by ambulance to the emergency department (ED) after a friend reported seeing her in the bathroom with slit wrists and an empty bottle of acetaminophen by her side. In the ED, the patient was alert and oriented to person, place, and time. Vital signs were: blood pressure 120/65 mm Hg; pulse 95 beats/min; respiratory rate 16 breaths/min; and temperature 99.1Â°F (37.3Â°C). A rapid bedside glucose was 120 mg/dL. She had bandages on her wrists placed by emergency medical services. The patient stated that she ingested the acetaminophen approximately 5 hours earlier. The healthcare team wished to measure acetaminophen levels to determine whether *N*-acetylcysteine should be administered. The patient refused a venipuncture and stated that she would refuse

any medications offered. The physicians informed the patient that she might suffer irreparable damage to her liver and possibly die if not treated immediately.

Deciding to medically treat an individual against their will poses a difficult problem. Even if justified, forcible treatment violates a patient's autonomy, and an individual's right to privacy. Is the physician ever justified in administering medication to an alert and oriented individual who refuses treatment? Does the patient need to be suffering from a mental illness such as depression to treat against their will? If the harm that faces the patient is not immediate, but subacute, or chronic, does the physician have the same authority to treat? For example, compare detoxification programs for substance abusers versus *N*-acetylcysteine after an acetaminophen overdose. The right to die will not be specifically discussed here as it is far too complex for a cursory analysis, however, general principles of patient autonomy and informed consent will be elucidated.

A patient's right to choose their own course of medical treatment was first recognized in the early 19th century in a landmark case decided by the US Supreme Court, *Schloendorff v Society of New York Hospital*.[16] Mary Schloendorff was treated at the hospital with abdominal pain and was subsequently found to have a mass on abdominal examination. Her physicians offered her a more thorough examination under anesthesia and the option for surgery. She consented only for the examination; however, during that examination the mass was removed. Schloendorff experienced a number of postoperative complications and sued the hospital. In its decision, the Court upheld Schloendorff's right to self-determination, and the right to refuse treatment. It stated:

> Every human being of adult years and sound mind has a right to determine what shall be done with his own body and a surgeon who performs

> an operation without his patient's consent commits an assault, for which he is liable in damages, except in cases of emergency in which the patient is unconscious and it is necessary to operate before consent can be obtained.[16]

This decision became the foundation for the â€œDoctrine of Informed Consent.â€• Informed consent serves to protect a patient's autonomy, the concept that each individual has the right to choose the course of medical treatment.[27] This includes the right to refuse care, and

the right to terminate care already in process. In a nonemergent situation, it is the physician's responsibility to obtain approval from the patient or their surrogate before rendering treatment.

Generally accepted components to the informed consent process consist of (1) an explanation of the treatment/procedure, (2) alternative choices to the intervention, and (3) relevant risks, benefits, and uncertainties to each alternative. Furthermore, it is the duty of the physician to assess how well the patient understands the above information. Before a physician may accept a patient's approval the patient must demonstrate adequate understanding of the information discussed.

State courts may apply one of two standards to determine if the information communicated by the physician was sufficient. The reasonable person standard requires that a physician disclose to the patient information that which a reasonable person in the same position as the patient would need to make an informed decision.[5] The alternative is the reasonable physician standard, which requires that a physician reveal information that a reasonable physician in a similar circumstance would disclose.[5] With this standard, the physician must assess what another physician might disclose if placed in a similar circumstance. States

vary on which standard they apply.

Courts recognize that the requirement for informed consent is not absolute, and that there are exceptions in which a physician does not need to obtain permission before rendering treatment. In *Schloendorff v Society of New York Hospital*, the Court recognized that consent is not required in emergency situations. Situations are generally considered emergent if a patient's care would be compromised if there were a delay in treatment. In New York, an emergency is defined as a situation that includes both the immediate endangerment of life or health or the need for the immediate alleviation of pain.[19] Physicians need to determine the specific requirements of informed consent in their states.

Often a physician's well-intended efforts to communicate treatment information to an impaired patient prove ineffectual and present the practitioner with a medical-legal dilemma. The physician is unable to discuss in a meaningful way the implications of the proposed treatment with the patient; nevertheless, there is a duty to treat a patient who presents with a life-threatening condition or the potential for permanent disability. In these situations, consent on the part of the impaired patient is considered to be implied, and emergent treatment should be provided. Support for this view of implied consent is a general tenet of tort law.[14]

Risk Management Consideration and Documentation

Patient 2 6:05 PM. A 28-year-old woman was brought to the ED by the police. The police believed she might be a â€œbodystufferâ€• (an individual who swallows drugs to avoid arrest and prosecution).

6:10 PM. The triage nurse helped the patient onto a stretcher and brought her to the treatment area. The physician was asked to see

the patient. Her vital signs were: blood pressure, 130/70 mm Hg; pulse 78 beats/min; respiratory rate 24 breaths/min; temperature 98Â°F (36.7Â°C).

As the physician initiated the examination, the patient became combative and uncooperative. The physician verbally ordered that the patient be restrained. The patient was given 40% oxygen via face mask, cardiac monitoring was begun, and an intravenous line was started with 0.9% sodium chloride at 125 mL/hr; a bolus of 100 mL of $D_{50}W$ and 100 mg of thiamine were then administered IV. Orogastric lavage was then performed, and 50 g of activated charcoal (AC) were administered.

