eighth edition

Goldfrank's TOXICOLOGIC EMERGENCIES

Flomenbaum
Goldfrank
Hoffman
Howland
Lewin
Nelson

Editors: Flomenbaum, Neal E.; Goldfrank, Lewis R.; Hoffman, Robert S.; Howland, Mary Ann; Lewin, Neal A.; Nelson, Lewis S.
Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Editors

Neal E. Flomenbaum MD, FACP, FACEP
Emergency Physician-in-Chief
New York-Presbyterian Hospital, Weill Cornell Medical Center; Professor of Clinical Medicine, Weill Medical College, Cornell University; Consultant, New York City Poison Center, New York, New York

Lewis R. Goldfrank MD, FACEP, FAAEM, FAACT, FACMT, FACP
Professor and Chair
Department of Emergency Medicine, New York University School of Medicine; Director, Emergency Medicine, Bellevue Hospital Center and New York University Medical Center; Medical Director, New York City Poison Center, New York, New York

Robert S. Hoffman MD, FAACT, FACMT
Director
New York City Poison Center; Attending Physician, Department of Emergency Medicine, Bellevue Hospital Center and New York University Medical Center; Associate Professor, Emergency Medicine and Medicine (Clinical Pharmacology), New York University School of Medicine, New York, New York

Mary Ann Howland PHARMD, DABAT, FAACT

Clinical Professor of Pharmacy
St. John's University, College of Pharmacy Consultant, Department of Emergency Medicine, Bellevue Hospital Center and New York University Medical Center; Senior Consultant in Residence, New York City Poison Center, New York, New York

Neal A. Lewin MD, FACP, FACEP, FACMT
Director
Didactic Education; Attending Physician, Department of Emergency Medicine; Clinical Associate Professor of Emergency Medicine and Medicine (Clinical Pharmacology), New York University School of Medicine; Consultant, New York City Poison Center, New York, New York

Lewis S. Nelson MD, FACEP, FACMT
Director
Medical Toxicology Fellowship Program; Associate Director, New York City Poison Center; Attending Physician, Department of Emergency Medicine, Bellevue Hospital Center and New York University Medical Center; Assistant Professor of Emergency Medicine, New York University School of Medicine, New York, New York

Secondary Editors

The index was prepared by Kathrin Unger.

Courier Kendallville was printer and binder.

Contributors

Judith C. Ahronheim MD
Chief
Division of Geriatrics; Visiting Professor of Medicine, State University of New York, Downstate Medical Center, Brooklyn, New York

Chapter 32, â€œGeriatric Principlesâ€•

Michael H. Allen MD
Associate Professor of Psychiatry; Director of Emergency Psychiatry
University of Colorado Health Sciences Center, Denver, Colorado

Chapter 18, â€œPsychiatric Principlesâ€•

Vincent L. Anthony MD
Fellow in Nephrology, Nassau University Medical Center, East Meadow, New York

Chapter 27, â€œRenal Principlesâ€•

Kavita Babu MD
Fellow in Medical Toxicology, Department of Emergency Medicine, University of Massachusetts Medical Center, Worcester, Massachusetts

Chapter 80, â€œHallucinogensâ€•

Fermin Barrueto MD
Assistant Professor of Surgery
Division of Emergency Medicine, University of Maryland, Baltimore, Maryland

Chapter 106, â€œSodium Monofluoroacetate and Fluoroacetamideâ€•

Dina Began MD
Clinical Assistant Professor of Dermatology
Weill Medical College, Cornell University, New York, New York

Chapter 29, â€œDermatologic Principlesâ€•

Martin G. Belson MD
Medical Toxicologist
National Center for Environmental Health, Centers for Disease Control and Prevention, Georgia Poison Control Center, Department of Pediatric Emergency Medicine, Children's Healthcare of Atlanta, Atlanta, Georgia

Chapter 36, â€œNonsteroidal Antiinflammatory Drugsâ€•

Jeffrey N. Bernstein MD
Medical Director
Florida Poison Information Center/Miami; Voluntary Associate Professor of Pediatrics, University of Miami, Miller Medical School; Attending Physician, Emergency Care Center, Jackson Memorial Hospital, Miami, Florida

Antidotes in Depth A32, â€œAntivenom (Scorpion and Spider)â€•

Joseph M. Betz PhD
Director

Dietary Supplement Methods and Reference Materials Program, Office of Dietary Supplements, National Institutes of Health, Bethesda, Maryland

Chapter 114, â€œPlantsâ€•

Steven B. Bird MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, Division of Medical Toxicology, University of Massachusetts Medical Center, Worcester, Massachusetts

Chapter 88, â€œChromiumâ€•

Kenneth E. Bizovi MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, Oregon Health and Science University; Consultant, Oregon Poison Center, Portland, Oregon

Chapter 34, â€œAcetaminophenâ€•

G. Randall Bond MD, FACMT
Medical Director
Cincinnati Drug and Poison Information Center; Attending Physician, Division of Emergency Medicine, Cincinnati Children's Hospital Medical Center; Professor of Clinical Pediatrics and Clinical Emergency Medicine, University of Cincinnati, Cincinnati, Ohio

Chapter 56, â€œAntimalarialsâ€•

George M. Bosse MD
Associate Professor of Emergency Medicine
University of Louisville; Medical Director, Kentucky Regional Poison Center, Louisville, Kentucky

Chapter 48, â€œAntidiabetics and Hypoglycemicsâ€•

Nicole C. Bouchard MD
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 49, â€œThyroid and Antithyroid Medicationsâ€•

Edward W. Boyer MD, PhD
Associate Professor of Emergency Medicine; Chief
Division of Medical Toxicology, University of Massachusetts Medical Center, Worcester, Massachusetts; Instructor in Pediatrics, Harvard Medical School, Boston, Massachusetts

Chapter 55, â€œAntituberculous Medicationsâ€•

Jeffrey R. Brubacher MD
Clinical Associate Professor
University of British Columbia; Emergency Physician, Department of Emergency Medicine, Vancouver General Hospital, Vancouver, British Columbia, Canada

Chapter 59, â€œÎ²-Adrenergic Antagonistsâ€•

D. Eric Brush MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, Division of Medical Toxicology, University of Massachusetts Medical Center, Worcester, Massachusetts

Chapter 116, â€œMarine Envenomationsâ€•

Keith K. Burkhart MD
Professor of Clinical Emergency Medicine

Pennsylvania State University College of Medicine; Regional Medical Toxicologist, Division of Regional Operations, Agency for Toxic Substances and Disease Registry, Hershey, Pennsylvania

Chapter 112, â€œMethyl Bromide and Other Fumigantsâ€•

Michele Burns Ewald MD
Medical Director
Regional Center for Poison Control and Prevention serving Massachusetts and Rhode Island; Fellowship Director, Medical Toxicology, Children's Hospital Boston; Instructor in Pediatrics, Harvard Medical School; Attending Physician, Division of Emergency Medicine, Children's Hospital, Boston, Massachusetts

Chapter 95, â€œSilverâ€•

Chapter 97, â€œZincâ€•

Chapter 107, â€œPhosphorusâ€•

Diane P. Calello MD
Fellow in Medical Toxicology
The Poison Control Center of Philadelphia, University of Pennsylvania School of Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Chapter 94, â€œSeleniumâ€•

Louis R. Cantilena Jr. MD, PhD
Professor of Medicine and Pharmacology; Director
Division of Clinical Pharmacology and Medical Toxicology, Uniformed Services University of the Health Services, Bethesda, Maryland

Chapter 133, â€œAdverse Drug Events and Postmarketing Surveillanceâ€•

Gar Ming Chan MD
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 89, â€œCobaltâ€•

Yiu-Cheung Chan MD
Medical Officer
Accident and Emergency Department, United Christian Hospital, Hong Kong SAR, China

Chapter 108, â€œStrychnineâ€•

Alan N. Charney MD
Adjunct Professor of Medicine
New York University School of Medicine, New York, New York

Chapter 17, â€œFluid, Electrolyte, and Acid-Base Principlesâ€•

William K. Chiang MD
Associate Director
Department of Emergency Medicine, Bellevue Hospital Center; Associate Professor of Emergency Medicine, New York University School of Medicine, New York, New York

Chapter 21, â€œOtolaryngologic Principlesâ€•

Chapter 73, â€œAmphetaminesâ€•

Anne-Bolette J. Christophersen MD
Department of Clinical Pharmacology, Bispebjerg Hospital, University of Copenhagen, Copenhagen, Denmark

Chapter 8, â€œTechniques Used to Prevent Gastrointestinal Absorptionâ€•

Jason Chu MD
Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons; Associate Attending Emergency Physician, St. Luke'sâ€“Roosevelt Hospital Center, New York, New York

Chapter 28, â€œGenitourinary Principlesâ€•

Chapter 51, â€œAntimigraine Medicationsâ€•

Cathleen Clancy MD
Associate Medical Director
National Capital Poison Center; Assistant Professor of Emergency Medicine, Department of Emergency Medicine, George Washington University Medical Center; Attending Physician, Department of Emergency Medicine, National Naval Medical Center, Bethesda, Maryland; Attending Physician, Sibley Memorial Hospital, Washington, District of Columbia

Chapter 5, â€œElectrocardiographic Principlesâ€•

Richard F. Clark MD
Medical Director
San Diego Division, California Poison Control System; Director, UCSD Division of Medical Toxicology; Professor of Medicine, University of California, San Diego, San Diego, California

Chapter 109, â€œInsecticides: Organic Phosphorus Compounds and Carbamatesâ€•

Pat Croskerry MD, PhD
Associate Professor
Department of Emergency Medicine and Faculty of Medical Education, Dalhousie University, Halifax, Nova Scotia, Canada

Chapter 134, â€œMedications, Errors, and Patient Safetyâ€•

Steven C. Curry MD
Director
Department of Medical Toxicology, Banner Good Samaritan Medical Center; Associate Professor of Clinical Medicine, University of Arizona College of Medicine, Phoenix, Arizona

Chapter 14, â€œNeurotransmitters and Neuromodulatorsâ€•

John Curtis MD
Fellow in Medical Toxicology, Division of Medical Toxicology, Drexel University College of Medicine, Philadelphia, Pennsylvania

Chapter 93, â€œNickelâ€•

Andrew Dawson MD
Visiting Professor of Medicine
South Asian Clinical Toxicology Research Collaboration, University of Peradeniya, Sri Lanka

Chapter 105, â€œBariumâ€•

Kathleen A. Delaney MD
Professor and Vice Chair
Division of Emergency Medicine, University of Texas Southwestern Medical School; Medical Director, Emergency Department, Parkland Memorial Hospital, Dallas, Texas

Chapter 13, â€œBiochemical and Metabolic Principlesâ€•

Chapter 16, â€œThermoregulatory Principlesâ€•

Chapter 26, â€œHepatic Principlesâ€•

Antidotes in Depth A11, â€œDextroseâ€•

Francis DeRoos MD
Residency Director
Department of Emergency Medicine, Hospital of the University of Pennsylvania; Associate Professor of Emergency Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Chapter 58, â€œCalcium Channel Blockersâ€•

Chapter 60, â€œOther Antihypertensivesâ€•

Suzanne Doyon MD
Medical Director
Maryland Poison Center, University of Maryland School of Pharmacy, Baltimore, Maryland

Chapter 47, â€œAnticonvulsantsâ€•

Dainius A. Drukteinis MD, JD
Resident
Department of Emergency Medicine, New York University School of Medicine, New York, New York

Chapter 135, â€œRisk Management and Legal Principlesâ€•

Michael Eddleston PhD, MRCP
Wellcome Trust Career Development Fellow, Centre for Tropical Medicine, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, United Kingdom

Chapter 131, â€œInternational Perspectives in Medical Toxicologyâ€•

Donald A. Feinfeld MD
Nephrology Fellowship Director
Beth Israel Medical Center; Professor of Medicine, Albert Einstein

College of Medicine; Consultant in Nephrology, New York City Poison Center, New York, New York

Chapter 27, â€œRenal Principlesâ€•

Robert P. Ferm MD
Associate Professor of Emergency Medicine
Division of Medical Toxicology, Department of Emergency Medicine, University of Massachusetts Medical School; Attending Physician, Department of Emergency Medicine, University of Massachusetts Medical Center, Worcester, Massachusetts

Chapter 80, â€œHallucinogensâ€•

Jeffrey S. Fine MD
Assistant Professor
Pediatrics and Emergency Medicine, New York University School of Medicine; Assistant Director, Pediatric Emergency Medicine, Bellevue Hospital Center; Consultant, New York City Poison Center, New York, New York

Chapter 30, â€œReproductive and Perinatal Principlesâ€•

Chapter 31, â€œPediatric Principlesâ€•

Mark Flomenbaum MD, PhD
Chief Medical Examiner; Office of the Chief Medical Examiner
State of Massachusetts, Boston, Massachusetts

Chapter 33, â€œPostmortem Toxicologyâ€•

Marsha D. Ford MD
Director
Carolinas Poison Center; Director, Division of Medical Toxicology, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina; Clinical Professor of Emergency

Medicine, School of Medicine, University of North Carolinaâ€“Chapel Hill, Chapel Hill, North Carolina

Chapter 85, â€œArsenicâ€•

Frederick W. Fraunfelder MD
Cornea/Refractive Surgery, Casey Eye Institute, Portland, Oregon

Chapter 20, â€œOphthalmic Principlesâ€•

Jessica A. Fulton DO
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 100, â€œCausticsâ€•

Beth Y. Ginsburg MD
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 41, â€œVitaminsâ€•

Jeffrey A. Gold MD
Assistant Professor of Medicine
Department of Medicine; Medical Director of Critical Care, New York University School of Medicine, New York, New York

Chapter 76, â€œEthanol Withdrawalâ€•

David S. Goldfarb MD
Chief
Nephrology Section, New York Harbor Veterans Affairs Medical Center; Professor of Medicine, Physiology and Neuroscience, New York University School of Medicine; Consultant, New York City

Poison Center, New York, New York

Chapter 10, â€œPrinciples and Techniques Applied to Enhance Eliminationâ€•

Michael I. Greenberg MD, MPH, FAAEM, FACPM, FACOEM, FACMT
Professor of Emergency Medicine and Public Health
Drexel University College of Medicine, Philadelphia, Pennsylvania

Chapter 93, â€œNickelâ€•

Howard A. Greller MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, New York University School of Medicine; Consultant, New York City Poison Center, New York, New York

Chapter 68, â€œLithiumâ€•

Martin Griffel MD
Director
Cardiovascular ICU, Department of Anesthesiology, New York University Medical Center; Associate Professor of Anesthesiology, New York University School of Medicine, New York, New York

Chapter 65, â€œInhalational Anestheticsâ€•

David D. Gummin MD
Medical Director
Wisconsin Poison Center, Children's Hospital of Wisconsin; Assistant Clinical Professor, Medical College of Wisconsin; Attending Emergency Physician, Infinity HealthCare Incorporated, Milwaukee, Wisconsin

Chapter 102, â€œHydrocarbonsâ€•

Jason B. Hack MD
Associate Chair
Division of Medical Toxicology; Assistant Professor, Department of Emergency Medicine, Brody Medical School at East Carolina University, Greenville, North Carolina

Chapter 62, â€œCardioactive Steroidsâ€•

In-Hei Hahn MD
Assistant Professor of Clinical Medicine
Columbia University College of Physicians and Surgeons; Associate Attending Emergency Physician; Assistant Director of Research, St. Luke'sâ€“Roosevelt Hospital Center, New York, New York

Chapter 115, â€œArthropodsâ€•

S. Eliza Halcomb MD
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 42, â€œEssential Oilsâ€•

Christine A. Haller MD
Assistant Adjunct Professor of Medicine and Laboratory Medicine; Assistant Medical Director
San Francisco Division, California Poison Control System, San Francisco General Hospital, San Francisco, California

Chapter 39, â€œDieting Agents and Regimensâ€•

Richard J. Hamilton MD
Associate Professor of Emergency Medicine; Program Director of Emergency Medicine
Drexel University College of Medicine, Philadelphia, Pennsylvania

Chapter 15, â€œWithdrawal Principlesâ€•

Robert G. Hendrickson MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, Oregon Health and Science University; Associate Medical Director, Oregon Poison Center, Portland, Oregon

Chapter 34, â€œAcetaminophenâ€•

Fred M. Henretig MD
Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine; Director, Section of Clinical Toxicology, Division of Emergency Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Chapter 91, â€œLeadâ€•

Robert A. Hessler MD
Associate Professor of Emergency Medicine
New York University School of Medicine; Assistant Director, Department of Emergency Medicine, Bellevue Hospital Center, New York, New York

Chapter 23, â€œCardiovascular Principlesâ€•

Aaron Hexdall MD
Assistant Professor of Emergency Medicine; Co-Director
International Emergency Medicine, Bellevue Hospital Center, Department of Emergency Medicine, New York University School of Medicine, New York, New York

Chapter 131, â€œInternational Perspectives in Medical Toxicologyâ€•

Lotte C. G. Hoegberg MS(Pharm), PhD
Department of International Health, Centre for Medical Parasitology, University of Copenhagen, Copenhagen, Denmark

Chapter 8, â€œTechniques Used to Prevent Gastrointestinal Absorptionâ€•

Robert J. Hoffman MD
Research Director
Beth Israel Medical Center; Assistant Clinical Professor, Department of Emergency Medicine, Albert Einstein College of Medicine; Consultant, New York City Poison Center, New York, New York

Chapter 63, â€œMethylxanthines and Selective Î²2 Adrenergic Agonistsâ€•

Michael G. Holland MD
Clinical Assistant Professor of Emergency Medicine
State University of New York, Upstate Medical University; Consultant Medical Toxicologist, Central New York Poison Center, Syracuse, New York; Occupational Medical Director, Glens Falls Hospital, Glens Falls, New York

Chapter 110, â€œInsecticides: Organic Chlorines, Pyrethrins/Pyrethroids and DEETâ€•

Christopher P. Holstege MD
Director
Division of Medical Toxicology; Medical Director, Blue Ridge Poison Center; Associate Professor, Departments of Emergency Medicine and Pediatrics, University of Virginia, Charlottesville, Virginia

Chapter 121, â€œCyanide and Hydrogen Sulfideâ€•

Chapter 123, â€œSmoke Inhalationâ€•

Daniel O. Hryhorczuk MD
Professor and Director
Great Lakes Centers for Occupational and Environmental Safety and Health, University of Illinois at Chicago School of Public Health; Director, Toxikon Consortium; Chief of Clinical Toxicology, Cook County Hospital, Chicago, Illinois

Chapter 102, â€œHydrocarbonsâ€•

Oliver L. Hung MD
Attending Physician
Department of Emergency Medicine, Morristown Memorial Hospital, Morristown, New Jersey

Chapter 43, â€œHerbal Preparationsâ€•

Gary E. Isom PhD
Professor of Toxicology
Department of Medicinal Chemistry and Molecular Pharmacology, School of Pharmacy and Pharmaceutical Sciences, Purdue University, West Lafayette, Indiana

Chapter 121, â€œCyanide and Hydrogen Sulfideâ€•

David N. Juurlink MD, PhD
Assistant Professor of Medicine
Pediatrics and Clinical Epidemiology, University of Toronto; Attending Physician, Divisions of General Internal Medicine, Clinical Pharmacology, and Toxicology, Sunnybrook and Women's College Health Sciences Centre; Clinical Toxicologist, Ontario Regional Poison Information Centre, Toronto, Ontario

Chapter 67, â€œAntipsychoticsâ€•

Brian Kaufman MD
Associate Professor of Anesthesiology

Medicine, and Neurosurgery, New York University School of Medicine; Director, Critical Care Section, Department of Anesthesiology, New York University Medical Center, New York, New York

Chapter 64, â€œLocal Anestheticsâ€•

Chapter 65, â€œInhalational Anestheticsâ€•

Chapter 66, â€œNeuromuscular Blockersâ€•

Antidote in Depth A20, â€œDantrolene Sodiumâ€•

Mark A. Kirk MD
Director
Medical Toxicology Fellowship, Division of Medical Toxicology; Associate Medical Director, Blue Ridge Poison Center; Assistant Professor, Departments of Emergency Medicine and Pediatrics, University of Virginia, Charlottesville, Virginia

Chapter 11, â€œIntensive Careâ€•

Chapter 121, â€œCyanide and Hydrogen Sulfideâ€•

Chapter 123, â€œSmoke Inhalationâ€•

Barbara M. Kirrane MD
Fellow in Medical Toxicology
Department of Emergency Medicine, New York University School of Medicine, New York City Poison Center, New York, New York

Chapter 135, â€œRisk Management and Legal Principlesâ€•

Kurt C. Kleinschmidt MD
Associate Professor of Surgery
Division of Emergency Medicine; Director, Toxicology Fellowship Program, University of Texas Southwestern Medical Center, Emergency Department; Associate Medical Director, Parkland

Memorial Hospital, Dallas, Texas

Chapter 13, â€œBiochemical and Metabolic Principlesâ€•

Lada Kokan MD
Kaiser Permanente, San Francisco, San Francisco, California

Chapter 69, â€œMonoamine Oxidase Inhibitorsâ€•

Donald P. Kotler MD
Chief
Gastrointestinal Division, St. Luke'sâ€“Roosevelt Hospital Center; Professor of Medicine, Columbia University College of Physicians and Surgeons, New York, New York

Chapter 25, â€œGastrointestinal Principlesâ€•

Edwin K. Kuffner MD
Assistant Clinical Professor
University of Colorado; Attending Toxicologist, Rocky Mountain Poison and Drug Center, Denver, Colorado

Chapter 77, â€œDisulfiram and Disulfiramlike Reactionsâ€•

Chapter 99, â€œCamphor and Moth Repellentsâ€•

Melisa W. Lai MD
Fellow in Medical Toxicology
Regional Center for Poison Control and Prevention serving Massachusetts and Rhode Island, Harvard Medical School, Boston, Massachusetts

Chapter 95, â€œSilverâ€•

David C. Lee MD
Director of Research
Department of Emergency Medicine, North Shore University

Hospital, Manhasset, New York; Assistant Professor of Emergency Medicine, New York University School of Medicine, New York, New York

Chapter 72, â€œSedative-Hypnoticsâ€•

Erica L. Liebelt MD
Associate Professor of Pediatrics and Emergency Medicine
University of Alabama School of Medicine at Birmingham; Director, Medical Toxicology Services, Children's Hospital and University of Alabama Hospital, Birmingham, Alabama

Chapter 71, â€œCyclic Antidepressantsâ€•

Heather Long MD
Attending Physician
Department of Emergency Medicine, North Shore University Hospital, Manhasset, New York; Consultant, New York City Poison Center

Chapter 79, â€œInhalantsâ€•

Daniel Matalon MD
Fellow in Nephrology
Department of Medicine, New York University School of Medicine, New York, New York

Chapter 10, â€œPrinciples and Techniques Applied to Enhance Eliminationâ€•

Michael McGuigan MD, CM, MBA
Professor of Clinical Emergency Medicine
State University of New York, Stony Brook, New York; Medical Director, Long Island Regional Poison and Drug Information Center, Winthrop University Hospital, Mineola, New York

Chapter 81, â€œCannabinoidsâ€•

Charles McKay MD
Associate Medical Director
Connecticut Poison Control Center; Associate Professor of Emergency Medicine, University of Connecticut School of Medicine; Chief, Division of Medical Toxicology, Department of Traumatology and Emergency Medicine, Hartford, Connecticut

Chapter 124, â€œRisk Assessment and Risk Communicationâ€•

Maria Mercurio-Zappala RPh, MS
Managing Director
New York City Poison Center, New York, New York

Chapter 96, â€œThalliumâ€•

Sanford M. Miller MD
Clinical Associate Professor of Anesthesiology
Department of Anesthesiology, New York University School of Medicine; Assistant Director of Anesthesiology, Bellevue Hospital Center, New York, New York

Chapter 66, â€œNeuromuscular Blockersâ€•

Antidotes in Depth A20, â€œDantrolene Sodiumâ€•

Kirk C. Mills MD
Associate Residency Director
Emergency Medicine, Department of Emergency Medicine, Wayne State University, Detroit Receiving Hospital, Detroit, Michigan

Chapter 14, â€œNeurotransmitters and Neuromodulatorsâ€•

Heikki E. Nikkanen MD
Attending Physician
Medical Toxicology, Children's Hospital Boston; Attending Physician, Department of Emergency Medicine, Brigham and Women's Hospital; Instructor in Medicine, Harvard Medical School, Boston, Massachusetts

Chapter 107, â€œPhosphorusâ€•

Sean Patrick Nordt MD, PharmD
Resident
Division of Emergency Medicine, Departments of Surgery and Pediatrics, University of Maryland, Baltimore, Maryland

Chapter 53, â€œPharmaceutical Additivesâ€•

Ruben Olmedo MD
Assistant Professor of Emergency Medicine
Mount Sinai School of Medicine; Chief, Division of Toxicology, Department of Emergency Medicine, Mount Sinai School of Medicine, New York, New York

Chapter 83, â€œPhencyclidine and Ketamineâ€•

Kevin C. Osterhoudt MD, MSCE
Associate Professor of Pediatrics; Associate Scholar
Center for Clinical Epidemiology and Biostatistics, University of Pennsylvania School of Medicine; Medical Director, Poison Control Center, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Chapter 132, â€œPrinciples of Epidemiology and Research Designâ€•

Edward J. Otten MD
Professor of Emergency Medicine and Pediatrics; Director

Division of Toxicology, University of Cincinnati College of Medicine, Cincinnati, Ohio

Chapter 117, â€œSnakes and Other Reptilesâ€•

Antidotes in Depth A33, â€œAntivenom (Crotaline and Elapid)â€•

Mary E. Palmer MD
Assistant Professor of Emergency Medicine
George Washington University School of Medicine, Washington, District of Columbia

Chapter 114, â€œPlantsâ€•

Jeanmarie Perrone MD
Director
Division of Toxicology, Department of Emergency Medicine, University of Pennsylvania School of Medicine; Associate Professor of Emergency Medicine, Pediatrics, and Laboratory Medicine, University of Pennsylvania School of Medicine; Attending Physician, Emergency Department, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Chapter 40, â€œIronâ€•

Anthony F. Pizon MD
Fellow in Medical Toxicology
Department of Medical Toxicology, Banner Good Samaritan Medical Center, Phoenix, Arizona

Chapter 117, â€œSnakes and Other Reptilesâ€•

Antidotes in Depth A33, â€œAntivenom (Crotaline and Elapid)â€•

J. Samuel Pope MD

Fellow in Pulmonary and Critical Care Medicine
Department of Internal Medicine, University of Virginia, Charlottesville, Virginia

Chapter 11, â€œIntensive Careâ€•

Dennis Price MD
Assistant Professor of Emergency Medicine
New York University School of Medicine; Attending Physician, Department of Emergency Medicine, Bellevue Hospital Center, New York, New York

Chapter 122, â€œMethemoglobin Inducersâ€•

Lawrence S. Quang MD
Assistant Professor of Pediatrics
Case Western Reserve University, School of Medicine; Medical Director, Greater Cleveland Poison Control Center, Division of Pediatric Pharmacology and Critical Care, Rainbow Babies and Children's Hospital, University Hospitals of Cleveland, Cleveland, Ohio

Chapter 78, â€œÎ³ Hydroxybutyric Acidâ€•

Petrie M. Rainey MD, PhD
Professor of Laboratory Medicine; Head
Division of Clinical Chemistry; Director, Clinical Chemistry Laboratory; Director, Toxicology Laboratory, Department of Laboratory Medicine, University of Washington School of Medicine, Seattle, Washington

Chapter 7, â€œLaboratory Principlesâ€•

Rama B. Rao MD
Assistant Professor of Emergency Medicine and Forensic Pathology
Department of Emergency Medicine, New York University School of

Medicine; Consultant, New York City Poision Center, New York, New York

Chapter 19, â€œNeurologic Principlesâ€•

Chapter 33, â€œPostmortem Toxicologyâ€•

Chapter 86, â€œBismuthâ€•

Chapter 100, â€œCausticsâ€•

Chapter SC-1, â€œSpecial Considerations: Organ Procurement from Poisoned Patientsâ€•

Joseph Rella MD
Assistant Professor of Emergency Medicine
University of Medicine and Dentistry of New Jersey, New Jersey Medical School; Attending Physician, Department of Emergency Medicine, The University Hospital, Newark, New Jersey

Chapter 128, â€œRadiationâ€•

Bradley D. Riley MD
Fellow in Medical Toxicology
Department of Medical Toxicology, Banner Good Samaritan Medical Center, University of Arizona College of Medicine, Phoenix, Arizona

Chapter 117, â€œSnakes and Other Reptilesâ€•

Antidotes in Depth A33, â€œAntivenom (Crotaline and Elapid)â€•

James R. Roberts MD
Chair
Emergency Medicine, Mercy Catholic Medical Center; Professor and Vice Chair, Emergency Medicine, Drexel University College of Medicine, Philadelphia, Pennsylvania

Chapter 117, â€œSnakes and Other Reptilesâ€•

Antidotes in Depth A33, â€œAntivenom (Crotaline and Elapid)â€•

Anne-Michelle Ruha MD
Associate Fellowship Director
Department of Medical Toxicology, Banner Good Samaritan Medical Center; Clinical Assistant Professor, Department of Emergency Medicine, University of Arizona College of Medicine, Phoenix, Arizona

Chapter 14, â€œNeurotransmitters and Neuromodulatorsâ€•

Chapter 117, â€œSnakes and Other Reptilesâ€•

Antidotes in Depth A33, â€œAntivenom (Crotaline and Elapid)â€•

Morton E. Salomon MD
Chairman
Department of Emergency Medicine, St. Vincent's Medical Center, Bridgeport, Connecticut; Professor of Clinical Emergency Medicine; Associate Professor of Pediatrics, Albert Einstein College of Medicine, Bronx, New York

Chapter 82, â€œNicotine and Tobacco Preparationsâ€•

Joshua G. Schier MD
Medical Toxicologist
Centers for Disease Control and Prevention, Medical Toxicology Attending, Medical Toxicology Fellowship; Assistant Professor of Emergency Medicine, Emory University School of Medicine, Atlanta, Georgia

Chapter 37, â€œColchicine and Podophyllinâ€•

David R. Schwartz MD
Section Chief
Critical Care Medicine; Assistant Professor of Medicine, New York University School of Medicine, New York, New York

Chapter 64, â€œLocal Anestheticsâ€•

David T. Schwartz MD
Associate Professor of Emergency Medicine
New York University School of Medicine; Attending Physician, Department of Emergency Medicine, New York University Medical Center/Bellevue HospitalCenter, New York, New York

Chapter 6, â€œDiagnostic Imagingâ€•

Lauren Schwartz MPH
Public Education Coordinator
New York City Poison Center, New York, New York

Chapter 129, â€œPoison Prevention and Educationâ€•

Mark R. Serper PhD
Associate Professor of Psychology
Hofstra University; Research Associate Professor of Psychiatry, New York University School of Medicine, New York, New York

Chapter 18, â€œPsychiatric Principlesâ€•

Adhi Sharma MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine, Mount Sinai School of Medicine, Elmhurst Hospital Center, Elmhurst, New York; Consultant, New York City Poison Center, New York, New York

Chapter 20, â€œOphthalmic Principlesâ€•

Marco L. A. Sivilotti MD, MSc
Consultant
Ontario Regional Poison Information Center, Hospital for Sick Children, Toronto; Assistant Professor, Departments of Emergency Medicine, Pharmacology, and Toxicology, Queen's University, Kingston, Ontario, Canada

Chapter 24, â€œHematologic Principlesâ€•

Martin J. Smilkstein MD
Adjunct Associate Professor
Department of Emergency Medicine, Oregon Health and Science University; Research Associate, Portland VA Medical Center; Research Professor, Department of Chemistry, Portland State University, Portland, Oregon

Chapter 20, â€œOphthalmic Principlesâ€•

Christine M. Stork PharmD
Clinical Associate Professor; Director
Central New York Poison Control Center, Department of Emergency Medicine, University Hospital, State University of New York Health Science Center, Syracuse, New York

Chapter 54, â€œAntibiotics, Antifungals, and Antiviralsâ€•

Chapter 70, â€œSerotonin Reuptake Inhibitors and Atypical Antidepressantsâ€•

Mark Su MD
Assistant Professor of Emergency Medicine; Assistant Residency Director; Director of Medical Toxicology
State University of New York, Downstate Medical Center, Kings County Hospital Center, Brooklyn, New York; Consultant, New York City Poison Center

Chapter 57, â€œAnticoagulantsâ€•

Chapter 101, â€œHydrofluoric Acid and Fluoridesâ€•

Jeffrey R. Suchard MD
Associate Professor of Clinical Emergency Medicine
Department of Emergency Medicine, University of California Irvine Medical Center, Orange, California

Chapter 126, â€œChemical Weaponsâ€•

Chapter 127, â€œBiological Weaponsâ€•

Young-Jin Sue MD
Clinical Associate Professor
Division of Pediatric Emergency Medicine, Department of Pediatrics, Albert Einstein College of Medicine; Attending Physician, Pediatric Emergency Services, Children's Hospital at Montefiore, Bronx, New York

Chapter 92, â€œMercuryâ€•

Kenneth M. Sutin MD
Associate Professor of Anesthesiology and Surgery
Department of Anesthesiology, New York University School of Medicine; Director of Critical Care, Department of Anesthesiology, Bellevue Hospital Center, New York, New York

Chapter 66, â€œNeuromuscular Blockersâ€•

Antidotes in Depth A20, â€œDantrolene Sodiumâ€•

Asim F. Tarabar MD, MS
Assistant Professor of Surgery
Section of Emergency Medicine, Department of Surgery, Yale University School of Medicine, Yale New Haven Hospital, New Haven, Connecticut

Chapter 84, â€œAntimonyâ€•

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The editors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Editors: Flomenbaum, Neal E.; Goldfrank, Lewis R.; Hoffman, Robert S.; Howland, Mary Ann; Lewin, Neal A.; Nelson, Lewis S.
Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Dedicated to â€¦

The staffs of our hospital emergency departments who have worked with remarkable courage, concern, compassion, and understanding in treating the patients discussed in this text and many thousands more like them

The staff of the New York City Poison Control Center who have quietly and conscientiously integrated their skills with ours to serve these patients; and to the many others who never needed a hospital visit because of their efforts

To the memories of my parents Mollie and Lieutenant H. Stanley Flomenbaum whose constant encouragement to help others nonjudgmentally led me to consider toxicologic emergencies many years ago. To my wife Meredith Altman Flomenbaum, RNP, and to my children Adam, David, and Sari who have competed with this text for my attention but who have underscored the importance of these efforts

N. F.

To my children Rebecca, Jennifer, Andrew and Joan, Michelle and James; to my grandchildren Benjamin, Adam, Sarah, Kay, and Samantha who have kept me acutely aware of the ready availability of possible poisons; and to my wife, partner, and best friend Susan whose support was and is essential and whose

contributions will be found throughout the text

L. G.

To my wife Ali, my children Casey Jesse, my parents, my friends, family, and colleagues for their never-ending patience and forgiveness for the time spent away from them

R. H.

To my husband Bob; to my children Robert and Marcy; to my mother and to the loving memory of my father; and to family, friends, colleagues, and students for all their help and continuing inspiration

M. A. H.

To my wife Gail; to my children Justin and Jesse; for their support and patience; and to my parents, who made it possible

N. L.

To my wife Laura for her unwavering support; to my children Daniel, Adina, and Benjamin for their boundless enthusiasm and infinite wisdom; to my parents Dr. Irwin and Myrna Nelson for the foundation which they provided; and to my family and friends who keep me focused on that which is important

L. N.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Acknowledgments

We are grateful to Joan Demas, who not only helped manage the growth of this eighth edition and development but also transformed scrawl into manuscript with precision and dedication.

The many letters and verbal communications we have received with the reviews of the previous editions of this book continue to improve our efforts. We are deeply indebted to our friends, associates, and students, who stimulated us to begin this book with their questions and then faithfully criticized our answers.

We appreciate the compulsive and critical review of the entire seventh edition by Dr. Steven C. Curry, which has improved this edition. We appreciate the detailed and thoughtful analysis of the acetaminophen chapter by Barry H. Rumack. We appreciate the careful and thoughtful review of the pralidoxime antidote in depth by Professor Dr. Peter Eyer of the Walter-Straub-Institute of Pharmacology and Toxicology at the Ludwig-Maximilians-University, Munich, Germany. We are indebted to Michael Eddleston for his thoughtful editing with regard to the management of organic phosphorus pesticides.

We thank the many volunteers, students, librarians, and particularly the St. John's University College of Pharmacy students and drug information staff who provide us with vital technical assistance in our daily attempts to deal with toxicologic

emergencies.

No words can adequately express our indebtedness to the many authors who worked on earlier editions of many of the chapters in this book. As different authors write and rewrite topics with each new edition, we recognize that without the foundation work of their predecessors this book would not be what it is today.

We appreciate the conscientious and tireless work of James Semidey, who has found so many essential articles and prepared so many copies for editorial review.

We thank Doson Chua, BSc(Pharm), and Dr. Heather D'Oyley for assistance with Lada Kokan's research; we thank Eric Schweiger for his assistance with Dina Began's research.

We gratefully acknowledge the contributions of Oliver Hung, MD, to the alkaline diuresis section and Donald Feinfeld, MD, to the renal pathophysiology and extracorporeal management sections of the chapter on salicylates. We appreciate the contribution of Dawn Hui and Nadine Levick to the analysis of the Web-based Injury Statistics Query and Reporting System (WIQARS) database. We appreciate David T. Schwartz's analytic discussion of diagnostic imaging in the chapter on caustics. Dr. Patrick Croskerry is indebted to his pharmacist colleagues Drs. David U, Neil MacKinnon, and David Rosenbloom for helpful comments and suggestions in the preparation of his chapter; he gratefully acknowledges the assistance of Sherri Lamont at Dartmouth General Hospital and Pamela Gray at the Department of Emergency Medicine at Dalhousie University and the support provided to him by a Senior Clinical Research Fellowship from Dalhousie University. The authors of the chapter on neuromuscular blockers appreciate the thoughtful comments of Dr. Aaron F. Kopman, Department of Anesthesiology, St. Vincent's Hospital, New York.

We greatly appreciate the artistic efforts of Joseph Lewy, graphic

designer who created several of our new graphics.

We appreciate the calm, thoughtful, and cooperative spirit of Karen Edmonson at McGraw-Hill. Her intelligence and commitment to our efforts has been wonderful. We are pleased with the creative copy editing efforts of Freelance Editorial Services. We greatly appreciate the compulsion and rigor that Kathi Unger has applied to make this edition's index one of unique value. We appreciate the editorial leadership and assistance offered by Peter Boyle.

Editors: Flomenbaum, Neal E.; Goldfrank, Lewis R.; Hoffman, Robert S.; Howland, Mary Ann; Lewin, Neal A.; Nelson, Lewis S.
Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Preface

In this eighth edition of *Goldfrank's Toxicologic Emergencies*, we continue to proudly offer readers an approach to medical toxicology based on case studies. The addition of almost 30 new chapters and five Antidotes in Depth and the elimination of seven other chapters are a reflection of major advances, changes in understanding new intellectual approaches, and of the ever expanding role of toxicologists at the beginning of the twenty-first century.

We have expanded the number of authors in this edition and have reassigned more than 15 percent of the chapters in an attempt to capture new and unique perspectives on toxicology. Critical events and concerns at the turn of the new century led us to add a chapter on chemical and biological weapons to the seventh edition, which we now have expanded into two independent chapters. We have also tried to prepare an appropriate context for discussing these issues more effectively by adding a chapter on risk assessment and risk communication.

The increasing emphasis on improving our use of medications is reflected by new chapters on patient safety and poison prevention that focus on public health, the potential of medical informatics, and the critical roles that providers play in improving clinical care.

We have added a new chapter on international toxicology that

describes the worldwide epidemiology of toxicology and further added to our international focus by enlisting international authors to broaden the scope of many chapters.

Goldfrank's Toxicologic Emergencies, originally a collection of medical toxicology case discussions by two authors, is now a multi-authored text of more than 2000 pages prepared by utilizing the principles we apply at the New York City Poison Center. As the text has expanded in size and scope over the past two decades, we have sought to address issues in medical toxicology in unique and creative ways that would continue to make the book a valuable resource to the growing number of clinicians and researchers working in the field. In the second edition of our text (1982), we expanded the case study material to make the work a more comprehensive clinical resource. In the third edition (1986), we added an organ-system approach to medical toxicology and also began a series of Antidotes in Depth to provide specific detailed information about newer and, in some cases, experimental antidotes. In the fourth edition (1990), we expanded both of these newer sections and began to address such subjects as nursing care, medical-legal issues, and the toxicology of AIDS treatments. For the fifth edition (1994), we added a section addressing the needs of special populations, including reproductive, perinatal, pediatric and geriatric principles, and intensive care unit patients; we also began to extensively expand basic science issues such as neurotransmitters and biochemical and metabolic pathways.

In the last two editions we have continued our analytic approach to medical toxicology by adding, fusing, and splitting chapters based on the evolving educational principles and in response to reviews by and suggestions of our many readers and colleagues. For example, a single chapter on metals in prior editions has been divided into separate chapters on antimony, bismuth, cadmium, chromium, cobalt, copper, selenium, silver, and zinc in order to describe these important elements and other related xenobiotics in greater detail. Similarly, the single chapter on rodenticides has

been divided into an introductory discussion of rodenticides among other pesticides followed by detailed discussions of barium, monofluoroacetate and fluoroacetamide, phosphorus, and strychnine.

The appearance of the eighth edition marks our first extensive use of the â€œelectronic deliveryâ€• of the text. The complete â€œtextâ€• now consists of a hard copy component that faithful readers can read and consult as they have previously and also an electronic component available by pass code and user registration to *Goldfrank's Toxicologic Emergencies* Web site (http://www.goldfrankstoxicology.com). The electronic version includes six core chapters with a large number of faithfully reproduced visual images that are critical to the understanding of these chapters. The six chapters are Dermatology, Plants, Mushrooms, Marine Envenomations, Snakes, and Arthropods. Electronic delivery allows us to offer you a large selection of pertinent images for these highly visual chapters as well as several other valuable images.

Similarly, the workbook including case studies and annotated multiple choice questions will now be available on this Web site. Some of the cases are still relevant classic examples of toxicologic emergencies from previous editions, and the remainder are new, extensively discussed cases from our regional monthly meetings at the New York City Poison Center. The collective wisdom of many of the current and former text authors continues to guide these sessions as it has for more than 20 years. Lewis Nelson and Robert Hoffman have analyzed these problems, distilled the discussions, and recreated the spirit of these meetings in the printed versions of the cases. As previously, 10 annotated multiple choice questions based on each chapter were developed by the respective chapter authors in an attempt to enhance self-learning and meet the intellectual needs of our readers.

All our principles developed in detail in the textbook and workbook

will be adapted into a concise handbook of medical toxicology. We expect this lighter and less expensive version of our text to be more portable and affordable yet equally rigorous. We hope this new approach to the description of medical toxicology will be useful for students and many others who may not as yet be fully committed to an in-depth study of our field.

After long and serious discussions in preparation of the seventh edition we came to the conclusion that the format of utilizing cases to begin each chapter in: *Part C. The Clinical Basis of Medical Toxicology* is an important and useful feature that distinguishes our text from others and therefore should be retained. At the same time, we decided that the ease with which readers can find needed information in a traditionally organized comprehensive medical textbook is also valuable. We have therefore formatted each chapter into standard sections to allow readers to find essential information easily when reviewing a topic or preparing for and treating a toxicologic emergency. Most chapters in this section now begin with a case followed by a brief Introduction, the History and Epidemiology, Pharmacology, Pharmacokinetics and Toxicokinetics, Pathophysiology, Clinical Manifestations, Diagnostic Testing, and Management, concluding with a brief summary.

The usefulness of this chapter organization is improved by our further development of the indexing features of the text. The index has now been restructured in such a way that each chapter component is listed under the aforementioned subheads and includes almost all cross-references from other chapters within their subheads. Additional alphabetical listings of unique and important terms are also retained.

Even more than previously, the rewriting and reorganization of this edition of the text has required an enormous personal effort by each author which we hope will facilitate your learning, reading and patient care. Work on the next edition of this text literally begins the day that the current edition is published. Although

many of the chapters in this eighth edition may appear familiar to readers of previous editions, every chapter has been discussed, analyzed, criticized, dissected, updated, and rewritten accordingly by its old or new authors.

Although â€œtearing downâ€• and reconstructing the text between each edition may seem like an extreme exercise to some, only in this manner can we hope to prevent ourselves from accepting and promulgating unfounded treatments and outdated concepts. We hope that you agree that this exercise is worthwhile and that each â€œnew textâ€• continues to serve you well. As always, we encourage your comments and thoughtful criticism, and we will do our best once again to incorporate your suggestions into future editions.

If this text helps to provide better patient care and stimulates interest in medical toxicology by students of medicine, nursing, and pharmacy; by residents in emergency medicine, internal medicine, pediatrics, preventive health, critical care, family practice, and others; by fellows in medical and clinical toxicology; and by attending physicians and faculty, as well as diverse toxicologists, then our efforts; will have indeed been worthwhile.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Table of Antidotes in Depth

Readers of previous editions of Goldfrank's Toxicologic Emergencies *are undoubtedly aware that the editors have always felt that an emphasis on general management of poisoning or overdoses coupled with sound medical management is more important or as important as the selection and use of a specific antidote in the vast majority of cases. Nevertheless, there are some instances where nothing other than the timely use of a specific antidote or antagonist will save a patient. For this reason, and also because the use of such antidotes may be problematic, controversial, or unfamiliar to the practitioner (as new antidotes continue to emerge), we have included a section (or sections) at the end of each chapter where an in-depth discussion of such antidotes is relevant. The following Antidotes in Depth are included in this edition.*

Anthony F. Pizon, Bradley D. Riley, Anne-Michelle Ruha, James R. Roberts, Edward J. Otten

- Antivenom (Scorpion and Spider)
  Jeffrey N. Bernstein
- Atropine
  Mary Ann Howland
- Botulinum Antitoxin
  Lewis R. Goldfrank
- Calcium
  Mary Ann Howland
- L-Carnitine
  Mary Ann Howland
- Dantrolene Sodium
  Kenneth M. Sutin, Brian Kaufman, and Sanford M. Miller
- Deferoxamine
  Mary Ann Howland
- Dextrose
  Larissa I. Velez and Kathleen A. Delaney
- Digoxin-Specific Antibody Fragments (Fab)
  Mary Ann Howland
- Dimercaprol (British Anti-Lewisite or BAL)
  Mary Ann Howland
- Edetate Calcium Disodium ($CaNa_2EDTA$)
  Mary Ann Howland
- Ethanol
  Mary Ann Howland
- Flumazenil
  Mary Ann Howland
- Fomepizole

- Sodium Thiosulfate
  Mary Ann Howland
- Succimer (2,3-Dimercaptosuccinic Acid)
  Mary Ann Howland
- Syrup of Ipecac
  Mary Ann Howland
- Thiamine Hydrochloride
  Robert S. Hoffman
- Vitamin K_1
  Mary Ann Howland
- Whole-Bowel Irrigation and Other Intestinal Evacuants
  Mary Ann Howland

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 1

Historical Principles and Perspectives

Paul M. Wax

The term *poison* first appeared in the English literature around the year 1230 A.D. to describe a potion or draught that was prepared with deadly ingredients.[42 , 141] The history of poisons and poisoning, however, dates back thousands of years. Throughout the millennia, poisons have played an important role in human historyâ€”from political assassination in Roman times, to weapons of war, to contemporary environmental concerns, and to weapons of terrorism.

This chapter offers a perspective on the impact of poisons and poisoning on history. It also provides a historic overview of human understanding of poisons and the development of toxicology from antiquity to the present. The development of the modern poison control center, the genesis of the field of medical toxicology, and the recent increasing focus on medication errors and biologic and chemical weapons are examined. An Antidote in Depth at the end of the chapter scrutinizes changes in poison management over the years, analyzing obsolete antidotes and other discarded

therapeutic modalities. Chapter 2 describes poison plagues and unintentional disasters throughout history and examines the societal consequences of these unfortunate events. An appreciation of past failures and mistakes in dealing with poisons and poisoning promotes a keener insight and a more critical evaluation of present-day toxicologic issues, and helps in the assessment and management of future toxicologic problems.

Poisons, Poisoners, and Antidotes of Antiquity

The earliest poisons consisted of plant extracts, animal venoms, and minerals. They were used for hunting, waging war, and sanctioned and unsanctioned executions. The *Ebers Papyrus* , an ancient Egyptian text written about 1500 B.C. that is considered to be among the earliest medical texts, describes many ancient poisons, including aconite, antimony, arsenic, cyanogenic glycosides, hemlock, lead, mandrake, opium, and wormwood.[94 , 141] These poisons were thought to have mystical properties, and their use was surrounded by superstition and intrigue. Some agents, such as the Calabar bean (*Physostigma venenosum*) containing physostigmine, were referred to as â€œordeal poisons.â€• Ingestion of these substances was believed to be lethal to the guilty and harmless to the innocent.[94] The â€œpenalty of the peachâ€• involved the administration of peach pits, which we now know contain the cyanide precursor amygdalin, as an ordeal poison. Magicians, sorcerers, and religious figures were the toxicologists of antiquity. The Sumerians, in about 4500 B.C., were said to worship the deity Gula, who was known as the â€œmistress of charms and spellsâ€• and the â€œcontroller of noxious poisonsâ€• (Table 1-1).[141]

Arrow and Dart Poisons

The prehistoric Masai hunters of Kenya, who lived 18,000 years ago, used arrow and dart poisons to increase the lethality of their weapons.[20] One of these poisons appears to have consisted of extracts of *Strophanthus* species, an indigenous plant that contains strophanthin, a digitalis-like substance.[94] Cave paintings of arrowheads and spearheads reveal that these weapons were crafted with small depressions at the end to hold the poison.[142] In fact, the term *toxicology* is derived from the Greek terms *toxikos* (â€œbowâ€•) and *toxikon* (â€œpoison into which arrowheads are dippedâ€•).[8 , 142]

References to arrow poisons are cited in a number of other important literary works. The ancient Indian text *Rig Veda* , written in the 12th century B.C., refers to the use of *Aconitum* species for arrow poisons.[20] In the *Odyssey* , Homer (ca. 850 B.C.) wrote that Ulysses anointed his arrows with a variety of poisons, including extracts of *Helleborus orientalis* (thought to act as a heart poison) and snake venoms.[109] Aristotle (384â€“322 B.C.) described how the Scythians prepared and used arrow poisons.[143] Finally, reference to weapons poisoned with the blood of serpents can be found in the writings of Ovid (43 B.C.â€“ 18 A.D.).[148]

Classification of Poisons

The first attempts at poison identification and classification, and the introduction of the first antidotes, took place during Greek and Roman times. An early categorization of poisons divided them into fast poisons, such as strychnine, and slow poisons, such as arsenic. In his treatise, *Materia Medica* , the Greek physician Dioscorides (40â€“80 A.D.), categorized poisons by their origin: animal, vegetable, or mineral.[142] This categorization remained the standard classification for the next 1500 years.[142]

Animal Poisons

Animal poisons usually referred to the venom from poisonous animals. Although the venom from poisonous snakes has always been among the most commonly feared poisons, poisons from toads, salamanders, jellyfish, stingrays, and sea hares are also of concern. Nicander of Colophon (204â€“135 B.C.), a Greek poet and physician who is considered to be one of the earliest toxicologists, experimented with animal poisons on condemned criminals.[128] Nicander's poems *Theriaca* and *Alexipharmaca* are considered to be the earliest extant Greek toxicologic texts, describing the presentations and treatment of poisonings from animal

toxins.[141] A notable fatality from the effects of an animal toxin was Cleopatra (69â€“30 B.C.), who reportedly committed suicide by deliberately falling on an asp.[72]

Gula
ca. 4500 B.C.
First deity associated with poisons
Shen Nung
ca. 2000 B.C.
Chinese emperor who experimented with poisons and antidotes and wrote treatise on herbal medicine
Homer
ca. 850 B.C.
Wrote how Ulysses anointed arrows with the venom of serpents
Aristotle
384â€“322 B.C.
Described the preparation and use of arrow poisons
Theophrastus
ca. 370â€“286 B.C.
Referred to poisonous plants in *De Historia Plantarum*
Socrates
ca. 470â€“399 B.C.
Executed by poison hemlock

Nicander

204â€“135 B.C.

Wrote two poems that are among the earliest works on poisons: *Theriaca* and *Alexipharmaca*

King Mithridates VI

ca. 132â€“63 B.C.

Fanatical fear of poisons; developed mithradatum, one of first universal antidotes

Sulla

81 B.C.

Issued *Lex Cornelia*, the first antipoisoning law

Cleopatra

69â€“30 B.C.

Committed suicide from deliberate cobra envenomation

Andromachus

37â€“68 A.D.

Refined mithradatum; known as the Theriac of Andromachus

Dioscorides

40â€“80 A.D.

Wrote *Materia Medica*, which classified poison by animal, vegetable, and mineral

Galen

ca. 129â€“200 A.D.

Prepared â€œNut Theriacâ€• for Roman emperors, a remedy against bites, stings, and poisons; wrote *De Antidotis I* and *II*, which provided recipes for different antidotes, including mithradatum and panacea

Ibn Wahshiya

9th Century

Famed Arab toxicologist; wrote toxicology treatise *Book on Poisons*, combining contemporary science, magic, and astrology

Moses Maimonides

1135â€“1204

Wrote *Treatise on Poisons and Their Antidotes*

Petrus Abbonus
1250â€“1315
Wrote *De Venenis* , major work on poisoning

Person Date Importance

TABLE 1-1. Important Early Figures in the History of Toxicology

Vegetable Poisons

Theophrastus (ca. 370â€“286 B.C.) described vegetable poisons in his treatise *De Historia Plantarum* .[74] Notorious poisonous plants included *Aconitum* species (aconite, monkshood), *Conium maculatum* (poison hemlock), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Papaver somniferum* (opium poppy), and *Veratrum album* (hellebore). Aconite was among the most frequently encountered poisonous plants and was described as the â€œqueen mother of poisons.â€•[141] Hemlock was the official poison used by the Greeks and was employed in the execution of Socrates (ca. 470â€“399 B.C.) and many others.[130] Poisonous plants used in India at this time included *Cannabis indica* (marijuana), *Croton tiglium* (croton oil), and *Strychnos nux vomica* (poison nut, strychnine).[74]

Mineral Poisons

The mineral poisons of antiquity consisted of the metals antimony, arsenic, lead, and mercury. Undoubtedly the most famous of these was lead. Lead was discovered as early as 3500 B.C. Although controversy continues about whether an epidemic of lead poisoning among the Roman aristocracy contributed to the fall of the Roman Empire, lead was certainly used extensively during this period.[54 , 108] In addition to its considerable use in plumbing, lead was also used in the production of food and drink containers.[61] It

was common practice to add lead directly to wine, or to intentionally prepare the wine in a lead kettle to improve its taste. Not surprisingly, chronic lead poisoning became widespread. Nicander described the first case of lead poisoning in the 2nd century B.C.[145] Dioscorides, writing in the 1st century A.D., noted that fortified wine was â€œmost hurtful to the nerves.â€•[145] Lead-induced gout (â€œsaturnine goutâ€•) may have also been widespread among the Roman elite.[108]

Gases

Although not animal, vegetable, or mineral in origin, the toxic effects of gases were also appreciated during antiquity. In the 3rd century B.C., Aristotle commented that â€œcoal fumes (carbon monoxide) lead to a heavy head and deathâ€•[71] and Cicero (106â€“43 B.C.) referred to the use of coal fumes in suicide and execution.

Poisoners of Antiquity

Given the increasing awareness of the toxic properties of some naturally occurring substances and the lack of analytical detection techniques, homicidal poisoning was common during Roman times. In an attempt to curtail this practice, in 81 B.C. the Roman dictator Sulla issued the first law against poisoning, the *Lex Cornelia* . According to its provisions, if convicted of poisoning, the perpetrator was sentenced to either loss of property and exile (if the perpetrator was of high social rank) or exposure to wild beasts (if the perpetrator was of low social rank). During this period, members of the aristocracy commonly employed â€œtastersâ€• to shield themselves from potential poisoners, a practice that was also in vogue during the reign of Louis XIV in 16th century France.[148]

One of the most infamous poisoners of Ancient Rome was Locusta, who was known to experiment on slaves with poisons, including

aconite, arsenic, belladonna, henbane, and poisonous fungi. In 54 A.D., Nero's mother, Agrippina, hired Locusta to poison Emperor Claudius (Agrippina's husband and Nero's stepfather) as part of a scheme to make Nero emperor. As a result of these activities, Claudius, who was a great lover of mushrooms, died from *Amanita phalloides* poisoning,[18] and in the next year, Britannicus (Nero's stepbrother) also became one of Locusta's victims. In this case, Locusta managed to fool the taster by preparing unusually hot soup that required additional cooling after the soup had been officially tasted. At the time of cooling, the poison was surreptitiously slipped into the soup. Almost immediately after drinking the soup Britannicus collapsed and died. The exact poison remains debatable, but some authorities suggest that it was a cyanogenic glycoside.[134]

Early Quests for the Universal Antidote

The recognition, classification, and use of poisons in Ancient Greece and Rome were accompanied by an intensive search for a universal antidote. In fact, many of the physicians of this period

devoted significant parts of their careers to this endeavor.[141] Mystery and superstition surrounded the origin and source of these proposed antidotes. One of the earliest specific references to a protective agent can be found in Homer's *Odyssey* , when Ulysses is advised to protect himself by taking the antidote â€œmoli.â€• Recent speculation suggests that moli referred to *Galanthus nivalis* , which contains a cholinesterase inhibitor. This agent could have been used as an antidote against poisonous plants such as *Datura stramonium* (jimsonweed) that contain the anticholinergic alkaloids scopolamine, atropine, and hyoscyamine.[115]

Theriacs and the Mithradatum

The Greeks referred to the universal antidote as the *alexipharmaca*

or *theriac* .[141] The term *alexipharmaca* was derived from the words *alexipharmakos* (â€œwhich keeps off poisonâ€•) and *antipharmakon* (â€œantidoteâ€•). Over the years, *alexipharmaca* increasingly was used to refer to a method of treatment, such as the induction of emesis by using a feather. *Theriac* , which originally had referred to poisonous reptiles or wild beasts, was later used to refer to the antidotes. Consumption of the early theriacs (ca. 200 B.C.) was reputed to make people â€œpoison-proofâ€• against bites of all venomous animals except the asp. Their ingredients included aniseed, anmi, apoponax, fennel, meru, parsley, and wild thyme.[141]

The quest for the universal antidote was epitomized by the work of King Mithradates VI of Pontus (132â€“63 B.C.).[73] After repeatedly being subjected to poisoning attempts by his enemies during his youth, Mithradates sought protection by the development of universal antidotes. To find the best antidote, he performed acute toxicity experiments on criminals and slaves. The theriac he concocted, known as the â€œmithradatum,â€• contained a minimum of 36 ingredients and was thought to be protective against aconite, scorpions, sea slugs, spiders, vipers, and all other poisonous substances.[71] Mithradates took his concoction every day. Ironically, when an old man, Mithradates attempted suicide by poison but supposedly was unsuccessful because he had become poison-proof. Having failed at self-poisoning, Mithradates was compelled to have a soldier kill him with a sword. Galen described Mithradates' experiences in a series of three books: *De Antidotis I, De Antidotis II* , and *De Theriaca ad Pisonem* .[73 , 146]

The Theriac of Andromachus, also known as the â€œVenice treacleâ€• or â€œgalene,â€• is probably the most famous theriac. According to Galen, this preparation, formulated during the 1st century A.D., was considered an improvement over the mithradatum.[146] It was prepared by Andromachus (37â€“68 A.D.), physician to Emperor Nero. Andromachus added to the mithradatum ingredients such as the flesh of vipers, squills, and

generous amounts of opium.[151] Other ingredients were removed. Altogether, 73 ingredients were required. It was advocated to â€œcounteract all poisons and bites of venomous animals,â€• as well as a host of other medical problems, such as colic, dropsy, and jaundice, and it was used both therapeutically and prophylactically.[141 , 146] As evidence of its efficacy, Galen demonstrated that fowl receiving poison followed by theriac had a higher survival rate than fowl receiving poison alone.[141] It is likely, however, that the scientific rigor and methodology employed differed from current scientific practice.

By the Middle Ages, the Theriac of Andromachus contained more than 100 ingredients. Its synthesis was quite elaborate; the initial phase of production lasted months, followed by an aging process that lasted years, somewhat like vintage wine.[90] The final product was often more solid than liquid in consistency.

Other theriac preparations were named after famous physicians (Damocrates, Nicolaus, Amando, Arnauld, and Abano) who contributed additional ingredients to the original formulation. Over the centuries certain localities were celebrated for their own peculiar brand of theriac. Notable centers of theriac production included Bologna, Cairo, Florence, Genoa, Istanbul, and Venice. At times, theriac production was accompanied by great fanfare. For example, in Bologna, the mixing of the theriac could take place only under the direction of the medical professors at the university.[141]

Whether these preparations were of actual benefit is uncertain. Some suggest that the theriac may have had an antiseptic effect on the gastrointestinal tract, whereas others state that theriac's sole benefit derived from its formulation with opium.[90] Theriacs remained in vogue throughout the Middle Ages and Renaissance, and it was not until 1745 that their efficacy was finally questioned by William Heberden in *Antitheriaka: An Essay on Mithradatum and Theriaca* .[73] Nonetheless, pharmacopeias in France, Spain, and

Germany continued to list these agents until the last quarter of the 19th century and theriac was still available in Italy and Turkey in the early 20th century.[19 , 90]

Sacred Earth

Beginning in the 5th century B.C., an adsorbent agent called *terra sigillata* was promoted as a universal antidote. This agent, also known as the â€œsacred sealed earth,â€• consisted of red clay that could be found on only one particular hill on the Greek island of Lemnos. Perhaps somewhat akin to the 20th-century â€œuniversal antidote,â€• it was advocated as effective in counteracting all poisons.[141] With great ceremony, once per year, the terra sigillata was retrieved from this hill and prepared for subsequent use. According to Dioscorides, this clay was formulated with goat's blood to make it into a paste. At one time, it was included as part of the Theriac of Andromachus. Demand for terra sigillata continued into the 15th century. Similar antidotal clays were found in Italy, Malta, Silesia, and England.[141]

Charms

Charms, such as toadstones, snakestones, unicorn horns, and bezoar stones, were also promoted as universal antidotes. Toadstones, found in the heads of old toads, were reputed to have the capability to extract poison from the site of a venomous bite or sting. In addition, the toadstone was supposedly able to detect the mere presence of poison by producing a sensation of heat upon contact with a poisonous substance.[141]

Similarly, snakestones extracted from the heads of cobras (known as *piedras della cobra de Capelos*) were also reported to have similar magical qualities.[15] The 17th-century Italian philosopher Athanasius Kircher (1602â€“1680) became an enthusiastic supporter of snakestone therapy for the treatment of snakebite after conducting experiments, demonstrating the antidotal

attributes of these charms â€œin front of amazed spectators.â€• Kircher attributed the snakestone's efficacy to the theory of â€œattraction of like substances.â€• Francesco Redi (1626â€“1698), a court physician and contemporary of Kircher, debunked this quixotic approach. A harbinger of future experimental toxicologists, Redi was unwilling to accept isolated case reports and field demonstrations as proof of the snakestone's utility. Using a considerably more rigorous approach, *provando et riprovando* (by testing and retesting), Redi assessed the antidotal efficacy of snakestone on different animal species and different toxins and failed to confirm any benefit.[15]

Much lore has surrounded the antidotal effects of the mythical unicorn horn. Ctesias, writing in 390 B.C., was the first to chronicle the wonders of the unicorn horn, claiming that drinking water or

wine from the â€œhorn of the unicornâ€• would protect against poison.[141] The horns were usually narwhal tusks or rhinoceros horns and during the Middle Ages, the unicorn horn may have been worth as much as 10 times the price of gold. Similar to the toadstone, the unicorn horn was used both to detect poisons and to neutralize them. Supposedly a cup made of unicorn horn would sweat if a poisonous substance was placed in it.[88] To give further credence to its use, a 1593 study on arsenic-poisoned dogs reportedly showed that the horn was protective.[88]

Bezoar stones, also touted as universal antidotes, consisted of stomach or intestinal calculi formed by the deposition of calcium phosphate around a hair, fruit pit, or gallstone. They were removed from wild goats, cows, and apes and administered orally to humans. The Persian name for the bezoar stone was *pad zahr* (â€œexpeller of poisonsâ€•); the ancient Hebrews referred to the bezoar stone as *bel Zaard* (â€œevery cure for poisonsâ€•). Over the years, regional variations of bezoar stones were popularized, including an Asian variety from wild goat of Persia, an Occidental

variety from llamas of Peru, and a European variety from chamois of the Swiss mountains.[49 , 141]

Opium, Coca, and Hallucinogens in Antiquity

Although it was not until the mid-19th century that the peril of opiate addiction was first recognized, juice from the *Papaver somniferum* was known for its medicinal value in Egypt at least as early as the writing of the *Ebers Papyrus* in 1500 B.C. Egyptian pharmacologists of that time reportedly recommended opium poppy extract as a pacifier for children who exhibited incessant crying.[127] In Ancient Greece, Dioscorides and Galen were early advocates of opium as a therapeutic agent. During this time, it was also used as a means of suicide. Mithradates' lack of success in his own attempted suicide by poisoning may have been the result of an opium tolerance that had developed from previous repetitive use.[127] One of the earliest descriptions of the abuse potential of opium is attributed to Epistratos (304â€“257 B.C.), who criticized the use of opium for earache because it â€œdulled the sight and is a narcotic.â€•[127]

Cocaine use dates back to at least 300 B.C., when South American Indians reportedly chewed coca leaves during religious ceremonies.[102] Chewing coca to increase work efficacy and to elevate mood has remained commonplace in some South American societies for thousands of years. An Egyptian mummy from about 950 B.C. revealed significant amounts of cocaine in the stomach and liver, suggesting oral use of cocaine during this time period.[106] Large amounts of tetrahydrocannabinol (THC) were found in the lung and muscle of the same mummy. Another investigation of 11 Egyptian (1079 B.C.â€“ 395 A.D.) and 72 Peruvian (200â€“1500 A.D.) mummies, found cocaine, thought to be indigenous only to South America, and hashish, thought to be indigenous only to Asia, in both groups.[114]

Other currently abused agents that were known to the ancients include cannabis, hallucinogenic mushrooms, nutmeg, and peyote. As early as 1300 B.C., Peruvian indian tribal ceremonies included the use of mescaline-containing San Pedro cacti.[102] The hallucinogenic mushroom, *Amanita muscaria* , known as â€œfly agaric,â€• was used as a ritual drug and may have been known in India as â€œsomaâ€• around 2000 B.C. Cannabis use in China dates back even further, to around 2700 B.C., when it was known as the â€œliberator of sin.â€•[102] In India and Iran, cannabis was used as early as 1000 B.C. as an intoxicant known as *bhang* .[105]

Early Attempts at Gastrointestinal Decontamination

Nicander's *Alexipharmaca* (â€œAntidotes for Poisonsâ€•) recommended induction of emesis by one of several methods: (a) ingesting warm linseed oil; (b) tickling the hypopharynx with a feather; or (c) â€œemptying the gullet with a small twisted and curved paper.â€•[90] Nicander also advocated the use of suction to limit envenomation.[142] The Romans referred to the feather as the â€œvomiting featherâ€• or â€œpinna.â€• Most commonly, the feather was used after a hearty feast to avoid the gastrointestinal discomfort associated with overeating. At times, the pinna was dipped into a nauseating mixture to increase its efficacy.[93]

Toxicology During the Medieval and Renaissance Periods

After Galen (ca. A.D. 129â€“200), there is relatively little documented attention to the subject of poisons until the works of Ibn Wahshiya in the 9th century. Citing Greek, Persian, and Indian texts, Wahshiya's work, entitled *Book of Poisons* , combines contemporary science, magic, and astrology during his discussion of poison mechanisms (as they were understood at that time),

symptomatology, antidotes, including his own recommendation for a universal antidote, and prophylaxis. He categorized poisons as lethal by sight, smell, touch, and sound, as well as by drinking and eating. For victims of an aconite-containing dart arrow, Ibn Wahshiya recommended excision, followed by cauterization and topical treatment with onion and salt.[85]

Another significant medieval contribution to toxicology can be found in Moses Maimonides' (1135â€“1204) *Treatise on Poisons and Their Antidotes* (1198). In part one of this treatise, Maimonides discussed the bites of snakes and mad dogs, and the stings of bees, wasps, spiders, and scorpions.[125] He also discussed the use of cupping glasses for bites (a progenitor of the modern suctioning device), and was one of the first to differentiate the hematotoxic (hot) from the neurotoxic (cold) effects of poison. In part two, he discussed mineral and vegetable poisons and their antidotes. He described belladonna poisoning as causing a â€œredness and a sort of excitation.â€• [125] He suggested that emesis should be induced by hot water, *Anethum graveolens* (dill), and oil, followed by fresh milk, butter, and honey. Although he rejected some of the popular treatments of the day, he advocated the use of the great theriac and the mithradatum as first- and second-line agents in the management of snakebite.[125]

On the subject of oleander poisoning, Petrus Abbonus (1250â€“1315) wrote that those who drink the juice, spines, or bark of oleander will develop anxiety, palpitations, and syncope.[22] He described the clinical presentation of opium overdose as someone who â€œwill be dull, lazy, and sleepy, without feeling, and he will neither understand nor feel anything, and if he does not receive succor, he will die.â€• Although this â€œsuccorâ€• is not defined, he recommended that treatment of opium intoxication include drinking the strongest wine, rubbing the extremities with alkali and soap, and olfactory stimulation with pepper. To treat snakebite, Abbonus suggested the immediate application of a tourniquet, as well as oral suctioning of the bite

woundâ€”preferably performed by a servant. Interestingly, from a 21st-century perspective, Abbonus also suggested that St. John's wort had the magical power to free anything from poisons and attributed this virtue to the influence of the stars.[22]

Paracelsus
1493â€“1541
Introduced dose-response concept to toxicology
Ambroise Pare
1510â€“1590
Spoke out against unicorn horns and bezoars as antidotes
William Piso
1611â€“1678
First to study emetic qualities of ipecacuanha
Bernardino Ramazzini
1633â€“1714
Father of occupational medicine; wrote *De Morbis Artificum Diatriba*
Richard Mead
1673â€“1754
Wrote English-language book dedicated to poisoning
Percivall Pott
1714â€“1788
First description of occupational cancer, relating the chimney sweep occupation to scrotal cancer
Felice Fontana
1730â€“1805
First scientific study of venomous snakes
Philip Physick
1767â€“1837
Early advocate of orogastric lavage to remove poisons
Baron Guillaume Dupuytren
1777â€“1835
Early advocate of orogastric lavage to remove poisons
Edward Jukes

1820

Self-experimented with orogastric lavage apparatus known as Jukes' syringe

Grand Marshall Bertrand

1813

Demonstrated the efficacy of charcoal in arsenic ingestion

Pierre Touery

1831

Demonstrated the efficacy of charcoal in strychnine ingestion

Alfred Garrod

1846

First systematic study of charcoal in an animal model

Benjamin Howard Rand

1848

First study of the efficacy of charcoal in humans

Bonaventure Orfila

1787â€“1853

Father of modern toxicology; wrote *Traite des Poisons* ; first to isolate arsenic from humans organs

Robert Christison

1797â€“1882

Wrote *Treatise on Poisons* , one of the most influential texts in early 19th century

Francois Magendie

1783â€“1855

Discovered emetine and studied mechanism of cyanide and strychnine

Claude Bernard

1813â€“1878

Studied mechanism of toxicity of carbon monoxide and curare

O.H. Costill

1848

Wrote first book on symptoms and treatment of poisoning

Theodore Wormley

Person	Date	Importance
Wrote *Micro-Chemistry of Poisons* , the first American book devoted exclusively to toxicology	1826â€“1897	James Marsh
Developed reduction test for arsenic	1794â€“1846	Hugo Reinsch
Developed qualitative tests for arsenic and mercury	1842â€“1884	Max Gutzeit
Developed method to quantitate small amounts of arsenic	1847â€“1915	Albert Niemann
Isolated cocaine alkaloid	1860	Rudolf Kobert
Studied digitalis and ergot alkaloids	1854â€“1918	Louis Lewin
Studied many toxins, including methanol, chloroform, snake venom, carbon monoxide, lead, opiates, and hallucinogenic plants	1850â€“1929	Alice Hamilton
Conducted landmark investigations associating worksite chemical hazards with disease; led reform movement to improve worker safety	1869â€“1970	

TABLE 1-2. Important Figures in the Field of Toxicology from Paracelsus to the 1900s

The Scientists

Paracelsus' (1493â€“1541) study on the doseâ€“response relationship is usually considered the beginning of the scientific approach to toxicology (Table 1-2). He was the first to emphasize the chemical nature of toxic agents.[112] Paracelsus stressed the need for proper observation and experimentation regarding the true response to chemicals. He underscored the need to differentiate between the therapeutic and toxic properties of chemicals when he stated in his *Third Defense* , â€œWhat is there that is not poison? All things are poison and nothing [is] without poison. Solely, the dose determines that a thing is not a poison.â€• [41]

Although Paracelsus is the best known Renaissance toxicologist, Ambroise Pare (1510â€“1590) and William Piso (1611â€“1678) also contributed to the field. Pare argued against the use of the unicorn horn and bezoar stone.[92] He also wrote an early treatise on carbon monoxide poisoning. Piso is credited as one of the first to recognize the emetic properties of ipecacuanha.[122]

Medieval and Renaissance Poisoners

Along with these advances in toxicologic knowledge, the Renaissance is mainly remembered as the age of the poisoner, a time when the art of poisoning reached new heights (Table 1-3). In fact, poisoning was so rampant during this time that in 1531 King Henry VIII decreed that convicted poisoners should be boiled alive.[51] From the 15th to 17th centuries, schools of poisoning existed in Venice and Rome. In Venice, poisoning services were provided by a group called the Council of Ten, whose members were hired to perform murder by poison.[148]

Members of the infamous Borgia family were credited with many poisonings during this period. They preferred to use a poison called â€œLa Cantarella,â€• a mixture of arsenic and

phosphorus.[143] Rodrigo Borgia (1431â€“1503), who became Pope Alexander VI, and his son, Cesare Borgia, were reportedly responsible for the poisoning of cardinals and kings.

In the late 16th century, Catherine de Medici, wife of Henry II of France, introduced Italian poisoning techniques to France. She experimented on the poor, the sick, and the criminal. By analyzing the subsequent complaints of her victims, she is said to have learned the site of action and time of onset, the clinical signs and symptoms, and the efficacy of poisons.[55]

Murder by poison remained quite popular during the latter half of the 17th and the early part of the 18th centuries in Italy and France.

The Marchioness de Brinvilliers (1630â€“1676) tested her poison concoctions on hospitalized patients and on her servants, and allegedly murdered her husband, father, and two siblings.[53 , 134] Among the favorite poisons of the Marchioness were arsenic, copper sulfate, corrosive sublimate (mercury bichloride), lead, and tartar emetic (antimony potassium tartrate).[143] Catherine Deshayes (1640â€“1680), a fortuneteller and sorcerer, was one of the last â€œpoisoners for hire,â€• and was implicated in countless poisonings, including the killing of more than 2000 infants.[55] Better known as â€œLa Voisine,â€• she reportedly sold poisons to women wishing to rid themselves of their husbands. Her particular brand of poison was a

concoction of aconite, arsenic, belladonna, and opium known as â€œla poudre de succession.â€•[143] Ultimately, de Brinvilliers was beheaded and Deshayes was burned alive for their crimes. In an attempt to curtail these rampant poisonings, Louis XIV issued a decree in 1662 banning the sale of arsenic, mercury, and other poisons to customers not known to the apothecaries and requiring poison buyers to sign a register declaring the purpose for their purchase.[134]

Locusta
54â€“55 A.D.
Claudius and Britannicus
Amanita phalloides , cyanide
Cesare Borgia
1400s
Cardinals and kings
La Cantarella (arsenic and phosphorus)
Catherine de Medici
1519â€“1589
Poor, sick, criminals
Unknown agents
Hieronyma Spara
Died 1659
Taught women how to poison their husbands
Mana of St. Nicholas of Bari (arsenic trioxide)
Marchioness de Brinvilliers
Died 1676
Hospitalized patients, husband, father
Antimony, arsenic, copper, lead, mercury
Catherine Deshayes
Died 1680
>2000 infants, many husbands
La poudre de succession (arsenic mixed with aconite, belladonna, and opium)
Madame Giulia Toffana
Died 1719
>600 people
Aqua toffana (arsenic trioxide)
Mary Blandy
1752
Father
Arsenic
Anna Maria Zwanizer

1807

Poisoner	Date	Victim(s)	Poison(s)

TABLE 1-3. Notable Poisoners from Antiquity to the Present[134, 141, 143]

A major center for poison practitioners was Naples, the home of the notorious Madame Giulia Toffana. She reportedly poisoned more than 600 people, preferring a particular solution of white arsenic (arsenic trioxide), better known as â€œaqua toffana,â€• and dispensed under the guise of a cosmetic. Eventually convicted of poisoning, Madame Toffana was executed in 1719.[21]

Eighteenth- and Nineteenth-Century Developments in Toxicology

The development of toxicology as a distinct specialty began during the 18th and 19th centuries (see Table 1-2).[113] The poison mystiqueâ€”mythologic and magicalâ€”was gradually replaced by an increasingly rational, scientific, and experimental approach to the study of these agents. Much of the poison lore that had survived for almost 2000 years was finally debunked and discarded. The 18th-century Italian Felice Fontana was one of the first to usher in the modern age. He was an early experimental toxicologist who studied the venom of the

European viper and wrote the classic text *Traite sur le Venin de la*

Vipere in 1781.[77] Through his exacting experimental study on the effects of venom, Fontana brought a scientific insight to toxicology that had previously been lacking, demonstrating that clinical symptoms are a result of the poison (venom) acting on specific target organs. During the 18th and 19th centuries, attention focused on the detection of poisons and the study of toxic effects of drugs and chemicals in animals.[107] Issues relating to adverse effects of industrialization and unintentional poisoning in the workplace and home environment were raised. Also during this time, early experience and experimentation with methods of gastrointestinal decontamination took place.

Development of Analytical Toxicology and the Study of Poisons

The French physician Bonaventure Orfila (1787â€“1853) is often called the father of modern toxicology.[107] He emphasized toxicology as a distinct, scientific discipline, separate from clinical medicine and pharmacology.[12] He also was an early medical-legal expert who championed the use of chemical analysis and autopsy material as evidence to prove that a poisoning had occurred. His treatise *Traite des Poisons* (1814)[111] had five editions and was regarded as the foundation of experimental and forensic toxicology.[149] This text classified poisons into six groups: acrids, astringents, corrosives, narcoticoacrids, septics or putrefiants, and stupefacients and narcotics.

A number of other landmark works on poisoning also first appeared during this period. In 1829, Robert Christison (1797â€“1882), a professor of medical jurisprudence and Orfila's student, wrote *A Treatise on Poisons* .[31] This work simplified Orfila's poison classification schema by categorizing poisons into three groups: irritants, narcotics, and narcoticoacrids. Less concerned with jurisprudence than with clinical toxicology, O.H. Costill's *A Practical Treatise on Poisons* , published in 1848, was

the first modern clinically oriented text to emphasize the symptoms and treatment of poisoning.[35] In 1867, Theodore Wormley (1826â€“1897) published the first American book written exclusively on poisons entitled the *Micro-Chemistry of Poisons* .[47, 150]

During this time, important breakthroughs in the chemical analysis of poisons resulted from the search for a more reliable assay for arsenic. Arsenic was widely available and was the suspected etiology of a large number of deaths. In one study, arsenic was employed in 31% of 679 homicidal poisonings.[143] A reliable means of detecting arsenic was much needed by the courts.

Until the 19th century, poisoning was mainly diagnosed by symptoms rather than by analytic tests. The first use of a chemical test as evidence in a poisoning trial occurred in the 1752 trial of Mary Blandy, who was accused of poisoning her father with arsenic.[96] Although Blandy was convicted and hanged publicly, the test employed in this case was not very sensitive and depended in part on eliciting a garlic odor upon heating the gruel that the accused had fed to her father.

During the 19th century, James Marsh (1794â€“1846), Hugo Reinsch, and Max Gutzeit (1847â€“1915) each worked on this problem. Assays bearing their names are important contributions to the early history of analytic toxicology.[97, 107] The â€œMarsh testâ€• to detect arsenic was first used in a criminal case in 1839 during the trial of Marie Lefarge, who was accused of using arsenic to murder her husband.[134] Orfila's trial testimony that the victim's viscera contained minute amounts of arsenic helped to convict the defendant although subsequent debate suggested that contamination of the forensic specimen may have also played a role.

In a further attempt to curtail criminal poisoning by arsenic, the British Parliament passed the Arsenic Act in 1851. This bill, which was one of the first modern laws to regulate the sale of poisons,

required that the retail sale of arsenic be restricted to chemists, druggists, and apothecaries, and that a poison book be maintained to record all arsenic sales.[16]

Homicidal poisonings remained common during the 19th and early 20th century. Infamous poisoners of the late 19th century and early 20th century included William Palmer, Edward Pritchard, Harvey Crippen, and Frederick Seddon.[143] Many of these poisoners were physicians who used their knowledge of medicine and toxicology in an attempt to solve their domestic and financial difficulties by committing the â€œperfectâ€• murder. Some of the poisons employed were aconitine (Lamson, who was a classmate of Christison), *Amanita phalloides* (Girard), arsenic (Maybrick, Seddon, others), antimony (Pritchard), cyanide (Molineux, Tawell), digitalis (Pommerais), hyoscine (Crippen), and strychnine (Palmer, Cream) (see Table 1-3).[24 , 141 , 143]

In the early 20th century, forensic investigation into suspicious deaths, including poisonings, was significantly advanced with the development of the medical examiner system that replaced the much-flawed coroner system that was subject to widespread corruption. In 1918, the first centrally controlled medical examiner system was established in New York City. Alexander Gettler, considered the father of forensic toxicology in the United States, established a toxicology laboratory within the newly created New York City Medical Examiner's Office. Gettler pioneered new techniques for the detection of a variety of substances in biologic fluids including carbon monoxide, chloroform, cyanide, and heavy metals.[48 , 107]

Systematic investigation into the underlying mechanisms of toxic substances also commenced during the 19th century. To cite just a few important accomplishments, Francois Magendie (1783â€“1855) studied the mechanisms of toxicity and sites of action of cyanide, emetine, and strychnine.[46] Claude Bernard (1813â€“1878), the pioneering physiologist and a student of Magendie, made

important contributions to the understanding the toxicity of carbon monoxide and curare.[84] Rudolf Kobert (1854â€“1918) studied digitalis and ergot alkaloids, and also authored a textbook on toxicology for physicians and students.[79 , 109] Louis Lewin (1850â€“1929) was the first person to intensively study the differences between the pharmacologic and toxicologic actions of drugs. Lewin studied chronic opium intoxication, as well as the toxicity of carbon monoxide, chloroform, lead, methanol, and snake venom. He also developed a classification system for psychoactive drugs, dividing them into euphorics, phantastics, inebriants, hypnotics, and excitants.[91]

The Origin of Occupational Toxicology

The origins of occupational toxicology can be traced to the early 18th century and to the contributions of Bernardino Ramazzini (1633â€“1714). Considered the father of occupational medicine, Ramazzini wrote *De Morbis Artificum Diatriba* (*Diseases of Workers*) in 1700, which was the first comprehensive text discussing the relationship between disease and workplace hazards.[52] Ramazzini's essential contribution to the care of the patient is epitomized by the addition of a question to the medical history, â€œWhat occupation does the patient follow?â€•[50] Altogether Ramazzini described diseases associated with 54 occupations, including hydrocarbon poisoning in painters, mercury poisoning in mirror makers, and pulmonary diseases in miners.

In 1775, Sir Percivall Pott proposed the first association between workplace exposure and cancer when he noticed a high incidence of scrotal cancer in English chimney sweeps. Pott's belief that the scrotal cancer was caused by prolonged exposure to tar and soot was confirmed by other investigation in the 1920s, indicating that the polycyclic aromatic hydrocarbons contained in coal tar (including benzo[*a*]pyrene) are carcinogenic.[69]

Dr. Alice Hamilton (1869â€“1970) was another pioneer in occupational toxicology, whose rigorous scientific inquiry had a profound impact on linking chemical toxins with human disease. A physician, scientist, humanitarian, and social reformer, Hamilton, who would become the first female professor at Harvard University, conducted groundbreaking studies of many different occupational exposures and problems, including carbon monoxide poisoning in steelworkers, mercury poisoning in hatters, and wrist drop in lead workers. Her overriding concerns about these â€œdangerous tradesâ€• and her commitment to improve the health of workers would lead to extensive voluntary and regulatory reforms in the workplace.[59,63]

Advances in Gastrointestinal Decontamination

Using gastric lavage and charcoal to treat the poisoned patient was introduced in the late 18th and early 19th century. A stomach pump was first designed by Munro Secundus in 1769 to administer neutralizing substances to sheep and cattle for the treatment of bloat.[25] The American surgeon Philip Physick (1768â€“1837) and the French surgeon Baron Guillaume Dupuytren (1777â€“1835) were two of the first physicians to advocate gastric lavage for the removal of poisons.[25] As early as 1805, Physick demonstrated the use of a â€œstomach tubeâ€• for this purpose. Using brandy and water as the irrigation fluid, he performed stomach washings in twins to wash out excessive doses of tincture of opium.[25] Dupuytren performed gastric emptying by first introducing warm water into the stomach via a large syringe attached to a long flexible sound and then withdrawing the â€œsame water charged with poison.â€•[25] Edward Jukes, a British surgeon, was another early advocate of poison removal by gastric lavage. Jukes first experimented on animals, performing gastric lavage after the oral administration of tincture of opium. Attempting to gain human

experience, he experimented on himself, by first ingesting 10 drams (600 g) of tincture of opium and then performing gastric lavage using a 25-inch-long, 0.5-inch-diameter tube, which became known as Jukes' syringe.[101] Other than some nausea and a 3-hour sleep he suffered no ill effects, and the experiment was deemed a success.