7:10 PM. The patient's vital signs were: blood pressure 120/70 mmHg; pulse 82 beats/min; and respiratory rate 24 breaths/min. The patient was noted to be stable and transferred to the other observation unit. Oxygen and cardiac monitoring were discontinued. No further orders were written, and the patient remained restrained.

11:15 PM. The vital signs were: blood pressure, 110/60 mm Hg; pulse 92 beats/min; and respiratory rate 18 breaths/min. A nurse's note stated the patient was resting comfortably.

11:50 PM. The initial physician completed his shift and was replaced at midnight by another physician. The first physician informed his replacement that the patient was stable and resting in the holding area.

4:20 AM. The patient was found unresponsive, with agonal respirations. She was hypotensive and had a weakly palpable pulse. She felt very hot to the touch and had a rectal temperature of 108Â°F (42.4Â°C). Resuscitative efforts were initiated but unsuccessful.

4:50 AM. The patient was pronounced dead.

Several important risk management questions frequently arise in

medical malpractice litigation involving the ED. To prove that a case constitutes medical malpractice, a plaintiff's attorney must show clear and convincing evidence of a departure from good practice by the physician. The attorney must further demonstrate that the negligent act or omission by the physician proximately caused the patient's injury. Courts have held that where â€œthere is substantial probability that the [defendant physician's] negligent conduct caused the resulting injury, that sufficient evidence has been developed against [the] physician.â€• [26]

The problems associated with an improperly documented ED record are numerous, but they can be minimized if the practitioner is cognizant of risk management principles. When the attorney for the patient (plaintiff's attorney) introduces evidence to prove the case, the central document in the medical malpractice trial is likely to be the ED record. Thus, every entry in that record is scrutinized with great care by both parties (plaintiff and defendants), and the importance of completing it with knowledge of risk management implications should be a concern for all healthcare providers.

The physician is required to write a medical record that will amply support the basis for the medical judgments exercised. When a physician chooses to write only a summary statement on the record without noting supporting clinical data or patient history, claims alleging failure to diagnose will be extremely difficult, if not impossible, to defend. One of the basic elements of the defense in a medical malpractice case is that the physician's judgment was appropriate, given the clinical facts and the patient's history available at that time. Therefore, physicians who do not record supporting clinical data and history deprive themselves of a strong â€œmedical judgmentâ€• defense.

Inappropriate entries or markings on the medical record can weaken the defense in a liability case. For example, in attempting to correct and error in entering a PO_2 value, if the physician or nurse totally obliterates the number, an attorney representing a

patient may suggest to the jury that the obliteration was done intentionally to conceal clinical data harmful to the position of the defense. If a physician must correct a prior entry made on the record, the preferable method is to draw a single line through the value or word to be changed, insert the correct information directly above and initial

the correction. Dating the correction also precludes potentially difficult questions of timing and responsibility in a courtroom setting. By following these suggestions, the physician avoids any accusations that he or she intentionally concealed an error in judgment (Figure 135-1).

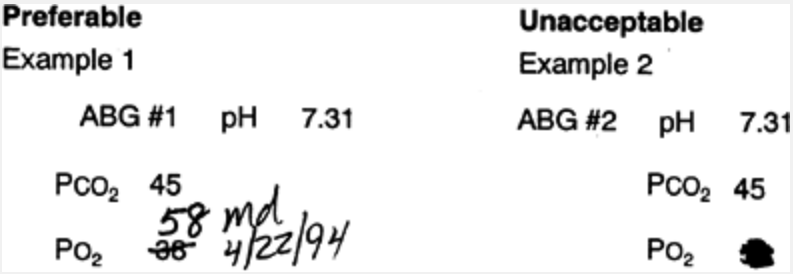

Figure 135-1. Examples of the preferred and an unacceptable procedure for correcting an error in the medical record.

A frequent claim is that the patient was abandoned or improperly monitored. For the above patient, although the chart appears to document repeated vital signs at appropriate intervals, no temperature is included after the first set until the patient is moribund; nor is any mention made again of the continued use of restraints, the patient's continued need for these restraints, or any

adverse effects developing from the use of restraints. Quality assurance reviews of ED records often demonstrate inadequate charting by physicians and nurses monitoring patients who remain in the department for prolonged periods of time. Under any circumstances, a lapse of documentation of the patient's clinical condition for four hours or more after the initial physician and nursing assessment creates a potential risk management problem. In a lawsuit, the plaintiff's attorney would undoubtedly use such a record to develop the theory that no care whatsoever was given to the patient during this time interval, and that the patient was abandoned.

Monitoring notations in the patient's record are considered inadequate when they do not offer insight into the patient's clinical status. Thus, any monitoring note for a patient who must be restrained in the ED for a lengthy period of evaluation, observation, or until an inpatient bed becomes available must include specific clinical data and observations (laboratory results, radiographic findings, hemodynamic changes, and infusion of medications and solutions). All of these deficiencies would undoubtedly be noticed and highlighted at trial by a plaintiff's expert, who frequently is a board-certified physician in the specialty in question.

Any documentation supporting the restraint of an impaired patient against his will must include a clinical description to support such a forcible impediment to the patient's right to liberty and freedom of movement. Such a clinical description should specifically describe any manifestation of agitation and uncooperative behavior. The record should refer to the specific uncooperative acts of the patient and, most importantly, should comment on the difficulties in providing care to the patient because of the patient's actions. If such documentation is present, a theory of negligence against the physician for inappropriate restraints would be virtually impossible to sustain.