The principle of using charcoal to adsorb poisons was first described by Scheele (1773) and Lowitz (1785), but the medicinal use of charcoal dates to ancient times.[34] The earliest reference to the medicinal uses of charcoal is found in the Egyptian Papyrus of about 1500 B.C.[34] The charcoal employed during Greek and Roman times, referred to as wood charcoal, was used to treat anthrax, chlorosis, epilepsy, and vertigo. By the late 18th century, topical application of charcoal was recommended for gangrenous skin ulcers, and internal use of a charcoal-water suspension was recommended for use as a mouthwash and in the treatment of bilious conditions.[34]

The first hint that charcoal might have a role in the treatment of poisoning came from a series of courageous self-experiments in France during the early 19th century. In 1813, the French chemist M. Bertrand publicly demonstrated the antidotal properties of charcoal by surviving a 5-g ingestion of arsenic trioxide that had been mixed with charcoal.[66] Eighteen years later, before the French Academy of Medicine, the pharmacist P.F. Touery survived an ingestion consisting of 10 times the lethal dose of strychnine mixed with 15 g of charcoal.[66] One of the first reports of charcoal used in a poisoned patient was in 1834 by the American Hort, who successfully treated a mercury bichloride-poisoned patient with large amounts of powdered charcoal.[4]

In the 1840s, A. Garrod performed the first controlled study of charcoal when he examined its utility on a variety of poisons in animal models.[66] Garrod used dogs, cats, guinea pigs, and rabbits to demonstrate the potential benefits of charcoal in the

management of strychnine poisoning. He also emphasized the importance of early use of charcoal and the proper ratio of charcoal to poison. Other toxic substances, such as aconite, hemlock, mercury bichloride, and morphine were also studied during this period. The first charcoal efficacy studies in humans were performed by the American physician B. Rand in 1848.[66]

It was not until the early 20th century that an activation process was added to the manufacture of charcoal. In 1900, the Russian Ostrejko demonstrated that treating charcoal with superheated steam significantly enhanced its adsorbing power.[34] Despite this improvement and the favorable reports mentioned, charcoal was only occasionally used in gastrointestinal decontamination until the early 1960s, when Holt and Holz repopularized its use.[62]

The Increasing Recognition of the Perils of Drug Abuse

Opioids

Although the medical use of opium was promoted by Paracelsus in the 16th century, the popularity of this agent was given a significant boost when the distinguished British physician Thomas Sydenham (1624â€“1689) formulated laudanum, which was a tincture of opium containing cinnamon, cloves, saffron, and sherry. Sydenham also formulated a different opium concoction known as â€œsyrup of poppies.â€•[82] A third opium preparation called Dover's powder was designed by Sydenham's protÃ©gÃ©, Thomas Dover; this preparation contained ipecac, licorice, opium, saltpeter, and tartaric acid.

John Jones, the author of the 18th century text *The Mysteries of Opium Reveal'd* , was another enthusiastic advocate of the medicinal uses of opium.[82] A well-known opium user himself, Jones provided one of the earliest descriptions of opiate addiction.

He insisted that opium offered many benefits if the dose was moderate, but that discontinuation or a decrease in dose, particularly after â€œleaving off after long and lavish use,â€• would result in such symptoms as sweating, itching, diarrhea, and melancholy. His recommendation for the treatment of these withdrawal symptoms included decreasing the dose of opium by 1% each day until the drug was totally withdrawn. During this period, a number of English writers became well-known opium addicts, including Elizabeth Barrett Browning, Samuel Taylor Coleridge, and Thomas De Quincey. De Quincey, author of *Confessions of an English Opium Eater* , was an early advocate of the recreational use of opiates. The famed Coleridge poem *Kubla Khan* referred to opium as the â€œmilk of paradise,â€• and De Quincey's *Confessions* suggested that opium held the â€œkey to paradise.â€• In many of these cases, the initiation of opium use for medical reasons led to recreational use, tolerance, and dependence.[82]

Although opium was first introduced to Asian societies by Arab physicians some time after the fall of the Roman Empire, the use of opium in Asian countries grew considerably during the 18th and

19th centuries. In one of the more deplorable chapters in world history, China's growing dependence on opium was spurred on by the English desire to establish and profit from a flourishing drug trade.[127] Opium was grown in India and exported east. Despite Chinese protests and edicts against this practice, the importation of opium persisted throughout the 19th century, with the British going to war twice in order to maintain their right to sell opium. Not surprisingly, by the beginning of the 20th century, opium abuse in China was endemic.

In England, opium use continued to increase during the first half of the 19th century. During this period, opium was legal and freely available from the neighborhood grocer. To many, its use was considered no more problematic than alcohol.[57] The Chinese

usually self-administered opium by smoking, a custom that was brought to the United States in the mid-19th century by Chinese immigrants, whereas the English use of opium was more often by ingestion, that is, â€œopium eating.â€•

The liberal use of opiates as infant-soothing agents was one of the most unfortunate aspects of this period of unregulated opiate use.[81] Godfrey's Cordial, Mother's Friend, Mrs. Winslow's Soothing Syrup, and Quietness were among the most popular of children's opiates.[86] They were advertised as producing a natural sleep and recommended for teething and bowel regulation, as well as for crying. Because of the wide availability of opiates during this period, the number of acute opiate overdoses in children was consequential and would remain problematic until these unsavory remedies were condemned and removed from the market.

With the discovery of morphine in 1805 and Alexander Wood's invention of the hypodermic syringe in 1853, parenteral administration of morphine became the preferred route of opiate administration for therapeutic use and abuse.[68] A legacy of the generous use of opium and morphine during the United States Civil War was â€œsoldiers' disease,â€• referring to a rather large veteran population that returned from the war with a lingering opiate habit.[119] One hundred years later, opiate abuse and addiction would again become common among US military serving during the Vietnam War. Surveys indicated that as many as 20% of American soldiers in Vietnam were addicted to opiates during the warâ€”in part because of its widespread availability and high purity in Vietnam.[124]

Growing concerns about opiate abuse in England led to the passing of the Pharmacy Act of 1868, which restricted the sale of opium to registered chemists. But in 1898, the Bayer Pharmaceutical Company of Germany synthesized heroin from opium (Bayer also introduced aspirin that same year).[135] Although initially touted as a nonaddictive morphine substitute, problems with heroin use soon

became evident in the United States.

Cocaine

Ironically, during the later part of the 19th century, Sigmund Freud and Robert Christison, among others, were enthusiastically recommending cocaine as a treatment for opiate addiction. After Albert Niemann's isolation of cocaine alkaloid from coca leaf in 1860, growing enthusiasm for cocaine as a panacea ensued.[76] Some of the most important medical figures of the time, including William Halsted, the famed Johns Hopkins surgeon, enthusiastically promoted the use of cocaine. Halsted championed the anesthetic properties of this drug, although his own use of cocaine and subsequent morphine use in an attempt to overcome his cocaine dependency would later take a considerable toll.[110] In 1884, Freud wrote *Uber Cocaine* ,[27] advocating cocaine as a cure for opium and morphine addiction and as a treatment for fatigue and hysteria.

During the last third of the 19th century, cocaine was added to many popular over-the-counter tonics of the day. In 1863, Angelo Mariani, a Frenchman, introduced a new wine, â€œVin Mariani,â€• that consisted of a mixture of cocaine and wine (6 mg of cocaine alkaloid per ounce) and was sold as a digestive aid and restorative.[102] In direct competition with the French tonic was the American-made Coca-Cola, developed by J.S. Pemberton. Coca-Cola was originally formulated with coca and caffeine and was marketed as a headache remedy and invigorator. With the public demand for cocaine increasing, patent medication manufacturers were adding cocaine to thousands of products. One such asthma remedy was â€œDr. Tucker's Asthma Specific,â€• which contained 420 mg of cocaine per ounce and was applied directly to the nasal mucosa.[76] By the end of the 19th century, the first American cocaine epidemic was underway.[104]

Similar to the medical and societal adversities associated with opiate use, the increasing use of cocaine led to a growing concern

about comparable adverse effects. In 1886, the first reports of cocaine-related cardiac arrest and stroke were published.[120] Reports of cocaine habituation occurring in patients using cocaine to treat their underlying opiate addiction also began to appear. In 1902, a popular book, *Eight Years in Cocaine Hell* , described some of these problems. *Century Magazine* called cocaine â€œthe most harmful of all habit-forming drugs,â€• and a report in the *New York Times* stated that cocaine was destroying â€œits victims more swiftly and surely than opium.â€•[40] In 1910, President William Taft proclaimed cocaine to be Public Enemy Number 1.

In an attempt to curb the increasing problems associated with drug abuse and addiction, the 1914 Harrison Narcotics Act mandated stringent control over the sale and distribution of narcotics (defined as opium, opium derivatives, and cocaine).[40] It was the first federal law in the United States to criminalize the nonmedical use of drugs. The bill required doctors, pharmacists, and others who prescribed narcotics to register and to pay a tax. A similar law, the Dangerous Drugs Act, was passed in the United Kingdom in 1920.[57] To help enforce these drug laws in the United States, the Narcotics Division of the Prohibition Unit of the Internal Revenue Service (a progenitor of the Drug Enforcement Agency) was established in 1920. In 1924, the Harrison Act was further strengthened with the passage of new legislation that banned the importation of opium for the purpose of manufacturing heroin, essentially outlawing the medicinal uses of heroin. With the legal venues to purchase these drugs now eliminated, users were forced to buy from illegal street dealers, creating a burgeoning black market that still exists today.

Sedative-Hypnotics

The introduction to medical practice of the anesthetic agents nitrous oxide, ether, and chloroform during the 19th century was accompanied by the recreational use of these agents and the first

reports of volatile substance abuse. Chloroform â€œjags,â€• ether â€œfrolics,â€• and nitrous parties became a new type of entertainment. Humphrey Davies was an early self-experimenter with the exhilarating effects associated with nitrous oxide inhalation. In certain Irish towns, especially where the temperance movement was strong, ether drinking became quite popular.[99] Horace Wells, the American dentist who introduced chloroform as an anesthetic, became dependent on this volatile solvent and later committed suicide.

Until the last half of the 19th century aconite, alcohol, hemlock, opium, and prussic acid (cyanide) were the primary agents used for sedation.[32] During the 1860s, new, more specific

sedative-hypnotics, such as chloral hydrate and potassium bromide, were introduced into medical practice. In particular, chloral hydrate was hailed as a wonder drug that was relatively safe, as compared to opium, and recommended for insomnia, anxiety, and delirium tremens, as well as for scarlet fever, asthma, and cancer. But within a few years, problems with acute toxicity of chloral hydrate, as well as its potential to produce tolerance and physical dependence, became apparent.[32] Mixing chloral hydrate with ethanol was noted to produce a rather powerful â€œknockoutâ€• combination that would become known as a â€œMickey Finn.â€• Abuse of chloral hydrate, as well as other new sedatives such as potassium bromide, would prove to be a harbinger of 20th-century sedative-hypnotic abuse.

Hallucinogens

American Indians used peyote in religious ceremonies since at least the 17th century. Hallucinogenic mushrooms, particularly *Psilocybe* mushrooms, were also used in the religious life of Native Americans. These were called â€œteonanacatl,â€• which means â€œGod's sacred mushroomsâ€• or â€œGod's flesh.â€•[116]

Interest in the recreational use of cannabis also accelerated during the 19th century after Napoleon's troops brought the drug back from Egypt, where its use among the lower classes was widespread. In 1843, several French Romantics, including Balzac, Baudelaire, Gautier, and Hugo, formed a hashish club called â€œLe Club des Hachichinsâ€• in the Parisian apartment of a young French painter. Fitz Hugh Ludlow's *The Hasheesh Eater* , published in 1857, was an early American text espousing the virtues of marijuana.[89]

Absinthe, an ethanol-containing beverage that was manufactured with an extract from wormwood (*Artemisia absinthium*), was very popular during the last half of the 19th century.[83] This emerald-colored, very bitter drink was memorialized in the paintings of Degas, Toulouse-Lautrec, and Van Gogh and was a staple of French society during this period.[13] Î±-Thujone, a psychoactive component of wormwood, and a noncompetitive Î³-aminobutyric acid type A ($GABA_A$) blocker is thought to be responsible for the pleasant feelings, as well as for the hallucinogenic effects, hyperexcitability, and significant neurotoxicity associated with this drink.[65] Van Gogh's debilitating episodes of psychosis were likely exacerbated by absinthe drinking.[138] Given the medical problems associated with its use, absinthe was banned throughout most of Europe by the early 20th century.

A more recent event that would have significant impact on modern-day hallucinogen use was the synthesis of lysergic acid diethylamide (LSD) by Albert Hofmann in 1938.[64] Working for Sandoz Pharmaceutical Company, Hofmann synthesized LSD while investigating the pharmacologic properties of ergot alkaloids. Subsequent self-experimentation by Hofmann led to the first description of its hallucinogenic effects and stimulated research into the use of LSD as a therapeutic agent. Hofmann is also credited with isolating psilocybin as the active ingredient in *Psilocybe mexicana* mushrooms in 1958.[102]

Twentieth-Century Events

Early Regulatory Initiatives

The development of the specialty of medical toxicology and the role of poison control centers began shortly after World War II. Prior to this time, serious attention to the problem of household poisonings in the United States had been limited to a few federal legislative antipoisoning initiatives (Table 1-4). The 1906 Pure Food and Drug Act was the first federal legislation that sought to protect the public from problematic and potentially unsafe drugs and food. The driving force behind this reform was Dr. Harvey W. Wiley, the chief chemist at the Department of Agriculture. Beginning in the 1880s, Wiley investigated the problems of contaminated food. In 1902, he organized the â€œpoison squad,â€• which consisted of a group of volunteers who did self-experiments with food preservatives.[5] Revelations from the â€œpoison squad,â€• as well as the publication of Upton Sinclair's muckraking novel *The Jungle* [133] in 1906, exposing unhygienic practices of the meatpacking industry, led to growing support for legislative intervention. Samuel Hopkins Adams' reports about the patent medicine industry revealed that some drug manufacturers added opiates to soothing syrups for infants, and added to the call for reform.[121] Although the 1906 regulations were mostly concerned with protecting the public from adulterated food, regulations protecting against misbranded patent medications were also included.

The Federal Caustic Poison Act of 1927 was the first federal legislation to specifically address household poisoning. As early as 1859, bottles clearly demarcated â€œpoisonâ€• were manufactured in response to a rash of unfortunate dispensing errors that occurred when oxalic acid was unintentionally substituted for a similarly appearing Epsom salts solution.[28] Prior to 1927, however, â€œpoisonâ€• warning labels were not

required on chemical containers, regardless of toxicity or availability. The 1927 Caustic Act was spearheaded by the efforts of Dr. Chevalier Jackson, an otolaryngologist, who showed that unintentional exposures to household caustic agents were an increasingly frequent cause of severe oropharyngeal and gastrointestinal burns. Under this statute, for the first time, alkali and acid-containing products had to clearly display a â€œpoisonâ€• warning label.[140]

The most pivotal regulatory initiative in the United States prior to World War II, and perhaps the most significant American toxicologic regulation of the 20th century, was the Federal Food, Drug, and Cosmetic Act of 1938. Although the Food and Drug Administration (FDA) had been established in 1930, and legislation to strengthen the 1906 Pure Food and Drug Act was considered by Congress beginning with President Franklin Roosevelt's first inauguration in 1933, by 1938 proposed revisions still had not been passed. The Elixir of Sulfanilamide tragedy in 1938 (Chap. 2) claimed the lives of 105 people who ingested a prescribed liquid preparation of the antibiotic sulfanilamide inappropriately dissolved in diethylene glycol. This event finally provided the catalyst for legislative intervention.[100 , 147] Prior to the elixir disaster, proposed legislation called only for the banning of false and misleading drug labeling and for the outlawing of dangerous drugs without mandatory drug safety testing. After the tragedy, the 1938 proposal was strengthened, requiring assessment of drug safety prior to marketing, and ultimately passed.

The Development of Poison Control Centers

World War II led to the rapid proliferation of new drugs and chemicals in the marketplace and in the household.[38] At the same time, suicide as a leading cause of death from these agents was recognized.[10] Both of these factors led the medical community to

develop a response to the serious problems of both unintentional and intentional poisonings. In Europe during the late 1940s, special toxicology wards were organized in Copenhagen and Budapest,[58] and a poison information service was begun in the Netherlands

(Table 1-5).[144] A 1952 American Academy of Pediatrics study revealed that more than 50% of childhood â€œaccidentsâ€• in the United States were the result of unintentional poisonings.[60] This study led to the opening of the first US poison control center in Chicago in 1953, under the leadership of Dr. Edward Press.[117] Press believed that it had become extremely difficult for the individual physician to keep abreast of product information, toxicity, and treatment for the rapidly increasing number of potentially poisonous household products. This initial center was organized as a cooperative effort among the departments of pediatrics at several Chicago medical schools, with the goal of collecting and disseminating product information to inquiring physicians, mainly pediatricians.[117]

1906
Pure Food and Drug Act
Early regulatory initiative. Prohibits interstate commerce of misbranded and adulterated foods and drugs.
1914
Harrison Narcotics Act
First federal law to criminalize the nonmedical use of drugs. Taxed and regulated distribution and sale of narcotics (opium, opium derivatives, and cocaine). It required doctors, pharmacists, and others who prescribed narcotics to register and pay a tax.
1927
Federal Caustic Poison Act
Mandated labeling of concentrated caustics.
1930
Food and Drug Administration (FDA) established

Successor to the Bureau of Chemistry; promulgation of food and drug regulations.

1937

Marijuana Tax Act

Applied controls to marijuana similar to those applied to narcotics.

1938

Federal Food, Drug, and Cosmetic Act

Required toxicity testing of pharmaceuticals prior to marketing.

1948

Federal Insecticide, Fungicide, and Rodenticide Act

Provided federal control for pesticide sale, distribution, and use.

1951

Durham-Humphrey Amendment

Restricted many therapeutic drugs to sale by prescription only

1960

Federal Hazardous Substances Labeling Act

Mandated prominent labeling warnings on hazardous household chemical products.

1962

Kefauver-Harris Drug Amendments

Required drug manufacturer to demonstrate efficacy before marketing

1963

Clean Air Act

Regulated air emissions by setting maximum pollutant standards.

1966

Child Protection Act

Banned hazardous toys when adequate label warnings could not be written.

1970

Comprehensive Drug Abuse and Control Act

Replaced and updated all previous laws concerning narcotics and other dangerous drugs.

1970

Environmental Protection Agency (EPA) established
Established and enforced environmental protection standards.
1970
Occupational Safety and Health Act (OSHA)
Enacted to improve worker and workplace safety. Created National Institute for Occupational Safety and Health (NIOSH) as research institution for OSHA.
1970
Poison Prevention Packaging Act
Mandated child-resistant safety caps on certain pharmaceutical preparations to decrease unintentional childhood poisoning.
1972
Clean Water Act
Regulated discharge of pollutants into US waters.
1972
Consumer Product Safety Act
Established Consumer Product Safety Commission to reduce injuries and deaths from consumer products.
1972
Hazardous Material Transportation Act
Authorized the Department of Transportation to develop, promulgate, and enforce regulations for the safe transportation of hazardous materials.
1973
Drug Enforcement Administration (DEA) created
Successor to the Bureau of Narcotics and Dangerous Drugs; charged with enforcing federal drug laws.
1973
Lead-based Paint Poison Prevention Act
Regulated the use of lead in residential paint. Lead in some paints later banned by Congress in 1978.
1974
Safe Drinking Water Act
Set safe standards for water purity.

1976

Resource Conservation and Recovery Act (RCRA)

Authorized EPA to control hazardous waste from the â€œcradle-to-grave,â€• including the generation, transportation, treatment, storage, and disposal of hazardous waste.

1976

Toxic Substance Control Act

Emphasis on law enforcement. Authorized EPA to track 75,000 industrial chemicals produced or imported into the United States. Required testing of chemicals that pose environmental or human health risk.

1980

Comprehensive Environmental Response Compensation and Liability act (CERCLA)

Set controls for hazardous waste sites. Established trust fund (Superfund) to provide cleanup for these sites. Agency for Toxic Substances and Disease Registry (ATSDR) created.

1983

Federal Anti-Tampering Act

Response to cyanide-Tylenol deaths. Outlawed tampering with packaged consumer products.

1986

Controlled Substance Analogue Enforcement Act

Instituted legal controls on analog (designer) drugs with chemical structures similar to controlled substances.

1986

Drug-Free Federal Workplace Program

Executive order mandating drug testing of federal employees in sensitive positions.

1986

Superfund Amendments and Reauthorization Act (SARA)

Amendment to CERCLA. Increased funding for the research and cleanup of hazardous waste (SARA) sites.

1988

Labeling of Hazardous Art Materials Act	Required review of all art materials to determine hazard potential and mandated warning labels for hazardous materials.
1994	
Dietary Supplement Health and Education Act	Permitted dietary supplements including many herbal preparations to bypass FDA scrutiny.
1997	
FDA Modernization Act	Accelerated FDA reviews, regulated advertising of unapproved uses of approved drugs
2002	
The Public Health Security and Bioterrorism Preparedness and Response Act	Tightened control on biologic agents and toxins; increased safety of the US food and drug supply, and drinking water; and strengthened the Strategic National Stockpile.

Date Federal Legislation Intent

TABLE 1-4. Protecting Our Health: Important US Regulatory Initiatives Pertaining to Xenobiotics Since 1900

By 1957, 17 poison control centers were operating in the United States.[38] With the Chicago center serving as a model,

these early centers responded to physician callers by providing ingredient and toxicity information about drug and household products, and making treatment recommendations. Records were kept of the calls, and preventive strategies were introduced into the community. As more poison control centers opened, a second important function, providing information to callers from the general public, became increasingly commonplace. The physician

pioneers in poison prevention and poison treatment were predominantly pediatricians who focused on unintentional childhood ingestions.[1][2][3]

1949
First toxicology wards open in Budapest and Copenhagen
1949
First poison information service begins in the Netherlands
1952
American Academy of Pediatrics study shows that 51% of children's â€œaccidentsâ€• are the result of the ingestion of potential poisons
1953
First US poison control center opens in Chicago
1957
National Clearinghouse for Poison Control Centers established
1958
American Association of Poison Control Centers (AAPCC) founded
1961
First Poison Prevention Week
1963
Initial call for development of regional Poison Control Centers (PCCs)
1964
Creation of European Association for PCCs
1968
American Academy of Clinical Toxicology (AACT) established
1972
Introduction of microfiche technology to poison information
1974
American Board of Medical Toxicology (ABMT) established
1978
AAPCC introduces standards of regional designation
1983
First examination given for Specialist in Poison Information (SPI)

Year	Milestone
1985	American Board of Applied Toxicology (ABAT) established
1992	Medical Toxicology recognized by American Board of Medical Specialties (ABMS)
1994	First ABMS examination in Medical Toxicology
2000	Accreditation Council for Graduate Medical Education (ACGME) approval of residency training programs in Medical Toxicology
2000	Poison Control Center Enhancement and Awareness Act
2004	Institute of Medicine (IOM) Report on the future of poison centers is released calling on a greater integration between public health sector and poison control services

TABLE 1-5. Milestones in the Development of Medical Toxicology

During these early years in the development of poison control centers, each center had to collect its own product information, which was a laborious, and often redundant, task.[37] In an effort to coordinate poison control center operations and to avoid unnecessary duplication, Surgeon General Dr. James Goddard responded to the recommendation of the American Public Health Service and established the National Clearinghouse for Poison Control Centers in 1957.[98] This organization, placed under the Bureau of Product Safety of the Food and Drug Administration, disseminated 5-inch by 8-inch index cards containing poison information to each center to help standardize poison center information resources. The Clearinghouse also collected and

tabulated poison data from each of the centers.

Between 1953 and 1972, a rapid, uncoordinated proliferation of poison control centers occurred in the United States.[95] In 1962, there were 462 poison control centers.[1] By 1970, this number had risen to 590,[87] and by 1978, there were 661 poison control centers in the United States, including 100 centers in the state of Illinois.[129] The nature of calls to centers changed as lay public-generated calls began to outnumber physician-generated calls. Recognizing the publicity value and strong popular support associated with poison centers, some hospitals started poison control centers for public relations reasons without adequately recognizing or providing for the associated responsibilities. Unfortunately, many of these centers offered no more than a part-time telephone service located in the back of the emergency department or pharmacy, staffed by poorly trained personnel.[129]

Despite the growing pains of the poison control services during this period, there were many significant achievements. A dedicated group of physicians and other healthcare professionals began devoting an increasing proportion of their time to matters pertaining to poisoning. In 1958, the American Association of Poison Control Centers (AAPCC) was founded to promote closer cooperation between poison centers, to establish uniform standards, and to develop educational programs for the general public and other healthcare professionals.[60] Annual research meetings were held, and important legislative initiatives were stimulated by the organization's efforts.[98] Examples of such legislation include the Federal Hazardous Substances Labeling Act of 1960, which improved product labeling; the Child Protection Act of 1966, which extended labeling statutes to pesticides and other hazardous substances; and the Poison Prevention Packaging Act of 1970, which mandated safety packaging. In 1961, in an attempt to heighten public awareness of the dangers of unintentional poisoning, the third week of March was designated as the Annual National Poison Prevention Week.

Another organization that would become important, the American Academy of Clinical Toxicology (AACT), was founded in 1968 by a diverse group of toxicologists.[33] This group was â€œinterested in applying principles of rational toxicology to patient treatmentâ€• and in improving the standards of care on a national basis.[126] The journal *Clinical Toxicology* , sponsored by AACT, also began publication in 1968. The first modern textbooks of clinical toxicology began to appear in the mid-1950s with the publication of Dreisbach's *Handbook of Poisoning* (1955),[44] Gleason, Gosselin, and Hodge's *Clinical Toxicology of Commercial Products* (1957),[56] and Arena's *Poisoning* (1963).[11] Major advancements in the storage and retrieval of poison information were instituted during these years. Information regarding consumer products initially appeared on index cards distributed regularly to poison centers by the National Clearinghouse. By 1978, more than 16,000 individual product cards had been assembled.[129] The introduction of microfiche technology in 1972 enabled the storage of much larger amounts of data in much smaller spaces at the individual poison centers. Toxifile and POISINDEX, two large drug and poison databases employing microfiche technology, were introduced and gradually replaced the much more limited index card system.[129] During the 1980s, POISINDEX, which had become the standard database, was made more accessible by using CD-ROM technology. Sophisticated information about the most obscure toxins was now instantaneously available by computer at every poison center.

In 1978, the poison control center movement entered an important new stage in its development when the AAPCC introduced standards for regional poison center designation.[95] By defining strict criteria, the AAPCC sought to upgrade poison center operations significantly and to offer a national standard of service. These criteria included employing poison specialists dedicated

exclusively to operating the poison control center 24 hours per day and serving a catchment area of between 1 and 10 million people.

Not surprisingly, this professionalization of the poison center movement led to a rapid consolidation of services, and the number of centers decreased to 62 by 2005. Fifty-one of the 62 centers (82%) are regionally certified. An AAPCC credentialing examination for poison information specialists was inaugurated in 1983 to help ensure the quality and standards of poison center staff.[9]

In 2000, the Poison Control Center Enhancement and Awareness Act was passed by Congress and signed into law by President William Clinton. For the first time, federal funding became available to provide assistance for poison prevention and to stabilize the funding of regional poison control centers. This federal assistance has permitted the establishment of a single nationwide toll-free phone number (800-222-1222) to access poison centers.

A poison control center movement has also evolved in Europe over the last 35 years, but unlike the movement in the United States, from the beginning its growth focused on the development of strong centralized toxicology treatment centers. In the late 1950s, Dr. M. Gaultier in Paris developed an inpatient unit that was dedicated to the care of poisoned patients.[58] In Great Britain, the National Poison Information Service was developed at Guys Hospital in 1963 under Dr. Roy Goulding.[58] Dr. Henry Matthew initiated a regional poisoning treatment center in Edinburgh about the same time,[118] and in 1964, the European Association for Poison Control Centers was formed at Tours, France.[58]

The Rise of Environmental Toxicology and Further Regulatory Protection from Toxic Substances

The rise of the environmental movement during the 1960s can be traced, in part, to the publication of Rachel Carson's *Silent Spring*

in 1962, which revealed the perils of an increasingly toxic environment,[29] and to the increasing awareness among those involved with the poison control movement of the growing menace of toxins in the home environment.[26] Battery casing fume poisoning, which resulted from the burning of discarded lead battery cases, and acrodynia, which resulted from exposure to a variety of mercury-containing products,[39] demonstrated that young children seemed particularly vulnerable to low-dose exposures from certain toxins. Worries about the persistence of pesticides in the ecosystem and the increasing number of chemicals introduced into the environment added to the concern that the environment was a potential source of illness, heralding a drive for additional regulatory protection.

Starting with the Clean Air Act in 1963, laws were passed to help reduce the toxic burden on our environment (see Table 1-4). The establishment of the Environmental Protection Agency in 1970 spearheaded this attempt at protecting our environment, and during the next 10 years, numerous protective regulations were introduced. Among the most important initiatives were the Occupational Safety and Health Act of 1970 that established the Occupational Safety and Health Administration (OSHA). This act mandated that employers provide safe work conditions for their employees. Specific exposure limits to toxic chemicals in the workplace were promulgated. The Consumer Product Safety Commission was created in 1972 to protect the public from consumer products that posed an unreasonable risk of illness or injury. Cancer-producing substances, such as asbestos, benzene, and vinyl chloride, were banned from consumer products as a result of these new regulations. Toxic waste disasters at Love Canal, New York, and Times Beach, Missouri, led to the passing of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund) in 1980. This fund would help to pay for cleanup of hazardous substance releases that posed a potential threat to public health. The

Superfund legislation also led to the creation of the Agency for Toxic Substances and Disease Registry (ATSDR) a federal public health agency that is charged with determining the nature and extent of health problems at Superfund sites and advising the US Environmental Protection Agency and state health and environmental agencies on the need for clean-up and other actions to protect the public's health. In 2003, ATSDR became part of the National Center for Environmental Health of the Centers for Disease Control.

Medical Toxicology Comes of Age

Over the last 25 years, the primary specialties of medical toxicologists have changed. The development of emergency medicine and preventive medicine as medical specialties led to the training of more physicians with a dedicated interest in toxicology. By the early 1990s, emergency physicians accounted for more than half the number of medical toxicologists.[43] The increased diversity of medical toxicologists with primary training in emergency medicine, pediatrics, preventive medicine, or internal medicine has helped to broaden the goals of poison control centers and medical toxicologists beyond the treatment of acute unintentional childhood ingestions. The broad scope of medical toxicology now includes a much wider array of toxic exposures including acute and chronic, adult and pediatric, unintentional and intentional, occupational and environmental.

The development of medical toxicology as a medical subspecialty began in 1974, when the AACT established the American Board of Medical Toxicology (ABMT) to recognize physician practitioners of medical toxicology.[7] From 1974 to 1992, 209 physicians obtained board certification from the ABMT. Formal subspecialty recognition of medical toxicology by the American Board of Medical Specialties (ABMS) was granted in 1992, and a conjoint subboard with representatives from the American Board of Emergency Medicine,

American Board of Pediatrics, and American Board of Preventive Medicine was created. The first ABMS-sponsored examination in medical toxicology was offered in 1994. By 2004, more than 300 physicians were board-certified in medical toxicology by the ABMT and/or ABMS. The American College of Medical Toxicology was founded in 1994 as a physician-based organization designed to advance clinical, educational, and research goals in medical toxicology. In 1999, the Accreditation Council of Graduate Medical Education (ACGME) in the United States formally recognized postgraduate education in medical toxicology, and by 2004, 24 training programs had been approved.

During the 1990s in the United States, some medical toxicologists began to work on establishing regional toxicology treatment centers. Adapting the European model, toxicology treatment centers would serve as referral centers for patients requiring advanced toxicologic evaluation and treatment. Goals of such inpatient regional centers included enhancing care of the poisoned patient, strengthening toxicology training, and facilitating research. The evaluation of the clinical efficacy and fiscal viability of such programs is ongoing.

The professional maturation of advanced practice pharmacists and nurses with a primary interest in clinical toxicology has also

taken place over the past two decades. In 1985, the AACT established the American Board of Applied Toxicology (ABAT), to administer a certifying examination for nonphysician practitioners of medical toxicology who meet their rigorous standards.[6] By 2004, more than 70 toxicologists were certified by this board, most of whom held either a PharmD or a PhD in pharmacology or toxicology.

Recent Poisonings and Poisoners

Although accounting for just a tiny fraction of all homicidal deaths

(0.16% in the United States), notorious lethal poisonings continued throughout the 20th century (Table 1-3).[2]

In England, Graham Frederick Young developed a macabre fascination with poisons.[75] In 1971, at age 14 he killed his stepmother and other family members with arsenic and antimony. Sent away to a psychiatric hospital, he was released at age 24 years, when he was no longer considered to be a threat to society. Within months of his release he again engaged in lethal poisonings, killing several of his coworkers with thallium. Ultimately, he died in prison in 1990.

In 1978, Georgi Markov, a Bulgarian defector living in London, developed multisystem failure and died 4 days after having been stabbed by an umbrella carried by an unknown assailant. The postmortem examination revealed a pinhead-sized metal sphere embedded in his thigh where he had been stabbed. Investigators hypothesized that this sphere had most likely carried a lethal dose of ricin into the victim.[36] This theory was greatly supported when ricin was isolated from the pellet of a second victim who was stabbed under similar circumstances.

In 1982, deliberate tampering with nonprescription acetaminophen preparations with potassium cyanide caused 7 deaths in Chicago.[45] Because of this tragedy, packaging of nonprescription medications was changed to decrease the possibility of future product tampering.[103] The perpetrator(s) were never apprehended, and other deaths from nonprescription product tampering were reported in 1991.[30]

In 1998, Judias Buenoano, known as the â€œblack widow,â€• was executed for murdering her husband with arsenic in 1971 in order to collect insurance money. She was the first female executed in Florida in 150 years. The fatal poisoning had remained undetected until 1983, when Buenoano was accused of trying to murder her fiancÃ© with arsenic and by car bombing. Exhumation of the husband's body, 12 years after he died, revealed substantial

amounts of arsenic in the remains.[3]

Healthcare providers have been implicated in several poisoning homicides. An epidemic of mysterious cardiopulmonary arrests at the Ann Arbor Veterans Administration Hospital in Michigan, in July and August 1975, was attributed to the homicidal use of pancuronium by two nurses.[139] Intentional digoxin poisoning by hospital personnel may have explained some of the increased number of deaths on a cardiology ward of a Toronto pediatric hospital in 1981, but the cause of the high mortality rate remained unclear.[23] In 2000, an English general practitioner Harold Shipman was convicted of murdering 15 female patients with heroin and may have murdered as many as 297 patients during his 24-year career. These recent revelations prompted calls for strengthening the death certification process, for improving preservation of case records, and for better procedures for monitoring controlled drugs.[67]

Also in 2000, an American physician Michael Swango pleaded guilty to the charge of poisoning a number of patients under his care during his residency training. Succinylcholine, potassium chloride, and arsenic were some of the agents he used to kill his patients.[137] Attention to more careful physician credentialing and to maintenance of a national physician database arose from this case because the poisonings occurred at several different hospitals across the country. Continuing concerns about health care providers acting as serial killers is highlighted by a recent case in New Jersey where a nurse Charles Cullen was found responsible for killing patients with digoxin.[17]

By the end of the 20th century, 24 centuries after Socrates was executed by poison hemlock, the means of implementing capital punishment had come full circle. Government-sanctioned execution in the United States again favored the use of a â€œstateâ€• poison: this time, the combination of sodium thiopental, pancuronium, and potassium chloride.

The use of a poison to achieve a political end resurfaced in December 2004 when it was announced that the Ukrainian presidential candidate Viktor Yushchenko was poisoned with the potent dioxin, 2,3,7,8-tetrachlorodibenzo-*p* -dioxin (TCDD).[131] The dramatic development of chloracne over the face of this public person during the previous several months suggested dioxin as a possibly culprit. Given the paucity of reports of acute dioxin poisoning, however, it wasn't until laboratory tests confirmed that Yushenko's dioxin levels were more than 6000 times normal that this diagnosis was confirmed.

Medical Errors

In late 1999, the problem of medical errors became a highly visible issue in the United States with the publication and subsequent reaction to an Institute of Medicine (IOM) report suggesting that 44,000 to 98,000 fatalities each year were the result of medical errors.[80] Many of these errors were attributed to preventable medication errors. The IOM report focused on the fact that errors usually resulted from system faults and not solely from the carelessness of individuals.

Several recent, highly publicized, medication errors received considerable public attention and provided a stimulus for the initiation of change in policies and systems. Ironically, all of the cases occurred at nationally preeminent university teaching hospitals. In 1984, 18-year-old Libby Zion died from severe hyperthermia soon after hospital admission. Although the cause of her death was likely multifactorial, drugâ€“drug interactions and the failure to recognize and appropriately treat her agitated delirium also contributed to her death.[14] State and national guidelines for closer house staff supervision, improved working conditions, and a heightened awareness of consequential drugâ€“drug interactions resulted from the medical, legislative, and legal issues of this case. In 1994, a prominent health

journalist for the *Boston Globe* , Betsy Lehman, was the unfortunate victim of another preventable dosing error when she inadvertently received four times the dose of the chemotherapeutic agent cyclophosphamide as part of an experimental protocol.[78] Despite treatment at a world-renowned cancer center, multiple physicians, nurses, and pharmacists failed to notice this erroneous medication order. An overhaul of the medication-ordering system was implemented at that institution after this tragic event.

Another highly publicized death occurred in 1999, when 18-year-old Jesse Gelsinger died after enrolling in an experimental gene-therapy study. Mr. Gelsinger, who had ornithine transcarbamylase deficiency, died from multiorgan failure 4 days after receiving, by hepatic infusion, the first dose of an engineered

adenovirus containing the normal gene. While this unexpected death was not the direct result of a dosing or drugâ€“drug interaction error, the FDA review concluded that major research violations had occurred, including failure to report adverse effects with this therapy in animals and earlier clinical trials and to properly obtain informed consent.[132] In 2001, Ellen Roche, a 24-year-old healthy volunteer in an asthma study at John Hopkins University, developed a progressive pulmonary illness and died 1 month after receiving 1 g of hexamethonium by inhalation as part of the study protocol.[136] Hexamethonium, a ganglionic blocker, was once used to treat hypertension but was removed from the market in 1972. The investigators were cited for failing to indicate on the consent form that hexamethonium was experimental and not FDA approved. Calls for additional safeguards to protect patients in research studies resulted from these cases.

Chemical Terrorism and Preparedness

The terrorist attacks on the World Trade Center and the Pentagon

on September 11, 2001, and the mailing of letters containing lethal amounts of anthrax in October 2001, resulted in profound changes in preparedness strategies against future terrorist strikes. Defending against biologic and chemical terrorism suddenly took on a much heightened sense of urgency. The asymmetric nature of the terrorism menace has led to increasing concerns that traditional industrial chemicalsâ€”so-called chemical agents of opportunityâ€”may pose a more likely threat than a military chemical warfare agent attack. Responding to these events, medical toxicologists and poison control centers are playing an increasingly visible role in terrorism preparedness. Medical toxicologists from both emergency response and public health backgrounds provide leadership in preparedness planning and training.

These events have led to a new realization that poison control centers serve an essential public health function that extends significantly beyond the traditional prevention of childhood poisonings. Responding to these new challenges an IOM report released in 2004 calls for a more formal integration of poison center services into local, state, and federal public health preparedness and response.[70]

Summary

Since the dawn of recorded history, toxicology has had a great impact on human events. And although over the millennia the important poisons of the day have changed to some degree, toxic substances continue to challenge our safety. The era of poisoners for hire may have long ago reached its pinnacle, but problems with drug abuse, intentional self-poisoning, exposure to environmental chemicals, and the potential for biological and chemical terrorism continues to challenge us. Unfortunately, knowledge acquired by one generation is often forgotten or discarded inappropriately by the next generation, leading to a cyclical historic course. This

historic review is meant to describe the past and to better prepare toxicologists and society for the future.

Antidotes in Depth

Antiquated Antidotes

Paul M. Wax

While the judicious use of certain antidotes (eg, *N* -acetylcysteine, naloxone, pyridoxine) is critically important in the management of select poisoned patients, other antidotes do not necessarily offer a distinct clinical advantage and may create additional problems (eg, flumazenil, physostigmine). A perpetual search for better and improved antidotes features prominently in the history of toxicology. Unfortunately, many of the â€œantidotal breakthroughsâ€• over the years have not lived up to their promise (Table A1-1). A number of these antidotes, such as caffeine, are ineffective. Others, such as propylene glycol, were insufficiently tested or were replaced by â€œsafer,â€• more effective treatment such as paraldehyde.[13] Most troubling, the use of some of these agents, such as analeptics and copper sulfate, actually worsened the clinical situation. Unfortunately, just as the various classic theriac preparations remained popular into the 20th century, the use of many of these â€œmodern antidotesâ€• had persisted long after scientific investigation demonstrated their ineffectiveness. An emphasis on physiologic antagonism with antidotes, such as analeptics, has often taken precedence over good supportive care. Not surprisingly, the use of modern-day

theriacs, such as the â€œuniversal antidote,â€• persisted until quite recently, despite a lack of serious scientific support. This section highlights some of the critical changes in poison management during the last century.

Analeptics

One of the most interesting changes in poison management took place during the 1940s and 1950s with regard to the use of analeptics in the treatment of barbiturate overdose.[58] Analeptics are nonspecific arousal agents and include such stimulants as strychnine, camphor, caffeine, picrotoxin, pentylenetetrazol, nikethamide, amphetamine, and methylphenidate. Barbiturates, the first widely available sedative-hypnotics, were introduced in the early 20th century. Within a few years they became the most common cause of serious overdose.[6] In the 1920s, barbiturate overdose management recommendations still included blood-letting techniques.[41] By the next decade, as interest in principles of antagonism between stimulants and depressants became widespread, much attention was focused on the use of analeptic agents to combat the sedative effects of barbiturates. Proponents of analeptics argued that because the effects of cocaine intoxication appeared to be neutralized by barbiturates, a reciprocal approachâ€”treating depressant overdoses with stimulantsâ€”should also be effective.[41] The principal goal of analeptic therapy was to awaken the patient as soon as possible.

Numerous analeptic agents were recommended over the years. Prior to the development of the first synthetic analeptics in the late 1920s, naturally occurring stimulants, such as caffeine, lobeline, strychnine, cocaine, and camphor, were utilized for this purpose. According to Leschke's *Clinical Toxicology* , a standard textbook published in 1934, the most effective remedy for the treatment of a sedative-hypnotic overdose was the intrathecal injection of 10% camphorated oil.[37]

Picrotoxin, obtained from the berries of the *Cocculus indicus* plant, was first suggested as an antagonist to morphine in 1847.[35] After a series of animal studies in the early 1930s, picrotoxin was enthusiastically endorsed as the analeptic of choice.[40] Picrotoxin acts as a Î³-aminobutyric acid type A ($GABA_A$) and type C ($GABA_C$) receptor antagonist and as a glycine-receptor antagonist facilitating excitatory neurotransmission.[21] Although picrotoxin remains one of the most powerful CNS and respiratory stimulants in our pharmacopeia, it is a proconvulsant.

The subsequent introduction of synthetic analeptics, such as pentylenetetrazol (Metrazol, Cardiazol) and nikethamide (Coramine), increased the growing dependence on analeptics as the major treatment modality for barbiturate overdose.[31, 34, 42] During his search for an effective camphor substitute, Schmidt synthesized pentylenetetrazol, the first synthetic analeptic, in 1924, and it was initially introduced as a cardiac stimulant.[57] Mechanistically, it reduces GABAergic inhibition and interacts with picrotoxin-binding sites. It may also work by changing extraneuronal potassium permeability, thereby partially depolarizing neuronal membranes and increasing excitability. Pentylenetetrazol was employed as a CNS stimulant in the treatment of depressant overdoses from the 1930s through the 1960s,[19, 31] but was considered less effective than picrotoxin or strychnine.

Nikethamide was also used as a cardiac and respiratory stimulant and was reputed to be helpful in overcoming the respiratory depression of morphine, sedative-hypnotics, and volatile anesthetics.[42] Further experience showed that it was a less efficacious analeptic than either picrotoxin or pentylenetetrazol.[23] Its exact mechanisms of enhancing excitation are unknown.

Analeptic treatment strategies were often referred to as â€œvery energetic,â€• because large doses of multiple analeptics were frequently used.[45] As recently as the 1950s, newer analeptics,

such as bemegride, were being introduced as the â€œreal antidoteâ€• to barbiturate overdoses.[53] During this time, methylphenidate was also used in the treatment of barbiturate overdoses. In 1967, one enthusiastic methylphenidate proponent emphasized, â€œDon't let comatose patients remain comatose after barbiturate overdose. Methylphenidate will waken them safely.â€•[42] Toxicology textbooks published in the 1950s and 1960s continued to recommend caffeine, picrotoxin, and nikethamide as useful analeptic agents.[15,22,38] Subconvulsive electric shock therapy was also advocated as an alternative or adjunct to these chemical convulsants during this period.[48]

Unfortunately, many adverse effects occurred with the use of these analeptics, including hyperthermia, dysrhythmias, seizures, and psychoses.[33,42,47] It gradually became evident that analeptic therapy, despite its theoretic benefits, offered no real advantage, did not reduce mortality, and, placed the patient at risk for significant iatrogenic complications.[9] A different strategy was required.

Beginning in the mid-1940s, a distinctive approach to barbiturate overdose was pioneered by Eric Nilsson and Carl Clemmesen at the Bispebjerg Hospital in Copenhagen, Denmark.[9,44] This treatment regimen, known as the *Scandinavian method*, abandoned the use of analeptics in the treatment of barbiturate overdoses. Instead

of primarily emphasizing the termination of coma, attention was directed at intensive supportive therapy with respiratory ventilation, oxygenation, and cardiovascular support. This strategy was analogous to the postanesthetic recovery room care provided to surgical patients. Using this â€œrevolutionaryâ€• approach, barbiturate overdose mortality significantly dropped from approximately 20% with stimulation therapy to 1â€“2% with the Scandinavian method.[9]

Analeptic

Amphetamine
Sedative overdose
Seizures, hyperthermia, aspiration
Bemegride
Sedative overdose
Seizures, hyperthermia, aspiration
Caffeine
Sedative overdose
Seizures, hyperthermia, aspiration
Camphorated oil
Sedative overdose
Seizures, hyperthermia, aspiration
Lobeline
Sedative overdose
Seizures, hyperthermia, aspiration
Nikethamide (Coramine)
Sedative overdose
Seizures, hyperthermia, aspiration
Pentylenetetrazol (Metrazol)
Sedative overdose
Seizures, hyperthermia, aspiration
Picrotoxin
Sedative overdose
Seizures, hyperthermia, aspiration
Strychnine
Sedative overdose
Seizures, hyperthermia, aspiration
Adsorbent
Universal antidote
Gastrointestinal decontamination
Ineffective; tannic acid hepatotoxicity
Burnt toast
Gastrointestinal decontamination
Ineffective

Complexing agent
Sodium phosphate (Phospho-Soda)
Iron
Hyperphosphatemia
Emetic
Apomorphine
Gastric emptying
CNS depression, aspiration
Copper sulfate
Gastric emptying
Caustic; increased copper load
Mechanical stimulation
Gastric emptying
Oropharyngeal trauma; ineffective
Mustard powder
Gastric emptying
Ineffective
Salt water
Gastric emptying
Hypernatremia
Tartar emetic
Gastric emptying
GI toxicity
Zinc sulfate
Gastric emptying
GI toxicity
Metal antidote
Ascorbic acid
Lead, arsenic
Ineffective
Calcium bromide
Lead
Ineffective
Ferric hydroxide/magnesium hydroxide

Arsenic
Ineffective
Potassium ferrocyanide
Copper
Ineffective
Potassium iodide
Lead
Ineffective
Sodium formaldehyde sulfoxylate
Mercury bichloride
Ineffective
Miscellaneous
Acetazolamide
Salicylate
Acidemia; increased CNS salicylates
Hypochlorites
Snakebites
Ineffective
Potassium permanganate
Alkaloids (morphine, strychnine, aconite)
Caustic
Propylene glycol
Phenolphthalein

Raw rabbit brain
Amanita phalloides
Ineffective
Neutralizing agent
Calcium carbonate
Acid
Exothermic reaction; gas formation; ineffective
Hydrochloric acid
Alkali
Exothermic reaction; gas formation; ineffective

Lemon juice
Alkali
Exothermic reaction; gas formation; ineffective
Lime water
Acid
Exothermic reaction; gas formation; ineffective
Magnesium hydroxide
Acid
Exothermic reaction; gas formation; ineffective
Sodium bicarbonate
Acid
Exothermic reaction; gas formation; ineffective
Vinegar
Alkali
Exothermic reaction; gas formation; ineffective
Sedative
Chloroform
Delirium tremens, strychnine
Hepatotoxin, dysrhythmias
Digitalis
Delirium tremens
Ineffective
Ethanol
Delirium tremens
Difficult to titrate; metabolic abnormalities
Ether
Delirium tremens; agitation/seizures
Difficult to administer; irritating
Paraldehyde
Delirium tremens
Acidosis; difficult to administer
Sodium bromide
Delirium tremens
Difficult to use; bromism

Tribromoethanol (Avertin)
Agitation/seizures
Sedation

Type of Antidote	Therapeutic Agent	Uses	Adverse Effects

TABLE A1-1. Antiquated Antidotes

Early Treatments of Opioid Overdoses

Prior to the 1950s, opioid overdose was treated with many of the same analeptic agents. In the early 1950s, an important development in the history of poison management occurred when two

specific opioid antidotes were introduced: nalorphine (Nalline) and levallorphan (Lorfan).[16] These drugs were capable of reversing the respiratory effects of an opioid overdose by blocking opioid receptors. Nalorphine was also routinely administered to determine the presence or absence of opioids in suspected opioid abusers. This test, known as the *Nalline test* , was used as a monitoring tool in drug abuse programs.[25] The test was considered positive if it precipitated signs of opioid withdrawal such as pupillary dilation.

Unfortunately, neither nalorphine nor levallorphan was a pure opioid antagonist. Instead, the mixed agonistâ€“antagonist properties of these drugs significantly limited their usefulness. Respiratory depression could be potentiated, especially in opioid-free patients. This was most likely to occur when these drugs were administered to comatose patients with mild hypoventilation who had overdosed on sedative-hypnotics or ethanol.

Naloxone, which was introduced in the 1970s, is a much safer drug

because of its pure opioid antagonistic properties. It has completely replaced nalorphine and levallorphan in the treatment of opioid overdoses.[18] Naloxone has no agonist properties, does not cause any additional respiratory depression, regardless of the ingestion, is short-acting and safe to use for patients with coma following an undefined overdose. In addition, it is useful in treating patients with an overdose of other mixed agonistâ€“antagonist opioids, such as pentazocine, who do not typically respond to nalorphine.

Outmoded Treatments for Ethanol Withdrawal

The treatment modalities employed in the treatment of ethanol withdrawal have changed considerably over the last 200 years.[17] Until the development of the first inhalational anesthetics in the mid 19th century, opium and, later, morphine were the primary pharmacologic treatments of severe ethanol withdrawal. Unfortunately, this approach was associated with problems related to opioid toxicity in these unmonitored patients. Adjuncts used with the opioids included digitalis that was thought to provide benefit to counteract the adverse cardiac effects associated with ethanol withdrawal. Once the first general anesthetics were introduced, a new treatment approach for delirium tremens was advocated in which ether or chloroform was inhalationally administered to induce sleep for up to 24 hours. Case reports from this time suggested that such an approach was effective and that patients would awaken without further signs of ethanol withdrawal.[30] Other drugs that were employed included the bromide salts but they proved difficult to use and in some cases were associated with the development of bromism.

By the early 20th century, chloral hydrate was routinely administered in the treatment of ethanol withdrawal and opioid use in this setting decreased.[55] Soon thereafter, barbiturates and

paraldehyde also became a mainstay of ethanol withdrawal therapy. While some patients responded well to paraldehyde, it proved very difficult to administer at times and was also associated with the development of metabolic acidosis. It is considerably more toxic than benzodiazepines and is very difficult to titrate because of variable rates of absorption. Other disadvantages include hepatotoxicity, gastritis when given orally, sterile abscesses when given intramuscularly, and proctitis following rectal administration. It also has a notoriously unpleasant odor.[28]

Ethanol administered intravenously or orally also has been used to suppress withdrawal for many years. Recent advocacy for prophylactic use of ethanol in hospitalized patients can be found in the surgical literature.[50] However, there are several problems with the use of ethanol in the treatment of ethanol withdrawal.[27] It has a very short duration of action and is difficult to titrate, and its CNS and hepatotoxicity are well known. Continued intravenous use of ethanol intensifies the biochemical abnormalities associated with ethanol metabolism, shifting energy production toward lactate and ketogenesis. Finally, extravasation of ethanol may cause local tissue necrosis, which in a recent report required excision and grafting.

Other discredited approaches popularized in the 1940s include insulin therapy[49] as a means to replenish glycogen and improve hepatic function, and nonconvulsive electroshock therapy.[7] Gradually, increased attention to adequate hydration, nutrition, vitamin replacement, and proper monitoring, as well as the need for appropriate sedation with cross-tolerant drugs such as the benzodiazepines, became the modern standard for the care of the ethanol-withdrawal patient.

Outdated and Dangerous Emetics

The role of emetics in poison management, both in the home and

at the hospital, has undergone significant transformation over the years. The antimony salt commonly known as tartar emetic had a long history of use as an emetic, as well as a sedative, expectorant, cathartic, and diaphoretic. During the 19th century, tartar emetic was one of the three most widely prescribed drugs, the other drugs being opium and calomel (mercurous chloride).[26] Tartar emetic is no longer recommended for any purpose because of its inherent toxicity.[8]

Standard gastrointestinal decontamination recommendations during the 1960s included mechanical stimulation of the throat and the ingestion of saltwater emetics, or mustard water in the home, and copper sulfate, zinc sulfate, or apomorphine in the hospital.[1, 32] Many authorities recommended mechanical stimulation of the pharynx (finger-down-the-throat technique) as a quick-and-easy home remedy when induction of emesis was desirable.[1, 11] This method, however, is both ineffective and potentially traumatic, and is no longer encouraged.[11] Similarly, the use of saltwater emetics was abandoned after numerous cases of severe salt poisoning resulted from their administration.[4, 14] Mustard powder has never been proven effective.[8] The use of copper sulfate as an emetic[32] also fell out of favor because of its caustic properties, its potential to cause acute copper poisoning, and its unreliability.[29, 54] Zinc sulfate also is no longer used as an emetic.[8]

Until the 1980s, apomorphine was advocated as an emetic.[10, 43] One reason for its use was the thought that it was safer and more effective than copper sulfate.[29] It was supposed to be particularly useful for the combative or uncooperative patient because it could be administered parenterally, it had a rapid onset of action, and in this setting, was frequently used instead of syrup of ipecac.[44] Apomorphine's propensity to cause CNS depression, however, increased the risk of subsequent aspiration and made its use potentially very dangerous. Moreover, a sterile injectable form of apomorphine has not been available in the United States for many years. For all of these reasons, apomorphine is no longer used as

an emetic.[39]

The Universal Antidote

Two other â€œantidotesâ€• that were once commonly used for decontamination but that have fallen into disfavor are the â€œuniversal antidoteâ€• and burnt toast. For many years the universal antidote, sold

under the trade names Unidote and Res-Q, was a medical tradition[46] and was advocated by many textbooks as part of the standard management of the poisoned patient.[15, 22, 38] Commercial preparations consisted of one part magnesium oxide, one part tannic acid, and two parts activated charcoal. An alternative home recipe consisted of milk of magnesia, strong tea, and burnt toast. Combination therapy of this sort was thought to offer a broader spectrum of action than activated charcoal alone. It was theorized that the magnesium oxide would neutralize acids and the tannic acid would precipitate alkaloids and metals.[38] The use of the universal antidote declined by the mid-1980s and is no longer available. Studies demonstrated that activated charcoal was superior to the universal antidote in decreasing absorption[12, 46] and that the decreased efficacy of the universal antidote was caused by tannic acid interfering with activated charcoal's adsorbence of other toxins.[12] Furthermore, the potential hepatotoxicity of tannic acid was increasingly recognized.[46] Although burnt toast had been advocated as an activated charcoal substitute in the home,[3] its use was also abandoned because of its lack of significant adsorbent activity.[36]

Other Antiquated Antidotes

The use of drugs for the chemical restraint of agitated individuals has also undergone significant evolution during the past decades. Depressant agents, such as tribromoethanol (Avertin) and ether,

are no longer used because of the availability of safer alternative agents. Likewise, paraldehyde and ethanol, which were commonly used for the treatment of alcohol withdrawal,[24] have been replaced by the much safer and less toxic benzodiazepines. The use of analeptics to treat the depressive effects of ethanol is also obsolete.[56]

Another change in treatment involves the abandonment of neutralizing agents for caustic ingestions. Until the 1970s, typical recommendations for the treatment of alkali ingestions included the use of vinegar (acetic acid), lemon juice, or, in some cases, dilute hydrochloric acid.[38] Suggestions for neutralizing acid ingestions included the use of magnesium hydroxide, lime water, or calcium carbonate.[38] Because of the extremely rapid onset of action of caustic agents, concerns arose over whether it was already too late to reverse the caustic process. Furthermore, the addition of neutralizing agents could increase the potential for a consequential exothermic reaction and/or gas production.[51] Such reactions in an already weakened hollow viscus may be poorly tolerated and lead to extension of the tissue injury or perforation. For all of these reasons, the use of neutralizing agents is no longer recommended.

Other antiquated antidotes include ferric hydroxide (*antidotum arsenici*), which was used in the treatment of arsenic poisoning. Acetazolamide, which was advocated for alkalinizing the urine in salicylate poisoning,[52] causes a systemic acidemia that can worsen the salicylate toxicity, and is therefore no longer used. The use of sodium phosphate (Phospho-Soda) in the management of iron overdose in an attempt to create insoluble ferrous phosphate has also ceased because of problems with its marginal efficacy and resultant hyperphosphatemia.[20]

Some abandoned antidotes have found new uses. At one time potassium iodide was believed to be helpful as a means to enhance lead excretion, a practice that was later discarded. More recently,

potassium iodide has been touted as a specific blocker of thyroid radioiodine uptake which may reduce the risk of thyroid cancer after radiation exposure.[2]

Finally, enthusiasm has waned for raw rabbit brain, which was recommended as recently as the 1930s as a â€œchance of lifeâ€• for patients with *Amanita phalloides* poisoning.[37] The raw brain approach was pioneered in the early 1800s after it was observed that rabbits could eat poisonous mushrooms without ill effects.[5] Postulating that rabbits had some sort of protective mechanism that neutralized the mushroom toxin, investigators formulated an antidotal concoction consisting of seven rabbit brains and three rabbit stomachs. The preparation was minced and ground into pellets and administered with a sweetener. When patients who received the rabbit brain antidote survived the mushroom poisoning, it was erroneously concluded that these uncontrolled observations provided proof of efficacy.[5]

Many of our current antidotes have not undergone rigorous scientific evaluation regarding efficacy and safety. In time, some of these antidotes will undoubtedly join this list of antiquated antidotes. Lessons learned from the past, such as the abandonment of analeptics, help to optimize present-day patient care and to better prepare us to investigate and evaluate the next generation of antidotes.

Chapter 2

Toxicologic Plagues and Disasters in History

Paul M. Wax

Throughout history, mass poisonings have caused suffering and misfortune. From the ergot epidemics of the Middle Ages to contemporary industrial disasters, these plagues have had great political, economic, social, and environmental ramifications. Particularly within the last 100 years, as the number of toxins and potential toxins has risen dramatically, toxic disasters have become an increasingly common event. The sites of some of these eventsâ€”Bhopal (India), Chernobyl (Ukraine), Jonestown (Guyana), Love Canal (New York), Minamata Bay (Japan), Seveso (Italy), West Bengal (India)â€”have come to symbolize our increasingly toxic habitat. This chapter provides an overview of some of the most consequential and historically important toxin-associated disasters. Globalization has led to the proliferation of toxic chemicals throughout the world. Many chemical factories are not secure despite their storage of large amounts of potentially lethal chemicals. Given the increasing attention to terrorism preparedness, an appreciation of chemicals as agents of

opportunity for terrorists to employ as weapons has suddenly assumed much greater importance.

Gas Disasters

Inhalation of toxic gases and oral ingestions resulting in food poisoning tend to subject the greatest number of people to adverse consequences of a toxic exposure. Toxic gas exposures may be the result of a natural disaster (volcanic eruption), industrial mishap (fire, chemical release), chemical warfare, or an intentional homicidal or genocidal endeavor (concentration camp gas chamber). Depending on the toxin, the clinical presentation may be acute, with a rapid onset of toxicity (cyanide), or subacute/chronic, with a gradual onset of toxicity (air pollution).

One of the earliest recorded toxic gas disasters resulted from the eruption of Mount Vesuvius near Pompeii, Italy, in 79 A.D. (Table 2-1). Poisonous gases generated from the volcanic activity reportedly killed thousands.[24] A much more recent natural disaster occurred in 1986 in Cameroon, when excessive amounts of carbon dioxide spontaneously erupted from Lake Nyos, a volcanic crater lake.[8] Seventeen hundred human and countless animal fatalities resulted from exposure to this asphyxiant.

A toxic gas leak at the Union Carbide pesticide plant in Bhopal, India, in 1984, resulted in one of the greatest civilian toxic disasters in modern history.[126] An unintended exothermic reaction at this carbaryl-producing plant caused the release of over 24,000 kg of methyl isocyanate. This gas was quickly dispersed through the air over the densely populated area surrounding the factory where many of the workers lived, resulting in at least 2500 deaths and 200,000 injuries.[74] The initial response to this disaster was greatly limited by a lack of pertinent information about the toxicity of this agent as well as the poverty of the residents. A followup study 10 years later showed persistence of small-airway obstruction among survivors.[20] Chronic eye problems also were

reported.[3] Calls for improvement in disaster preparedness and strengthened right-to-know laws regarding potential toxic exposures resulted from this tragedy.[43 , 126]

The release into the atmosphere of 26 tons of hydrofluoric acid at a petrochemical plant in Texas, in October 1987, resulted in 939 people seeking medical attention at nearby hospitals. Ninety-four people were hospitalized, but there were no deaths.[133]

More than any other single toxin, carbon monoxide has been involved with the largest number of toxic disasters. Catastrophic fires, such as the Cocoanut Grove Nightclub fire in 1943, have caused hundreds of deaths at a time, many of them from carbon monoxide poisoning.[27] The 1990 fire at the Happy Land Social Club in the Bronx, New York, claimed 87 victims, including a large number of nonburn deaths,[67] and the 2003 fire at The Station nightclub in West Warwick, Rhode Island, killed 98 people.[109] Carbon monoxide poisoning was a major toxin in many of these deaths, although hydrogen cyanide gas and simple asphyxiation may also have contributed to the overall mortality.

Another notable toxic gas disaster involving a fire occurred at the Cleveland Clinic, Cleveland, Ohio, in 1929, where a fire in the radiology department resulted in 125 deaths.[23] The burning of nitrocellulose radiographs produced nitrogen dioxide, cyanide, and carbon monoxide gases that were thought to be responsible for many of the fatalities. In 2003, at least 243 people died and 10,000 people became ill after a drilling well exploded in Gaogiao, China, releasing hydrogen sulfide and natural gas into the air.[136] A toxic gas cloud covered 25 square kilometers. Ninety percent of the villagers who lived in the village adjoining the gas well died.

The release of a dioxin-containing chemical cloud into the atmosphere from an explosion at a hexachlorophene production factory in Seveso, Italy, in 1976, resulted in one of the most serious exposures to dioxin (2,3,7,8-tetrachlorodibenzo-*p* -dioxin).[42] The

lethality of this agent in animals has caused considerable concern for acute and latent injury from human exposure. Despite this apprehension, chloracne was the only significant clinical finding related to the dioxin exposure at 5-year followup.[107]

TABLE 2-1. Gas Disasters

Air pollution is another source of toxic gases causing significant disease and death. Complaints about smoky air date back to at least 1272, when King Edward I banned the burning of sea-coal.[124] By the 19th centuryâ€"the era of rapid industrialization in Englandâ€"winter â€œfogsâ€• became increasingly problematic. An 1873 London fog was responsible for 268 deaths from bronchitis. Excessive smog in the Meuse Valley of Belgium in 1930, and in Donora, Pennsylvania, in 1948, was also blamed for excess morbidity and mortality. In 1952, another dense sulfur dioxide-laden smog in London was responsible for 4000 deaths.[65] Both the initiation of long-overdue air-pollution reform in England and Parliament's passing of the 1956 Clean Air Act resulted from this latter â€œfog.â€•

Warfare and Terrorism

Exposure to xenobiotics with the deliberate intent to inflict harm claimed an extraordinary number of victims during the 20th century (Table 2-2). During World War I, chlorine and phosgene gases and the liquid vesicant mustard were used as battlefield weapons, with mustard causing approximately 80% of the chemical casualties.[112] Reportedly, 100,000 deaths and 1.2 million casualties were attributable to these chemical attacks.[24] These toxic exposures resulted in severe airway irritation, acute lung injury, hemorrhagic pneumonitis, skin blistering, and ocular damage. Chemical weapons were used again in the 1980s during the Iran-Iraq war.

Chlorine, mustard gas, phosgene

Sarin	Tokyo	1995	Subway exposure; 5510 people seek medical attention
Dust and other particulates	New York City	2001	World Trade Center collapse from terrorist air strike resulted in persistent cough among some rescuers

TABLE 2-2. Warfare and Terrorism Disasters

The Nazis used poisonous gases during World War II to commit mass murder and genocide. Initially, the Nazis employed carbon monoxide to kill. To expedite the killing process, Nazi scientists developed Zyklon-B gas (hydrogen cyanide gas). As many as 10,000 people per day were killed by the rapidly acting cyanide, and millions of deaths were attributable to the use of these gases.

Agent Orange was widely used as a defoliant during the Vietnam War. This herbicide consisted of a mixture of 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid (2,4-D), as well as small amounts of a contaminant, 2,3,7,8-tetrachlorodibenzo-*p* -dioxin (TCDD), better known as dioxin. Over the years a large number of adverse health effects had been attributed to Agent Orange exposure. A 2002 Institute of Medicine study concluded that among Vietnam veterans there is sufficient evidence to demonstrate an association between this herbicide exposure and chronic lymphocytic leukemia, soft-tissue sarcomas, non-Hodgkin lymphomas, Hodgkin disease, and chloracne.[48]

Mass exposure to the very potent organic phosphorus compound sarin occurred in March 1995, when terrorists released this chemical warfare agent in three separate Tokyo subway lines.[91] Eleven people were killed, and 5510 people sought emergency medical evaluation at more than 200 hospitals and clinics in the area.[111] This mass disaster introduced the spectra of terrorism to the modern emergency medical services system, resulting in a

greater emphasis on hospital preparedness, including planning for the psychological consequences of such events. Sarin exposure also resulted in several deaths and hundreds of casualties in Matsumoto, Japan, in June 1994.[79 , 87]

During recent wars and terrorism events, a variety of physical and neuropsychologic ailments have been attributed to possible exposure to toxic agents.[16 , 47] Gulf War syndrome is a

constellation of chronic symptoms, including fatigue, headache, muscle and joint pains, ataxia, paresthesias, diarrhea, skin rashes, sleep disturbances, impaired concentration, memory loss, and irritability, noted in thousands of Persian Gulf War veterans without a clearly identifiable cause. A number of etiologies have been advanced to explain these varied symptoms, including exposure to the smoke from burning oil wells; chemical and biologic warfare agents, including nerve agents; and medical prophylaxis, such as the use of pyridostigmine bromide or anthrax and botulinum toxin vaccines, although the actual etiology remains unclear.[29 , 38 , 47 , 49 , 58 , 123]

Most recently, persistent cough and increased bronchial responsiveness was noted among 8% of New York City Fire Department workers who were exposed to large amounts of dust and other particulates following the collapse of World Trade Center in September 2001.[97] The risk of development of hyperreactivity and reactive airways dysfunction was clearly associated with the intensity of exposure.[6]

Food Disasters

Unintentional contamination of food and drink has led to numerous toxic disasters (Table 2-3). Ergot, produced by the fungus *Claviceps purpurea* , caused epidemic ergotism as the result of eating breads and cereals made from rye that was contaminated by *C. purpurea* . In some epidemics, convulsive manifestations predominated, and in others, gangrenous manifestations predominated.[76] Ergot-induced severe vasospasm was thought responsible for both types of presentations.[75] In 994 A.D., 40,000 people died in Aquitania, France, in one such epidemic.[63] Convulsive ergotism was initially described as a â€œfire which twisted the people,â€• and the term â€œSt. Anthony's fireâ€• (*ignis sacer*) was used to refer to the excruciating burning pain experienced in the extremities that is an early manifestation of

gangrenous ergotism. The events surrounding the Salem, Massachusetts witchcraft trials have also been attributed to the ingestion of contaminated rye. The bizarre neuropsychiatric manifestations exhibited by some of the individuals associated with this event may have been caused by the hallucinogenic properties of ergotamine, a lysergic acid diethylamide (LSD) precursor.[12 , 72]

Xenobiotic Location Date Significance

TABLE 2-3. Food Disasters

During the last half of 20th century, unintentional mass poisoning from food and drink contaminated with toxic chemicals became all too common. One of the more unusual poisonings occurred in Turkey, in 1956, when wheat seed treated with the fungicide hexachlorobenzene and intended for planting was inadvertently used for human consumption. Approximately, 4000 cases of porphyria cutanea tarda were attributed to the ingestion of this wheat seed.[104]

Another example of chemical food poisoning took place in Epping, England, in 1965. In this incident, a sack of flour became contaminated with methylenedianiline when the chemical unintentionally spilled onto the flour during transport to a bakery. Subsequent ingestion of bread baked with the contaminated flour produced hepatitis in 84 people. This outbreak of toxic hepatitis became known as Epping jaundice.[55]

The manufacture of polybromated biphenyls (PBBs) in a factory that also produced food supplements for livestock resulted in the unintentional contamination of a large amount of livestock feed in Michigan in 1973.[13] Significant morbidity and mortality among the livestock population resulted. Increased human tissue levels of PBBs were reported,[134] although human toxicity seemed limited to vague constitutional symptoms and abnormal liver function tests.[2]

The chemical contamination of rice oil in Japan in 1968 caused a syndrome called Yusho (â€œrice oil diseaseâ€•). This occurred when heat-exchange fluid containing polychlorinated biphenyls (PCBs) and polychlorinated dibenzofurans (PCDFs) leaked from a heating pipe into the rice oil. More than 1600 people developed chloracne, hyperpigmentation, an increased incidence of liver cancer, and/or adverse reproductive effects. In 1979, 2000 people in Taiwan developed similar clinical manifestations after ingesting another batch of PCB-contaminated rice oil. This latter epidemic was referred to as Yu-Cheng (â€œoil diseaseâ€•).[50]

In another oil contamination epidemic, consumption of illegally marketed cooking oil in Spain, in 1981, was responsible for a mysterious poisoning epidemic that affected more than 19,000 people and resulted in at least 340 deaths. Exposed patients developed a multisystem disorder referred to as toxic oil syndrome (or toxic epidemic syndrome), which was characterized by pneumonitis, eosinophilia, pulmonary hypertension, scleroderma-like features, and neuromuscular changes. Although this syndrome

was associated with the consumption of rapeseed oil denatured with 2% aniline, the exact etiologic agent was never definitively identified.[53 , 121]

In 1999, an outbreak of Coca-Colaâ€“related health complaints occurred in Belgium, when 943 people, mostly children, complained of gastrointestinal symptoms, malaise, headaches, and palpitations, after consuming Coca-Cola.[88] Many of those affected complained of an off-taste or bad odor to the soft drink. Millions of cans and bottles were removed from the market at a cost of $103 million.[88] In some of the bottles the carbon dioxide was contaminated with small amounts of carbonyl sulfide, which hydrolyzes to hydrogen sulfide, and may have been responsible for odor-triggered reactions. Mass psychogenic illness may have contributed to the large number of medical complaints as the concentrations of the carbonyl sulfide (5â€“14 Âµg/L) and hydrogen sulfide (8â€“17 Âµg/L) were very low and unlikely to cause systemic toxicity.[31]

Epidemics of heavy metal poisoning from contaminated food and drink have also occurred throughout history. Epidemic lead poisoning is associated with many different vehicles of transmission, including leaden bowls, kettles, and pipes. A famous 18th-century epidemic was known as the Devonshire colic. Although the exact etiology of this disorder was unknown for many years, later evidence suggested that the ingestion of lead-contaminated cider was responsible.[127]

Intentional chemical contamination of food may also occur. Multiple cases of metal poisoning occurred in Buenos Aires, in 1987, when vandals broke into a butcher's shop and poured an unknown amount of acaricide (45% sodium arsenite solution) over 200 kg of partly minced meat.[101] The contaminated meat was purchased by 718 people. Of 307 meat purchasers who submitted to urine sampling, 49 had urine arsenic levels of 76â€“500 Âµg/dL, and 12 had urine arsenic levels above 500 Âµg/dL (normal urine

arsenic is <50â€“100 Âµg/dL).

In 2003, 92 people became ill after they ingested contaminated ground beef that was deliberately contaminated with a nicotine pesticide by a supermarket employee.[89] These mass poisoning have heightened concerns about food safety and security.

At the end of the 20th century and into the 21st century, what some observers call the greatest mass poisoning in history is occurring in Bangladesh and India's West Bengal State.[22, 81, 98, 116] In Bangladesh alone, 60 million people are routinely drinking arsenic-contaminated ground water. At least 220,000 inhabitants of India's West Bengal have been diagnosed with symptoms of arsenic poisoning.[80] Reported symptoms include melanosis, depigmentation, hyperkeratosis, hepatomegaly, splenomegaly, squamous cell carcinoma, intraepidermal carcinoma, and gangrene.[22] In a country that was long plagued with dysentery, attempts to purify the water supply led to the drilling of millions of wells into the superficial water table. Unknown to the engineers, this water was naturally contaminated with arsenic creating several thousand tube wells with extremely high concentrations of arsenicâ€”up to 40 times the acceptable concentration. Although toxicity from arsenic-contaminated groundwater was previously reported from other areas of the world, including Argentina, China, Mexico, Taiwan (Black Foot disease), and Thailand, the number of people at risk in Bangladesh and West Bengal is by far the largest.

Methyl mercury was the etiologic agent for several recent poisoning epidemics. During the 1950s, a Japanese chemical factory that manufactured vinyl chloride and acetaldehyde routinely discharged mercury into Minamata Bay, resulting in contamination of the aquatic food chain. An epidemic of methyl mercury poisoning ensued as the local people ate the poisoned fish.[96, 122] Chronic brain damage, tunnel vision, deafness, and severe congenital defects were associated with this outbreak.[96]

Another mass epidemic of methyl mercury poisoning occurred in

Iraq in 1971, when the local population consumed homemade bread prepared from wheat seed treated with a methyl mercury fungicide.[5] Six thousand hospital admissions and more than 400 deaths were associated with this disaster. As in the case of the hexachlorobenzene exposure in Turkey 25 years previously, the treated grain, intended for use as seed, was instead used as food.

Contamination of the local water supply with the wastewater runoff from a zinc-lead-cadmium mine in Japan, from 1939 to 1954, was believed responsible for causing Itai-Itai (â€œouch-ouchâ€•) disease, an unusual chronic syndrome manifested by extreme bone pain and osteomalacia. The local water was used for drinking and irrigation of the rice fields. Approximately 200 people who lived along the banks of the Jintsu River developed these peculiar symptoms, which were thought most likely to be caused by the cadmium.[10]

Medicinal Drug Disasters

Illness and death as a consequence of therapeutic drug use occur as sporadic events, usually affecting individual patients, or as mass disasters, affecting multiple (sometimes hundreds or thousands) patients. Sporadic single-patient medication-induced tragedies usually result from errors (Chap. 1) or unforeseen idiosyncratic reactions. Mass therapeutic drug disasters generally have occurred secondary to poor safety testing, a lack of understanding of diluents and excipients, drug contamination, or problems with unanticipated drugâ€“drug interactions or drug toxicity (Table 2-4).

In September and October 1937, more than 100 deaths were associated with the use of one of the early sulfa preparationsâ€”elixir of sulfanilamide-Massengillâ€”that contained 72% diethylene glycol as the vehicle for drug delivery. Little was known about diethylene glycol toxicity at the time, and many cases of renal failure and death occurred.[33] As a result of this

catastrophe, animal drug testing was mandated by the Food, Drug, and Cosmetic Act of 1938 to avoid similar tragedies in the future.[128] Unfortunately, diethylene glycol continues to be sporadically used in other countries as a medicinal diluent, resulting in additional deaths in South Africa (1969), India (1986), Nigeria (1990), Bangladesh (1990â€“1992), and Haiti (1995â€“1996).[129] In the most recent disaster in Haiti, at least 88 children died (case fatality rate 98% for those

who remained in Haiti) after ingesting an acetaminophen elixir formulated with diethylene glycolâ€“contaminated glycerin.[90 , 103]

TABLE 2-4. Medicinal Disasters

A lesser-known drug manufacturing event, also involving an early sulfa antimicrobial, occurred in 1940â€“1941, when at least 82 people died from the therapeutic use of sulfathiazole that was contaminated with phenobarbital (Luminal).[117] The responsible pharmaceutical company, Winthrop Chemical, produced both sulfathiazole and phenobarbital, and the contamination likely occurred during the tableting process, because the tableting machines for the two medications were adjacent to each other and were used interchangeably. Each contaminated sulfathiazole tablet contained about 350 mg of phenobarbital (and no sulfathiazole), and the typical sulfathiazole dosing regimen was several tablets within the first few hours of therapy. Twenty-nine percent of the production lot was contaminated. Food and Drug Administration (FDA) intervention was required to assist with the recovery of the suspect sulfathiazole, although 22,000 contaminated tablets were never found.[117]

In the early 1960s, one of the greatest modern-day events occurred with the release of thalidomide as an antiemetic and sedative-hypnotic.[21] Its use as a sedative-hypnotic by pregnant women resulted in about 5000 babies born with severe congenital anomalies.[76] This tragedy was largely confined to Europe, Australia, and Canada, where the drug was initially marketed. Only the length of time required for review and the rigorous scrutiny of new drug applications by the FDA prevented a concurrent disaster in the United States.[73]

A major therapeutic drug event that did occur in the United States involved the widespread use of diethylstilbestrol (DES) for the treatment of threatened and habitual abortions. Despite the lack of convincing efficacy data, as many as 10 million Americans received

DES during pregnancy, or in utero, during a 30-year period, until the drug was prohibited in pregnancy in 1971. Adverse health effects associated with DES use include increased risk for breast cancer in â€œDES mothersâ€• and increased risk of a rare form of vaginal cancer, reproductive tract anomalies, and premature births in â€œDES daughters.â€•[35,41]

Thorotrast (thorium dioxide 25%) is an intravenous radiologic contrast medium that was widely used between 1928 and 1955. Its use was associated with the delayed development of hepatic angiosarcomas, as well as skeletal sarcomas, leukemia, and â€œthorotrastomasâ€•â€”malignancies at the site of extravasated thorotrast.[115,130]

The use of thallium to treat ringworm infections in the 1920s and 1930s also led to needless morbidity and mortality.[36] Understanding that thallium caused alopecia, dermatologists and other physicians prescribed thallium acetate, both as pills and as a topical ointment (Koremlu), to remove the infected hair. A 1934 study found 692 cases of thallium toxicity after oral and topical application and 31 deaths after oral use.[83] Medicinal thallium was subsequently taken off the market.

The â€œStalinon affairâ€• in France, in 1954 involved the unintentional contamination of a proprietary oral medication that was marketed for the treatment of staphylococcal skin infections, osteomyelitis, and anthrax. Although it was supposed to contain diethyltin diiodide and linoleic acid, triethyltin, a potent neurotoxin and the most toxic of organotin compounds, and trimethyltin were present as impurities. Of the approximately 1000 people who received this medication, 217 patients developed symptoms, and 102 patients died.[7,114]

An unusual syndrome, featuring a constellation of abdominal symptoms (pain and diarrhea), followed by neurologic symptoms (peripheral neuropathy and visual disturbances including blindness), was experienced by approximately 10,000 Japanese

between 1955 and 1970, resulting in several hundred deaths.[57] This presentation, subsequently labeled subacute myelooptic neuropathy (SMON), was associated with the use of the gastrointestinal disinfectant clioquinol, known in the West as Entero-Vioform and most often used for the prevention of travelers' diarrhea.[86] In Japan, this drug was referred to as â€œsei-cho-zaiâ€• (â€œactive in normalizing intestinal functionâ€•). It was incorporated into more than 100 nonprescription proprietary medications and was used by millions of people, often for weeks or months. The exact mechanism of toxicity has not been determined, but recent investigators theorize that clioquinol may enhance the cellular uptake of certain metals, particularly zinc, and that the clioquinol-zinc chelate may act as a mitochondrial toxin causing this syndrome.[4] New cases declined rapidly when clioquinol was banned in Japan.

In 1981, a number of premature neonates died with a â€œgasping syndrome,â€• manifested by severe metabolic acidosis, respiratory depression with gasping, and encephalopathy.[34] Prior to the development of these findings, the infants had all received multiple injections of heparinized bacteriostatic sodium chloride solution (to flush their indwelling catheters) and bacteriostatic water (to mix medications), both of which contained 0.9% benzyl alcohol.

Accumulation of large amounts of benzyl alcohol and its metabolite benzoic acid in the blood was thought responsible for this syndrome.[34]

A nursery mass poisoning occurred in 1967, when 9 neonates developed extreme diaphoresis, fever, and tachypnea, without rash or cyanosis. Two fatalities resulted, although the others responded dramatically to exchange transfusion. The illness was traced to sodium pentachlorophenate that had been used as an antimildew agent in the hospital laundry.[93]

In 1989 and 1990, eosinophilia-myalgia syndrome, a debilitating syndrome somewhat similar to toxic oil syndrome, developed in more than 1500 people who had taken the dietary supplement L-tryptophan.[52, 125] These patients presented with disabling myalgias and eosinophilia, often accompanied by extremity edema, dyspnea, and arthralgias. Skin changes, neuropathy, and weight loss sometimes developed. Intensive investigation revealed that all affected patients had ingested L-tryptophan produced by a single manufacturer that had recently introduced a new process involving genetically altered bacteria to improve L-tryptophan production. A contaminant produced by this process probably is responsible for this syndrome.[9] The banning of L-tryptophan by the FDA set in motion the passage of the Dietary Supplement Health and Education Act of 1994. This legislation, which attempted to regulate an uncontrolled industry, inadvertently facilitated industry marketing of dietary supplements bypassing FDA scrutiny.

In recent years, a number of therapeutic drugs, previously approved by the FDA, were withdrawn from the market because of concern about health risks. In a number of cases, the drugs that were withdrawn had been responsible for causing serious drugâ€“drug interactions (astemizole, cisapride, mibefradil, terfenadine).[82] Other drugs were withdrawn because of a propensity to cause hepatotoxicity (troglitazone), anaphylaxis (bromfenac sodium), valvular heart disease (fenfluramine, dexfenfluramine), rhabdomyolysis (cerivastatin), hemorrhagic stroke (phenylpropanolamine), and other adverse cardiac and neurologic effects (ephedra, rofecoxib). One of the most disconcerting drug problems to arise was the development of cardiac valvulopathy and pulmonary hypertension in patients taking the weight-loss drug-combination fenfluramine and phentermine (fen-phen) or dexfenfluramine.[18, 110] The histopathologic features observed with this condition were similar to the valvular lesions associated with ergotamine and carcinoid. Interestingly, appetite suppressant medications, as well as

ergotamine and carcinoid all increase available serotonin.

TABLE 2-5. Alcohol and Illicit Drug Disasters

While many of these withdrawals involved drugs were only recently approved, the withdrawal of phenylpropanolamine in 2000 removed an over-the-counter agent that was consumed as a component of many cough and cold remedies for several decades. Despite the accumulation of increasing numbers of case reports and case series of medical problems associated with phenylpropanolamine use, drug production was only halted after a well-designed case-control study demonstrated that phenylpropanolamine use was an independent risk factor for hemorrhagic stroke.[51]

Alcohol and Illicit Drug Disasters

Unintended toxic disasters have also resulted from the use of alcohol and other drugs of abuse (Table 2-5). Arsenical neuropathy developed in an estimated 40,000 people in France in 1828, when wine and bread were unintentionally contaminated by

arsenious acid.[71] The use of arsenic-contaminated sugar in the production of beer in England in 1900 resulted in at least 6000 cases of peripheral neuropathy and 70 deaths (Staffordshire beer epidemic).[30]

During the early 20th century, and particularly during prohibition, the ethanolic extract of Jamaican ginger (sold as â€œthe Jakeâ€•) was a popular ethanol substitute in the southern and midwestern United States.[77] It was sold legally because it was considered a medical supplement to treat headaches and aid digestion and was not subject to prohibition. For years, the Jake was sold adulterated with castor oil, but in 1930, as the price of castor oil rose, the Jake was reformulated with an alternative adulterant, triorthocresyl phosphate (TOCP). Little was previously known about the toxicity of this compound, but TOCP proved to be a potent neurotoxin. From 1930 to 1931 at least 50,000 people who drank the Jake developed TOCP poisoning, which was manifested by upper and lower extremity weakness (â€œginger Jake paralysisâ€•) and gait impairment (â€œJake walkâ€• or â€œJake legâ€•).[77] A quarter century later, in Morocco, the dilution of cooking oil with a turbojet lubricant containing TOCP caused an additional 10,000 cases of TOCP-induced paralysis.[113]

In the 1960s, cobalt was added to several brands of beer as a foam stabilizer. Certain local breweries in Quebec City, Canada, Minneapolis, Minnesota, Omaha, Nebraska, and Louvain, Belgium, added 0.5â€“5.5 ppm cobalt to their beer. This resulted in epidemics of fulminant heart failure among heavy beer drinkers (cobalt-beer cardiomyopathy).[1,78]

Epidemic methanol poisoning among those seeking ethanol and other inebriants is well described. In one such incident in Atlanta, Georgia, in 1951, the ingestion of methanol-contaminated bootleg whiskey caused 323 cases of methanol poisoning, resulting in 41 deaths. In another epidemic in 1979, 46 prisoners became ill after

ingesting a methanol-containing diluent used in copy machines.[118]

In recent years, major mass methanol poisonings have continued to occur in developing countries where store-bought alcohol is often prohibitively expensive. In Baroda, India, in 1989, at least 100 people died and another 200 became ill after drinking a homemade liquor that was contaminated with methanol.[26] In New Delhi, India, in 1991, an inexpensive antidiarrheal medicine, advertised as containing large amounts of ethanol, was contaminated with methanol, and caused more than 200 deaths.[17] The following year, in Cuttack, India, 162 people died and an additional 448 were hospitalized after drinking methanol-tainted liquor.[119] A major epidemic of methanol poisoning occurred in 1998 in Cambodia, when rice wine was contaminated with methanol.[11] At least 60 deaths and 400 cases of illness were attributed to the methanol.

So-called designer drugs are responsible for several toxicologic disasters. In 1982, several injection drug users living in San Jose, California, who were attempting to use a meperidine analog MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine), developed a peculiar, irreversible neurologic disease closely resembling parkinsonism.[60] Investigation revealed that these patients had unknowingly injected trace amounts of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), present as an inadvertent product of the clandestine MPPP synthesis. The subsequent metabolism of MPTP to MPP^+ resulted in a toxic compound that selectively destroyed cells in the substantia nigra, causing severe irreversible parkinsonism. The vigorous pursuit of the cause of this disaster led to a better understanding of the pathophysiology of parkinsonism and the development of possible future treatments.