Physicians who order restraints for patients must exercise extreme caution in the language used to describe such patients. A judgmental physician's note stating that a patient is â€œa chronic drunk and obnoxiousâ€• could undermine the support for the use of restraints. Poorly written physician's notes can become an issue in a medical malpractice action, with the plaintiff's attorney focusing on the derogatory nature of such a statement and suggesting a less-than-caring attitude by the doctor toward the patient. A plaintiff's appeal criticizing the ethical and social consciousness of the physician could very likely be seized by a jury and result in a punitive verdict against the physician. As a general rule, all healthcare professionals should depict a compassionate and professional manner by describing patient behavior and life styles in objective and concrete terms. An alternative and more appropriate description of a patient comparable to the one above would note that the patient had a â€œhistory of alcohol abuse and was uncooperative and combative.â€• To summarize, a well-documented ED record consistent with the accepted risk management principles set forth is the best course for the physician managing a difficult overdose situation in which legal principles may appear to present problems in providing proper medical management.

Forcible Restraint of the Impaired Patient

Patient 3 A 31-year-old woman was found unresponsive on the street and brought to the ED by emergency medical services. Friends on the scene reported that the patient used methadone. In the ED she was unresponsive and apneic. She was immediately administered oxygen by bag-valve mask and intravenous access was obtained. The patient was then administered naloxone IV, and shortly thereafter regained consciousness. After 20 minutes of care in the ED, the patient stated that she had taken methadone

and demanded to be discharged. On re-evaluation, she was noted to be fully alert and oriented, with no evidence of hypoxia or other clinical signs to suggest impaired judgment.

The right of a hospital to retain and physically restrain a person who has an altered level of consciousness for evaluation and emergency intervention is generally well supported by states and case law.[6] Reasonably clear guidelines for the management of such impaired patients have evolved from legal precedents governing appropriate medical assessment, from risk management considerations, and from the predictability of patient injury in the event of premature discharge.

A staff decision to allow a treated or partially treated patient with a drug overdose who subsequently becomes alert to return to the community must be based on an assessment of several factors. The initial concern is the patient's capacity to comprehend. Before the patient can be permitted to leave the hospital, a determination would have to be made that the patient is capable of understanding the information presented and has neither a medical nor a psychiatric problem preventing such a voluntary decision. The next consideration is that of medical stability. Has the initial process that caused the clinical scenario completed its course? The history of drug use in this patient is cause for concern that the underlying toxic metabolic process is not yet resolved, and alteration in mental status, significant respiratory compromise, or other medical symptoms may recur when the naloxone is metabolized, again placing the patient at risk.

Common ED practice and sound legal principles suggest that both the hospital and its staff have a duty to prevent such a person from leaving if the duration of the effect of the involved xenobiotics is longer than that expected for the antidote. Because the duration of

effect for naloxone is considerably shorter than that of methadone,

the physician can predict with reasonable certainty that coma or apnea will reoccur in the near future. The physician has the duty to inform the individual of the life-threatening nature of the condition, and then to retain, with restraints if necessary, the patient in the hospital until he or she is medically stable.

Liability in this situation is further reduced when the chart substantiates the medical judgment that was the basis for the decision to retain the patient and, if applicable, the use of restraints. Such documentation should specifically note the likely relapse of the patient into a symptomatic state and that this occurrence could place the patient and others in a life-threatening situation. When documented in a clear manner, legal challenges to the decision to restrain the patient have a limited chance at success. Sound risk management principles support treatment and detainment. Conversely, prematurely releasing a patient with a significant overdose exposes both the physician and the hospital to a claim of negligence on the grounds of failure to foresee a likely and harmful event.

Blood Alcohol and Evidence Collection

Patient 4 A 41-year-old man who was the driver involved in a motor vehicle crash was taken to the ED by ambulance. Two motorists in another car were killed. The patient had no physical complaints, but was brought to the hospital for medical clearance. On arrival, he was alert and oriented, responded appropriately to all commands, and demonstrated a normal gait and motor function. Police officers suspected that he was driving while intoxicated but he refused a breath alcohol test at the scene.

The police officers informed the ED staff that he was arrested and might be charged with vehicular homicide. The officers then requested that the emergency physician draw a blood specimen to determine the blood alcohol concentration. The patient stated that he would not allow the ED staff to draw blood for a determination

of an alcohol level.

Traffic crashes are the leading cause of death in person's age 3â€“33 years and the eighth leading cause of death in all age groups.[9] In 2003, alcohol was involved in 40% of traffic fatalities. Of these crashes, 74% of drivers had a blood alcohol concentration (BAC) of 0.08% (80 mg/dL) or higher.[10]

The judicial system has historically been one of the most effective tools to combat drunk driving, and its effectiveness depends on the ability to identify and punish individuals who violate the law. It is essential, however, that the collection of evidence does not violate the rights afforded by the US Constitution. Does forced phlebotomy for patients suspected of driving while intoxicated violate these protected rights? This has long been debated in the courts, and issues specifically brought into question include the Fourth Amendment,[22] the right against unreasonable search and seizure; the Fifth Amendment,[23] the right against self-incrimination; and the Due Process clause of the Fourteenth Amendment.[24] Past decisions on these issues help guide current laws and practices.

Every state, and the District of Columbia, has driver â€œimplied consentâ€• laws. When a person obtains a driver's license, he or she consents at the time of acquisition to a chemical alcohol test if suspected of driving while intoxicated. Under the implied consent laws, when a person suspected of driving while intoxicated refuses to take an alcohol test, he or she is then subject to a penalty. Specific penalties for refusals vary from state to state. At a minimum, the refusal results in suspension or revocation of a driver's license. Some states assign additional fines and penalties for this action. A few states allow the refusal itself to be submitted at the trial in support of the prosecution, making it possible to be convicted of an intoxication charge without chemical evidence.[1] Certain states, for example Texas and Illinois, allow blood tests to be performed on patients as ordered by a law officer, when there

is probable cause of driving while intoxicated resulting in severe injury.[13,21] Other states, such as New York and California, allow forced blood samples with a warrant issued by a judge.[3,11] State laws regarding the approach to this situation vary and it is important that the ED staff be familiar with the specific requirements of the law of that state.

How much force may be used to collect chemical evidence? Is a physician violating human dignity and privacy in obtaining evidence for the state? These issues have been addressed by the United States Supreme Court. In *Rochin v California*,[15] the Court overturned a conviction of drug possession based on violation of the Fourteenth Amendment. In this case, police were informed that Rochin was selling drugs. While entering the defendant's home, the police witnessed the defendant swallow 2 pills that were lying on the nightstand. When the officers failed to recover the pills on the scene, the officers took Rochin to the ED, where they directed the physician to administer an emetic through a nasogastric tube. The capsules were recovered from the vomit, identified as containing morphine, and *Rochin* was convicted by the trial court for possessing morphine.[1,15] The Supreme Court reversed this decision, based on the 14th amendment, â€œnor shall any State deprive any person of life, liberty or property, without due process of lawâ€¦.â€•[25] The term due process is vague, and is defined on a case-by-case basis, but it essentially means that states must use fair legal procedures when depriving an individual of life, liberty, or property. In *Rochin*, the court concluded that forced emesis by a physician was believed to violate Due Process, stating

> This is conduct that shocks the conscience. Illegally breaking into the privacy of the petitioner, the struggle to open his mouth and remove what was there, the forcible extraction of stomach contents-this course of proceeding by

> agents of government to obtain evidence is bound to offend even hardened sensibilities. They are methods too close to the rack and the screw to permit constitutional differentiation.[15]

The Supreme Court revisited the issues presented in *Rochin* four years later in *Breithaupt v Abram*.[2] Breithaupt was the driver of a truck that killed three occupants of another vehicle. In the ED, a police officer requested that a blood alcohol level be drawn. The blood, drawn while the patient was unconscious, was above the legal limit for alcohol and the patient was convicted of involuntary manslaughter. Breithaupt argued that the blood draw, as in forced emesis in *Rochin*, violated Due Process as he did not consent to its collection. Justice Clark disagreed, stating â€œthe distinction rests on the fact that there is nothing â€˜brutalâ€™ or â€˜offensiveâ€™ when done, as in this case, under the protective eye of a physicianâ€• and that the â€œblood test procedure has become routine in our everyday life.â€•[1,2] Phlebotomy while the patient is unconscious and unable to give consent, did not violate the Due Process Clause of the Fourteenth Amendment.

The Supreme Court continued to expand the scope of permissible phlebotomy in *Schmerber v California*.[17] Schmerber was

involved in a motor vehicle crash in which the officer suspected he was intoxicated. Unlike in *Breithaupt*, Schmerber was not unconscious, and a physician drew a blood sample on the officer's request despite the patient's verbal refusal. Schmerber argued that this act violated several constitutional rights. He argued that forced phlebotomy violated the Fourth and Fifth Amendment. Schmerber argued that a forced blood draw without his consent denied him Due Process of law under the Fourteenth Amendment, violated his privilege against self-incrimination, and his right not to be subjected to unreasonable searches and seizures in violation of the Fourth and Fourteenth Amendments.[1,17] The court rejected

all of Schmerber's arguments. The phlebotomy did not violate the Due Process clause because â€œthe extraction was made by a physician in a simple, medically acceptable manner in a hospital environment. â€¦we cannot see that it should make any difference whether one states unequivocally that he objects or resorts to physical violence in protest or is in such condition that he is unable to protest.â€• [17] Furthermore, the forced blood draw did not violate the Fifth Amendment's privilege against self-incrimination because the Fifth Amendment only protects evidence of a â€œtestimonial or communicative nature,â€• such as writings or speech. Finally, there was no violation of the Fourth and Fourteenth Amendments' protecting against unreasonable searches and seizures of property:

> The delay necessary to obtain a warrant, under the circumstances, threatened the destruction of evidenceâ€¦. Similarly, we are satisfied that the test chosen to measure petitioner's blood-alcohol level was a reasonable one. Extraction of blood samples for testing is a highly effective means of determining the degree to which a person is under the influence of alcohol. Such tests are a commonplace in these days of periodic physical examinations and experience with them teaches that the quantity of blood extracted is minimal, and that for most people the procedure involves virtually no risk, trauma, or pain.

To ensure compliance with standards set forth in *Schmerber*, the states have tailored laws and regulations governing the seizure of blood for the purpose of blood alcohol testing. Laws generally require the procedure be (1) done in a reasonable, medically approved manner, (2) be incident to a lawful arrest, and (3) be based on the belief that the arrestee is intoxicated. It should be

remembered that the issues raised by any one case are complex, and the application in real situations is difficult. Laws and regulations governing blood draws for alcohol testing vary from state to state and are the subject of frequent restructuring and amendment. It is therefore recommended that medical staff review with hospital counsel the local laws and regulations that pertain to these issues. It should be remembered, however, that physician and patient safety must always be the priority. The benefits of determining a patient's alcohol level must be weighed against the risks of the procedure. For example, drawing blood in an agitated patient may place the staff at risk of a needle stick.