Another example of a â€œdesigner-drugâ€• mass poisoning occurred in the New York City metropolitan area in 1991, when a sudden epidemic of opioid overdoses occurred among heroin users who bought envelopes labeled â€œTango and Cash.â€•[28]

Expecting to receive a new brand of heroin, the drug users instead purchased the much more potent fentanyl. Increased and unpredictable toxicity resulted from the inability of the dealer to adjust (â€œcutâ€•) the fentanyl dose properly. Some purchasers presumably received little or no fentanyl, while others received potentially lethal doses. A similar epidemic involving 3-methylfentanyl occurred in 1988 in Pittsburgh, Pennsylvania.[69]

TABLE 2-6. Occupational Disasters

At least 325 cases of anticholinergic poisoning occurred among heroin users in New York City, Newark, New Jersey, Philadelphia, Pennsylvania, and Baltimore, Maryland, from 1995 to 1996.[105] The â€œstreet drugâ€• used in these cases was adulterated with scopolamine. Whereas naloxone treatment was associated with increased agitation and hallucinations, physostigmine administration resulted in resolution of symptoms. Why the heroin was adulterated was unknown, although the use of an opiate-scopolamine mixture was reminiscent of the morphine-scopolamine combination therapy known as â€œtwilight sleepâ€• that was heavily used in obstetric anesthesia during the early 20th century.[94]

Another unexpected complication of heroin use was observed in the Netherlands in the 1980s, when 47 heroin users developed mutism and spastic quadriparesis that was pathologically documented to be spongiform leukoencephalopathy.[135] In these cases, as well as in subsequent cases in Europe and the United States, the users inhaled heroin vapors after the heroin powder

had been heated on aluminum foil, a drug administration technique known as â€œchasing the dragon.â€•[56,135] The exact toxic mechanism has not been elucidated.

Occupational-Related Chemical Disasters

Unfortunately, occupation-related toxic epidemics have become increasingly common (Table 2-6). These poisoning syndromes tend to have an insidious onset and may not be recognized clinically until years after the exposure. A specific toxin may cause a myriad of problems; among the most worrisome being the carcinogenic and mutagenic potentials.

Although the 18th-century observations of Ramazzini and Pott introduced the concept that certain diseases were a direct result of toxic exposures in the workplace, it was not until the height of the 19th-century industrial revolution that the problems associated with the increasingly hazardous workplace became apparent.[46] During the 1860s, a peculiar disorder, attributed to the effects of inhaling mercury vapor, was described among manufacturers of felt hats in New Jersey.[131] Mercury nitrate was used as an essential part of the felting process at the time. â€œHatter's shakesâ€• refers to the tremor that developed in an estimated 10â€“60% of hatters surveyed.[131] Extreme shyness, another manifestation of

mercurialism, also developed in many hatters in later studies. Five percent of hatters during this period died from renal failure.

TABLE 2-7. Radiation Disasters

Other notable 19th-century and early 20th-century occupational tragedies included an increased incidence of mandibular necrosis (phossy jaw) among workers in the matchmaking industry who were exposed to white phosphorus,[44] an increased incidence of bladder tumors among synthetic dye makers who used Î²-naphthylamine,[37] and an increased incidence of aplastic anemia among artificial leather manufacturers who used benzene.[108] The epidemic of phossy jaw among matchmakers had a latency period of 5 years and a mortality rate of 20% and has been called the â€œgreatest tragedy in the whole story of occupational disease.â€•[14] The problem continued in the United States until Congress passed the White Phosphorus Match Act in 1912, which

established a prohibitive tax on white phosphorus matches.[85]

Since antiquity, occupational lead poisoning has been a constant threat. Workplace exposure to lead was particularly problematic during the 19th century and early 20th century, because of the large number of industries that relied heavily on lead. One of the most notorious of the â€œlead tradesâ€• was the actual production of white lead and lead oxides. Palsies, encephalopathy, and death from severe poisoning were reported.[40] Other occupations that entailed dangerous lead exposures included pottery glazing, rubber manufacturing, pigment manufacturing, painting, printing, and plumbing.[68] Given the increasing awareness of harm suffered in the workplace, the British Factory and Workshop Act was enacted in 1895, which required governmental notification of occupational diseases caused by lead, mercury, and phosphorus poisoning, as well as of occupational diseases caused by anthrax.[62]

Exposure to asbestos during the 20th century has become one of the most consequential occupational and environmental disasters in recent memory.[19 , 84] Despite the fact that the first case of asbestosis was reported in 1907, asbestos was heavily used in the shipbuilding industries in the 1940s as an insulating and fireproofing material. Since the early 1940s, 8â€“11 million individuals were occupationally exposed to asbestos,[64] including 4.5 million individuals who worked in the shipyards. Asbestos-related diseases include mesothelioma, lung cancer, and pulmonary fibrosis (asbestosis). A 3-fold excess of cancer deaths is observed in asbestos-exposed insulation workers, primarily as a consequence of excess lung cancer deaths.[106]

The manufacture and use of a variety of newly synthesized chemicals has also resulted in cases of mass occupational poisoning. In Louisville, Kentucky, in 1974, an increased incidence of angiosarcoma of the liver was first noticed among polyvinyl chloride polymerization workers who were exposed to vinyl

chloride monomer.[25] In 1975, chemical factory workers exposed to the organochlorine insecticide chlordecone (Kepone) experienced a high incidence of neurologic abnormalities, including tremor and chaotic eye movements.[120] An increased incidence of infertility among male Californian pesticide workers exposed to dibromochloropropane (DBCP) was noted in 1977.[132]

Radiation Disasters

A discussion of mass poisonings is incomplete without mention of a growing number of radiation disasters that have occurred during the 20th century (Table 2-7). The first significant mass exposure to radiation occurred among several thousand teenage girls and young women employed in the dial-painting industry.[15] These workers painted luminous numbers on watch and instrument dials with paint that contained radium. Exposure occurred by licking the paint brushes and inhaling radium-laden dust. Studies showed an increase in bone-related cancers, as well as aplastic anemia and leukemia, in exposed workers.[70 , 95]

At the time of the â€œwatchâ€• disaster, radium was also being sold as a nostrum touted to cure all sorts of ailments, including rheumatism, syphilis, multiple sclerosis, and sexual dysfunction. Referred to as â€œmild radium therapy,â€• in order to differentiate it from the higher-dose radium that was used in the treatment of cancer at that time, such Î±-particle-emitting isotopes were hailed as a powerful natural elixir that acted as a metabolic catalyst by delivering direct energy transfusions.[66]

During the 1920s, dozens of patent medications contained small doses of radium and were sold as radioactive tablets, liniments, or liquids. One of the most infamous preparations was Radithor. Each half-ounce bottle contained slightly more than 1 ÂµCi of radium-228 and radium-226. This radioactive water was sold all over the world â€œas harmless in every respectâ€• and was heavily promoted as a sexual stimulant and aphrodisiac, taking on the

glamour of a recreational drug for the wealthy.[66] More than 400,000 bottles were sold. The 1932 death of a prominent socialite and Radithor connoisseur from chronic radiation poisoning drew increased public and governmental scrutiny to this unregulated radium industry and helped end the era of radioactive patent medications.[66]

Concerns about the health effects of radiation have continued to escalate since the dawn of the nuclear age in 1945. Long-term followup studies 50 years after the atomic bombings at Hiroshima and Nagasaki show an increased incidence of leukemia, other cancers, radiation cataracts, hyperparathyroidism, delayed growth and development, and chromosomal anomalies in exposed individuals.[54]

The unintentional nuclear disaster at Chernobyl, Ukraine, in April 1986, again forced us to confront the medical consequences of 20th-century scientific advances that brought us the atomic age.[32] The release of radioactive material resulted in the hospitalization of more than 200 people for acute radiation sickness

and 31 deaths. By 2003, the predominant main long-term effects from the event appear to be childhood thyroid cancer and the psychological consequences.[99] In some areas with heavy contamination, the increase in childhood thyroid cancer has increased 100-fold.[102]

Another serious radiation event occurred in Goiania, Brazil, in 1987. When an abandoned radiotherapy unit was opened in a junkyard, 244 people were exposed to cesium-137. Of those people exposed to cesium-137, 104 showed evidence of internal contamination, 28 had local radiation injuries, and 8 developed acute radiation syndrome. There were at least 4 deaths.[92, 100]

In September 1999, a nuclear event at a uranium processing plant in Japan set off an uncontrolled chain reaction exposing 49 people to radiation.[25, 60] Radiation measured outside the facility reached

4000 times the normal ambient level. Two workers died from the effects of the radiation.

Mass Suicide by Poison

Toxic disasters have also manifested themselves as events of mass suicide. In 1978, in Jonestown, Guyana, 911 members of the Peoples Temple died when they ingested a beverage to which cyanide had been added.[39] Although the majority of those deaths may have been by suicide, some appear to have been involuntary.[61]

In 1997, phenobarbital and ethanol (sometimes assisted by physical asphyxiation) was the suicidal method favored by 39 members of the Heavens Gate cult in Rancho Santa Fe, California. This means of suicide was recommended in the book *Final Exit* .[45] Apparently, the cult members committed suicide in order to shed their bodies in hopes of hopping aboard an alien spaceship they believed was in the wake of the Hale-Bopp comet.[59]

Summary

Unfortunately, toxicologic plagues and disasters have had an all too prominent role in our history. An understanding of the pathogenesis of these toxic plagues that pertain to drug, food, and occupational safety is critically important if future disasters are to be prevented. These events teach us awareness that many of these toxic agents may have a potential role as agents of opportunity for terrorists and others who seek to harm. Given the practical and ethical limitations in studying the effects of many specific toxins in humans, lessons from these unfortunate tragedies must be fully mastered and retained for future generations.

Chapter 3

Initial Evaluation of the Patient: Vita Signs and Toxic Syndromes

Neal E. Flomenbaum

Lewis R. Goldfrank

Robert S. Hoffman

Mary Ann Howland

Neal A. Lewin

Lewis S. Nelson

For more than 200 years the American medical community has attempted standardize its approach to the assessment of patients. At the New York Hospital in 1865, pulse rate, respiratory rate, and temperature were incorporated into the bedside chart and called â€œvital signs.â€• [6] It was until the early part of the 20th century, however, that blood pressure determination also become routine. Additional components of the standar emergency assessment, such as oxygen saturation by pulse oximetry and severity using standardized scales, are now also beginning to be consider vital signs. Although both oxygen saturation and pain severity are essent components of the clinical assessment and are important considerations

throughout this text, neither is considered a vital sign here.

In the practice of medical toxicology, vital signs play an important role b assessing and monitoring the overall status of a patient, as they frequent provide valuable physiologic clues to the toxicologic etiology and severity illness. The vital signs also are a valuable parameter with which to assess monitor a patient's response to supportive treatment and antidotal therap

Table 3-1 presents the normal vital signs for various age groups. Howeve broad range of values considered normal should serve merely as a guide. a complete assessment of a patient can determine whether or not a parti vital sign is truly clinically normal. This table of normal vital signs is usef assessing children, as normal values for children vary considerably with a and knowing the range of variation is essential. The normal temperature defined as 95â€“100.4Â°F (35â€“38Â°C).

The difficulty in defining the â€œnormalcyâ€• of vital signs in an emerge setting has been inadequately addressed and may prove to be an impossi undertaking. Published normal values may have little relevance to an acu or anxious patient in the emergency setting, yet that is precisely the environment in which we need to define abnormal vital signs and address accordingly. For these reasons descriptions of vital signs as â€œnormalâ€ â€œstableâ€• are too nonspecific to be meaningful, and therefore should never be accepted as defining normalcy in an individual patient. Converse patient should be considered too agitated or too gravely ill to obtain a co set of vital signs; indeed, these patients urgently need a thorough evalua which includes all of the vital signs. Also the vital signs must be recorded accurately as possible first in the prehospital setting, and again with pre and reliability as soon as a patient arrives in the emergency department, serially thereafter.

Many xenobiotics affect the autonomic nervous system, which, in turn, a the vital signs via the sympathetic and/or parasympathetic pathways. Meticulous attention to both initial and repeated determinations of vital si of extreme importance in identifying a pattern of changes suggesting a particular xenobiotic or group of xenobiotics. The value of serial monitorin the vital signs is demonstrated by the patient who presents with an

anticholinergic overdose who is then given the antidote, physostigmine. I situation it is important to recognize when tachycardia becomes bradycar (ie, anticholinergic syndrome followed by physostigmine excess). Meticul attention to these changes assures that the therapeutic interventions can modified or adjusted accordingly.

Another common situation, perhaps, is the course of a patient who has o induced bradypnea (a decreased rate of breathing) who then develops tachypnea (an increased rate of breathing) following the administration of opioid antagonist naloxone. However the analysis becomes exceedingly complicated when the patient may have been exposed to two or more substances, such as an opioid and cocaine. In this situation the effects of cocaine may be â€œunmaskedâ€• by the naloxone used to counteract th opioid, and the clinician must then be forced to differentiate naloxone-in opioid withdrawal from cocaine toxicity. The assessment starts by analyzi combination of information, including history, vital signs, and physical examination.

Table 3-2 describes the most typical toxic syndromes. This table includes those vital signs that are thought to be characteristically abnormal or pathognomonic and directly related to the toxicologic effect of the xenob The primary purpose of the table, however, is to include many findings, i addition to the vital signs, that together constitute a toxic syndrome. Mo and Greensher[5] coined the term *toxidromes* from the words *toxic syndro* describe the groups of signs and symptoms that consistently result from particular toxins. These syndromes are usually best described by a comb of the vital signs and clinically obvious end-organ manifestations. The sig that prove most clinically useful are those involving the central nervous s (mental status); ophthalmic system (pupil size); gastrointestinal system (peristalsis); dermatologic system: skin (dryness vs. diaphoresis) and mu membranes

(moistness vs. dryness); and genitourinary system (urinary retention vs. incontinence). Table 3-3 includes some of the most important signs and symptoms and the xenobiotics most commonly responsible for these manifestations. A detailed analysis of each sign, symptom, and toxic syn

can be found in the pertinent chapters throughout the text. In this chapte most typical toxic syndromes (Table 3-2) are considered to enable the appropriate assessment and differential diagnosis of a poisoned patient.

In considering a toxic syndrome the reader should always remember that actual clinical manifestations of an ingestion or exposure are far more va than the syndromes described in Table 3-2 . The concept of the toxic syr is most useful when thinking about a clinical presentation and formulating framework for assessment. Although some patients may present as â€œclassicâ€• cases, others will manifest partial toxic syndromes or *forr frustes.* Incomplete syndromes still may provide at least a clue to the co diagnosis. It is important to understand that partial presentations (partic in the presence of multiple toxins) do not necessarily imply less-severe c and, therefore, are no less important to appreciate.

In some instances, an unexpected combination of findings may be particu helpful in identifying a toxin or a combination of toxins. For example, a dissociation between such typically paired changes as an increase in pulse a decrease in blood pressure (cyclic antidepressants or phenothiazines), c presentation of a decrease in pulse with an increase in blood pressure (e alkaloids) may be extremely helpful in diagnosing a toxic etiology. The us these unexpected or atypical clinical findings is demonstrated in Chap. 23

Vital Signs

Group	BP	P	R	T	Mental Status	Puple Size	Peristaisis	Diaphoresls	C

TABLE 3-2. Toxic Syndromes

Blood Pressure

Xenobiotics cause hypotension by four major mechanisms: decreased peripheral resistance, decreased myocardial contractility, dysrhythmias, intravascular volume depletion. Many xenobiotics can initially cause seve orthostatic hypotension, without marked supine hypotension, and any xenobiotic that affects autonomic control of the heart or peripheral capa vessels may lead to orthostatic hypotension (Table 3-4).

Blood pressure and pulse rate may vary significantly as a result of change receptor responsiveness, degree of physical fitness, and degree of atherosclerosis, or general cardiovascular function. Changing patterns of pressure often assist in the diagnostic evaluation: exposure to a monoam oxidase inhibitor (MAOI) overdose characteristically causes an initial norr blood pressure, to be followed by severe hypertension which, in turn, may followed abruptly by severe hypotension (Chap. 69).

Agitation
Anticholinergics[a] , hypoglycemia, phencyclidine, sympathomimetics[b] , withdrawal from ethanol and sedative-hypnotics
Alopecia

Dysesthesias, paresthesias

Acrylamide, arsenic, ciguatera, cocaine, colchicine, thallium

Gum discoloration

Arsenic, bismuth, hypervitaminosis A, lead, mercury

Hallucinations

Anticholinergics[a], dopamine agonists, ergot alkaloids, ethanol, ethanol a sedative-hypnotic withdrawal, LSD, phencyclidine, sympathomimetics[b], tryptamines (eg, AMT)

Headache

Carbon monoxide, hypoglycemia, monoamine oxidase inhibitor/food inter (hypertensive crisis), serotonin syndrome

Metabolic acidosis (elevated anion, gap) [MUDPILES]

Methanol, uremia, ketoacidosis (diabetic, starvation, alcoholic), paraldeh phenformin, metformin, iron, isoniazid lactic acidosis, cyanide, protease inhibitors, ethylene glycol, salicylates, toluene

Miosis

Cholinergics[c], clonidine, opioids, phencyclidine, phenothiazines

Mydriasis

Anticholinergics[a], botulism, opioid withdrawal, sympathomimetics[b]

Nystagmus

Barbiturates, carbamazepine, carbon monoxide, ethanol, lithium, monoar oxidase inhibitors, phencyclidine, phenytoin, quinine

Purpura

Anticoagulant rodenticides, clopidogrel, corticosteroids, heparin, pit viper venom, quinine, salicylates, warfarin

Radiopaque ingestions

Arsenic, chloral hydrate, enteric coated tablets, halogenated hydrocarbor metals (eg, iron, lead)

Red skin

Anticholinergics[a] , boric acid, disulfiram, scombroid, vancomycin

Rhabdomyolysis

Carbon monoxide, doxylamine, HMG CoA reductase inhibitors, sympathomimetics[b] , *Tricholoma equestre*

Salivation

Arsenic, caustics, cholinergics[c] , ketamine, mercury, phencyclidine, stryc

Seizures

Bupropion, carbon monoxide, cyclic antidepressants, *Gyromitra* mushroor hypoglycemia, isoniazid, methylxanthines, withdrawal from ethanol and sedative-hypnotics

Tremor

Antipsychotics, arsenic, carbon monoxide, cholinergics[c] , ethanol, lithium mercury, methyl bromide, sympathomimetics[b] , thyroid replacement

Weakness

Botulism, diuretics, magnesium, paralytic shellfish, steroids, toluene

Yellow skin

Acetaminophen (late), pyrrolizidine alkaloids, Î² carotene, amatoxin mushrooms, dinitrophenol

[a] Anticholinergics: eg, antihistamines, atropine, cyclic antidepressants, scopolamine.

[b] Sympathomimetics: eg, amphetamines, Î² adrenergic agonists, cocaine, ephedrine.

[c] Cholinergics: eg, muscarinic mushrooms, organic phosphorus compounds carbamates including select Alzheimer drugs and physostigmine, pilocarp and other direct acting drugs.

Hypotension Hypertension

TABLE 3-4. Common Xenobiotics That Affect Blood Pressure

Pulse Rate

Extremely useful clinical information can be obtained by evaluating the p rate (Table 3-5 and Chap. 23). Although the carotid artery is usually eas palpable, for reasons of both safety and reliability, the brachial artery is preferred in infants and adults greater than 60 years old. The normal hea

rate for adults was defined by consensus more than 50 years ago as a re rate >60 beats/min and <100 beats/min. More recent studies[7, 8] suggest 95% of the population have bradycardia and tachycardia thresholds of 50 beats/min and 90 beats/min, respectively. These lower limits are more consistent with our current understanding of the delicate balance imposed the sympathetic and parasympathetic nervous systems. In our text we ha chosen to retain the standard values although the lower values would de our sensitivity and increase our specificity with regard to the detection of clinically relevant bradycardias and tachycardias.

Because pulse rate is the net result of a balance between adrenergic and cholinergic (muscarinic and nicotinic) tone, many xenobiotics that exert therapeutic or toxic effects, cause pain syndromes, fever, or volume dep also cause pulse rate abnormalities.

There is a direct correlation between heart rate and temperature in that rate increases approximately 8 beats/min for each 1.8Â°F (1Â°C) elevatio temperature.[4]

Yohimbine
Chap. 23 lists additional agents affecting heart rate.

Bradycardia Tachycardia

TABLE 3-5. Common Xenobiotics That Affect Pulse

The inability to differentiate easily between the sympathomimetic and anticholinergic xenobiotics by vital signs alone illustrates the principle tha single vital sign abnormality can definitively establish a toxicologic diagnc etiology. In trying to differentiate between sympathomimetic and anticholinergic toxicity, it should be understood that although a tachycar commonly results from both sympathomimetic and anticholinergic xenobi when tachycardia is accompanied by diaphoresis and/or increased bowel sounds, adrenergic toxicity is suggested, whereas when tachycardia is accompanied by decreased sweating, absent bowel sounds, and urinary retention, anticholinergic toxicity is likely.

Respirations

As always, establishment of an airway and evaluation of respiratory statu the initial priorities in patient stabilization. Although respirations are typ assessed initially for rate alone, careful observation of the depth and patt essential (Table 3-6) for establishing the etiology of a systemic illness o toxicity.[1] Unfortunately very few investigators have actually measured th respiratory rate in large populations of normal people, let alone in emerg department patients. Two papers[2] , [3] investigating respiratory rates in emergency department patients differ substantially in their determinations normal ranges from the remainder of the literature. The results of these investigations suggest â€œnormalâ€• respiratory rates are 16â€“24 breaths/min in adults with more rapid rates that are inversely related to a children. These respiratory rate ranges define normal in this text.

Salicylates
Sympathomimetics
Chap. 22 lists additional agents affecting respiratory rate.

Bradypnea Tachypnea

TABLE 3-6. Common Xenobiotics That Affect Respiration

The term *hyperventilation* may mean tachypnea, or hyperpnea, (an increa tidal volume), or both. When hyperventilation results solely or predomina from hyperpnea, the less-astute clinician may miss this important finding entirely, instead erroneously describing such a hyperventilating patient a normally ventilating, or even *hypoventilating* , if bradypnea is also prese

Tachypnea may result from the direct effect of a CNS stimulant, such as salicylates, acting on the brainstem. However, salicylate poisoning can al result in only an increased tidal volume or hyperpnea without tachypnea. Pulmonary injury from any source, including aspiration of gastric contents

lead to hypoxemia with a resultant tachypnea. Later, tachypnea may char bradypnea and/or hypopnea (shallow breathing). Bradypnea can occur ev sooner when a CNS depressant acts on the brainstem. A progression from to slow breathing can also occur in a patient exposed to increasing levels cyanide or carbon monoxide.

The toxic alcohols methanol and ethylene glycol can transiently produce hypoventilation as a consequence of bradypnea or hypopnea from direct depression. In time, however, hyperventilation will predominate as meta acidosis develops.

Temperature

Temperature evaluation and control are critical. However, temperature assessment can be done only if safe and reliable equipment is used. The of inaccuracy are substantial when an oral temperature is taken in a tach patient, an axillary temperature is taken in any patient but especially in patients found outdoors, or a tympanic temperature is taken in a patient cerumen impaction. Obtaining rectal temperatures using a nonglass probe essential for safe and accurate temperature determinations in agitated individuals and is considered the standard method of temperature determination in this text.

The core temperature or deep internal temperature (T) is relatively stable (98.6 Â± 1.08Â°F; 37 Â± 0.6Â°C) under normal physiologic circumstance Both hypothermia (T <95Â°F; <35Â°C) and hyperthermia (T >100.4Â°F; >38Â°C) are common manifestations of xenobiotic toxicity. Severe or significant hypothermia and hyperthermia, unless immediately recognized managed appropriately, can result in grave complications and inappropria inadequate resuscitative efforts. Life-threatening hyperthermia (T >106Â >41.1Â°C) from any cause can lead to extensive rhabdomyolysis, myoglobinuric renal failure, and direct liver and brain injury, and must therefore be identified and corrected immediately.

Hyperthermia can result either from a distinct neurologic response to a s demanding thermal â€œupregulationâ€• or from an externally imposed

physical or environmental factor, such as the environmental conditions c heat stroke or the excessive swaddling in clothing causing hyperthermia i infants. Core temperatures higher than 106Â°F (41.1Â°C) are extremely unless normal feedback mechanisms are overwhelmed. Hyperthermia of t extreme nature is usually attributed to heat stroke, psychomotor agitation xenobiotic-related temperature disturbances such as malignant hyperthe and the neuroleptic malignant syndrome.

Drug-induced fevers coincide with the administration of a drug and disap within 48â€“96 hours of the discontinuation of the drug. A common xeno related hyperthermia pattern that frequently occurs in the emergency department is defervescence after an acute temperature elevation resulti from agitation or seizure activity. Table 3-7 is a representative list of xenobiotics that affect body temperature (Chap. 16 provides greater deta

Hyperthermia Hypothermia

TABLE 3-7. Common Xenobiotics That Affect Temperature

Hypothermia is probably less of an immediate threat to life than hyperth but it requires rapid appreciation, accurate diagnosis, and skilled manage Hypothermia will impair the metabolism of many xenobiotics, leading to unpredictable delayed effects when the patient is warmed. Many xenobio impair judgment and CNS function, thereby placing patients at great risk becoming hypothermic from exposure to cold climates. Most importantly, hypothermic patient should never be declared dead without both an exte assessment and a full resuscitative effort, particularly if the body temper remains less than 95Â°F (35Â°C) (Chap. 16).

Summary

Early, accurate determinations followed by serial monitoring of the vital s are as essential in medical toxicology as in any other type of emergency critical care medicine. For this reason, the vital signs are an essential par the initial evaluation of every case, and repeated vital signs are always necessary throughout the subsequent case management. Careful observat the vital signs helps to determine appropriate therapeutic interventions a guide the clinician in making necessary adjustments to initial and subseq therapeutic interventions. When pathognomonic clinical and laboratory fi are combined with accurate initial and sometimes changing vital signs, a syndrome may become evident, which will aid in both general supportive specific antidotal treatment. Toxic syndromes will also guide further diag testing.

Mary Ann Howland

Neal A. Lewin

Lewis S. Nelson

Case 1

A 30-year-old woman was found unconscious in her apartment in the early afternoon. The paramedics found a suicide note alongside her, stating that the patient had ingested pills earlier in the morning. Reportedly, several empty bottles of pills were on the floor near her body, but unfortunately none were brought to the emergency department (ED).

The woman's initial vital signs in the ED were blood pressure, 120/75 mm Hg; pulse, 90 beats/min; respirations, 18 breaths/min; and

temperature, 98.6Â°F (37.0Â°C). Pulse oximetry was 99% while the patient was breathing room air. A rapid reagent bedside glucose test done prior to the patient's arrival in the ED was 95 mg/dL; consequently, dextrose was not administered. Physical examination demonstrated no trauma. The patient localized noxious cutaneous stimulation but did not open her eyes or respond verbally. Pupils were 4 mm and normally reactive. The neck was supple and the cardiopulmonary and abdominal examinations were normal. There were no lesions on the patient's extremities and, specifically, no signs of injection drug use. Neither flumazenil nor naloxone was administered.

An electrocardiogram revealed a sinus rhythm, normal electrical axis, and normal intervals without ectopy. A venous blood gas analysis was immediately available: pH, 7.35; PCO_2, 45 mm Hg; PO_2, 40 mm Hg. Serum acetaminophen and ethanol concentrations were zero. The patient was attached to a continuous cardiac monitor and pulse oximeter.

Case 2

A lethargic, 38-year-old woman presented to the ED at 6:45 A.M. According to her roommate, the patient had returned home from work at a nightclub at about 3 A.M. and â€œsmelled like alcohol.â€• At 5:30 A.M., the roommate saw the patient crying and then witnessed the patient ingest about 40 pills, possibly from the patient's bottle of quetiapine, before going into the bathroom. When the roommate went to check on her a short time later, she found the patient lethargic. The patient had a past history of depression, and was currently being treated with quetiapine and paroxetine. The patient also had a history of cocaine use.

In the ED, the patient was lethargic and had pinpoint pupils. Her vital signs were blood pressure, 90/60 mm Hg; pulse, 147 beats/min; respiratory rate, 20 breaths/min; and O_2 saturation was

90% on a 100% non-rebreather mask; in addition, she was afebrile. The patient was given naloxone 0.8 mg IV with no response. A nasogastric tube was inserted, and the patient vomited. After the tube was removed and then replaced, the patient was given a dose of activated charcoal (AC) through the nasogastric tube. The patient vomited again. The patient was observed to have increased lethargy and â€œKussmaul breathing.â€• Corresponding arterial blood gas (ABG) values at that time were: pH, 7.30; PCO_2, 57 mm Hg; PO_2, 105 mm Hg; and HCO_3, 30 mEq/L.

Intubating the patient was an extremely difficult-to-perform procedure, lasting 45 minutes. The endotracheal tube initially was inserted into the esophagus. Postintubation ABG values were pH, 7.4; PCO_2, 36 mm Hg; PO_2, 317 mm Hg; and HCO_3, 23 mEq/L. Chemistry values were sodium, 137 mEq/L; potassium, 3.6 mEq/L; chloride, 104 mEq/L; bicarbonate 23 mEq, BUN 10 mg/dL; creatinine 0.6 mg/dL; and glucose 150 mg/dL. The complete blood count (CBC) showed a white blood cell count (WBC) of 5100/mm^3; hemoglobin of 16 g/dL; hematocrit of 47%; and platelets of 192,000/mm^3. Ethanol was 79 mg/dL; acetaminophen and salicylates were negative. Urine toxicology studies were sent. ECG revealed normal ST segments and normal intervals.

The patient's vital signs were: blood pressure, 139/86 mm Hg; pulse 132 beats/min, and O_2 saturation 88% on 100% FiO_2. She was receiving IV fluids and lorazepam as needed for agitation. She also received clindamycin empirically for possible aspiration pneumonitis. The patient was then admitted to the ICU.

At this point the poison center (PC) was consulted and recommended supportive care, continued IV fluids, and benzodiazepines for sedation.

The patient remained intubated and sedated with a continuous propofol infusion until the next day, at which time her vital signs were blood pressure, 148/82 mm Hg; pulse, 126 beats/min; respiration, 32 breaths/min; and temperature, 102.3Â°F (39Â°C).

Chemistries were normal. CBC revealed a WBC of 14,000/mm^3. Chest radiography revealed an infiltrate and clindamycin was continued. The patient was extubated and continued to do well afterwards. Four days after the patient arrived, she was transferred out of the intensive care unit to a regular floor bed.

Case 3

A 16-month-old girl was given a bottle of ferrous sulfate â€œas a toy.â€• The mother felt that the cap was firmly in place and was childproof. After an absence from the room for several minutes, the mother noted on returning that the child had opened the bottle and that several tablets were missing. The child was asymptomatic en route to the hospital and on arrival the child had a blood pressure of 80/40 mm Hg; a pulse of 100 beats/min; respirations of 28 breaths/min; and a temperature of 99.7Â°F (37.6Â°C). Examination of the head, eyes, ears, nose, and throat was unremarkable. The mouth was free of tablets or obvious red discoloration from the iron tablets. The heart and lungs were normal. The abdomen was soft and nontender with no masses; bowel sounds were normal. The neurovascular examination was normal.

Prior to the trip to the hospital, the child had been given 15 mL of syrup of ipecac and had vomited up several partially digested pills 30 minutes later. However, an abdominal radiograph revealed at least 4 tablets in the GI tract. At 3 hours following ingestion the serum iron concentration was 286 Âµg/dL. Although the child had already vomited several times, whole-bowel irrigation with polyethylene glycol electrolyte solution was administered via a nasogastric tube at 500 mL/h. Guaiac-negative, red-tinged stool and fluid with tablet fragments were passed via the rectum.

Other than crying and persistent vomiting for an additional hour, the child remained asymptomatic and the clinical parameters remained

stable. A repeat abdominal radiograph taken 4 hours after the initial radiograph showed no remaining tablets. During the 24 hours that the child was hospitalized, she remained asymptomatic.

The 3 cases above illustrate several principles in the modern management of poisonings and overdoses. In all confirmed or suspected cases, thorough but rapid evaluation and reevaluation are always required, even when no specific interventions are subsequently indicated (case 1). In other cases, although some interventions may be appropriate, others are either unnecessary, harmful, or counterproductive (case 2). The prehospital use of syrup of ipecac is no longer recommended in almost any instance, and its use may not obviate the need for a more effective and less dangerous procedure, such as whole-bowel irrigation, to achieve intestinal evacuation (the iron tablets in case 3).

Overview

For almost 4 decades, medical toxicologists and information specialists at poison centers have used a clinical approach to the poisoned or overdosed patient that emphasizes treating the patient rather than treating the poison. Too often in the past, patients were initially all but neglected while attention was focused on the ingredients listed on the containers of the product(s) to which they presumably were exposed. Although the astute clinician must always be prepared to administer a specific antidote immediately in those instances when nothing else will save a patient, all poisoned or overdosed patients will benefit from an organized, rapid, clinical management plan (Fig. 4-1).

In the past 15 years, some basic tenets and long-held beliefs regarding the initial therapeutic interventions in toxicologic management have been questioned and subjected to an â€œevidence-basedâ€• analysis. For example, in the mid-1970s most medical toxicologists began to advocate a standardized

approach to a comatose and possibly overdosed adult patient, typically calling for the intravenous administration of 50 mL of $D_{50}W$, 100 mg of thiamine, and 2 mg of naloxone, as well as 100% oxygen at high flow rates. The rationale for this approach was to compensate for the previously idiosyncratic style of overdose management encountered in different healthcare settings and for the unfortunate likelihood that omitting any one of these measures at the time that care was initiated in the emergency department would result in omitting it altogether. It was not unusual then to discover from a laboratory chemistry report more than an hour after a supposedly overdosed comatose patient had arrived in the ED, that the initial blood glucose was 30 or 40 mg/dLâ€”a critical delay in the management of unsuspected and consequently untreated hypoglycemic coma. Today, however, with the widespread availability of accurate rapid reagent bedside testing for blood glucose and pulse oximetry for oxygen saturation, coupled with a much greater appreciation by all physicians of what needs to be done for each suspected overdose patient, clinicians can safely provide a more rational, individualized approach to determine the need for and in some instances more precise amounts of dextrose, thiamine, naloxone, and oxygen.

A second major approach to providing more rational individualized early treatment for toxicologic emergencies involves a closer examination of the actual benefits and risks of various gastrointestinal emptying interventions. Appreciation of the potential for significant adverse effects associated with all types of gastrointestinal emptying interventions and recognition of the absence of clear evidence-based support of efficacy, have led to a significant reduction in the routine use of syrup of ipecac-induced emesis or orogastric lavage as well as cathartic-induced intestinal evacuation. In 2004, the American Academy of Pediatricians (AAP) all but entirely abandoned its recommendations for the use of syrup of ipecac in the home. The efficacy of orogastric lavage, even when indicated by the nature or type of ingestion, is limited by the amount

of time elapsed since the ingestion. The value of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte solution (PEG-ELS) appears to be much more specific and limited than originally thought. Some of the limitations and (uncommon) adverse effects of AC are now more widely recognized.

Similarly, interventions to eliminate absorbed xenobiotics from the body are now much more narrowly defined or, in some cases, abandoned: Multiple-dose activated charcoal (MDAC) is useful for some but not all xenobiotics. Ion-trapping in the urine is only beneficial, achievable, and relatively safe when the urine can be maximally alkalinized after a significant salicylate, phenobarbital, or chlorpropamide poisoning. Finally, the roles of hemodialysis, hemoperfusion and other extracorporeal techniques are now much more specifically defined. With the foregoing in mind, this chapter represents our current efforts to formulate a logical and effective approach to managing a patient with probable or actual toxic exposure.

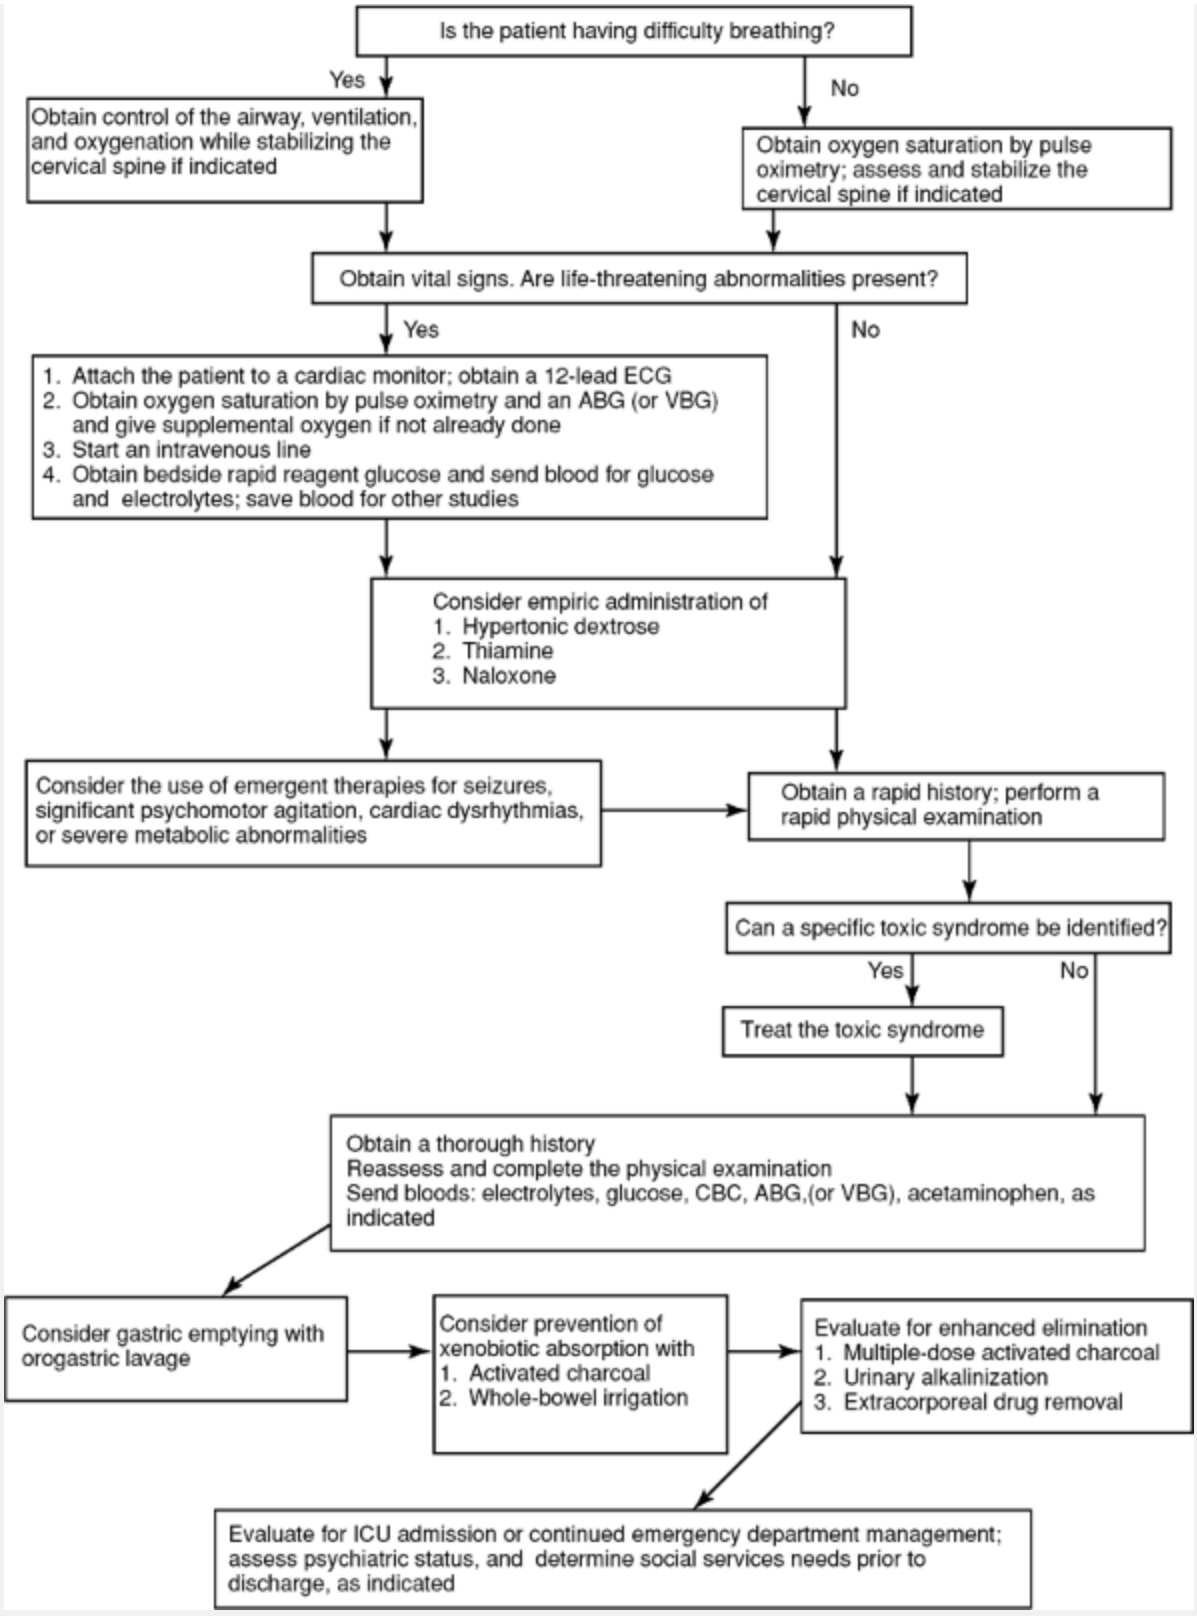
Table 4-1 provides a recommended stock list of antidotes and therapeutics for the treatment of poisonings and overdoses.

Managing the Poisoned or Overdosed Patient

The 3 cases at the beginning of this chapter illustrate many of the problems clinicians face in managing ill patients with possible xenobiotic exposures. Rarely, if ever, are all of the circumstances known: the history may be incomplete, unreliable, or unobtainable; multiple drugs, xenobiotics may be involved; and even when a xenobiotic etiology is identified, it may not be easy to determine whether the

problem is an overdose, an allergic or idiosyncratic reaction, or a drugâ€“drug interaction. Similarly, it is sometimes difficult or

impossible to differentiate between adverse effects of a correct dose of medication or the consequences of a deliberate or unintentional overdose. The patient's presenting signs and symptoms may force an intervention at a time when there is almost no information available about the etiology of the patient's condition, and as a result therapeutics must be thoughtfully chosen empirically to treat or diagnose a condition without exacerbating the situation.



Is the patient having difficulty breathing?
Yes
No
Obtain control of the airway, ventilation, and oxygenation while stabilizing the cervical spine if indicated
Obtain oxygen saturation by pulse oximetry; assess and stabilize the cervical spine if indicated
Obtain vital signs. Are life-threatening abnormalities present?
Yes
No
1. Attach the patient to a cardiac monitor; obtain a 12-lead ECG
2. Obtain oxygen saturation by pulse oximetry and an ABG (or VBG) and give supplemental oxygen if not already done
3. Start an intravenous line
4. Obtain bedside rapid reagent glucose and send blood for glucose and electrolytes; save blood for other studies
Consider empiric administration of
1. Hypertonic dextrose
2. Thiamine
3. Naloxone
Consider the use of emergent therapies for seizures, significant psychomotor agitation, cardiac dysrhythmias, or severe metabolic abnormalities
Obtain a rapid history; perform a rapid physical examination
Can a specific toxic syndrome be identified?
Yes
No
Treat the toxic syndrome
Obtain a thorough history
Reassess and complete the physical examination
Send bloods: electrolytes, glucose, CBC, ABG,(or VBG), acetaminophen, as indicated
Consider gastric emptying with orogastric lavage
Consider prevention of xenobiotic absorption with
1. Activated charcoal
2. Whole-bowel irrigation
Evaluate for enhanced elimination
1. Multiple-dose activated charcoal
2. Urinary alkalinization
3. Extracorporeal drug removal
Evaluate for ICU admission or continued emergency department management; assess psychiatric status, and determine social services needs prior to discharge, as indicated

Figure 4-1. This algorithm is a basic guide to the management of poisoned patients. A more detailed description of the steps in management may be found in the accompanying text. This algorithm is only a guide to actual management, which must, of course, consider the patient's clinical status.

TABLE 4-1. Antidotes and Therapeutics for the Treatment of Poisonings and Overdoses[a]

Therapeutics[b]	Uses
Activated charcoal (p. 128)	Adsorbs xenobiotics in GI tract
Antivenom *(Crotalinae)* (p. 1657)	Crotaline snake envenomations
Antivenom *(Latrodectus mactans)* (p. 1623)	Black widow spider envenomations
Antivenom *(Elapidae)* (p. 1657)	Coral snake envenomations
Atropine (p. 1519)	Bradydysrhythmias, cholinesterase inhibitors (organic phosphorus agents, physostigmine) muscarinic mushrooms *(Clitocybe*, *Inocybe)* ingestions

Botulinum antitoxin (ABE-trivalent) (p. 728)	Botulism
Calcium chloride, calcium gluconate (p. 1424)	Fluoride, hydrofluoric acid, ethylene glycol, calcium channel blockers, hypomagnesemia, Î²-adrenergic antagonists
L-Carnitine (p. 746)	Valproic acid
Cyanide kit (nitrites, p. 1725, sodium thiosulfate, p. 1728)	Cyanide
Dantrolene (p. 1037)	Malignant hyperthermia
Deferoxamine mesylate (Desferal) (p. 638)	Iron
Dextrose in water (50% adults; 20% pediatrics; 10% neonates) (p. 764)	Hypoglycemia
Diazepam or lorazepam	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal
Digoxin-specific antibody fragments (Digibind and Digifab) (p. 983)	Cardioactive steroids

Dimercaprol (BAL, British anti-Lewisite) (p. 1265)	Arsenic, mercury, gold, and lead
Diphenhydramine	Dystonic reactions, allergic reactions
Edetate calcium disodium (calcium disodium versenate, $CaNa_2$ EDTA) (p. 1331)	Lead, and other selected metals
Ethanol (oral and parenteral dosage forms) (p. 1465)	Methanol and ethylene glycol
Flumazenil (Romazicon) (p. 1112)	Benzodiazepine
Folinic acid (Leucovorin) (p. 826)	Methotrexate, methanol
Fomepizole (Antizole) (p. 1460)	Ethylene glycol, methanol
Glucagon (p. 942)	Î²-Adrenergic antagonists and calcium channel blockers
Hydroxocobalamin (p. 1731)	Cyanide

Ipecac, syrup of (p. 124)	Induces emesis
Magnesium sulfate or magnesium citrate (p. 135)	Induces catharsis
Magnesium sulfate injection	Cardioactive steroids, hydrofluoric acid, hypomagnesemia, ethanol withdrawal, torsades de pointes
Methylene blue (1% solution) (p. 1746)	Methemoglobinemia
N-acetylcysteine (Mucomyst and Acetadote) (p. 544)	Acetaminophen and other causes of liver failure
Naloxone hydrochloride (Narcan) (p. 614)	Opioids, clonidine
Norepinephrine (Levarterenol)	Hypotension (preferred for cyclic antidepressants)
Octreotide (Sandostatin) (p. 770)	Oral hypoglycemic agent-induced hypoglycemia
Oxygen (oxygen, hyperbaric) (p. 1705)	Carbon monoxide, cyanide, hydrogen sulfide

D-Penicillamine (Cuprimine) (p. 1303)	Copper, lead
Phenobarbital	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal
Phentolamine (p. 1140)	MAOI interactions, cocaine, epinephrine, and ergot alkaloids
Physostigmine salicylate (Antilirium) (p. 794)	Anticholinergics
Polyethylene glycol electrolyte solution (p. 135)	Decontaminates GI tract
Pralidoxime chloride (2-PAM-chloride) (Protopam) (p. 1513)	Acetylcholinesterase inhibitors (organic phosphorus agents and carbamates)
Protamine sulfate (p. 907)	Heparin anticoagulation
Prussian blue (Radiogardase) (p. 1373)	Thallium and radioactive cesium
Pyridoxine hydrochloride (Vitamin B_6) (p. 872)	Ethylene glycol, isoniazid, gyromitrin-containing mushrooms

Sodium bicarbonate (p. 565)	Ethylene glycol, methanol, salicylates, cyclic antidepressant, methotrexate, phenobarbital, quinidine, chlorpropamide, type 1 antidysrhythmics, chlorphenoxy herbicide
Sorbitol (p. 135)	Induces catharsis
SSKI (p. 1816)	Radioactive iodine

[a]Each emergency department should have all the above agents readily available to its staff. Some of these antidotes may be stored in the pharmacy, and others may be available from the Centers for Disease Control and Prevention, but the precise mechanism for locating each one must be known by each staff member.

[b]A detailed analysis of each of these agents is found in the

text, in the Antidotes in Depth section on the page cited to the right of each therapeutic agent listed.

P.45

P.46

Patients with a suspected overdose or poisoning and an altered mental status present some of the most serious initial challenges. Conscious patients, asymptomatic patients, and pregnant patients with possible xenobiotics exposures raise additional management issues, as do the victims of toxic cutaneous or ophthalmic exposures. One of the most frequent toxicologic emergencies that clinicians must deal with is a patient with a suspected toxic exposure to an unidentified xenobiotic (medication or substance), sometimes referred to as an *unknown overdose.* Considering not only those patients who have an altered mental status but those who are suicidal, those who use illicit drugs, or those who are exposed to xenobiotics that they are unaware of, many toxicologic emergencies at least partly involve an unknown component.

Initial Management of a Patient with a Suspected Exposure

Similar to the management of any seriously compromised patient, the clinical approach to the patient potentially exposed to a xenobiotic begins with the recognition and treatment of life-threatening conditions: airway compromise, breathing difficulties, and circulatory problems such as hemodynamic instability and serious dysrhythmias. Once the â€œABCsâ€• (airway, breathing, and circulation) are addressed, the patient's level of consciousness should be assessed, as this helps determine the techniques to be used for further management of the exposure.

The Patient with an Altered Mental

Status

After airway patency is established or secured and, when indicated, cervical spine trauma either excluded or the cervical spine protected, an initial bedside assessment should be made regarding the adequacy of respiration. If it is not possible to assess the depth and rate of respiration, then at least the presence or absence of regular breathing should be determined. In this setting, any irregular breathing pattern should be considered a possible sign of the incipient cessation of breathing requiring ventilation with 100% oxygen by bag-valve-mask followed, as soon as possible, by endotracheal intubation and mechanical ventilation. Endotracheal intubation may be indicated for some cases of coma resulting from a toxic exposure in order to insure and maintain control of the airway and to enable safe performance of procedures to prevent gastrointestinal absorption or eliminate previously absorbed xenobiotics.

Although the widespread availability of pulse oximetry to determine O_2 saturation has in many instances made an ABG analysis less of an immediate priority, pulse oximetry has not eliminated the importance of ABG analysis entirely: an ABG determination will more accurately define the adequacy not only of oxygenation (PO_2, O_2 saturation) and ventilation (PCO_2), but may also alert the physician to possible toxic-metabolic etiologies of coma characterized by acid base disturbances (pH, PCO_2) (Chap. 17). In addition, when clinically indicated, a carboxyhemoglobin determination is necessary to diagnose or exclude carbon monoxide poisoning (Chap. 120). In all cases, a bedside rapid reagent blood glucose determination should be obtained as soon as possible.

After the patient's respiratory status is assessed and managed appropriately, the strength, rate, and regularity of the pulse should be evaluated, the blood pressure determined, and a rectal temperature obtained. Both a 12-lead ECG and continuous ECG monitoring are essential. Monitoring will alert the clinician to

dysrhythmias that are related to toxic exposures either directly, or indirectly via hypoxemia or electrolyte imbalance. A 12-lead ECG demonstrating QRS widening and a right axis deviation might indicate a life-threatening exposure to a cyclic antidepressant, an IA or IC antidysrhythmics, or another xenobiotic with sodium-channel-blocking properties. In these cases, the physician can anticipate such serious sequelae as ventricular tachydysrhythmias, seizures, and cardiac arrest, and consider both the early use of specific treatment (antidotes), such as intravenous sodium bicarbonate, and avoiding medications, such as procainamide and other IA and IC antidysrhythmics, that could exacerbate the situation. Other ECG changes such as PR and QTc interval lengthening or shortening, baseline changes, and T- and U-wave abnormalities may point to cardioactive drug toxicity or serious electrolyte abnormalities (Chap. 5).

Extremes of core body temperature must be addressed early in the evaluation and treatment of a comatose patient. Life-threatening hyperthermia (temperature >105Â°F; >40.5Â°C) is usually appreciated when the patient is touched (although the widespread use of gloves as part of standard precautions has made this less apparent than previously). Most of these individuals, regardless of the etiology, should have their temperatures immediately reduced to about 101.5Â°F (38.7Â°C) by ice water immersion to prevent catastrophic complications or death (Chap. 16). Hypothermia is probably easier to miss than hyperthermia, especially in northern regions during winter months, when most arriving patients feel cold to the touch. Early recognition of hypothermia, however, helps to avoid administering a variety of medications that may be ineffective until the patient becomes relatively euthermic when iatrogenic drug toxicity may result.

For the hypotensive patient with clear lungs and an unknown overdose, a fluid challenge with intravenous 0.9% sodium chloride or lactated Ringer solution may be started. If the patient remains hypotensive or cannot tolerate fluids, a vasopressor or an inotropic

agent may be indicated, as well as more invasive monitoring.

At the time that the IV catheter is inserted, blood samples for glucose, electrolytes, BUN, a CBC, and any indicated toxicologic analysis can be drawn. If the patient has an altered mental status, there may be a temptation to send blood and urine specimens to identify any CNS depressants and/or so-called drugs of abuse, along with other medications, but the indiscriminate ordering of these tests rarely provides clinically useful information. For the potentially suicidal patient, an acetaminophen concentration should be routinely requested, along with tests affecting the management of any specific xenobiotic such as carbon monoxide, lithium, theophylline, iron, salicylates, and digoxin (or other cardioactive steroids), as suggested by history, physical examination, or bedside diagnostic tests. In the vast majority of cases, the blood tests that are most useful in diagnosing toxicologic emergencies are not the toxicologic assays but the â€œnontoxicologicâ€• routine metabolic profile tests such as BUN, glucose, electrolytes, and ABGs or venous blood gases (VBGs).

Xenobiotic-related seizures may broadly be divided into three categories: (a) those that respond to standard anticonvulsant treatment (typically a benzodiazepine); (b) those that either require specific antidotes to control seizure activity or that do not respond consistently to standard anticonvulsant treatment, such as isoniazid-induced seizures requiring pyridoxine administration; and (c) those that may *appear* to respond to initial treatment with cessation of tonicâ€“clonic activity, but which leave the patient exposed to the underlying, unidentified toxin or to continued electrical seizure activity in the brain, such as carbon monoxide or hypoglycemia.

Within the first 5 minutes of managing a patient with an altered mental status, 4 therapeutic agents should be *considered*, and if indicated, administered: (a) hypertonic dextrose 0.5â€“1.0 g/kg of $D_{50}W$ for an adult, or a more dilute dextrose solution ($D_{10}W$ or $D_{25}W$)

for a child. The dextrose is administered to diagnose and treat or exclude hypoglycemia; (b) thiamine 100 mg IV for an adult (usually unnecessary for a child) to prevent or treat Wernicke encephalopathy; (c) naloxone 0.05 mg IV for an adult or child with opioid (or clonidine)-induced respiratory compromise; and (d) high-flow oxygen (8â€“10 L/min) to treat a variety of xenobiotic-induced hypoxic conditions.

The clinician must consider that hypoglycemia may be the sole or contributing cause of coma even when the patient manifests focal neurologic findings and therefore dextrose administration should only be omitted when hypoglycemia can be definitely excluded by accurate rapid reagent bedside testing. Also, while examining a patient with an altered mental status (AMS) for clues to the etiology of a presumably toxic-metabolic form of AMS, it is important to search for any indication that trauma may have caused, contributed to, or resulted from the patient's condition. Conversely, the possibility of a concomitant drug ingestion or toxic metabolic disorder in the patient with obvious head trauma should also be considered.

The remainder of the physical examination should be performed rapidly, but thoroughly. In addition to evaluating the patient's level of consciousness, the physician should note abnormal posturing (decorticate or decerebrate), abnormal or unilateral withdrawal responses, and pupil size and reactivity. Pinpoint pupils suggest exposure to opioids or organic phosphorus insecticides, and widely dilated pupils suggest anticholinergic or sympathomimetic poisoning. The presence or absence of nystagmus, abnormal reflexes, and any other focal neurologic findings may provide important clues to a structural cause of AMS. For those clinicians accustomed to applying the Glasgow Coma Score (GCS) to all patients with altered mental status, assigning a score to the overdosed or poisoned patient may provide a useful measure for assessing changes in neurologic status, but in this situation, *the GCS should never be used for prognostic purposes*, because complete recovery from properly managed toxic-metabolic coma despite a low GCS is the rule rather than the

exception.

Characteristic breath or skin odors may identify the etiology of coma. The fruity odor of ketones on the breath suggests diabetic or alcoholic ketoacidosis, but also the possible ingestion of acetone or isopropyl alcohol, which is metabolized to acetone. The pungent, minty odor of oil of wintergreen on the breath or skin suggests methyl salicylate poisoning. The odors of other substances such as cyanide (â€œbitter almondsâ€•), hydrogen sulfide (â€œrotten eggsâ€•), and organic phosphorus compounds (â€œgarlicâ€•) are described in detail in Chap. 21 and summarized in Table 21-1.

Further Evaluation of all Patients with Suspected Xenobiotic Exposures

Reauscultation of breath sounds, particularly after a fluid challenge, helps to diagnose pulmonary edema, acute lung injury, or aspiration pneumonia when present. Coupled with an abnormal breath odor of hydrocarbons or organic phosphorus compounds, for example, crackles and rhonchi may point to a pulmonary *etiology* instead of a cardiac etiology; this is important because the administration of cardiac medications may be inappropriate or dangerous in these circumstances.

Heart murmurs in an injection drug user, especially when accompanied by fever, may indicate bacterial endocarditis. Dysrhythmias may suggest overdoses or inappropriate use of cardioactive medications (such as digoxin and other cardioactive steroids, Î²-adrenergic antagonists, calcium channel blockers, and cyclic antidepressants).

The abdominal examination may reveal signs of trauma or alcohol-related hepatic disease. The presence or absence of bowel sounds helps to exclude or to diagnose anticholinergic toxicity and is important in considering whether to manipulate the gastrointestinal tract in an attempt to remove toxin.

Examination of the extremities might reveal clues to current or former drug use (track marks, skin-popping scars), metal poisoning (Mees lines, arsenical dermatitis), and the presence of cyanosis or edema suggesting preexisting cardiac, pulmonary, or renal disease.

Repeated evaluation of the patient suspected of an overdose is essential for identifying new or developing findings or toxic syndromes, and for early identification and treatment of a deteriorating condition. Until the patient is completely recovered or considered no longer at risk for the consequences of a xenobiotic exposure, frequent reassessment must be provided, even as the procedures described below are carried out. Toxicologic etiologies of abnormal vital signs and physical findings are summarized in Tables 3-1, 3-2, 3-3, 3-4, 3-5, 3-6 and 3-7. Toxic syndromes, sometimes called â€œtoxidromes,â€• are summarized in Table 3-2.

Typically in the management of patients with toxicologic emergencies, there is both a necessity and an opportunity to obtain various diagnostic studies and ancillary tests interspersed with stabilizing the patient's condition, obtaining the history, and performing the physical examination exist. Chaps. 5, 6, and 7 discuss the timing and indications for qualitative and quantitative diagnostic laboratory studies, the use and interpretation of the electrocardiogram, and diagnostic imaging procedures in evaluating and managing the poisoned or overdosed patient.

The Role for Gastrointestinal Evacuation

A series of highly individualized treatment decisions must now be made. As noted previously and as discussed in detail in Chap. 8, the decision to evacuate the GI tract and/or administer AC can no longer be considered standard or routine toxicologic care for all patients. Instead, the decision should be based on the type of ingestion; estimated quantity and size; time since ingestion; concurrent ingestions; ancillary medical conditions; and age and size of the patient. The indications, contraindications, and procedures for

performing orogastric lavage and for administering WBI, AC,

MDAC, and cathartics are listed in Tables 8-1, 8-2, 8-3 and 8-4 and discussed both in Chap. 8 and in the specific Antidotes in Depth sections immediately following Chap. 8.

Eliminating Absorbed Xenobiotics from the Body

After deciding whether or not an intervention to try to *prevent* absorption of a xenobiotic is indicated, the clinician must next consider the applicability of techniques available to eliminate xenobiotics already absorbed. Detailed discussions of the indications for and techniques of manipulating urinary pH (ion trapping), diuresis, hemodialysis, hemoperfusion, hemofiltration, and exchange transfusion are found in Chap. 10. Briefly, patients who may benefit from these procedures are those who have systemically absorbed xenobiotics amenable to one of these techniques and whose clinical condition is both serious (or potentially serious) and unresponsive to supportive care, or whose physiologic route of elimination (liverâ€“stools, kidneyâ€“urine) is impaired.

Alkalinization of the urinary pH for acidic xenobiotics has only limited applicability. Commonly, sodium bicarbonate can be used to alkalinize the urine (as well as the blood) and enhance salicylate, phenobarbital, and chlorpropamide elimination and prevent toxicity from methotrexate (see Antidotes in Depth: Sodium Bicarbonate). Attempts to acidify the urine in order to hasten the elimination of alkaline substances is difficult to accomplish, probably useless, possibly dangerous, and therefore has no role in poison management. *Forced diuresis* has no indication and may endanger the patient by causing pulmonary or cerebral edema.

If extracorporeal elimination is contemplated, consider *hemodialysis* (HD) for salicylates, methanol, ethylene glycol, lithium, and drugs

that are both dialyzable and cause fluid and electrolyte problems. If available, consider *hemoperfusion* (HP) for theophylline, phenobarbital, phenytoin, and carbamazepine (though rarely, if ever, for the last three). When HP is the method of choice (as for a theophylline overdose) but not available, HD is a logical, effective alternative and certainly preferable to delaying treatment until HP becomes available. *Peritoneal dialysis* (PD) is too ineffective to be of practical utility, and *hemofiltration* (HF) is not as efficacious as HD or HP, although it may play a role between multiple runs of dialysis. In theory, both HD and HP *in series* may be useful for certain life-threatening overdoses such as salicylates.

Avoiding Pitfalls

The history alone is not a reliable indication of which patients require naloxone, hypertonic dextrose, thiamine, and oxygen. Instead, these therapies should be *considered* for all patients with altered mental status, unless specifically contraindicated. The physical examination should be used to guide the use of naloxone. If dextrose or naloxone is indicated, sufficient amounts should be administered to exclude and/or treat hypoglycemia or opioid toxicity, respectively.

In a patient with a suspected or unknown overdose, avoid the use of vasopressors in the initial management of hypotension prior to administering fluids or assessing filling pressures.

Attributing an altered mental status to alcohol because of its odor on a patient's breath is potentially dangerous and misleading: Small amounts of alcohol and its congeners generally produce the same breath odor as do intoxicating amounts. Conversely, even when an extremely high blood-ethanol concentration is *confirmed* by the laboratory, it is dangerous to ignore other possible etiologies of an altered mental status; chronic alcoholics may be awake and seemingly alert with ethanol concentrations in excess of 500 mg/dL, a concentration that would result in coma and possibly apnea and death in a nonalcoholic patient.

The metabolism of ethanol is fairly constant at 15â€“30 mg/dL/h. Therefore, as a general rule, regardless of the initial blood alcohol concentration, a presumably â€œinebriatedâ€• comatose patient who is still unarousable 3â€“4 hours after arrival should be considered to have structural CNS damage (head trauma) and/or another toxic-metabolic etiology for the alteration in consciousness, until proven otherwise. Careful neurologic evaluation supplemented by a head CT scan is frequently indicated in such a case. This is especially important in dealing with a seemingly â€œintoxicatedâ€• patient who appears to have only a minor bruise, as the early treatment of a subdural or epidural hematoma or subarachnoid hemorrhage is critical to a successful outcome.

Additional Considerations in Managing a Patient with a Normal Mental Status

As in the case of the patient with AMS, vital signs must be obtained and recorded. Initially, an assumption may have been made that the patient was breathing adequately, and if the patient is alert, talking and in no respiratory distress, all that remains to document is the respiratory rate and rhythm. Because the patient is alert, additional history should be obtained, keeping in mind that information regarding the number and types of xenobiotics ingested, time elapsed, prior vomiting and other critical information may be unreliable, depending in part on whether the ingestion was intentional or unintentional.

When indicated for the potential benefit of the patient, another history should be privately and independently obtained from a friend or relative after the patient has been initially stabilized. Recent emphasis on compliance with the federal Health Insurance Portability and Accountability Act (HIPAA) may inappropriately discourage clinicians from attempting to obtain information necessary to evaluate and treat patients. Obtaining such information from a friend or relative without unnecessarily giving that person information

about the patient may be the key to successfully helping such a patient without violating confidentiality.

Speaking to a friend or relative of the patient may provide an opportunity to learn useful and reliable information regarding the ingestion, the patient's frame of mind, a history of previous ingestions, and the type of support that is available should the patient be discharged from the ED. At times, it may be essential to initially separate the patient from any relatives or friends in order to obtain greater cooperation from the patient, avoid violating confidentiality and also because their anxiety may interfere with therapy. Even if the history obtained from a patient with an overdose proves to be unreliable, it may nevertheless provide clues to an overlooked possibility or a second ingestant or reveal the patient's mental and emotional condition. As is often true of the history, physical examination, or laboratory assessment in other clinical situations, the information obtained may confirm but never exclude possible etiologies.

At this point in the management of a conscious patient, a focused physical examination should be performed, concentrating on the pulmonary, cardiac and abdominal examinations. A neurologic survey should emphasize reflexes and/or any focal findings.

Approaching the Patient with an Intentional Exposure

Initial efforts at establishing rapport with the patient by indicating to the patient concern about the problems that led to the ingestion and the availability of help after the xenobiotic is removed (if such procedures are planned), may help make management easier. If gastrointestinal decontamination is deemed necessary, the reason for and nature of the procedure should be clearly explained to the patient together with reassurance that after the procedure is

completed, there will be ample time to discuss related problems and provide additional care. These considerations are especially important in managing the patient with an intentional overdose who may be seeking psychiatric help or emotional support. In deciding on the necessity of gastrointestinal decontamination, it is important to consider that a resistant patient may transform a procedure of only potential value into one with predictable adverse consequences.

Special Considerations for Managing the Pregnant Patient

In general, a successful outcome for both mother and fetus is dependent on optimum management of the mother and proven effective treatment for a potentially serious toxic exposure to the mother should never be withheld based on theoretical concerns regarding the fetus.

Physiologic Factors

A pregnant woman's total blood volume and cardiac output are elevated through the second trimester and into the later stages of the third trimester. This means that signs of hypoperfusion and hypotension will manifest later than they would in a woman who is not pregnant and when they do, uterine blood flow may already be compromised. For these reasons, the possibility of hypotension in the pregnant woman must be more aggressively sought and, if found, more rapidly treated. Maintaining the patient in the left-lateral decubitus position will help prevent supine hypotension resulting from impairment of systemic venous return by compression of the inferior vena cava. The left lateral decubitus position is also the preferred position for orogastric lavage, deemed necessary.

Because the tidal volume is increased in pregnancy, the baseline PCO_2 will normally be lower by approximately 10 mm Hg. Appropriate adjustment for this effect should be made when interpreting arterial

blood gas results.

Use of Antidotes

Few data are available on the use of antidotes in pregnancy. In general, antidotes should not be used if the indications for use are equivocal. On the other hand, antidotes should not be withheld if their use may reduce potential morbidity and mortality. Risks and benefits of either decision must be considered. For example, reversal of opioid-induced respiratory depression calls for the use of naloxone, but in an opioid-dependent woman, the naloxone can precipitate acute withdrawal, including uterine contractions and possible induction of labor. Very slow, careful, intravenous titration starting with 0.05 mg naloxone may be indicated, unless apnea is present, cessation of breathing appears imminent, or the PO_2 or O_2 saturation is already grossly inadequate. In these instances, naloxone may have to be administered in higher doses (ie, 0.4â€“2.0 mg) or assisted ventilation provided or a combination of assisted ventilation and small doses of naloxone used.

An acetaminophen overdose is a serious *maternal* problem when it occurs throughout pregnancy, but the *fetus* is at greatest risk in the third trimester. Although acetaminophen crosses the placenta easily, *N*-acetylcysteine has somewhat diminished transplacental passage. During the third trimester, when both the mother and the fetus may be at substantial risk from a significant acetaminophen overdose, immediate delivery of a mature or viable fetus may need to be considered.

In contrast to the situation with acetaminophen, the fetal risk from iron poisoning is less than the maternal risk. Because deferoxamine is a large charged molecule with little transplacental transport, deferoxamine should never be withheld out of unwarranted concern for fetal toxicity when indicated to treat the mother.

Carbon monoxide (CO) poisoning is particularly threatening to fetal

survival. The normal PO_2 of the fetal blood is approximately 15â€“20 mm Hg. Oxygen delivery to fetal tissues is impaired by the presence of carboxyhemoglobin, which shifts the oxyhemoglobin dissociation curve to the left, potentially compromising an already tenuous balance. For this reason, hyperbaric oxygen (HBO) is recommended for much lower carboxyhemoglobin concentrations in the pregnant compared to the nonpregnant woman (Chap. 120 and Antidotes in Depth: Hyperbaric Oxygen). Early notification of the obstetrician and close cooperation among involved physicians are essential for best results in all of these instances.

Management of Patients with Cutaneous Exposure

The xenobiotics that people are commonly exposed to externally include household cleaning materials; organic phosphorus or carbamate insecticides from crop dusting, gardening, or pest extermination; acids from leaking or exploding batteries; alkalis, such as lye; and lacrimating agents that are used in crowd control. In all cases, the principles of management are as follows:

- Avoid secondary exposures by wearing protective (rubber or plastic) gowns, gloves, and shoe covers. Cases of serious secondary poisoning have occurred in emergency personnel after contact with xenobiotics such as organic phosphorus compounds on the victim's skin or clothing.
- Remove the patient's clothing and place it in plastic bags, then seal it.
- Wash the patient with soap and copious amounts of water *twice*, regardless of how much time has elapsed since the exposure.
- Make no attempt to neutralize an acid with a base, or a base with an acid. Further tissue damage may result from the heat generated by this reaction.

- Avoid using any greases or creams as they will only keep the xenobiotic in close contact with the skin and ultimately make removal more difficult.

Chap. 29 discusses the principles of managing cutaneous exposures.

Management of Patients with Ophthalmic Exposures

Although the vast majority of toxicologic emergencies result from ingestion, injection, or inhalation, the eyes are occasionally the routes of systemic absorption or are the organs at risk. The eyes should be irrigated with lids fully retracted for no less than 20 minutes. To facilitate irrigation, a drop of an anesthetic (eg, proparacaine) in each eye may be used and the eyelids should be kept open with a lid retractor. An adequate irrigation stream may be obtained by running 1 L of normal saline through regular IV tubing held a few inches from the eye or by using an irrigating lens. Checking the lid fornices with pH paper strips is important to ensure adequate irrigation; the pH should normally be 6.5â€“7.6 if accurately tested, although when using paper test strips, the measurement will often be near 8.0. Chap. 20 describes the management of toxic ophthalmic exposures in more detail.

Identifying the Patient with a Nontoxic Exposure

There is ample opportunity to needlessly subject a patient to potential harm when the patient with a nontoxic exposure is treated aggressively with gastrointestinal evacuation techniques and other forms of management indicated for serious exposures. More than 40% of exposures reported to poison centers annually are judged to be nontoxic. The following general guidelines for considering an

exposure nontoxic or minimally toxic will assist clinical decision making:

- Identification of the product and its ingredients is possible.
- None of the US Consumer Product Safety Commission â€œsignal wordsâ€• â€”CAUTION, WARNING, or DANGERâ€”appear on the product label.
- The history permits the route(s) of exposure to be determined.
- The history permits a reliable approximation of the maximum quantity involved with the exposure.
- Based on the available medical literature and clinical experience, the potential effects related to the exposure are expected to be at most benign and self-limited, and do not require referral to health care.
- The patient is asymptomatic, or has developed the expected benign self-limited toxicity.

(Adapted from McGuigan MA, Guideline Consensus Panel: Guideline for the out-of-hospital management of human exposures to minimally toxic substances. J Toxicol Clin Toxicol 2003;41:907â€“917; and Mofenson HC, Greensher J: The nontoxic ingestion. Pediatr Clin North Am 1970;17:583â€“590.)

Assuring Optimal outcome for the Patient

The best way to assure an optimal outcome for the patient with a suspected toxic exposure is to apply the principles of basic and advanced life support in conjunction with a planned and staged approach, always bearing in mind that a toxicologic etiology or coetiology for any abnormal conditions necessitates modifying whatever standard approach is brought to the bedside of a severely

ill patient. For example, it is extremely important to recognize that xenobiotic-induced dysrhythmias and cardiac instability require alterations in standard protocols that assume a primary cardiac or nontoxicologic etiology (Chap. 23).

Typically, only some of the xenobiotics to which a patient is exposed will ever be confirmed by laboratory analysis. The thoughtful combination of stabilization, general management principles, and specific treatment when indicated, will result in successful outcomes in the vast majority of patients with actual or suspected exposures.

Chapter 5
Electrocardiographic Principles

Cathleen Clancy

The electrocardiogram (ECG) is ubiquitous in emergency departments and intensive care units and its interpretation is widely understood by physicians of nearly all disciplines. It is an invaluable diagnostic tool for patients with acute cardiovascular complaints. However, it is also a valuable source of information in poisoned patients and has the potential to enhance and direct their care. Although it seems obvious that an ECG would be required following exposure to a drug used for cardiovascular indications, many drugs with no overt cardiovascular effects with therapeutic dosing become cardiotoxic in overdose. In patients with unknown exposures, the ECG can suggest specific xenobiotics or demonstrate electrolyte abnormalities, long before blood is even drawn. For example, oropharyngeal or dermal burns in a patient whose ECG has evidence of hyperkalemia or hypocalcemia suggests exposure to hydrofluoric acid.[47, 48] Alternatively, a patient manifesting signs of the opioid toxidrome with runs of ventricular tachycardia might have been exposed to propoxyphene.[25] QTc prolongation may be a clue to the etiology of an overdose with an atypical antipsychotic agent such as

quetiapine. The ECG can also be used to predict complications of poisoning, such as seizures following a tricyclic antidepressant overdose. Therefore, an ECG should be examined critically early in the initial evaluation of most poisoned patients.

History

The knowledge of a relationship between electricity and muscular movement can be traced back to 1790, when Luigi Galvani electrically stimulated an ex vivo preparation of the legs of a frog, and made them â€œdance.â€• In 1887, Waller developed a â€œcapillary electrometerâ€• that transmitted electrical impulses from a man's skin to a capillary tube. Pulsations similar to the patient's heartbeat were visible in the tube.[43] In the 1900s, Willem Einthoven graphically displayed the electrical activity of the heart and named the different wavesâ€”P, QRS, and T. He called this tracing an â€œelektrokardiogramme.â€• In 1924, he was awarded a Nobel Prize for his efforts. The acronym *EKG* , still employed by some authors, was derived from Einthoven's spelling. The acronym *ECG* , which is consistent with our current spelling of electrocardiogram, is used throughout this text.

Since this initial description, both the normal electrophysiology of the heart and the pharmacologic effects of various xenobiotics on the ECG have been described. Despite the large number, diversity, and complexity of the various cardiac toxins, there are only a limited number of electrocardiographic manifestations.

Basic Electrophysiology of the Myocardial Cell

The resting myocardial cell, or myocyte, is negatively charged, or polarized. When the myocytes in the sinus node depolarize, ion channels in the nearby myocardium open and allow a net influx of positively charged sodium and calcium ions. This influx raises the

electrical potential of the cell toward and then past neutral and initiates an impulse that propagates throughout the myocardium, producing electrical and mechanical systole. The membrane depolarization is maintained by an outward potassium current and an inward calcium current throughout systole. After a well-defined time period the myocardial membrane is repolarized by a growing outward current of potassium and a reduction in the inward calcium current. Final repolarization requires the repartitioning of sodium out of the cell and potassium into the cell by an adenosine triphosphate (ATP)-using pump [ATPase] (Table 5-1).

Figure 5-1 shows schematically the relationship of the major ion flux across the myocardial cell membrane, the phases of the action potential, and the surface ECG recording. Chap. 23 provides a more detailed description of ion fluxes and channels.

Basic Electrophysiology of an Electrocardiogram

Simplistically, a positive or upward deflection on the oscilloscope is generated when an electrical force moves toward an electrical sensor or electrode, and a downward deflection occurs if the force moves away. An ECG represents the sum of movement of all electrical forces in the heart in relation to the surface electrode, and the height above baseline represents the magnitude of the force

(Fig. 5-2). Only during depolarization or repolarization does the ECG tracing leave the isoelectric baseline, because it is only during these periods that measurable currents are flowing in the heart. During the other periods, mechanical effects are occurring in the myocardium, but large amounts of current are not flowing.

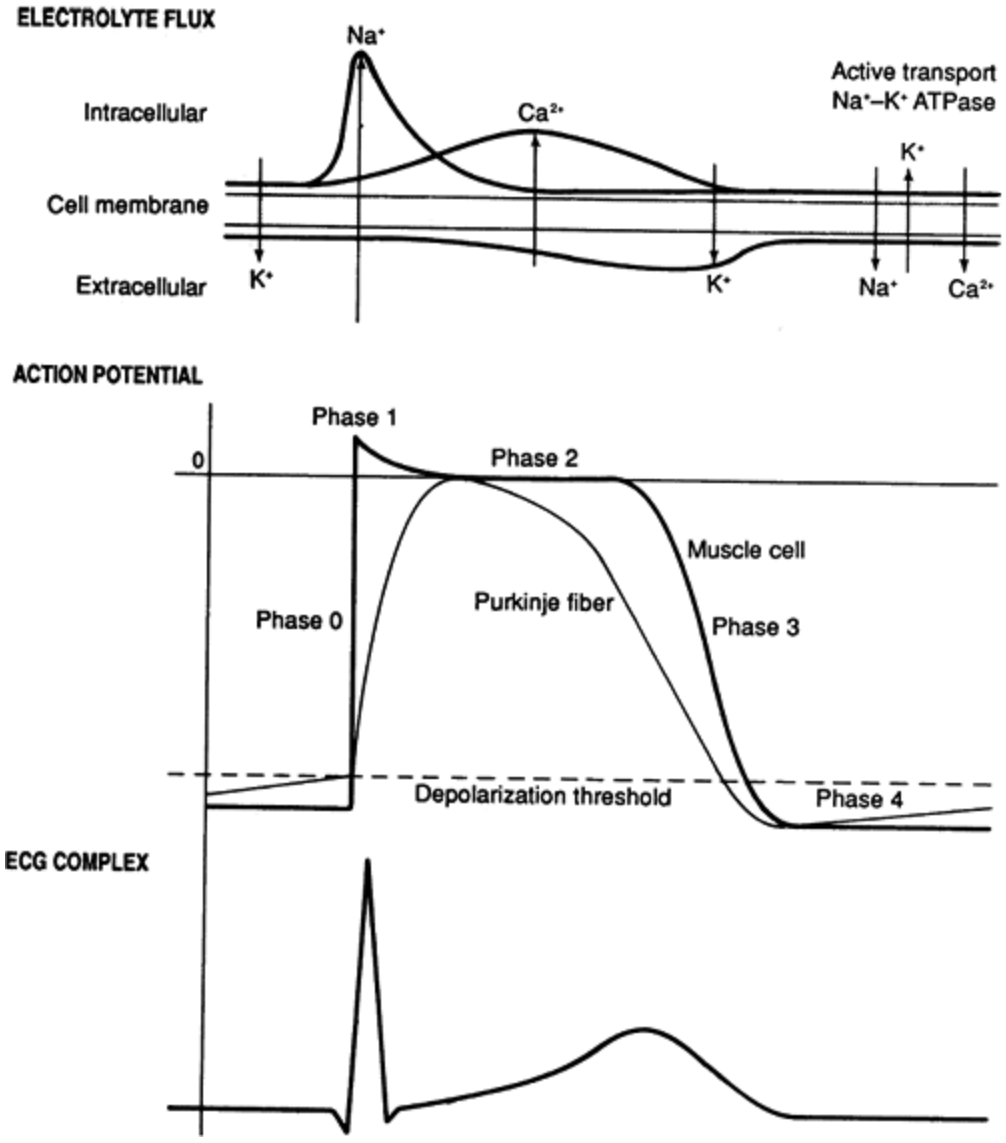

Figure 5-1. Relationship of electrolyte movement across the cell membrane to the action potential and the surface ECG recording.

Leads

Although the reading from a single electrocardiogram lead provides an immense amount of information, to visualize the heart in a nearly three-dimensional perspective, multiple leads must be assessed simultaneously. Given the cylindrical nature of both the heart and thorax, at any given moment some of these leads will

record positive voltage and others negative. The lead placement that was described and refined in the early 1900s by Einthoven forms the basis for the bipolar or limb leads, described as I, II, and III (Fig. 5-3). The Einthoven triangle is an equilateral triangle formed by the sum of these leads. Unipolar limb leads and precordial leads were subsequently added to the standard electrocardiogram. Wilson and colleagues connected limb leads, called V_R , V_L , and V_F , to a common point where the sum of the potentials from

leads I, II, and III was zero. A unipolar potential was measured.[44] The currently used, augmented (a) leads (aV_R , aV_L , and aV_F) are based on these unipolar leads (Fig. 5-4).[16] The precordial leads, called V_1 through V_6 , are also unipolar measurements of the change in electric potential measured from a central point to the 6 anterior and left lateral chest positions (Fig. 5-5). If V_2 is placed over the right ventricle, part of the initial positive ventricular deflection (QRS complex) reflects right ventricular activation, with electrical forces moving toward the electrode. The majority of the subsequent terminal negative deflection reflects activation of other muscle tissue (septum, left ventricular wall) when the electrical forces are moving away from the electrode. Recordings from each of these 12 leads (I, II, III, aV_R , aV_L , aV_F , $V_{1â€“6}$) evaluate the heart from two different planes in 12 different positions, yielding a three-dimensional electrical â€œpictureâ€• of the heart, with respect to time and voltage.

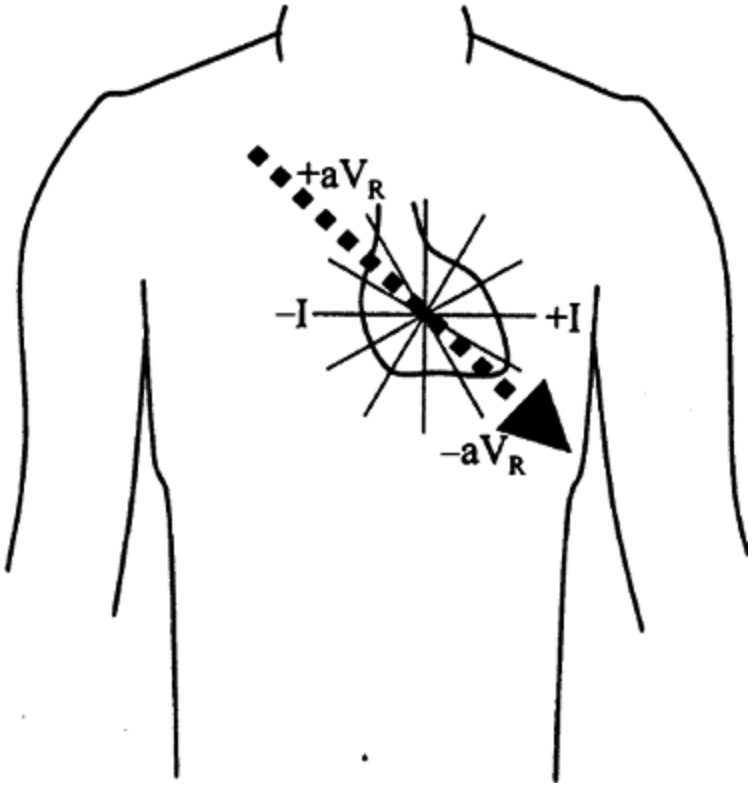

Figure 5-2. A simplistic correlation between cardiac anatomy and electrocardiographic representation.

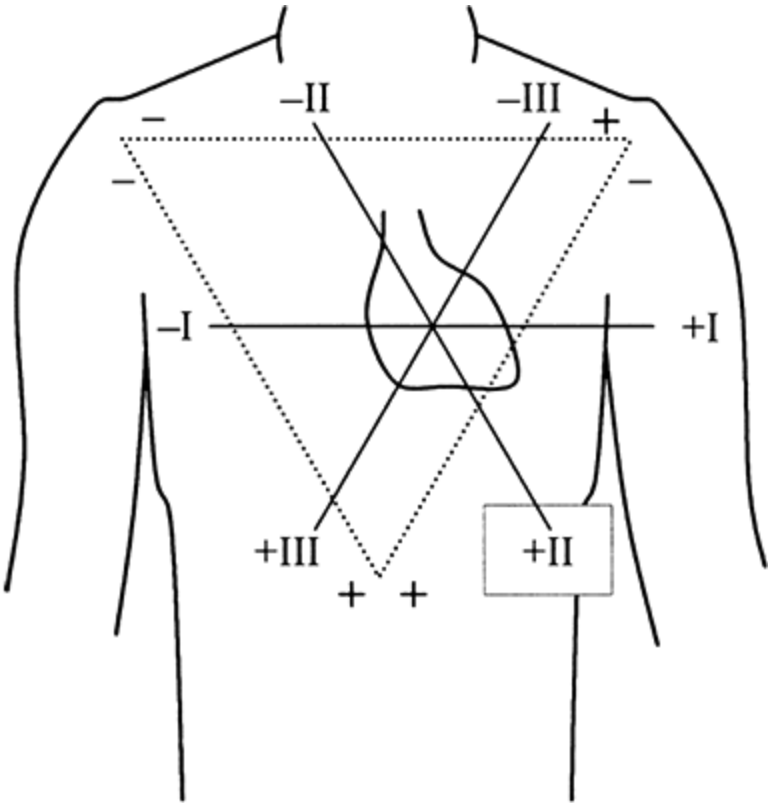

Figure 5-3. The relationships of the original three limb leads are illustrated. The equiangular (60Â°) Einthoven triangle formed by leads I, II, and III is shown *(dotted lines)* with positive and negative poles of each of the leads indicated. Leads I, II, and III are also presented as a triaxial reference system that intersects in the center of the ventricles.

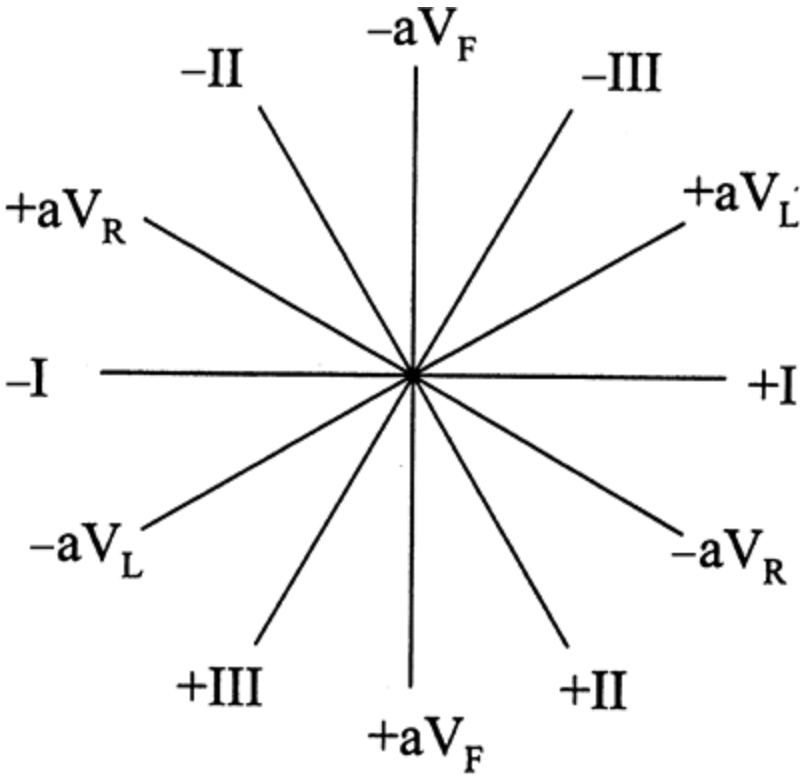

Figure 5-4. The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography.