Confidentiality

Patient 5 A 32-year-old woman was fired from her job as a high school mathematics teacher. The school board called for her termination after learning that she had a history of alcohol dependence and had a previous hospitalization for detoxification at the local community hospital. A parent on the school board was also employed as a nurse at the hospital, where the teacher had received alcohol therapy. The school board member (and nurse) had inadvertently accessed the teacher's medical record while caring for a patient with the same last name.

The Health Insurance Portability and Accountability Act (HIPAA) was created in 1996. Initially, the purpose of HIPAA was to increase the portability of health insurance, and allow employees to maintain insurance when they changed jobs. The Act called for the establishment of several provisions, among them an electronic database designed to facilitate the exchange of information between healthcare providers, insurance companies, and those involved in financial and administrative transactions.[8] However, the idea of developing an electronic database brought to light already growing concerns regarding the maintenance of patient privacy. For the first time, patients' medical records would be

accessible to an unlimited amount of people working in healthcare, from billings processors to pharmacists to clinicians. Would a patient's right to privacy be jeopardized by a system designed to increase efficiency?

Prior to HIPAA, individual hospitals or physician offices designed their own methods for maintaining confidential patient information. Records were maintained on computers in some circumstances and on paper in others. Accessibility to that information was largely regulated by state laws, and supported by some federal regulations and ethical codes of conduct. During the 1990s, however, the weaknesses of the existing system gained attention as multiple high profile breeches of confidentiality surfaced. For example, the medical records of a congresswoman were released to the media during her campaign, making her history of depression and a past suicide attempt public knowledge.[18] There were also several cases of the medical records of hospital employee's being read by staff members not involved in the employees' care, health insurance companies releasing heath care information to employers without permission, and physicians releasing information to pharmaceutical companies that subsequently solicited the patient.[28] These breaches of ethics were each a testament to the fact that a patient's right to privacy needed more stringent regulation. If these examples could occur in the previous system for recording information, then it could be assumed that further increases in access would occur through an electronic database.

The Privacy Rule of HIPAA has become the most well publicized aspect of this Act among healthcare personnel. The Privacy Rule governs the use and disclosure of protected health information in the hands of healthcare providers, health plans, and healthcare clearinghouses.[8] The terminology used in the Privacy Rule is extensively defined. The following is a brief summary of the terms used:

Protected Health Information: This includes any individually identifiable information concerning the past, present, or future health of an individual. This includes medical information pertaining to assessment and treatment in addition to payment and billing information. All forms of information, written, oral, or electronic, are protected by this rule.

Covered Entities: This includes any person or business that provides health-related services or products. All those providing health-related services, for example clinicians, pharmacists, medical equipment providers, and other healthcare providers, are considered covered entities. Companies that provide disability insurance, car insurance, or casualty insurance are not included in the rule.[8,25]

Healthcare Clearinghouses: These are entities that compile healthcare information, such as billing companies or data processing centers.

Institutions are required to provide all individuals with written notice of their privacy policy when they first seek medical care. Patients must be informed of how the institution may use and disclose information. The notice must also describe patients' rights, including the right to access their medical information and their right to file a complaint if they believe their rights are violated. The notice must be written in plain language, and the individual must provide written acknowledgement that they received the information.

The Privacy Rule of HIPAA was not intended to impede healthcare. There are several exceptions to the rule. A covered entity is permitted to use and disclose protected health information for the purposes of evaluation and treatment. Physicians have the freedom to consult with each other, in their own institution and outside, to provide clinical care. Additionally, there are several specific exceptions to the Privacy Rule listed within the document-

situations in which protected health information may and often must be disclosed, and may be done without an individual's permission. For example, activities related to public health, such as reporting communicable diseases, information necessary to report actual or suspected abuse, neglect or domestic violence, or information pertaining to cadaveric organ or tissue donation are specifically exempt from the Privacy Rule.[7]

The HIPAA Privacy Rule specifically addresses consultations with poison centers (PCs). It states: â€œWe consider the counseling and follow-up consultations provided by poison control centers with individual providers regarding patient outcomes to be treatment. Therefore, poison control centers and other healthcare providers can share protected health information about the treatment of an individual without a business associate contract.â€•[7]

Violations of the Privacy Rule are subject to penalties, the severity of which is dependent on the type of infraction. Simple noncompliance violations may be charged financial penalties, however, more significant or intentional disclosures of information may have steeper fines in addition to criminal charges and potential jail time.[28]

Legal Considerations for Poison Centers and Information Specialists

Patient 6 The PC received a call from a concerned mother that her daughter might have ingested one of the grandmother's diabetes medications. The mother stated that the child was acting normally all day at the grandmothers' house, but when the family returned home the child had become drowsy. When contacted, the grandmother had confirmed that 1 pill was missing from her purse although she did not know the name of her medication. The PC advised that the parents give the child juice and closely observe

her for the next 6 hours. Approximately 2 hours later, while sleeping, the child had a seizure. The child continued to seize in the hospital, where medical evaluation revealed hypoglycemia. The patient subsequently suffered permanent neurological damage. The medication was later identified as glyburide. Action was brought against the local PC, alleging inappropriate advice and failure to recommend transport to a hospital.