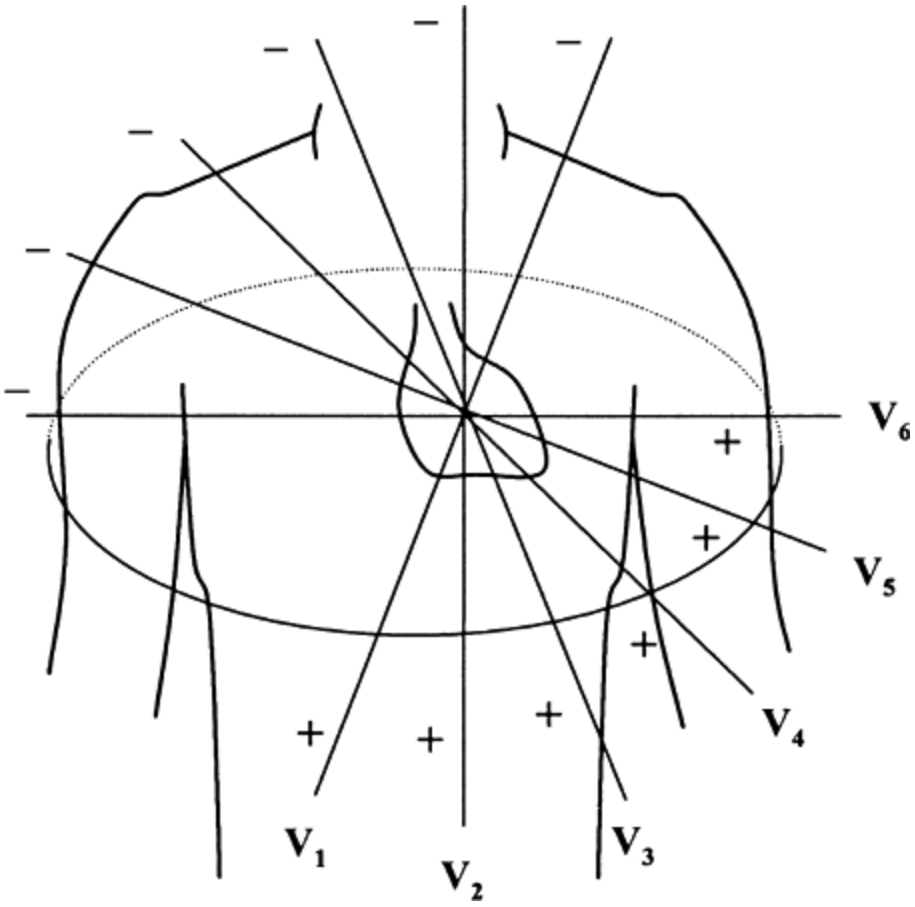

Figure 5-5. Visualized as a cross-section, each of the chest leads is oriented through the atrioventricular (AV) node and exits through the patient's back, which is negative.

A continuous cardiac monitor usually relies on recordings from one of two bipolar leads: a modified left chest lead (MCL_1) or a lead II. The recording from an MCL_1 , in which the positive electrode is in the V_1 position, is similar in appearance to a V_1 recording on a 12-lead ECG. This lead visualizes ventricular activity well; however, lead II shows atrial activity (ie, the P wave) much more clearly.

The Various Intervals and Waves

The ECG tracing has specific nomenclature to define the

characteristic patterns. Waves refer to positive or negative deflections from baseline, such as the P, T, or U wave. A segment is defined as the distance between two waves, such as the ST segment, and an interval measures the duration of a wave plus a segment, such as QT or PR interval. Complexes are a group of waves without intervals or segments between them (QRS). Electrophysiologically, the P wave and PR interval on the ECG tracing represent the depolarization of the atria. The QRS complex represents the depolarization of the ventricles. The plateau is depicted by the ST segment and repolarization is visualized as the T wave and the QT interval (QTc). The U wave, when present, generally represents an afterdepolarization (Fig. 5-6).

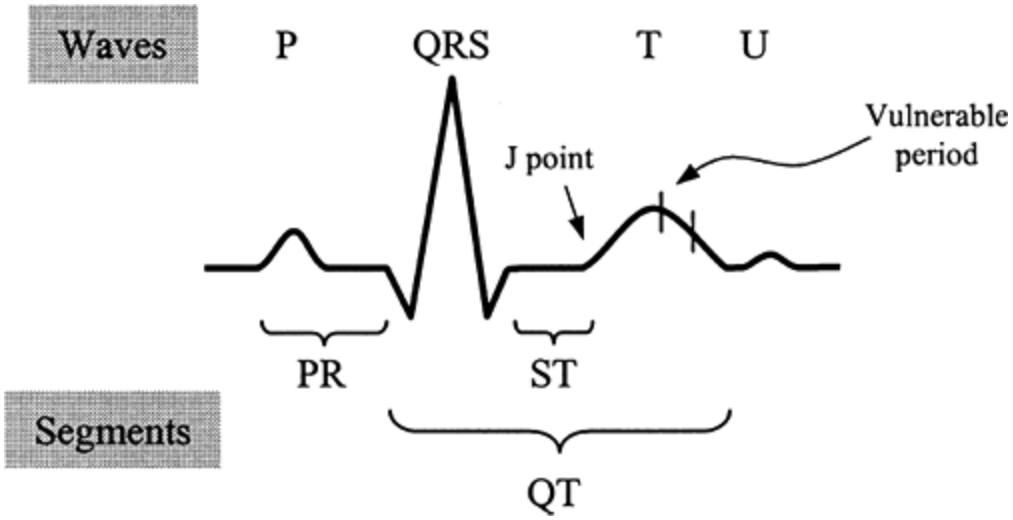

Figure 5-6. The normal ECG: P wave, atrial depolarization; QRS, ventricular depolarization; ST segment, T wave, QT interval, and U wave, ventricular repolarization. The U wave is the small, positive deflection following the T wave.

The P Wave

The P wave is the initial deflection on the ECG that occurs with the initiation of a new cardiac cycle.

Electrophysiology

The early, middle, and late portions of the P wave are represented sequentially by the electrical potential initiated by the sinus node. The impulse is propagated directly through the right atrial muscle, producing contraction. The impulse is also propagated by specialized conduction tissue across the interatrial septum, to produce contraction of the left atrium. Additionally, internodal pathways rapidly conduct the impulse to the atrioventricular (AV) node. The electrical excitation of the sinus node differs from that of the ventricular myocardium in that current is mediated primarily by calcium ion influx via slow T-type calcium channels, not by sodium entering through fast sodium channels. Furthermore, the vagus nerve exerts a profound suppressive influence on the nodal tissues.

The Abnormal P Wave

Clinically, abnormalities of the P wave occur with xenobiotics that depress automaticity of the sinus node, causing sinus arrest and nodal or ventricular escape rhythms (Î²-adrenergic antagonists, calcium channel blockers). The P wave is absent in rhythms with sinus arrest, such as occurs with xenobiotics that produce vagotonia such as cardioactive steroids and cholinergic agents. A notched P wave suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning. P waves decrease in amplitude as hyperkalemia becomes more severe until they become indistinguishable from the baseline (Chap. 17).

The PR Interval

The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex (normal is 120â€“200 milliseconds).

Electrophysiology

Despite rapid conduction by specialized conduction tissue from the sinoatrial (SA) to the AV node, the AV node delays transmission of the impulse into the ventricles, ostensibly to allow for complete atrial emptying. Thus, the PR interval represents the interval between the onset of atrial depolarization and the onset of ventricular depolarization. Children usually have more rapid conduction and a shorter PR interval, and older adults generally have a longer PR interval. The segment between the end

of the P wave and the beginning of the QRS complex (the PQ segment) reflects atrial contraction and is usually isoelectric. Atrial repolarization coincides with the Q wave, but its ECG findings, or atrial T waves, are obscured by the QRS complex.

The Abnormal PR Interval

Xenobiotics that decrease interatrial or AV nodal conduction cause marked lengthening of the PR segment until such conduction completely ceases. At this point, the P wave no longer relates to the QRS complex; this is AV dissociation, or complete heart block. Some xenobiotics suppress AV nodal conduction by blocking calcium channels in nodal cells, as does magnesium, antagonizing at the Î²-adrenergic receptors, or enhancing vagal tone. Although the therapeutic use of digoxin, as well as early cardioactive steroid poisoning, causes PR prolongation through vagotonic effects, direct electrophysiologic effects account for the bradycardia of poisoning (see â€œBradydysrhythmias â€• section later in this chapter, as well as Chap. 62 and Antidotes in Depth: Digoxin-Specific Antibody Fragments [Fab]).

The QRS Complex

The QRS complex is the second and typically larger deflection on

the ECG. The normal QRS duration in adults varies between 60 and 120 msec. The normal range for the QRS axis in the frontal plane is between -30Â° and 90Â°, although most people will have values between 30Â° and 75Â°. This axis will vary with the weight and age of the patient. Alterations in myocardial function may also alter the electrical axis of the heart.

Electrophysiology

The QRS complex reflects the electrical forces generated by ventricular depolarization mediated primarily by sodium influx into the myocardial cells. Although under normal conditions both ventricles depolarize nearly simultaneously, the greater mass of the left ventricle causes it to contribute the majority of the electrical forces. The QRS complex is primarily positive in leads I and aV_L on the surface ECG recording because under normal conditions the depolarization vector is directed at 60Â° and is thus moving toward the positive electrodes in these leads.

The simultaneous and rapid depolarization of the ventricles results in a very short period of electrical activity recorded on the electrocardiogram. Of course, mechanical systole lasts well past the end of the QRS complex and is maintained by continued depolarization during the plateau phase of the action potential. The return and maintenance of the baseline, or isoelectric potential, is simply a result of the fact that the entire heart is depolarized and there is no significant flow of current during this period.

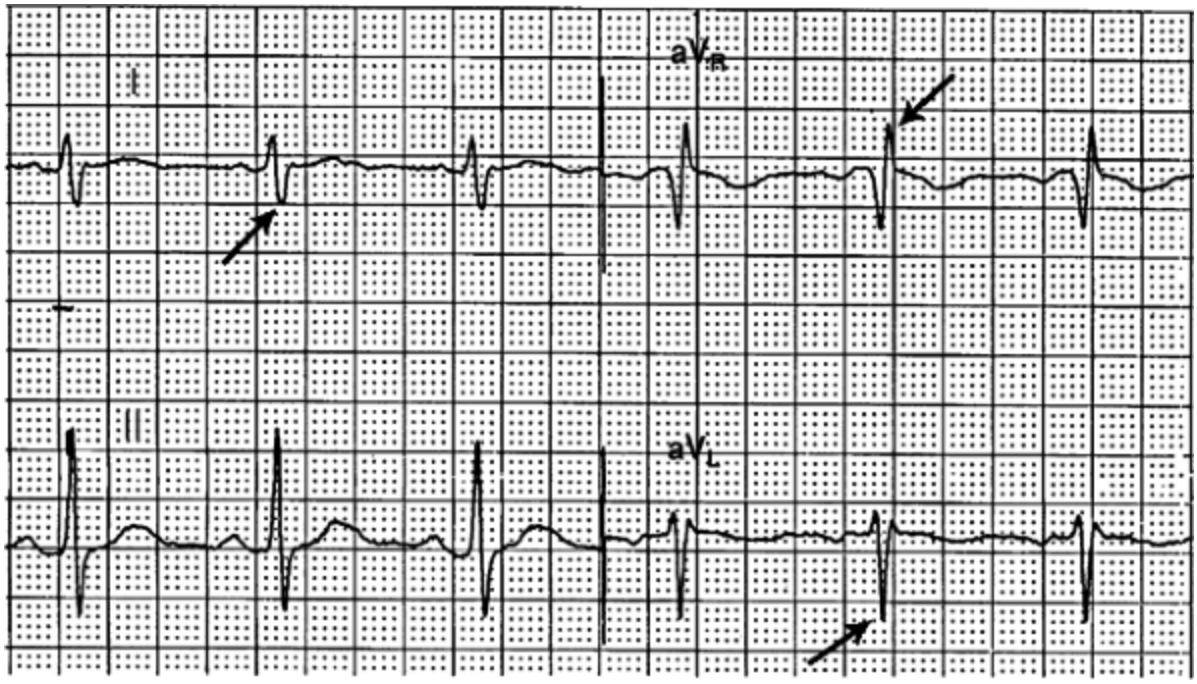

Figure 5-7. ECG showing leads I, II, aV_R , and aV_L of a patient with a tricyclic antidepressant overdose. The prominent S wave in leads I and aV_L and R wave in aV_R demonstrate the terminal 40-msec rightward axis shift.

The axis of the terminal 40 msec (0.04 seconds) of the QRS complex represents the late stages of ventricular depolarization and generally follows the direction of the overall axis. This axis is determined by examining the last box (0.04 seconds or 40 msec) of the QRS complex on the electrocardiogram paper.

The Abnormal QRS Complex

In the presence of a bundle-branch block, the two ventricles depolarize sequentially rather than concurrently. Although, conceptually, conduction through either the left or right bundle may be affected, many xenobiotics preferentially affect the right bundle. This effect typically results in the left ventricle depolarizing slightly more rapidly than the right. The consequence on the ECG is both a widening of the QRS complex and the

appearance of the right ventricular electrical forces that were previously obscured by those of the left ventricle. These changes are a result of the effects of a xenobiotic that blocks fast sodium channels. Implicated xenobiotics include cyclic antidepressants, quinidine and other type IA and IC antidysrhythmic agents, phenothiazines,[3] amantadine, diphenhydramine,[11] carbamazepine, and cocaine. In the setting of tricyclic antidepressant poisoning, this finding has both prognostic and therapeutic value (Chap. 71).[1 , 14 , 18 , 19 , 34] Specifically, in a prospective analysis of ECGs the maximal limb lead QRS duration was prognostic of seizures (0% if <100 msec; 30% if greater) and ventricular dysrhythmias (0% if <160 msec; 50% if greater).[7]

This terminal 40-msec axis of the QRS complex contains critical information regarding the likelihood, but not the extent, of poisoning by sodium channel blocking agents. In a poisoned patient, the terminal portion of the QRS has a rightward deviation greater than 120Â°. The common abnormalities include, an R wave (positive deflection) in lead aV_R and an S wave (negative deflection) in leads I and aV_L .[21] The combination of a rightward axis shift in the terminal 40 msec of the QRS complex (Fig. 5-7) with a prolonged QTc and a sinus tachycardia is highly specific and sensitive for cyclic antidepressant poisoning. Absence of these findings, in one study at least, excluded serious tricyclic antidepressant (TCA) poisoning.[31 , 45] Another study suggests that although ECG changes, like a prolonged QRS duration, are better at predicting severe outcomes than the TCA level, neither is very accurate.[1] One prospective study

suggests that an absolute height of the terminal portion of aV_R that is greater than 3 mm, predicted seizures or dysrhythmias in TCA-poisoned patients.[20] In infants younger than 6 months old, however, a rightward deviation of the terminal 40-msec QRS axis is physiologic and not predictive of tricyclic antidepressant toxicity.[6] In older children, retrospective chart review of 37

children diagnosed with tricyclic antidepressant overdose and 35 controls (all younger than 11 years old) found interpatient variability, unrelated to age, so great that a rightward deviation of the terminal 40-msec QRS axis could not distinguish between poisoned and healthy children.[6]

An apparent increase in QRS duration and morphology, which is actually an elevation or distortion of the J point called a J wave or an Osborn wave (Fig. 16-2), is a common finding in patients with hypothermia.[33] Hypermagnesemia is also associated with a widening the QRS duration and a slight narrowing of the QRS complex may occur with hypomagnesemia.[29] Significant elevation in the serum concentrations of potassium may also cause widening and distortion of the QRS complex.

The ST Segment

The ST segment is defined as the distance between the end of the QRS complex and the beginning of the T wave.

Electrophysiology

This segment reflects the period of time between depolarization and the start of repolarization, or the plateau phase of the action potential. During this period, no major currents flow within the myocardium, which explains why under normal circumstances the ST segment is isoelectric. Although both the degree of displacement from the baseline and the length of this segment are important, the ST segment duration is usually measured by its effects on the QT duration (see â€œThe QT Interval â€• section, below).

The Abnormal ST Segment

Displacement of the ST segment from its baseline typically characterizes myocardial ischemia or infarction (Fig. 5-8). The

subsequent appearance of a Q wave is diagnostic of myocardial infarction. The ECG patterns of these entities reflect the different underlying electrophysiologic states of the heart. Ischemic regions are highly unstable and produce currents of injury because of inadequate repolarization, which is related to lack of energy substrate to power the Na^+ -K^+ ATPase. Infarction represents the loss of electrical activity from the necrotic, inactive ventricular tissue, allowing the contralateral ventricular forces to be predominant on the ECG. Patients who are poisoned by xenobiotics that cause vasoconstriction, such as cocaine (Chap. 74), other Î±-adrenergic agonists, or the ergot alkaloids, are particularly prone to develop focal myocardial ischemia and infarction. The specific electrocardiographic manifestations help to identify the region of injury and may, to some extent, be correlated with an arterial flow pattern: inferior (leads II, III, aV_F ; right coronary artery); anterior (leads I, aV_L ; left anterior descending artery); or lateral (leads aV_L , $V_{5â€“6}$; circumflex branch). However, any poisoning that results in profound hypotension or hypoxia may also result in ECG changes of ischemia and injury. In this situation, the injury may be more global, involving more than one arterial distribution. Diffuse myocardial damage may not be identifiable on the electrocardiogram because of global, symmetric electrical abnormalities. In this situation, the diagnosis is made by other noninvasive testing, such as by echocardiogram or by finding elevations in serum markers for myocardial injury (eg, troponin).

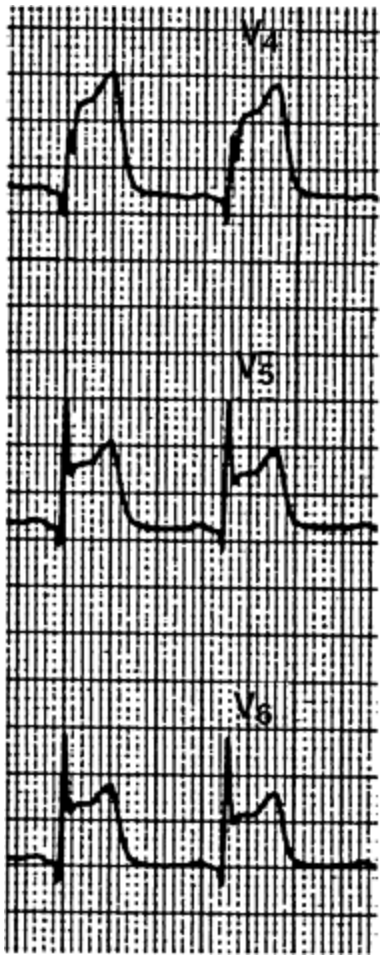

Figure 5-8. Leads V_4 â€“ V_6 are shown from the ECG of a 27-year-old man with substernal chest pain after using crack cocaine.

Many young, healthy patients have ST segment abnormalities that mimic those of myocardial infarction. The most common normal variant is termed â€œearly repolarizationâ€• or â€œJ-point elevation,â€• and is identified as diffusely elevated, upwardly concave ST segments, located in the precordial leads and typically with corresponding T waves of large amplitude.[9] The J point is located at the beginning of the ST segment just after the QRS complex. Because this electrocardiographic variant is common in patients with cocaine-associated chest pain (Chap. 74),[17] its recognition is critical to instituting appropriate therapy.

The Brugada electrocardiographic pattern (Fig. 5-9) is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads. The Brugada pattern is found in some patients with mutations of the gene that codes for the sodium channel Î± subunit. These patients are at risk for sudden death, but a similar ECG pattern often occurs in patients who are poisoned by sodium channel blocking xenobiotics, including TCAs,[5] cocaine,[32] class IA (procainamide), and class IC (flecainide, encainide) antidysrhythmic agents.[23 , 28] In TCA-poisoned patients this pattern is associated with an increased risk of hypotension, but not sudden death or dysrhythmias.[4 , 28] Sagging ST segments, inverted T waves, and normal or shortened QT intervals are characteristic effects of cardioactive steroids, such as digoxin, on the ECG. These repolarization abnormalities are sometimes identified by their similar appearance to â€œSalvador Dali's mustache.â€• As a group, these findings, along with PR prolongation, are commonly described as the â€œdigitalis effectâ€• (Chap. 62). They are found in patients with therapeutic drug levels and in patients with cardioactive steroid poisoning. As the serum level or, more precisely, the tissue concentration increases,

clinical and electrocardiographic manifestations of toxicity will appear (Chap. 62), which include profound bradycardia or ventricular dysrhythmias.

Figure 5-9. The Brugada pattern is characterized by terminal positivity of the QRS complex and ST-segment elevation in the right precordial leads and is a similar ECG pattern to that noted in patients poisoned by sodium channel blocking agents such as tricyclic antidepressants.[4] *(Reproduced with permission of Vikhyat Bebarta, MD.)*

Changes in the ST segment duration are frequently caused by abnormalities in the serum calcium concentration. Hypercalcemia causes shortening of the ST segment through enhanced calcium influx during the plateau phase of the cardiac cycle speeding the onset of repolarization. For practical purposes this effect is more commonly identified by reduction of the QTc (Fig. 5-10 ; see The QT Interval below). In patients with hypercalcemia, the morphology and duration of the QRS complex and T and P waves remain essentially unchanged. Xenobiotic-induced hypercalcemia may result from exposure to antacids (milk alkali syndrome), diuretics (eg, hydrochlorothiazide), cholecalciferol (vitamin D), vitamin A, and other retinoids. Hypocalcemia causes prolongation of the ST segment and QTc (Fig. 5-10).

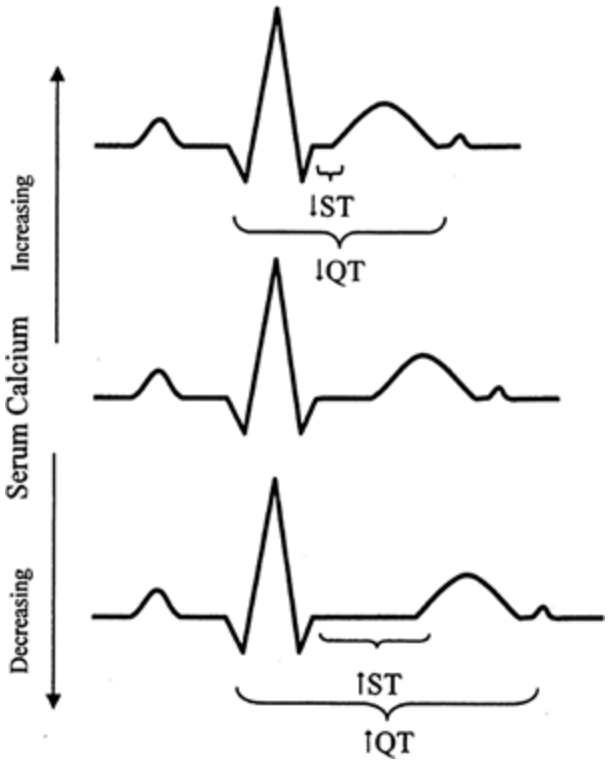

Figure 5-10. Electrocardiographic findings associated with changes in serum calcium.

The T Wave

The T wave is the third deflection that occurs on the ECG.

Electrophysiology

The T wave represents ventricular repolarization, during which current is again flowing, although at a cellular level in the opposite direction from that during depolarization. Cardiac repolarization on the larger level generally follows the same pattern as depolarization and thus the deflection is usually in the same direction as the QRS complex. During repolarization, the intracellular potential of the cardiac myocyte becomes more negative as a result of a net loss of positive charge because of the increasing outward flow of potassium ions. As repolarization

progresses, the voltage-dependent ion channels â€œresetâ€• themselves as the intracellular potential falls past their set points. Thus, the initial part of the T wave represents the absolute refractory period of the heart, because at this time there are an insufficient number of reset voltage-dependent calcium channels to allow an impulse to cause a contraction. The latter part of the T wave represents the relative refractory period of the heart, during which time a sufficient number of these calcium channels are available to open with an aberrant depolarization and initiate a contraction.

The Abnormal T Wave

Isolated peaked T waves are usually evidence of early hyperkalemia.[27] Hyperkalemia initially causes tall, tented T waves with normal QRS, QTc, and P wave (Fig. 5-11). As the measured potassium rises to 6.5â€“8 mEq/L, the P wave diminishes in amplitude and the PR and QRS intervals prolong. Progressive widening of the QRS complex causes it to merge with the ST segment and T wave, forming a â€œsine wave.â€• Electrocardiographic manifestations of hyperkalemia may occur following chronic exposure to numerous therapeutic agents, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors (Chap. 60), or potassium supplements. Either fluoride or cardiac glycoside poisoning produces acute hyperkalemia, but the latter rarely produces hyperkalemic ECG changes (Chap. 62). Peaked T waves also occur following myocardial ischemia and may also be confused with early repolarization effects (see The ST Segment above). Consequently, the ability to properly identify electrolyte abnormalities by electrocardiography is often limited.

Hypokalemia typically reduces the amplitude of the T wave and, ultimately, causes the appearance of prominent U waves (Fig. 5-11). Its effects on the electrocardiogram are manifestations of

altered myocardial repolarization. Lithium similarly affects myocardial ion fluxes and causes reversible changes on the electrocardiogram that may mimic mild hypokalemia, although documentation of

low cellular potassium levels is lacking.[12, 37, 46] Patients chronically poisoned with lithium have more T-wave abnormalities (typically flattening) than do those who are acutely poisoned, but these abnormalities are rarely of clinical significance.[8, 22, 38]

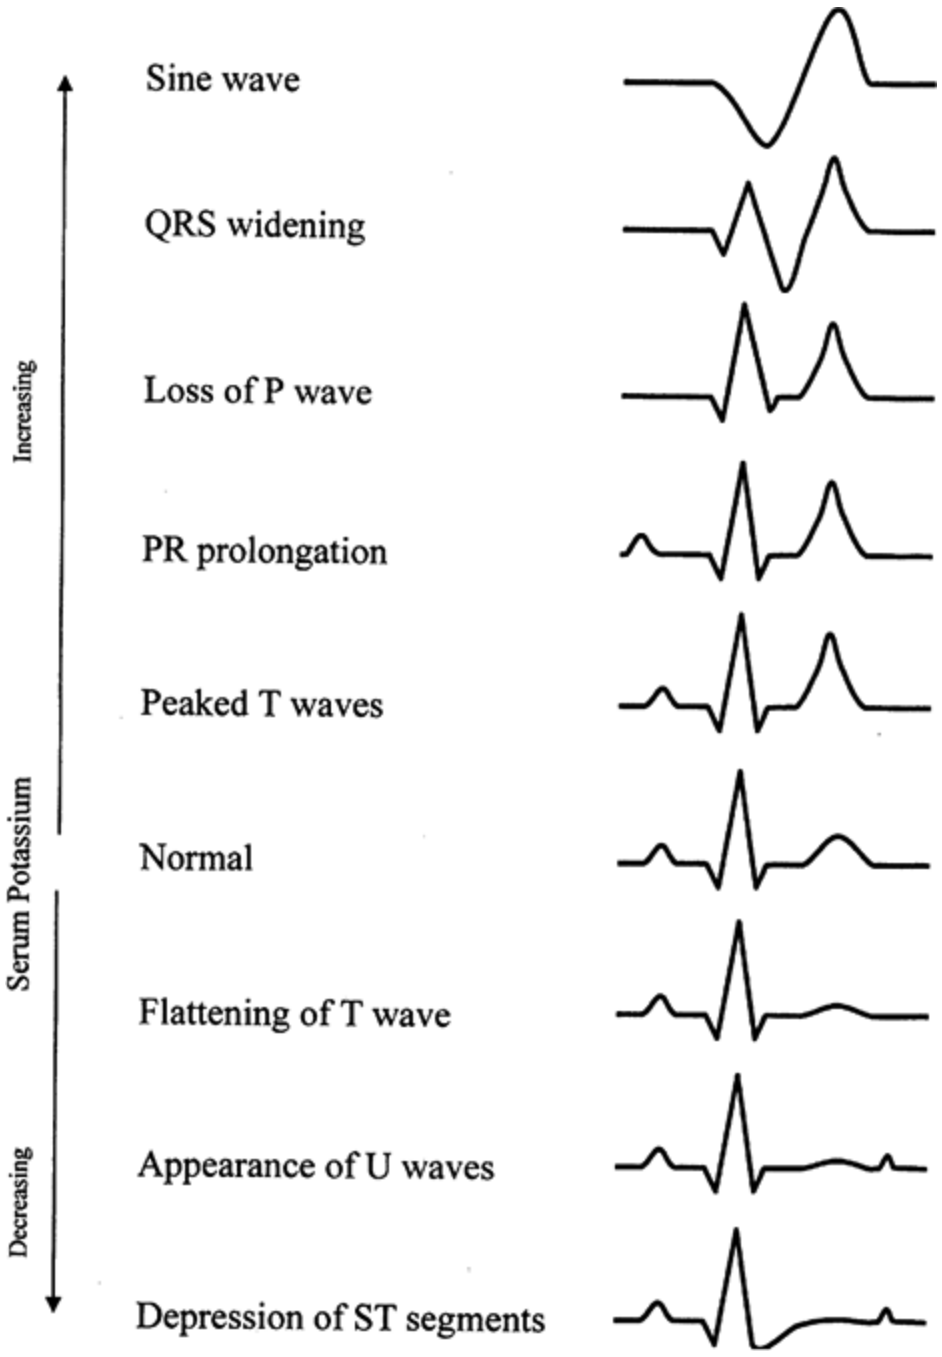

Figure 5-11. Electrocardiographic manifestations associated with changes in serum potassium.

The QT Interval

The QT is measured from the beginning of the QRS complex to the end of the T wave. The bipolar limb lead with the largest T wave should be used for this measurement. As the normal QT varies with the heart rate, numerous formulas (eg, the QT divided by $\sqrt{\text{R-R interval}}$ in seconds) and tables are available to obtain the corrected QT, known as the QTc.[15] Using the QTc allows the determination of the appropriateness of the QTc independent of the heart rate. With slow heart rates, a prominent U wave can obscure the terminal portion of the T wave and with fast heart rates the subsequent P wave can obscure the terminal portion of the T wave. In these cases the QTc should be estimated by following the downslope of the T wave. The QTc is often measured to approximate repolarization, although this is not fully appropriate because alterations in depolarization, such as excess Na^+ entry, may affect it.

Electrophysiology

The QT represents the entire duration of ventricular systole and thus is made up of several electrophysiologic periods. Although as noted above depolarization abnormalities can affect the QT, these are uncommon, and the plateau phase and repolarization are primarily reflected by the QT.

The Abnormal QT Interval

A prolonged QTc reflects an increase in the time period that the heart is â€œvulnerableâ€• to the initiation of ventricular dysrhythmias[36] (Fig. 5-6). This occurs because although some myocardial fibers are refractory during this time period, others are not (i.e., relative refractory period). Early afterdepolarizations may occur in patients with lengthened repolarization time (Table 5-2).[30] An early afterdepolarization (EAD) occurs when a

myocardial cell spontaneously depolarizes before its repolarization is complete (Fig. 23-4). If this depolarization is of sufficient magnitude, it may capture and initiate a premature ventricular contraction, which itself may initiate ventricular tachycardia, ventricular fibrillation, or torsades de pointes. There are two types of EADs that occur when the membrane potential is decreased either during phase 2 (type 1) or phase 3 (type 2) of the cardiac action potential. The ionic basis of EADs is unclear, but may be via the L-type calcium channel; EADs are suppressed by magnesium.[2, 39]

Xenobiotics that cause sodium channel blockade (Chap. 61), prolong the QT duration by slowing cellular depolarization during phase 0. Thus, the QT duration increases because of a prolongation of the QRS complex duration, and the ST segment duration remains near normal. Xenobiotics that cause potassium channel blockade similarly prolong the QT, but through prolongation of the plateau and repolarization phases. This specifically prolongs the ST segment duration. Although at a cellular level these agents are antidysrhythmic, the multicellular effects may be prodysrhythmic.[32]

Hypocalcemia is caused by a number of xenobiotics, including fluoride, calcitonin, ethylene glycol, phosphates, and mithramycin (Table 17-9). Hypokalemia alone does not usually prolong the QTc. Arsenic poisoning may cause prolongation of the QTc and

torsades de pointes.[5, 40, 41] The mechanism is unknown, although either a direct dysrhythmogenic effect or an autoimmune myocarditis are postulated.

Antidysrhythmics
- Class IA and class IC drugs
- Class III

Electrolyte disturbances
- Hypokalemia

Hypomagnesemia

Nonantidysrhythmics

Psychotropics: phenothiazines, haloperidol, atypical antipsychotics tricyclic and tetracyclic antidepressants

Antihypertensives: bepridil, ketanserin

Antimicrobials: erythromycin, trimethoprim-sulfamethoxazole, pentamidine, amantidine, chloroquine

Antifungals: ketoconazole, itraconazole

Antihistaminics: terfenadine, astemizole

Other drugs: cisapride, cocaine, organic phosphorus insecticides, arsenic, vasopressin

Other conditions

Cardiac disorders; myocarditis, ventricular tumor

Endocrine disorders: hypothyroidism, hypoparathyroidism, pheochromocytoma, hyperaldosteronism

Intracranial disorders; subarachnoid hemorrhage, cerebrovascul accident, encephalitis, head injury

Nutritional disorders: liquid protein diet, starvation

Severe bradycardia

TABLE 5-2. Classification and Causes of an Acquired Long QTc

The U Wave

The U wave is a small deflection that occurs after the T wave and usually with a similar orientation. Distinguishing a U wave from a notched T wave is difficult. The apices of a notched T wave are usually less than 150 msec apart, and the peaks of a TU complex are greater than 150 msec apart.

Electrophysiology

U waves occur when there is fluctuation in the membrane potential

following myocardial repolarization. Although they may be physiologic, when prominent, U waves are generally representative of an underlying electrophysiologic abnormality. Physiologic U waves may be caused by repolarization of the Purkinje fibers.

The Abnormal U Wave

Abnormal U waves are typically caused by spontaneous afterdepolarization of membrane potential that occurs in situations where repolarization is prolonged. EAD occurs in situations where the prolonged repolarization period allows calcium channels (which are both time and voltage dependent) to close and spontaneously reopen because they may close at a membrane potential that is above their threshold potential for opening. In this situation, the opening of the calcium channels produces a slight membrane depolarization that is identified as a U wave. Delayed afterdepolarization occurs when the myocyte is overloaded with calcium, as in the setting of cardioactive steroid toxicity. The excess intracellular calcium can trigger the ryanodine receptors on the myocyte sarcoplasmic reticulum to release calcium, causing slight depolarization that is recognized as a U wave. If the U waves are of sufficient magnitude to reach threshold, the cell may depolarize and initiate a premature ventricular contraction. Transient U-wave inversion can also be caused by myocardial ischemia or systemic hypertension.

The Abnormal QU Interval

The QU interval is the distance between the end of the Q wave and the end of the U wave. Differentiation between the QU and the QT intervals is difficult if the T and U waves are superimposed. When hypomagnesemia coexists with hypokalemia, as is usually the case, QU prolongation and torsades de pointes may occur.[40]

Electrocardiogram Disturbances

The distinction between xenobiotics that cause a rapid rate and those that cause a slow rate on the ECG is somewhat artificial, because many can do both. For example, patients poisoned by tricyclic antidepressants almost always develop sinus tachycardia, but most die with a wide complex bradycardia. In either case, abnormalities in the pattern or rate on the electrocardiogram can provide the clinician with immediate information about a patient's cardiovascular status. Any rhythm other than normal sinus rhythm is referred to as a dysrhythmia in this text. Electrocardiographic disturbances in many poisoned patients may be categorized in more than one manner (abnormal pattern, fast rate, slow rate). In any case, when electrocardiographic abnormalities are detected, appropriate interpretation, evaluation, and therapy must be rapidly performed.

Tachydysrhythmias

The intrinsic pacemaker cells of the heart undergo spontaneous depolarization and reach threshold at a predictable rate. Under normal circumstances the sinus node is the most rapidly firing pacemaker cell of the heart; because of this, it controls the heart rate. Spontaneous depolarization occurs via ion entry through potassium, sodium, and calcium channels via phase 4 of the action potential. Other potential pacemakers exist in the heart, but their rate of spontaneous depolarization is considerably slower than that of the sinus node. Thus, they are reset during depolarization of the myocardium and they never spontaneously reach threshold. Xenobiotics that speed the rate of rise of phase 4, or diastolic depolarization, speed the rate of firing of the pacemaker cells. As long as the sinus node is preferentially affected, it maintains the pacemaker activity of the heart. If the firing rate of another intrinsic pacemaker exceeds that of the sinus node, ectopic rhythms may develop. This effect may be either pathologic or lifesaving, depending on the clinical circumstances.

Because the rate of impulse formation at the sinus node is regulated by the balance between parasympathetic and sympathetic tone, varying the influences of these parts of the autonomic nervous system is responsible for regulating the heart rate under normal conditions. Sympathomimetic agents, such as cocaine and amphetamines, increase sympathetic tone, producing sinus tachycardia and enhancing AV nodal conduction. Sinus tachycardia may be the first manifestation of exposure to a sympathomimetic agent. However, other supraventricular or ventricular dysrhythmias may develop if an abnormal rhythm is generated in another part of the heart. Similarly, xenobiotics that antagonize acetylcholine released from the vagus nerve onto the sinus node enhance the rate of firing, producing sinus tachycardia. Such xenobiotics include the belladonna alkaloids atropine and scopolamine, antihistamines, and the tricyclic antidepressants. Table 23-7 lists a wide variety of agents that often cause tachydysrhythmias.

Certain xenobiotics are more highly associated with ventricular tachydysrhythmias following poisoning. Those that alter myocardial repolarization and prolong the QTc predispose to the development of afterdepolarization-induced contractions during the relative refractory period (R on T phenomena), which initiates ventricular tachycardia. If torsades de pointes is noted (Fig. 5-12) this is undoubtedly the mechanism, and the QTc should be carefully assessed and appropriate treatment initiated. Alternatively, xenobiotics that increase the adrenergic tone on the heart, either directly or indirectly, may cause ventricular dysrhythmias. Whether a result of excessive circulating catecholamines observed with cocaine and sympathomimetics, myocardial sensitization secondary to halogenated hydrocarbons or thyroid hormone, or increased second messenger activity secondary to theophylline, the extreme inotropic and chronotropic effects cause dysrhythmias. Altered repolarization, increased intracellular calcium concentrations, or myocardial ischemia can

cause the dysrhythmia. Additionally, xenobiotics that produce focal myocardial ischemia, such as cocaine or ephedrine, can lead to malignant ventricular dysrhythmias. Finally, an uncommon cause of xenobiotic-induced ventricular dysrhythmias is persistent activation of sodium channels, without distinguishing

electrocardiographic findings that occur following aconitine poisoning.[37] Not all wide QRS complex tachydysrhythmias are ventricular in origin, but making this assumption is generally considered to be prudent. For example, in a patient known to be poisoned with tricyclic antidepressants, cocaine, or similar agents (see The QRS Complex above), the differentiation of aberrantly conducted sinus tachycardia (common) from ventricular tachycardia (rare) is important, but difficult. Although guidelines for determining the origin of a wide complex tachydysrhythmia exist,[10] they are imperfect, difficult to apply, and unstudied in poisoned patients.

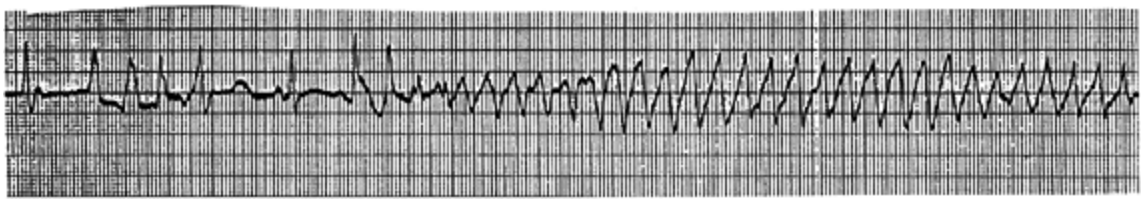

Figure 5-12. Torsades de pointes in a patient who ingested an unknown amount of thioridazine.

Bidirectional ventricular tachycardia is associated with severe cardioactive steroid toxicity and results from alterations of intraventricular conduction, junctional tachycardia with aberrant intraventricular conduction, or, on rare occasions, alternating ventricular pacemakers (Fig. 5-13). The only other xenobiotic that commonly causes this dysrhythmia is aconitine, usually obtained from traditional or alternative therapies that contain the plant Aconitum (Chaps. 43 and 114).

Bradydysrhythmias

Bradycardia and asystole are the terminal events following fatal ingestions of many xenobiotics, but some xenobiotics tend to cause sinus bradycardia (Table 23-7) and conduction abnormalities (Table 23-2) early in the course of toxicity. Sinus bradycardia with an otherwise normal electrocardiogram is characteristic of xenobiotics that reduce central nervous system outflow. Examples include benzodiazepines, ethanol, and clonidine. Differentiating among these agents is not possible based on electrocardiographic criteria alone. Xenobiotics that directly affect ion flux across myocardial cell membranes cause abnormalities in AV nodal conduction. Calcium channel blockers, Î²-adrenergic receptor antagonists, and cardioactive steroids (Chaps. 58 , 59 , and 62) are the leading causes of sinus bradycardia and conduction disturbances.

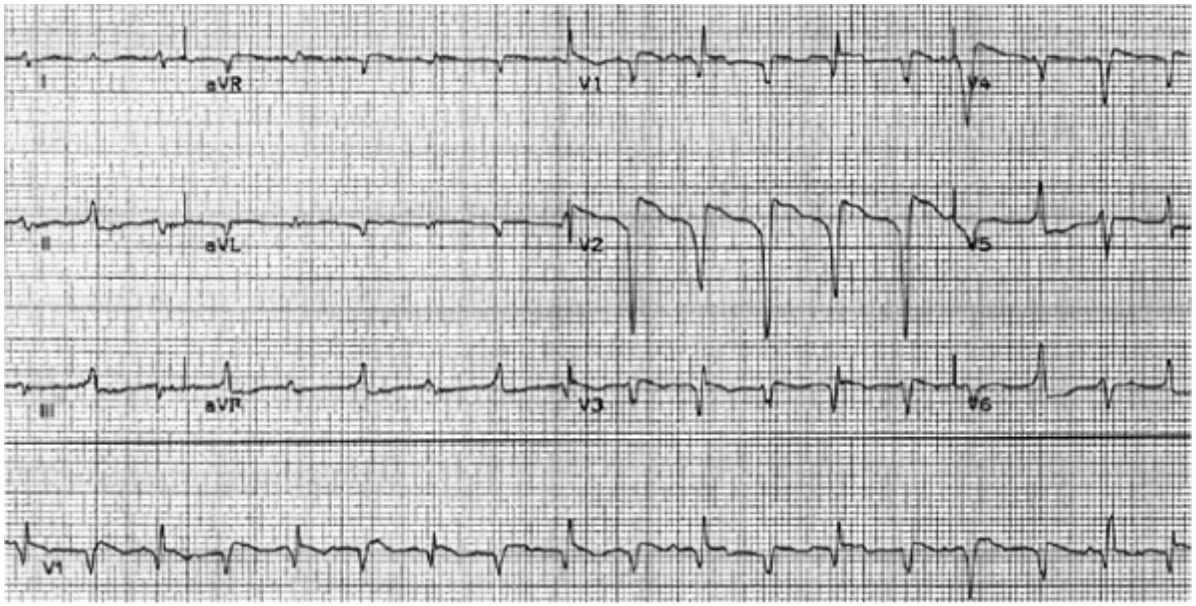

Figure 5-13. Digoxin-induced bidirectional ventricular tachycardia. The ECG demonstrates the alternating QRS axis characteristic of bidirectional ventricular tachycardia and is nearly pathognomonic for cardioactive steroid poisoning. The 89-year-old patient's serum digoxin concentration was 4.0 ng/mL. *(Courtesy of*

Ruben Olmedo, MD, Mount Sinai School of Medicine.)

The ECG manifestations of calcium channel blocker and Î²-adrenergic antagonist overdoses are difficult to distinguish. In general, both drug classes cause decreased dromotropy (conduction), although the specific pharmacologic actions of the drugs differ even within the class (Chaps. 58 and 59). For example, most members of the dihydropyridine subclass of calcium channel blockers do not have any antidromotropic effect, whereas verapamil and diltiazem routinely produce PR prolongation. Similarly, while most Î²-adrenergic antagonists produce sinus bradycardia and first-degree heart block, certain members of this group, such as propranolol, may prolong the QRS complex through their sodium channel blocking abilities.[24] Others, such as sotalol, which have properties of the class III agents, block myocardial potassium channels and prolong the QTc duration. The bradycardia produced by cardioactive steroids is typically accompanied by signs of â€œdigitalis effect,â€• including PR prolongation and ST segment depression (Chap. 62).

Ectopy

Ectopy is the electrocardiographic manifestation of myocardial depolarization initiated from a site other than the sinus node. Ectopy may be lifesaving under circumstances in which the atrial rhythm cannot be conducted to the ventricles, as during high-degree AV blockade induced by cardioactive steroids. Alternatively, ectopy may lead to dramatic alterations in the physiologic function of the heart or deteriorate into lethal ventricular dysrhythmias (Fig. 5-14).

Several mechanisms by which ectopic rhythms may develop are noted. An impulse that occurs after completion of repolarization (phase 4) is called a *delayed afterdepolarization* (DAD) (Fig. 23-4 and Table 5-3). The mechanism of DADs is related to increases in

intracellular calcium that activate a nonselective cation channel or an electrogenic Na^+ -Ca^{2+} exchanger that causes a transient inward current carried primarily by sodium ions. This inward sodium current generates the DAD. The increased calcium concentrations may come from extensive sympathetic stimulation,[26] large doses of cardioactive steroids, or other abnormal physiologic conditions. DADs are the likely cause of some dysrhythmias induced by cardioactive steroid poisoning (Chap. 62). Compared with EADs, DADs generally arise when the membrane potential is more negative.

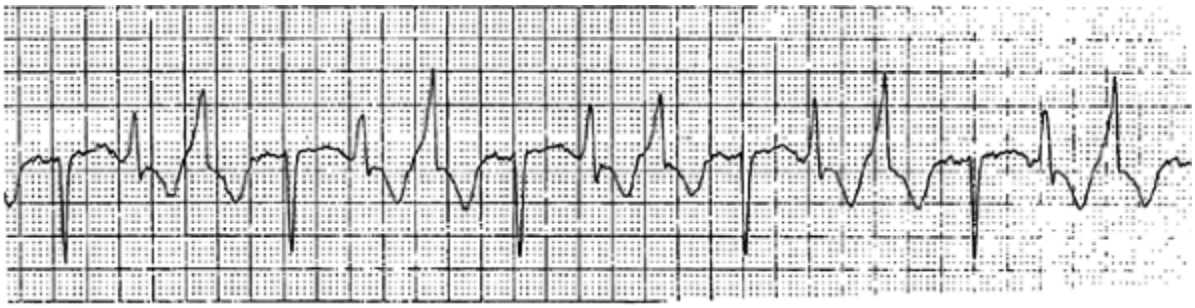

Figure 5-14. This rhythm strip shows ventricular ectopy in a patient following a chloral hydrate overdose. Following the administration of propranolol the ectopy resolved.

The Pediatric Electrocardiogram

The Normal Pediatric ECG

The normal pediatric ECG differs in many ways from the normal adult ECG. The resting heart rate of infants and children is substantially higher than that of adults and, in general, conduction is faster. In a term infant, the right ventricle is substantially larger than the left, and the ECG demonstrates prominent R waves in the right precordium and deep S waves in the left lateral precordium.[13] An adult ratio of left-right ventricular size is usually

reached by the age of 6 months. In infants, Q waves commonly exist in the inferior and lateral precordial leads, but are abnormal in leads I and aV_L . The T waves are the most notable difference between pediatric and adult electrocardiograms. The T waves in the right precordial leads in children are deeply inverted until age 7 years and sometimes beyond (persistent juvenile T-wave pattern).

The Abnormal Pediatric ECG

Although congenital heart disease is the most common cause of electrocardiographic abnormalities in children, electrolyte disorders and drugs may also cause changes in electrophysiology that are reflected on the ECG. Abnormalities that are useful markers on the adult ECG may not always be as useful in the pediatric population.

Delayed after depolarization (DAD)

TABLE 5-3. The Electrophysiologic Basis for Delayed Afterdepolarization and Early Afterdepolarization

Summary

The ECG is one of the few widely available diagnostic procedures that reveal immediate, useful clinical information. This has far-reaching implications in toxicology, where other diagnostic test results often return too late to effectively impact the care of an acutely poisoned patient.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 6
Diagnostic Imaging

David T. Schwartz

Diagnostic imaging can play a significant role in the management of many toxicologic emergencies. In some cases, radiographic studies can directly visualize the xenobiotic, whereas in others, they reveal the xenobiotic's effect on various organ systems (Table 6-1). Radiography can confirm a diagnosis, assist in such therapeutic interventions as monitoring gastrointestinal decontamination, and detect complications of the xenobiotic exposure.[165]

Conventional radiography is readily available in the emergency department (ED) and is the imaging modality most frequently used in acute patient management. However, many other imaging modalities are employed in toxicologic emergencies including computed tomography (CT), enteric and intravascular contrast studies, ultrasonography, magnetic resonance imaging (MRI), and nuclear scintigraphy.

Visualizing the Xenobiotic

A number of xenobiotics are *radiopaque* and can potentially be

detected by conventional radiography. If ingested, the xenobiotic may be seen on an abdominal radiograph. Injected radiopaque xenobiotics are also amenable to radiographic detection. If the toxic material is available for examination, it can be radiographed outside of the body to detect any radiopaque contents (Fig. 99-1 and Case Studies Fig. 2).

The radiopacity of a xenobiotic is determined by several factors. First, the *intrinsic radiopacity* of a substance depends on its physical density (g/cm^3) and the atomic numbers of its constituent atoms. Biologic tissues are composed mostly of carbon, hydrogen, and oxygen, and have an average atomic number of approximately 6. Substances that are more radiopaque than soft tissues include bone, which contains calcium (atomic number 20); radiocontrast agents containing iodine (atomic number 53) and barium (atomic number 56); iron (atomic number 26); and lead (atomic number 82). Some medications and xenobiotics have constituent atoms of high atomic number, such as chlorine (atomic number 17), potassium (atomic number 19), and sulfur (atomic number 16), that contribute to their radiopacity.

The thickness of an object affects its radiopacity. Small particles of a moderately radiopaque xenobiotic are often not visible on a radiograph. The radiographic appearance of the surrounding area also affects the detectability of an object. A moderately radiopaque tablet is easily seen against a uniform background, but in a patient, overlying bone or bowel gas often obscures the tablet.

Ultrasonography

In comparison to conventional radiography, ultrasonography theoretically is a useful tool for detecting ingested xenobiotics because it depends on *echogenicity* rather than radiopacity for visualization. Solid pills within the fluid-filled stomach have an

appearance similar to gallstones within the gallbladder. In one in vitro study using a water-bath model, virtually all intact pills could be seen.[4] These authors were also successful at detecting pills within the stomachs of human volunteers who ingested pills. Nonetheless, reliably finding pills scattered throughout the gastrointestinal tract, which often contains air and feces that block the ultrasound beam, is a formidable task. Ultrasonography, therefore, has limited clinical practicality.

Ultrasonography has been used in persons suspected of smuggling drugs by â€œbody packing.â€• Sonography was able to visualize the numerous uniform drug-containing packages in the gastrointestinal tract in a large proportion of cases.[68 , 122]

Ingestion of an Unknown Xenobiotic

Although a clinical policy issued by the American College of Emergency Physicians in 1995 suggested that an abdominal radiograph should be obtained in the unresponsive overdosed patient in an attempt to identify the involved xenobiotic,[2] the role of abdominal radiography in screening patients who have ingested an unknown xenobiotic is questionable. The number of potentially ingested xenobiotics that are radiopaque is limited. In addition, the radiographic appearance of an ingested xenobiotic is not sufficiently distinctive to determine its identity (Fig. 6-1).[189] However, when ingestion of a radiopaque xenobiotic such as iron tablets or metals is suspected, abdominal radiographs are helpful.[3] In addition, knowledge of potentially radiopaque xenobiotics is useful in suggesting diagnostic possibilities when a radiopaque xenobiotic is discovered on an abdominal radiograph that was obtained for reasons other than suspected xenobiotic ingestion, such as in a patient with abdominal pain (Fig. 6-2).[164 , 170]

Several investigators have studied the radiopacity of various medications.[45 , 52 , 70 , 77 , 86 , 133 , 161 , 173 , 180] The investigators used an in vitro water-bath model to simulate the

radiopacity of abdominal soft tissues.[161] These studies found that only a small number of medications exhibit some degree of radiopacity. A short list of the more consistently radiopaque xenobiotics is summarized in the mnemonic CHIPESâ€“â€“chloral hydrate, heavy metals, iron, phenothiazines, and enteric-coated and sustained-release preparations.

Xenobiotic	Imaging Study[a]	Finding	Page

TABLE 6-1. Xenobiotics with Diagnostic Imaging Findings

The CHIPES mnemonic has several limitations.[161] It does not include all of the pills that are radiopaque in vitro (eg, acetazolamide and busulfan). Most of these medications, however, are only moderately radiopaque and, when ingested, dissolve rapidly and become difficult or impossible to detect. Psychotropic medications include a wide variety of compounds of varying radiopacity.[133, 161] For example, trifluoperazine (containing fluorine, atomic number 9) is radiopaque in vitro, whereas chlorpromazine (containing chlorine, atomic number 17) is not.[161] Finally, sustained-release preparations and those with enteric coatings have variable composition and radiopacity. Pill formulations of fillers, binders, and coatings vary between manufacturers, and even a specific product can change depending on the date of manufacture. The insoluble matrix of some sustained-release preparations is radiopaque; however, when

seen on a radiograph these pills may no longer contain active medication. Some sustained-release cardiac medications such as verapamil and nifedipine have inconsistent radiopacity.[106, 172, 181]

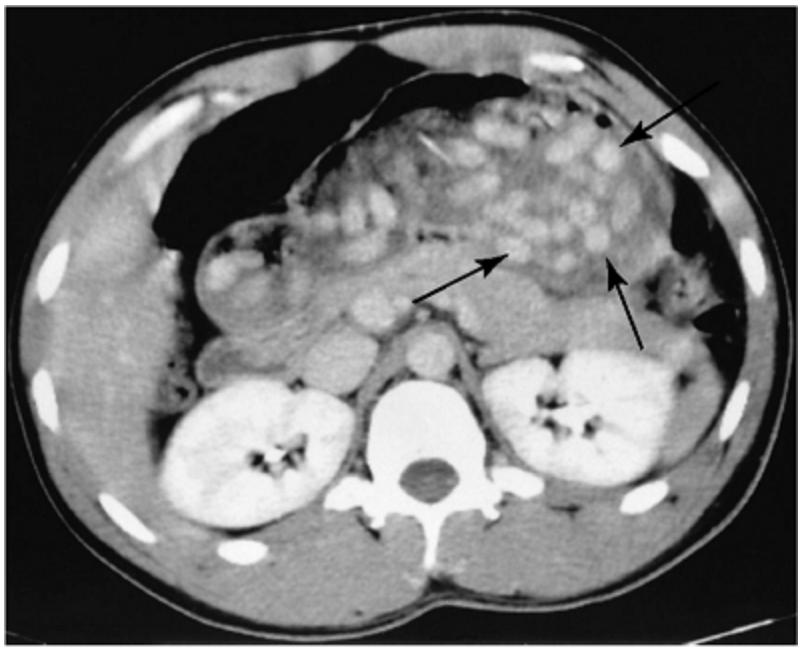

Figure 6-1. Ingestion of an unknown substance. A 46-year-old male presented to the ED with a depressed level of consciousness. Because he also complained of abdominal pain and mild diffuse abdominal tenderness, a CT scan of the abdomen was obtained. The CT revealed innumerable tablet-shaped densities within the stomach (*arrows*). The CT finding was suspicious for an overdose of an unknown medication. Orogastric lavage was attempted and the patient vomited a large amount of whole navy beans. CT is able to detect small, nearly isodense structures such as these, which cannot be seen using conventional radiography. *(Courtesy of Earl J. Reisdorff, MD, Michigan State University, Lansing, Michigan.)*

Exposure to a Known Xenobiotic

When a xenobiotic that is known to be radiopaque is involved in a poisoning, radiography plays an important role in patient care.[3] Radiography can confirm the diagnosis of a radiopaque xenobiotic exposure, quantify the approximate amount of xenobiotic involved, and monitor its removal from the body. Examples include

sustained-release potassium chloride,[176] ferrous sulfate, and heavy metals.

Iron Tablet Ingestion

Ferrous sulfate tablets are readily detected radiographically because they are highly radiopaque and disintegrate slowly when ingested. Radiographs repeated after whole-bowel irrigation help to determine whether further gastrointestinal decontamination is needed (Fig. 6-3).[44 , 54 , 90 , 132 , 137 , 139 , 188] However, caution must be exercised in using radiography to exclude an iron ingestion. Some iron preparations are not radiographically detectable. Liquid, chewable, or encapsulated (â€œSpansuleâ€•) iron preparations rapidly fragment and disperse after ingestion. Even when intact, these preparations are less radiopaque than ferrous sulfate tablets.[45]

Metals

Metals of high atomic number, such as lead, mercury, arsenic, and thallium, can be detected radiographically. Examples of metal exposure include leaded ceramic glaze (Fig. 6-4);[152] paint chips containing lead (Fig. 91-5);[99 , 119] mercuric oxide (Fig. 92-1);[109] thallium salts (atomic number 81; Case Studies Fig. 2);[37 , 120] Zinc (atomic number 30);[20] and arsenic (atomic number 33; Fig. 6-5);[67 , 103 , 186] with lower atomic numbers are also radiopaque.

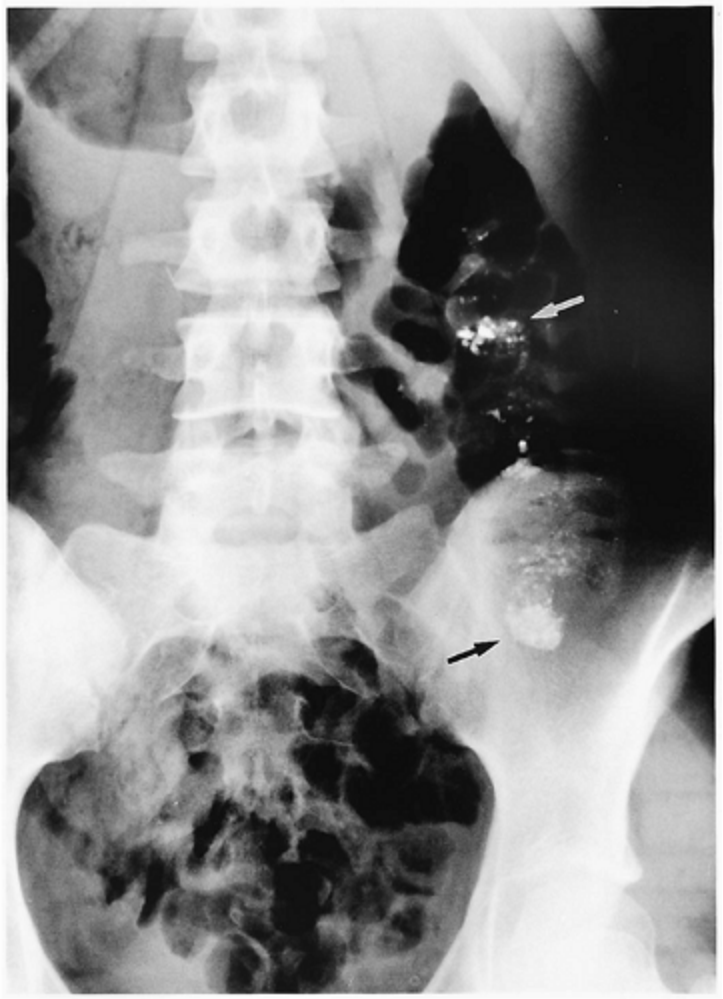

Figure 6-2. Detection of a radiopaque substance on an abdominal radiograph. An abdominal radiograph obtained on a patient with upper abdominal pain revealed radiopaque material throughout the intestinal tract (*arrows*). Further questioning of the patient revealed that he had been consuming bismuth subsalicylate (Pepto-Bismol) tablets to treat his peptic ulcer (bismuth, atomic number 83). The identification of radiopaque material does not allow determination of the nature of the substance.

Mercury

Unintentional ingestion of elemental mercury can occur when a

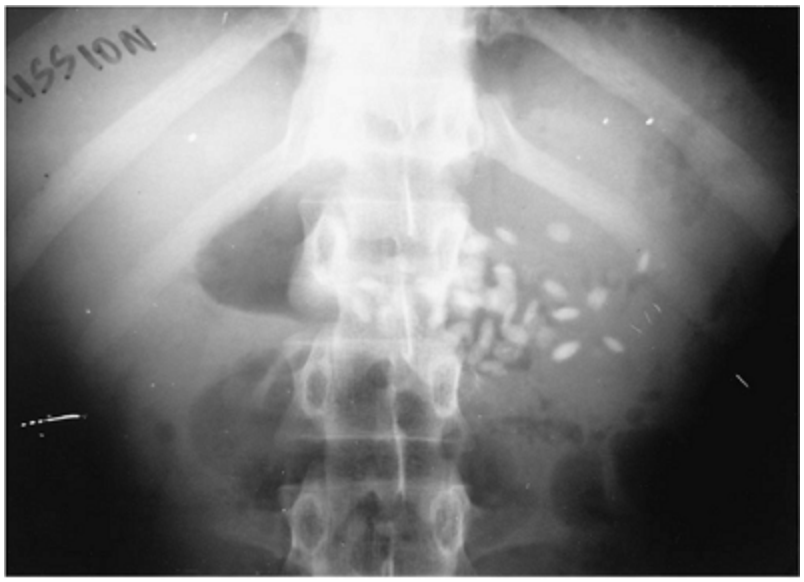
glass thermometer or a long intestinal tube with a mercury containing balloon breaks. Liquid elemental mercury can be injected subcutaneously or intravenously. Radiographic studies assist dÃ©bridement by detecting mercury that remains after the initial excision. Elemental mercury that is injected intravenously produces a dramatic radiographic picture of pulmonary embolization (Fig. 6-6).[20 , 23 , 99 , 112 , 116 , 129]

Lead

Although metallic lead (eg, a bullet) that is embedded in soft tissues is not usually systemically absorbed, when the bullet is in contact with an acidic environment such as synovial fluid or cerebrospinal fluid (CSF), there can be significant absorption. Over many years, mechanical and chemical action within the joint causes the bullet to fragment and to gradually dissolve.[36 , 38 , 46 , 175 , 179] Radiography can confirm the source of lead poisoning by revealing metallic material in the joint or CSF (Fig. 6-7). An abdominal radiograph in a child with lead poisoning can confirm the source of lead as ingested paint chips.

Xenobiotics in Containers

In some circumstances, ingested xenobiotics can be seen even though they are of similar radiopacity to surrounding soft tissues. If a xenobiotic is ingested in a container, the container itself may be visible.



A

B

Figure 6-3. Iron tablet overdose. A . The identification of the large amount of radiopaque tablets confirms the diagnosis in a patient with a suspected iron overdose and permits rough quantification of the amount ingested. B. Following emesis and whole-bowel irrigation, a second radiograph revealed some remaining tablets and indicated the need for further intestinal decontamination. A third radiograph after additional bowel

irrigation demonstrated clearing of the intestinal tract. *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Body Packers

â€œBody packersâ€• are individuals who smuggle large quantities of illicit drugs across international borders in securely sealed packets.[12, 13, 22, 30, 49, 85, 96, 111, 118, 167, 183] The uniformly shaped oblong packets can be seen on abdominal radiographs either because there is a thin layer of air or metallic foil within the container wall or because the packets are outlined by bowel gas (Fig. 6-8). In some cases, a â€œrosetteâ€• representing the knot at the end of the packet is seen.[167] In other cases, intraabdominal calcifications (pancreatic calcifications and bladder stones) have been misinterpreted as drug-containing packets.[184, 201]

The sensitivity of abdominal radiography for such packets is high, in the range of 85â€“90%. The major role of radiography is as a rapid screening test to confirm the diagnosis in individuals highly suspected of smuggling drugs. However, because packets are occasionally not visualized and the risk of rupture can be fatal, abdominal radiography should not be relied on to exclude the diagnosis of body packing. Ultrasonography has also been used to rapidly detect packets in persons being held by airport customs agents. It was able to confirm 40 of 42 cases (sensitivity 95%), although the negative predicative value was approximately 77%; consequently, sonography should not be relied on to exclude such a life-threatening ingestion.[68, 122]

Figure 6-4. An abdominal radiograph of a patient who intentionally ingested ceramic glaze containing 40% lead. *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Because rupture of a single container can be fatal, care must be taken to ensure that all packets are removed. One or two retained packets can be difficult to detect on an abdominal radiograph, and an upper GI series with oral contrast can reveal any remaining packets.[81] CT with enteric contrast is also capable of disclosing remaining packets.[134] However, in one reported case, a single retained packet was not seen on CT and was identified on a subsequent abdominal film with oral contrast.[69]

Body Stuffers

The â€œbody stufferâ€• is an individual who, in an attempt to avoid imminent arrest, hurriedly ingests contraband in insecure packaging.[155] The risk of leakage from such haphazardly constructed containers is high. Unfortunately, radiographic studies cannot reliably confirm or exclude an ingestion. In one series, none of 98 patients had a positive abdominal radiograph.[171]

Occasionally, a radiograph will demonstrate the ingested material (Fig. 6-9). If the drug is in a glass or in a hard-plastic crack vial, the container may be seen. However, only a small number of crack vials are detected radiographically, and the radiograph cannot determine whether the vial still contains any drug. In one series, crack vials were seen on abdominal radiographs in only 2 of

11 patients (18%).[80] If the body stuffer swallows soft plastic bags containing the drug, the containers are not usually visible. However, in three reported cases, â€œbaggiesâ€• were visualized by abdominal CT.[72, 92, 142, 165] Occasional reports have noted that some crack cocaine â€œrocksâ€• can be detected by radiography or CT because they contain radiopaque contaminants.[31, 72, 75] However, CT is not always able to detect such packets.[41]

Figure 6-5. An abdominal radiograph in an elderly woman incidentally revealed radiopaque material in the pelvic region. This was residual from gluteal injection of antisyphilis therapy she had received 35â€“40 years earlier. The injections may have contained an arsenical. (*Courtesy of Dr. Emil J. Balthazar, Professor of Radiology, New York University* .)

Halogenated Hydrocarbons

Some halogenated hydrocarbons can be visualized

radiographically.[32] Radiopacity is proportionate to the number of chlorine atoms, and both carbon tetrachloride (CCl_4) and chloroform ($CHCl_3$) are radiopaque. Because these liquids are immiscible in water, a triple layer is seen within the stomach on an upright abdominal film: an uppermost air bubble, a middle radiopaque chlorinated hydrocarbon layer, and a lower gastric fluid layer. However, these ingestions are rare and the quantity ingested is usually too small to show this effect. Other halogenated hydrocarbons such as methylene iodide are highly radiopaque.[200]

Mothballs

Different types of mothballs can be distinguished by radiography. Relatively nontoxic paradichlorobenzene mothballs (containing chlorine, atomic number 17) are moderately radiopaque, whereas more toxic naphthalene mothballs are radiolucent.[177] Radiographs of mothballs outside of the patient can help distinguish these two types (Fig. 99-1).

Radiolucent Xenobiotics

A radiolucent substance may be visible because it is less radiopaque than surrounding soft tissues. Hydrocarbons such as gasoline are relatively radiolucent when embedded in soft tissues. The radiographic appearance resembles subcutaneous gas as seen in a necrotizing soft-tissue infection (Fig. 6-10).

Summary

Obtaining an abdominal radiograph in an attempt to identify pills or other xenobiotics in a patient with an unknown ingestion is unlikely to be helpful and is, in general, not warranted. Radiography is most useful when the suspected substance is known to be radiopaque, as is the case with iron tablets and heavy

metals. The xenobiotic can be radiographed either within the patient's abdomen, elsewhere in the patient's body, or outside of the patient if the material is available.

Extravasation of Intravenous Contrast Material

Extravasation of radiographic contrast material is a common occurrence. In most cases, the volume extravasated is small and there are no clinical sequelae.[14, 29, 47, 154] Rarely, there is an extravasation large enough to cause cutaneous necrosis and ulceration. In the past, the most common radiographic procedure associated with contrast extravasation was lower extremity venography. This is because in venography a small peripheral vein of an edematous leg or foot is injected and often a metal needle rather than a plastic intravenous cannula is used.

Recently, the incidence of sizable extravasations has increased because of the use of rapid-bolus automated power injectors for spiral CT studies. Fortunately, nonionic low-osmolality contrast solutions are currently nearly always used for these studies. These solutions are far less toxic to soft tissues than older ionic high-osmolality contrast materials.

The treatment of contrast extravasation has not been studied in a large series of human subjects and is therefore controversial. Various strategies have been proposed. The affected extremity should be elevated to promote drainage. Although topical application of heat causes vasodilation and could theoretically promote absorption of extravasated contrast material, the intermittent application of ice packs is shown to lower the incidence of ulceration.[29] Rarely, an extremely large volume of liquid is injected into the soft tissues, which requires surgical decompression when there are signs of a compartment syndrome. A radiograph of the extremity will demonstrate the extent of

extravasation.[29]

Precautions should be taken to prevent extravasation. A recently placed, well-running intravenous catheter should be used. The distal portions of the extremities (hands, wrist, and feet) should be avoided. Patients at greater risk, such as infants, debilitated patients, and those with an impaired ability to communicate, must be closely monitored to determine if extravasation occurs.

Visualizing the effects of a Xenobiotic on the Body

The lungs, central nervous system, gastrointestinal tract, and skeleton are the organ systems most amenable to diagnostic imaging. Disorders of the lungs and skeletal system are seen by plain radiography. For abdominal pathology, contrast studies and computed

tomography are more effective, although plain radiographs can diagnose intestinal obstruction, perforation, and radiopaque foreign bodies. Imaging of the central nervous system employs CT, MRI, and nuclear scintigraphy (PET and SPECT).

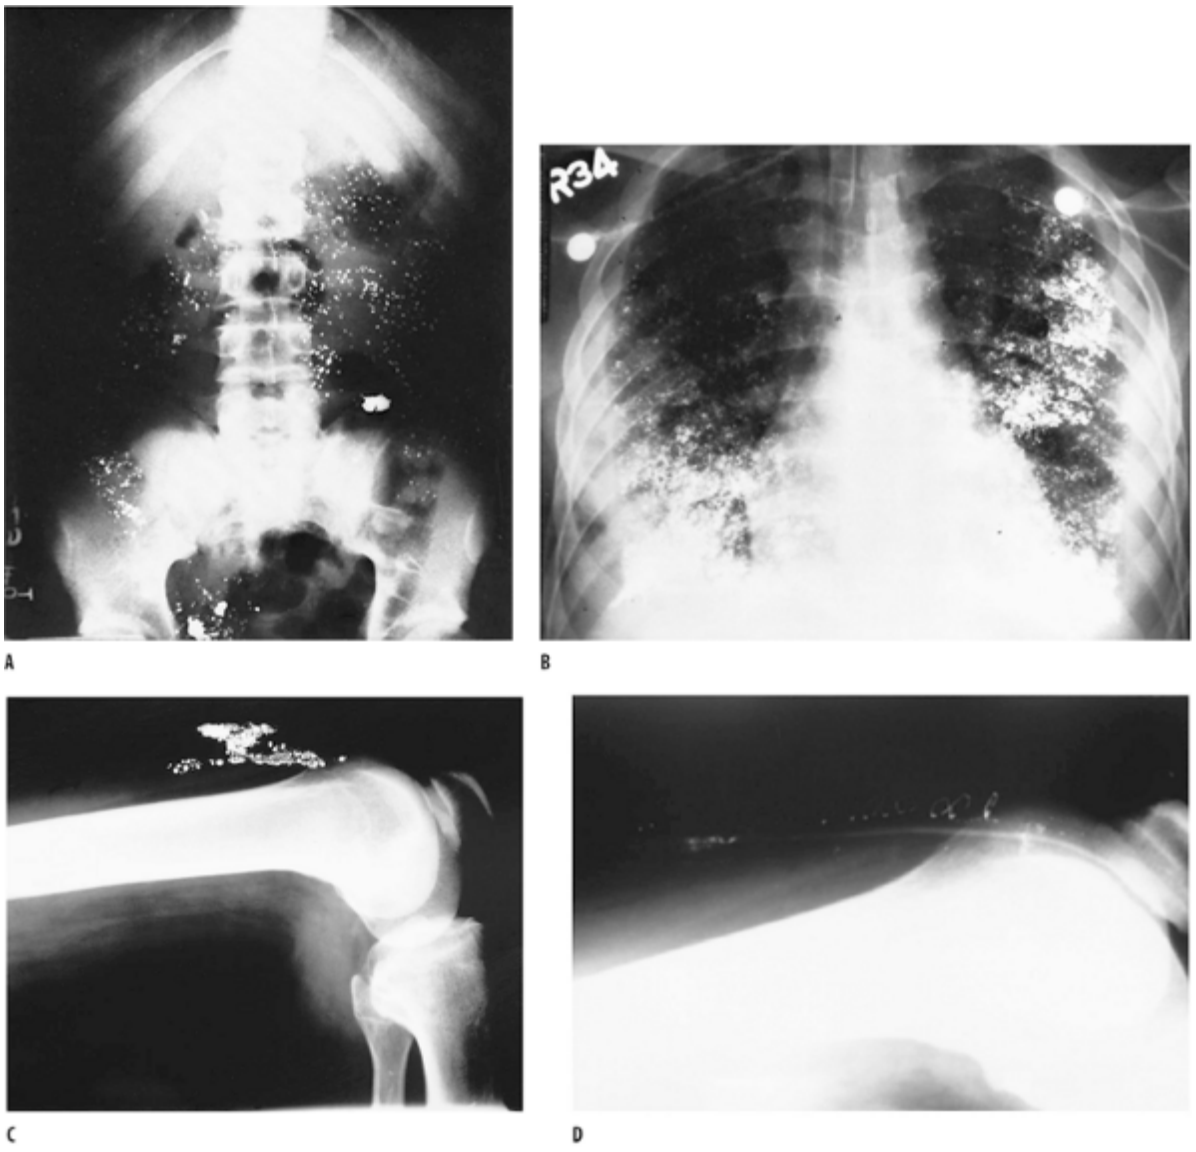


Figure 6-6. Liquid elemental mercury exposures. A. Unintentional rupture of a Cantor intestinal tube distributed mercury throughout the bowel. (Courtesy of Dr. Richard Lefleur, Associate Professor of Radiology, New York University.) B. The chest radiograph in a patient following intravenous injection of elemental mercury showing metallic pulmonary embolism. The patient developed respiratory failure, pleural effusions, and uremia, and expired despite aggressive therapeutic interventions. (*Courtesy of Dr. N. John Stewart.*) C. Subcutaneous injection of liquid elemental mercury is readily detected radiographically. Because mercury is

systemically absorbed from subcutaneous tissues, it must be removed by surgical excision. (*Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.*) D. A radiograph following surgical dÃ©bridement reveals nearly complete removal of the mercury deposit. Surgical staples and a radiopaque drain are visible. *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Skeletal Changes Caused by Xenobiotics

A number of xenobiotics affect bone mineralization. Toxicologic effects on bone result in either increased or decreased density (Table 6-2). Some xenobiotics produce a characteristic radiographic picture, although the exact diagnosis usually depends on correlation with the clinical scenario.[7 , 131] Furthermore, alterations in skeletal structure develop gradually and are usually not visible unless the exposure continues for at least 2 weeks.

Lead Poisoning

Skeletal radiography can support the diagnosis of chronic lead poisoning before the blood lead concentration

is obtained. With lead poisoning, the metaphyseal regions of rapidly growing long bones develop transverse bands of increased density along the growth plate (Fig. 6-11).[18 , 145 , 148 , 159] Characteristic locations are the distal femur and proximal tibia. Flaring of the distal metaphysis also occurs. Lead lines are also seen in the vertebral bodies and iliac crest. Lead lines are detected in approximately 80% of children with a mean lead level of 49 Â± 17 Âµg/dL.[18] They usually occur in children 2â€“9 years of age. It usually takes several weeks for lead lines to appear,

although in very young infants (2â€“4 months old) lead lines can develop within days of exposure.[205] After exposure ceases, lead lines diminish and may eventually disappear. Lead lines are caused by lead's toxic effect on bone growth and do not represent deposition of lead in bone. Lead impedes resorption of calcified cartilage in the zone of provisional calcification adjacent to the growth plate. This is termed *chondrosclerosis* .[18 , 40] Other xenobiotics that cause metaphyseal bands are yellow phosphorus, bismuth, and vitamin D (Chap. 41).

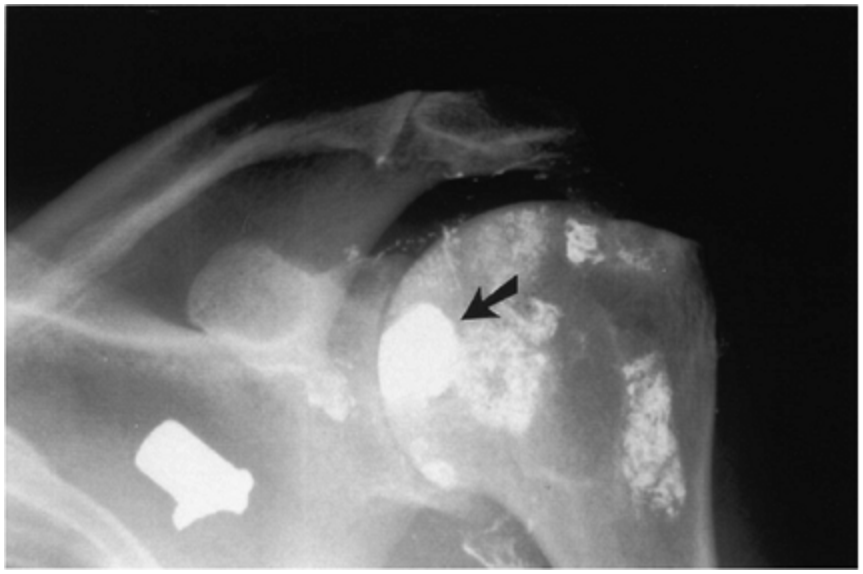

Figure 6-7. A â€œlead arthrogramâ€• discovered many years after a bullet wound to the shoulder. At the time of the initial injury, the bullet was embedded in the articular surface of the humeral head (*arrow*). The portion of the bullet that protruded into the joint space was surgically removed, leaving a portion of the bullet exposed to the synovial space. A second bullet is embedded in the muscles of the scapula. Eight years after the injury, the patient presented with weakness and anemia. Extensive lead deposition throughout the synovium is seen. Lead level was 91 Âµg/dL. *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Fluorosis

Fluoride poisoning causes a diffuse increase in bone mineralization. Endemic fluorosis occurs where drinking water contains very high levels of fluoride (at least 2 or more parts per million) or as an occupational exposure for aluminum workers handling cryolite (sodium-aluminum fluoride). The skeletal changes associated with fluorosis are osteosclerosis, osteophytosis, and ligament calcification. Fluorosis primarily affects the axial skeleton, especially the vertebral column and pelvis, and the teeth. Thickening of the vertebral column can cause compression of the spinal cord and nerve roots. Without a history of fluoride exposure, the clinical and radiographic findings can be mistaken for osteoblastic skeletal metastases. The diagnosis of fluorosis is confirmed by histologic examination of the bone and measurement of fluoride levels in the bone and urine.[19, 193]

Focal Loss of Bone Density

Skeletal disorders associated with focal diminished bone density (or mixed sclerosis and rarefaction) include osteonecrosis, osteomyelitis, and osteolysis. *Osteonecrosis* , also known as avascular necrosis, most often affects the femoral head, the humeral head, and proximal tibia.[113] There are many causes of osteonecrosis. Xenobiotic causes include long-term corticosteroid use and alcoholism. Radiographically, there are focal skeletal lucencies and sclerosis, with loss of bone volume and collapse (Fig. 6-12A).

Acroosteolysis refers to bone resorption of the distal phalanges and is associated with occupational exposure to vinyl chloride monomer. Protective measures have reduced its incidence since it was first described in the early 1960s.[149]

Osteomyelitis is a serious complication of injection drug use. It

usually affects the axial skeleton, especially the vertebral bodies, and the sternomanubrial and sternoclavicular joints (Fig. 6-12B). Back pain or neck pain in intravenous drug users warrants careful consideration. A spinal epidural abscess causing spinal cord compression can accompany vertebral osteomyelitis.[82 , 111] Plain films are negative early in the disease course, and the diagnosis is confirmed by CT or MRI (Fig. 6-12C).

Soft Tissue Changes

Various abnormalities in soft tissues, predominantly as a consequence of infectious complications of injection drug use, are amenable to radiographic diagnosis.[66 , 88] In an injection drug user who presents with signs of local soft-tissue infections, radiography is indicated to detect a retained metallic foreign body, such as a

needle fragment or subcutaneous gas, as may be seen in a necrotizing soft-tissue infection such as necrotizing fasciitis or gas gangrene. CT is more sensitive at detecting soft-tissue gas than conventional radiography. CT and ultrasonography can distinguish subcutaneous or deeper abscess formation that will require surgical or guided percutaneous drainage.

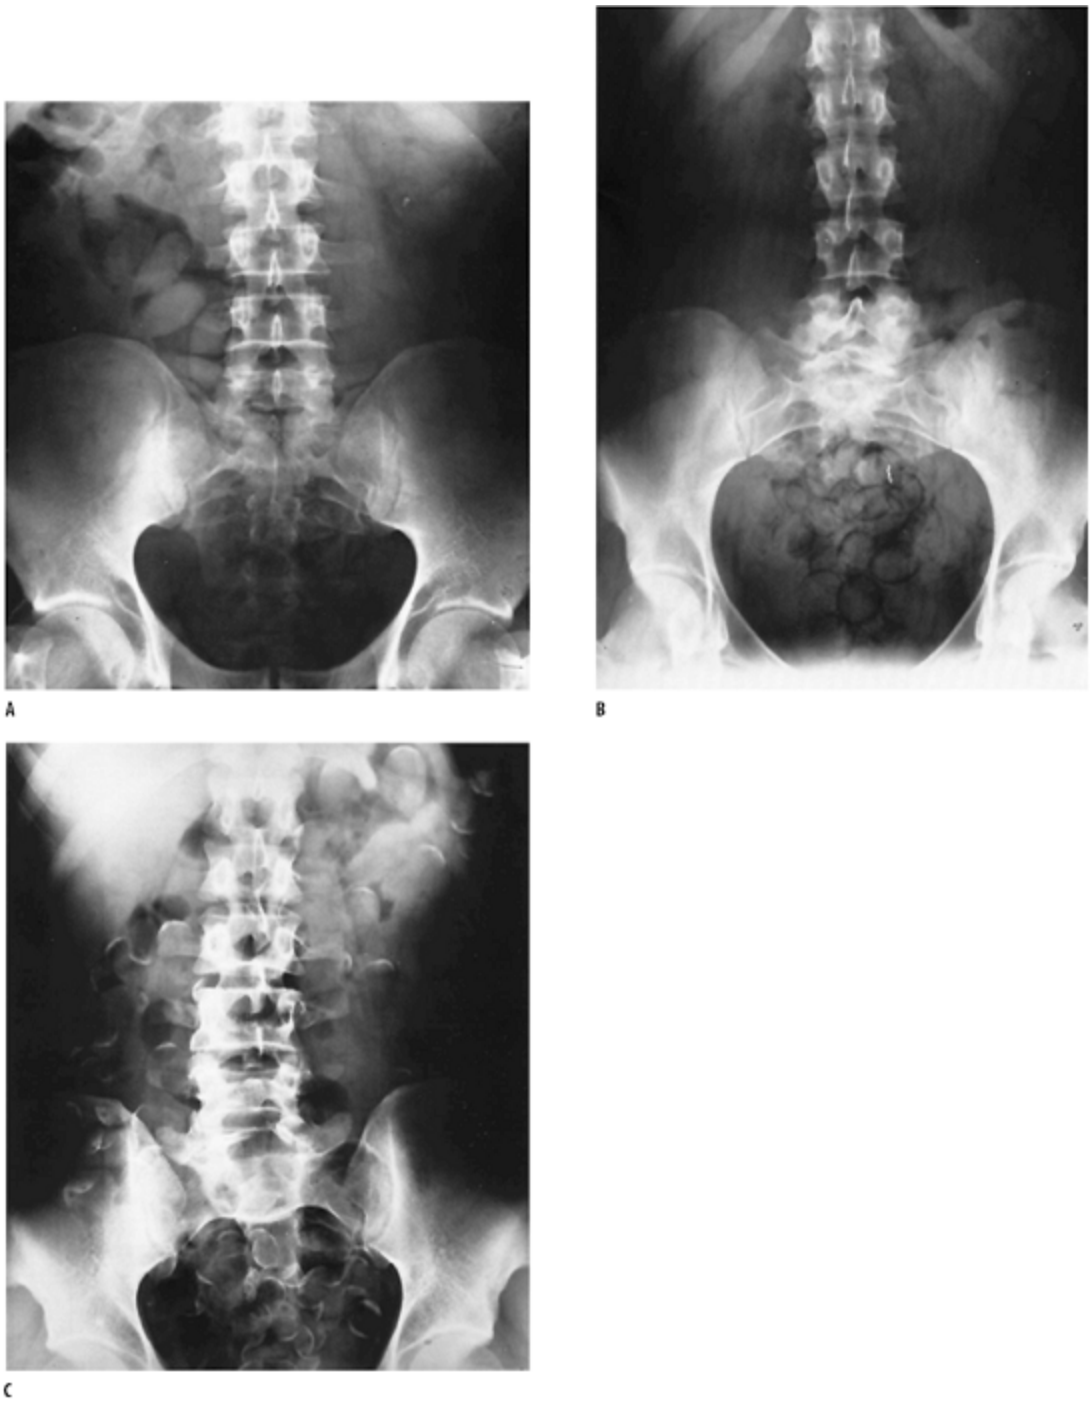

Figure 6-8. Radiographs of three â€œbody packersâ€• showing the various appearances of drug packets. Drug smuggling is accomplished by packing the gastrointestinal tract with large numbers of manufactured, well-sealed containers. A. Multiple oblong packages of uniform size and shape are seen throughout

the bowel. B. The packets are visible in this patient because they are surrounded by a thin layer of air within the wall of the packet. C. Metallic foil is part of the packet's container wall in this patient. *(Courtesy of Dr. Emil J. Balthazar, Professor of Radiology, New York University.)*

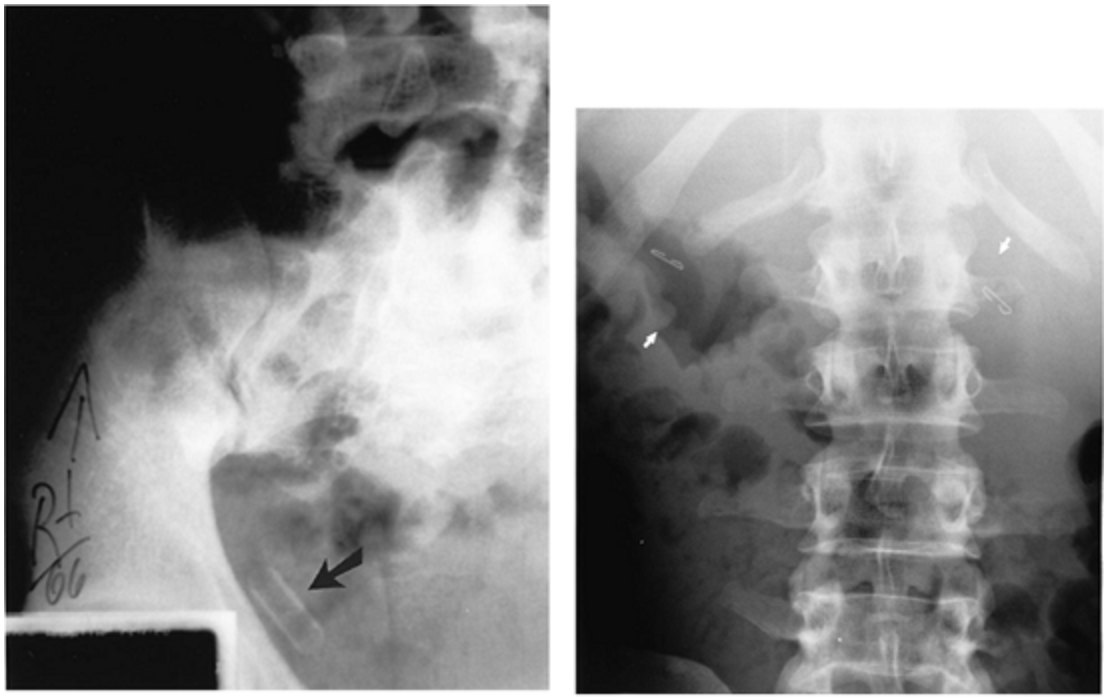

Figure 6-9. Two â€œbody stuffers.â€• Radiography infrequently helps with the diagnosis. A. An ingested glass crack vial is seen in the distal bowel (*arrow*). The patient had ingested his contraband several hours earlier at the time of a police raid. Only the tubular-shaped container, and not the drug, is visible radiographically. The patient did not develop signs of cocaine intoxication during 24 hours of observation. B. Another patient in police custody was brought to the ED for allegedly ingesting his drugs. The patient repeatedly denied this. The radiographs revealed â€œnonsurgicalâ€• staples in his abdomen (*arrows*). When questioned again, the patient admitted that he had swallowed several plastic bags that were stapled closed. *(Courtesy of the*

The radiolucent hydrocarbon mimics gas in the soft tissues that is seen with a necrotizing soft-tissue infection such as necrotizing fasciitis or gas gangrene (*arrows*). *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Metaphyseal bands (children)
Corticosteroids:
Lead, bismuth, phosphorus:
Osteoporosis: diffuse.
Chondrosclerosis caused by toxic effect on bone growth.

Diffuse increased bone density
Fluorosis:
Osteonecrosis: focal lesions, eg. avascular necrosis of the femoral head; loss of volume with both increased and decreased bone density; osteonecrosis also occurs in alcoholism, bismuth arthropathy, Caisson disease (dysbarism), trauma.

Osteosclerosis, osteophytosis, ligament calcification. Usually involves the axial skeleton (vertebrae and pelvis) and can cause compression of the spinal cord and nerve roots.

Hypervitaminosis D (adult):

Focal or generalized osteoporosis.

Injection drug use:

Osteomyelitis (focal lytic lesions) caused by septic emboli; usually affects vertebral bodies and sternomanubrial joint.

Hypervitaminosis A (pediatric):

Vinyl chloride monomer:

Cortical hyperostosis and sub-periosteal new bone formation.

Diaphyses of long bones have an undulating appearance.

Acroosteolysis (distal phalanges).

Hypervitaminosis D (pediatric):

Generalized osteosclerosis, cortical thickening, and metaphyseal bands.

Increased Bone Density	Diminished Bone Density (Either Diffuse Osteoporosis or Focal Lesions)

TABLE 6-2. Xenobiotic Causes of Skeletal Abnormalities

Pulmonary and Other Thoracic Complications

Many xenobiotics that affect intrathoracic organs produce pathologic changes that can be detected on chest radiographs.[6, 9, 21, 42, 55, 66, 126, 157, 203] The lungs are most often affected, but the pleura, hilum, heart, and great vessels may also be involved.[2] Patients with chest pain may have a pneumothorax, pneumomediastinum, or aortic dissection. Patients with fever, with

or without respiratory symptoms, may have a focal infiltrate, pleural effusion, or hilar lymphadenopathy.

The chest radiographic findings will suggest certain diseases, although the diagnosis ultimately depends on a thorough clinical history. When a specific xenobiotic exposure is known or suspected, the chest radiograph can confirm the diagnosis and assess its severity. If the history of xenobiotic exposure is not known, a patient with an abnormal chest radiograph may initially be misdiagnosed as having pneumonia or another disorder that is more common than xenobiotic-mediated lung disease.[150] Therefore, all patients with chest radiographic abnormalities must be carefully questioned regarding possible xenobiotic exposures at work or at home, as well as the use of medications or other drugs.

Many pulmonary disorders are radiographically detectable because they result in fluid accumulation within the normally air-filled lung. The fluid accumulates within the alveolar spaces or interstitial tissues of the lung, producing the two major radiographic patterns of pulmonary disease: airspace filling and interstitial lung disease (Table 6-3). Most xenobiotics are widely distributed throughout the lungs and produce a diffuse rather than a focal radiographic abnormality.

Diffuse Airspace Filling

Overdose with various compounds, including salicylates, opioids, and paraquat, causes *acute lung injury* , which is characterized pathologically by leaky capillaries (Figs. 6-13 and 111-2).[66 , 74 , 79 , 168 , 174 , 202] There are many other causes of acute lung injury, including sepsis, anaphylaxis, and major trauma.[196] Other xenobiotic exposures resulting in diffuse airspace filling include inhalation of irritant gases that are of low water solubility such as phosgene ($COC1_2$), nitrogen dioxide (silo filler's disease), chlorine, and sulfur dioxide (Chaps. 119 and 123). Organic phosphorus insecticide poisoning causes cholinergic

hyperstimulation, resulting in bronchorrhea (Chap. 109). Smoking â€œcrackâ€• cocaine is associated with diffuse alveolar hemorrhage.[53 , 66 , 203]

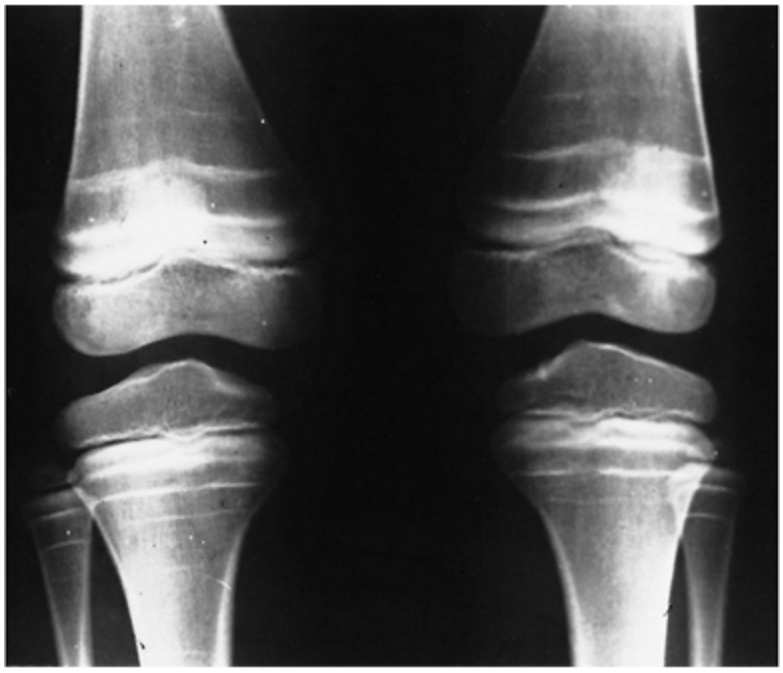
Focal Airspace Filling

Most focal infiltrates are caused by bacterial pneumonia, although aspiration also causes localized airspace disease.[66 , 178] Aspiration of gastric contents can occur during sedative-hypnotic or alcohol intoxication, or during a seizure. Low-viscosity hydrocarbons often enter the lungs when they are swallowed (Figs. 6-14 and 102-2). Because of the delay in development of radiographic abnormalities, the chest radiograph may not be abnormal until 6 hours after the ingestion.[5] During aspiration, the most dependent portions of the lung are affected. When the patient is upright at the time of aspiration, the lower lung segments are involved. When the patient is supine, the posterior segments of the upper and lower lobes are affected.

Multifocal Airspace Filling

Multifocal airspace filling occurs with septic pulmonary emboli, a complication of injection drug

use and right-sided bacterial endocarditis. The foci of pulmonary infection often undergo necrosis and cavitation (Fig. 6-15).[66]



A

B

Figure 6-11. A. A radiograph of the knees of a child with lead poisoning. The metaphyseal regions of the distal femur and proximal tibia have developed transverse bands representing bone

growth abnormalities caused by lead toxicity. The multiplicity of lines implies repeated exposures to lead. B. The abdominal radiograph of the child shows many radiopaque flakes of ingested leaded paint chips. Lead poisoning also caused abnormally increased cortical mineralization of the vertebral bodies, which gives them a boxlike appearance. *(Courtesy of Dr. Nancy Genieser, Professor of Radiology, New York University.)*

Interstitial Lung Diseases

Toxicologic causes of interstitial lung disease include hypersensitivity pneumonitis, medications with direct pulmonary toxicity, and inhalation or injection of inorganic particulates.[66] Interstitial lung diseases can have an acute, subacute, or chronic course. On the chest radiograph, acute and subacute disorders cause a fine reticular or reticulonodular pattern (Fig. 6-16). Chronic interstitial disorders cause a coarse reticular â€œhoneycombâ€• pattern.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis is a delayed-type hypersensitivity reaction to an inhaled or ingested allergen.[34 , 150] Inhaled organic allergens such as those in moldy hay (farmer's lung) and bird droppings (pigeon breeder's lung) cause hypersensitivity pneumonitis in sensitized individuals. There are two clinical syndromes: an acute, recurrent illness and a chronic, progressive disease. The acute illness presents with fever and dyspnea. The chest radiograph is normal or may show fine interstitial or alveolar infiltrates. Chronic hypersensitivity pneumonitis causes progressive dyspnea. The radiograph shows interstitial fibrosis.

The most common medication causing hypersensitivity pneumonitis is nitrofurantoin. Respiratory symptoms occur after taking the medication for 1â€“2 weeks. Other medications that can cause

hypersensitivity pneumonitis include sulfonamides and penicillins.

Chemotherapeutic Agents

Various chemotherapeutic agents, such as busulfan, bleomycin, cyclophosphamide, and methotrexate, cause pulmonary injury by their direct cytotoxic effect on alveolar cells.[33, 57] The radiographic pattern is usually interstitial (reticular or nodular), but can include airspace filling or mixed patterns. The patient presents with dyspnea, fever, and pulmonary infiltrates that begin after several weeks of therapy. The clinical and radiographic findings must be distinguished from opportunistic infection, pulmonary carcinomatosis, pulmonary edema, and intraparenchymal hemorrhage. Symptoms usually resolve with discontinuation of the offending medication.

Amiodarone

Amiodarone toxicity causes phospholipid accumulation within alveolar cells and can cause pulmonary fibrosis. An interstitial radiographic pattern is seen, although airspace filling can also occur (Fig. 6-16). (See Chap. 61 .)

Particulates

Inhaled inorganic particulates such as asbestos, silica, and coal dust cause *pneumoconiosis.* This is a chronic interstitial lung disease characterized by interstitial fibrosis and loss of lung volume.[124, 151, 199] The intravenous injection of illicit drugs that have particulate contaminants, such as talc, causes a chronic interstitial lung disease.[48, 195]

Pleural Disorders

Asbestos-related calcified pleural plaques develop many years after asbestos exposure (Fig. 6-17). These lesions do not cause

clinical symptoms and have only a minor association with malignancy and interstitial lung disease. Asbestos-related pleural plaques should not be called asbestosis because that term refers specifically to the interstitial lung disease caused by asbestos. Pleural plaques must be distinguished from a mesothelioma, which is not calcified, enlarges at a rapid rate, and erodes into nearby structures such as the ribs.

Pleural effusions occur in drug-induced systemic lupus erythematosus.[126] The medications most frequently implicated are procainamide, hydralazine, isoniazid, and methyldopa. The patient presents with fever and other symptoms of systemic lupus erythematosus.

Pneumothorax pneumomediastinum are associated with illicit drug use, and are related to the route of administration rather than to the particular drug. Barotrauma and pneumocardium associated with

Valsalva maneuver or intense inhalation with breath holding during the smoking of â€œcrackâ€• cocaine or marijuana results in pneumomediastinum (Fig. 6-18A).[17 , 43 , 66 , 136] Pneumomediastinum is one cause of cocaine-related chest pain that can be diagnosed by chest radiography. Forceful vomiting after ingestion of syrup of ipecac or alcohol can produce esophageal tears, pneumomediastinum, and mediastinitis.[204] Attempted injection into the subclavian and internal jugular veins is a cause of pneumothorax in intravenous drug users.[39]

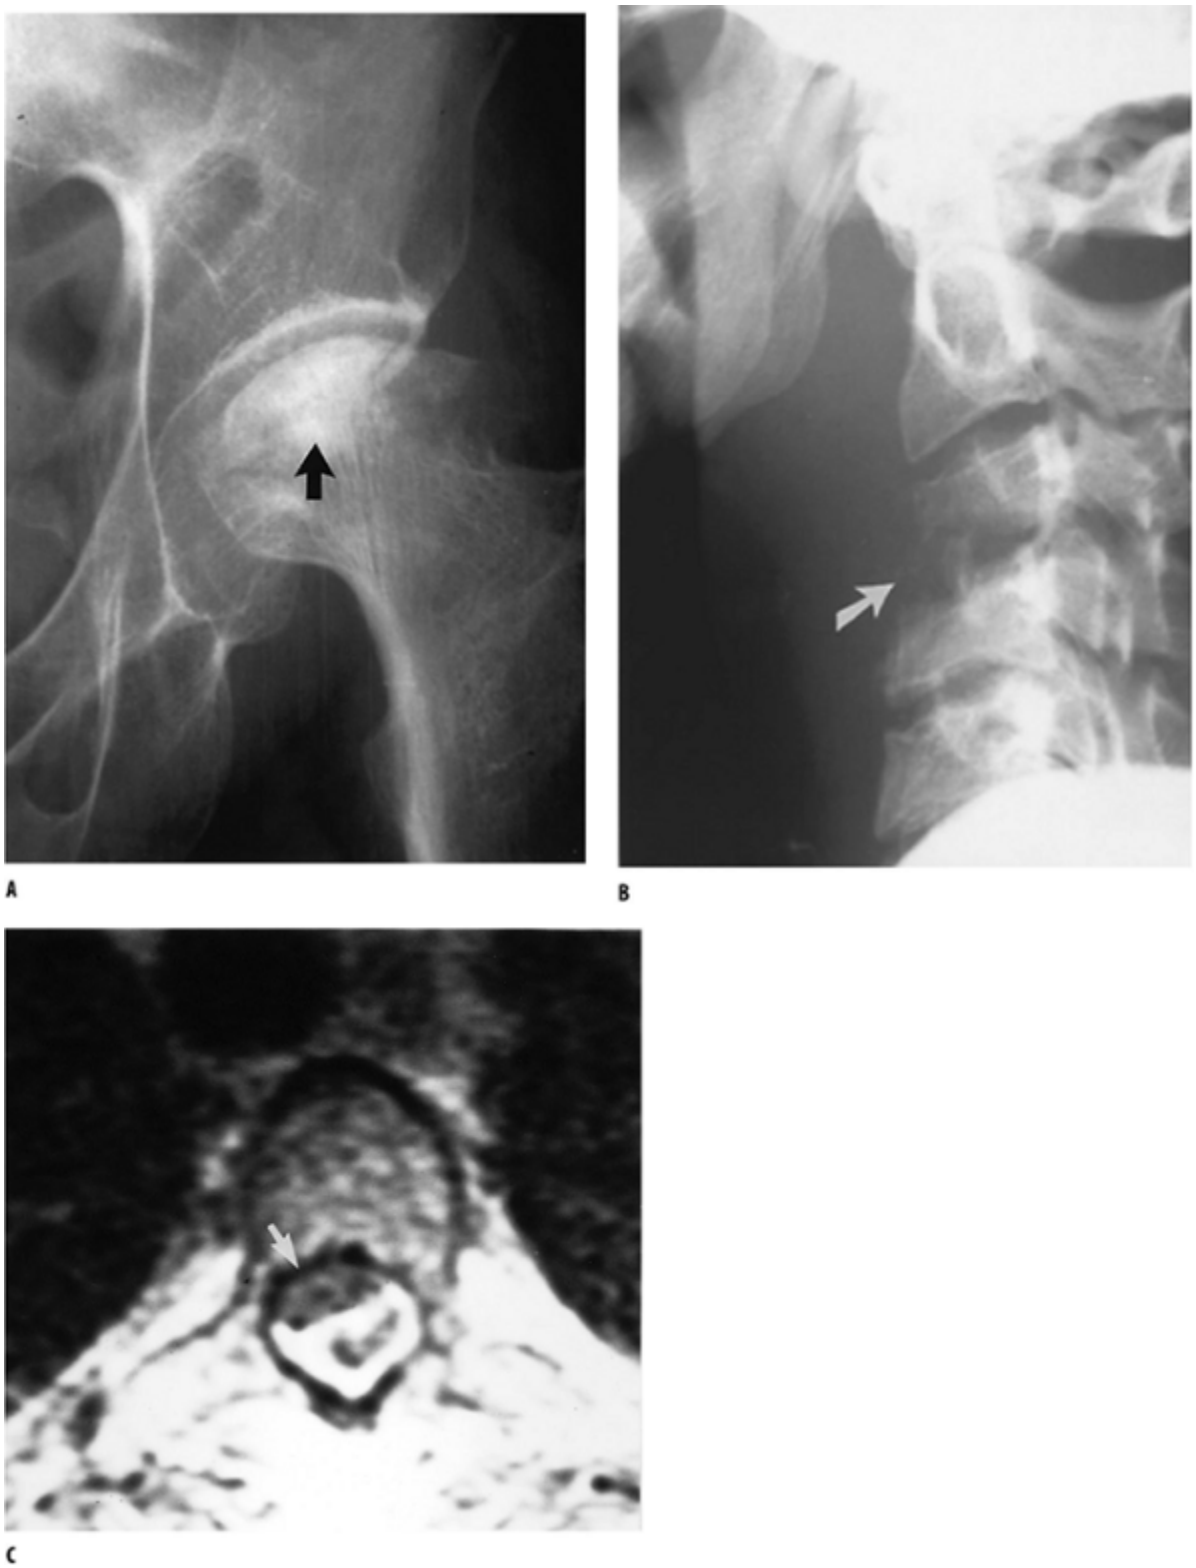


Figure 6-12. A. Avascular necrosis causing collapse of the

femoral head in a patient with long-standing steroid-dependent asthma (*arrow*). B. A patient with vertebral body osteomyelitis complicating injection drug use. Destruction of the intervertebral disk and endplates of C3 and C4 are seen (*arrow*). Operative culture of the bone grew *Staphylococcus aureus.* C. 	Drug-induced systemic lupus erythematosus (procainamide, hydralazine, INH)	Pericardial effusion
		Aortic enlargement
	Cocaine	Aortic dissection

TABLE 6-3. Chest Radiographic Findings in Toxicologic Emergencies

Lymphadenopathy

Phenytoin can cause drug-induced lymphoid hyperplasia with hilar lymphadenopathy.[126] Chronic beryllium exposure results in hilar lymphadenopathy that mimics sarcoidosis, and granulomatous changes in the lung parenchyma. Silicosis is associated with â€œeggshellâ€• calcification of hilar lymph nodes.

Cardiovascular Abnormalities

Dilated cardiomyopathy occurs in chronic alcoholism and exposure to cardiotoxic medications such as doxorubicin (Adriamycin). Enlargement of the cardiac silhouette can also be caused by a pericardial effusion, which can accompany a drug-induced systemic lupus erythematosus. *Aortic dissection* is associated with use of cocaine.[58, 66, 101, 138, 147] The chest radiograph may show an enlarged or indistinct aortic knob or ascending or descending aorta (Fig. 6-18B).

Abdominal Complications

Abdominal imaging modalities include conventional radiography, CT, GI contrast studies, and angiography.[60] Conventional radiography is limited in its capability to detect most intraabdominal pathology because most pathologic processes involve soft-tissue structures that are not well seen. Plain radiography readily visualizes gas in the abdomen and is therefore usable to diagnose pneumoperitoneum (free intraperitoneal air) and bowel distension caused by mechanical obstruction or diminished gut motility (adynamic ileus). Other abnormal gas collections, such as intramural gas associated with intestinal infarction, are seen infrequently (Table 6-4).[65 , 107 , 114 , 123 , 170]

Pneumoperitoneum

Gastrointestinal perforation is diagnosed by seeing free intraperitoneal air under the diaphragm on an upright chest radiograph. Peptic ulcer perforation is associated with

crack cocaine use.[1 , 26 , 94] Esophageal or gastric perforation can be a complication of large-bore orogastric tube placement and forceful emesis induced by syrup of ipecac or alcohol intoxication (Fig. 6-19).[204] Esophageal and gastric perforation can also occur following the ingestion of caustics such as iron, alkali, or acid. Esophageal perforation causes pneumomediastinum and mediastinitis.

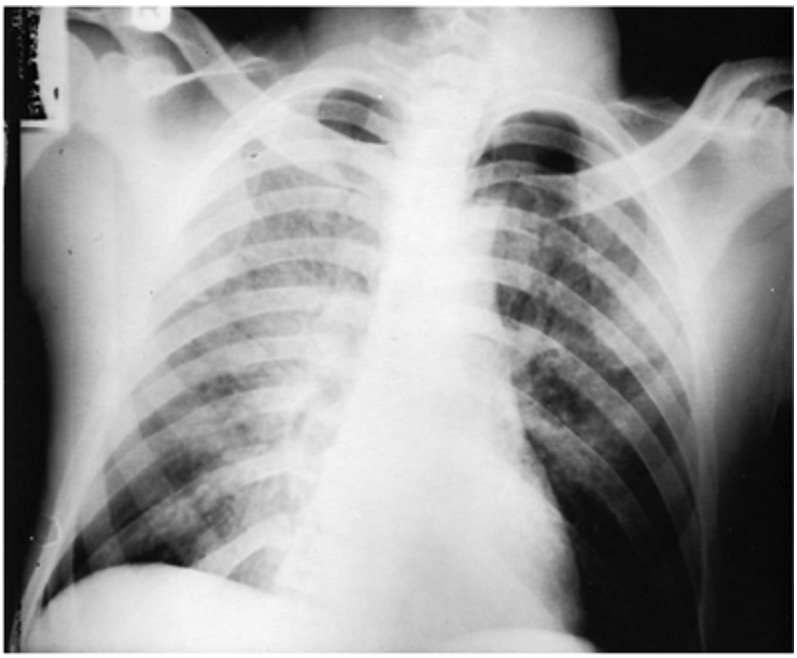

Figure 6-13. Diffuse airspace filling. The chest radiograph of a patient who had recently injected heroin intravenously presented with respiratory distress and acute lung injury. The heart size is normal.

Figure 6-14. Focal airspace filling as a result of hydrocarbon aspiration. A 34-year-old male aspirated gasoline. The chest radiograph shows bilateral lower lobe infiltrates.

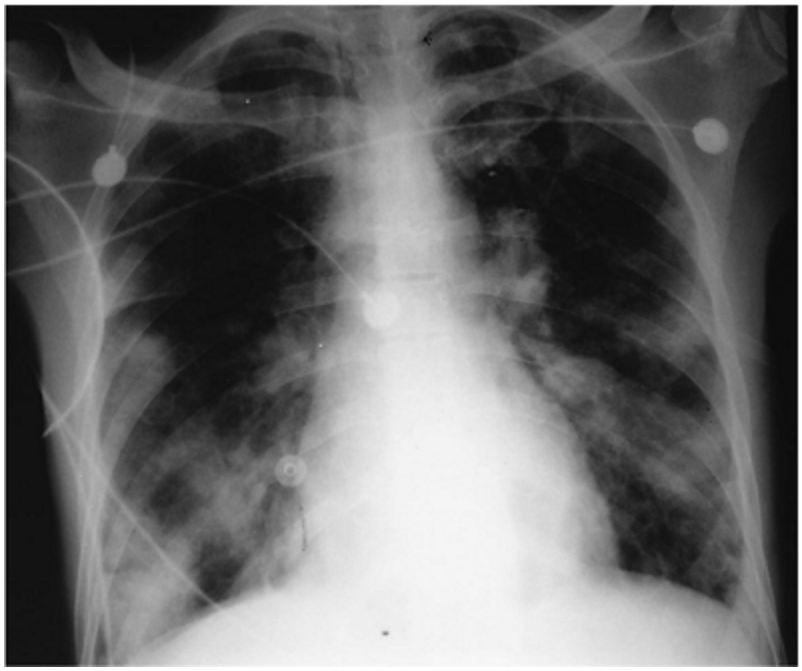

Figure 6-15. Multifocal airspace filling. The chest radiograph in an injection drug user who presented with high fever but without pulmonary symptoms. There are multiple ill-defined pulmonary opacities throughout both lungs, which are characteristic of septic pulmonary emboli. His blood cultures grew *Staphylococcus aureus* .

Obstruction and Ileus

Both mechanical bowel obstruction and adynamic ileus cause bowel distension. With mechanical obstruction, there is a greater amount of intestinal distension proximal to the point of obstruction and a relative paucity of gas and intestinal collapse distal to the point of obstruction. In adynamic ileus, the bowel distension is relatively uniform throughout the entire intestinal tract. On the upright abdominal radiograph, both mechanical obstruction and adynamic ileus show air-fluid levels. In mechanical obstruction, air-fluid levels are seen at different heights and produce a â€œstep-ladderâ€• appearance.

Mechanical bowel obstruction can be caused by large intraluminal foreign bodies such as a body packer's packets or a medication bezoar.[56, 180] Adynamic ileus can complicate ingestions of opioids, anticholinergics, and tricyclic antidepressants (Fig. 6-20).[12, 60] Because adynamic ileus is seen in many diseases, the radiographic finding of an ileus is not helpful diagnostically. When the diagnosis of obstruction is uncertain based on the abdominal radiographs, abdominal CT can clarify the diagnosis.[121]

Mesenteric Ischemia

In most patients with intestinal ischemia, plain abdominal radiographs show only a nonspecific or adynamic ileus pattern. In a small proportion of patients with ischemic bowel (5%), intramural gas is seen.[12] Rarely, gas is also seen in the hepatic portal venous system. CT is better able to detect signs of mesenteric ischemia (Case Studies Fig. 9).[11]

Intestinal ischemia and infarction can be caused by cocaine, ergot alkaloids, and other sympathomimetic agents which induce mesenteric vasoconstriction.[97, 116] Calcium channel blocker overdoses cause splanchnic vasodilation and hypotension that may result in intestinal ischemia and infarction.[197] Superior mesenteric vein thrombosis can be caused by hypercoagulability associated with oral contraceptives.

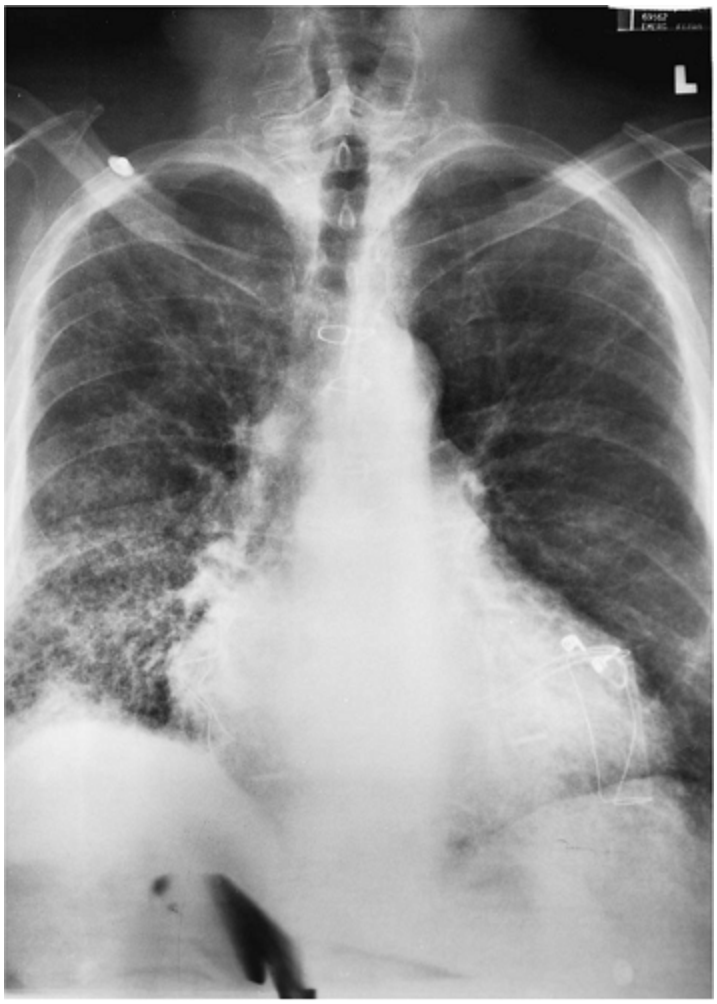

Figure 6-16. Reticular interstitial pattern. The chest radiograph of a patient with cardiac disease who presented to the ED with progressive dyspnea. The initial diagnostic impression was interstitial pulmonary edema. The patient was on amiodarone for malignant ventricular dysrhythmias (note the implanted automatic defibrillator). The lack of response to diuretics and the high-resolution CT pattern suggested that this was toxicity to amiodarone. The medication was stopped and there was partial clearing over several weeks. *(Courtesy of Dr. Georgeann McGuinness, Department of Radiology, New York University.)*

GI Hemorrhage and Hepatotoxicity

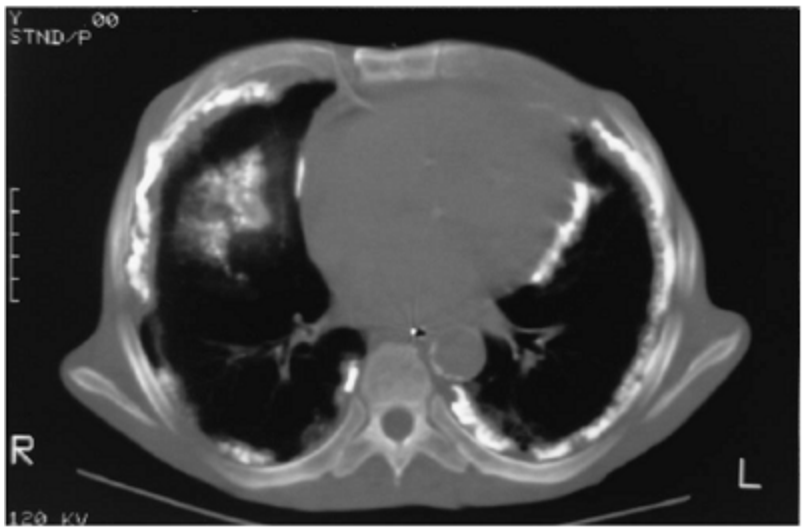
Radiography is not usually helpful in the diagnosis of such common abdominal complications as gastrointestinal bleeding and hepatotoxicity.

The now obsolete radiocontrast agent *thorium dioxide* (Thorotrast; thorium, atomic number 90) provides a unique example of pharmaceutical-induced hepatotoxicity. It was used as an angiographic contrast agent until 1947, when it was found to cause hepatic malignancies. The radioactive isotope of thorium has a half-life of 400 years. It accumulates within the reticuloendothelial system and remains there for the life of the patient. It has a characteristic radiographic appearance with multiple punctate densities in the liver, spleen, and lymph nodes (Fig. 6-21). These patients are at risk for hepatic malignancies and pneumococcal sepsis.[15 , 187]

Contrast Esophagram and Upper GI Series

Ingestion of a caustic substance can cause severe damage to the mucosal lining of the esophagus. This can be demonstrated by a contrast esophagram. However, in the acute setting, upper endoscopy should be performed because it provides more information about the extent of injury and prognosis.[98] In addition, administration of barium will coat the mucosa, making endoscopy difficult. For later evaluation, a contrast esophagram identifies mucosal defects, scarring, and stricture formation (Figs. 6-22 and 100-3).[115]

A



B

Figure 6-17. A. Calcified plaques typical of asbestos exposure are seen on the pleural surfaces of the lungs, diaphragm, and heart. The patient was asymptomatic; this was an incidental radiographic finding. B. The CT scan demonstrates that the opacities seen on the chest radiograph do not involve the lung itself. A lower thoracic image shows calcified pleural plaques (the diaphragmatic plaque is seen on the right). The CT confirms that there is no interstitial lung disease (â€œasbestosisâ€•).

The choice of radiographic contrast agent (barium or water-soluble material) depends on the clinical situation. If the esophagus is severely strictured and there is risk of aspiration, barium should be used because water-soluble contrast material is damaging to the pulmonary parenchyma. If, on the other hand, esophageal or gastric perforation is suspected, water-soluble contrast is safer because extravasated barium is highly irritating to mediastinal and peritoneal tissues.

Ingested objects can cause esophageal and gastric outlet obstruction. Esophageal obstruction because of a drug packet can be demonstrated by a contrast esophagram. Concretions of ingested

material in the stomach can cause gastric outlet obstruction. This has been reported with potassium chloride tablets and enteric-coated aspirin.[8, 169]

patient's chest pain resolved during a 24-hour period of observation. B. Thoracic aortic dissection and rupture following cocaine use. The patient presented with chest pain radiating to the back. Chest radiography reveals a wide and indistinct aortic contour (*arrow*). *(Courtesy of the Toxicology Fellowship of the New York City Poison Control Center.)*

Abdominal Computed Tomography

CT provides great anatomic definition of intraabdominal organs and plays an important role in the diagnosis of a wide variety of abdominal disorders. In most cases, both oral and intravenous contrast are administered. Oral contrast delineates the intestinal lumen. Intravenous contrast is needed to reliably detect lesions in hepatic and splenic parenchyma, the kidneys, and bowel wall.

Certain abdominal complications of poisonings are amenable to CT diagnosis. Intestinal ischemia causes bowel wall thickening, intramural hemorrhage, and, at a later stage, intramural gas and hepatic portal venous gas (Case Studies Fig. 9).[11] Splenic infarction and splenic and psoas abscesses are complications of intravenous drug use that can be diagnosed on CT.[12] Radiopaque foreign substances can be detected and accurately localized by CT such as intravenously injected elemental mercury.[112] Radiolucent foreign bodies, such as a body packer's packets, can be detected by using enteric contrast.[72 , 75] However, in one case, a retained packet was missed by CT and detected on an upper GI oral contrast study.[69]

Vascular Lesions

Angiography can detect such complications of injection drug use as venous thrombosis and arterial laceration causing pseudoaneurysm formation (Figs. 6-23 and 6-24). Intravenous injection of amphetamine, cocaine, or ergotamine causes necrotizing angiitis

that is associated with microaneurysms, segmental stenosis, and arterial thrombosis. These lesions are seen in the kidneys, small bowel, liver, pancreas, and cerebral circulation (Fig. 6-25).[28 , 146] Complications include aneurysm rupture and visceral infarction. Renal lesions cause severe hypertension and renal failure.[160]

Neurologic Complications

Imaging studies have revolutionized the diagnosis of central nervous system (CNS) disorders.[50 , 63] Both acute focal brain lesions and chronic degenerative changes can be detected (Table 6-5).[105] Some xenobiotics have a direct effect on the CNS, whereas with others, neurologic injury is an indirect sequela of the xenobiotic exposure caused by hypoxia, hypotension, hypertension, cerebral vasoconstriction, head trauma, or infection.

Imaging Modalities

Computed tomography can directly visualize brain tissue and many intracranial lesions.[62] CT is the imaging study of choice in the emergency setting because it readily detects acute intracranial hemorrhage as well as parenchymal lesions that are causing mass effect. Infusion of intravenous contrast further delineates intracerebral mass lesions such as tumors and abscesses. CT is fast, widely available on an emergency basis, and can accommodate critical support and monitoring devices.

Magnetic resonance imaging has supplanted CT in nearly all areas of nonemergency neurodiagnosis. It offers greater anatomic discrimination of brain tissues and of areas of cerebral edema and demyelination. However, in the emergency setting, the disadvantages of MRI outweigh its strengths. MRI is no better than CT in detecting acute blood collections. Furthermore, MRI is usually not readily available on an emergency basis, image acquisition time is long, and critical care supportive and monitoring devices are often incompatible with MR scanning

machines.[108]

Nuclear scintigraphy that uses computed tomography technology (SPECT and PET, discussed later under Nuclear Scintigraphy) is being employed as a tool to elucidate functional characteristics of the central nervous system. Examples include both immediate and long-term effects of various xenobiotics on regional brain metabolism, blood flow, and neurotransmitter function.[102, 140, 191]

Emergency Head CT Scanning

An emergency noncontrast head CT scan is obtained to detect acute intracranial hemorrhage and focal brain lesions causing cerebral edema and mass effect. Patients

with these lesions present with focal neurologic deficits, seizures, headache, or altered mental status. Toxicologic causes of intraparenchymal and subarachnoid hemorrhage include cocaine or other sympathomimetics (Fig. 6-26).[100, 104] Cocaine-induced vasospasm can cause ischemic infarction, although this is not seen by CT until 6 to 24 or more hours after onset of the neurologic deficit. Drug-induced CNS depression, most commonly ethanol intoxication, predisposes the patient to head trauma, which can result in a subdural hematoma or cerebral contusion (Fig. 6-27). Toxicologic causes of intracerebral mass lesions include septic emboli complicating injection drug use and HIV-associated CNS toxoplasmosis and lymphoma (Fig. 6-28).[16, 135] On a contrast CT, such tumors and focal infections exhibit a pattern of â€œring enhancement.â€•

Radiographic Finding	Xenobiotic
Pneumoperitoneum (hollow viscus perforation)	Caustics: iron, alkali, acids Cocaine GI decontamination (ipecac, lavage tube)
Mechanical obstruction (intraluminal foreign body) Intestinal Gastric outlet } Upper GI Esophageal } series	Foreign-body ingestion: body packer, enteric-coated pills (bezoar)
Ileus (diminished gut motility)	Opioids Anticholinergics Tricyclic antidepressants Mesenteric ischemia caused by cocaine, oral contraceptives, cardioactive steroids, induced hypokalemia, hypomagnesemia
Intramural gas (intestinal infarction) Bowel wall thickening Hepatic portal venous gas (CT is more sensitive)	Cocaine Ergot alkaloids Oral contraceptives Calcium channel blockers Systemic hypotension
Foreign-body ingestion	Iron pills Metals (Hg, Pb, Tl, As) Body packers and stuffers Bismuth subsalicylate Calcium carbonate Enteric-coated and sustained-release tablets Pica (calcareous clay)

TABLE 6-4. Plain Abdominal Radiography in Toxicologic Emergencies

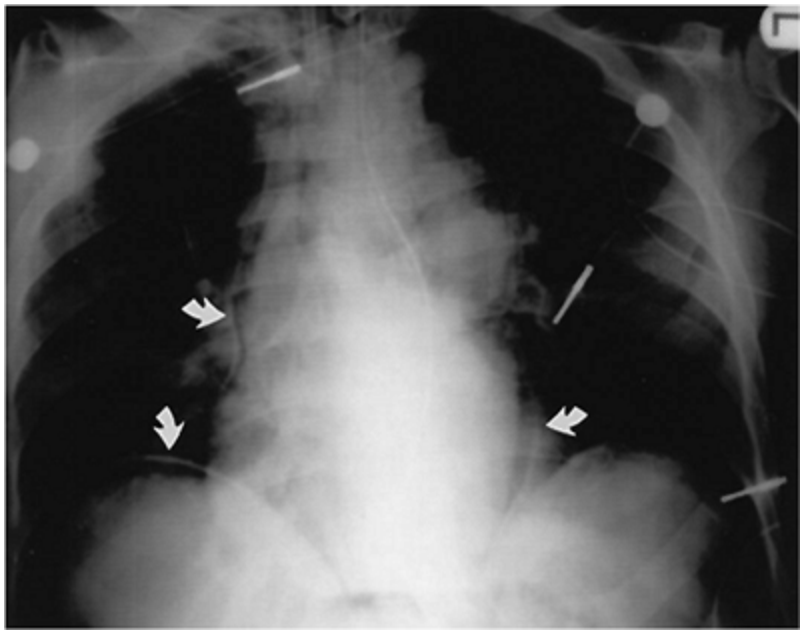

Figure 6-19. GI perforation following gastric lavage with a large-bore orogastric tube. The upright chest radiograph shows air under

the right hemidiaphragm and pneumomediastinum (*arrows*). An esophagram with water-soluble contrast did not demonstrate the perforation. Laparotomy revealed perforation of the anterior wall of the stomach.

Xenobiotic-Mediated Neurodegenerative Disorders

A number of xenobiotics directly damage brain tissue, which produces morphologic changes that are detectable using CT and MRI. Such changes include generalized atrophy, focal areas of neuronal loss, demyelinization, and cerebral edema. Imaging abnormalities can help establish a diagnosis or predict prognosis in a patient with neurologic dysfunction following a xenobiotic exposure. In some cases, the imaging abnormality will suggest a toxicologic diagnosis in a patient with a neurologic disorder in whom a xenobiotic exposure was not suspected clinically.[10 , 50 , 89 , 91 , 141 , 198]

Atrophy

Ethanol is the most widely used neurotoxin. With long-term ethanol use, there is a widespread loss of neurons with resultant atrophy. In some alcoholics, the loss of brain tissue is especially prominent in the cerebellum. However, the amount of cerebral or cerebellar atrophy does not always correlate with the extent of cognitive impairment or gait disturbance.[35 , 59 , 73 , 76 , 93 , 192 , 194] Chronic toluene exposure (occupational and illicit use) also causes diffuse cerebral atrophy.[83 , 156]

Focal Degenerative Lesions

Carbon monoxide poisoning produces focal degenerative lesions in the brain. In about half of

patients with severe neurologic dysfunction following carbon monoxide poisoning, CT scans show bilateral symmetric lucencies in the basal ganglia, particularly the globus pallidus (Figs. 6-27 and 120-1).[25 , 84 , 89 , 127 , 141 , 143 , 144 , 162 , 163 , 166 , 182 , 190] The basal ganglia are especially sensitive to hypoxic damage because of their limited blood supply and high metabolic requirements. Subcortical white matter lesions also occur following carbon monoxide poisoning. Although less frequent than lesions of the basal ganglia, white matter lesions are more clearly associated with poor neurologic outcome. MRI is more sensitive than CT at detecting these CNS lesions, especially at detecting white matter abnormalities.[25 , 50 , 91 , 144 , 182]

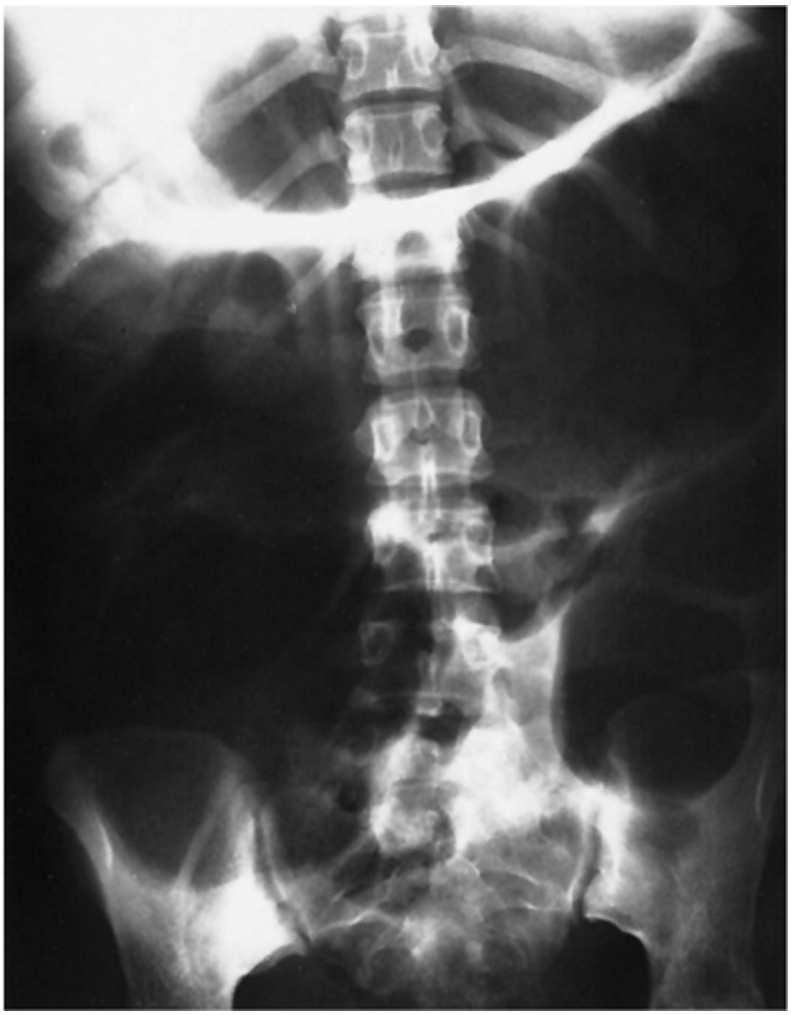

Figure 6-20. Methadone maintenance therapy causing marked abdominal distension. The radiograph reveals striking large bowel dilatation, termed colonic ileus, caused by chronic opioid use. A similar radiographic picture is seen with anticholinergic poisoning. A contrast enema can clarify the diagnosis. *(Courtesy of Dr. Emil J. Balthazar, Professor of Radiology, New York University.)*

Figure 6-21. The abdominal radiograph of a patient who had received thorium dioxide (Thorotrast) for a radiocontrast study many years previously. The spleen (*vertical white arrow*), liver (*horizontal black arrow*), and lymph nodes (*horizontal white arrow*) are demarcated by thorium retained in the reticuloendothelial system. *(Courtesy of Dr. Emil J. Balthazar, Professor of Radiology, New York University.)*

Basal ganglion lucencies, white matter lesions, and atrophy are caused by other xenobiotics such as methanol (putaminal lesions),[9 , 61 , 71 , 128 , 153 , 158] ethylene glycol, cyanide,[51 , 125] hydrogen sulfide, inorganic and organic mercury,[117] manganese,[10] heroin,[91 , 95] barbiturates, chemotherapeutic agents, solvents such as toluene,[50 , 83 , 156] and podophyllin.[24 , 130] Similar imaging abnormalities can be caused by nontoxicologic disorders including hypoxia, hypoglycemia, and infectious encephalitis.[71 , 78]

Nuclear Scintigraphy

Both CT and MRI display cerebral anatomy, whereas nuclear medicine studies provide functional information about the brain. Nuclear scintigraphy uses radioactive isotopes that are bound to carrier molecules (ligands). The choice of ligand depends on the biologic function being studied. Brain cells take up the radiolabeled ligand in proportion to their physiologic activity or the regional blood flow. The radioactive emission from the isotope is detected by a scintigraphic camera, which produces an image showing the quantity and distribution of tracer. Better anatomic detail is provided by using computed tomography techniques to generate cross-sectional images. There are two such technologies: *single photon emission computed tomography* (SPECT) and *positron emission tomography* (PET). These imaging

modalities have been used in the research and clinical settings to study the neurologic effects of particular xenobiotics and the mechanisms of xenobiotic-induced neurologic dysfunction.

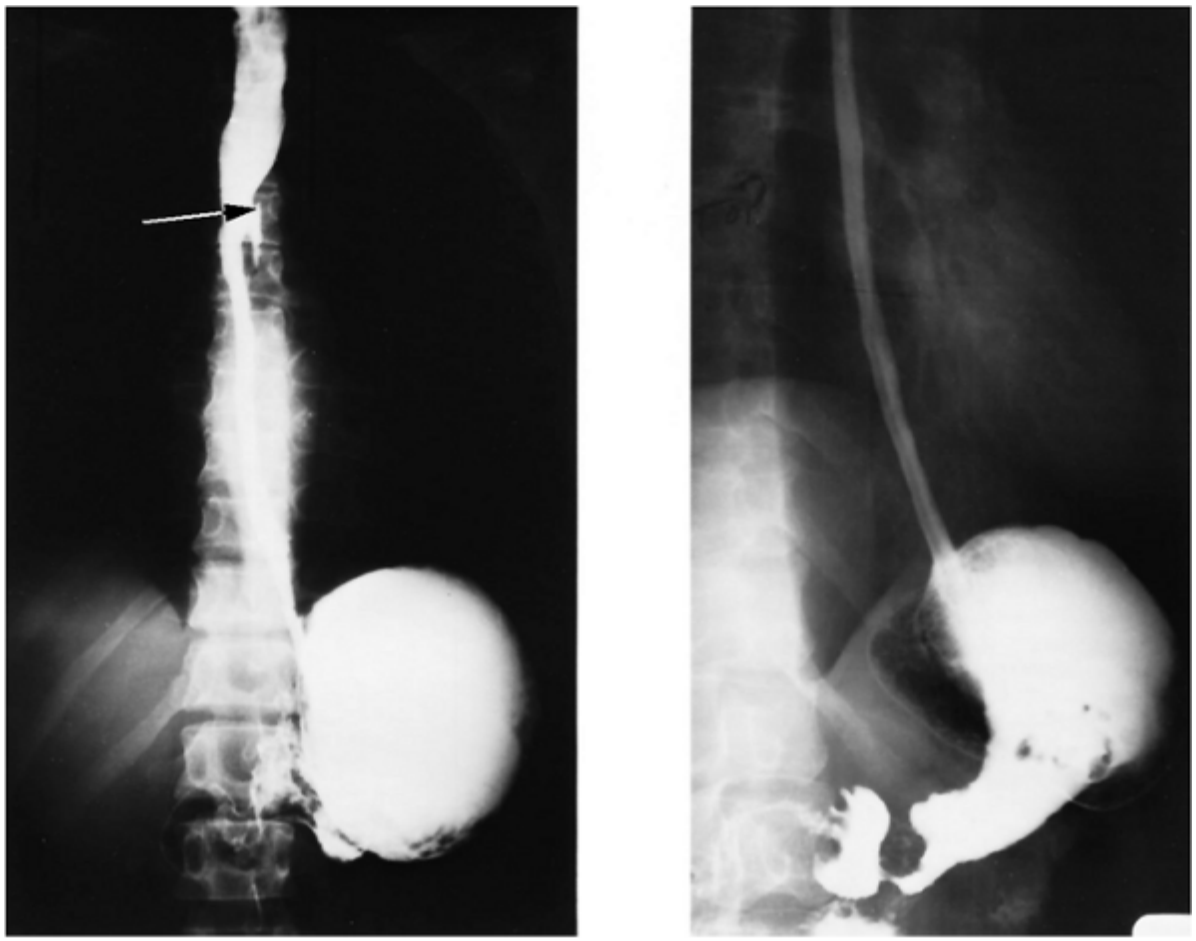

Figure 6-22. A. A barium swallow performed several days after ingestion of liquid lye shows intramural dissection and extravasation of barium with early stricture formation. B. At 3 weeks' postingestion, there is an absence of peristalsis, diffuse narrowing of the esophagus, and reduction in size of the fundus and antrum of the stomach as a result of scarring. *(Courtesy of Dr. Emil J. Balthazar, Professor of Radiology, New York University.)*

SPECT employs conventional isotopes such as technetium-99m and iodine-123.[102] These isotopes are bound to ligands that are taken up in the brain in proportion to regional blood flow, reflecting the local metabolic rate.

PET uses radioactive isotopes of biologic elements such as carbon-

11, oxygen-15, nitrogen-13, and fluoride-18 (a substitute for hydrogen).[140] These radioisotopes have very short half-lives so that PET scanning requires an onsite cyclotron to produce the isotope. The isotopes are incorporated into molecules such as glucose, oxygen, water, various neurotransmitters, and drugs. Labeled glucose is taken up in proportion to the local metabolic rate for glucose. Uptake of labeled oxygen demonstrates the local metabolic rate for oxygen. Labeled neurotransmitters generate images reflecting their concentration and distribution within the brain.

Both PET and SPECT have been used to study the effects of various xenobiotics on cerebral function. For example, although both CT and MRI can detect cerebellar atrophy in chronic alcoholics, there is a poor correlation between the magnitude of cerebellar atrophy and the clinical signs of cerebellar dysfunction. PET scans can demonstrate diminished cerebellar metabolic rate for glucose, which correlates more accurately with the patient's clinical status.[64 , 192]

In patients with severe neurologic dysfunction following carbon monoxide poisoning, SPECT regional blood flow measurements show diffuse hypometabolism in the frontal cortex.[27] In one patient, severe perfusion abnormalities improved slightly over several months in proportion with the patient's gradual clinical improvement.[87] In another patient treated with hyperbaric oxygen, a SPECT scan revealed increased blood flow in the frontal lobes, although the blood flow still remained significantly less than normal.[110]

In patients who chronically use cocaine, SPECT blood flow scintigraphy demonstrates focal cortical perfusion defects. The extent of these perfusion defects correlates with the frequency of drug use. Focal perfusion defects probably represent local vasculitis or small areas of infarction.[82 , 185] PET scanning has been used to demonstrate the effects of cocaine on cerebral blood

flow and regional glucose metabolism. PET neurotransmitter studies show

promise in elucidating potential mechanisms of action of cocaine. Using radiolabeled dopamine analogs, downregulation of dopamine (D_2) receptors has been noted following a cocaine binge. This finding may be responsible for cocaine craving that occurs during cocaine withdrawal. Using ^{11}C-labeled cocaine, uptake of cocaine can be demonstrated in the basal ganglia, a region rich in dopamine receptors.[191]

Figure 6-23. A. Chest radiograph of a young drug abuser who used the supraclavicular approach for heroin injection. The large mass in the left chest was suspicious for a pseudoaneurysm. B. An arch aortogram performed on the patient revealed a large pseudoaneurysm and hematoma subsequent to an arterial tear during attempted injection. Surgical repair was performed. *(Courtesy of Richard Lefleur, Department of Radiology, Bellevue Hospital.)*

Figure 6-24. Venogram of a 50-year-old patient who routinely injected heroin into his groin. Occlusion of the femoral vein *(black arrow)* with diffuse aneurysmal dilation *(small arrow)* and extensive collaterals are shown. Incidental radiopaque materials are noted in the right buttock *(double arrow)* . By history, this represents either bismuth or arsenicals he received as antisyphilitic therapy. *(Courtesy of Richard Lefleur, Department of Radiology, New York University.)*

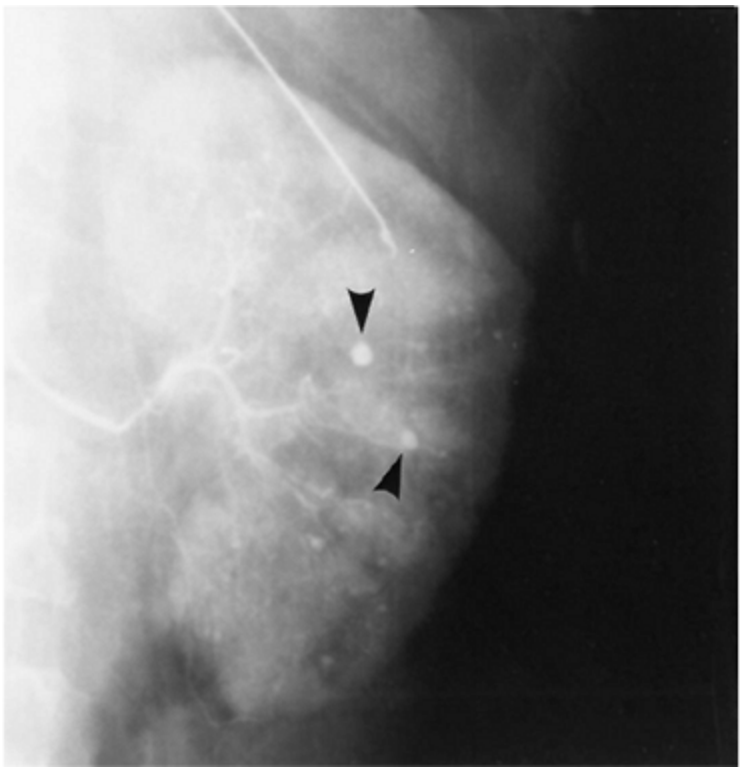

Figure 6-25. A selective renal angiogram in an injection methamphetamine user demonstrating multiple small and large aneurysms (*arrows*). *(Courtesy of Dr. Richard Lefleur, Associate Professor of Radiology, New York University.)*

Hemorrhage
Intraparenchymal hemorrhage
Subarachnoid hemorrhage
Sympathomimetics: cocaine (â€œcrackâ€•), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine
Mycotic aneurysm rupture (IDU)
Subdural hematoma
Trauma secondary to ethanol, sedative-hypnotics, seizures
Anticoagulants
Brain lucencies
Basal ganglia local necrosis (also subcortical white matter lucencies)

Carbon monoxide, cyanide, hydrogen sulfide, methanol
Strokeâ€”vasoconstriction
Sympathomimetics: cocaine (â€œcrackâ€•), amphetamine, phenylpropanolamine, phencyclidine; ephedrine, pseudoephedrine; ergotamine
Mass lesionâ€”tumor, abscess
Septic emboli, AIDS-related
CNS toxoplasmosis or lymphoma
Loss of brain tissue
Atrophyâ€”cerebral, cerebellar
Alcoholism, toluene

CT Finding Brain Lesion Xenobiotic Etiology

TABLE 6-5. Head CT (Noncontrast) in Toxicologic Emergencies

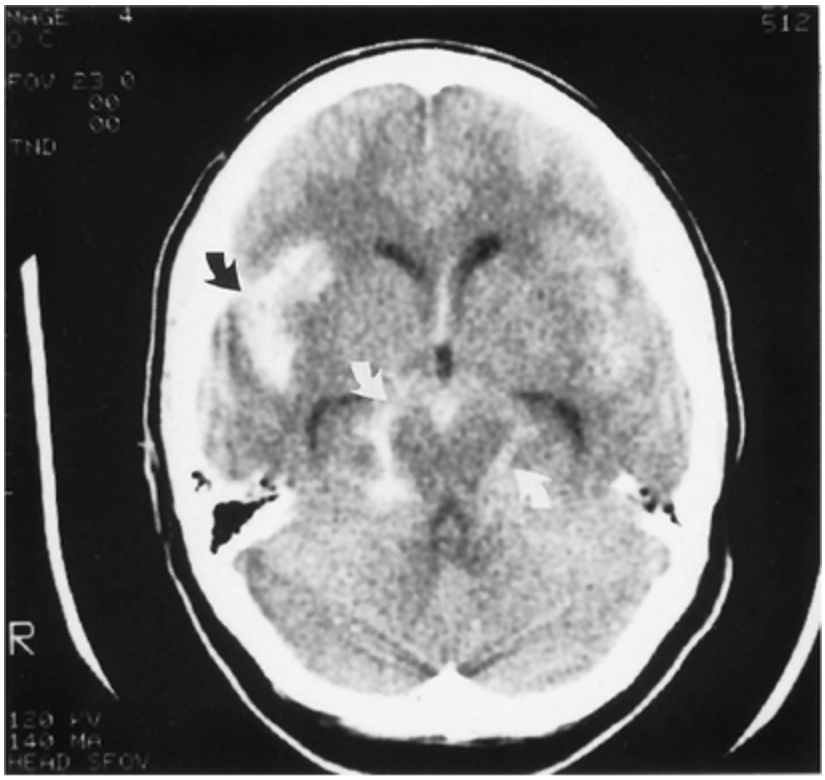

Figure 6-26. Subarachnoid hemorrhage following intravenous cocaine use. The patient had sudden severe headache followed by a generalized seizure. Extensive hemorrhage is seen surrounding the midbrain (*white arrows*) and in the right sylvian fissure (*black arrow*). Angiography revealed an aneurysm at the origin of the right middle cerebral artery.

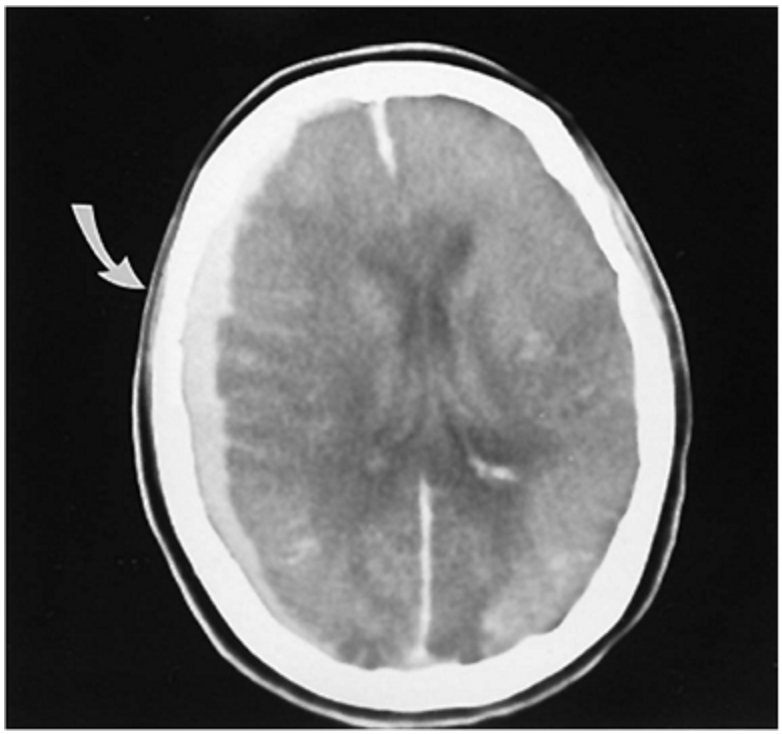

Figure 6-27. An acute subdural hematoma in an alcoholic patient following an alcohol binge. A crescent-shaped blood collection is seen between the right cerebral convexity and the inner table of the skull (*arrow*).

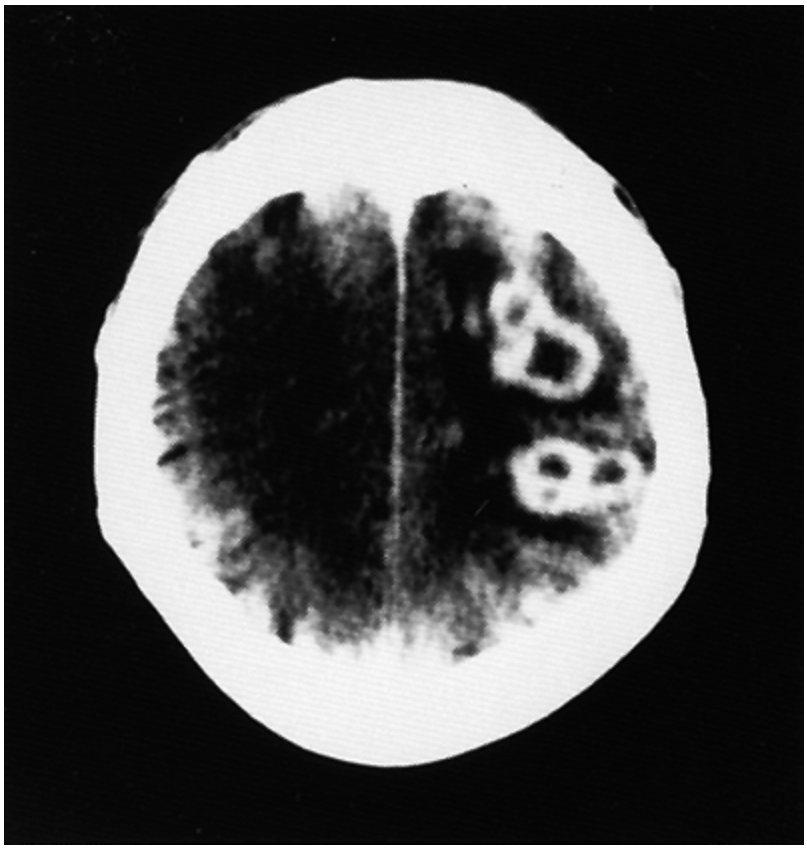

Figure 6-28. An injection drug user with ring-enhancing intracerebral lesions. The patient presented with fever and altered mental status. In this patient, the lesions represent multiple septic emboli complicating acute *Staphylococcus aureus* bacterial endocarditis. A similar ring-enhancing appearance is seen with lesions caused by toxoplasmosis or primary CNS lymphoma in patients with AIDS. This patient was HIV-negative.

P.82

P.83

Much has been learned about these imaging modalities and initial applications can be applied to patient care. They are capable of demonstrating abnormalities in many patients with xenobiotic exposures, although other patients with significant cerebral dysfunction have normal studies.

Summary

This chapter has highlighted a variety of situations in which diagnostic imaging studies are useful in toxicologic emergencies. Imaging can be an important tool in establishing a diagnosis, assisting in the treatment of patients, or in detecting complications of a toxicologic emergency. The imaging modalities include plain radiography, CT, enteric or intravascular contrast studies, nuclear scintigraphy, and ultrasonography. Effective use of a diagnostic test requires understanding of the clinical situations in which the test can be useful, knowledge of the test's capabilities and limitations, and how the results should be applied to the care of an individual patient.

Figure 6-29. A head CT of a patient with mental status changes following carbon monoxide poisoning. The scan shows characteristic bilateral symmetrical lucencies of the globus pallidus (*arrows*). *(Courtesy Dr. Paul Blackburn, Maricopa Medical Center, Arizona.)*

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 7
Laboratory Principles

Petrie M. Rainey

Medical toxicology addresses harm caused by acute and chronic exposures excessive concentrations of a substance. The management of toxicologic emergencies is a major component of medical toxicology. Detecting the presence or measuring the concentration of drugs and other acutely toxic substances is the primary activity of the medical toxicology laboratory. S testing is closely intertwined with therapeutic drug monitoring, in which concentrations are measured as an aid to optimizing drug-dosing regimen addition to drugs, measurements may be made of substances that lack a therapeutic purpose; for example pesticides, herbicides, and naturally oc plant and animal poisons. The unify characteristic of the substances typic measured is their common presentation in patients with toxicologic emergencies, and the subsequent need for testing results within a relativ short time frame.

The toxicology laboratory is frequently viewed in much the same way as clinical laboratories often areâ€”as a black box that converts orders into results. Because toxicology testing volumes are relatively low and menus extensive, testing is not as highly automated as other clinical laboratorie Many results may be â€œhand-made the old-fashioned way.â€• The dov

of this may be somewhat longer turnaround times. But the upside is that toxicology personnel have the incentive and flexibility to develop substar expertise, as well as the desire to share that expertise. The medical toxi who learns how toxicology testing is done will be able to use the results effectively. The toxicologist who invests the time to get to know the local toxicology laboratory will have developed an invaluable resource.

Recommendations for Routinely Available Toxicology Tests

Despite a common focus, there is remarkable variability in the range of t offered by medical toxicology laboratories. Test menus may range from c daily testing for routinely monitored drugs and common drugs of abuse to around-the-clock availability of a broad array of assays with the theoretic potential to identify several thousand compounds. Recently, consensus documents have been developed that recommend tests that should be av to support management of poisoned patients presenting to emergency departments.[24, 35] While making specific recommendations, these guide recognize that no set of recommendations will be universally appropriate also note that it is impossible for a clinical laboratory to offer a full spect toxicology testing in real time. Decisions on the menu of tests to be offer any specific laboratory should be decided by the laboratory director in consultation with clinicians who will use the service, and should take into account regional patterns of use of licit and illicit drugs, as well as resou available and competing priorities.

The recommendations in Table 7-1 were developed by the National Acade Clinical Biochemists (NACB) from a consensus process that involved clinic biochemists, medical toxicologists, forensic toxicologists and emergency physicians.[35] Although these tests should be readily available in the clinic laboratory, they should not be considered as a test panel for possibly po patients. As with all laboratory tests, they should be selectively ordered on presentation. Suggested turnaround time for reporting serum concent was 1 hour or less. Quantitative tests for serum methanol and ethylene g were also recommended, with the reservations that these tests are not n

in all settings and that a realistic turnaround time is 2â€“4 hours. Serum cholinesterase testing with a turnaround time of less than 4 hours was proposed by some participants, but did not achieve a general consensus. United Kingdom, the National Poisons Information Service and the Assoc of Clinical Biochemists have recommended a nearly identical list of tests, omitting the anticonvulsants.[24]

Although the consensus for the menu of serum assays was generally exc there was less agreement as to the need for qualitative urine assays. This largely a result of issues of poor sensitivity and specificity, poor correlati with clinical effects, and infrequent alteration of patient management. Wh these were potential issues for all of the urine drug tests, they led to exp omission of tests for tetrahydrocannabinol (THC) and benzodiazepines fro recommended list, despite their wide use. THC results were thought to ha little value in managing acute problems, and tests for benzodiazepines w believed to have an inadequate spectrum of detection. Testing for amphetamines, propoxyphene, and phencyclidine were only recommended areas where use was prevalent. It was also suggested that diagnosis of t antidepressant toxicity not be based solely on the results of a urine scree immunoassay, because a number of other drugs may cross-react. The significance of tricyclic antidepressant results should always be correlated electrocardiographic findings. The only urine test included in the United Kingdom guidelines was a spot test for paraquat.[24] Paraquat testing was omitted in the NACB guidelines because of a very low incidence of paraqu exposure in North America.[35]

Acetaminophen
Amphetamines
Carbamazepine
Barbiturates
Cooximetry (carboxyhemoglobin, methemoglobin, oxygen saturation)
Cocaine
Opiates
Digoxin
Propoxyphene

Serum Assays, Quantitative	Urine Assays, Qualitative
Ethanol	
Phencyclidine	
Iron (plus transferrin or unfilled iron-binding capacity)	
Tricyclic antidepressants	
Lithium	
Phenobarbital	
Salicylate	
Theophylline	
Valproic acid	

TABLE 7-1. Toxicology Assays Recommended by the National Aca of Clinical Biochemists

The NACB guidelines also recommend the availability of broad-spectrum toxicology testing, to be used for selected patients with presentations compatible with poisoning, but who remain undiagnosed by using the test Table 7-1 , and who are not improving. In general, such testing should nc ordered until the patient is stabilized and input obtained from a medical toxicologist or poison control center. This second level of testing may be provided directly by the local laboratory or by referral to a reference lab or a regional toxicology center.

Many physicians will order a broad-spectrum toxicology screen on a poisc patient if one is readily available, but only approximately 3% of clinical laboratories provide relatively comprehensive toxicology services (as est from proficiency testing data[4]). Although broad-spectrum toxicology scr can identify most drugs present in overdosed patients,[13] the results of b spectrum screens infrequently alter management or outcomes.[12 , 13 , 17 25 , 26] Consequently, many laboratories provide a more limited menu of toxicologically useful tests.

The extent to which the NACB recommendations are being followed may l

estimated from the numbers of laboratories participating in various types proficiency testing. Result summaries from the 2003 series of proficiency surveys administered by the College of American Pathologists suggest tha quantitative serum assays for acetaminophen, salicylate, cooximetry, theophylline, valproic acid, carbamazepine, digoxin, phenobarbital, iron, ethanol are available in 50â€“60% of laboratories that offer routine clinic testing, as are screening tests for drugs of abuse in urine. About one-thir laboratories offer testing for lithium, while only 1 in 6 offers measuremen transferrin and/or unfilled iron-binding capacity.[4]

Only 3% of laboratories participated in proficiency testing for a full range toxicology services. These laboratories typically offer quantitative assays additional therapeutic drugs, particularly tricyclic antidepressants, as well assays that are designated as broad-spectrum or comprehensive toxicolo screens. About half of these full-service toxicology laboratories (less than of all clinical laboratories) offer testing for volatile alcohols other than e

While relatively few laboratories offer a wide range of in-house testing, r laboratories will send out specimens to reference laboratories that offer l toxicology menus. The turnaround time for such â€œsendoutâ€• tests ca range from a few hours to several days, depending on the proximity of th reference laboratory and the type of test requested.

Even in full-service toxicology laboratories, the test menu may vary substantially from institution to institution. Larger laboratories typically o one or more broad-spectrum testing choices, often referred to as â€œtox screens.â€• There is as much variety in the range of compounds detecte various toxicologic screens as there is in the total menu of toxicologic tes Routinely available tests are usually listed in a printed or online laborato manual. Laboratories with comprehensive services may be able to offer ad chromatographic assays for additional substances that are not listed. Tes that is sent to a reference laboratory is often not listed in the laboratory manual. The best way to determine if a particular substance can be detec quantitated is to ask the director or supervisor of the toxicology section, laboratory clerical staff may only be aware of testing listed in the manual

Using the Toxicology Laboratory

There are many reasons for toxicologic testing. The most common functio confirm or exclude toxic exposures suspected from the history and physic examination. A laboratory result provides a level of confidence not readil obtained otherwise and may avert other unproductive diagnostic investig driven by the desire for completeness and medical certainty. Testing incr diagnostic certainty in more than half of cases.[2,12,17] In some instance diagnosis may be based primarily on the results of testing. This can be particularly important in poisonings with substances having delayed onset clinical toxicity, such as acetaminophen, or in patients with ingestion of multiple substances. In these instances, characteristic clinical findings ma have not yet developed at the time of presentation, or may be obscured altered by the effects of coingestants.

Testing can provide two key parameters that will have a major impact on clinical course, namely, the poison involved and the intensity of the expo This information can assist in triage decisions, such as whether to admit a patient or to observe the individual for expectant discharge. Serum concentrations can facilitate decisions to employ specific antidotes or spe interventions to hasten elimination. Well-defined exposure information ca facilitate provision of optimum advice by poison control centers, whose personnel do not have the ability to make decisions based on direct obse of the patient. Serum concentrations can be used to determine when to institute and when to terminate interventions such as hemodialysis or an administration, and can support the decision to transfer from intensive ca discharge from the hospital. Finally, positive findings for ethanol or drugs abuse in trauma patients may serve as a risk marker for the likelihood of trauma.[12]

The confirmation of a clinical diagnosis of poisoning provides an importan feedback function, whereby the physician may evaluate the diagnosis aga â€œgold standard.â€• Another important benefit is reassurance; for exa reassurance that an unintentional ingestion did not result in absorption of toxic amount of drug. Such reassurance can allow a physician to avoid sp excessive time with patients who are relatively stable. It can allow admis

to be made and interventions undertaken more confidently and efficiently would be likely based solely on a clinical diagnosis. This can be especially beneficial in a setting where multiple cases are competing for the physici attention.

Testing may also be indicated for medicolegal reasons. Diagnoses with le implications should be established â€œbeyond a

reasonable doubt.â€• While testing for illicit drugs is often done for mec purposes, it is almost impossible to dissociate such testing from legal considerations. Documentation is also important in malevolent poisonings intentional or unintentional child abuse involving therapeutic or illicit drug pharmacologic elder abuse. Where test results may be used to document criminal activity, consideration should be given to having testing done in forensic laboratory maintaining full chain of custody.

The documentation function is also important outside the medicolegal are Results of testing in a central laboratory are almost invariably entered int patient's medical record and can often provide definitive confirmation of a problem. Documentation has an additional importance that goes beyond t individual cases. Medical toxicology does not lend itself readily to experi human investigation. Much of toxicologic knowledge has been derived fro experiments of nature, recorded in case reports and case series. Hard da such as drug concentrations, can serve as key quantitative variables in summarizing and correlating the data. That laboratory results can be reli and generally easily found in the medical record makes them particularly valuable in retrospective reviews. A related service that the toxicology laboratory may provide is testing in support of experimental investigation

The key to optimum use of the toxicology laboratory is communication. T begins with learning the laboratory's capabilitiesâ€”what drugs are on its menus, which ones can be measured and which merely detected, and wha anticipated turnaround times. For screening assays, one should know whi drugs are routinely detected, which ones can be detected if specifically requested, and which ones cannot be detected, even when present at tox levels.

A key item is learning which specimens are appropriate for the test requ
A general rule is that quantitative tests require serum (red stopper) or
heparinized plasma (green stopper), but not ethylenediamine tetraacetic
(EDTA) plasma (lavender stopper) or citrate plasma (light-blue stopper).
and citrate bind divalent cations that may serve as cofactors for enzymes
as reagents or labels in various assays. Additionally, liquid EDTA and citr
anticoagulants dilute the specimen. Serum separator tubes or plasma se
tubes, identifiable by the separator gel in the tube, should be avoided, b
some drugs may diffuse into the gel, leading to falsely low results. A ran
clean urine specimen is generally preferred for toxicology screens, becaus
higher drug concentrations usually found in urine can compensate for the
sensitivity of the broadly focused screening techniques. A urine specimen
mL is usually optimal. Requirements for all specimens may vary from lab
to laboratory.

TABLE 7-2. Relative Comparison of Toxicology Methods

An important, and often overlooked, item of communication is specifying that are particularly suspected when making a request for a screening tes knowledge can allow the laboratory to set up the tests for those drugs fir possibly adjust the protocols to increase sensitivity or specificity. This ma an hour or more in the time needed to receive the critical information.

Consultation with the laboratory regarding puzzling cases or unusual need allow consensus on an effective and feasible testing strategy. The full capabilities of a toxicology laboratory are often not apparent from publish lists of tests available. Most full-service laboratories will devote substant efforts to meeting reasonable requests, and will provide consultations at charge.

The laboratory should also be contacted whenever results are inconsisten clinical presentation. The most common causes for this are interferences preanalytical errors. Analytical interference is caused by materials in the specimen that interfere with the measurement process, leading to falsely or low results. For example, hemoglobin can interfere with a variety of spectrophotometric tests by absorbing the light used to make the measurement. Preanalytical errors are events that occur prior to laborato analysis and produce incorrect or misleading results, such as mislabeling, specimen contamination by intravenous solutions, and incorrect collection or technique. The laboratory will be familiar with the common sources of discrepancies. If the discrepancy is the result of laboratory error, it is cri that the laboratory be informed, so that steps can be taken to understand

source of the error and avoid a recurrence.

Methods used in the Toxicology Laboratory

Most tests in the toxicology laboratory are directed toward the identificat and/or quantitation of drugs and poisons. The primary techniques used i spot tests, spectrochemical tests, immunoassays and chromatographic techniques. Mass spectrometry may also be used, usually in conjunction gas chromatography or liquid chromatography. Table 7-2 compares the b features of these methodologies. Other methodologies include ion-selecti electrode measurements of lithium, atomic absorption spectroscopy or inductively coupled plasma mass spectroscopy for lithium and heavy met and anodic stripping methods for heavy metals. There are also many adj tests that may be useful in the management of the poisoned patient, incl glucose, creatinine, electrolytes, osmolality, metabolic products, and enz activities. The focus here is on the major methods used for directly meas drugs and poisons.

Spot Tests

The simplest tests are spot tests. These rely on the rapid reaction of a dr with a chemical reagent to produce a colored product; for example, the formation of a colored complex between salicylate and ferric ions. Becaus reagents may cause precipitation of serum proteins, spot tests are more commonly performed on urine specimens or gastric aspirates. Such tests once a mainstay of toxicologic testing. Because of the poor selectivity of chemical reagents, as well as substantial variability in visual interpretatic these assays suffer from fairly frequent false-positive results and occasic false-negative results. As more sensitive and more specific methods have become available, spot tests have waned in popularity. Only a few are sti use, largely to fill gaps in testing menus, or to rapidly exclude some com poisonings. The introduction of point-of-care testing devices that have be sensitivity and specificity and are designed to facilitate compliance with regulations is likely to further reduce the use of spot tests.

Spectrochemical Tests

Spectrochemical tests are sophisticated versions of spot tests. They also a chemical reaction to form a light-absorbing substance. They differ in th reaction conditions and reagent concentrations are carefully controlled an amount of light absorbed is quantitatively measured at one or more spec wavelengths. The use of specific wavelengths enhances the sensitivity an particularly, the specificity of the detection, and the measurement of the amount of light absorbed under controlled conditions allows quantitation c substance.

When an analyte is intrinsically light absorbing, no reaction may be nece Cooximetry represents a sophisticated application of spectrophotometry to measurement of various forms of hemoglobin in a hemolyzed blood samp Measurement of light absorbance at several wavelengths allows multiple hemoglobin species to be simultaneously quantitated. For mathematical reasons, the number of wavelengths used must be greater than the numb different types of hemoglobin present. This is why pulse oximetry, which only two wavelengths, yields spurious results in the presence of significa amounts of methemoglobin or carboxyhemoglobin (Chaps. 22 and 122).

Most analytes are neither as deeply colored, nor as highly concentrated, hemoglobin species. Their detection requires the generation of an intense light-absorbing product, as is done in spot tests. Most spot test reactions been used for spectrochemical assays; for example, salicylate assays usi Trinder reagent (a variation on ferric chloride). The difference between a test and a spectrochemical one lies in whether the colored product is vis observed or quantitatively measured in a spectrophotometer. Because spectrophotometers can also measure ultraviolet and infrared light, it is necessary that the product have a visible color. Early spectrochemical as typically measured the absorbance after conversion of all of the analyte t light-absorbing product. Modern assays usually employ rate spectrophoto taking multiple absorbance measurements over time to determine the rat change in light absorbance as the reaction proceeds. During the initial ph the reaction, this rate is constant and proportional to the initial concentr

of the analyte. This significantly reduces the time needed to obtain a res because the reaction does not have to go to completion first, and it allow averaging of multiple measurements, improving precision. Furthermore, it unaffected by nonreacting substances that absorb light at the test wavel because the absorbance of the nonreacting substances is constant and do contribute to the rate of change in the absorbance.

Rate spectrophotometry remains subject to interference by substances th react to produce a light-absorbing product, thereby falsely increasing the apparent concentration. Substances that inhibit the assay reaction, or tha consume reagents without producing a light-absorbing product, will give low results. For example, ascorbic acid produces negative interference in spectrophotometric assays that use oxidation reactions to generate color products.

Cooximetry is generally relatively free of interferences because the concentrations of the hemoglobins are so much higher than other substar the blood. However, the presence of intensely colored substances may lea spurious answers. Methylene blue, which is used to treat methemoglobin typically causes falsely increased methemoglobin measurements by coox This interference does not occur when methemoglobin is measured by oth methods, such as electrophoresis.

One way to improve the selectivity of a spectrochemical assay is to increa selectivity of the reaction that generates the light-absorbing product. En which can catalyze highly selective reactions, are often used for this purp For example, many assays for ethanol use alcohol dehydrogenase to cata the oxidation of ethanol to acetaldehyde, with concomitant reduction of t cofactor NAD^+ (oxidized form of nicotinamide adenine dinucleotide) to NA (reduced form of nicotinamide adenine dinucleotide). The initial rate of i in light absorption produced by the conversion of NAD^+ to NADH is propo to the concentration of ethanol. Although other alcohols such as isopropa and methanol can also be oxidized by alcohol dehydrogenase, they are m poorer substrates with low rates of reaction and correspondingly low leve interference.

Many other enzymatic assays also rely on measuring the change in light

absorption at 340 nm when NAD^+ is converted to NADH or vice versa. Th include enzymatic assays for ethylene glycol, as well as some enzyme-lin immunoassays, such as EMIT (enzyme-multiplied immunoassay technique assays. All such assays are potentially subject to interference by specime with high concentrations of lactate. Lactate dehydrogenase, which is natu present in serum, will oxidize this lactate to pyruvate if NAD^+ becomes available for simultaneous reduction to NADH. When a serum specimen w high lactate is mixed with assay reagents that contain NAD^+ , oxidation o lactate contributes to the total rate of NADH production. The increased ra NADH production results in a false increase in the measured concentration the target analyte.

Immunoassays

The need to measure very low concentrations of an analyte with a high d of specificity led to the development of immunoassays. The combination o affinity and high selectivity makes antibodies ideal assay reagents. There two common types of immunoassays: noncompetitive and competitive. In noncompetitive immunoassays, the analyte is sandwiched between two antibodies, each of which recognizes a different epitope on the analyte. I competitive immunoassays, analyte from the patient's specimen competes limited number of antibody binding sites with a labeled version of the an provided in the reaction mixture. Because most drugs are too small to ha distinct antibody binding sites, drug immunoassays are usually competiti

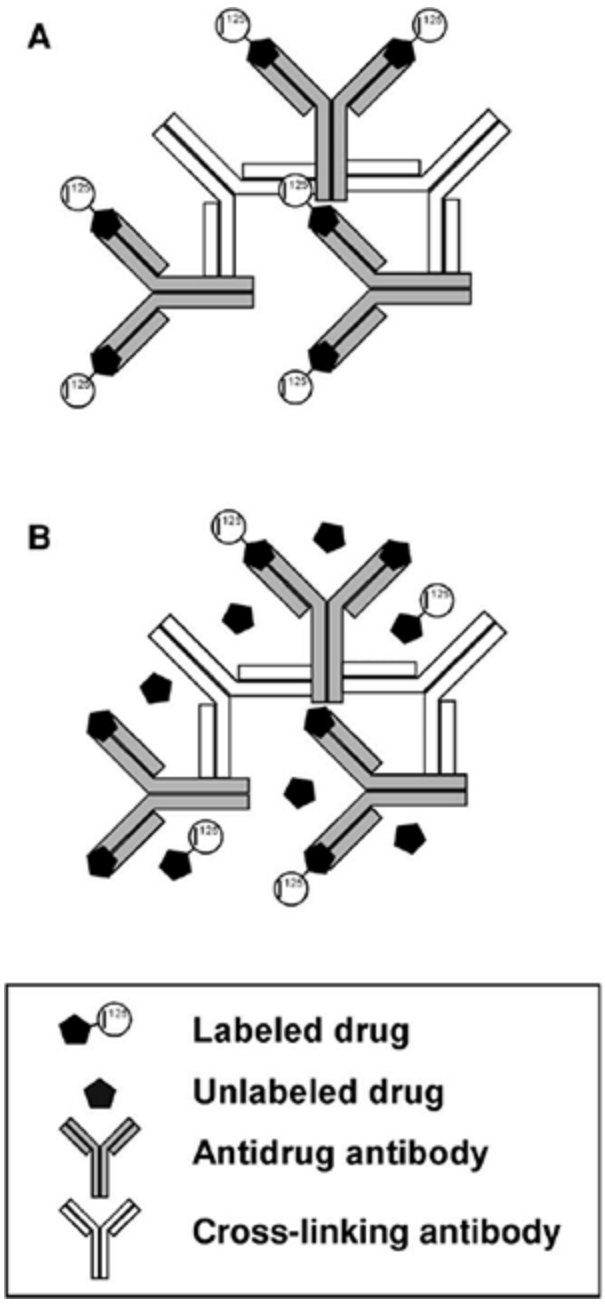

Figure 7-1. Competitive radioimmunoassay. A. No drug from the specime present to displace the ^{125}I-labeled drug. Adding the cross-linking antib precipitates the assay antibody, along with high amounts of bound radio B. Unlabeled drug in the specimen displaces some of the labeled drug. Th displaced label is left in solution when the cross-linking antibody is added resulting in less radioactivity in the precipitate.