As a general rule, any physician who decides to treat a patient enters into a physician-patient relationship that creates well-established legal duties. Courts have ruled that the physician-patient encounter need not be a face-to-face interaction to have legal consequences. For example, the absence of physical contact between a physician and patient as in the practice of radiology and pathology does not preclude a patient from asserting that a duty of care exists.[4] More particularly and quite relevant to the practice of a PC, a New York State court ruled that an initial telephone call from a patient to a physician can be sufficient basis to hold that physician responsible for inappropriate advice or a significant error in judgment.[12] Given the legal precedents previously stated, it is eminently clear that contact with a poison information specialist is a sufficient foundation for a subsequent legal action if inappropriate advice was given.

Standards of Care Applicable to Poison Information Specialists

Any discussion of the standard of care to which a poison information specialist should be held would be misleading without mentioning several operational aspects of most PCs. The specialists are required to have a rapid and accurate access to a standard information resource system, that contains both basic information and recommendations to deal with most encountered toxic exposures. Advice that differs significantly from an existing protocol or standard of care could be subject to critical review in a

civil lawsuit. If a patient were to bring an action, the negligence theory against the PC might rely particularly on deviations from the standard recommendations.

It would be inaccurate to suggest, however, that the duty of care owed by a poison information specialist can be measured only by how closely the advice given compares with the standard resources. Frequently, an information specialist may encounter situations that cannot be managed in accordance with an information system alone, and may seek counsel from a clinical pharmacist or a medical toxicologist working with the PC. If this were to occur, any subsequent legal proceeding would also review carefully the content of the information given to the consultant regarding its accuracy and appropriateness regarding the underlying toxicologic problem.

Practices of Regional Poison Centers that can Reduce Potential Liabilities

Clearly there are some inherent risks of potential liability for a PC. To minimize such risk and the risk of civil actions against a PC, quality assurance and risk management programs should be a regular function. Daily audits or monitoring of the advice given by poison information specialists should be done. Such interactions enhance care and ensure patient safety for the individual and establish a higher general standard.

The medical toxicologists and clinical pharmacists responsible for supervising the poison information specialists must be able to adequately assess the competence and capabilities of the staff and to make recommendations, take corrective actions, and provide suggestions for improvement to involved members. This process is facilitated by such actions as audiotaping calls made to the PC and the subsequent advice given, and reviewing written records maintained by the information specialist on each particular case.

Documentation is extremely important, because in the event of a

lawsuit, the most likely area of dispute will be what was actually said to the patient.

Summary

The risk management and legal issues of an active ED have implications for many patients. The ability of providers to function responsibly is dependent on an understanding of these ever-evolving principles. Those patients whose consciousness is abnormal because of a toxin represent an acute complex medicolegal emergency. A well-organized hospital is dependent on a close working relationship among the legal, risk management, and medical personnel. Only in this manner can they learn, cooperate, and meet the needs of the ever-evolving clinical dilemmas they confront.

Selected Emergency Antidotes with Common Initial Doses*

N -acetylcysteine
Acetaminophen: *IV* : 150 mg/kg infused IV over 60 min, followed by 50 mg/kg over 4 hours, then 100 mg/kg over 16 hours. Must dilute in D_5 W 140 mg/kg, followed by 70 mg/kg every 4 hours for 17 doses. NOTE : Sp IV dilution required for children.
544
Atropine
Cholinesterase inhibitors: *Adults* : 1â€“5 mg IV, doubled every 3â€“5 until bronchorrhea resolves. *Children* : 50 Âµg/kg (min 0.1 mg; max 0.5 IV, doubled as for adults. NOTE : Use 3â€“5 mg starting dose for adults severe poisoning.
1519
L-Carnitine
Valproic acidâ€“induced hyperammonemia or valproic acidâ€“indu elevated AST/ALT: *Clinically ill:* 100 mg/kg (up to 6 g) infused IV over min, followed by 15 mg/kg infused over 30 min every 4 hours. *Clinically* 100 mg/kg/day oral divided every 6 hours up to 3 grams/day.
746
Cyanide antidotes (Nitrites and sodium thiosulfate)
Cyanide: *Adults:* 1) Sodium nitrite: 300 mg (10 mL of a 3% conc) infuse over 2â€“5 min. 2) Sodium thiosulfate: 12.5 g (50 mL of a 25% conc) in IV over 10â€“30 min or as a bolus. *Children* : 1) Sodium nitrite: 6â€“8 m (0.2 mL/kg of a 3% conc) (max 300 mg) infused IV over 2â€“5 min. 2) S thiosulfate: 7 g/m^2 (0.5 g/kg) (max 12.5 g) infused over 10â€“30 min or bolus. NOTE: In both adults and children, avoid sodium nitrite when

carboxyhemoglobin is expected to be elevated.
1725 , 1728
Deferoxamine
Iron: Begin continuous IV infusion at 5 mg/kg/h, titrate to 15 mg/kg/h a tolerated with a total dose of 6â€“8 g/day.
638
Dimercaprol (BAL)
Lead encephalopathy: 75 mg/m^2 deep IM every 4 hours. First dose to precede edetate calcium disodium ($CaNa_2$ EDTA) by 4 hours. Contraindica peanut allergy.
1265
Digoxin-specific antibody fragments (Fab)
Cardioactive steroids: Known level : # of vials = [wt (kg) Ã— level (ng/mL)/100] rounded up to nearest vial. Empiric dosing : Acute: 10-20 Chronic: *Adults* : 3â€“6 vials; *Children* : 1â€“2 vials. Usually given as IV infusion over 30 min. An IV bolus is acceptable for asystole. NOTE : Non-digoxin cardioactive steroids, use empiric dose.
983
Edetate calcium disodium ($CaNa_2$ EDTA)
Lead encephalopathy: 1500 mg/m^2 /day as a continuous IV infusion. N Dimercaprol (BAL) should be administered 4 hours prior to starting this c
1331
Folinic acid (leucovorin)
Methotrexate: 100 mg/m^2 infused IV over 15â€“30 min every 3â€“6 hou several days or until methotrexate serum conc < 1 Ã— 10^{-8} M in the abs of bone marrow toxicity.
826
Fomepizole
Methanol or ethylene glycol: 15 mg/kg infused IV over 30 min; next 4 at 10 mg/kg every 12 hours; additional doses at 15 mg/kg every 12 hour needed.
1460
Glucagon
Î²-Adrenergic antagonists: IV infusion over 1â€“2 minutes. *Adults:* 50

Âµg/kg. *Children* : 50 mcg/kg. Dose may be increased up to 10 mg in an as needed.