In competitive immunoassays, increasing the concentration of drug in the specimen results in increased displacement of labeled drug from the anti The amount of drug in the specimen can be determined by measuring eith amount of label remaining bound to the assay antibodies or the amount o free in solution. In the earliest immunoassays, the label was a radioisoto typically iodine-125, tritium, or carbon-14. The bound and free radioactiv were physically separated; for example, by using a second antibody to cr link and precipitate the assay antibody, along with its bound radioactivity 7-1), or by adsorbing the free label with activated charcoal. Today, radioimmunoassays are relatively uncommon because of problems associ with handling and disposal of radioactivity. They are primarily used for a with insufficient demand to justify the development costs of more sophis nonisotopic assays.

Nonisotopic immunoassays are currently the most widely used methodolo for the measurement of drugs. They offer high selectivity and good preci and are readily adapted to automated analyzers, thereby decreasing both cost and the turnaround time of the assays. The effort involved in develo these assays is substantial. Accordingly, the drugs for which immunoassa available are limited to those for which there is a high demand, such as monitored therapeutic drugs and the drugs of abuse included in workplac screening. However, after assay development is completed, production co are relatively low, allowing the tests to be widely distributed at reasonab prices.

The most widely used nonisotopic drug immunoassays are in the category homogenous immunoassays. Homogenous immunoassays measure differe in the properties of bound and free labels, rather than directly measuring or the other after their physical separation. Avoiding a separation step al homogenous immunoassays to be readily adapted to automated analysis. Homogenous techniques that are in wide use include EMIT (Fig. 7-2), fluorescence polarization immunoassay (FPIA, Fig. 7-3), kinetic inhibition microparticles in solution (KIMS), and cloned enzyme donor immunoassay (CEDIA).

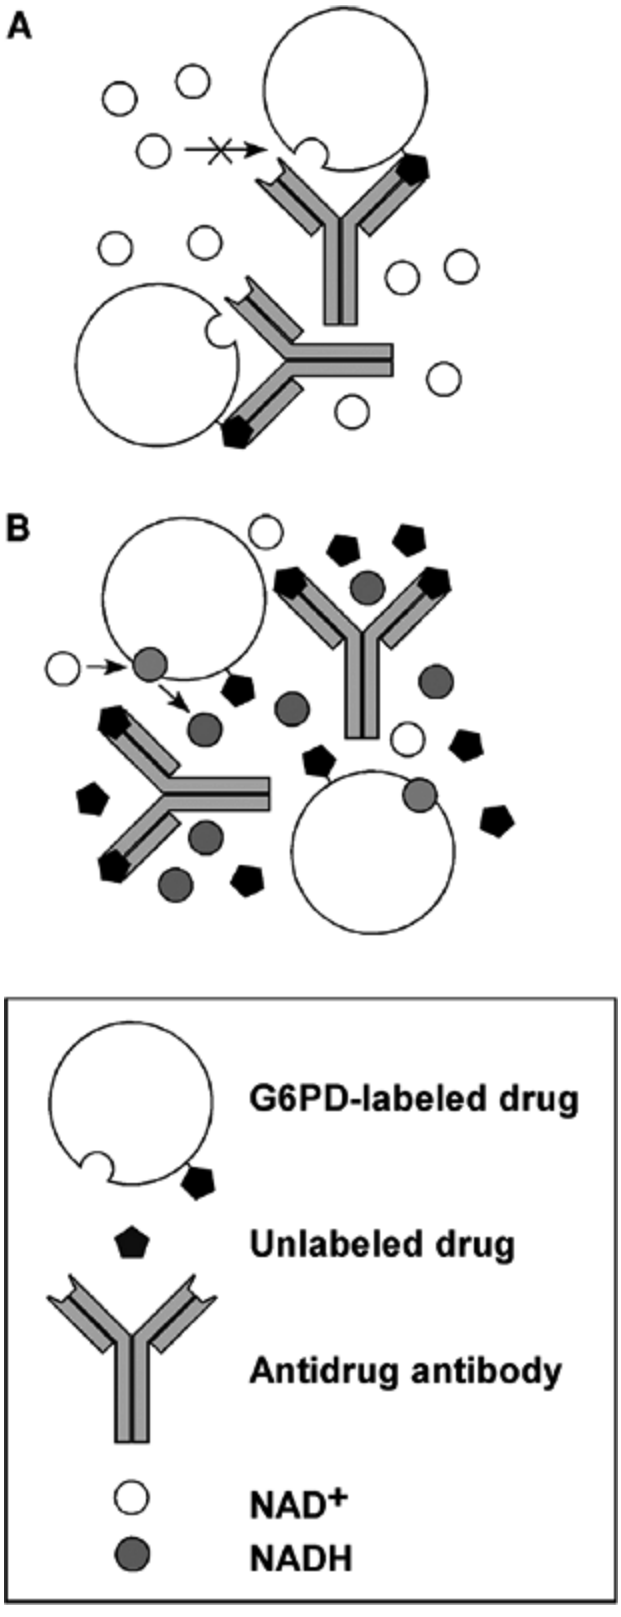

Figure 7-2. EMIT immunoassay. The drug to be measured is labeled by l

attached to the enzyme, glucose-6-phosphate dehydrogenase (G6PD), nea active site. A. Binding of the enzyme-labeled drug to the assay antibody the active site, inhibiting conversion of NAD^+ to NADH. B. Unlabeled drug the specimen can displace the drug-enzyme conjugate from the antibody, thereby unblocking the active site and increasing the rate of reaction.

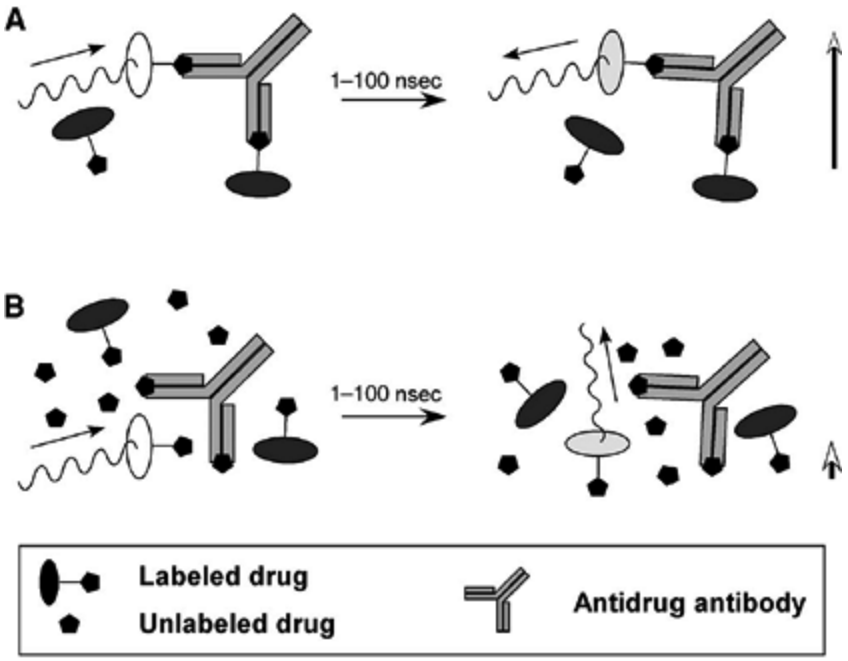

Figure 7-3. FPIA immunoassay. A. After drug labeled with fluorescein competes with unlabeled drug from the specimen for assay antibodies, th fluorescein is photoexcited with a flash of polarized light. Fluorescein mo aligned with the plane of polarization can absorb the light, entering an e state (*white fill*). The excited fluorescein decays over a few nanoseconds lower energy state (*light-gray fill*) and reemits the light at a lower wave The polarization of the emitted light is determined by the orientation of fluorescein. Fluorescein that is attached by the drug to the large assay a move little before reemission, so the emitted light retains most of the polarization (*vertical arrow at right*). B. Drug from the specimen can pre binding of the drugâ€“fluorescein conjugates. The unbound conjugates ca tumble rapidly and randomize their orientation prior to reemission of ligh resultant loss of polarization. The residual polarization of the emitted ligh

inversely proportional to the drug concentration in the specimen.

Some of the newest automated immunoassays are again using physical separation techniques. In these assays, the detection antibody is physica attached to a solid support and separation occurs by a simple wash step. wash step removes the patient's serum along with many potentially inter substances. Newer solid supports consist of fine glass fibers or latex microparticles. These have very high total surface areas that allow for ra equilibration and short assay times. Older assays of this type used antibo bound to large plastic beads or wells of microtiter plates, and required lo incubation steps because of substantial times required for diffusion of the reactants to the antibodies. These new techniques are readily automated allow the measurement of bound label with more sensitive methods, such chemiluminescent, electroluminescent, and total fluorescence labels, than available with homogenous immunoassays.

Microparticle capture assays are a type of competitive immunoassays that become very popular, especially for urine drug screening tests. The use o colored microparticles, either latex or colloidal gold, as the label enables result to be read visually as the presence or absence of a colored band, w special instrumentation required. Competitive binding occurs as the assay mixture is drawn by capillary action through a porous membrane. This de feature is responsible for alternate names for the technique: lateral flow immunoassay or immunochromatography.

The simplest design employs an antidrug antibody bound to colored microparticles and a capture zone consisting of immobilized drug (Fig. 7-4 the specimen is drug-free, the beads will bind to the immobilized analyte forming a colored band. When the amount of drug in the patient specimen exceeds the detection limit, all of the antibody sites will be occupied by d from the specimen, and no labeled antibody will be retained in the captur zone. The use of multiple antibodies and discrete capture zones with diff immobilized analytes can allow several drugs to be detected with a single device.

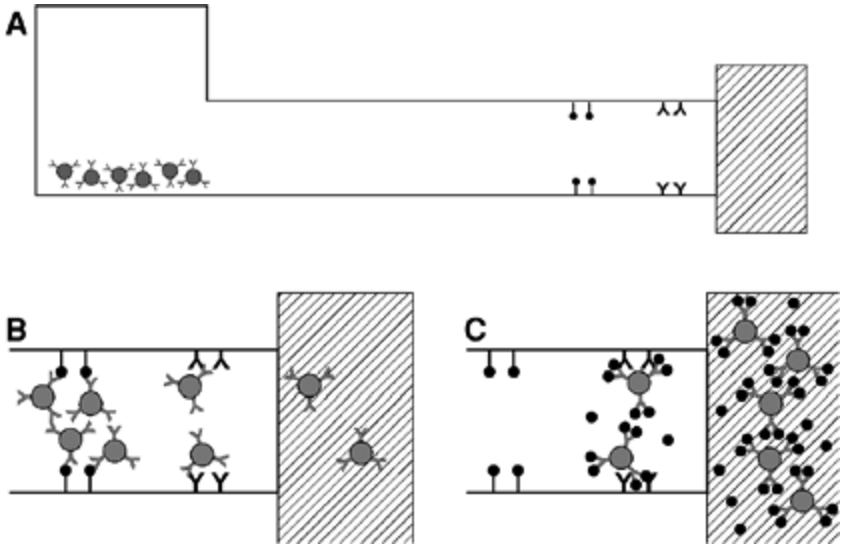

Figure 7-4. Microparticle capture immunoassay. A. Diagram of a device to specimen addition. Colored microbeads (about the size of red blood ce coated with antidrug antibodies (Y) are in the specimen well. At the far er porous strip are capture zones with immobilized drug molecules (â€¢) and control zone with antiantibodies recognizing the antibodies that coat the microbeads. B. Adding the urine specimen suspends the microbeads, whic drawn by capillary action through the porous strip and into an absorbent reservoir (*hatched area*) at the far end of the strip. In the absence of dr the urine, the antibodies will bind the beads to the capture zone containir immobilized drug and form a colored band. Excess beads will be bound by antibodyâ€“antibody interactions in the control zone, forming a second c band that verifies the integrity of the antibodies in the device. C. If the u contains the drug (â€¢) in concentrations exceeding the detection limit, a the antibodies on the microbeads will be occupied by drug from the speci and the microbeads will not be retained by the immobilized drug in the c zone. No colored band will form. However, the beads will be bound and fo band in the control zone.

A disadvantage of this design is the potential for causing confusion, becau positive result is indicated by the absence of a band. More complex (and expensive) variations have been developed in which a colored band denot positive result.

Although immunoassays have a high degree of sensitivity and selectivity, are also subject to interferences and problems with cross-reactivity. Cros reactivity refers to the ability of the assay antibody to bind to molecules than the target analyte. Molecules with similar chemical structures may b efficiently bound, which can lead to falsely elevated results. In some situ cross-reactivity can be beneficially exploited. For example, some immun effectively detect classes of drugs rather than one specific drug. Immun for opiates employ antibodies that recognize various molecules that are structurally related to morphine, including codeine, hydrocodone, and hydromorphone. However, they have little or no cross-reactivity with structurally unrelated synthetic opioids, such as meperidine or methadon Immunoassays for the benzodiazepine class react with a wide variety of benzodiazepines, but with varying degrees of sensitivity.[19]

Class specificity can be a two-edged sword. Assays for the tricyclic antidepressant family have similar reactivity with amitriptyline, nortripty imipramine, and desipramine, and can be used to provide a semiquantita estimate of the total concentration of any combination of these. However, large number of other drugs with tricyclic structures, including carbamaz many phenothiazines, and diphenhydramine, also cross-react and generat signal, particularly at concentrations found in patients who overdose on s drugs. Qualitative tests, such as microparticle capture assays, may then false-positive results, if the signal generated by the cross-reacting drug (carbamazepine) exceeds the detection limit of the immunoassay. With quantitative or semiquantitative assays, however, the apparent tricyclic antidepressant concentration generated by a cross-reacting drug is gene well below concentrations associated with toxicity.

Even when an antibody is selected to be specific to a single drug, it is co that metabolites of the target drug show some cross-reactivity. This too r beneficial. When the metabolite is an active one (eg, carbamazepine epo the contribution of its cross-reactivity may yield results that correlate be with the drug effect than the true concentration of the parent drug alone.

Immunoassays are also subject to interference by substances that impair

detection of the label. The mechanism by which elevated lactate concent may lead to spuriously increased drug concentrations in specimens tested EMIT is described above. Immunoassays that rely on enzyme labels are particularly sensitive to nonspecific interference because enzyme activity highly dependent on reaction conditions. A number of substances that car inhibit the enzyme reaction in EMIT assays are used to adulterate urine submitted for drug-abuse testing with the intent of producing false-negat results (see the discussion of drug-abuse screening tests under Special Considerations for Drug-Abuse Screening Tests below). Such adulteration be detected when the rate of reaction is lower than the rate observed wit drug-free control.

Chromatography

Chromatography encompasses several related techniques in which analyt specificity is achieved by physical separation. The unifying mechanism fo separation is the partition of the analytes and other substances between stationary phase and a moving phase (mobile phase). In most instances, stationary phase consists of very fine particles arranged in a thin layer or enclosed within a column. The mobile phase flows through the spaces be the particles. Analytes are in a rapid equilibrium between solution in the phase and adsorption to the surfaces of the particles. They move when in mobile phase and stop when adsorbed to the stationary phase. The avera velocity of the analyte molecules depends on the relative time spent in th moving versus stationary phase. Molecules that partition primarily into th mobile phase have average velocities slightly less than the mobile phase velocity. Average velocity decreases as the proportion of time adsorbed t stationary phase increases. Under controlled conditions, these average velocities are highly reproducible. Substances may be provisionally ident based on their characteristic velocity. This is measured as the distance t relative to the solvent migration distance in thin-layer chromatography, o amount of time required to traverse the length of a chromatography colu These characteristic parameters are referred to as the R_F value and rete time, respectively.

Chromatography is a separation method and must be combined with a de method to allow identification and measurement of the separated substa The sensitivity of chromatographic methods depends on both the amount specimen available and the sensitivity of the detection method. The dete limit may range from less than 10 ng with mass spectrometric detection t more than 10 Âµg when detection is achieved by forming a colored produ using a postchromatographic chemical reaction. Chromatographic behavio sufficiently reproducible that the failure to detect a signal at an R_F value retention time characteristic of a compound effectively excludes the prese that compound in amounts greater than the detection limit. On the other a number of different substances may have migration velocities that are identical or nearly so. A positive finding is therefore not completely speci Definitive identification depends on having additional information, which r obtained through selective detection techniques or by confirmatory testin using a second method.

A major advantage of chromatographic techniques is that multiple substa may be detected and measured in a single procedure. It is not always necessary to know in advance the specific material to be looked for. For reason, chromatographic techniques have a major role in the performance screening tests.

Most chromatographic procedures require extraction and concentration of substances to be analyzed prior to the chromatography. Extraction results removal of salts, proteins and other materials that may exhibit unfavorab interactions with either of the chromatographic phases. Concentration all the substances to be introduced in a narrow â€œband,â€• so that compo with slightly different relative mobilities become completely resolved, or separated from one another, rather than overlapping. This also results in more intense signal as a band passes through the detector and increases sensitivity.

Extraction of drugs is most commonly done with organic solvents, but â€ phase extractionâ€• is also very popular.[11] Solid-phase extraction is a modified chromatographic procedure in which a urine or serum specimen passed through a short chromatography column with a hydrophobic stati

phase. Most drugs are sufficiently hydrophobic that they partition almost completely into the stationary phase and are retained on the column. Subsequently, the retained compounds are eluted with an organic solvent organic solvents from either extraction technique are evaporated to conc the extracted substances. The extraction process allows the analyte from large volume of specimen to be concentrated. Detection sensitivity can t be increased, provided large volume specimens can be readily obtained, a true with urine.

Often there is a preextraction treatment to increase the hydrophobicity of substances to be extracted. The most common manipulation is pH adjust either upward or downward, to convert charged forms of drugs into unch extractable ones. In other instances, enzymatic or chemical hydrolysis ma employed to convert water-soluble glucuronide metabolites back to their readily extracted parent compounds; for example, conversion of morphin glucuronide to morphine.

In thin-layer chromatography (TLC), the concentrated extracts are redis in a small amount of solvent and spotted onto a thin layer of silica gel tha supported on a glass or plastic plate, or embedded in a fiber matrix. A ty TLC plate will have room for several different spots of extracts from sam and controls. The plates are placed vertically in closed tanks containing a shallow layer of an organic solvent mixture. As the solvent is drawn upwa through the silica gel by capillary action, various compounds are carried at characteristic velocities determined by

their partition between the moving organic solvent and the stationary silic (Fig. 7-5). Silica gel is polar, so hydrophobic compounds migrate rapidly hydrophilic ones more slowly. Adjusting the composition of the solvent m allows optimization of the migration rates. After sufficient solvent migrat the plates are removed from the tanks, dried and sprayed with a series o reagents that convert the drugs to be detected into various colored deriv The drugs are thereby visualized as colored spots and identified by their migration distance (R_F value), as well as by the various colors produced each spray. Drugs that are metabolized can be further confirmed by the of additional spots corresponding to characteristic metabolites. Identifica

can be most confidently made when an authentic sample of the drug has included as a control on the plate.

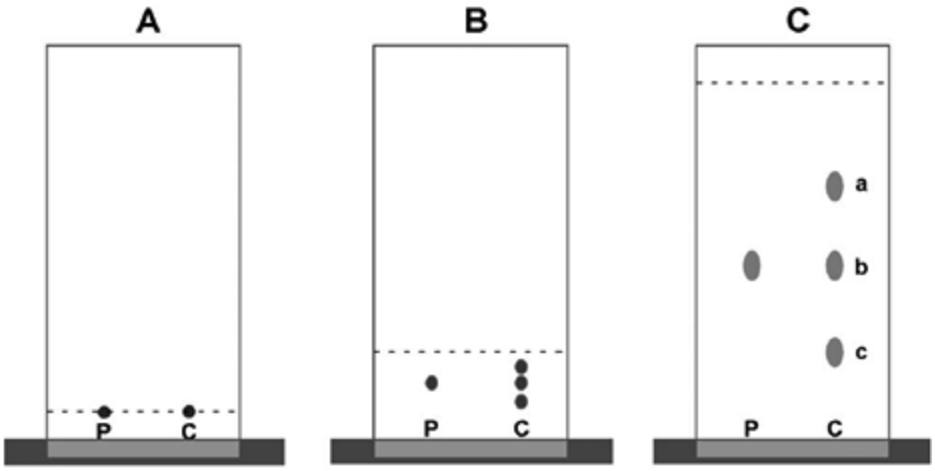

Figure 7-5. Thin-layer chromatography. A. Concentrated extracts from p (*P*) and control (*C*) specimens are dried in small spots on a plate coated a thin layer of silica gel particles. The plate is placed vertically into an or solvent mixture, which is being drawn up the plate by capillary action. Th leading edge (or solvent front, shown by the *dotted line*) reaches the ex and begins to dissolve them. B. Various substances are moving at differe rates, depending on the relative proportion of time spent in the moving s (mobile phase) and adsorbed to the silica gel (stationary phase). C. The development of the chromatogram is stopped when the solvent front near top. Various substances are seen at characteristic positions relative to th solvent front. The patient specimen contains a substance that can be tentatively identified as compound *b* in the control mixture, based on its relative mobility. Although shown as shaded spots here for clarity, most are colorless and are visualized at the end of the chromatography by beir dipped or sprayed with reagents that form colored products. The tentativ identification of the unknown drug as compound *b* requires that it show t same behavior with the visualizing reagents.

TLC has the ability to identify the presence of a large number of drugs an widely used in â€œdrug screens.â€• Visualization as colored spots gene requires fairly large amounts of material. For this reason, TLC is usually

with urine and gastric aspirate specimens because they typically have hig concentrations of many drugs than do corresponding serum specimens, a because they are readily available in large volumes.

Drawbacks to TLC include the need for multiple steps: extraction, concentration, chromatography, and a series of detection reactions. This TLC a relatively slow and labor-intensive procedure. Interpretation of the requires a skilled technologist who knows the TLC behavior of commonly encountered drugs. Quantitation of the drugs detected is difficult and rar attempted. Therefore, TLC is primarily used to demonstrate the presence drug. It is of limited value in identifying a drug not previously seen by th chromatographer, unless a possible candidate is suggested to the laborat and an authentic sample (ie, a standard) can be obtained to verify its be in the TLC system. Drugs that have limited excretion in the urine might n readily detected.

In the past, full-service toxicology laboratories used classical TLC procedu screen urine for a variety of drugs. The development of a commercial kit TLC of drugs in urine (Toxilab, Varian, Inc., Palo Alto, CA) has reduced th time, labor, and expertise required, and has extended its practicability to broader range of laboratories.[14] The use of a standardized procedure also allows tentative identification of a drug not previously encountered by comparing its characteristics with those of a broad range of drugs provide compendium by the manufacturer. Identifications made solely on the basi agreement with characteristics described in the compendium should be considered provisional until confirmed by additional testing.

In the related technique of high-performance liquid chromatography (HPL the stationary phase is packed into a column and the mobile phase is pur through under high pressure (Fig. 7-6). This allows good flow rates to be achieved, even when solid phases with very small particle sizes are used. Smaller particle size increases surface area, decreases diffusion distances improves resolution, but the spaces between the particles are also smalle increasing the resistance to flow. The use of high pressure and small par allows better separations in a fraction of the time required for TLC.

Another way that HPLC often differs from TLC is that HPLC typically empl

â€œreverse-phaseâ€• chromatography. Reverse-phase chromatography employs stationary phases in which the silica gel particles have had hydrocarbon molecules covalently linked to the outer surface. This reduce surface charge on the silica, thereby reducing its hydrophilicity, and simultaneously coats the particles with a permanently bonded oil-like laye the same time, solvent polarity is increased by using a primarily aqueous mobile phase with varying amounts of organic solvent. Because of these modifications, hydrophobic molecules are more strongly adsorbed by the stationary phase, whereas hydrophilic ones tend to remain in the mobile This results in an order of elution from the column that is approximately reverse of that seen with organic solvents and unmodified silica gel. Thus term â€œreverse-phase chromatographyâ€• is used. (Both TLC and HPLC be done using either â€œnormal-phaseâ€• or â€œreverse-phaseâ€• conditions. However, TLC is more commonly done in normal phase and HI more commonly in reverse phase.) A variety of hydrocarbons can be used derivatize the silica gel. By far the most common reverse phase columns octadecyl hydrocarbon as the outer coating and are often referred to as C columns.

In HPLC, the drugs are detected after they exit the chromatographic colu this case, they are identified by their retention time (the characteristic ti required to traverse the column). Because most drugs absorb ultraviolet detection is commonly by ultraviolet spectroscopy using specially designe flow-through cuvettes. Measuring light absorbance at a selected wavelen allows the amount of the drug to be determined. Accuracy is often enhan comparing the absorbance of the target analyte with absorbance of an in standard; that is, a compound with a different retention time that is adde fixed amount to all specimens. The ratio of the drug absorbance to the in standard absorbance is proportional to the drug concentration in the spe

Although most HPLC detectors allow a selection of the detection wavelen commonly only one wavelength is used during a

given run. Some detectors, however, allow absorbance at multiple wavel to be determined, either by rapidly and repeatedly scanning through a ra wavelengths, or by breaking white light into its component wavelengths c

after it has passed through the detection cuvette and then using an array photodiode detectors to make measurements at multiple wavelengths simultaneously. These techniques can allow the absorbance spectrum of a compound to be determined as it elutes from the column. This information supplement the retention time and allow more specific identifications to b made.

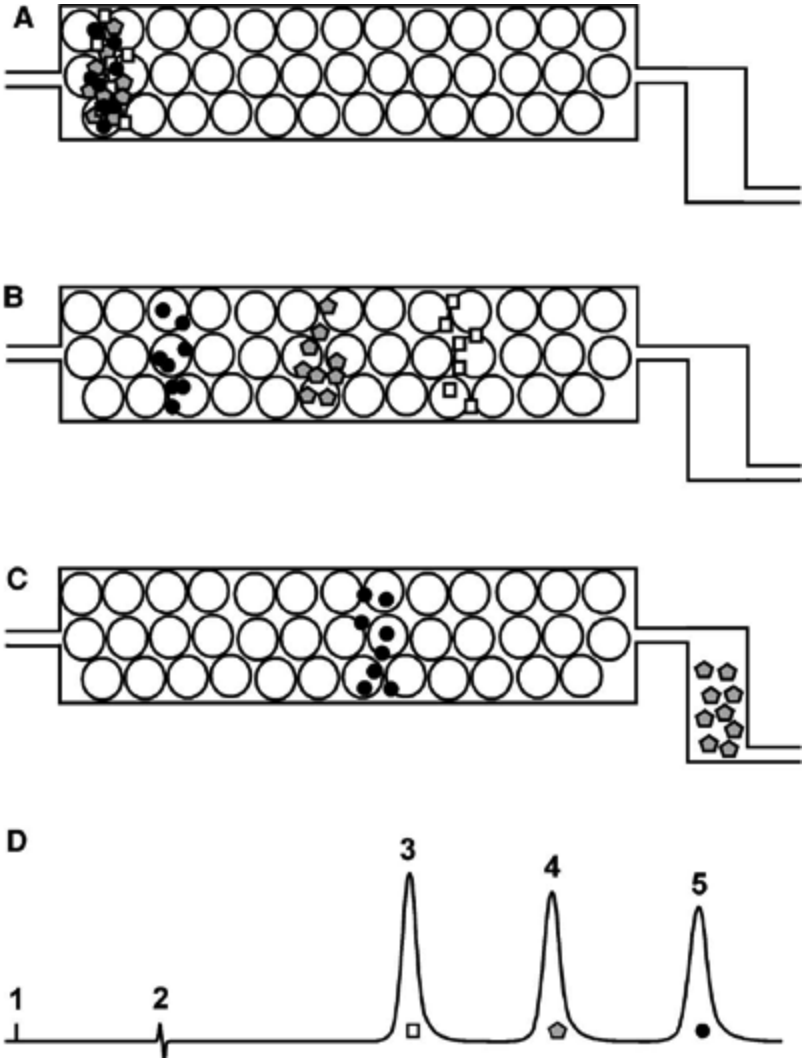

Figure 7-6. High-performance liquid chromatography. HPLC is schematic shown. A. A mixture of three compounds is injected into a column with a reversed-phase packing (⬟). B. The compounds move through the columr characteristic speeds. The most hydrophilic compound (â–¡) moves most quickly, whereas the most hydrophobic compound (⬟) moves most slowly The compound of intermediate polarity (⬟) has reached the detection cel

where it absorbs light directed through the cell and generates a signal proportional to its concentration. D. Illustration of the HPLC tracing that result: *1* indicates the time of injection. The artifact at *2* results when the injection solvent reaches the detector, and indicates the retention time of completely unretained compound. The peaks at *3, 4* , and *5* correspond to separated compounds. For example, peak *4* might be amitriptyline; peak might be the more polar metabolite, nortriptyline; and peak *5* could be th more hydrophobic internal standard *N* -ethylnortriptyline. Later-emerging are typically wider and shorter, because of more time for diffusive forces spread out the molecules.

TLC generally requires one or more hours to complete and provides qual identification of drugs present at concentrations of 1 mg/L or higher in contrast, HPLC can routinely provide quantitation of drugs at 10-fold lowe concentrations in less than 1 hour (provided the calibration was done in advance). Thus, HPLC is often the method of choice for measuring serum concentrations of drugs for which no immunoassay is available. Relative disadvantages of HPLC in comparison with TLC are the much higher costs equipment, the inability to analyze multiple samples simultaneously, and relative inability to analyze drugs with a wide range of polarities with a s assay. The latter limitation inhibits the use of HPLC as a broad drug-scre technique.

Gas chromatography (GC) is similar in principle to HPLC, except that the moving phase is a gas, usually the inert gas helium but occasionally nitro The schematic illustration of HPLC in Figure 7-6 is also applicable to GC. low flow resistance of gas allows high flow rates that make possible substantially longer columns than are used in HPLC. This offers the dual advantages of high resolution and fast analysis. As was true in HPLC, mos assays incorporate an internal standard to increase precision.

Because the inert carrier gas does not engage in intermolecular interacti partition of the analytes into the moving gas phase depends primarily on natural volatility. Elevated column temperatures are required to achieve sufficient volatility for analysis of most substances. The use of a tempera gradient (the column temperature is programmed to increase throughout course of the analysis) can allow compounds with a wide range of volatilit

be analyzed in a single run. This feature makes GC suitable for screening assays encompassing a broad range of drugs.

Gas chromatography is limited to molecules that are reasonably volatile a temperatures below 572Â°F (300Â°C), above which the stationary phase begin to break down. Two principal attributes of a molecule limit its vola its size and its ability to form hydrogen bonds. Molecules that form hydro bonds via amino, hydroxyl, and carboxylate moieties can be made more by replacing hydrogens on oxygen and nitrogen atoms with a nonbonding preferably large, substituent. (Large substituents sterically hinder access acceptor electron pairs on the nitrogen and oxygen atoms.) A number of derivatizing agents can be used to add appropriate substituents. The mos common derivatives involve the trimethylsilyl (TMS) group. Although derivatization with TMS substantially increases the molecular weight, the resulting derivative is much more volatile as a consequence of the loss of hydrogen bonding.

In traditional packed-column GC, the packing may consist of inert suppor particles with a fine coating of nonvolatile, high-molecular-weight oil that comprises the stationary phase. It is increasingly common for the station phase to be covalently bonded to the support particles. A highly useful v of GC is capillary chromatography. A long, fine capillary tube of fused silic coated on the inside with a covalently bonded stationary phase. The mobi phase flows through the tiny channel in the middle. These capillaries are flexible, allowing very long columns (10 meters or longer) to be coiled int small space. The long column length, coupled with highly uniform conditi throughout the column, results in extremely high resolution. The fineness column allows rapid thermal equilibration and the use of steep temperatu gradients that can speed analysis. The major drawback to capillary chromatography is a very limited column capacity. Special techniques are needed to restrict the amount of material introduced into the column and avoid overloading it. High-sensitivity detectors are required to measure t small quantities that can be chromatographed.

A number of detectors are available for GC. The most common detector,

particularly for packed columns, is the flame ionization detector. This inv directing the outflow of the column into a hydrogen flame. Organic molec emerging from the column are burned, creating charged combustion intermediates that can be measured as a current. The amount of current largely determined by the mass of carbon that is being burned. Nitrogen-phosphorus detectors are also widely used in drug analysis. In this modi of a flame ionization detector, a heated bead coated with an alkali metal used to selectively generate ions from compounds containing nitrogen or phosphorus. These devices detect broad ranges of substances, but do not identify them. The identity of the compounds detected must be inferred f the retention time.

The mass spectrometer can serve as a highly sensitive GC detector and possesses, in addition, the ability to generate highly characteristic mass from the compounds it is detecting. A special requirement of the mass spectrometer is that it requires a high vacuum in order to prevent the ion particles that it creates from interacting with other molecules or ions. Thi requires removal of the inert carrier gas and is easiest when there is a lo gas flow, such as occurs with capillary GC. The mass spectrometer, in tur provides good sensitivity for the small amounts of analyte that can be accommodated in capillary GC.

This detection process also begins by generating ions from the analyte molecules. This is usually done using electron impact ionization. The gas analyte is separated from the bulk of the carrier gas and introduced into ionization chamber, where it is bombarded by a stream of electrons. Elec impact can dislodge an electron from the analyte, creating a positively cl ion and frequently imparting sufficient energy to the ion to break it into If fragmentation occurs, conservation of charge requires that one of the resulting fragments be a positively charged ion. The fragments into which molecular ion breaks are characteristic of the molecule, as is the relative probability that a given fragment will carry the positive charge.

The mass spectrometer then uses electromagnetic filtering to direct only a specified mass-to-charge (m/z) ratio to a detector. Because most of th produced have a single positive charge, the observed peaks generally

correspond to the mass of the ions. The detector has sufficient electronic amplification that a single ion could theoretically be detected, accounting the high sensitivity of mass spectrometric detection. By rapidly scanning through a range of masses that are sequentially allowed to reach the det a mass spectrum may be generated. The mass spectrum records the mas the pieces produced by fragmentation of the parent ion, as well as the re frequency with which these fragments are produced and detected. The hi mass observed in the spectrum usually corresponds to the mass of intact ions generated from collisions that were not energetic enough to cause fragmentation.

Figure 7-7 shows the mass spectrum obtained from a gas chromatograph time when the trimethylsilyl derivative of the cocaine metabolite benzoylecgonine was emerging from the capillary column. The mass spec of any compound is highly distinctive and usually unique. The primary ex involves optical enantiomers, both of which have the same mass spectrur Toxicologically significant examples of enantiomers include *d* -methamphetamine, a drug of abuse, and *l* -methamphetamine, found in decongestant inhalers; and dextrorphan, the major metabolite of the cou suppressant dextromethorphan, and levorphan (levorphanol), a controlle substance.

To avoid the need to scan the full range of masses in a typical mass spec selected ion monitoring is often used. Here, the mass spectrometer is ty programmed to filter and detect only three of the larger and more chara peaks in the spectrum. In the case of trimethylsilyl benzoylecgonine (TMS BZE), the peaks at *m/z* 240, 256, and 361 are used. The concentration of BZE in the specimen is determined from the ratio of the peak height at *m* to a peak height at *m/z* 243 that results from a corresponding fragment o triply deuterium-labeled internal standard, d_3 -TMS-BZE (see Fig. 7-7). T specificity of the identification is verified by finding peaks at *m/z* 256 and 361, with peak height ratios to the peak at *m/z* 240 comparable to the ra seen with authentic TMS-BZE. The detection at the correct retention time substance producing all three peaks in the correct ratios produces an ex specific identification.

The high sensitivity and specificity afforded by gas chromatography/mass spectroscopy is being further extended by the related hybrid technique of chromatography/tandem mass spectroscopy, often abbreviated as LC/MS Initially restricted to research settings, the technique is now available in toxicology laboratories.[20] In LC/MS/MS, a tandem mass spectrometer is u the detector for liquid chromatography system. The initial ionization is do under conditions that do not promote fragmentation and yield primarily th intact parent ions of the molecules emerging from the HPLC. The first ma spectrometer is used to selectively filter only those ions with the molecul mass of the intact molecule of interest. As the selected ions exit the first spectrometer, they are allowed to collide with molecules of an inert gas. collisions cause the ions to break apart to create the mass spectrum that detected by the second mass spectrometer. The additional selection step provided by the first mass spectrometer greatly enhances specificity, and reduces background signal, enhancing sensitivity.

Quantitative Drug Measurements

When properly used to guide dosing adjustments, drug concentration measurements improve medical outcomes.[8] However, many therapeutic d measurements are made without an appropriate therapeutic question in m are drawn at inappropriate times. An essential requirement for interpreta drug concentrations is that the relationship between drug concentrations drug effects be known. Such knowledge is available for routinely monitore drugs and is often encapsulated in published ranges of therapeutic concentrations and toxic concentrations. Concentrations designated as â€œtoxicâ€• are usually higher than the upper end of the therapeutic ra and typically represent concentrations at which toxicity is acute and pote serious.

The relationships between toxic concentrations and effects cannot be systematically studied in humans and consequently are often incompletely defined. These relationships are largely inferred from data provided in ov case reports and case series. The measurement of drug concentrations in overdose cases where concentrationâ€“effect relationships are not well d

may contribute more to the management of future overdosed patients tha the management of the patient in whom the measurements were made.

For the toxicologist, drug concentrations are especially useful in two ways drugs whose toxicity is delayed or is clinically inapparent during the early phases of an overdose, drug concentrations may have substantial progno value. These concentrations

may be used to make decisions regarding the employment of antidotes or interventions to hasten drug elimination, such as hemodialysis or hemoperfusion. Specific concentrations can provide prognostic informatio facilitating anticipatory management.

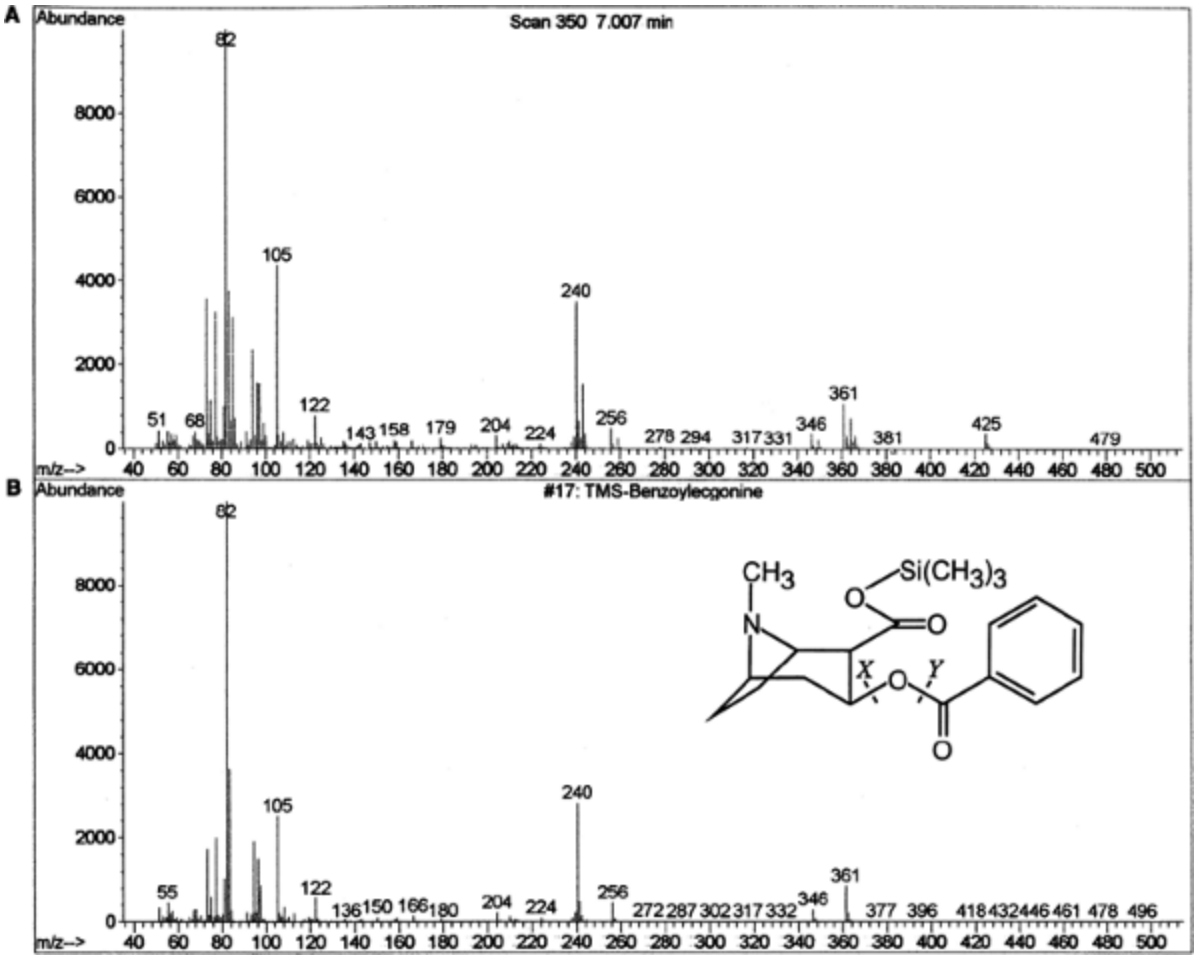

Figure 7-7. Mass spectrum of the trimethylsilyl derivative of benzoylecg (TMS-BZE). A. Mass spectrum of effluent from a GC column at the retent

time of TMS-BZE. The unfragmented parent ion of TMS-BZE is at *m/z* 361 two fragment peaks at *m/z* 243 and 259 result from fracture of the bonds and *Y* , respectively, in structure of TMS-BZE (inset in B). Additional pea *m/z* 243, 259 and 364 are derived from trideuterated TMS-BZE (d_3 -TMS- added as an internal standard. The mass spectrometer can identify and c TMS-BZE and d_3 -TMS-BZE independently of one another by measuring th heights of the peaks unique for each compound. The peak at *m/z* 425 is f coeluting contaminant. B. Mass spectrum of pure TMS-BZE.

Quantitative drug measurements are subject to various interferences, but are less problematic than in qualitative assays. Signals generated by cros reacting substances are weaker than those from the target analyte, and a relatively unlikely to lead to a false diagnosis of toxicity, particularly if th target analyte is absent. Such cross-reactivity can be exploited in some instances to provide confirmatory evidence of a poison for which no spec assay is immediately available. For example, the immunoassay finding of apparent subtoxic levels of tricyclic antidepressants can help confirm a diphenhydramine overdose, and the finding of a measurable digoxin concentration in an unexposed patient may suggest poisoning with other cardioactive steroids of plant or animal origin. Negative interferences are less frequent. Table 7-3 summarizes some of the more common interfere quantitative assays for drugs and poisons. Extensive information on interferences with laboratory tests, including toxicology tests, may be fou online at http://www.fxol.org .

Interferences in chromatographic methods usually result from the presenc other compounds with migration rates similar to the target analyte. Beca the migration rates are rarely exactly the same, the laboratory can usual recognize the presence of the interference as an overlapping peak when compounds are present. In such instances, the interference may impair accurate measurement of the drug concentration. When there is no target present, misidentification of the interfering peak as the target becomes r more likely, because a single peak is seen at

approximately the expected position. Because interferences in chromatog

methods are generally unique to a specific method, information about the interferences should be obtained by asking the laboratory.

Acetaminophen
Spectrochemical
Bilirubin, phenacetin, renal failure, salicylates

Immunoassay
Phenacetin
Carboxyhemoglobin
Spectrochemical
Fetal hemoglobin

TABLE 7-3. Interferences in Quantitative Assays for Xenobiotics

Drug measurements are unlike most other laboratory measurements in th concentrations are highly dependent on the timing of the measurement. Knowledge of a drug's pharmacokinetics can substantially enhance the ab draw meaningful conclusions from a measured concentration. Some drugs their pharmacokinetic behavior at very high concentrations. These change pharmacokinetics may be predictable from the mechanisms of drug clearа and the extent of binding to plasma proteins and to tissues (Chap. 9).

Knowledge of the relationship between drug concentrations and drug effe pharmacodynamics, is also important. Drug effects depend on local concentrations at the site of action, typically at cell membranes or intrac locations. Serum or plasma concentrations can be correlated with effects when these concentrations are in equilibrium with concentrations at the s action. Table 7-4 lists several circumstances that may alter the normal ra drug concentrations measured in serum or plasma to concentrations found the site of action, thereby altering the usual concentrationâ€“effect relationships. During the absorption and distribution phases, the concent ratio will be higher than its equilibrium value, yet often the only drug concentration measured after an acute overdose is one obtained while absorption and distribution are still ongoing. This effect may explain som observations of apparent poor correlation between measured concentrati and toxic effects.

Measurement during absorption phase
Underestimation of eventual effects
Sustained-release preparations; large ingestions of poorly soluble drugs salicylates); drugs that slow gastric emptying (eg, tricyclic antidepressar
Measurement during distribution phase
Overestimation of effects

Lithium, digoxin, tricyclic antidepressants	Decreased binding to proteins	Underestimation of effects
Phenytoin	Saturation of binding proteins	Underestimation of effects
Salicylate, valproic acid	Binding by antidote	Variable
Digoxin/digoxin immune Fab		

Factor Effect Examples

TABLE 7-4. Factors that May Alter Concentrationâ€”Effect Relationships

For drugs that bind significantly to plasma proteins, it is the concentration drug that is not bound to proteins (the free-drug concentration) that is in equilibrium with concentrations at the site of action. For most drugs at therapeutic levels, the free-drug concentration is an approximately const percentage of the total drug concentration. The total concentration is wha usually measured in the laboratory. Under these conditions, the ratio of concentration to active site concentration is approximately constant, and reasonable correlation between total concentration and drug effects can b expected.

Increasing the percentage of drug in free form results in stronger effects would be predicted from the total drug concentration. The free fraction of phenytoin may increase from its usual value of 10% when the number of albumin binding sites are decreased, either by hypoalbuminemia or by occupancy of the sites by other drugs, such as valproic acid, or by pheny metabolites when the latter accumulate in patients with renal failure. Whe protein binding sites become filled, as occurs with higher concentrations salicylate or valproate, any additional drug beyond the saturating concer will be 100% in free form, thereby increasing the average percentage of

free form.

A major change in the free fraction occurs after treatment of digoxin toxi with digoxin immune Fab, when the free digoxin concentration falls from approximately 75% of the total concentration to less than 1% as a conse of digoxin binding by the antidigoxin antibody fragments. At the same tin there is extensive redistribution of digoxin from tissues to plasma, leading substantial increases in total digoxin concentration. This situation may be further complicated by complex digoxin immune Fab interference in many digoxin immunoassays.

Measurement of free-drug concentrations can clarify such situations.[18] As for free phenytoin are available in many laboratories. Assays for other fr drug concentrations may require special arrangements. Availability and expected turnaround time can be provided by the laboratory. For patients treated with digoxin immune Fab, newer immunoassays that use antibodi attached to microparticles or glass fibers give results that can be used to upper bound on free-digoxin concentrations and thereby verify adequacy treatment.[27]

Toxicology Screening

A test unique to the toxicology laboratory is the toxicology screen, or â€ screen.â€• Depending on the laboratory, this term may refer to a single testing methodology with the ability to detect multiple drugs, such as a t layer or gas chromatography; or it may refer to a panel of individual test as a drug-abuse screen; or it may be a combination of broad-spectrum an individual tests. The widespread use of the term â€œtox screenâ€• is unfortunate, because this wrongly implies for many physicians the availa of a test that can exclude poisoning as a diagnosis. Unfortunately, no suc exists.

There are more toxic substances in the world than there are named disea However, a relatively limited number of substances account for most seri poisonings. As a result, in one study a comprehensive toxicology screenin

protocol using multiple detection methods applied to both serum and urin specimens was able to identify more than 98% of implicated substances.[1] suggests that a comprehensive â€œtox screenâ€• can exclude poisoning substantial degree of reliability. However, this study was done some time when the rate of introduction of new drugs was much slower than is curr the case. Many newer therapeutic drugs may not be identified even by â€œcomprehensiveâ€• screens currently in use.[34] Moreover, comprehen toxicology screens typically do not detect elemental ions, including brom lithium, iron, lead, and other heavy metals. Nor do they necessarily detec substances that are toxic at extremely low concentrations, such as digoxi fentanyl. Table 7-5 lists a number of substances encountered in emergen toxicology that may not be detected by routine toxicology screening.

It should be apparent that a negative toxicology screen cannot exclude poisoning. It is equally true that a positive finding does not necessarily c a diagnosis of poisoning. For assays that detect only the presence of a dr is not possible to distinguish benign or therapeutic levels from toxic ones Quantitative tests may falsely suggest toxicity when drug concentrations measured during the drug's distribution phase, which may extend for sev hours with drugs such as digoxin and lithium. Moreover, the phenomenon tolerance may allow chronic drug users to be relatively unaffected by concentrations that would be quite toxic to a nonusing individual. Becaus comprehensive drug screens may differ widely between institutions, and patterns of exposure also show substantial regional variation, there is lin ability to draw meaningful conclusions from any study of the sensitivity a specificity of such screens for detecting or excluding poisoning.

TABLE 7-5. Substances of Concern that are Often Not Detected Toxicology Screens

The predictive power of the result of a toxicology screen will depend on a number of factors, including the likelihood of poisoning prior to receiving test results (the prior probability or the prevalence), the range of substa effectively detected, and the frequency of false-positive results. It should noted that false-positive and false-negative results may be either analytic clinical in origin. A clinical false positive occurs when a drug is detected t not contributing to the medical problem; for example, a therapeutic amou acetaminophen. A clinical false negative may occur when the wrong test i

ordered; for example, a screen for drugs of abuse for a patient with acetaminophen poisoning.

Table 7-6 explores the positive and negative predictive values of two hypothetical toxicology screens. The sensitivity of 98% and specificity of in one scenario reflect the sensitivity of a broadly comprehensive toxicol screen[13] and an achievable false-positive rate of 2%. The second scenari a sensitivity of only 80% and a specificity of 95% and represents plausibl mediocre performance. Three sets of prior probabilities are considered: 1 50%, and 95%. A prior probability of 10% might be seen if screening we indiscriminately applied to all patients in an emergency department, or in scenario where drugs were being excluded as a secondary cause of lethar an older patient who fell and struck his head. Both screens do well at ex drugs when their presence is already unlikely. However, a positive findin either does not yield a fully convincing diagnosis of drug presence. A pric probability of 50% falls into the range of prevalence actually observed in patients for whom toxicology screens were ordered (see below). In this scenario of maximum uncertainty, both screens do a good job of diagnos poisoning, but drug exclusion by the mediocre screen will be incorrect in 1 instances.

A prior probability of 95% represents testing where the clinical presentat strongly suggests poisoning, as in the investigation of lethargy in a know regular drug user. While positive findings in either screen raise the proba to almost complete certainty, negative findings from the excellent screen incorrect 1 time out of 4, whereas negative results from the mediocre sc are wrong 4 times out of 5. Overall, toxicology screens have better positi predictive value than negative predictive value. This observation

should give pause to those who primarily order toxicology screens â€œto out poisoning.â€•

TABLE 7-6. Positive and Negative Predictive Values of Toxicolo Screens

Although only approximately 3% of laboratories offer comprehensive tox screening,[4] most laboratories will offer some sort of testing in response t request for a toxicology screen. This may consist of a panel of immunoas for drugs of abuse or a urine TLC screen, or it may result in a compreher screening test performed at a reference laboratory. Other laboratories ma offer a focused, rather than a comprehensive, screening panel. Larger laboratories may have several types of â€œtox screensâ€• available for different situations. Among laboratories that do not limit their tests exclu to commercially available methods, it is likely that no two will have exact same menu of drugs that can be reliably detected. A survey of emergency physicians found that more than 75% were not fully aware of the range o drugs detected, and not detected, by their laboratory's toxicology screen. majority believed that the screen was more comprehensive than it actual was.[9]

Comprehensive toxicology screens typically require several hours of fairly intense labor, particularly if confirmatory testing is included. Given the t toward increasing automation and decreasing personnel in clinical labora it is relevant to ask what benefits may be derived from such testing. Stu show that comprehensive toxicologic screening has the potential to provi significant information, with utility varying with the indication for testing. prevalence of positive results has ranged from 34â€“86% of specimens submitted for testing. When drug exposure, as predicted from the history

physical, was compared with screening results, clinically unsuspected substances were found in 7â€“48% of the cases and clinically suspected substances were not found in 9â€“25%.[12,13,17,25,26] However, limit utility is suggested by studies showing that the results of comprehensive screening affect management in less than 15% of cases,[25] and in many instances, in less than 5% of cases.[12,17,23,26,32]

One reason for a limited effect on management is the substantial time de before results of comprehensive screening are available. Generally, more 3 hours are required for the report of a negative result and an even long is required for a positive finding. By this time, most consequential manag decisions have been implemented. Another possible explanation for scree limited utility is that comprehensive screening is largely available only in medical centers, where consultation from a medical toxicologist is more l to be available. Such experts may be more able to make correct diagnose initiate appropriate management relying on clinical findings alone.

Some laboratories address the issue of providing useful information in a fashion through the use of focused, rather than comprehensive, screening protocols.[33] These screens include drugs locally prevalent in overdose ca and/or drugs for which there are specific interventions. The goal is typica provide results within 1 hour, including quantitation of those substances management decisions require concentration data. A combination of serur urine tests is used. Table 7-7 suggests the possible composition of a focu screen. Such a screen should be supplemented with additional specific te when indicated.

Several recently introduced point-of-care devices are capable of rapidly screening urine for the presence of drugs of abuse, as well as tricyclic antidepressants. Results are typically available in 20â€“30 minutes. In a study of one such device, diagnosis was believed to have been aided in 8 cases and clinical management was changed in 25%.[2] Additional studies needed to ascertain the utility of point-of-care drug screening in emerge toxicology.

Serum Tests Urine Tests

TABLE 7-7. Components of a Focused Toxicology Screen

A useful alternative to the toxicology screen is the *toxicology hold* . This set of serum and urine specimens drawn at the time of presentation, whe

concentrations are likely to be near maximum levels, and initially held refrigerated or frozen without testing. A maxim for management of the poisoned patient is that an evaluation is not complete until it has been re over time. In many instances, observation will clarify the diagnosis, allow toxicology screening to be dispensed with or replaced by a specific assay. the other hand, the specimens remain available for subsequent testing if diagnosis remains unclear, or if there are unexplained findings. Most laboratories will hold such specimens for several days, if necessary.

Bedside Toxicology Tests

Testing at the bedside is attractive for emergency toxicology. When a sp diagnosis is being considered, a bedside test can provide confirmation or exclusion quickly, and often inexpensively,[21] enabling appropriate manag to be initiated. This benefit must be balanced against the generally poore sensitivity and specificity of bedside tests in comparison with testing in th clinical laboratory, the lack of quantitative information for most tests, the to perform testing in accord with regulatory requirements (see below), an erosion of the time advantage when multiple bedside tests are done on th same patient.

Table 7-8 lists some tests that can be conveniently performed at the bed Spot tests can also be done at the bedside, although many spot tests em hazardous reagents that may not be suitable for use in many bedside se A major problem with bedside tests that are not done with commercial de is that these are considered â€œhighly complexâ€• tests under federal regulations, although they may be very simple to perform. This classifica results from the fact that they are not subject to the validation processes required for FDA-approved commercial devices. Meeting the regulations requires significant initial and ongoing investment of time. The Meixner t (for amatoxins in mushrooms) and breath analysis (for ethanol or carbon monoxide) are exempted

from these regulations, because they do not involve human specimens (s Regulatory Issues Affecting Toxicology Testing below).

Alcohol dehydrogenase
Saliva
Ethanol
Other alcohols may interfere. Some tests only give concentration ranges.
Breath analysis
Breath
Carbon monoxide
Ethanol may interfere.
Breath analysis

Amatoxins
Paper must contain lignin (use filter paper, which is lignin-free, as negati control). Requires strong acid. Some false positives and false negatives.
Microparticle agglutination
Urine
Drugs of abuse
KIMS variant with visual endpoint. Separate test for each drug.
Microparticle capture
Urine
Drugs of abuse
Single device detects one or more of the drugs listed in Table 7-10 , in a variety of menus available from multiple manufacturers. Some multitest include tricyclic antidepressants. Higher false-positive and false-negative than for clinical laboratory testing.
Oxalate crystals

Urine			
Ethylene glycol			
Metabolic end-product. Not detected during early stages. Nonspecific.			

Test	Substrate	Drug or Poison	Comments

TABLE 7-8. Bedside Toxicology Tests

Two studies compared results obtained with point-of-care drug screening devices to a gold standard of gas chromatography-mass spectrometry (G using cutoff values recommended for federal workplace testing. Both stu had disproportionately large proportions of specimens (one-half to two-t with concentrations close to the cutoff value. In these samples, false-pos and false-negative rates ranged from 0â€“50%, depending on both the d and the drug.[3,15] In actual testing practice, specimens with concentrati near the cutoff concentration should be much less frequent, with many specimens having drug concentrations that are either quite high or zero. extensive study using a more representative range of urine drug concent observed higher rates of correct results, but performance remained inferi that of immunoassays conducted with laboratory instrumentation[10].

A clinical and methodologic issue with bedside drug-screening assays is v positive results will subsequently be subjected to confirmatory testing. Th extra investment of labor needed to submit a specimen tends to discoura laboratory confirmation. The argument for confirmation is that this is an accepted standard of practice for screening assays that have lower false-positive rates than the point-of-care devices (see Special Considerations Drug Abuse Screening Tests below). The counterargument is that if testin limited to populations with a high prior probability of drug exposure, the predictive value of a positive test is high. The NACB guidelines recommer against routine confirmation of positive results of drug-screening immun done solely for medical reasons, but suggest that all such unconfirmed p results be reported as being â€œpresumptive.â€•[35]

Regulatory Issues Affecting Toxicology

Testing

Since 1992, medical laboratory testing has been governed by federal regulations (42 CFR part 405 et seq) issued under the authority of the C Laboratory Improvement Amendments of 1988 (often referred to as CLIA- simply CLIA). These regulations apply to all laboratory testing of human specimens for medical purposes, regardless of site. They include the univ requirement for possession of an appropriate certificate to perform even simplest of tests. The remaining requirements depend on the complexity test. These regulations become important to the emergency toxicologist whenever testing is done at the bedside, whether using spot tests, or commercial point-of-care devices such as dipsticks, glucose meters, or u drug-screening devices.

The regulations divide testing into three categories: waived, moderate complexity, and high complexity. Waived tests include a number of speci designated simple tests, including urine dipsticks, urine pregnancy tests, drug-screening immunoassay devices, and blood glucose measurements w hand-held monitor. The only legal requirement for performing waived tes are the possession of an appropriate CLIA certificate (certificate of waiver higher) and performance of the test in accordance with the manufacturer instructions.

There are substantial additional requirements for both moderate and high complex testing, most of which simply represent good laboratory practice 7-9 lists the most significant of these requirements. Most assays perform with commercial kits or devices are classified as belonging to the modera complex category. All tests not specifically classified as waived or moder complex are considered highly complex. This includes essentially all noncommercial tests, including spot tests, because the testing materials not been subject to review and approval by the Food and Drug Administr

These regulations have had a substantial impact in all areas of laboratory testing. Some of the most significant effects have been on bedside testin including spot tests and point-of-care devices. While clinical laboratories been following most required practices prior to the implementation of the

regulations, this was usually not the case for testing done at other sites. institutions have now established point-of-care testing programs to facili compliance with the regulations, as well as with additional requirements accrediting agencies, such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Any

toxicologic or other testing done at the point-of-care should be set up in consultation with the institutional program. Often, all point-of-care testing done under a CLIA certificate held by the program. There is frequently a of-care testing coordinator who may make recommendations or personall assist in efficiently addressing the assorted requirements.

Waived Tests
- Certificate of Waiver
- Follow manufacturer's instructions exactly

Moderate-Complexity Tests
- CLIA certificate
- Record keeping
- Test method verification
- Written procedures
- Qualified lab director
- Personnel educational requirements
- Documented training of all testing personnel
- Annual competency testing of all personnel
- Two levels of controls daily
- Participate in proficiency testing every 4 months
- Verify calibration and reportable range at least every 6 months
- Quality assessment program
- Biennial inspection and certification

High-Complexity Tests
- All moderate-complexity requirements *plus*
- Qualified on-site supervisor *or*
- Daily review of all results by qualified supervisor

This table lists only the most significant requirements of the regulations implementing the Clinical Laboratory Improvement Amendments of 1988

(CLIA). These regulations continue to evolve. Regulatory agencies such as Joint Commission on Accreditation of Healthcare Organizations (JCAHO) r have additional requirements. Consultation with the clinical laboratory or an institutional point-of-care coordinator is recommended prior to impler any testing.

TABLE 7-9. Major CLIA Requirements for Laboratory Testing

Breath tests for ethanol and carbon monoxide and the Meixner test[1] for amatoxins in mushrooms are not regulated by CLIA, because no human specimen is involved. However, such testing may be covered by state law by institutional or accrediting agency policies. The NACB guidelines recor that breath testing be overseen by the clinical laboratory and meet the s standards as other point-of-care testing.[35]

Personnel unaccustomed to quality control and assessment practices may the CLIA requirements initially burdensome. Nonetheless, compliance is important. Following these practices may lead to a 3-fold reduction in in results,[31] improving the quality of care provided to the patient. Moreover noncompliant testing is illegal under federal law and also may be illegal u state law. Any untoward outcome associated with illegal testing creates a risk management liability for both the institution and the individual. Additionally, billing for any testing that is not CLIA-compliant may be considered fraudulent.

Another area where the CLIA regulations have impacted toxicology testing the provision of infrequently requested tests. Meeting regulatory require involves a substantial labor investment even when few patient specimens being tested. Mounting pressures to reduce laboratory costs make it less that laboratories will continue to maintain such assays.

Another important regulation, although not part of CLIA regulations, requ that the medical reason for ordering a test be provided with the order. F regulations require that the ordering physician provide the diagnosis that establishes the medical necessity for the test, either by name or by diagn code (CPT code). Laboratories may not use a â€œbest guessâ€• to assig

codes to undocumented test requests.

Special Considerations for Drug-Abuse Screening Tests

Testing for drugs of abuse is a significant component of medical toxicolog testing. Initial testing is usually done with a screening immunoassay. Pos results may be confirmed by retesting using a nonimmunologic test, but t frequently not done. (Drug-abuse testing for nonmedical reasons is gene considered to be forensic testing, and confirmation is considered mandatc such circumstances.) Drug-screening immunoassays were initially develop use in workplace drug-screening programs and are not always optimal for medical purposes, but their wide availability in inexpensive, easy-to-use formats led to their nearly universal adoption in clinical laboratories. Grov the market for medical drug screening has led to the development of poi care tests specifically for medical use, but these devices largely retain th deficiencies of their predecessors.

The most commonly tested-for drugs are amphetamines, cannabinoids, c opiates, and phencyclidine. These are often referred to as the NIDA 5, be they are the five drugs that were recommended in 1988 by the National Institute on Drug Abuse (NIDA) for drug screening of federal employees. (Responsibility for recommendations for federal drug testing now lies with Substance Abuse and Mental Health Services Administration, or SAMHSA.) Drug-screening immunoassays are also frequently done for barbiturates a benzodiazepines, and less frequently for methadone and propoxyphene. I screening devices intended primarily for medical use may also include a t tricyclic antidepressants. Table 7-10 lists some of the general characteris these tests. There are also commercial urine immunoassays for lysergic a diethylamide (LSD), methaqualone, methylenedioxymethamphetamine (â€œecstasyâ€•), and oxycodone. Drug-screening immunoassays are av in a number of formats, which may differ in performance. All are designec used with urine specimens, because these can be obtained noninvasively generally have higher concentrations than serum, enhancing the sensitivit the test.

The drug-screening tests for cannabinoids and cocaine are directed towar inactive drug metabolites rather than the active parent compound. The p drugs, cocaine and tetrahydrocannabinol, are both short-lived and persist more than a few hours after use. The metabolites remain present substa longer. Detection of the metabolites increases the ability to detect any re drug use. However, this limits the utility of the assays for determining w a patient is currently under the influence of the drug. Because the metab are rapidly formed, a negative test generally excludes intoxication, but a positive test indicates only past use, not current intoxication.

To increase sensitivity for detection of less-recent drug use, substrates o than urine have been employed for drug screening, including hair and meconium. The latter is used to document intrauterine drug exposure (Ch). SAMHSA is developing regulations governing the use of hair, saliva, an sweat specimens for federal workplace testing. This can be expected to h the side

effect of increasing the availability of clinical testing using these substrat However, testing performed on hair and sweat are unlikely to offer adva over testing of serum and urine for the management of toxicologic emergencies.

Amphetamines
1000 ng/mL
500 ng/mL
1â€“2 d (2â€“4 d)
Decongestants and ephedrine may give false positives; MDA and MDMA a variably detected. Confirmation of methamphetamine requires detection o >500 ng/mL with >200 ng/mL of metabolite, amphetamine.
Barbiturates
200 ng/mL secobarbital

2â€“4 d
Phenobarbital may be detected for up to 4 weeks.
Benzodiazepines

100â€“300 ng/mL

1â€“30 d
Benzodiazepines vary in reactivity and potency. Hydrolysis of glucuronide increases sensitivity. False positives with oxaprozin.
Cannabinoids
50 ng/mL;
20 ng/mL;
25 ng/mL;
100 ng/mL THCA
15 ng/mL THCA
1â€“3 d (>1 mo)
Screening assays detect inactive and active cannabinoids; confirmatory a detects inactive metabolite tetrahydrocannabinoic acid (THCA). Duration positivity highly dependent on screening assay detection limits.
Cocaine
300 ng/mL BZE
150 ng/mL BZE
2 d (1 wk)
Screening and confirmatory assays detect inactive metabolite benzoylecg (BZE). False positives unlikely.
Opiates
2000 ng/mL;
300 ng/mL
2000 ng/mL;
morphine or codeine
1â€“2 d;
2â€“4 d (<1 wk)
>10 ng/mL of heroin metabolite 6-monoacetyl morphine is also confirma Semisynthetic opiates derived from morphine show variable cross-reactiv Fully synthetic opioids (eg, fentanyl, meperidine, methadone, propoxyphe tramadol) have minimal cross-reactivity.
Methadone
300 ng/mL

1â€“4 d
Doxylamine may cross-react.
Phencyclidine
25 ng/mL
25 ng/mL
4â€“7 d (>1 mo)
Dextromethorphan and ketamine diphenhydramine may cross-react.
Propoxyphene
300 ng/mL

3â€“10 d
Duration of positivity depends on cross-reactivity of metabolite norpropoxyphene.

[a] Performance characteristics vary with manufacturer and may change ov time. For most accurate information, consult the package insert of the cu lot or contact the manufacturer.

[b] SAMHSA recommendations[7] are shown as first value for amphetamines, cannabinoids, cocaine, opiates, and phencyclidine immunoassays, and as values for confirmatory assays. Other commercial immunoassay cutoffs ar listed. Other GC/MS cutoffs are set by the laboratory.

[c] Values are after typical use; values in parentheses are after heavy or prolonged use.

Drug/Class	Detection Limits[b]	Confirmation Limits[b]	Detection Interval[c]	Comr

TABLE 7-10. Performance Characteristics of Common Drug-Abu Screening Immunoassays [a]

The stigma attached to a positive test for an abused drug requires that s care be exercised in performing and reporting the tests. To protect citize rights, many states have legislated specific requirements for workplace d screening. In some states, the requirements apply only to screening in th

workplace, exempting testing for medical purposes. Laws in other states apply to all drug screening. Although they are not always legally required workplace drug-screening practices have been widely applied to all drug screening.

The use of specific cutoff concentrations is nearly universal. Test results considered positive only when the concentration of drugs in the specimen exceeds a predetermined threshold. This threshold should be set sufficien high that false-positive results as a consequence of analytic variability or because cross-reactivity are extremely infrequent. They should also be lo enough to consistently give a positive result in persons who are using dr Cutoff concentrations used vary with the drug or drug class under invest In some drug-screening immunoassays, the laboratory has the option of selecting from several cutoff values.

The use of cutoff values sometimes creates confusion when a patient who known to have recently used a drug has a negative result reported on a screen. In such instances, the drug is usually present, but at a concentra below the cutoff value. Another potential problem occurs when a patient's screening test is positive after previously having become negative. This i usually interpreted as indicating renewed drug use, but it may be an arti Urine drug concentrations are directly proportional to the serum drug concentrations, but inversely proportional to the rate of urine production. rate of the urine flow may vary up to 100-fold, with a resulting possible fold change in the urine drug concentration. This effect is often exploited individuals who drink large quantities of water prior to taking a urine dru in order to increase urine flow and decrease urine drug concentrations. In contrast, a decrease in the rate of urine production can result in a positiv following a negative one, despite no new drug exposure. A similar effect be produced by changes in urine pH. Drugs containing a basic nitrogen m demonstrate ionic trapping, with increasing concentrations as urine pH decreases. Similarly, excretion of the phenobarbital anion may increase w increasing pH. (This phenomenon is medically exploited by alkalinizing th to increase phenobarbital excretion.)

Another widely used practice is the confirmation of positive screening res using an analytical methodology different from that used in the screen, su an immunoassay screen followed by chromatographic confirmation. The possibility of simultaneous false-positive results by two distinct methods quite low. Clinical laboratories may differ in their policies with regard to confirmatory testing. Some may confirm all positive results from screenir immunoassays, whereas others may not provide any confirmatory testing unless it is explicitly requested.

The most common confirmatory method is GC/MS. The high specificity af by the combination of the retention time and the mass spectrum makes f positive results extremely unlikely. GC/MS also has greater sensitivity tha screening immunoassays, minimizing failed confirmations because of drug concentrations below the sensitivity of the confirmatory assay. Some sta require GC/MS confirmation for workplace drug screening and it may be required for all drug screening.

If confirmation by GC/MS is not required, a common practice is to confirm screening immunoassays by TLC and vice versa. Positive findings by both methods provide a high degree of specificity. A disadvantage of the appro the low sensitivity of TLC relative to immunoassays. True positive immunoassays may fail to be confirmed, leading to false-negative final r Some laboratories accept this, because false negatives are unlikely in the presence of serious overdoses. Other laboratories may retest TLC-negativ specimens with a more sensitive method, such as GC/MS. Sometimes, confirmatory testing may be done on positive results for illicit drugs, but legal drugs such as barbiturates, benzodiazepines, and ethanol.

Immunoassay results can generally be obtained within 1 hour. Confirmat testing usually requires at least several hours. This can create a problem confirmation of initial immunoassay results is considered mandatory. Mos laboratories will provide a verbal report of a presumptive positive result t facilitate medical management, but may not enter the result into a perma record, such as the laboratory computer, until after confirmation has bee completed.

The importance of confirmatory testing in workplace drug screening follov

from the relatively low prevalence of positive results. A screening test wi sensitivity and specificity of 98% will produce 2 false-positive results per subjects tested. A workforce with a 2% prevalence of illicit drug use will true-positive results per 100 subjects. The predictive value of a positive will only be 50% (2 of 4). This is an unacceptable level of certainty for r that might be used to terminate employment. While the prevalence of re drug use in the workforce is low, rates of positivity of 34â€“86% have be reported for selective drug screening of emergency department populatio Given a 50% prevalence of recent drug use, the positive predictive value same screening test rises to 98% (see Table 7-6).

A high prior probability of drug positivity for patients tested in medical s results in a very high posterior probability after a positive test. Confirma testing is much less critical in such a setting, particularly because a posit finding infrequently has consequences that extend beyond the medical management of the patient. An exception may occur where results of tes performed on motor vehicle crash victims can be subsequently subpoenae evidence in legal proceedings.

One workplace drug screening practice that is not widely followed in med toxicology is maintenance of a chain of custody. Employers generally insis chain of custody for workplace testing because actions taken in response positive result may be contested in court. A chain of custody provides re that are readily defended in court. Laboratories providing testing for med purposes rarely keep a chain of custody because it is quite expensive and not benefit the patient. Additionally, the medical personnel responsible fo obtaining the specimens are rarely trained in collection requirements for chain of custody.

The lack of chain of custody can create problems when persons with no r complaints present at an emergency department or other medical facility requesting the performance of a drug-screening test. Unless the facility is prepared to initiate the chain of custody at the time of specimen collectio the laboratory is prepared to maintain it, such persons should be redirect a site maintained by a commercial laboratory that routinely performs wo drug testing and has appropriate procedures in place. Many laboratories

had the experience of unwittingly performing drug-abuse testing for non purposes, because the reason for the testing is not always included on th requisition. To avoid liability issues, the laboratory may choose to include disclaimer with every drug-screening report indicating that the results are purposes of medical management only.

Another practice common in workplace testing but rare in medical labora is testing for specimen validity. It is common for individuals to try to â€œbeatâ€• a workplace drug test through a variety of means, including diluting the specimen (either physiologically by water ingestion or by dire addition of water to the specimen), substituting â€œcleanâ€• urine obta from another individual, or adding various substances that will either des drugs in the specimen or will inactivate the enzymes and/or antibodies us the screening immunoassays. Such substances include acids, bases, oxid agents (bleach, nitrite, peroxide, peroxidase, iodine, chromate), glutaraldehyde, pyridine, detergents, and soap. SAMHSA requires validity testing for all specimens in federal workplace testing, including measurem urinary pH, specific gravity, and creatinine concentration, as well as tests the presence of adulterants.[7] Dipsticks are available that detect the most common adulterants. However, manipulation or adulteration is rarely a p in medical specimens, and clinical laboratories infrequently provide validi testing.

Performance Characteristics of Common Dr Screening Assays

Medical toxicologists, toxicology laboratory directors, and practicing phys may frequently get questions about the significance of drug-screening as particularly about the causes of false-positive results. Often these questi come from an individual who recently had a positive test. Table 7-10 summarizes drug-screening test performance characteristics, which are discussed in more detail below.

Immunoassays for opiates are directed toward morphine but have good c reactivity with many (but not all) structurally similar natural and semisyr

opiates. The extent of cross-reactivity may vary between manufacturers. example, oxycodone exhibits approximately 30% cross-reactivity relative morphine in a fluorescence polarization immunoassay, but less than 5% reactivity in a number of other screening assays.[19] A failure to appreciate poor detection of oxycodone can create problems when opiate-screening immunoassays are used to confirm that patients receiving prescription oxycodone for chronic pain are indeed

taking it, rather than diverting it for illicit sale. If a low cross-reactivity a used, a patient taking oxycodone as prescribed might have a negative re whereas another patient who was selling the oxycodone and using the pr to buy heroin would have a positive result. To address this problem, a ne assay specific for oxycodone has been introduced. This assay is sensitive therapeutic amounts of oxycodone, but relatively insensitive to other opi

Synthetic opioids such as dextromethorphan, fentanyl, meperidine, meth propoxyphene, and tramadol show little or no cross-reactivity in opiate immunoassays. Urine immunoassays specific for methadone and propoxy are available. Given the increasing importance of buprenorphine in maint therapy for opiate dependency, it is worth noting that the combination of potency and low cross-reactivity means that buprenorphine will generally detected by opiate immunoassays.

A positive immunoassay result may reflect multiple contributions from va opiates and opiate metabolites. Concentrations of morphine glucuronide ir urine may be up to 10-fold higher than the concentrations of unchanged morphine and can contribute substantially to positive results. A positive result following use of heroin (diacetylmorphine) is primarily a result of t morphine and morphine glucuronide that result from heroin metabolism. Distinguishing heroin from other opiates requires detection of 6-monoacetylmorphine, the heroin-specific metabolite. Small amounts of th metabolite may be detected by GC/MS for up to 24 hours after use. A ha of 5 minutes means that unchanged heroin can only be found in the urine sampling is done immediately after use.

The duration of positivity of an opiate immunoassay after last use depend

the identity and amount of the opiate used, the specific immunoassay, th cutoff value, and the pharmacokinetics of the individual. Currently, SAMH recommends a cutoff equivalent to 2000 ng/mL of morphine for workplac screening, because poppy seeds can rarely produce transient positive res with the previously recommended cutoff of 300 ng/mL. Most toxicology laboratories continue to use a 300 ng/mL cutoff.

Drug-screening assays for â€œcocaineâ€• are actually assays for the in cocaine metabolite benzoylecgonine, which is eliminated more slowly tha cocaine. This extends the duration of positivity after last use from a few to 2 days, and sometimes to a week or longer after prolonged heavy use. Because the assay is directed toward an inactive metabolite, positive resu not equate with intoxication but merely indicate recent exposure. The ass highly specific for benzoylecgonine, and false-positive results are extrem uncommon.

Immunoassays for cannabinoids are also directed toward an inactive metabolite, in this case tetrahydrocannabinoic acid. These immunoassays exhibit cross-reactivity with other cannabinoids, but little else. Because cannabinoids are structurally unique and occur only in plants of the genus *Cannabis* , false positives are quite uncommon. It is unusual, although p to become exposed to sufficient â€œsecond-handâ€• or sidestream mar smoke to develop a positive urine test.[5] Legal hemp products include fibe and seedcake derived from *Cannabis* varieties with low levels of cannabi Although hemp food products contain insufficient amounts of tetrahydrocannabinol to produce psychoactive effects, their ingestion may urinary cannabinoid concentrations above screening thresholds.[6]

Interpretation of a positive result for cannabinoids can be problematic. U may be positive for up to 3 days after occasional recreational use. Howev with heavy or prolonged use, there may be significant accumulation of cannabinoids in adipose tissue. These stored cannabinoids are slowly rele into the bloodstream and can produce positive findings for a month or mo Consequently, little can be concluded from a positive finding in terms of intoxication. Because positive results in the absence of intoxication are v common, and because tetrahydrocannabinol rarely is responsible for seri

acute toxicity, NACB guidelines recommend against its routine inclusion in screening for patients with acute symptoms.[35]

Amphetamine-screening tests have the greatest problems with false-positi results. A number of structurally related compounds may have significant reactivity, including nonprescription decongestants such as pseudoephedri well as L-ephedrine, which is found in a variety of herbal preparations. Th cross-reactivity is beneficial from the point of view of the medical toxicol because all of these compounds may produce serious stimulant toxicity. B is problematic in drug-abuse screening because of the widespread legitim use of cold medications. Assays with greater selectivity for amphetamine methamphetamine have been developed. Although these assays produce false-positive results caused by decongestant cross-reactivity, they are a less sensitive for the detection of other abused amphetamine-like compo including methylenedioxyamphetamine (MDA), methylenedioxymethamphetamine (MDMA, Ecstasy), and phentermine. C reactivity patterns vary from assay to assay.[19] Manufacturer's literature be consulted for specific details.

Testing for benzodiazepines is complicated by the wide array of benzodiazepines that differ substantially in their potency, cross-reactivity, half-lives. There are also substantial differences in the detection patterns various immunoassays.[19] This heterogeneity complicates the interpretatio benzodiazepine-screening assays. Screening results may be positive in p using low therapeutic doses of diazepam, but negative after an overdose highly potent benzodiazepine such as clonazepam. To improve breadth of detection, some assays employ antibodies to oxazepam, which is a metal of a number of different benzodiazepines. These assays may have poor sensitivity to benzodiazepines that are not metabolized to oxazepam. Fals negative results may occur for benzodiazepines that are excreted in the almost entirely as glucuronides that have poor cross-reactivity with antib directed toward an unmodified benzodiazepine. This is one reason for the detectability of lorazepam in some screening assays. The latter situation led to the recommendation that specimens be treated with Î²-glucuronida prior to analysis.[22] Some assays now include Î²-glucuronidase in the reag mixture, or employ antibodies directed toward glucuronidated metabolites

frequency of false negative results, as well as the fact that benzodiazepin relatively benign in overdose, have led the NACB guidelines to withhold recommendation for routine screening of urine for benzodiazepines until problems with the immunoassays are addressed.[35]

Barbiturates are comparable to benzodiazepines in heterogeneity of pote cross-reactivity, and half-lives, although the differences are less substan Specific assays for serum phenobarbital can often help to clarify the significance of a positive barbiturate screen.

Some phencyclidine (PCP) screening assays may give positive results with dextromethorphan, ketamine or diphenhydramine, but only when these a used in amounts well above usual therapeutic quantities. A positive result serve as a clue to a possible overdose with either of these substances.

Measurement of Ethanol Concentrations

Measuring ethanol may have ramifications beyond guiding medical management, particularly when performed on crash victims. Although tes for ethanol in urine is common in workplace drug screening, most testing clinical laboratories is done using serum or plasma. Concentrations are m commonly measured enzymatically using alcohol dehydrogenase. In large toxicology laboratories, ethanol measurements are often done using a GC that can also distinguish and measure isopropanol and methanol, as well isopropanol metabolite acetone. Alcohols with lower volatility, including ethylene and propylene glycol, are usually not detected by this assay. Be both enzymatic and chromatographic assays have substantial specificity f ethanol, confirmatory testing with a second method is uncommon.

Breath alcohol analyzers may also be employed in assessing ethanol intoxication, as may point-of-care devices that measure salivary ethanol. measurements are less precise than laboratory assays[16, 30] and more su to interference by other alcohols and other organic solvents. Breath-alcol analyzers require good cooperation from the patient to obtain an appropr breath sample and are typically calibrated to give results approximating

blood alcohol concentrations. For the above reasons, confirmation of pos findings with a laboratory measurement may sometimes be desirable.

Blood alcohol concentrations used legally to define driving under the influ have no particular clinical significance, but may have risk management implications for patient discharge. Legal standards are written in terms of whole-blood alcohol concentrations, whereas clinical laboratories usually measure alcohol in serum or plasma. Serum and plasma alcohol concentr are essentially identical, but both will be higher than the alcohol concent measured in a whole-blood specimen obtained at the same time. This is a of the lower concentration of alcohol in the red blood cells. The ratio of s alcohol to whole-blood alcohol varies from individual to individual, with a median value of 1.15.[28] It is more likely than not that an individual with serum alcohol concentration of less than 115 mg/dL will have a whole-blo alcohol concentration of less than 100 mg/dL (<0.10%, w/v).

Chapter 8

Techniques Used to Prevent Gastrointestinal Absorption

Anne-Bolette J. Christophersen

Lotte C.G. Hoegberg

Gastrointestinal decontamination is the most controversial issue in medical toxicology. It plays a central role in the initial management of the orally poisoned patient, and frequently is the only treatment available other than routine supportive care. Unfortunately, as is true in most areas of medical toxicology, valid studies that demonstrate the effects of gastrointestinal decontamination on clinically meaningful end points are difficult to find. The heterogeneity of poisoned patients demands that very large randomized studies be performed because most patients who present to an emergency department (ED) generally have an unreliable history and a low-risk exposure. These factors, as well as other significant sources of bias, are often hidden in inclusion and exclusion criteria. These consequential determinants contribute to the difficulties in designing and completing studies that provide sound evidence for or against a particular therapeutic

option. Incontrovertible end points, such as a change in xenobiotic or complication specific mortality, also demand exceptionally large studies, because the overall mortality of poisoned patients is generally quite low. Whereas other end points, such as the length of stay in the hospital or intensive care unit, rate of secondary complications, and need for specific treatments such as expensive antidotes, must be considered, these surrogate markers are not adequately rigorous and are less than ideal. In the science of gastrointestinal decontamination, we are also faced with the dilemma that randomizing half of a group of potentially ill patients to no decontamination is a significant ethical concernâ€”we rarely omit decontamination unless a minimally toxic exposure has occurred or an effective, safe, readily available, and inexpensive antidote exists. Because acetaminophen poisoning fits this description, it has been used both as the xenobiotic of choice in volunteer overdose studies[26 , 47 , 138] and in a recent Australian evaluation of actually poisoned patients.[34] However, despite its widespread use as a model, the applicability of the management approach for acetaminophen poisoning to other ingestions is limited.

As might be suspected, no available study provides adequate guidance for the management of a patient who definitely has taken an unknown xenobiotic at an unknown time. Fortunately, in most cases there is some component of the history or clinical presentation, such as vital signs, physical examination, and routine diagnostic studies (such as ECG and anion gap), that offers insight into the nature of the ingested xenobiotic (Chap. 3).

For many, the ongoing controversy or debate on gastrointestinal decontamination culminated in 1997, with the publication of the position statements on activated charcoal, orogastric lavage, syrup-of-ipecac-induced emesis, and whole-bowel irrigation from the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT).[27 , 69 , 106 , 107 , 121 , 130 , 131 and 132] Contrary to

initial beliefs, these excellent reviews failed to end the debate; they simply highlighted many shortcomings and ambiguities within this field. A 2000 study concluded that despite having the evidence reviewed and consensus recommendations made, poison information specialists at North American poison control centers still offered a wide variety of recommendations for GI decontamination.[63] The study evaluated decontamination options for a theoretical patient with a difficult scenario of an overdose of enteric-coated aspirin. The recommendations made were often inconsistent with the published position statements, and in some cases, were frankly dangerous. Even toxicologists who made substantial contributions to the development of these consensus statements disagreed on certain aspects of the treatment, although to a lesser extent. These differences in recommendations suggest that there is inadequate evidence available to produce a proper evidence-based answer for many of the decisions in question. In most of the clinical studies that provide evidence to form the basis for these consensus statements, either there were very few patients with ingestions of enteric-coated aspirin or, if such patients existed, they were excluded from the study. Similarly, there are no studies for most drugs with modified release kinetics, or for new drugs. Thus the clinician must often make decisions based on a philosophic approach and an understanding of specific principles rather than evidence.

This chapter does not discuss details with regard to the evaluation of the amount and type of xenobiotic ingested, or other strategies for managing a patient with an unknown overdose; these issues are discussed in Chap. 4 . Rather, the focus is on determining which decontamination technique or combination of techniques is preferred once an indication for gastrointestinal

decontamination is established. The literature published since the previously mentioned position statements is emphasized, existing evidence is summarized, and those areas necessitating further

investigation are identified. Detailed discussions of emesis, catharsis, and activated charcoal can be found in the corresponding Antidotes in Depth sections, â€œSyrup of Ipecac ,â€• â€œWhole-Bowel Irrigation and Other Intestinal Evacuants ,â€• and â€œActivated Charcoal .â€• In addition, when the ingested xenobiotic is known, readers should refer to the decontamination sections found in Chaps. 34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 and 128 , as they will offer insight into xenobiotic-specific issues that may alter decontamination strategies.

The xenobiotic has limited toxicity at any dose
Although the xenobiotic ingested is potentially toxic, the dose ingested is less than that expected to produce significant illness
The ingested xenobiotic is well adsorbed by activated charcoal, and the amount ingested is not expected to exceed the adsorptive capacity of activated charcoal
Significant spontaneous emesis has occurred
The patient presents many hours postingestion and has minimal signs or symptoms of poisoning
The ingested xenobiotic has a highly efficient antidote (such as acetaminophen)
There is reason to believe that, given the time of ingestion, a significant amount of the ingested xenobiotic is still present in the stomach
The ingested xenobiotic is known to produce serious toxicity *or* the patient has obvious signs or symptoms of life-threatening toxicity
The ingested xenobiotic is not adsorbed by activated charcoal
Although the ingested xenobiotic is adsorbed by activated charcoal, the amount ingested exceeds the activated charcoal-to-

xenobiotic ratio of 10:1 even with a double-standard dose of activated charcoal
The patient has not had spontaneous emesis
No highly effective specific antidote exists or alternative therapies (such as hemodialysis) pose a significant risk to the patient
[a] Patients who fulfill these criteria can be decontaminated safely with activated charcoal alone or may require no decontamination at all.
[b] Patients who fulfill these criteria should be considered candidates for gastric emptying *if* there are no contraindications. For individuals who meet some of these criteria but who are judged not to be candidates for gastric emptying, single or multiple-dose activated charcoal and/or whole-bowel irrigation should be considered.

Gastric Emptying Is Usually Not Indicated If[a]	Gastric Emptying May Be Indicated If[b]

TABLE 8-1. Risk Assessment: When to Consider Gastric Emptying

Gastric Emptying

The principle theory governing gastric emptying is very simple: If a portion of xenobiotic can be removed prior to absorption, its potentially toxic effect should either be prevented or minimized. From 1982 to 1995 several important clinical trials attempted to define the role of gastrointestinal decontamination in poisoned patients.[3,19,29,60,70,86,105,129] Although all of these studies were flawed because of the inclusion of a large number of low-risk patients, numerous restrictive exclusion criteria, and a variety of other biases, they clearly demonstrated that many patients can be successfully managed without aggressive gastric emptying. The clinical parameters listed in Table 8-1 help to

identify those individuals for whom gastric emptying is usually not indicated based on a risk-to-benefit analysis. In contrast, for a small subset of patients (Table 8-1) gastric emptying may be indicated. A thorough understanding of this risk analysis is essential when deciding whether or not gastric emptying is appropriate for a patient who ingests a xenobiotic.

Time is an important consideration, in that for gastric emptying to be beneficial, a consequential amount of xenobiotic must still be present in the stomach. Demographic studies have found that very few poisoned patients arrive at the ED within 1â€“2 hours after an ingestion. In most studies, the average time from ingestion to presentation was approximately 3â€“4 hours with significant variations.[64 , 70 , 105 , 123] This delay diminishes the likelihood of recovering a large percentage of the xenobiotic from the stomach, unless the patient has ingested a xenobiotic that slows gastric-emptying rates.

As is discussed in the â€œOrogastric Lavage â€• section below, many authors advise against interventions beyond 1-hour after ingestion. Recent data highlight the arbitrary nature of this limitation. One human volunteer study evaluated the pharmacokinetic effects of diphenhydramine and oxycodone in a simulated acetaminophen overdose.[51] This model is relevant because of the rapid absorption of acetaminophen and the presence of many such combination products in the marketplace. Whereas diphenhydramine did not delay gastric emptying significantly, oxycodone delayed the time to peak acetaminophen concentration by approximately 1 hour. Although gastrointestinal decontamination was not part of the study protocol, it can be implied that acetaminophen was available for gastrointestinal decontamination for a longer time than the 1-hour guideline suggests.

In fact, markedly prolonged gastric-emptying half-lives and gastric hypomotility were demonstrated using gastric scintigraphy in a

prospective study on 85 actually poisoned patients.[1] Remarkably, these findings occurred with ingestions such as acetaminophen, which are not typically expected to prolong gastric emptying. Patients who underwent orogastric lavage did not have significantly different gastric-emptying half-lives, which suggests that this procedure was not the cause of the gastroparesis. There was also no evidence that activated charcoal affected gastric-emptying rates. The authors speculate that stress in the overdosed patient might be part of the etiology of the hypomotility observed, and that the management of patients should not be based on the assumption that gastrointestinal motility is normal.

Assessment of whether or not gastric emptying is appropriate for a patient continues with an evaluation for potential contraindications (Table 8-2). Regardless of the severity of the ingestion and other contributing factors, such as time, there must be no contraindication to gastric-emptying procedures. Because the demonstrable benefit of emptying is marginal at best, even relative contraindications usually dictate that the procedure should not be attempted.

Once the decision to perform gastric emptying is made, the clinician must choose between the two available methods. Either emesis can be induced with the administration of syrup of ipecac or orogastric lavage can be performed by cautious aspiration of gastric contents using a large-bore tube and small amounts of water. While the numerical benefit of either method of gastric emptying has, in

several studies, rarely averaged more than a 50% reduction in the absorption of a xenobiotic when performed under optimal research conditions,[69 , 132] this clinical benefit can be sizable if the ingested dose places the patient on the steep portion of the doseâ€“response curve (Chap. 9). Under those circumstances a small reduction in dose might translate into a significant reduction in toxicity.

The patient meets criteria for gastric emptying (Table 8-1).
The benefits of gastric emptying outweigh the risks.
The patient does not meet criteria for gastric emptying (Table 8-1).
The patient has lost or will likely lose his/her airway protective reflexes and has not been intubated. (Once intubated, orogastric lavage can be performed if otherwise indicated.)
Ingestion of an alkaline caustic.
Ingestion of a foreign body (such as a drug packet).
Ingestion of a xenobiotic with a high aspiration potential (such as a hydrocarbon) in the absence of endotracheal intubation.
The patient is at risk of hemorrhage or gastrointestinal perforation because of underlying pathology, recent surgery, or other medical condition that could be further compromised by the use of orogastric lavage.
Ingestion of a xenobiotic in a form known to be too large to fit into the lumen of the lavage tube (such as many modified-release preparations).

Indications Contraindications

TABLE 8-2. Indications and Contraindications to Orogastric Lavage

Orogastric Lavage

Many authors have adopted the consensus approach that orogastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a xenobiotic and the procedure can be undertaken within 60 minutes of ingestion.[70, 132] Since the publication of the clinical studies cited above[3, 19, 29, 60, 70, 86, 105, 129] studies of orogastric lavage have been scarce. One crossover study used 4 g of an acetaminophen

solution as a marker and randomized the subjects to either control or orogastric lavage performed at 30 minutes postingestion. Although the study found a mean 20% reduction in the AUC (area under the [plasma drug concentration versus time] curve) of acetaminophen with orogastric lavage compared to control, the confidence interval of Â±28% suggests a rather modest and very unreliable effect.[49]

Two other prospective, randomized, crossover studies in volunteers measured the effect of activated charcoal versus orogastric lavage, with interventions at either 5 or 30 minutes postingestion.[73 , 74] Both studies used therapeutic doses of moclobemide, temazepam, and verapamil. Interestingly, when orogastric lavage was performed 5 minutes after ingestion there was no significant pharmacokinetic effect for any of the drugs ingested. However, the AUC of moclobemide was reduced by 44%, compared to control, when orogastric lavage was performed 30 minutes after ingestion; there were no effects on the pharmacokinetic profiles of the other two drugs. These results most likely illustrate the very varied and unreliable effect of orogastric lavage, even when performed by the same experienced professionals under controlled experimental conditions. Another study evaluated the effect of activated charcoal compared to activated charcoal followed by orogastric lavage at 30 minutes postingestion.[73] Therapeutic doses of temazepam, ibuprofen, and citalopram were studied. In this model, the combination of activated charcoal and orogastric lavage was not superior to activated charcoal alone.

It is important to highlight the differences between volunteer studies using therapeutic doses of drugs and actual patients with clinically significant overdose. The most important aspect of this comparison is a bias toward a benefit of activated charcoal. The drugs used in these volunteer studies are all well-adsorbed by activated charcoal and the doses of activated charcoal are significantly in excess of the binding capacity for the drug. An

additional bias is introduced against gastric emptying because the small amounts of drugs used are unlikely to alter gastric motility and thus they may pass through the pylorus before gastric emptying can occur.

A synthesis of available data can be used to develop indications for orogastric lavage (Table 8-2). When deciding whether or not to actually perform orogastric lavage on a poisoned patient, these indications, contraindications, and potential adverse effects must be considered. Table 8-3 summarizes the technique of orogastric lavage.

Reported adverse effects of orogastric lavage include injury to the airway, esophagus,[21] and stomach,[36] as well as severe hypernatremia.[87] The case of hypernatremia resulted from a lavage that was performed using 12 L of hypertonic saline.[87] These cases, as

well as other well-known complications such as aspiration pneumonitis,[131 , 132] demonstrate that orogastric lavage is not risk free and should only be considered based on the rigorous indications for gastric emptying listed in Table 8-1 .

Select the correct tube size
Adults/adolescents: 36â€“40 French
Children: 22â€“28 French
Procedure

1. If there is potential airway compromise, endotracheal or nasotracheal intubation should precede orogastric lavage.
2. The patient should be kept in the left-lateral decubitus position. Because the pylorus points upward in this orientation, this positioning theoretically helps prevent the xenobiotic from passing through the pylorus during the procedure.
3. Prior to insertion, the proper length of tubing to be passed should be measured and marked on the tube. The length

should allow the most proximal tube opening to be passed beyond the lower esophageal sphincter.

4. After the tube is inserted, it is essential to confirm that the distal end of the tube is in the stomach.
5. Withdraw any material present in the stomach and consider the immediate instillation of activated charcoal for large ingestions of xenobiotics known to be adsorbed by activated charcoal.
6. Via a funnel (or lavage syringe) instill in an adult 250 mL aliquots of a room-temperature saline lavage solution. In children, aliquots should be 10â€“15 mL/kg to a maximum of 250 mL.
7. Orogastric lavage should continue for at least several liters in an adult and for at least 0.5â€“1 L in a child *or* until no particulate matter returns and the effluent lavage solution is clear.
8. Following orogastric lavage, the same tube should be used to instill activated charcoal if indicated.

TABLE 8-3. The Technique of Performing Orogastric Lavage

Syrup of Ipecac

A comprehensive summary of the pharmacology and the evidence for induced emesis is available in the Antidotes in Depth: Syrup of Ipecac . Since 1997 very little original work has been published other than reviews, and the position statement recommendations.[69] Additionally, a revision of the position paper found no new evidence to support any modification in recommendations.[106]

Although many animal and human studies show a reduction in drug concentrations with induced emesis, no clinical benefit for this

technique has been proved. Furthermore, as the benefits of activated charcoal are recognized and the time to its administration evaluated, it has become evident that the administration of syrup of ipecac delays the administration of activated charcoal, as well as any other oral treatment (symptomatic or specific antidotes).

Syrup of ipecac is absolutely contraindicated when the patient has ingested a caustic or a xenobiotic with a high aspiration potential, such as a hydrocarbon. Because vomiting in the setting of altered consciousness increases the likelihood for pulmonary aspiration, syrup of ipecac can only be used when the patient has a normal mental status *and* can be predicted to have a normal mental status at 30â€“60 minutes following administration, when emesis will occur. In the clinical setting, patients are rarely identified with consequential ingestions who present early enough to require gastric emptying, and who are expected to retain their airway protective reflexes for a minimum of 30â€“60 minutes. Therefore, most consensus statements correctly conclude that, given the lack of evidence demonstrating a clinically meaningful benefit of induced emesis *and* the significant contraindications, the routine administration of syrup of ipecac in the ED should be abandoned.[68, 106] Although other emetics, and methods to induce emesis exist, data are insufficient to support their routine use.

Gastric decontamination of children in the home has always been an attractive concept because both the xenobiotic and time of ingestion are known and there is a high likelihood that the xenobiotic is still in the stomach. A recent prospective observational study evaluated 75 cases of probably poisoned children (out of 14,603 human exposures) where home administration of syrup of ipecac had been recommended by a poison information specialist.[46] Cases where syrup of ipecac was indicated but not available in the home were included in this group if the parents stated that syrup of ipecac could be obtained within 15 minutes. The administration of syrup of ipecac occurred in less

than 30 minutes in only 20% of cases, and the overall mean time to emesis was 58 minutes. Initial emesis occurred in less than 60 minutes in only 36% of cases. Numerous studies illustrate that the time to performing gastrointestinal decontamination is critical. Clearly, the problem with syrup of ipecac is the time delay from administration to onset of emesis. Additionally, the uncertainty of the effect of the administered dose serves as a further delaying factor. A study in 12 adult volunteers showed that with a 20 mL dose, 2 of 6 volunteers had not vomited within 4 hours, whereas all volunteers (6 of 6) had vomited within 60 minutes after receiving a 30 mL dose.[136] A four-limb randomized study using 10 healthy volunteers, studied the effect of 30 mL of syrup of ipecac administered at 5, 30, and 60 minutes after the ingestion of 3.9 g of acetaminophen. The fourth limb served as control. Only the 5-minute intervention was significantly different from control and showed a decrease in bioavailability of approximately 67%.[113] This study also noted that sedation was a significant adverse effect of syrup of ipecac, which makes this therapy difficult to recommend in patients who have ingested any potentially sedating xenobiotic.

The patient meets criteria for gastric emptying (Table 8-1).
The patient does not meet criteria for gastric emptying (Table 8-1).
Orogastric lavage cannot be performed or is contraindicated because of the size of the xenobiotic formulation.
Either activated charcoal or another oral agent is expected to be necessary in the next few hours.
The history and/or physical examination suggest that there is likely to be a clinically significant amount of xenobiotic remaining in the stomach.
Airway protective reflexes might be lost within the next 30â€“60 minutes.
Ingestion of a caustic.
The benefits of gastric emptying outweigh the risks from the contraindications.

Ingestion of a foreign body such as a drug packet or sharp item.

Ingestion of a xenobiotic with a high aspirationpotential such as a hydrocarbon.
The patient is younger than 6 months of age, elderly, or debilitated.
The patient has a premorbid condition that wouldbe compromised by vomiting.

Indications Contraindications

TABLE 8-4. Indications and Contraindications for Syrup of Ipecac

A study using the 2003 Toxic Exposure Surveillance System (TESS) database (Chap. 130) evaluated the effect of home use of syrup of ipecac on the rate of referral to EDs across the United States. The study found that there was no reduction in ED use nor any improvement in patient outcome from home administration of syrup of ipecac.[18] Based on these findings and other data, the American Academy of Pediatrics published its policy statement on poison treatment in the home, concluding that syrup of ipecac should no longer be used as a standard home treatment in cases of poisoning.[6] Despite this, some authors still believe that there is a limited role for ipecac-induced emesis.[82] Table 8-4 summarizes the indications and contraindications for administration of syrup

of ipecac. The only reasonable conclusion is that induction of emesis has an extremely limited role in the contemporary management of poisoned patients.

Prevention of Xenobiotic Absorption

Activated Charcoal

Activated charcoal has long been recognized as an effective method for reducing the systemic absorption of many xenobiotics. For certain xenobiotics it also enhances elimination through interruption of either the enterohepatic or enteroenteric cycle.[17, 30, 65] Its superb adsorptive properties theoretically make it the single most useful agent in the management of a broad variety of patients with acute oral overdoses.[7, 8 and 9, 18, 26, 31, 59, 102, 103] But overall, as is true for the other methods of gastrointestinal decontamination, there is a lack of sound evidence of its benefits as defined by clinically meaningful end points. This opinion is reflected both in the consensus statements and in the overall trend toward no decontamination as shown in TESS data (Chap. 130).[27, 85, 86] The consensus opinion concluded that a single dose of activated charcoal should not be administered routinely in the management of poisoned patients and, based on volunteer studies, the effectiveness of activated charcoal decreased with time, providing the greatest benefit within 1 hour of ingestion. There was no evidence that the administration of a single dose of activated charcoal improved clinical outcome. Additionally, it is generally accepted that unless either airway protective reflexes are intact (and expected to remain so) or the patient's airway has been protected, the administration of activated charcoal is contraindicated.[27]

There are very few studies that used valid clinical end points in an attempt to demonstrate a benefit of gastrointestinal decontamination. One recent 2-year study concluded that activated charcoal was associated with a higher incidence of vomiting, a more prolonged emergency department stay, and a failure to improve clinical outcome when compared to supportive care.[85] However, in spite of randomizing 1479 patients to either activated charcoal on even days of no decontamination on odd days, only 399 patients were placed in the activated charcoal group and 1080 patients were placed in the control group. These very unevenly distributed numbers suggest a selection bias that is

inadequately described in the study. The authors concluded that there appeared to be no benefit to decontamination procedures, although they admitted that length of stay (one of their end points) for the most part was dependent on the wait for psychiatric evaluation and the availability of a mental health bed for patient transfer. The inclusion of a significant number of low-risk patients in this study introduced a clear bias against determining any benefit of decontamination. Furthermore, the validity of the study is questionable because patients with significant acetaminophen overdoses were excluded, given that there are sound data to support improved clinical outcomes in acetaminophen-poisoned patients treated with activated charcoal.[20]

Theoretically, the early administration of activated charcoal to patients presenting with a significant oral overdose of a potentially toxic xenobiotic would lower systemic exposure to that xenobiotic, and thus be of benefit to the patient. Surprisingly, this intuitive result has been difficult to demonstrate using clinically relevant end points selected in groups of poisoned patients.

Dosing

The optimal dose of oral activated charcoal has never been fully established. Since the beginning of its clinical use as a gastrointestinal decontaminant, various factors have been recommended for determining the optimal dose of activated charcoal. Two factors commonly discussed are the patient's weight, and the quantity of the xenobiotic ingested. The problem in using the quantity of the xenobiotic as a basis for activated charcoal dosing is that the amount is usually unknown, and there is an implication that nothing else in the gastrointestinal tract will occupy binding sites on activated charcoal. Additionally, the xenobiotic is often unknown and xenobiotics vary enormously in their toxicities, rate of absorption, and the clinical effects they produce (eg, respiratory depression, convulsions, effect on gastric

emptying rate). Some xenobiotics are very well adsorbed to activated charcoal, whereas others are not.[30] Because of variables such as the physical properties of the formulation ingested (liquid, solid, or sustained-release pill), the volume and pH of gastric and intestinal fluids, and the presence of other xenobiotics adsorbed by activated charcoal,[9 , 13 , 53 , 54 , 91 , 93 , 94] the optimal dose cannot be known with certainty in any given patient.

Information concerning the maximum adsorptive capacity of activated charcoal for the particular xenobiotic ingested permits a theoretical calculation of an adequate dose,[4 , 7 , 12 , 14 , 23 , 31 , 90 , 91 , 94 , 95 , 109 , 110 , 112 , 117 , 125 , 128] assuming that the amount of xenobiotic ingested is known. However, clinicians must remain cognizant of the risk of approaching or exceeding the adsorptive capacity of the standard dose of approximately 1 g/kg of activated charcoal. This possibility has been investigated in only a few studies.[4 , 14 , 23 , 112]

Thus, the idea that a fixed activated charcoal-to-xenobiotic ratio is appropriate for all xenobiotics is clearly imperfect. It is possible however, to develop a logical approach to dosing based on available data. The optimal activated charcoal dose is theoretically the minimum dose that completely adsorbs the ingested xenobiotic and, if relevant, that maximizes enhanced elimination. The results of in vitro studies show that the ideal activated charcoal-to-xenobiotic ratio varies widely, but a common recommendation is to deliver an activated charcoal-to-xenobiotic ratio of 10:1 or 50â€“100 g of activated charcoal to adult patients, whichever is greater. This amount from a theoretical perspective will adsorb 5â€“10 g of a xenobiotic, which should be adequate for most typical poisonings.[7 , 8 , 27 , 30 , 75 , 95] Based on available data from in vivo and in vitro studies, the actual recommended dosing regimen for activated charcoal is 25â€“100 g in adults (1 g/kg of body weight) and 0.5â€“2 g/kg of body weight in children.[27 , 30] These recommendations are generally based more on activated charcoal tolerance then on efficacy. When calculation of a 10:1

ratio exceeds these recommendations, either gastric emptying or multiple-dose activated charcoal (MDAC) therapy should be considered.

For example, consider a patient intentionally overdosing by ingesting thirty 0.25-mg digoxin pills (total dose of 7.5 mg). Achieving a 10:1 ratio is quite easy, and a standard dose of 1 g/kg might exceed a 10,000:1 ratio. In comparison, consider a patient who intentionally ingests thirty 325-mg aspirin pills (total dose of 9.75 g). In this case, obtaining a 10:1 activated charcoal-to-xenobiotic ratio is quite difficult, and is even less likely if a patient ingests 60 or 100 of the aspirin pills. Poisoning with a combination of xenobiotics may also approach or exceed the maximum adsorption capacity for the standard dose of activated charcoal.

Time Factor

Many authors state that administration of a single dose of activated charcoal should be considered if a patient has

ingested a potentially toxic amount of a xenobiotic (that is known to be adsorbed to activated charcoal) within the previous hour. This position was chosen as there are insufficient data to support or exclude the use of single-dose activated charcoal therapy more than 1 hour beyond the ingestion.[27] The efficacy of activated charcoal administered more than 1 hour after xenobiotic ingestion is continuously debated, and has been evaluated in several studies.

In volunteers, the effect of activated charcoal administered 2 and 4 hours after ingestion of acetaminophen demonstrated no significant difference in plasma acetaminophen concentration when compared to control. In contrast, when administered 1 hour after a simulated acetaminophen ingestion, activated charcoal reduced plasma acetaminophen concentrations significantly.[138] Likewise, when the effectiveness of activated charcoal administered 1, 2,

and 3 hours after xenobiotic ingestion was determined, only the 1-hour group had a different pharmacokinetic profile from the control group.[47] Although these data do not support the administration of activated charcoal as a gastrointestinal decontamination strategy more than 1 hour after an overdose, the applicability of these results to actual overdoses is questionable. The method in this volunteer study was an 8-hour fast, followed by a small meal 1 hour before the administration of 3â€“4 g acetaminophen.[47 , 138] Considering the rapid absorption of acetaminophen, and the small 3â€“4-g doses employed, it is highly probable that little or no acetaminophen would be left in the gastrointestinal tract to be adsorbed by activated charcoal, limiting the potential time to benefit from activated charcoal to approximately 1 hour.

In contrast, activated charcoal given 3 hours after a xenobiotic overdose was investigated in vivo, again using acetaminophen and a larger-than-standard dose (75 g) of activated charcoal. The results demonstrated some benefit in administering activated charcoal 3 hours after an overdose as there were significantly lower acetaminophen plasma concentrations in the activated charcoal group than in the control group.[115] In a similar study, activated charcoal was effective in reducing the systemic absorption of a xenobiotic (acetaminophen) when administered 1 and 2 hours after ingestion, although the effect of the 2-hour intervention was substantially less than at 1 hour, reemphasizing the importance of early intervention.[26]

It should be clear that the use of a 1-hour time frame is meant more as a guideline than an absolute cutoff. It is only logical that if an intervention is effective at 59 minutes, it will also be beneficial at 61 minutes. Although it is logical that efficacy decreases as time from ingestion increases, in certain cases some benefit may be derived many hours postingestion. As discussed above, there are good data from patients with actual ingestions to demonstrate that a significant amount of xenobiotic can be found

in the stomach beyond this arbitrary 1-hour time frame.[1]

The recommendation that activated charcoal should be administered within 1 hour of ingestion limits the potential to treat most poisoned patients. A study identifying 63 patients who had taken potentially serious overdoses over a 6-month period demonstrated a median time of arrival to healthcare of 136 minutes after the overdose. Only 15 patients presented within 1 hour and only 4 of 10 patients who qualified, received activated charcoal within 1 hour. The results demonstrate the implications for adherence to the recommended guidelines, unless activated charcoal can be safely administered to appropriate patients prior to hospitalization.[64]

Prehospital use of activated charcoal has not gained wide acceptance because of the concern that it would not be administered properly by the untrained lay public and that many children would refuse to drink the charcoal slurry. An 18-month consecutive case series demonstrated that activated charcoal can be administered successfully in the home by the lay public. Home use of activated charcoal significantly reduced the time to activated charcoal administration after xenobiotic ingestion from a mean of 73 Â± 18.1 minutes for ED treatment to a mean of 38 Â± 18.3 minutes for home treatment.[119] However, many still consider this evidence insufficient to recommend that activated charcoal be stored in the home. A prospective followup study from Finland looked at the adherence to a new protocol of administering activated charcoal in the prehospital setting. The protocol was implemented by either the first-response unit or paramedics. Activated charcoal was indicated in 722 of 2047 patients. Of these patients, 555 actually received activated charcoal at a mean of 88 minutes after ingestion. There were no adverse effects noted, although 72 patients refused to drink the charcoal. This study shows that it is feasible to administer activated charcoal in the prehospital setting, but its clinical implications are unknown.[2]

In reality, many factors, such as food, sustained-release formulations, and co-ingestion with anticholinergic or opioid properties, can slow the rate of absorption of a xenobiotic, which slows gastric emptying. These factors increase the time frame for possible adsorption to activated charcoal. An increased effect of activated charcoal was shown in a randomized crossover study where volunteers were administered acetaminophen in either the presence or absence of the anticholinergic drug atropine, and subsequently given a single dose of activated charcoal 1 hour after administration of the acetaminophen. Activated charcoal was more effective in reducing acetaminophen bioavailability in the presence of an anticholinergic agent.[48]

Methods to Increase the Palatability of Activated Charcoal

The problems surrounding the use of an activated charcoal slurry are clear to anyone who has tried to administer it to a patient. Activated charcoal has a pronounced gritty texture and it immediately sticks in the throat because it adheres to the mucosal surfaces and begins to cake.[30] In addition, the black appearance of activated charcoal makes it less attractive.

There have been numerous attempts at making activated charcoal more appealing by providing flavors, including jam,[38] chocolate syrup,[83, 89] cherry extract/syrup,[99, 137] juice,[99] sorbitol,[32, 35, 84] saccharin,[33] strawberry flavor,[98] orange or peppermint oil,[30] melted milk chocolate,[40, 41] chocolate milk,[99] soda,[99, 108] and ice cream.[24, 76, 122] Because activated charcoal adsorbs the flavoring agents, the palatable taste often disappears within minutes after mixing.[30, 32, 33, 38] But in cases where the activated charcoal does not completely adsorb the flavoring agents, they provided a pleasant taste without significantly reducing the adsorptive properties of the activated charcoal.[30, 32, 33]

Convincing children to drink the activated charcoal slurry is even more problematic than in adults.[10, 41, 50, 71, 76, 92] Providing a tasty vehicle for children could make the activated charcoal more acceptable than the recommended water slurry. Many additives have been tried to increase children's acceptance of activated charcoal.[32, 33, 108] Several investigations suggest mixtures of activated charcoal with, for example, ice cream,[24, 54, 71, 76, 92, 122] milk,[35, 71] yogurt,[71] milk chocolate,[41] or other palatability-increasing agents.[24, 30] The general recommendation, however, remains that activated charcoal should only be mixed with water.[62]

Contraindications/Complications

Vomiting frequently complicates the administration of activated charcoal. A prospective cohort study estimating the incidence of vomiting subsequent to the

therapeutic administration of activated charcoal to poisoned children younger than 18 years of age showed that 1 of 5 children and adolescents vomited. Children with previous vomiting or nasogastric tube administration were at highest risk.[100] This incidence of vomiting appears to be greater when activated charcoal is administered with sorbitol.[130] Also, although rare, inadvertent direct instillation of activated charcoal into the lungs has resulted from a misplaced nasogastric tube, leading to severe pulmonary complications and death. Administration of activated charcoal to already intubated patients is associated with a low incidence of aspiration pneumonia.[88] Another study found that pulmonary complications associated with activated charcoal aspiration might be primarily related to the aspiration of acidic gastric content and not directly related to aspiration of activated charcoal.[111] A retrospective study found that only 1.6% of unselected overdose patients aspirated, and that administration of activated charcoal was not found to be an associated risk factor.[61] Pulmonary aspiration in overdose patients who have received

activated charcoal is more easily documented, because the activated charcoal is a very identifiable marker.

The patient does not meet criteria for gastric emptying (Table 8-1) or gastric emptying is likely to be harmful.
Activated charcoal is known not to adsorb a clinically meaningful amount of the ingested xenobiotic.
Ingestion of a toxic amount of a xenobiotic that is known to be adsorbed by activated charcoal.
Airway protective reflexes are absent or expected to be lost and the patient is not intubated.
Gastrointestinal perforation is likely as in cases of caustic ingestions.
The ingestion has occurred within a time frame amenable to adsorption by activated charcoal or clinical factors are present that suggest that not all of the xenobiotic has already been systemically absorbed.
Therapy may increase the risk and severity of aspiration, such as in the presence of hydrocarbons with a high aspiration potential.
Endoscopy will be an essential diagnostic modality(acid or alkaline caustics).

Indications Contraindications

TABLE 8-5. Indications and Contraindications for Single-Dose Activated Charcoal Therapy Without Gastric Emptying

Although relatively few reports of clinically significant emesis and pulmonary aspiration resulting from the administration of activated charcoal exist, the severity of these complications is clear.
Consequently, it is important to evaluate, particularly in those patients determined to be at limited risk from their exposures, whether single-dose activated charcoal therapy is likely to be beneficial based on the indications and contraindications in Table

8-5 .

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal (MDAC) is typically defined as more than 2 sequential doses of activated charcoal.[130] In many cases, the actual number of doses administered is substantially greater. This technique serves two purposes: (a) to prevent ongoing absorption of a xenobiotic that persists in the gastrointestinal tract (usually in the form of a modified-release preparation), and (b) to enhance elimination by either disrupting enterohepatic recirculation or by â€œgut-dialysisâ€• (enteroenteric recirculation). The 1999 position statement of the AACT and the EAPCCT concluded that:

> Based on clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. With all of these drugs there are data to confirm enhanced elimination, though no controlled studies have demonstrated clinical benefit. Although volunteer studies have demonstrated that multiple-dose activated charcoal increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, there are insufficient clinical data to support or exclude the use of this therapy.[130]

Although technically correct, the preceding statements suffer from a lack of evidence. Because the clinical studies used to formulate this opinion all lack sufficient numbers of significantly poisoned

patients, they induce a bias against any benefit of MDAC. Additionally, none of the studies included a detailed analysis of sustained- or extended-release formulations, which are very popular.

A more recent single-blind, randomized, placebo-controlled trial was designed to assess the efficacy of MDAC in the treatment of patients with yellow oleander poisoning. This clinical study demonstrated that MDAC (defined as 50 g of activated charcoal every 6 hours for 3 days) effectively reduced life-threatening cardiac dysrhythmias, deaths, and the need for ICU admission.[37] In this dataset, to save 1 life only 18 patients needed to receive MDAC. This study demonstrates that consequential benefits of gastrointestinal decontamination may become evident when investigations are performed in significantly poisoned patients. It further highlights that general recommendations only apply to patients in general and that severely ill patients deserve individualized care.

Like single-dose activated charcoal, MDAC can produce emesis, with subsequent pulmonary aspiration of gastric contents containing activated charcoal. It is intuitive that these risks are greater with multiple-than with single-dose therapy. One retrospective study attempted to determine the frequency of complications associated with the use of MDAC.[39] The authors identified nearly 900 patients who had received MDAC and found that only

0.6% of patients had clinically significant pulmonary aspiration. Although no patients developed gastrointestinal obstruction, 9% had hypernatremia or hypermagnesemia without any clinical consequences noted. The authors did not specify whether the multiple-dose regimens administered included the use of cathartics, but the profile of the adverse reactions listed above suggests that this is probably the case. In spite of the obvious limitations, this study demonstrates a reasonably low rate of

complications associated with MDAC.

Ingestion of a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline
Any contraindication to single-dose activated charcoal
Ingestion of a life-threatening amount of another xenobiotic that undergoes enterohepatic or enteroenteric recirculation that is adsorbed to
The presence of an ileus or other causes of diminished peristalsis activated charcoal
Ingestion of a significant amount of any slowly released xenobiotic, or of a xenobiotic known to form concretions or bezoars

Indications Contraindications

TABLE 8-6. Indications and Contraindications for Multiple-Dose Activated Charcoal Therapy

Table 8-6 summarizes the indications and contraindications for MDAC therapy. Because the optimal doses and intervals for repeated doses of activated charcoal have not been established, recommendations are based more on amounts that can be tolerated, than on amounts that might be considered pharmacologically appropriate. Table 8-7 lists typical dosing regimens. Larger doses and shorter intervals should be used for patients with more severe toxicity. It is reasonable to base end points either on the patient's clinical condition or on xenobiotic concentrations when they are easily measured.

Further clinical studies concerning MDAC are needed in order to establish an optimal dosing regimen and to confirm an effect on relevant end points. The reader is referred to Antidotes in Depth: Activated Charcoal for a more detailed discussion of single- and

multiple-dose activated charcoal therapy.

Initial dose orally or via orogastric or nasogastric tube

Adults and children: 1 g/kg of body weight or a 10:1 ratio of activated charcoal-to-xenobiotic, whichever is greater. Following massive ingestions, 2 g/kg of body weight might be indicated, if such a large dose can be easily administered and tolerated.

Repeat doses orally or via orogastric or nasogastric tube

Adults and children: 0.25â€“0.5 g/kg of body weight every 1â€“6 hours, in accordance with the dose and dosage form of xenobiotic ingested (larger doses or shorter dosing intervals may occasionally be indicated).

Procedure

1. Add 8 parts of water to the selected amount of powdered form. All formulations, including prepacked slurries, should be shaken well for at least 1 minute to form a transiently stable suspension prior to drinking or instillation via orogastric or nasogastric tube.
2. Activated charcoal can be administered with a cathartic, *for the first dose only* , when indicated, but cathartics should never be administered routinely and never be repeated with subsequent doses of activated charcoal.
3. If the patient vomits the dose of activated charcoal, it should be repeated. Smaller, more frequent doses or continuous nasogastric administration may be better tolerated. An antiemetic may be needed.
4. If a nasogastric or orogastric tube is used for MDAC administration, time should be allowed for the last dose to pass through the stomach before removing the tube. Suctioning the tube itself prior to removal may prevent subsequent charcoal aspiration.

TABLE 8-7. Technique of Administering Multiple-Dose Activated Charcoal Therapy

Whole-Bowel Irrigation

Whole-bowel irrigation (WBI) represents a method of flushing the gastrointestinal tract in an attempt to prevent further absorption of xenobiotics. This is achieved through the oral or nasogastric administration of large amounts of an osmotically balanced polyethylene glycol electrolyte lavage solution (PEG-ELS). This decontamination technique was subjected to a thorough literature review, which was published as a position statement in 1997 and revised in 2004.[107, 121] The position statement was unable to establish a clear set of evidence-based indications for the use of WBI because no clinical outcome studies have been performed. When experimental, theoretical, and anecdotal human experience is considered, the use of WBI with PEG-ELS can be supported for patients with potentially toxic ingestions of sustained-release pharmaceuticals. Other theoretical indications include the ingestion of large amounts of a xenobiotic where morbidity is expected to be high, the ingested xenobiotic is not adsorbed by activated charcoal, and when

other methods of gastrointestinal decontamination are unlikely to be either safe or beneficial. The removal of packets of illicit drugs (eg, from body-packers) can be considered a unique indication for WBI.

The contraindications for WBI are more clearly defined. This technique cannot be applied safely if the gastrointestinal tract is not intact, there are signs of ileus or obstruction, or there is significant gastrointestinal hemorrhage, or in patients with inadequate airway protection, uncontrolled vomiting, or consequential hemodynamic instability that compromises

gastrointestinal function or integrity. Additionally, the combination of WBI and activated charcoal results in an in vitro decrease in the adsorption of xenobiotics by activated charcoal, especially when the WBI solution is premixed with activated charcoal. Activated charcoal seems to be most efficacious if administered before initiating WBI.[11,56,68,81] Since the publication of the position statement, only three studies of varying degrees of evidence and some case reports have been published, as discussed below.

The effect of WBI on the pharmacokinetics of a modified-release formulation of acetaminophen and the progression of radiopaque markers through the gastrointestinal tract was studied using a prospective randomized crossover design.[80] Ten volunteers ingested the acetaminophen in supratherapeutic doses of 75 mg/kg together with a capsule containing 24 small markers. One study day with no intervention served as control. On the intervention day, the volunteers were subjected to WBI beginning 30 minutes after ingestion and continued until rectal effluent was determined clear. The average duration of WBI was 6 hours. No tablets or markers were recovered in the effluent. Only 2 of 10 patients had adverse effects such as nausea and abdominal cramping, and 1 volunteer vomited. The authors found a nonsignificant 11.5% reduction in the AUC of acetaminophen. The study had an 80% power to detect a 25% difference in AUC, which was arbitrarily set because there is no clinically established minimal relevant difference for a reduction in the AUC of a xenobiotic. The significance of this reduction would also vary in relation to the toxic properties of a xenobiotic (small vs. large therapeutic index, availability of an effective antidote, etc). In theory, for some xenobiotics, an 11% reduction in absorption might mean the difference between serious and life-threatening toxicity. The authors also found that in 8 of 10 subjects the radiopaque markers were all located in the cecum after WBI, whereas the markers were scattered throughout the small intestine in the control group. This observation indicates that WBI

has the capability to move objects in the gastrointestinal tract, at least to some degree. Whereas the authors stated that they would discontinue WBI when the rectal effluent was clear, this did not occur, and they chose an end point where the final effluent was straw-colored to yellowish-brown, which might have been too short a time. Nevertheless, during the 6-hour mean duration of therapy they managed to move the markers out of the small intestine more rapidly with WBI. Of note, the entire model has limited applicability, as WBI would never be considered for an acetaminophen overdose.

A randomized 3-phase crossover study using 9 volunteers, studied the use of activated charcoal alone compared to activated charcoal followed by WBI, in preventing the absorption of 3 different sustained-release drugs (carbamazepine, theophylline, and verapamil), all of which were administered in therapeutic doses. This study also found that WBI seemed to decrease the efficacy of activated charcoal, but that the pharmacokinetic profile was still better than no intervention, although these results were probably largely an effect of activated charcoal.[72] As mentioned above, study designs using activated charcoal and small doses of xenobiotics tend to bias the study toward a benefit of activated charcoal. In an overdose scenario, when activated charcoal may become saturated, it is intuitive that the benefits of other modalities would be more evident.

The third study evaluating the combined use of activated charcoal and WBI found that there were significant decreases in the adsorption of fluoxetine to activated charcoal and an increase in the desorption of the xenobiotic from activated charcoal.[12] These data support the findings of the studies previously cited in the position statement, but may have limited applicability as WBI would rarely, if ever, be indicated for fluoxetine overdose.

A small retrospective descriptive case series of 16 body-packers treated with WBI support the safety of this method. Although the

complication rate was reported as 12.5% (2 of 16), these complications were not serious. One case of mild cocaine toxicity resulted from leakage and one heroin body-packer had to undergo surgery because of retained packages. There was no correlation between the dose of PEG-ELS, drug type, or packet quantity and length of hospital stay. As there was no control group, it is not possible to evaluate whether WBI influenced any clinical outcome.[43]

A randomized crossover study using 9 volunteers compared fluid volumes used in WBI in a simulated ibuprofen overdose. The study found that a total of 3 L of PEG-ELS seemed to be as effective as a volume of 8 L when the end point was the AUC of ibuprofen. The problem with this study was the lack of a control group. Ibuprofen was administered in doses of 75 mg/kg, and as there was no control AUC without intervention, it is impossible to determine if the WBI in either volume had any effect at all.[97]

Whole-bowel irrigation has also been used to treat xenobiotic overdoses in pregnant women and children. One such case involved an iron overdose in a woman during the third trimester of pregnancy; she was treated successfully and without complications.[133] A pediatric case report describes combined WBI with succimer therapy and eventually colonoscopic removal of ingested lead pellets. Abdominal radiographs showed 2 small lead pellets, which WBI failed to remove, therefore requiring endoscopic removal.[28] Several reports support the use of WBI in children: an intentional ingestion of mercury,[114] 2 pediatric body-packers,[127] and a 16-month-old boy who had ingested a significant amount of iron.[134] In the latter case, despite WBI, the iron bezoar was not removed and eventually treatment was stopped and the bezoar was expelled after a normal diet was resumed.[134]

Thus there is no new convincing evidence of the clinical efficacy of WBI. Additional case reports and series demonstrate the overall safety of this procedure as well as some beneficial effect on

secondary end points, but the benefits remain in general, theoretical. There is some evidence against the simultaneous administration of activated charcoal with WBI is increasing and there is little doubt that PEG-ELS reduce the adsorptive capacity of activated charcoal in vitro.

The indications for WBI must, at the present time, remain theoretical, as the only support for the efficacy of this procedure comes from surrogate markers and anecdotal experience. Table 8-8 summarizes the indications and the contraindications for WBI.

Cathartics

At present there is no indication for the routine use of cathartics as a method of either limiting absorption or enhancing elimination.

A single dose can be given as an adjunct to activated charcoal therapy when there are no contraindications and constipation or an increased gastrointestinal transit time is expected. (See Antidotes in Depth: Whole-Bowel Irrigation and Other Intestinal Evacuants for more information on cathartics and WBI.)

Potentially toxic ingestions of sustained-release drugs
Ingestion of a toxic amount of a xenobiotic that is not adsorbed to activated charcoal when other methods of gastrointestinal decontamination are not possible or not efficacious
Removal of packets of illicit drugs (eg, from body-packers)
Airway protective reflexes are absent or expected to become so in a patient who has not been intubated
Gastrointestinal tract is not intact
Signs of ileus obstruction, significant gastrointestinal hemorrhage, or hemodynamic instability that might compromise gastrointestinal motility
Persistent vomiting
Signs of leakage from illicit cocaine packets (indication for surgical

removal)

Indications Contraindications

TABLE 8-8. Indications and Contraindications for Whole-Bowel Irrigation

Surgery and Endoscopy

Surgery and endoscopy are occasionally indicated for decontamination of poisoned patients. As might be expected, there are no controlled studies, and potential indications are based largely on case reports and case series. A prospective uncontrolled series of 50 patients with cocaine packet ingestion was collected more than 20 years ago.[22] The patients were conservatively managed and only underwent surgery if there were signs of leakage or mechanical bowel obstruction. Bowel obstruction occurred in 3 patients who promptly underwent successful emergency laparotomy, whereas another 6 patients chose elective surgery. The authors concluded that body-packers should be treated conservatively and only operated on for xenobiotic leakage or bowel obstruction.[22] Similarly, another study performed a 16-year retrospective analysis of all body-packers treated in a single center.[116] Of the 2880 body-packers who were identified, 2.2% developed symptoms of severe cocaine toxicity following rupture of a package; 43 of the symptomatic patients (68%) died before surgery could be initiated and 20 (32%) underwent emergency laparotomy to remove the drug packets and survived. A recent report described 2 cases of body-packers who successfully underwent surgery to remove drug packets. In one case the indications were rupture and signs of cocaine toxicity. In the other cases, the indication for surgery was bowel obstruction.[96] Because most packages do not spontaneously rupture, mechanical obstruction is probably the most common reason for surgery on a

body-packer.[126] Leakage from heroin-containing packages can usually be managed by naloxone infusion, but the lack of antidote when cocaine packages rupture necessitates surgery (Chaps. 38 and 74).[126]

Over the years, a few case reports have presented mixed results for the endoscopic removal of drug packets from the stomach.[25 , 118 , 120 , 126] At present, this method is not generally recommended because of concerns about packet rupture. However, under exceptional circumstances, there is certainly a precedent for attempting this procedure in a highly controlled setting such as an ICU or operating room.

In rare cases of massive iron overdoses where emesis, orogastric lavage, and gastroscopy failed, gastrotomy was performed. The significant clinical improvement and postoperative recovery indicated that surgery in these particular cases was the correct approach.[44 , 101]

Other Adjunctive Methods used for Gastrointestinal Decontamination

Other agents, such as cholecystokinin, have been considered as adjuncts to standard measures for gastrointestinal decontamination.[42 , 55] Pharmaceuticals that either speed up gastrointestinal passage or slow down gastric emptying have been administered in an attempt to minimize the absorption of a xenobiotic. In all cases the results have been negligible, and the potential risks of administering additional pharmacologically active agents to an already poisoned patient seem to outweigh any benefit.[5 , 135] Agents other than activated charcoal that reduce the absorption of xenobiotics from the gastrointestinal tract have also been studied, including sodium polystyrene for lithium,[16 , 77 , 78 and 79 , 124] or thallium overdose.[57] There have also been case reports of the use of the lipid-lowering resins cholestyramine and

colestipol to interrupt the enterohepatic circulation of digoxin, digitoxin, and chlordane in order to increase elimination.[15 , 45 , 67 , 104] With the increased use of activated charcoal and availability of digoxin-specific Fab fragments, indications for lipid-lowering resins for cardioactive steroid ingestions seem obsolete.

Combination Treatments

The combination of several different methods of gastrointestinal decontamination has been studied and, more importantly, is extensively practiced clinically. The combination of gastric emptying (mainly orogastric lavage) followed by activated charcoal is the subject of many investigations, both in volunteers[26] and in 2 often-discussed central clinical studies.[70 , 105] Only the small subset of significantly ill patients who received the combination of orogastric lavage and activated charcoal, seemed to benefit from combined therapy. On closer examination, this group was comprised of only 3 patients, compared to 17 patients who received activated charcoal alone.[70] This comparison of small, uneven, and unpaired numbers,

together with a retrospective stratification, poses consequential statistical problems and limits the potential for generalization of the authors' results.

A volunteer study, although also small in numbers (n = 12), used a controlled, randomized, paired design.[26] The subjects received approximately 4 g of acetaminophen (as 30â€“40 tablets of 125 mg strength) 1 hour after a standardized breakfast meal. The interventions (orogastric lavage plus activated charcoal vs. activated charcoal alone) were carried out 1 hour after drug ingestion. There were no significant differences in the AUC of acetaminophen between the 2 arms (power of 80% to detect a minimum relevant difference of 15%), but there was a 50% reduction for both arms compared to control. It must be

emphasized, however, that the end point measured was the size of the AUC of the drug and not a clinical end point (because of the nature of the study).

Similarly, a clinical study of 981 consecutive acetaminophen poisonings over a 10-year period, found that those patients who had ingested >10 g of acetaminophen by history and had received activated charcoal were significantly less likely to have a concentration of acetaminophen requiring antidotal therapy when compared to patients who received no decontamination. However, orogastric lavage in addition to activated charcoal did not further decrease that risk.[20] Thus, the combination of orogastric lavage followed by activated charcoal only seems appropriate in cases where orogastric lavage is indicated and the xenobiotic is adsorbed to activated charcoal. In cases where activated charcoal alone is usually beneficial, there is little rationale to expose the patient to the additional risks of orogastric lavage. Although acetaminophen is a reasonable drug to study, the universal availability of a benign and inexpensive antidote contraindicates aggressive gastric emptying in acetaminophen overdose *even* if some benefit could be demonstrated.

The combination of activated charcoal and whole-bowel irrigation would seem to make sense in that it might speed up gastrointestinal passage and at the same time have the protective adsorptive effect of activated charcoal. However, based on the studies cited previously, it seems that if activated charcoal is administered with WBI, the adsorptive capacity of activated charcoal is reduced, and the recommendation is to administer the activated charcoal prior to the administration of PEG-ELS. There is concern about the practice of treating asymptomatic cocaine body-packers with WBI combined with activated charcoal because severe peritonitis can result if activated charcoal spills into the peritoneum following surgical intervention. The administration of activated charcoal is not expected to prevent routine surgery and because the use of activated charcoal may increase the risk of

surgical complications, activated charcoal should not be used under these circumstances.

General Aspects

Only a few gastrointestinal decontamination studies provide guidance based on meaningful clinical end points. One of the few studies addressing meaningful clinical parameters was a retrospective analysis reviewing the management of all patients presenting to an emergency department with a diagnosis of deliberate self-poisoning.[52] The study evaluated 561 patients who were treated in 1999, comparing them with patients treated in 1989, 1992, and 1996.[52] The authors found that despite dramatically changing trends of gastrointestinal decontamination, there were no significant changes in the proportion of patients admitted to the hospital, although there was a reduction in the rate of admission to the ICU. The patient populations did not change significantly over the years with regard to the female-to-male ratio, the age distribution, and the types of xenobiotics ingested. The authors mention that there might be unmeasured differences between the populations and unrecognized differences in practice that might have been influential. However, in 1989 most of the patients were treated with orogastric lavage, almost no patients received activated charcoal, and approximately 33% did not receive any gastric decontamination at all. In comparison, in 1996, more than 50% of patients received activated charcoal alone and less than 25% had no gastrointestinal decontamination at all. In 1999, only 13% of patients received activated charcoal, 0.7% a combination of orogastric lavage followed by activated charcoal, 0.5% were given WBI, and nearly 86% received no decontamination at all. There were no changes in overall mortality from poisonings over the years, although the mortality was generally very low. Thus, although the trends in gastrointestinal decontamination dramatically shifted toward less intervention over the years studied, there was no measurable worsening in outcome

when large groups of patients were studied. It must be emphasized that this was a retrospective analysis with fairly nonspecific outcome measures, and possible improvements in other aspects of clinical treatment of poisoned patients were not considered.

The trends in practice noted in the study above are reflective of the overall combined philosophy of the position statements, which are applicable to the vast majority of poisoned patients. They highlight the benign nature of many exposures and the benefits of good supportive care. In contrast, the previously mentioned survey of recommendations for a theoretical patient with a serious enteric-coated aspirin overdose reveal less consensus in that 36 different courses of action were proposed for the same case. Most of the poison centers and toxicologists did, however, recommend at least one dose of activated charcoal.[63] This distinction serves as a reminder that the existing studies and consensus statements cannot be applied to all cases, and that a lack of data produce significant uncertainty in choices for gastrointestinal decontamination in either atypical or severely poisoned patients.[58]

It is essential to note that only one study has ever demonstrated a survival advantage for any form of gastrointestinal decontamination of poisoned patients.[37] Its unique design, involving a cohort of patients with life-threatening toxicity, forces a reassessment of all previous literature and confirms that the principles of decontamination are sound. It also suggests that the failure of most studies to demonstrate a benefit results not from a failure of the techniques employed, but from applying decontamination techniques to subsets of patients who were likely to have good outcomes regardless of intervention.

Summary

The approach to gastrointestinal decontamination needs to be more individualized than previously thought. No decontamination

method is completely free of risks. The indications for when and when not to perform gastrointestinal decontamination must be well defined for each patient and the method of choice must depend

largely on what was ingested, how much was ingested, and when it was ingested. The absolute time frame for when decontamination is indicated is dependent on many factors, such as rate of gastric emptying, rate of xenobiotic absorption, and the possibility of enterohepatic cycling. The commonly stated short time frame of up to 1 hour postingestion for intervention is most likely an underestimation of the time frame during which a benefit is likely to be realized, although this has not yet been adequately investigated.

Judging from the evidence available today, activated charcoal must be the first choice, only accompanied by orogastric lavage when the desirable ratio of activated charcoal-to-xenobiotic cannot be achieved, and the xenobiotic is still thought to be accessible in the stomach. Orogastric lavage as a single intervention is reserved for those cases where the ingested xenobiotic is not adsorbed by activated charcoal and there is reason to believe that the ingested xenobiotic is both life-threatening *and* still in the stomach. Syrup of ipecac-induced emesis has a very small therapeutic role, but might be reserved for those situations where there is an absolute need for gastrointestinal decontamination, activated charcoal is not expected to be effective, and orogastric lavage and whole bowel irrigation are, for practical purposes, impossible. Multiple-dose activated charcoal and whole-bowel irrigation have defined indications, which may broaden in the future as more studies focus on subsets of significantly poisoned patients.

The advancement of medical toxicology is dependent on well-designed clinical studies that concentrate on measuring the effect of gastrointestinal decontamination using sound and relevant clinical end points. For each approach it must be determined if the benefits of decontamination outweigh the potential risks. If proven

beneficial, we need to set firm criteria for the future selection of patients for whom these treatments are beneficial and therefore indicated. One goal must be to reduce complications by identifying those patients who can be safely managed without decontamination. At the same time, we must be ever vigilant for patients with ingestions of unstudied highly lethal xenobiotics and massive amounts of studied xenobiotics, as well as those who present early in their clinical course with life-threatening signs and symptoms. This uncommon subset is most likely to benefit from more aggressive gastrointestinal decontamination. Thus it is recommended that some form of gastrointestinal decontamination be considered in *every* patient with potentially life-threatening toxicity regardless of the time since ingestion, as long as no absolute contraindications exist.

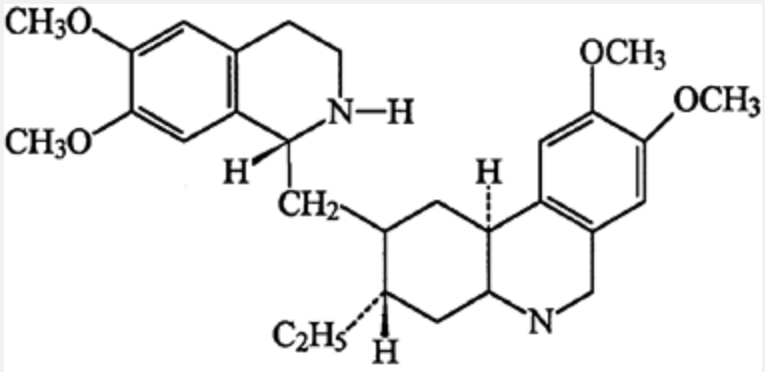
Antidotes in Depth

Syrup of Ipecac

Mary Ann Howland



Emetine

The role of syrup of ipecac has changed dramatically in the last decade. Once the mainstay of poison management for children and adults, a critical evaluation of animal, volunteer, and a limited number of clinical studies suggests that ipecac administration

should be reserved for a few selected circumstances rather than administered on a routine basis.[3] The rationale for this change is based on the facts that (a) most poisonings in children are benign; (b) many adults overdose with xenobiotics that rapidly cause an altered mental status which constitutes a contraindication to the administration of ipecac; (c) ipecac-induced vomiting may be delayed and/or persistent, thereby resulting in a delay in the administration of activated charcoal.

Syrup of ipecac is an emetic that has been used for the management of poisonings since the 1950s and has been available without prescription since the late 1960s. Pediatricians were encouraged to advise parents to keep syrup of ipecac in their homes. Many pediatricians currently believe that there is no role for syrup of ipecac in the prehospital or hospital setting and that the abuse of syrup of ipecac by patients with bulimia outweighs any benefit originating from keeping syrup of ipecac as a nonprescription drug. The FDA is reviewing whether to make syrup of ipecac available only by prescription. Advocates for maintaining the nonprescription status of syrup of ipecac support home stocking of ipecac for use in remote areas and limiting use in healthcare facilities to those rare instances when activated charcoal, orogastric lavage, or whole-bowel irrigation with polyethylene glycol lavage solution may be inappropriate or inadequate. Changing the availability of syrup of ipecac to prescription status only, could result in the complete disappearance of syrup of ipecac from the pharmaceutical market if the FDA required a new drug application. Under these circumstances it might not be profitable for any drug company to invest in a new drug application.

Composition

Ipecac is derived from the dried rhizome and roots of plants found in Brazil belonging to the family Rubiaceae, such as *Cephaelis*

acuminata or *Cephaelis ipecacuanha*.[51] Ipecacuanha originates from the plant's Portuguese name â€œipecaaguenâ€• which translates to â€œsmaller roadside sick-making plant.â€•[52] Cephaeline and emetine are the two alkaloids largely responsible for the production of nausea and vomiting, with cephaeline being the more potent.[28] Each 15-mL dose of syrup of ipecac contains 16â€“21 mg of cephaeline and 6.4â€“21 mg of emetine, resulting in variable cephaeline-to-emetine ratios. Syrup of ipecac also contains a small amount of psychotrine, which does not contribute to emesis but is currently under investigation for its potential anti-HIV effects.

Pharmacokinetics of Ipecac Alkaloids

After human volunteers were administered 20 or 30 mL of syrup of ipecac, plasma, vomitus and urine concentrations of emetine and cephaeline were determined by the use of high-performance liquid chromatography (HPLC).[56] Peak plasma levels of the alkaloids were reached by 1 hour and were undetectable at 6 hours. Only 2% of the total amount of alkaloids in the ipecac were excreted in the urine within 48 hours, and remained detectable in the urine for 2 weeks in all 12 volunteers and for 12 weeks in 1 of 2 subjects who were tested subsequently.

Mechanism of Action

Syrup of ipecac induces vomiting by local activation of peripheral emetic sensory receptors in the proximal small intestine, and by central stimulation of the chemoreceptor trigger zone that serves as a sensory area resulting in subsequent activation of the central vomiting center.[47] $5HT_3$ receptors mediate the nausea and vomiting produced by syrup of ipecac by both mechanisms. This was demonstrated in 40 volunteers by administering a specific $5HT_3$ antagonist 30 minutes prior to administration of the syrup of ipecac; the $5HT_3$ antagonist prevented or attenuated the nausea

and vomiting in a dose-dependent fashion.[18] In fact, syrup of ipecac is used to assess the efficacy of new $5HT_3$ antagonists and other antiemetics.[13,45]

Time to onset of Vomiting and Number of Vomiting Episodes

In one of the earliest studies evaluating the delay in onset to vomiting after syrup of ipecac administration, 88% of 214 children who were given 20 mL of syrup of ipecac and copious amounts of water vomited within 30 minutes (mean of 18.7 minutes).[40] Adverse events secondary to syrup of ipecac were not noted. Subsequent studies demonstrate similar findings.[6,12,14,16,20,27,29,49,50]

The onset of emesis following syrup of ipecac administration does not appear to be affected by fluid administration before or after syrup of ipecac, by the temperature of the fluids, or by gentle patient motion or walking.[16,17,20,46] Consequently, it is inadvisable to force fluids and safer to maintain the patient in an

appropriate stationary setting (chair or stretcher). Milk should not be given with the syrup of ipecac, as the onset of emesis may be delayed, although the success of inducing vomiting does not appear to be affected.[17] This delay is consistent with the ability of milk to delay gastric emptying and thereby retard ipecac's contact with the peripheral emetic sensory receptors.[53] Because when followed by water, syrup of ipecac is absorbed so quickly, vomiting still occurred in the majority of overdose patients who were also given activated charcoal 10 minutes after the syrup of ipecac.[19]

The average number of episodes of vomiting following syrup of ipecac administration is 3, with a range of 1 to 8.[27] The duration of syrup of ipecac-induced vomiting averaged 23â€“60 minutes.[27,39] Although some investigators suggested durations

lasting up to 3â€“4 hours,[35] it is probably reasonable to assume that vomiting that persists for more than 2 hours is unrelated to syrup of ipecac and another cause should be sought. This warning is of particular importance when syrup of ipecac is used in the home.

Volunteer Studies

Many studies have assessed the effectiveness of syrup of ipecac-induced emesis in decreasing absorption of a xenobiotic, and then compared the results to other methods of gastric decontamination, such as gastric lavage or activated charcoal.[35,37,43] These same studies support the concept that the sooner syrup of ipecac is administered after ingestion, the greater the amount of the ingested xenobiotic that will be recovered. The decrease in the amount of xenobiotic absorbed varies from study to study as a result of differences in study design, including time to initiation of the various techniques and the particular xenobiotic used to assess efficacy. Volunteer studies using small lavage tubes were further limited because of the quantity of xenobiotic that was administered and the limited potential of the tube to recover xenobiotic. In a small, well-quantified study, when 6 adult volunteers were given 20 mL of syrup of ipecac at 5 or 30 minutes after acetaminophen ingestion, absorption was inhibited by 65% and 0%, respectively.[37] In this same volunteer model, absorption was inhibited by 80% and 40% when 50 g of activated charcoal was given at 5 and 30 minutes postingestion.[36]

A subsequent investigation demonstrated that the reduction in the area under the plasma drug concentration versus time curve was equivalent for patients treated with syrup of ipecac-induced emesis and patients treated with activated charcoal plus a cathartic. Comparison of orogastric lavage, syrup of ipecac-induced emesis, and activated charcoal, all given at 60 minutes after ingestion of ampicillin by adult volunteers, showed reductions

of 32%, 38%, and 57%, respectively.[50] Adult volunteers given syrup of ipecac 5 minutes after 30 capsules containing a radionucleotide marker demonstrated a mean 54% removal (range, 21â€“89%) as compared to a mean removal of 35.5% (range, 1â€“71%) with orogastric lavage.[57] Other researchers demonstrated recoveries from 0% to 85%.[6,14,15,49] Children given a magnesium hydroxide marker before administration of syrup of ipecac demonstrated a mean recovery of 28%, although the range was 0â€“78%.[14]

Overdosed Patients

In a study of self-poisoned adults randomized to receive either syrup of ipecac or orogastric lavage with a 33-French lavage tube, all patients had subsequent gastric endoscopy.[42] Thirteen patients were given syrup of ipecac and vomited within 23 minutes (range, 11â€“25 minutes). Two of these patients had tablets in the vomitus. On endoscopy, only those 2 patients had residual tablets in the stomach. Ten of 17 patients who were lavaged had tablets in the lavage fluid. All of these patients had tablets in the stomach at the time of endoscopy. Two additional patients also had residual tablets in the stomach. This study suggests that the presence of tablets in the vomitus or lavage fluid supports the presence of additional tablets in the stomach.[42]

This same group of investigators subsequently used barium-marked 3 mm^3 pellets to evaluate the effectiveness of gastric emptying.[43] Forty self-poisoned patients were given 20 pellets on admission and randomized immediately to therapy with either orogastric lavage or syrup of ipecac-induced emesis. Approximately 45% of the pellets were removed in both the orogastric lavage and the syrup of ipecac groups. Two patients in the lavage group and 1 in the syrup of ipecac group had 100% removal of pellets, and 2 patients in the lavage group had no removal.[43]

Outcome Studies

A large emergency department (ED) study addressed whether gastric emptying with either syrup of ipecac followed by activated charcoal or orogastric lavage followed by activated charcoal was more effective than activated charcoal alone in overdosed patients.[25] Syrup of ipecac did not affect the outcome in treated patients.

Three subsequent studies (2 adult and 1 pediatric) failed to show a benefit of gastric emptying before activated charcoal administration[2,34] compared with the administration of activated charcoal alone.[23] Furthermore, aspiration was more common in patients who had the combined regimen.[2,34]

A study using the Toxic Exposure Surveillance System (TESS) database determined that home use of syrup of ipecac did not reduce the rate of ED referrals.[11] That this study did not identify an improvement in patient outcome was not unexpected. Most children have no clinical sequelae from exposure and group statistics cannot identify a potentially beneficial effect that occurs rarely.

Contraindications

Syrup of ipecac should not be administered to patients who have ingested acids or alkalis, are younger than 6 months of age, are expected to deteriorate rapidly, have a depressed mental status, have a compromised gag reflex, have ingested objects such as batteries or sharps, or have a need for rapid gastrointestinal evacuation to prevent absorption. Syrup of ipecac should not be administered to those for whom the hazards of vomiting and aspiration of the ingested substance outweigh the risks associated with systemic absorption (eg, hydrocarbons), those who have significant prior vomiting, or those for whom vomiting will delay administration of an oral antidote, or to those with a hemorrhagic

diathesis, or a nontoxic ingestion, or when toxin is no longer expected to be in the stomach.

Adverse Effects

Considering the number of times it has been administered without incident in this country, syrup of ipecac should be considered a

relatively safe drug when given in therapeutic doses to patients for whom there are no contraindications. Uncommon problems that have occurred after therapeutic doses of syrup of ipecac include a Mallory-Weiss esophageal tear in an adult given 30 mL of syrup of ipecac for a multidrug overdose;[48] herniation of the stomach into the left chest in a child who had a previously unrecognized underlying congenital defect of the diaphragm;[41] intracerebral hemorrhage;[22] and pneumomediastinum.[54] Additional problems associated with syrup of ipecac administration include pulmonary aspiration of stomach contents, volatile hydrocarbons or foreign bodies, and the associated time delay before it is possible to perform a necessary therapeutic intervention such as administration of activated charcoal or an oral antidote. Another reported problem is the emesis-induced vagal response of bradycardia.[33]

The surreptitious self-administration of frequent doses of syrup of ipecac by patients with bulimia and other related eating disorders results in substantial morbidity such as extreme muscle weakness and congestive cardiomyopathy, and mortality.[1,8,28,30,38,44,55] Myofibril analysis of ipecac abusing patients reveals degeneration, a â€œmoth-eatenâ€• appearance, and electron microscopy reveals Z-band streaming and disorganization.[26] When emetine was routinely used for the treatment of amebiasis in the early 1900s, cardiovascular and neuromuscular toxicity occurred. Similarly, inadvertent administration of the fluid extract of ipecac, which is 14 times more potent than syrup of ipecac, produces

violent and protracted vomiting; diarrhea; seizures; cardiac toxicity including PR interval prolongation, T-wave abnormalities, QRS complex abnormalities, atrial dysrhythmias, premature ventricular beats, and ventricular fibrillation; neuromuscular toxicity, including weakness and neuropathy; shock; and death.[28] Surreptitious chronic intentional ipecac poisoning of children, a form of Munchausen syndrome by proxy, is reported.[9,31] The findings in these children included vomiting, diarrhea, lethargy, irritability, hypothermia, and hypotonia. The children described were brought to healthcare providers by their parents for atypical patterns of vomiting and had multiple unsuccessful clinical evaluations. When surreptitious use of syrup of ipecac is suspected as the cause of chronic vomiting, screening the urine, plasma, and vomitus for emetine (thin-layer chromatography screenâ€"Toxi-Lab or HPLC) may be useful.[5,31,56]

Current Role of Syrup of Ipecac in Poison Management

Most authorities agree with the American Academy of Pediatrics' statement that syrup of ipecac should no longer be used routinely.[3,4] Instead of promoting the concept of the maintenance of syrup of ipecac in the home, the Academy of Pediatrics currently states that â€œthe first action for a caregiver of a child who may have ingested a toxic substance is to consult with the local poison control center.â€•[4] Logically, the sooner that syrup of ipecac is administered after ingestion, the more effective it may be in reducing absorption of the agent. For this reason, rather than completely abandoning syrup of ipecac, perhaps a targeted approach should be developed. This would mean continuing to promote the stocking of syrup of ipecac in the home setting in remote areas. Although the Academy of Pediatrics believes that it is premature to recommend the routine home stocking of activated charcoal, home stocking of activated charcoal in remote areas

seems logical.

Only a few groups of patients are considered appropriate candidates for the use of syrup of ipecac. Patients who are candidates for syrup of ipecac are those who (a) overdose on xenobiotics that do not cause a rapid change in mental status, such as acetaminophen or salicylates; (b) consume massive amounts of a toxin that may exceed the binding capacity of activated charcoal, such as salicylates; or (c) ingest a toxin not bound to activated charcoal, such as lithium. Under these circumstances, if the presence of unabsorbed drug in the stomach remains a potential problem, then the use of syrup of ipecac may be appropriate in rare instances when weighed against the utility of activated charcoal or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution. The time frame for this decision is usually within 1 to 2 hours following ingestion.

Administration

The dose of syrup of ipecac is 15 mL in children 1â€“12 years old and 30 mL in older children and adults. If vomiting does not ensue after the first dose, the same dose may be repeated once 20â€“30 minutes after administration of the first dose. For children 6â€“12 months of age, ipecac use should be limited to a maximum single dose of 10 mL.[10,24] Water can be offered, but is not essential for success. Vomiting will occur in most patients. Home users should be warned that persistent vomiting for more than 2 hours may indicate toxicity from the primary xenobiotics ingested and not the antidote, and necessitates medical evaluation.

Conclusion

There are very few cases in which syrup of ipecac is indicated in the home setting because typically either most ingestions are nontoxic or, conversely, are of such consequence that an imminent

deterioration in mental status may occur that would make syrup of ipecac administration dangerous. Parents in areas with poor access to a healthcare facility should still be encouraged to keep syrup of ipecac and activated charcoal at home as potential first aid measures, but caregivers should be cautioned to use them only on the advice of a regional poison center or physician.

In the ED, the role of syrup of ipecac is extremely limited. One of the only possible candidates for syrup of ipecac in the overdose setting is a child or adult who arrives in the ED shortly after the ingestion of a large number of poorly soluble tablets of a size unlikely to be removed by lavage and also unlikely to cause a rapid change in mental status. One other candidate is the child or adult who has taken such a large amount of a highly toxic substance that a favorable activated charcoal-to-drug ratio cannot be attained with certainty. Whole-bowel irrigation should be considered as a suitable alternative in either case.

Activated Charcoal

Mary Ann Howland

History

Activated charcoal (AC), a fine, black, odorless powder, has been recognized for almost 2 centuries as an effective adsorbent of many substances. In 1930, the French pharmacist Touery dramatically demonstrated his belief in the powerful adsorbent qualities of AC by ingesting several times the lethal dose of strychnine mixed with 15 g of AC in front of colleagues; he suffered no ill effects.[6] An American physician, Holt, first used AC to save a patient from mercury bichloride poisoning in 1934.[6] However, it was not until the 1940s that Anderson began to systematically investigate the adsorbency of AC and unquestionably demonstrated that AC is an excellent broad-spectrum gastrointestinal adsorbent.[6,7 and 8] The current debate regarding the role of AC in poison management centers on reconciling evidence-based studies in volunteers and small numbers of heterogeneous overdosed patients with clinical experience.[4] AC should be considered for administration to a poisoned or overdosed patient following a risk-to-benefit

assessment for the substance presumably ingested and ideally also for the circumstances of the exposure for a particular patient. The benefits include inactivating a potentially toxic xenobiotic, whereas the risks include vomiting and subsequent aspiration. The merits of AC as a decontamination strategy are discussed in detail in Chap. 8.

Adsorption: Mechanisms and Considerations

AC is produced in a two-step process, beginning with the pyrolysis of various carbonaceous materials such as wood, coconut, petroleum, or peat. This processing is followed by treatment at high temperatures with a variety of oxidizing (activating) agents such as steam or carbon dioxide to increase the adsorptive capacity of the agent through the formation of an internal maze of pores with a huge surface area.[29,53,104,129] The rate of adsorption depends on external surface area, while the adsorptive capacity is dependent on the far larger internal surface area.[29,97,103] The adsorptive capacity can be modified by altering the size of the pores. Current AC products have pore sizes that range from 10 to 1000 angstroms (Ã…) with most of the internal surface area created by the summation of 10â€“20-Ã…-sized pores.[25,27,29] Most xenobiotics are of moderate molecular weight (100â€“800 daltons) and adsorb well to pores in the range of 10â€“20 Ã…. Mesoporous charcoals with a pore size of 20â€“200 Ã… have a greater capacity to adsorb larger xenobiotics as well as those in their larger hydrated forms.[77]

The relationship between AC surface area and adsorptive capacity was studied in vitro and in vivo in animals and in humans. When surface area is large, adsorptive capacity is increased, but affinity is decreased because van der Waals forces and hydrophobic forces are diminished.[131] In 1996, a superactivated charcoal with a surface area approximately double the current AC formulations

was marketed. Both in vitro and in vivo studies of this preparation indicated a greater maximum adsorptive capacity.[30,116]

The actual adsorption of a xenobiotic by activated charcoal is believed to rely on hydrogen bonding, ion-ion, dipole, and van der Waals forces, suggesting that most xenobiotics are best adsorbed by activated charcoal in their dissolved, nonionized form.[29] Thus, according to the Henderson-Hasselbalch equation, weak bases are best adsorbed at basic pHs and weak acids are best adsorbed at acid pHs. For example, cocaine, a weak base, binds to AC with a maximum adsorptive capacity of 273 mg of cocaine per gram of AC at pH 7.0; this capacity is reduced to 212 mg of cocaine per gram of AC at pH 1.2.[76] Strongly ionized and dissociated salts like sodium chloride or potassium chloride are not adsorbed, whereas nonionized or weakly dissociated salts like iodine and mercuric chloride, respectively, are adsorbed. The adsorption to AC of a weakly dissociated metallic salt like mercuric chloride ($HgCl_2$) decreases with decreasing pH because the number of complex ions of the type $HgCl_3$ and $HgCl_4$ increases and the number of electroneutral molecules ($HgCl_2$) is reduced.[7] Nonpolar, poorly water soluble organic substances are more likely to be adsorbed from an aqueous solution than polar, water-soluble substances.[29] Among the organic molecules, aromatics are better adsorbed than aliphatics, molecules with branched chains are better adsorbed than those with straight chains, and molecules containing nitro groups are better adsorbed than those containing hydroxyl, amino, or sulfonic groups.[29] In vitro studies demonstrate that adsorption begins within about 1 minute of administration of AC, but may not reach equilibrium for 10â€“25 minutes.[30,92]

Accordingly, desorption (drug dissociation from activated charcoal) may occur, especially for weak acids, as the activated charcoal-drug complex passes from the stomach through the intestine and as the pH changes from acidic to basic.[12,42,98,103,128] Desorption may lead to systemic absorption of larger total amounts of xenobiotic over several days; in this case, the elimination half-life

of the xenobiotic appears to increase, but peak levels remain unaffected.[98] The clinical effects of desorption can be minimized by giving a sufficiently large dose of AC to overcome the decreased affinity of the xenobiotic secondary to pH change such as by using multiple-dose activated charcoal. Either whole-bowel irrigation or cathartic may reduce gastrointestinal transit time and possibly increase xenobiotic elimination. However, in spite of numerous human volunteer studies,[62,85,96,107,121] increased xenobiotic elimination has been demonstrated for cathartics only in a single study.[62]

Although ethanol and other solvents such as polyethylene glycol are minimally adsorbed by AC, they nonetheless may decrease the adsorptive capacity of AC for a coingested xenobiotic by competing for AC binding with that xenobiotic.[13,98,101]

AC decreases the systemic absorption of most xenobiotics, including aspirin, acetaminophen, barbiturates, glutethimide, phenytoin, theophylline, cyclic antidepressants, and most inorganic and organic materials.[41,92,106] Notable xenobiotics not amenable to AC are the alcohols, acids and alkalis, and iron,[45] potassium, magnesium, sodium, and lithium salts. Although the binding of AC to

cyanide is less than 4%, the toxic dose is small and 50 g of AC would theoretically be able to bind more than 10 lethal doses of potassium cyanide.

Efficacy of AC is directly related to the amount of AC administered. The effect of the AC-to-drug ratio on adsorption was demonstrated both in vitro and in vivo with *para*-aminosalicylate (PAS): In vitro, the fraction of unadsorbed PAS decreased from 55% to 3% as the AC-to-PAS ratio increased from 1:1 to 10:1 at pH 1.2.[102] This study most likely provides the best scientific basis for the 10:1 AC-to-drug ratio dose recommendation. In human volunteers, as the AC-to-PAS ratio increased from 2.5:1 to 50:1, the total 48-

hour urinary excretion decreased from 37% to 4%.[103] Presumably this occurred because more of the PAS was adsorbed by AC in the lumen of the gastrointestinal tract rather than being absorbed systemically. These same studies demonstrate AC saturation at low ratios of AC to drug and argue for a 10:1 ratio of AC to xenobiotic.

The clinical efficacy of administered AC is also inversely related to the time elapsed following ingestion of the substance to be adsorbed and depends largely on the rate of absorption of the drug. For example, early administration is much more important with rapidly absorbed drugs. In this situation, AC functions to prevent the absorption of drug into the body by achieving rapid adsorption in the GI tract. Once a drug is systemically absorbed or parenterally administered AC may still enhance elimination through a mechanism referred to as gastrointestinal dialysis. This is accomplished with multiple doses of AC.

Palatability

The black and gritty nature of AC has led to many formulations to increase palatability and patient acceptance. Bentonite, carboxymethyl cellulose, and starch[49,91,119] are used as thickening agents; cherry syrup, chocolate syrup, sorbitol, sucrose, saccharin, ice cream, and sherbet [30,71,78,135] are used as flavoring agents. Most of these additives do not decrease adsorptive capacity; however, improvement in palatability and acceptance is minimal or nonexistent with all of these formulations.[28] Although a milk chocolate formulation of AC evaluated by a group of children was rated superior in palatability to standard AC preparations,[38] it was never marketed. A marketed AC product with cherry flavoring was rated by adult human volunteers as preferable over plain AC and a statistically significant larger quantity of the flavored AC was ingested.[24] However, in adult overdosed patients, this was not the case, as

most patients consumed the entire bottle of AC with or without cherry flavoring. Many of the subjects did not like the taste and surprisingly preferred the plain AC.[58] Two studies in adult overdosed patients compared different brands of AC without additives or flavoring to determine the quantity of activated charcoal typically ingested.[17,43] In one study, approximately half of the 50 g of activated charcoal offered was ingested and 7% of the patients vomited.[17] In the other study, 60 g of AC as Liqui-Char or CharcoAid G was offered and approximately 95% of each formulation was consumed in 20 minutes. There was no difference in the amount consumed even though the palatability of the granular form of AC (CharcoAid G) was rated higher.[43]

Recently cold cola was used to enhance palatability in volunteer children and adults. Children preferred regular cola as compared to diet cola. The adults rated the cola charcoal combination preferable to the plain charcoal.[113,118]

Adverse Effects

The use of AC is relatively safe, although vomiting (which especially occurs after rapid administration), constipation, and diarrhea frequently occur following AC administration.[97] Constipation and diarrhea are more likely to result from the ingestion itself than from the AC. However, black (heme-negative) stools, tongues, and mucous membranes are frequently observed. Serious adverse effects of AC include the complications that may result from the pulmonary aspiration of AC with or without gastric contents,[9,39,47,50,51,59,86,92,108,120] peritonitis from spillage of AC into the peritoneum from gastrointestinal perforation caused by orogastric lavage,[79] and intestinal obstruction and pseudo-obstruction, especially following repeated doses of AC in the presence of either dehydration[18,73,88,114,132] or prior bowel adhesions.[48]

Although a significant number of patients aspirate gastric contents

prior to endotracheal intubation and administration of AC,[90,117] the incidence of AC aspiration following endotracheal intubation varies from 4% to 25%, depending on the nature of the study. A more recent retrospective investigation demonstrated a 1.6% incidence of aspiration pneumonitis in unselected overdosed patients. Altered mental status, spontaneous emesis, and tricyclic antidepressant overdose were associated risk factors, whereas AC was not.[57]

Home and Prehospital Administration

Prehospital administration of AC by emergency medical technicians and paramedics may offer a significant advantage in facilitating the administration of AC more rapidly following the time of overdose.[2,133] However, the cost of implementation of such a program would have to be weighed against the small number of patients who would actually benefit.[56]

In a study intended to simulate home administration of AC the acceptance of a dose of AC given as a water slurry in a paper cup was studied in 50 young children.[20] The children were told to drink the contents, that the substance did not taste bad, and that it would make them feel better and not feel ill. Eighty-six percent of the children readily drank the AC slurry, and 76% of them consumed 95â€“100% of the total dose. Of 7 children in a simulated home environment administered AC in regular cola, 3 drank 1 g/kg, 2 drank very little, and the other 2 drank about half a therapeutic dose.[118] A prospective poison center case series demonstrated successful administration of AC in the home. In this series the median age of the patients was 3 years and the median dose ingested was 12 g.[124] However, other attempts at getting children to ingest AC were not as successful; in one study difficulty was noted in 70% of attempts to administer a standard dose of AC to children in the home setting.[35]

Administration and Dosing

AC should not be administered routinely to all overdosed patients. Single-dose AC should be administered when xenobiotic is still expected to be available for adsorption in the GI tract and the benefit outweighs the risk. The optimal dose of AC is unknown.[4] However, most authorities recommend a dose of AC of 1 g/kg of body weight when the amount of xenobiotic exposure is unknown or when

known in a 10:1 ratio of AC to xenobiotic, up to an amount that is tolerated by the patient and safely administered. AC that is not premixed is best administered as a slurry in a 1:8 ratio of AC to suitable liquid, such as water or cola. Using cold cola may offer improved palatability.[113,118] Administering the mixture to children from an opaque, covered cup decorated with stickers and through a straw may be helpful.[134] Contraindications to AC include presumed GI perforation and the need for endoscopic visualization, as may be the case with caustic ingestion. To prevent aspiration pneumonitis from oral AC administration it is imperative that the patient's airway be assessed. When the potential for airway compromise is substantial, oral AC should be withheld until a decision about airway protection is made. A risk-to-benefit assessment with regard to the need for airway protection and the need for AC should be made. Other considerations that must be made prior to the administration of AC are the determination of normal gastrointestinal motility, normal bowel sounds, and a normal abdominal examination without distension or signs of an acute abdomen. If bowel function is compromised, the stomach should be decompressed to decrease the risk of subsequent vomiting and aspiration prior to administration of AC.

The use of Activated Charcoal, Cathartics, and Whole-Bowel Irrigation

with Polyethylene Glycol Electrolyte Lavage Solution

Cathartics are often used with AC, however the evidence suggests that AC alone is comparably effective to AC plus a single dose of cathartic (sorbitol or magnesium citrate).[3,62,80,81,85,91,97,105] If a cathartic is used, it should be used only once as repeated doses of magnesium-containing cathartics are associated with hypermagnesemia[89,123] and repeated doses of any cathartic can be associated with severe fluid and electrolyte problems. A child died following repeated doses of AC-sorbitol mixtures.[40]

Whole-bowel irrigation with polyethylene glycol electrolyte lavage solution may significantly decrease the in vitro and in vivo adsorptive capacity of AC[52] depending on the individual xenobiotic and the drug's formulation.[10,68] The most likely explanation is competition with the activated charcoal's surface for solute adsorption.

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal (MDAC) functions in two ways: (a) to prevent the absorption of xenobiotics that are slowly absorbed from the GI tract, and (b) to enhance the elimination of suitable xenobiotics that have already been absorbed.

MDAC decreases xenobiotic absorption when large amounts of xenobiotics are ingested and dissolution is delayed (eg, masses, bezoars), when xenobiotic formulations exhibit a delayed or prolonged release phase (eg, enteric coated, sustained release), or when reabsorption can be prevented (eg, enterohepatic circulation of either active drug, active metabolites, or conjugated xenobiotic hydrolyzed by gut bacteria to active xenobiotic).

The ability of MDAC to enhance elimination once absorption had already occurred was first reported in 1982.[14] This report

concluded that orally administered MDAC enhanced the total body clearance (nonrenal clearance) of 6 healthy volunteers given 2.85 mg/kg of body weight of intravenous (IV) phenobarbital.[14] The serum half-life of phenobarbital decreased from 110 Â± 8 to 45 Â± 6 hours. An accompanying editorial suggested that MDAC enhanced the diffusion of phenobarbital from the blood into the gastrointestinal tract and trapped it there, to be excreted later in the stool. In this manner, AC was said to perform as an â€œinfinite sinkâ€• allowing for â€œgastrointestinal dialysisâ€• to take place.[70] These findings were subsequently confirmed by studies in dogs and rats using intravenous aminophylline.[34,83] Using an isolated perfused rat small intestine the concept of gastrointestinal dialysis[83] was elegantly demonstrated, as AC dramatically affected the pharmacokinetics of theophylline and produced a constant intestinal clearance that was approximately equivalent to intestinal blood flow.[83] Although MDAC increases the elimination of digitoxin;[109] phenobarbital;[111] carbamazepine;[16] phenylbutazone;[93] dapsone;[94] nadolol;[37] theophylline;[15,75,127] salicylate;[112] quinine;[5] cyclosporine;[54] propoxyphene;[60] nortriptyline; and amitriptyline, its clinical utility remains to be defined.[5,61,125] The adsorptive capacities for these and other agents are well documented.[5,21,22,29,84]

Volunteer and Experimental Studies

An analysis of 28 volunteer studies involving 17 xenobiotics was unable to correlate the physiochemical properties of a particular xenobiotic with the ability of MDAC to decrease the plasma half-life of that xenobiotic.[21] Although the half-life was not thought to be the best marker of enhanced elimination, it was the only parameter consistently mentioned in all of the studies that otherwise substantially differed from one another with regard to study design. The xenobiotics with the longest intrinsic plasma half-lives seemed to demonstrate the largest percent reduction in plasma half-life when MDAC was used. A subsequent animal model

with therapeutic doses of four simultaneously administered intravenous xenobiotics (acetaminophen, digoxin, theophylline, and valproic acid) clarified the role of pharmacokinetics on the effectiveness of AC.[23] Theophylline, acetaminophen, and valproic acid all have small volumes of distribution. However, of the three, only valproic acid is highly protein-bound at the doses employed, which probably accounted for the inability of AC to increase its clearance. An increased clearance was demonstrated for the three other xenobiotics with MDAC. The most rapid and dramatic effect of MDAC was demonstrated on the clearance of theophylline. Large volumes of distribution alone may not exclude benefit from MDAC. Although digoxin has a large volume of distribution, it requires several hours to distribute from the blood to the tissues. MDAC is beneficial before distribution is complete, and the digoxin still remains accessible in the blood compartment.

The benefits of MDAC undoubtedly depend on a number of patient variables and xenobiotic exposure characteristics. Most important to remember, however, is that volunteer studies do not accurately reflect the overdose situation[84] in which saturation of plasma protein binding, saturation of first-pass metabolism, and acidâ€“base disturbances may make more free xenobiotics available for an enteroenteric effect and therefore more amenable to MDAC use.

Overdose Studies

As noted, MDAC appears to enhance gastrointestinal elimination of many xenobiotics by interfering with enteroenteric circulation, interrupting enterohepatic circulation, and/or minimizing desorption. Shortening the half-life of a xenobiotic in overdose would

logically benefit the patient clinically by limiting the time of associated central nervous system depression, risk of aspiration,

intensive care, nursing hours, and hospitalization, although the actual clinical evidence for these benefits is limited. In a randomized clinical study designed to determine whether these potential benefits could be achieved, some patients who overdosed with phenobarbital were given a single dose of AC, while others were given multiple doses.[111] Although the half-life of phenobarbital was significantly decreased in the MDAC group (36 vs. 93 hours), the length of intubation time required by each group did not differ from one another. This study has been criticized as being too small, having unevenly matched groups, and focusing on a single end point (extubation) that may be dependent on factors other than patient condition (such as the time of day) to determine potential clinical benefit. The most compelling demonstration of the benefits of MDAC in the overdose setting to date comes from a study done in Sri Lanka of patients with severe cardiac toxicity caused by intentional overdose with yellow oleander seeds.[33] An initial dose of 50 g of AC was administered to all patients who were then randomized to 50 g of AC every 6 hours for 3 days or placebo. There were statistically fewer deaths and fewer life-threatening cardiac dysrhythmias in the MDAC group.

Administration of MDAC

An initial loading dose of AC should be administered to adults and children in an AC-to-xenobiotic ratio of 10:1 or 1 g/kg of body weight (if drug exposure amount is unknown). The correct dose and interval of AC for multiple dosing, when it is indicated, is best tailored to the amount and dosage form of the xenobiotic ingested, the severity of the overdose, the potential lethality of the xenobiotic, and the patient's ability to tolerate AC. Benefit should always be weighed against risk. Doses of AC for multiple dosing have varied considerably in the past, ranging from 0.25 to 0.5 g/kg of body weight every 1â€“6 hours, to 20â€“60 g for adults every 1, 2, 4, or 6 hours. There is some evidence that the total dose administered may be more important than the frequency of

administration.[55,130] In some cases, continuous nasogastric administration of AC can be employed, especially when vomiting is a problem.[42,100,130] The editors of this text consider a dose of 0.5 g/kg of body weight every 2 to 4 hours for up to 12 hours to be an appropriate regimen in most circumstances.