942

Methylene blue

Methemoglobinemia: 1â€“2 mg/kg IV over 5 min followed by a 30 mL f flush.

1746

Naloxone

Opioid-induced respiratory depression: 50 Âµg IV titrated upward to reversal, while avoiding opioid withdrawal.

614

Octreotide

Sulfonylurea-induced hypoglycemia: *Adults* : 50 Âµg SQ every 6 h. *Children* : 1.25 Âµg/kg (max 50 Âµg) SQ every 6 hours.

770

Physostigmine

Anticholinergic syndrome: IV infusion over 5 min. *Adults* : 1â€“2 mg. *Children* : 20 Âµg/kg (max 0.5 mg).

794

Pralidoxime

Cholinesterase inhibitors: *Adults* : 1â€“2 g infused IV over 30 min and up to 500 mg/h by infusion for sickest patients. *Children* : 20â€“50 mg/k (max 1â€“2 g) infused IV over 30â€“60 min and then 10â€“20 mg/kg/h (500 mg/h).

1513

Pyridoxine

Isoniazid: 1 g for each gram of isoniazid up to 70 mg/kg (max 5 g) infus at 0.5 g/min until seizures stop, with the remainder infused IV over 4â€“ hours.

872

Succimer

Lead poisoning: *Adults:* 10 mg/kg orally every 8 hours for five days fol by every 12 hours for 14 days. *Children:* 350 mg/m^2 orally as for adults.

1325

<9.78 nmol/L
Thallium (urine)
<5.0 Âµg/L
<24.5 nmol/L
Theophylline
5â€“15 Âµg/mL
27.8â€–83 Âµmol/L
Thiocyanate
<30 Âµg/mL
<100 Âµmol/L
Valproic acid
50â€–120 mg/L
347â€–833 Âµmol/L
Therapeutic or generally acceptable levels are listed. Please see the appropriate chapter for details regarding specific situations. Normal rang may vary by laboratory. * = Level must be interpreted based on the pati serum pH and clinical status

Conventional SI

Common Standard Laboratory Values

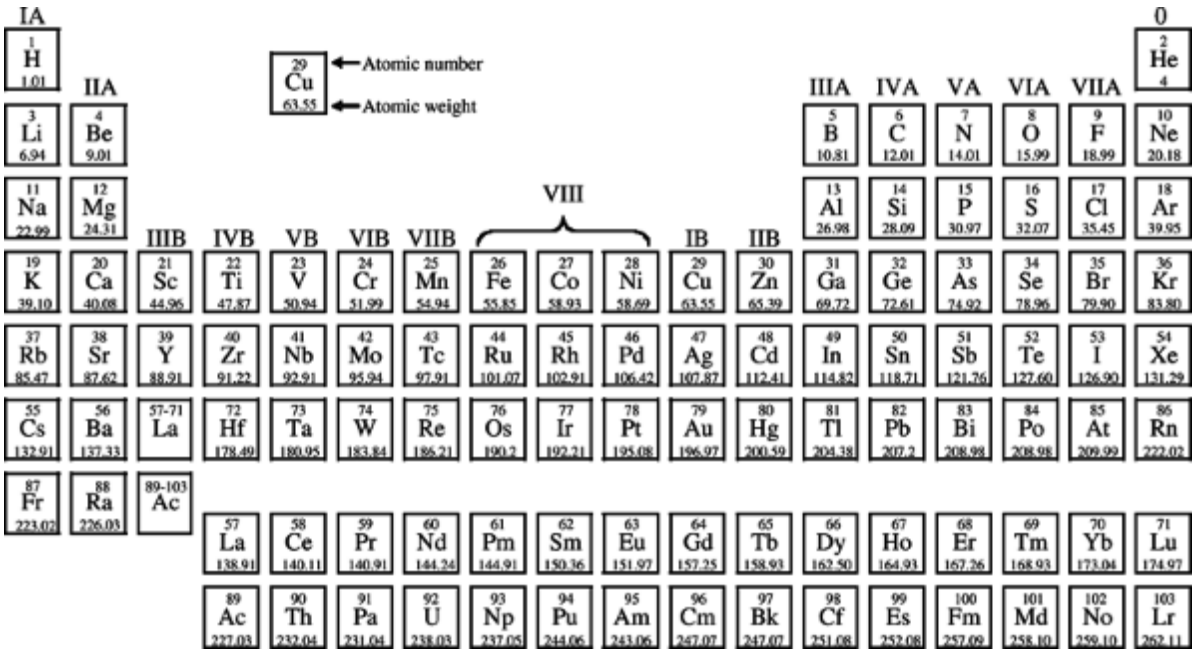
Ammonia
10â€“80 Âµg/dL

6â€“47 Âµmol/L
Bicarbonate
18â€“24 mEq/L
18â€“24 mmol/L
BUN
7â€“18 mg/dL
2.5â€“6.4 mmol/L
Calcium
8.4â€“10.2 mg/dL
2.10â€“2.55 mmol/L
Chloride
98â€“106 mEq/L
98â€“106 mmol/L
Creatinine
0.6â€“1.2 mg/dL
0.053â€“0.106 mmol/L
Glucose
60â€“110 mg/dL
3.3â€“6.1 mmol/L
Lactate
18 mg/dL
<2 mmol/L
Magnesium
1.3â€“2.1 mEq/L
0.65â€“1.05 mmol/L
PCO_2 (art)
35â€“45 mm Hg
4.7â€“6 kPa
PCO_2 (ven)
45â€“55 mm Hg
6.0â€“7.33 kPa
pH (art)
7.35â€“7.45
7.35â€“7.45

pH (ven)
7.33â€“7.4
7.33â€“7.4
PO_2 (art)
90â€“100 mm Hg
12â€“13.3 kPa
PO_2 (ven)
30â€“50 mm Hg
4.0â€“6.67 kPa
Phosphorus
3â€–4.5 mg/L
1â€–1.4 mmol/L
Potassium
3.5â€–5.0 mEq/L
3.5â€–5 mmol/L
Sodium
135â€–145 mEq/L
135â€–145 mmol/L
art = arterial; ven = venous

Conventional SI

Periodic Table of the Elements



Clinical and/or Laboratory Findings Poisoning

Agitation

Anticholinergics[a] , hypoglycemia, phencyclidine, sympathomimetics[b] , et and sedative-hypnotic withdrawal

Alopecia

Alkylating agents, radiation, selenium, thallium

Ataxia

Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycem lithium, mercury, phenytoin, nitrous oxide

Blindness or decreased visual acuity

Caustics (direct), cocaine, cisplatin, mercury, methanol, quinine, thallium

Blue skin

Amiodarone, FD&C #1 dye, methemoglobin, silver

Constipation

Anticholinergics[a] , botulism, lead, opioids, thallium (severe)

Tinnitus, deafness

Aminoglycosides, cisplatin, heavy metals, loop diuretics, quinine, salicyla

Diaphoresis

Amphetamines, cholinergics[c] , ethanol and sedative-hypnotic withdrawal, hypoglycemia, opioid withdrawal, salicylates, serotonin syndrome, sympathomimetics[b]

Diarrhea

Arsenic and other metals/metalloids, boric acid (blue-green), botanical irritants, cathartics, cholinergics[c] , colchicine, iron, lithium, opioid withdr radiation

Dysesthesias, paresthesias

Acrylamide, arsenic, ciguatera, cocaine, colchicine, thallium

Gum discoloration

Arsenic, bismuth, hypervitaminosis A, lead, mercury paresthesias

Hallucinations

Anticholinergics[a] , dopamine agonists, ergot alkaloids, ethanol, ethanol a sedative-hypnotic withdrawal, LSD, phencyclidine, sympathomimetics[b] , tryptamines (e.g., AMT)

Headache

Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor/food inter (hypertensive crisis), serotonin syndrome

Metabolic acidosis (elevated anion gap) [MUDPILES]

Methanol, uremia, ketoacidosis (diabetic, starvation, alcoholic), paraldeh phenformin, metformin, iron, isoniazid, lactic acidosis, cyanide, protease inhibitors, ethylene glycol, salicylates, toluene

Miosis

Cholinergics[c] , clonidine, opioids, phencyclidine, phenothiazines

Mydriasis

Anticholinergics[a] , botulism, opioid withdrawal, sympathomimetics[b]

Nystagmus

Barbiturates, carbamazepine, carbon monoxide, ethanol, lithium, monoar oxidase inhibitors, phencyclidine, phenytoin, quinine

Purpura

Anticoagulant rodenticides, clopidogrel, corticosteroids, heparin, pit viper

venom, quinine, salicylates, warfarin

Radiopaque ingestions

Arsenic, chloral hydrate, enteric coated tablets, halogenated hydrocarbor metals (e.g., iron, lead)

Red skin

Anticholinergics[a] , boric acid, disulfiram, scombroid, vancomycin

Rhabdomyolysis

Carbon monoxide, doxylamine, HMG CoA reductase inhibitors, sympathomimetics[b] , *Tricholoma* mushrooms

Salivation

Arsenic, caustics, cholinergics[c] , ketamine, mercury, phencyclidine, stryc

Seizures

Bupropion, carbon monoxide, cyclic antidepressants, ethanol and sedative hypnotic withdrawal, *Gyromitra* mushrooms, hypoglycemia, isoniazid, theophylline

Tremor

Antipsychotics, arsenic, carbon monoxide, cholinergics[c] , ethanol, lithium mercury, methyl bromide, sympathomimetics[b] , thyroid replacement

Weakness

Botulism, diuretics, magnesium, paralytic shellfish, steroids, toluene

Yellow skin

Acetaminophen (late), pyrrolizidine alkaloids, Î²-carotene, *Amanita* mushrooms, dinitrophenol

[a] Anticholinergics: e.g., antihistamines, atropine, cyclic antidepressants, scopolamine

[b] Sympathomimetics: e.g., amphetamines, Î²-adrenergic agonists, cocain ephedrine

[c] Cholinergics: e.g., muscarinic mushrooms, organic phosphorus compou and carbamates, including Alzheimer's drugs and physostigmine, pilocarp and other direct acting drugs