Adverse Effects

The adverse effects of MDAC include diarrhea (only when sorbitol-containing charcoal preparations are used), constipation, vomiting with a subsequent risk of aspiration, intestinal obstruction, and reduction of serum concentrations of therapeutically employed xenobiotics.[36,88,92,108] Obviously any complication observed with single-dose AC is a possibility with MDAC.

Summary

When administration is timely, AC is a very effective nonspecific adsorbent. AC should be of benefit to a patient with a potentially life-threatening ingestion involving a xenobiotic still expected to be accessible in the GI tract, adsorbable by AC, and for whom there are no contraindications. MDAC is useful to prevent systemic absorption of a xenobiotic with a prolonged absorptive phase such as a sustained-release formulation. In the postabsorptive phase of managing an exposure, MDAC can decrease the elimination half-lives of a variety of xenobiotics through diverse mechanisms, including gastrointestinal dialysis, thereby providing treatment even to some nonoral xenobiotic overdoses and exposures. For this postabsorptive effect to be of clinical importance the xenobiotic or active metabolite must first be characterized by a lengthy elimination phase, as MDAC is given every 2â€“6 hours. In addition, those xenobiotics with a small volume of distribution or that fit a two-compartment model with a prolonged initial distribution phase, and low or saturable plasma protein binding are theoretically most accessible to MDAC. In both the use of AC and

MDAC care must be taken to avoid pulmonary aspiration and intestinal obstruction. With respect to the use of AC prior to the patient's arrival at the hospital, home availability of AC should be encouraged especially in remote locations where organized healthcare is not immediately available. As more palatable forms of AC are developed, children may accept this agent more readily, but even without such forms, the problems may not be as significant as some believe them to be.[67,69]

Antidotes in Depth

Whole-Bowel Irrigation and Other Intestinal Evacuants

Mary Ann Howland

Drugs that promote intestinal evacuation are referred to as *laxatives, cathartics*, *purgatives, promotility agents*, and *evacuants*. Using different doses, the same drug may often accomplish any or all of these tasks, but with different side-effect profiles. Laxatives promote a soft-formed or semifluid stool within 6 hours to 3 days, depending on the agent and the dose employed. Cathartics promote a rapid watery evacuation within 1â€“3 hours.[30] Purgatives relate to the force associated with bowel evacuation. Promotility agents stimulate gastrointestinal motor function via the enteric nervous system by affecting acetylcholine, serotonin, or motilin. Evacuants are commonly used to cleanse the bowel prior to a procedure, with an onset of action of as little as 30 to 60 minutes, but typically requiring 4 hours for a more complete effect. The most effective process of evacuating the intestinal tract in poisoned patients is referred to as whole-bowel irrigation (WBI). WBI is typically accomplished using polyethylene

glycol 3350 (PEG) and an added electrolyte lavage solution (PEG-ELS).

The traditional classification of laxatives into the categories of bulk-forming, softener or emollient, lubricant, stimulant or irritant, saline, hyperosmotic, and evacuant is largely empirical. Bulk-forming agents include high-fiber products like methylcellulose, polycarbophil, and psyllium; softeners or emollients include docusate calcium. Mineral oil is the sole lubricant. None of these three classes of agents is employed therapeutically in medical toxicology because their onsets of action are often delayed several days. In addition, softeners cause an increase in intestinal permeability for a few hours and may therefore increase the absorption of some xenobiotics.[69] Mineral oil may enhance the absorption of lipid soluble drugs and aspiration could result in a lipoid pneumonia.[92]

Stimulant or irritant laxatives include anthraquinones (sennosides, aloe, and casanthranol), diphenylmethane (bisacodyl), and castor oil. Abdominal discomfort, cramping, and tenesmus often occur acutely. Long-term use produces bowel habituation and damage to intestinal tissue. Thus, stimulant and irritant laxatives are rarely used today in medical toxicology because of their significant gastrointestinal side effects.

Saline cathartics, which include magnesium citrate, magnesium hydroxide, magnesium sulfate, sodium phosphate, and sodium sulfate, are used cautiously in medical toxicology. Hyperosmotic agents, including sorbitol and lactulose, are also considered in poisoned patients.

When different cathartics were compared with respect to time to first stool and number of stools,[31,38,59,60,80] sorbitol produced 10â€“15 watery stools and the most abdominal cramping before catharsis. Additionally, its taste was rated second to that of magnesium citrate because of its nauseating sweetness. Sorbitol produced stools in the shortest amount of time but with the

highest incidence of nausea and vomiting. In comparison, the first bowel movement should occur about 1 hour after the start of WBI with PEG-ELS. In other studies, sorbitol resulted in nausea, vomiting, generated gas, abdominal cramping, and increased flatus.[34,35,62]

Potential adverse effects associated with cathartics and promotility agents include dehydration, absorption of magnesium or other absorbable electrolytes, hypokalemia and metabolic alkalosis from dehydration, activation of the reninâ€“angiotensinâ€“aldosterone system, and colonic fermentation of digestible sugars. Cathartic-induced rectal prolapse occurred in 2 geriatric patients.[37] The use of repetitive doses of cathartics, either by design or unintentionally, has led to further exaggeration of the serious sequelae such as hypermagnesemia and death. [33,61,76]

Following the use of hypertonic phosphate enemas and oral sodium phosphate, hypocalcemia, hyperphosphatemia, and hypokalemia were reported.[19,25,27,44,49,70,78] In many of these cases, the recommended dose of the therapeutic agent was used.[19] Frail elderly patients, children, and those with decreased renal function may be most susceptible to adverse effects.[9,11]

Multiple-dose activated charcoal regimens containing 70% sorbitol used to enhance elimination resulted in severe cathartic-related adverse effects in 4 case reports.[1,24,43,53] The potential for sorbitol related adverse events from the unintentional use of repetitive activated charcoal (AC) dosing was emphasized by a survey revealing that 16% of hospitals surveyed only stocked AC premixed with sorbitol.[93] The retention of sorbitol after repetitive doses in an aperistaltic gut may lead to significant morbidity due to the gas formation and abdominal distension as a result of the digestive action of gut bacteria.[43]

Mechanism of Action

The effects of saline cathartics are largely attributed to their relatively nonabsorbable ions that establish an osmotic gradient and draw water into the gut. The increased water leads to increased intestinal pressure and a subsequent increase in intestinal motility.[17] Magnesium ion also releases cholecystokinin from the duodenal mucosa, which stimulates intestinal motor activity and alters fluid movement, contributing to its effect.[12,79] The hyperosmotic laxatives, including sorbitol, lactulose, and glycerin, also draw water into the gut and produce diarrhea.

Polyethylene glycol is a nonabsorbable, isoosmotic indigestible agent that remains in the colon and together with the water diluent is evacuated, resulting in WBI without producing flatus and cramps. Electrolytes are added to limit the ensuing electrolyte and fluid shifts. Many studies of WBI using PEG-ELS demonstrate patient acceptance, effectiveness, and safety when used for bowel preparation.[3,10,18,20,22,68,84,87]

Promotility agents such as metoclopramide and erythromycin stimulate gut motor function. Metoclopramide does this through gastrointestinal $5HT_4$ receptor agonist and D_2 receptor antagonist activity that together increase acetylcholine release and gastrointestinal motility. Erythromycin also stimulates gut motor function but via direct stimulation of gastrointestinal motilin receptors.[66]

Gastrointestinal Evacuation and Poison Management

Although recommended for basic poison management for many years, cathartics should not be used routinely in the management of overdosed patients.[5] Intuitively, the advantages of cathartics appear to result from their ability to decrease the potential for constipation or obstruction from AC and hasten the delivery of AC

to the small intestine. However, these theoretical advantages have never been demonstrated clinically.

Studies demonstrate that when administered alone, cathartics such as sorbitol or sodium sulfate may decrease peak and/or total absorption of some drugs, but no study has achieved results comparable to that of AC alone.[2,16,52,67,91] When comparing the efficacy of a single dose of AC alone with that of AC plus a single dose of cathartic, studies suggest the combination to be equal to,[2,56,65,67,75] slightly better than,[16,34] or slightly worse than AC alone.[52,91]

WBI with PEG-ELS is currently advocated to hasten the elimination of poorly absorbed xenobiotics or sustained-release medications before they can be absorbed. This approach is theoretically sound, and does not produce the fluid and electrolyte complications associated with cathartics. Unfortunately, evidence of efficacy is limited to anecdotal case reports and volunteer studies.

Although animal models suggest WBI may enhance systemic clearance via gastrointestinal dialysis, much like multiple-dose activated charcoal (MDAC),[42] low flow rates, the typical delay in administering WBI in actual clinical situations, and the inconvenience of this procedure make it highly unlikely that enhanced systemic clearance can be achieved in humans.

In human volunteer studies, WBI was more effective than single-dose AC or MDAC for acetylsalicylic acid (ASA),[35] decreased peak lithium (Li) and Li AUC (area under the [plasma drug concentration versus time] curve) compared to control,[77] decreased the bioavailability of two sustained-release medications,[15,40] and propelled radiopaque markers through the gut more efficiently than control.[46]

Not unexpectedly, WBI was inferior to AC with regard to prevention of absorption when administered following 650 mg of immediate-release aspirin.[73] Additionally, once aspirin was

absorbed, WBI was unable to enhance systemic clearance.[51]

There are reports of successful use of WBI in the management of overdoses of iron,[23,48,82,83] sustained-release theophylline,[32] sustained-release verapamil,[13] zinc sulfate,[14] lead,[55,57,63,72] mercuric oxide powder,[45] arsenic-containing herbicide,[41] delayed-release fenfluramine,[58] and for body packers.[29,85,89] Although some clinicians express enthusiasm for the use of WBI for a variety of ingestions, others question its efficacy.[14,74,81] Whole-bowel irrigation for 5 hours following ingestion of 10 fluorescent coffee beans by each of 7 volunteers removed an average of only 4 beans (range, 1â€“8).[74] Similar failures were reported with jequirity beans[81] and button batteries.[82] It can be argued that because of their physical characteristics (density, solubility, size), these agents might not be representative of substances amenable to whole-bowel irrigation. Additionally, the experience of the editors of this text in caring for body packers demonstrates that whole-bowel irrigation may not always evacuate all of the drug packets because of inadequate dosing, partial obstruction, or the nature of the procedure. As a result of these failures, promotility agents were successfully added to WBI to enhance bowel evacuation in two body packers suspected of having ingested well-constructed drug packets.[86]

Adverse Effects of WBI

Adverse effects resulting from the use of WBI with PEG-ELS include vomiting, particularly following rapid administration, abdominal bloating, fullness, cramping, flatulence, and pruritus ani. Typically, the patient will need to remain on a commode for 4â€“6 hours to complete the procedure. Slow or low-volume administration of PEG-ELS results in sodium absorption. If a total of 500 mL of PEG-ELS were used instead of multiple liters, potentially 1.5 g of sodium may be absorbed.[21] This adverse effect may have resulted in the exacerbation of congestive heart failure

in an unstable patient with cardiac and renal dysfunction.[26]

An unusual complication of WBI is colonic perforation, which occurred in a patient with severe diverticulitis.[39] Other adverse effects noted by the manufacturer include isolated reports of upper GI bleeding from a Mallory-Weiss tear, esophageal perforation, aspiration pneumonitis after vomiting, and acute lung injury.

Unfortunately, administration of PEG-ELS by other than the enteral route has occurred. A 4-year-old child inadvertently received 390 mL of PEG-ELS intravenously with no obvious adverse result.[71] In contrast, acute lung injury developed in an 11-year-old child administered PEG-ELS through a nasogastric tube inadvertently inserted in the trachea.[64]

Interaction of AC and WBI

Several in vitro studies demonstrate that the addition of PEG-ELS to AC significantly decreases the adsorptive capacity of AC.[8,28,47] Some interactions were affected by pH and magnified by high ratios of PEG-ELS to AC.[7,36,47] The most likely explanation is competition with the AC surface for solute adsorption. Additionally, in an animal model, whole-bowel irrigation appeared to have an adverse effect by washing the AC away from the sustained-release theophylline.[15]

Contraindications

Contraindications to whole-bowel irrigation include prior, current or anticipated diarrhea; volume depletion; significant gastrointestinal pathology or dysfunction such as ileus, perforation, colitis, toxic megacolon, hemorrhage, and obstruction; an unprotected or compromised airway; and hemodynamic instability.[4,82]

Dosing

The recommended dose of WBI with PEG-ELS solutions is 0.5 L/h or 25 mL/kg/h for small children and 1.5â€“2 L/h or 20â€“30 mL/min for adolescents and adults. WBI solution may be administered orally or through a nasogastric tube for 4â€“6 hours or until the rectal effluent becomes clear. If the xenobiotic being removed is radiopaque, a diagnostic imaging technique demonstrating the xenobiotic's absence may serve as a reasonable clinical end point. An antiemetic such as metoclopramide or a serotonin antagonist may be required for the treatment of nausea or vomiting. Whole-bowel irrigation

with large volumes of fluid was used successfully in 2 pregnant women at 38 and 26 weeks of gestation.[88,90]

Available Forms of PEG-ELS for WBI

The original WBI solution was GoLYTELY from Braintree. This solution contained PEG with electrolytes and sodium sulfate as an added laxative. Colyte is manufactured by Schwartz Pharma and is very similar to GoLYTELY. Braintree later introduced NuLYTELY, a PEG formulation with 52% less total salt than GoLYTELY and no added sodium sulfate. These changes in formulation decreased the salty taste and the chances for fluid or electrolyte abnormalities.[54] NuLYTELY is available in flavors. The following lists the composition of the 3 available PEG-ELS products. All are prepared by filling the container to the 4-L mark with water and shaking vigorously several times to ensure dissolution. Lukewarm water facilitates dissolution but chilling afterward improves palatability. Chilled solutions, however, are not recommended for infants because of the risk of hypothermia. The product is stable with refrigeration for 48 hours after reconstitution.

GoLYTELY contains 236 g (17.6 mmol/L) polyethylene glycol 3350, 22.74 g sodium sulfate (anhydrous) (sulfate 40 mmol/L), 6.74 g sodium bicarbonate (bicarbonate 20 mmol/L), 5.86 g sodium

chloride (total sodium 125 mmol/L), and 2.97 g potassium chloride (potassium 10 mmol/L and total chloride 35 mmol/L). Colyte contains 240 g (18 mmol/L) polyethylene glycol 3350, 22.72g sodium sulfate (anhydrous) (40 mmol/L sulfate), 6.72 g sodium bicarbonate (20 mmol/L bicarbonate), 5.84 g sodium chloride (total sodium 125 mmol/L), and 2.98 g potassium chloride (potassium 10 mmol/L and total chloride 35 mmol/L). NuLYTELY contains 420 g polyethylene glycol 3350, 5.72 g sodium bicarbonate, 11.2 g sodium chloride, and 1.48 g potassium chloride.

MiraLax by Braintree (prescription only) contains PEG 3350 powder meant for oral administration after dissolution in water, juice, or soda. It is indicated for occasional constipation, with a recommended dose of 1 heaping teaspoon (17 g) in 240 mL liquid per day. For MiraLax to be useful in WBI, it would need to be administered at a dose of 2 L/h (8 heaping teaspoons in 2 L of water/h) in adults. This is not recommended for WBI because it does not contain any added electrolytes and may result in an electrolyte imbalance.

Summary

Cathartics should never be considered part of routine management of poisoning and overdose in either children or adults. Cathartics should never be used as an AC substitute when xenobiotics known to be adsorbed to AC are involved. Moreover, when total xenobiotic absorption is evaluated, a single dose of a cathartic given with AC appears to be only about as efficacious as AC given alone.

Although investigators have also studied the rapidity of stools resulting from the use of various cathartics, promotility agents, and WBI, administering a cathartic just to produce a faster onset of charcoal stools has never been shown to produce a better clinical outcome. In adults, when large amounts of xenobiotics

have been ingested or when desorption from charcoal may be an important consideration (such as with aspirin), a single dose of a cathartic, preferably magnesium citrate or sorbitol, may be given with the AC. When MDAC is being administered, if a cathartic is used at all, it should only be given with the first dose. Sufficient oral fluids should always be administered with a cathartic to avoid inspissation and dehydration. Unless contraindicated, WBI is preferable to repetitive dose cathartics for evacuation of sustained-release or poorly soluble xenobiotics not adsorbed to AC.

The precise role of WBI and the interactions between AC and PEG-ELS in the overdosed patient remain to be defined. There have been no controlled clinical studies assessing outcome, although theoretically, ingestions of sustained-release xenobiotics (theophylline, glyburide XL, verapamil), xenobiotics not adsorbed by charcoal (iron, lead, lithium), and drug packets (in body packers) may be amenable to the use of WBI. An added advantage of using PEG-ELS WBI is that should the patient require endoscopy, diagnostic imaging, or surgery, the gastrointestinal tract may be more easily visualized, facilitating the intervention or procedure. Activated charcoal should be given to those patients for whom it is indicated, and if WBI is being performed in conjunction, a comparable dose of AC should be given following the WBI to prevent or overcome the potential xenobiotic desorption and possible further systemic absorption of the xenobiotic.

Chapter 9

Pharmacokinetic and Toxicokinetic Principles

Mary Ann Howland

Xenobiotics are foreign to the body and include natural or synthetic chemicals, drugs, pesticides, environmental agents, and industrial agents.[43] *Pharmacokinetics* is the study of the absorption, distribution, metabolism, and excretion of xenobiotics. Mathematical models and equations are used to describe and to predict this behavior. *Pharmacodynamics* is the term used to describe an investigation of the relationship of xenobiotic concentration to clinical effect. *Toxicokinetics*, which is analogous to pharmacokinetics, is the study of the absorption, distribution, metabolism, and excretion of a xenobiotic under circumstances that produce toxicity or excessive exposure. *Toxicodynamics*, which is analogous to pharmacodynamics, is the study of the relationship of toxic concentrations of xenobiotics to clinical effect.

Humans with overdoses provide many challenges to the mathematical precision of toxicokinetics and toxicodynamics because many of the variables (eg, dose, time of ingestion, presence of vomiting) that

affect the result are often unknown. In contrast to the therapeutic setting, atypical solubility characteristics are noted and saturation of enzymatic processes occurs. Alterations in enzymatic saturation and protein binding may lead to enhanced absorption (decreased first-pass effect), more free drug available in the serum because of saturation of plasma protein binding, or prolonged elimination because of saturation of hepatic enzymes or active renal tubular secretion. In addition, age, obesity, gender, genetics, chronopharmacokinetics (diurnal variations), and the effects of critical illness and compromised organ perfusion all further inhibit attempts to achieve precise analyses.[3,15,35,40,61,65] In addition, various treatments may alter one or more kinetic parameters. There are numerous approaches to recognizing these variables, such as obtaining historical information from the patient's family and friends, performing pill counts, procuring sequential serum concentrations during the phases of toxicity, and occasionally repeating a pharmacokinetic evaluation during therapeutic dosing of that same agent to obtain comparative data.

Despite all of the confounding and individual variability, toxicokinetic principles can, nonetheless, be applied to facilitate our understanding and to make certain predictions. These principles can be used to help evaluate whether a certain antidote or extracorporeal removal method is appropriate for use, when the serum concentration might be expected to drop into the therapeutic range (if one exists), what ingested dose might be considered potentially toxic, what the onset and duration of toxicity might be, and what the importance is of a serum concentration. While considering all of these factors, the clinical status of the patient is paramount, and mathematical formulas and equations can never substitute for evaluating the patient. This chapter explains the principles, presents the mathematics in a â€œuser-friendlyâ€• fashion,[72] and demonstrates the application of these principles and mathematical approaches by example and case illustration.

Absorption

Absorption is the process by which a xenobiotic enters the body. For an agent to cause a systemic effect, it must reach the bloodstream and then be distributed to the site or sites of action. Both the rate (k_a) and extent of absorption (F) are measurable and important determinants of toxicity. The rate of absorption often predicts the onset of action and relies on dosage form, while the extent of absorption (*bioavailability*) often predicts the intensity of the effect and depends in part on first-pass effects.[32,33] Figure 9-1 depicts how changes in the rate of absorption may affect toxicity when the bioavailability is held constant versus how toxicity may be affected by changes in bioavailability when the rate of absorption is held constant.

The route by which the xenobiotic enters the body significantly affects both the rate and extent of absorption. As an approximation, the rate of absorption proceeds in the following order from fastest to slowest: intravenous, inhalation > intramuscular, subcutaneous, intranasal, oral > cutaneous, rectal. Following the oral intake of 200 mg of cocaine hydrochloride, the onset of action is 20 minutes, with an average peak concentration of 200 ng/mL.[64] In marked contrast, smoking 200 mg of cocaine freebase results in an onset of action of 8 seconds and a peak level of 640 ng/mL, or when administered intravenously as 200 mg cocaine hydrochloride, which then has an onset of action of 30 seconds and a peak level of 1000 ng/mL.[64]

A xenobiotic must diffuse through a number of membranes before it can reach its site of action. Figure 9-2 shows the number of membranes through which a xenobiotic typically diffuses. Membranes are predominantly composed of phospholipids and cholesterol in addition to other lipid compounds.[48] A phospholipid is composed of a polar head and a fatty acid tail, which are arranged

in membranes so that the fatty acid tails are inside and the polar heads face outward in a mirror image.[52] Proteins (in a 1:5 ratio with

lipids) are found on both sides of the membranes and may traverse the membrane.[48] These proteins may function as receptors and channels. Pores are found throughout the membranes. The principles relating to diffusion apply to absorption, distribution, certain aspects of elimination, and to each instance when a xenobiotic is transported through a membrane.

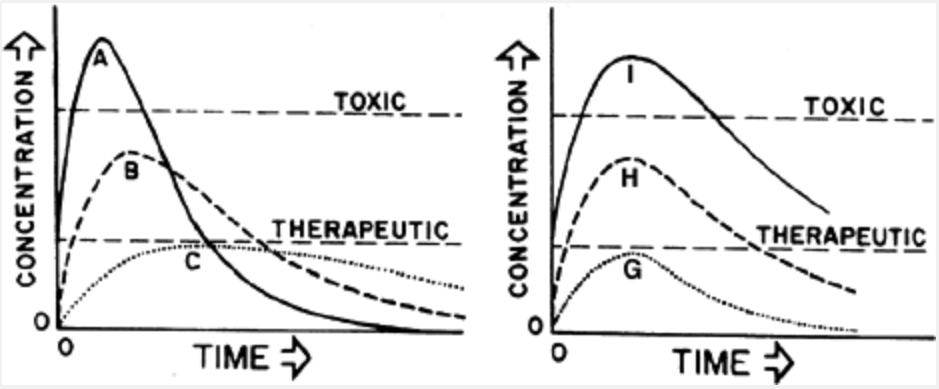

Figure 9-1. Effects of changes in k_a (rate of absorption) and F (bioavailability) on the blood concentration time graph and achieving a toxic threshold. In curves A, B, and C, F is constant as k_a is decreased. In curves G, H, and I, k_a is constant as F is increased. *(Reprinted, with permission, from Riviere JE: Absorption and distribution. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT, Appleton & Lange, 1994, p. 22.)*

Transport through membranes occurs via passive diffusion through the membrane, filtration (bulk flow is the major mechanism of transport which occurs with water directly through water pores [aquapores] for small molecules with a molecular weight [MW] < 100), carrier-mediated active or facilitated transport, and, rarely, endocytosis (Fig. 9-3). Most xenobiotics traverse membranes via

simple passive diffusion. The rate of diffusion is determined by the Fick Law of Diffusion (Eq. 9-1).

$$\text{Rate of diffusion} = \frac{dQ}{dt} = \frac{DAK(C_1 - C_2)}{h}$$

D = diffusion constant
A = surface area of the membrane
h = membrane thickness
K = partition coefficient
$C_1 - C_2$ = difference in concentrations of the xenobiotic at each side of the membrane

(Eq. 9–1)

The driving force for passive diffusion is the difference in concentration of the xenobiotic on both sides of the membrane. D is a constant for each xenobiotic and is derived when the difference in concentrations between the two sides of the membrane is 1. The larger the surface area A, the higher the rate of diffusion. Most ingested xenobiotics are absorbed more rapidly in the small intestine than in the stomach because of the tremendous increase in surface area created by the presence of microvilli. The partition coefficient K represents the lipid-to-water partitioning of the xenobiotic. To a substantial degree, the more lipid soluble a xenobiotic is, the more easily it crosses membranes. Membrane thickness (h) is inversely proportional to the rate at which a xenobiotic diffuses through the membrane. Xenobiotics that are uncharged, nonpolar, of low molecular weight, and of the appropriate lipid solubility have the highest rates of diffusion.

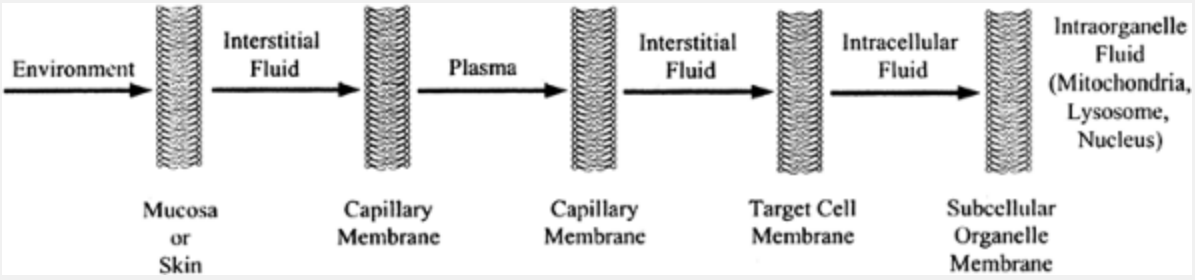

Figure 9-2. Illustration of the number of membranes encountered by a xenobiotic in the processes of absorption and distribution. *(Adapted from Riviere JE: Absorption and distribution. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT, Appleton & Lange, 1994, p. 12.)*

The extent of ionization of weak electrolytes (weak acids and weak bases) affects their rate of passive diffusion. Nonpolar and uncharged molecules penetrate faster. The Henderson-Hasselbalch relationship is used to determine the degree of ionization. An acid (HA), by definition, gives up a hydrogen ion and a base (B), accepts a hydrogen ion. RCOOH (HA) (ie, aspirin, phenobarbital) and RNH_3^+ (BH^+) are acids and $RCOO^-$ (A^-) and RNH_2(B) (amphetamines, tricyclic antidepressants [TCAs]) are bases. The equilibrium dissociation constant K_a can then be described by Equations 9-2A and 9-2B.

$$\text{For weak acids: } HA = H^+ + A^- \qquad K_a = \frac{[H^+][A^-]}{[HA]} \qquad \text{(Eq. 9–2A)}$$

$$\text{For weak bases: } BH^+ = B + H^+ \qquad K_a = \frac{[H^+][B]}{[BH^+]} \qquad \text{(Eq. 9–2B)}$$

To work with these numbers in a more comfortable fashion, the negative log of both sides is determined and results in Equations 9-3A and 9-3B.

$$\text{For weak acids: } -\log K_a = -\log [H^+] - \log \frac{[A^-]}{[HA]} \qquad \text{(Eq. 9–3A)}$$

$$\text{For weak bases: } -\log K_a = -\log [H^+] - \log \frac{[B]}{[BH^+]} \qquad \text{(Eq. 9–3B)}$$

Type of Transport	Example
Diffusion	Nonelectrolytes (ethanol) and unionized forms of weak acids (salicylic acid) and bases (phenobarbital)
Filtration and bulk flow	Molecules of varying sizes
Endocytosis	Sabin polio virus vaccine
Facilitated	5-Fluorouracil Lead Methyldopa Thallium
Active	Thiamine Pyridoxine

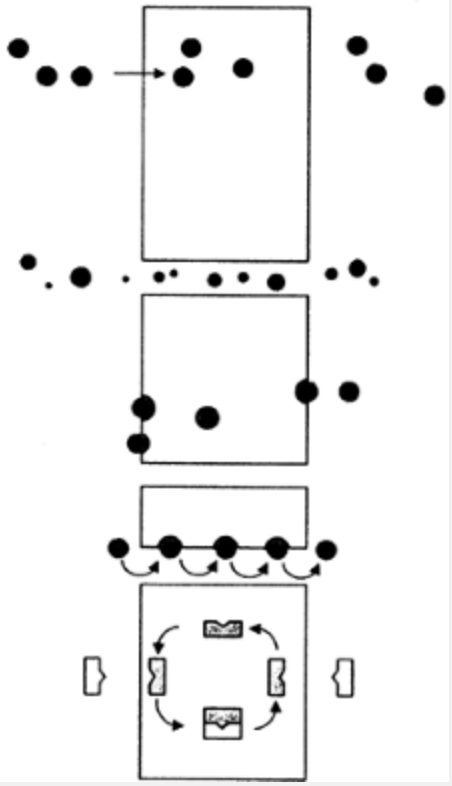

Figure 9-3. Illustration of transport mechanisms involved in the

passage of xenobiotics across membranes. *(Adapted from Gram TE: Drug absorption and distribution. In: Craig CR, Stitzel RE, eds: Modern Pharmacology with Clinical Applications. Boston, Little, Brown, 1997, p. 17.)*

By definition, the negative log of $[H^+]$ is expressed as pH and the negative log of K_a is pK_a. Rearranging the equations gives the familiar forms of the Henderson-Hasselbalch equations as shown in Equations 9-4A, 9-4B, and 9-4C.

$$pH = pK_a + \log \frac{\text{unprotonated species}}{\text{protonated species}} \qquad \text{(Eq. 9–4A)}$$

$$\text{For weak acids: } pH = pK_a + \log \frac{[A^-]}{[HA]} \qquad \text{(Eq. 9–4B)}$$

$$\text{For weak bases: } pH = pK_a + \log \frac{[B]}{[BH^+]} \qquad \text{(Eq. 9–4C)}$$

Because noncharged molecules traverse membranes more rapidly, it is understood that weak acids cross membranes more rapidly in an acidic environment and weak bases move more rapidly in a basic environment. When the pH equals the pK_a, half of the xenobiotic is charged and half is noncharged. An acid with a low pK_a is a strong acid while a base with a low pK_a is a weak base. For an acid, a pH less than the pK_a favors the protonated or noncharged species facilitating membrane diffusion, whereas for a base, a pH greater than the pK_a achieves the same result. Table 9-1 lists the pH of selected body fluids and Figure 9-4 illustrates the extent of charged versus noncharged xenobiotic at different pH and pK_a values.

Lipid solubility and ionization each have a distinct influence on absorption. Figure 9-5 demonstrates these characteristics for three different xenobiotics. Although the three xenobiotics have similar pK_a values, their different partition coefficients result in different degrees of absorption from the stomach.

Specialized transport mechanisms either require energy (adenosine triphosphate [ATP] dependent) to transport xenobiotics against a concentration gradient (active transport), or they can be energy independent (ATP independent) and lack the ability to transport against a concentration gradient (facilitated transport). These transport mechanisms are of importance in numerous parts of the body including the intestines, liver, lungs, kidneys, and the biliary systems. These same principles apply to a small number of lipid-insoluble molecules that resemble essential endogenous agents.[24,57] For example, 5-fluorouracil resembles pyrimidine and is transported by the same system, whereas thallium and lead are actively absorbed by the endogenous transport mechanisms that absorb and transport potassium and calcium, respectively.

TABLE 9-1. pH of Selected Body Fluids

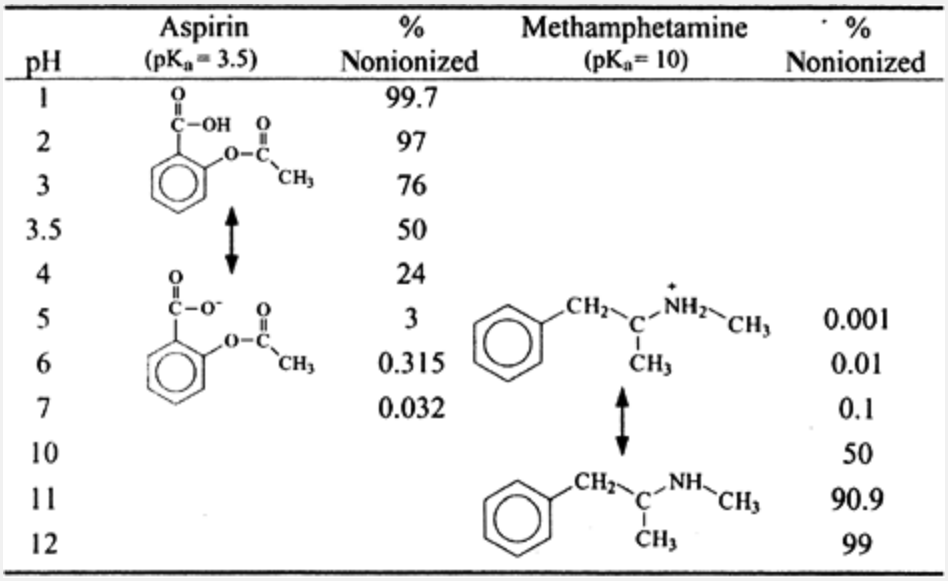
Fluids	pH
Cerebrospinal	7.3
Eye	7â€“8
Gastric secretions	1â€“3
Large intestinal secretions	8
Plasma	7.4
Rectal fluid: infants and children	7.2â€“12

Saliva	6.4â€“7.2
Small intestinal secretions: duodenum	5â€“6
Small intestinal secretions: ileum	8
Urine	4â€“8
Vaginal secretions	3.8â€“4.5

Adapted from Brody TM: Absorption, distribution, metabolism and elimination. In: Brody TM, Larner J, Minneman KP, Neu HC, eds: Human Pharmacology: Molecular to Clinical, 2nd ed. St. Louis, Mosby, 1994, p. 51.

P-glycoprotein is a transmembrane protein that is an example of a carrier used for carrier-mediated, active (ATP-dependent) transport. P-glycoprotein is being extensively investigated because of its role in controlling xenobiotic entry into the body and because of its contribution to drug interactions.[18,28,66] The discovery of P-glycoprotein resulted from an investigation into why certain tumors exhibit multidrug resistance to many cancer chemotherapy agents. P-glycoprotein is an efflux transporter located in the intestines, renal proximal tubule, hepatic bile canaliculi, and bloodâ€“brain barrier that is responsible for transporting compounds from inside to outside the cell.[14] First-generation transport inhibitors such as amiodarone, ketoconazole, quinidine, and verapamil are responsible for increasing body levels of P-glycoprotein substrates such as digoxin, the protease inhibitors, vinca alkaloids, and paclitaxel. St. John's wort is a transport inducer, and lowers serum concentrations of these same

agents. Second- and third-generation agents that will affect transport with a higher affinity and specificity are in development.[58] Many of the same agents that affect cytochrome P450 (CYP) 3A4 also affect P-glycoprotein.



pH	Aspirin (pK_a = 3.5)	% Nonionized	Methamphetamine (pK_a = 10)	% Nonionized
1		99.7		
2		97		
3		76		
3.5		50		
4		24		
5		3		0.001
6		0.315		0.01
7		0.032		0.1
10				50
11				90.9
12				99

Figure 9-4. Effect of pH on the ionization of aspirin (pK_a = 3.5) and methamphetamine (pK_a = 10).

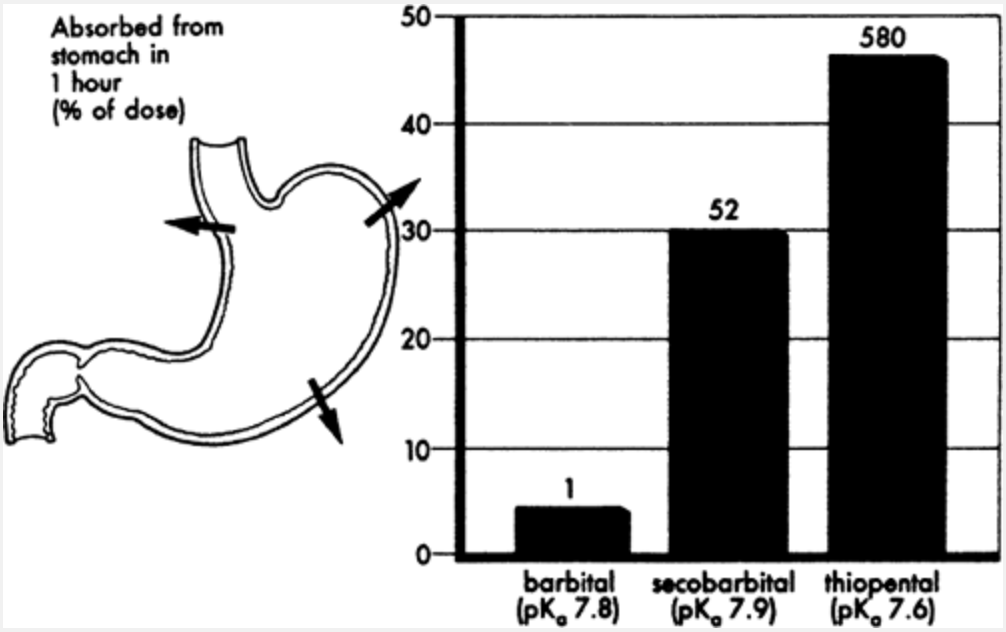


Figure 9-5. Influence of increasing lipid solubility on the amount of xenobiotic absorbed from the stomach for three xenobiotics with similar pK_a values. The number above each column is the oil/water equilibrium partition coefficient. *(Reprinted, with permission, from Brody T: Absorption, distribution, metabolism and elimination. In: Brody TM, Larner J, Minneman KP, Neu HP, eds: Human Pharmacology: Molecular to Clinical, 2nd ed. St. Louis, Mosby, 1994, p. 50.)*

Filtration is generally considered to be of limited importance in the absorption of most xenobiotics, but is substantially more important with regard to elimination. Endocytosis, which describes the encircling of a xenobiotic by a cellular membrane, is responsible for the absorption of large macromolecules such as the oral Sabin polio vaccine.[57]

Gastrointestinal absorption is affected by xenobiotic-related characteristics such as dosage form, degree of ionization, partition

coefficient, and patient factors such as gastrointestinal blood flow, gastrointestinal motility, and the presence or absence of food, ethanol, or other interfering substances (Fig. 9-6).

The formulation of a xenobiotic is extremely important in predicting GI absorption. Disintegration and dissolution must precede absorption. Controlled-release, extended-release, and sustained-release formulations are designed to release the xenobiotic over a prolonged period of time in order to simulate the blood concentrations achieved with the use of a constant intravenous infusion. These formulations minimize blood level fluctuations, reduce peak-related side effects, reduce dosing frequency, and improve patient compliance. A variety of products employ different pharmaceutical strategies, including dissolution control (encapsulation or matrix; Feosol), diffusion control (membrane or matrix; Slow K, Plendil ER), erosion (Sinemet CR), osmotic pump systems (Procardia XL, Glucotrol XL), and ion exchange resins (MS Contin suspension). Overdoses with controlled-release formulations result in a prolonged absorption phase, a delay to peak concentrations, and a prolonged duration of effect.[7] Enteric-coated (acetylsalicylic acid [ASA], divalproex sodium) formulations resist disintegration and delay the time to onset of effect.[6] Dissolution is affected by ionization, solubility, and the partition coefficient, as noted earlier. In the overdose setting, the formation of poorly soluble or adherent masses such as concretions (meprobamate) and bezoars (bromide) significantly delays the time to onset of toxicity (Table 9-2).[4,9,25,26]

Most ingested xenobiotics are primarily absorbed in the small intestine as a result of the large surface area and extensive blood flow of the small intestines.[53] Critically ill patients who are hypotensive, have a reduced cardiac output, or are receiving vasoconstrictors such

as norepinephrine, have a decreased perfusion of vital organs, including the GI tract, kidneys, and liver.[3] Not only is absorption

delayed, but elimination is also diminished.[51] Extremely short gastrointestinal transit times reduce absorption. This change in transit time is the unproven rationale for our prior substantial use of cathartics and current use of whole-bowel irrigation. Delays in emptying of the stomach impair absorption as a result of the delay in delivery to the small intestine. Delays in gastric emptying occur as a result of the presence of food, especially fatty meals; agents with anticholinergic, opioid, or antiserotonergic properties; ethanol; and any agent that results in pylorospasm (salicylates, iron).

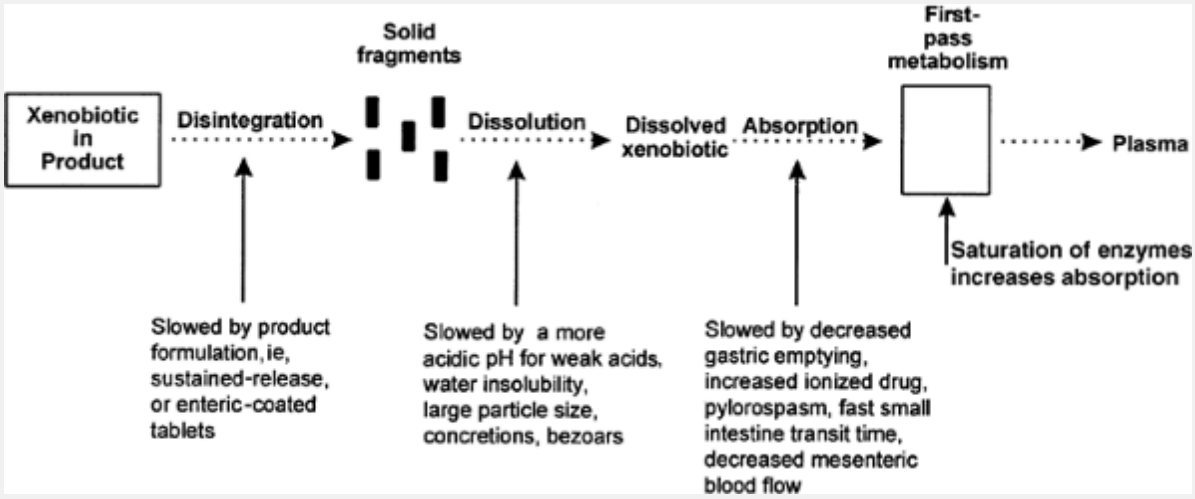

Figure 9-6. Determinants of absorption.

Bioavailability is a measure of the amount of xenobiotic that reaches the systemic circulation unchanged (Eq. 9-5).[34] The fractional absorption (F) of a xenobiotic is defined by the area under the plasma drug concentration versus time curve (AUC) of the designated route of absorption as compared to the AUC of the intravenous route. The AUC for each route represents the amount absorbed.

$$F = \frac{(AUC)_{\text{route under study}}}{(AUC)_{IV}} \qquad \text{(Eq. 9–5)}$$

Gastric emptying and activated charcoal are used to decrease the bioavailability of ingested xenobiotics. The oral administration of certain chelators (deferoxamine, D-penicillamine) actually enhances the bioavailability of the complexed xenobiotic. The net effect of some chelators, such as succimer, is a reduction in body burden via enhanced urinary elimination even though absorption is enhanced.[27] Historically, the enteral administration of sodium bicarbonate was used to theoretically reduce the solubility of iron salts; unfortunately, this approach was ineffective.[13]

Presystemic metabolism may decrease or increase the bioavailability of a xenobiotic or a metabolite.[47] The GI tract contains microbial organisms that can metabolize or degrade xenobiotics such as digoxin and oral contraceptives, and enzymes such as peptidases that metabolize insulin.[48] However, in rare cases, gastrointestinal hydrolysis can convert a xenobiotic into a toxic metabolite, as occurs when amygdalin is enzymatically hydrolyzed to produce cyanide, a metabolic step that is not produced following intravenous amygdalin administration.[23] Xenobiotic metabolizing enzymes and P-glycoprotein can also affect bioavailability. Xenobiotic metabolizing enzymes are found in the lumen of the small intestine and can substantially decrease the absorption of a xenobiotic.[39,66] Some of the xenobiotic that enters the cell can then be removed by the P-glycoprotein transporter out of the cell and back into the lumen to be exposed again to the metabolizing enzymes.[39,66] Venous drainage from the stomach and intestine delivers orally (and intraperitoneally) administered xenobiotics to the liver via the portal vein and avoids direct delivery to the systemic circulation. This venous drainage allows hepatic metabolism to occur before the xenobiotic reaches the blood and is referred to as the *first-pass effect*.[2,69] The hepatic extraction ratio is the percentage of xenobiotic metabolized in one pass of blood through the liver.[42] Drugs that undergo significant first-pass metabolism (eg, propranolol, verapamil) are used at much lower IV doses than oral doses. Some drugs are not administered by the oral route at all because of significant first-pass effect (eg,

lidocaine, nitroglycerin).[4] Instead, sublingual or rectal administration of agents such as nitroglycerin is used to bypass the portal circulation and avoid first-pass metabolism. In the overdose setting, presystemic metabolism may be saturated, leading to an increased bioavailability of xenobiotics such as cyclic antidepressants, phenothiazines, opioids, and many Î²-adrenergic antagonists.[50] Hepatic metabolism usually transforms the xenobiotic into a less-active metabolite, but occasionally results in the formation of a more toxic agent such as occurs with the transformation of parathion to paraoxon.[45] Biliary excretion into the small intestine usually occurs for these transformed xenobiotics of molecular weights >350 daltons and may result in a xenobiotic appearing in the feces, even though it had not been administered orally.[30,48,60] Hepatic conjugated metabolites such as glucuronides may be hydrolyzed in the intestines to the parent form or to another active metabolite that can be reabsorbed by the enterohepatic circulation.[36,43,46,48] The enterohepatic circulation may be responsible for what is termed a double-peak phenomenon following the administration of certain xenobiotics.[57] The double-peak phenomenon is characterized as a serum concentration which falls and then rises again as xenobiotic is reabsorbed from the GI tract.

Other causes include variability in stomach emptying, presence of food, or failure of a tablet dosage form.[57]

TABLE 9-2. Xenobiotics that Form Concretions or Bezoars, Delay Gastric Emptying, and/or Result in Pylorospasm

Anticholinergics	Meprobamate
Barbiturates	Methaqualone
Bromides	Opioids
Enteric-coated tablets	Phenytoin
Glutethimide	Salicylates
Iron	Verapamil

Distribution

After the xenobiotic reaches the systemic circulation or central compartment, it is available for transport to peripheral tissue compartments. Both the rate and extent of distribution depend on many of the same principles discussed with regard to diffusion. Additional factors include affinity of the xenobiotic for plasma and tissue proteins, acidâ€“base status of the patient (which affects ionization), and physiologic barriers to distribution (bloodâ€“brain barrier, placental transfer, bloodâ€“testis barrier).[20,31,52] Blood flow accounts for the initial phase of distribution, whereas xenobiotic affinities determine the final distribution pattern. Hypoperfusion of the various organs in the critically ill affects absorption, distribution, and elimination.[67]

Plasma and serum concentrations are terms often used

interchangeably by medical personnel. When a reference or calculation is made with regard to a concentration in the body, it is actually a plasma concentration. When concentrations are measured in the laboratory, a serum concentration (clotted and centrifuged blood) is often determined. In reality, the laboratory measurements of most xenobiotics in serum or plasma are nearly equivalent. Frequently, this is not the case for whole-blood determination if the xenobiotic distributes into the erythrocyte, such as lead and most other heavy metals.

Volume of distribution (Vd) is the proportionality term used to relate the dose of the xenobiotic that the individual receives and the resultant plasma concentration. Vd is an apparent or theoretic volume into which a xenobiotic distributes. It is a measure of how much xenobiotic is located inside and outside of the plasma compartment, because only the plasma compartment is routinely assayed. In a 70-kg adult male, the total body fluid (TBF) is 60% of total body weight or 42 L, with two-thirds (28 L) of the fluid accounted for by intracellular fluid. Of the 14 L of extracellular fluid, 8 L are considered interstitial or between the cells; 3 L, or 0.04 L/kg, is plasma; and 6 L, or 0.08 L/kg, is blood. If 42 g of a xenobiotic is administered and remains in the plasma compartment (Vd = 0.04 L/kg), the concentration would be 15 g/L. If the distribution of the 42 g of xenobiotic approximated TBF (methanol; 0.6 L/kg), the concentration would be 100 mg/dL. These calculations can be performed by using Equation 9-6, where S equals the percent pure drug if a salt form is used.

$$V_d = \frac{S \times F \times \text{dose (mg)}}{C_0} \qquad \text{(Eq. 9–6)}$$

Experimental determination of a Vd involves administering an IV dose of the xenobiotic and extrapolating the plasma concentration time curve back to time zero (C_0). If the determination takes place after steady state has been achieved, the volume of distribution is then referred to as the Vdss. For many xenobiotics the Vd is known and

readily available in the literature (Table 9-3). When the Vd and the dose ingested are known, a maximum predicted plasma concentration can be calculated, after assuming all of the xenobiotic is absorbed and no elimination occurred. This assumption usually overestimates the plasma concentration. Distribution is complex, and differential affinities for various storage sites (plasma proteins, liver, kidney, fat, and bone) in the body determine where a xenobiotic ultimately resides.

For the purposes of determining the utility of extracorporeal removal of a xenobiotic, a low Vd is often considered to be <1 L/kg. For some xenobiotics, as digoxin (Vd = 5 L/kg) or the cyclic antidepressants (Vd =10â€“15 L/kg), the Vd is much larger than the actual volume of the body. A large Vd indicates that the xenobiotic resides outside of the plasma compartment, but, again, it does not describe the site of distribution.

The site of accumulation of a xenobiotic may or may not be a site of action or toxicity. If the site of accumulation is not a site of toxicity, then the storage depot may be relatively inactive and the accumulation at that site may be theoretically protective to the animal/person.[52] Selective accumulation of xenobiotics occurs in certain areas of the body because of affinity for certain tissue-binding proteins. For example, the kidney contains metallothionein, which has a high affinity for metals such as cadmium, lead, and mercury.[20] The retina contains the pigment melanin, which binds and accumulates chlorpromazine, thioridazine, and chloroquine.[20] Other examples of xenobiotics accumulating at primary sites of toxicity are carbon monoxide binding to hemoglobin and myoglobin and paraquat distributing to type II alveolar cells in the lungs.[49] Dichlorodiphenyltrichloroethane (DDT), chlordane, and polychlorinated biphenyls are stored in fat, which can be mobilized following starvation.[70] Lead sequestered in bone[29] is not immediately toxic, but mobilization of bone through an increase in osteoclastic activity[52] (hyperparathyroidism, possibly pregnancy) may free lead for distribution to sites of toxicity (CNS, blood).

Several plasma proteins bind xenobiotics and act as carriers and storage depots. The percentage of protein binding varies among xenobiotics, as do their affinities and potential for reversibility. Once bound to plasma protein, a xenobiotic with high binding affinity will remain largely confined to the plasma until elimination occurs. However, dissociation and reassociation may occur if another carrier is available with a higher binding affinity. Most plasma measurements of xenobiotic concentration reflect total drug (bound plus unbound). Only the unbound drug is free to diffuse through membranes for distribution or for elimination. Albumin (a protein of MW 67,000 daltons) binds primarily to weakly acidic, poorly water-soluble xenobiotics, which include salicylates, phenytoin, and warfarin, as well as endogenous substances like free fatty acids, cortisone, aldosterone, thyroxine, and bilirubin.[55] Î±$_1$-Acid glycoprotein (a globulin of MW 44,000 daltons) usually binds basic xenobiotics including lidocaine, imipramine, and propranolol.[55] Transferrin, a Î²$_1$-globulin, transports iron, and ceruloplasmin carries copper.

Phenytoin is an example of a xenobiotic whose effects are significantly influenced by changes in concentration of plasma albumin. When albumin concentrations are in the normal range, approximately 90% of phenytoin is bound to albumin. As the albumin concentration decreases, however, more xenobiotic is free for distribution and a greater clinical response to the same serum phenytoin concentration is often observed. It is this free form of phenytoin that is active. The free plasma phenytoin concentration can be calculated based on the albumin concentration. This achieves an appropriate interpretation of total phenytoin within the conventional therapeutic range of 10â€“20 mg/L of free plus bound phenytoin (Eq. 9-7).

$$\text{Adjusted phenytoin concentration} = \frac{\text{actual phenytoin concentration}}{(0.25 \times [\text{albumin}]) + 0.1} \quad \text{(Eq. 9–7)}$$

The clinical implications are that a malnourished patient with an

albumin of 2 g/dL receiving phenytoin can manifest toxicity with a plasma phenytoin concentration of 14 mg/L. This measurement is total phenytoin (bound + unbound). Because the patient has a reduced albumin concentration, this actually represents a substantially higher proportion and absolute amount of active unbound phenytoin. Substitution into the above equation of 14 mg/L for actual

plasma phenytoin concentration and 2 g/dL for albumin gives an adjusted plasma phenytoin concentration of 23.33 mg/L (therapeutic range, 10â€“20 mg/L).

	Vd L/kg	Protein Binding %	Renal Elimination % Unchanged	Hepatic Metabolism (CYP)	Active Metabolite	Enterohepatic
Analgesics

TABLE 9-3. Pharmacokinetic Characteristics of Xenobiotics Associated with the Largest Number of Toxicologic Deaths

Although drug interactions are often attributed to the displacement of xenobiotics, usually concurrent metabolic interactions are more consequential. Displacement transiently increases the amount of unbound, active drug. This may result in an immediate increase in drug effect. This is followed by enhanced distribution and elimination of unbound drug. Gradually the unbound plasma concentration returns to predisplacement concentrations.[53]

Saturation of plasma proteins may occur in the therapeutic range for a drug such as valproic acid. Acute saturation of plasma protein binding following an overdose often leads to consequential adverse effects. Saturation of plasma protein binding with salicylates and iron after overdose increases distribution to the CNS (salicylates) or to the liver, heart, and other tissues (iron), producing increased

toxicity.

Specific therapeutic maneuvers in the overdose setting are designed to alter xenobiotic distribution by inactivating and/or enhancing elimination to limit toxicity. These therapeutic maneuvers include (a) manipulation of serum or urine pH (salicylates); (b) use of chelators (lead); and (c) the use of antibodies or antibody fragments (digoxin).

The Vd permits predictions about plasma concentrations and also assists in defining whether an extracorporeal method of removal is beneficial for a particular toxin. If the Vd is large (>1 L/kg), it is unlikely that hemodialysis, hemoperfusion, or exchange transfusion would be effective because most of the xenobiotic is outside of the plasma compartment. Plasma protein binding also influences this decision. If the xenobiotic is more tightly bound to plasma proteins than to activated charcoal, then hemoperfusion is unlikely to be beneficial even if the Vd of the xenobiotic is small. In addition, high plasma protein binding limits the effectiveness of hemodialysis, because only unbound xenobiotic will freely cross the dialysis membrane. Exchange transfusion can be effective for a xenobiotic with a small Vd and substantial plasma protein binding, because both bound and free xenobiotic are removed simultaneously.

Elimination

Removal of a parent compound from the body (*elimination*) begins as soon as the xenobiotic is delivered to clearance organs such as the liver, kidneys, and lungs. Elimination begins immediately, but may not be the predominant kinetic process until absorption and distribution are substantially completed. As expected, the functional integrity of the major organ systems (cardiovascular, lungs, renal, hepatic) are major determinants of the efficiency of xenobiotic removal and of therapeutically administered antidotes. The xenobiotics themselves may cause renal or hepatic failure (acetaminophen), subsequently compromising their own elimination. Other factors influencing elimination include age (enzyme

maturation), competition or inhibition of elimination processes by interacting xenobiotics, saturation of enzymatic processes, gender, genetics, and the physicochemical properties of the xenobiotic.[41]

Elimination can be accomplished by biotransformation to one or more metabolites, or by *excretion* from the body of unchanged xenobiotic. Excretion can occur via the kidneys, lungs, GI tract, and body secretions (sweat, tears, milk). Hydrophilic (polar) or charged xenobiotics and their metabolites, because of their water solubility, are generally excreted via the kidney. The majority of xenobiotic metabolism occurs in the liver but it also commonly occurs in the blood, skin, GI tract, placenta, or kidneys. Lipophilic (noncharged or nonpolar) xenobiotics are usually metabolized in the liver to hydrophilic metabolites, which are then excreted by the kidneys.[21,45] These metabolites are generally inactive, but if active, may contribute to toxicity. Examples include the metabolism of amitriptyline to nortriptyline, procainamide to *N*-acetylprocainamide, and meperidine to normeperidine (Table 9-4).

Metabolic reactions catalyzed by enzymes (categorized as either phase I or phase II) generally result in pharmacologically active

metabolites; frequently, the latter have different toxicities than the parent compounds. *Phase I*, or preparative metabolism, which may or may not precede phase II, is responsible for introducing polar groups onto nonpolar xenobiotics by oxidation, reduction, and hydrolysis or dealkylation. The result of phase I metabolism is commonly to add or expose polar groups.[19,43] *Phase II*, or synthetic reactions, conjugate the polar group with a glucuronide, sulfate or acetate (often a less-polar metabolite, which is reabsorbed), methyl groups, glutathione (mercapturic acid synthesis), and amino acids (glycine, taurine, and glutamic acid).[12,19,43]

TABLE 9-4. Examples of Xenobiotics Activated by Human P450

CYP1A1	Benzene
Benzo[*a*]pyrene and other polycyclic aromatic hydrocarbons	Carbon tetrachloride Chloroform
CYP1A2	Dichloromethane
Acetaminophen	Ethylene dibromide

Comparatively, phase II reactions produce a much larger increase in hydrophilicity than phase I reactions. The enzymes involved in these reactions have low substrate specificity, and those in the liver are usually localized to either the endoplasmic reticulum (microsomes) or the soluble fraction of the cytoplasm (cytosol).[43] The location of the enzymes becomes important if they form reactive metabolites which then concentrate at the site of metabolism and cause toxicity (Table 9-5). For example, acetaminophen causes centrilobular necrosis because the cytochrome P450 2E1 isoenzymes, which form *N*-acetyl-*p*-benzoquinoneimine (NAPQI), the toxic metabolite, are located in their highest concentration in that zone of the liver.

The enzymes that metabolize the largest variety of xenobiotics are heme-containing proteins referred to as *CYP monooxygenase enzymes*.[24,43] This group of enzymes, formerly called the mixed function oxidase system, is found in abundance in the microsomal

endoplasmic reticulum of the liver. These enzymes primarily catalyze the oxidation of xenobiotics. However, cytochrome P450 in a reduced state (Fe^{2+}) binds carbon monoxide. Its discovery and initial name resulted from spectral identification of the CO-bound cytochrome P450, which absorbs light maximally at 450 nm. The cytochrome P450 system is composed of many enzymes grouped into gene families and subfamilies, of which approximately 57 of these functional human genes have been sequenced. Members of a gene family have >40% similarity of their amino acid sequencing and subfamilies have >55% similarity. Toxicity may result from induction or inhibition of cytochrome P450 isoenzymes by another xenobiotic, resulting in a consequential drug interaction (Table 9-6). Many of these interactions are predictable based on the known xenobiotic affinities and their capability to induce or inhibit the P450 system.[10,37,43,44,59] However, *polymorphism* (individual genetic expression of isoenzymes),[1] stereoisomer variability[68] (enantiomers with different potencies and isoenzyme affinities), and the capability to metabolize a xenobiotic by alternate pathways, contribute to unexpected metabolic outcomes. The pharmaceutical industry is now exploiting the concept of chiral switching (marketing a single enantiomer instead of the racemic mixture) to alter efficacy or side-effect profiles. Enantiomers are named either according to the direction in which they rotate polarized light (*l* or â€“ for levorotatory, and *d* or + for dextrorotatory), or according to the absolute spatial orientation of the groups at the chiral center (S or R). Chiral means â€œhandâ€• in Greek, and the latter designations refer to either sinister (left-handed) or rectus (right-handed). There is no direct correlation between levorotatory or dextrorotatory and S and R.[63]

TABLE 9-5. General Pathways of Xenobiotic Biotransformation and Their Major Subcellular Location

Reaction	Enzyme	Localization
Phase 1		
Hydrolysis	Carboxylesterase	Microsomes, cytosol
	Peptidase	Blood, lysosomes
	Epoxide hydrolase	Microsomes, cytosol
Reduction	Azo- and nitro-reduction	Microflora, microsomes, cytosol
	Carbonyl reduction	Cytosol
	Disulfide reduction	Cytosol
	Sulfoxide reduction	Cytosol
	Quinone reduction	Cytosol, microsomes
	Reductive dehalogenation	Microsomes
Oxidation	Alcohol dehydrogenase	Cytosol
	Aldehyde dehydrogenase	Mitochondria, cytosol

Excretion is primarily accomplished by the kidneys, although, as mentioned earlier, biliary, pulmonary, and body fluid secretions contribute to lesser degrees. Urinary excretion occurs through glomerular filtration, tubular secretion, and passive tubular reabsorption. The glomerulus filters unbound xenobiotics of a particular size and shape in a manner that is not saturable, subject to renal blood flow and perfusion. Passive tubular reabsorption accounts for the reabsorption of noncharged, lipid-soluble xenobiotics, and is therefore influenced by the pH of the urine and the pK_a of the xenobiotic. The principles of diffusion discussed earlier permit, for example, the ion trapping of salicylate (pK_a = 3.5) in the urine through urinary alkalinization. Tubular secretion is an active process subject to saturation and drug interactions (Table 9-7). Tubular secretion is often less developed in the neonate.

Classical Versus Physiologic Compartment Toxicokinetics

Models exist to study and describe the movement of xenobiotics in the body with mathematical equations. Traditional *compartmental* models (one or two compartments) are data-based and assume that changes in plasma concentrations represent tissue concentrations

(Fig. 9-7).[42] Advances in computer technology facilitate the use of the classic concepts developed in the late 1930s.[62] Physiologic models consider the movement of xenobiotics based on known or theorized biologic processes and are unique for each xenobiotic. This allows the prediction of tissue concentrations, while incorporating the effects of changing physiologic parameters, and affording better extrapolation from laboratory animals.[72] Unfortunately, physiologic modeling is still in its infancy and the mathematical modeling it entails is often very complex.[16] Regardless, the most commonly used mathematical equations are based on traditional compartmental modeling.

P.149

P.150

P.151

The *one-compartment model* is the simplest for analytic purposes and is applied to xenobiotics that rapidly enter and distribute throughout the body. This model assumes that changes in plasma concentrations will result in, and reflect proportional changes in tissue concentrations. Many xenobiotics, such as digoxin, lithium, and lidocaine, do not instantaneously equilibrate with the tissues and are better described by a two-compartment model. In the *two-compartment model*, a xenobiotic is distributed instantaneously to highly perfused tissues (central compartment) and then is secondarily, and more slowly, distributed to a peripheral compartment. Elimination is assumed to take place from the central compartment.

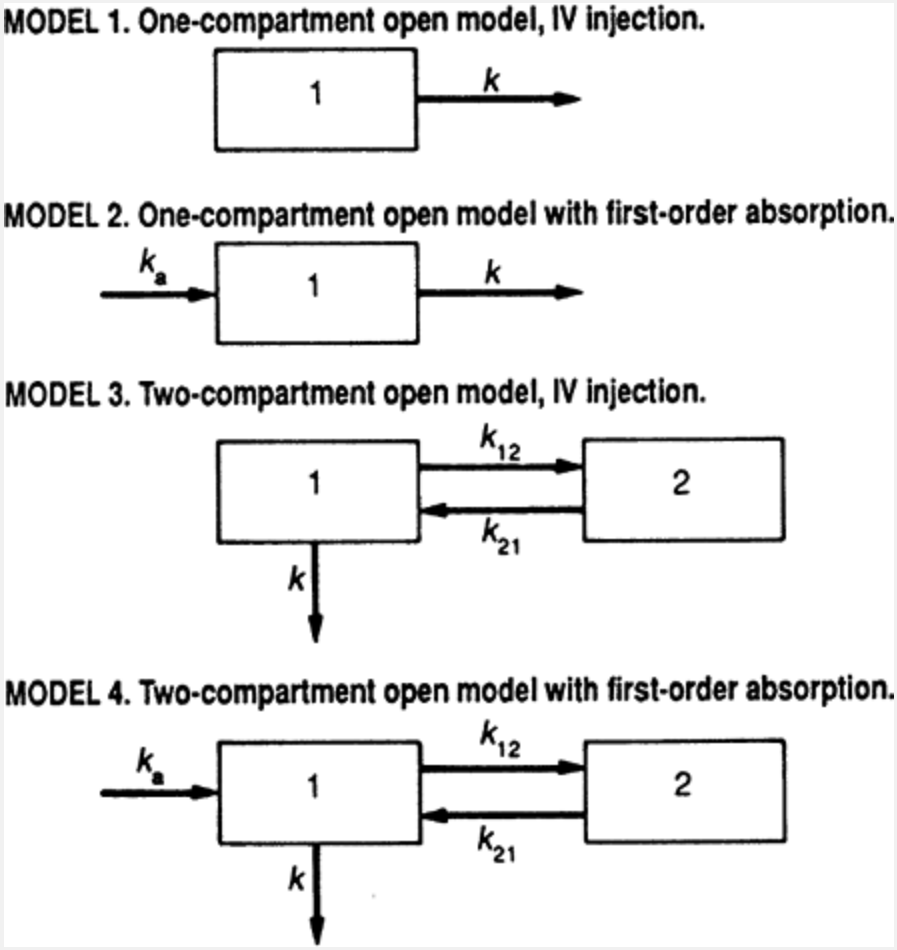

Figure 9-7. Various classical compartmental models. k =

pharmacokinetic rate constants; 1 = plasma or central compartment; 2 = tissue compartment; k_{12} = rate constant into tissue from plasma; k_{21} = rate constant into plasma from tissue; k_a = absorption rate constant. *(Reprinted, with permission, from Shargel L, Yu A: Introduction to Pharmacokinetics: Applied Biopharmaceutics and Pharmacokinetics, 3rd ed. Norwalk, CT, Appleton & Lange, 1993, p. 40.)*

If the rate of a reaction is directly proportional to the concentration of xenobiotic, it is termed *first order or linear*. Processes that are capacity limited or saturable are termed *nonlinear* (not proportional to the concentration of xenobiotic) and are described by the *Michaelis-Menten* equation, which is derived from enzyme kinetics. Calculus is used to derive the first-order equation, as done by Yang and Andersen.[72] Rate is directly proportional to concentration of xenobiotic as in Equation 9-8.

$$\text{Rate} \propto \text{concentration (C)} \qquad \text{(Eq. 9–8)}$$

An infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) is directly proportional to the concentration (C) of the xenobiotic as in Equation 9-9.

$$\frac{dC}{dt} \propto C \qquad \text{(Eq. 9–9)}$$

The proportionality constant k is added to the right side of the expression to mathematically allow the introduction of an equal sign. The constant k represents all of the bodily factors, such as metabolism and excretion, that contribute to the determination of concentration (Eq. 9-10).

$$\frac{dC}{dt} = kC \qquad \text{(Eq. 9–10)}$$

Introducing a negative sign to the left-hand side of the equation

describes the â€œdecayâ€• or decreasing xenobiotic concentration (Eq. 9-11).

$$-\frac{dC}{dt} = kC \qquad \text{(Eq. 9–11)}$$

This equation is impractical because of the difficulty of measuring infinitesimal changes in C or t. Therefore, the use of calculus allows the integration or summing of all of the changes from one concentration to another beginning at time zero and terminating at time *t*. This relationship is mathematically represented by the integration sign (âˆ«). âˆ« means to integrate the term from concentration at time zero (C_0) to concentration at a given time *t* (C_t). âˆ« means the same with respect to time, where t_0 = zero. Prior to this application, the previous equation is first rearranged (Eq. 9-12).

$$-\frac{dC}{C} = kdt$$

$$\int_{C_0}^{C_t} -\frac{dC}{C} = k\int_{t_0}^{t} dt \qquad \text{(Eq. 9–12)}$$

The integration of d*C* divided by *C* is the natural logarithm of *C* (ln *C*) and the integration of dt is *t* (Eq. 9-13).

$$-\ln C \Big|_{C_0}^{C_t} = kt \Big|_{t_0}^{t} \qquad \text{(Eq. 9–13)}$$

The vertical straight lines proscribe the evaluation of the terms between those two limits. The following series of manipulations are then performed (Eq. 9-14A-D).

$$-(\ln C_t - \ln C_0) = k(t - 0) \qquad \text{(Eq. 9–14A)}$$

$$-\ln C_t + \ln C_0 = kt \qquad \text{(Eq. 9–14B)}$$

$$-\ln C_t = -\ln C_0 + kt \qquad \text{(Eq. 9–14C)}$$

$$\underset{\substack{\text{Can be}\\\text{measured}}}{\ln C_t} = \underset{\text{Constant}}{\ln C_0} - \underset{\substack{\text{Can be}\\\text{selected}}}{kt} \qquad \text{(Eq. 9–14D)}$$

Equation 9-14D can be recognized as taking the form of an equation of a straight line (Eq. 9-15), where the slope is equal to the rate constant *k* and the intercept is C_0.

$$y = b + mx \qquad \text{(Eq. 9–15)}$$

Instead of working with natural logarithms, an exponential form (the antilog) of Equation 9-14D may be used (Eq. 9-16).

$$C_t = C_0 e^{-kt} \qquad \text{(Eq. 9–16)}$$

Graphing the ln (natural logarithm) of the concentration of the xenobiotic at various times for a first-order reaction is a straight line. Equation 9-16 describes the events when only one first-order process occurs. This is appropriate for a one-compartment model (Fig. 9-8).

In this model, regardless of the concentration of the xenobiotic, the rate (percentage) of decline is constant. The absolute amount of xenobiotic eliminated changes continuously while the percent eliminated remains constant. k is reported in h^{-1}. A k of 0.10 h^{-1} means that the xenobiotic is being processed (eliminated) at a rate of 10% per hour. k is often designated as k_e and referred to as the elimination rate constant. The time necessary for the xenobiotic concentration to be reduced by 50% is called the *half-life*. The half-life is determined by a rearrangement of Equation 9-14D whereby C_2 becomes C at time t_2 and C_1 becomes C at t_1, and by rearrangement giving Equation 9-17.

$$(t_1 - t_2) = \frac{(\ln C_1 - \ln C_2)}{k_e} \qquad \text{(Eq. 9–17)}$$

Substitution of 2 for C_1 and 1 for C_2 or 100 for C_1 and 50 for C_2 gives Equations 9-18A and 9-18B.

$$t_{1/2} = \frac{(\ln 2 - \ln 1)}{k_e} \qquad \text{(Eq. 9–18A)}$$

$$t_{1/2} = \frac{0.693}{k_e} \qquad \text{(Eq. 9–18B)}$$

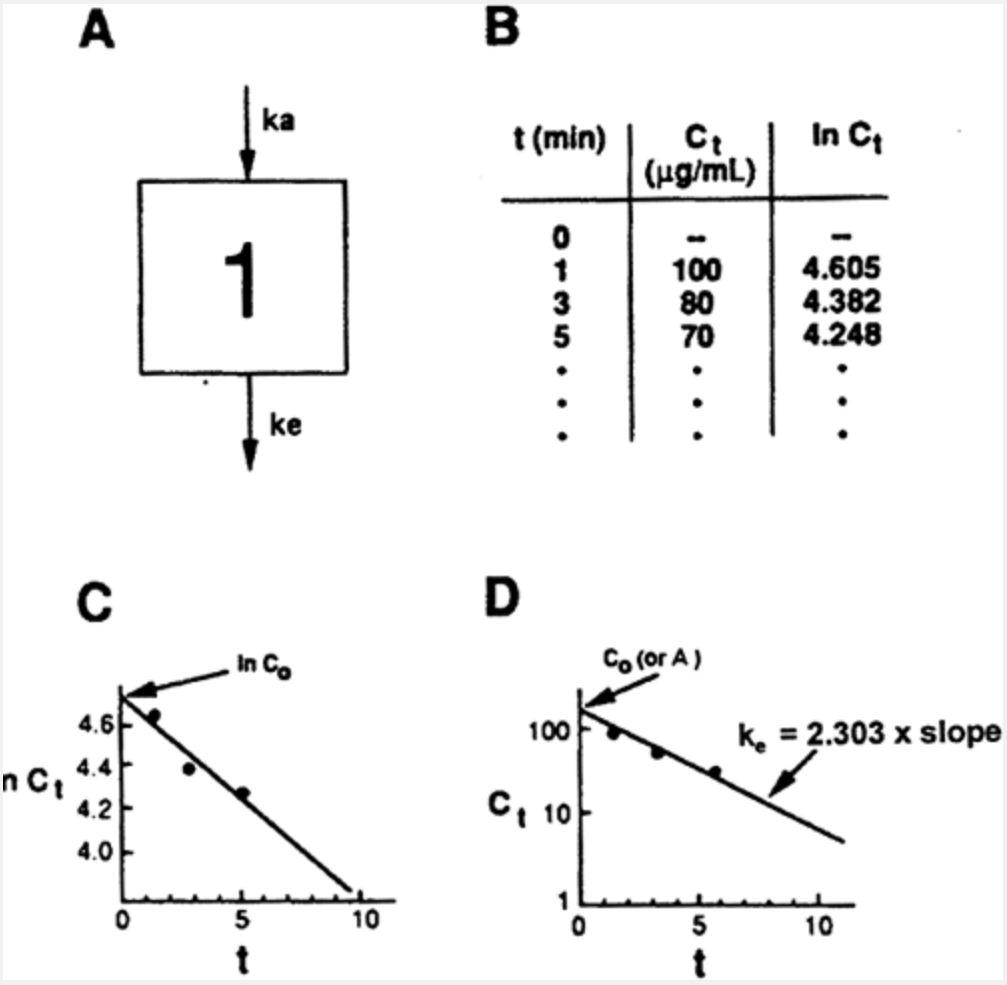

Figure 9-8. A one-compartment pharmacokinetic model

demonstrating (A) graphical illustration; (B) hypothetical dataset; (C) linear plot; and (D) semilogarithmic plot. *(Modified and reprinted, with permission, from Yang R, Andersen M: Pharmacokinetics. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT, Appleton & Lange, 1994, p. 54.)*

The use of semilog paper facilitates graphing the first-order equation. However, because semilog paper plots log (not ln) versus time, to retain appropriate mathematical relationships the rate constant or slope (k) must be divided by 2.303 (see Fig. 9-8).

The mathematical modeling becomes more complex when more than one first-order process contributes to the overall elimination process. The equation that incorporates two first-order rates is used for a two-compartment model and is Equation 9-19.

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 9–19)}$$

Figure 9-9 demonstrates a two-compartment model where Î± often represents the distribution phase and Î² is the elimination phase.

The rate of reaction of a saturable process is not linear (not proportional to the concentration of xenobiotic) when saturation occurs (Fig. 9-10). This model is best described by the Michaelis-Menten equation used in enzyme kinetics (Eq. 9-20) in which *v* is the velocity or rate of the enzymatic reaction; *C* is the concentration of the xenobiotic; V_{max} is the maximum velocity of the reaction between the enzyme and the xenobiotic; and K_m is the affinity constant between the enzyme and the xenobiotic.[72]

$$v = \frac{V_{max} \times C}{K_m + C} \qquad \text{(Eq. 9–20)}$$

Application of this equation to toxicokinetics requires *v* to become the infinitesimal change in concentration of a xenobiotic (dC) with respect to an infinitesimal change in time (dt) as previously

discussed (see Eq. 9-10). V_{max} and K_m both reflect the influences of diverse biologic processes. The Michaelis-Menten equation then becomes Equation 9-21, in which the negative sign again represents decay.

$$\frac{dC}{dt} = \frac{V_{max} \times C}{K_m + C} \qquad \text{(Eq. 9–21)}$$

When the concentration of the xenobiotic is very low ($C<<<K_m$), it can be dropped from the bottom right of the equation because its contribution becomes negligible and the resultant equation is described as a first-order process. (Eq. 9-22A and 9-22B). Conceptually, this is understandable, because at a very low xenobiotic concentration the process is not saturated.

$$-\frac{dC}{dt} = \frac{V_{max} \times C}{K_m} \qquad \text{(Eq. 9–22A)}$$

Because V_{max} divided by K_m is a constant, K, then:

$$-\frac{dC}{dt} = kC \qquad \text{(Eq. 9–22B)}$$

However, when the concentrations of the xenobiotic are extremely high and exceed the capacity of the system ($C>>>K_m$), the rate becomes fixed at a constant maximal rate regardless of the exact concentration of the xenobiotic, termed a zero-order reaction. Tables 9-8A and 9-8B compare a first-order reaction to a zero-order reaction. In this particular example, zero order is faster, but if the fraction of xenobiotic eliminated in the first-order example were

0.4, then the amount of xenobiotic in the body would fall below 100 before the xenobiotic in the zero-order example. It is inappropriate to perform half-life calculations on a xenobiotic displaying zero-order behavior because the metabolic rates are continuously changing. Following overdoses, enzyme saturation is a common occurrence as the capacity of enzyme systems are overwhelmed.

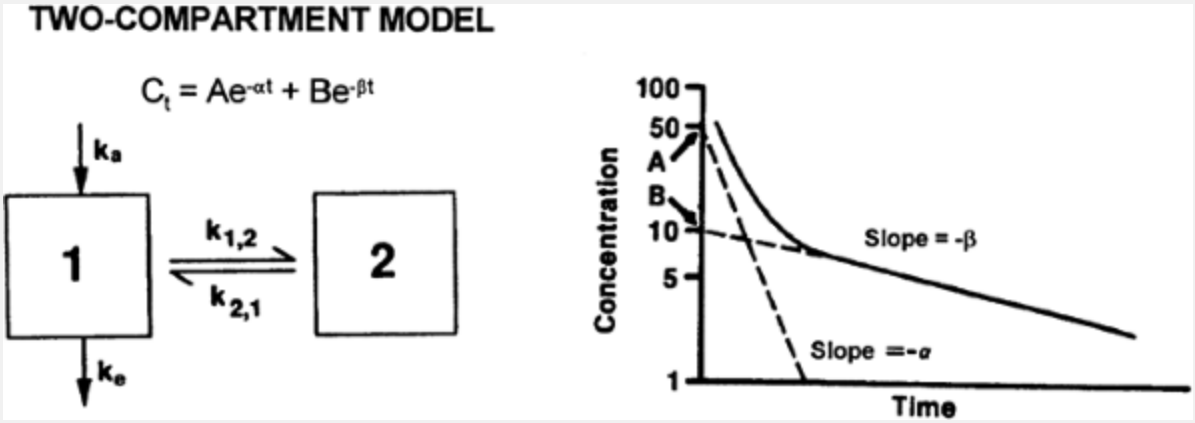

Figure 9-9. Mathematical and graphical forms of a two-compartment classical pharmacokinetic model. k_a represents the absorption rate constant, k_e represents the elimination rate constant, Î± represents the distribution phase, and Î² the elimination phase. *(Reprinted, with permission, from Yang R, Andersen M: Pharmacokinetics. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT, Appleton & Lange, 1994, p. 55.)*

Clearance

Clearance (Cl) is the relationship between the rate of transfer or elimination of a xenobiotic from a reference fluid (usually plasma) to the plasma concentration of the xenobiotic and is expressed in units of volume per unit time (ie, mL/min) (Eq. 9-23).[22,42,54]

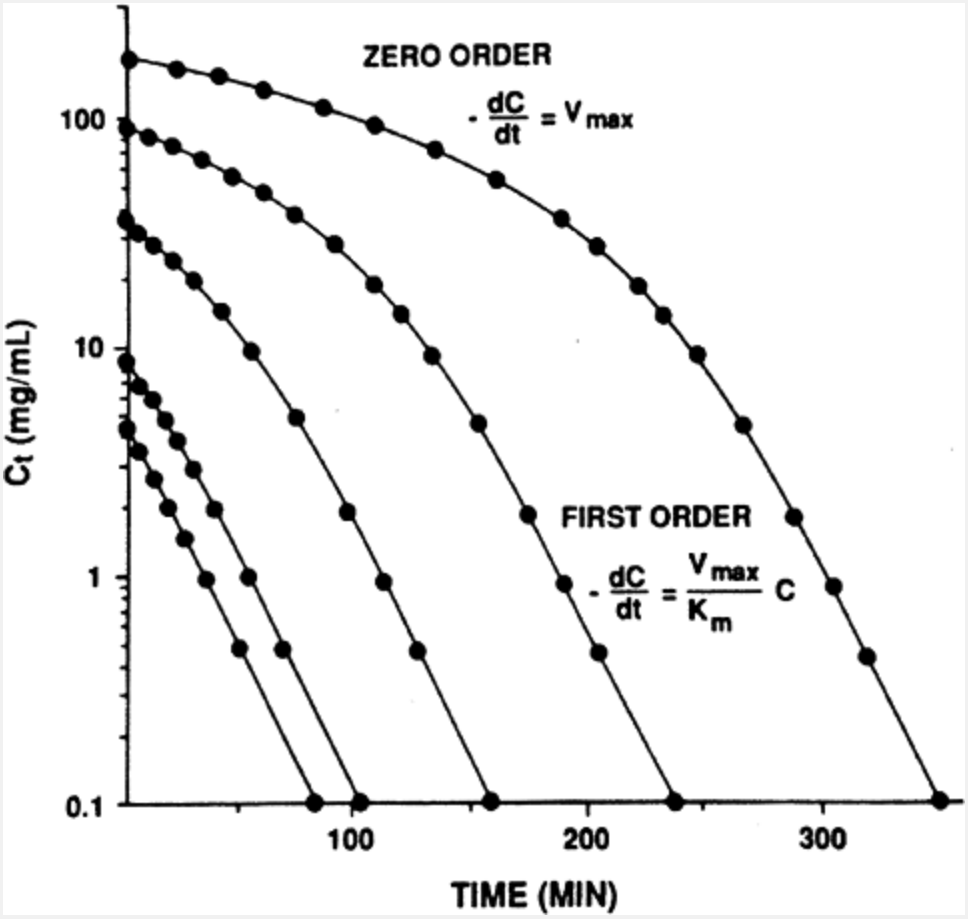

Figure 9-10. Concentration versus time curve for a xenobiotic showing nonlinear pharmacokinetics concentrations <10 mg/mL represent first order elimination. *(Reprinted, with permission, from Yang R, Andersen M: Pharmacokinetics. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT, Appleton & Lange, 1994, p. 57.)*

$$Cl = \frac{\text{Rate of elimination}}{C} \qquad \text{(Eq. 9–23)}$$

The determination of creatinine clearance is a well-known example of the concept of clearance. Creatinine clearance ($Cl_{creatinine}$) is

determined by Equation 9-24,

$$Cl_{creatinine} = \frac{U \times V}{C} \qquad \text{(Eq. 9–24)}$$

in which *U* is the concentration of creatinine in urine (mg/mL); *V* is the volume flow of urine (mL/min); *C* is the plasma concentration of creatinine (mg/mL); and the units for clearance are mL/min. A creatinine clearance of 100 mL/min means that 100 mL of plasma is completely cleared of creatinine each minute. Clearance for a particular eliminating organ or for extracorporeal elimination is calculated with Equation 9-25.

$$Cl = Q \times (ER) = Q \times \frac{(C_{in} - C_{out})}{C_{in}}$$

Cl = clearance for the eliminating organ or extracorporeal device
Q = blood flow to the organ or device
ER = extraction ratio
C_{in} = xenobiotic concentration in fluid (blood or serum) entering the organ or device
C_{out} = xenobiotic concentration in fluid (blood or serum) leaving the organ or device

(Eq. 9–25)

TABLE 9-8A. Illustration of 1000 mg of Xenobiotic in Body Following First-Order Elimination

Time After Drug Administration (h)	Amount of Drug in Body (mg)	Amount of Drug Eliminated Over Preceding Hour (mg)	Fraction of Drug Eliminated Over Preceding Hour
0	1000	â€”	â€”
1	850	150	0.15
2	723	127	0.15
3	614	109	0.15
4	522	92	0.15
5	444	78	0.15
6	377	67	0.15

TABLE 9-8B. Illustration of 1000 mg of Xenobiotic in Body Following Zero-Order Elimination

Time After Drug Administration (h)	Amount of Drug in Body (mg)	Amount of Drug Eliminated Over Preceding Hour (mg)	Fraction of Drug Eliminated Over Preceding Hour
0	1000	â€”	â€”
1	850	150	0.15
2	700	150	0.18
3	550	150	0.21
4	400	150	0.27
5	250	150	0.38
6	100	150	0.60

Clearance can be applied to any elimination process independent of the precise mechanisms (ie, first-order, Michaelis-Menten), and will represent the sum total of all of the rate constants for xenobiotic elimination. Total body clearance ($Cl_{totalbody}$) is the sum of the clearances of all of the individual eliminating processes, as seen in

Equation 9-26.

$$Cl_{\text{total body}} = Cl_{\text{renal}} + Cl_{\text{hepatic}} + Cl_{\text{intestinal}} + Cl_{\text{chelation}} + \cdots \quad \text{(Eq. 9–26)}$$

For a first-order process (one-compartment model), clearance is given by Equation 9-27.

$$Cl = k_e Vd \quad \text{(Eq. 9–27)}$$

Experimentally, the clearance can be derived by examining the intravenous dose of xenobiotic in relation to the AUC from time zero to time *t* (Eq. 9-28). The AUC is calculated using the trapezoidal rule or through integral calculus (units: eg, mg/mL) (Figs. 9-11 and 9-12).

$$Cl = \frac{\text{dose}_{IV}}{AUC_{0-t}} \quad \text{(Eq. 9–28)}$$

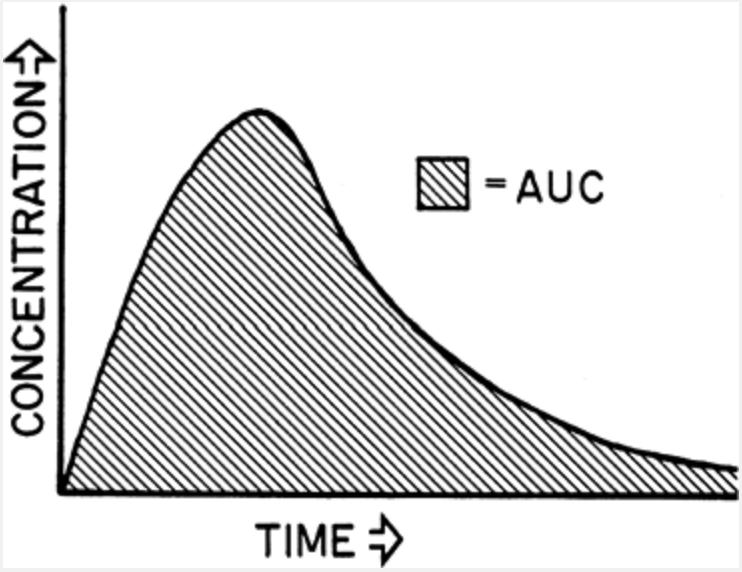

Figure 9-11. The AUC profile obtained after extravascular administration of a xenobiotic. *(Reprinted, with permission, from Riviere JE: Absorption and distribution. In: Hodgson E, Levi P, eds: Introduction to Biochemical Toxicology. Norwalk, CT,*

Appleton & Lange, 1994, p. 21.)

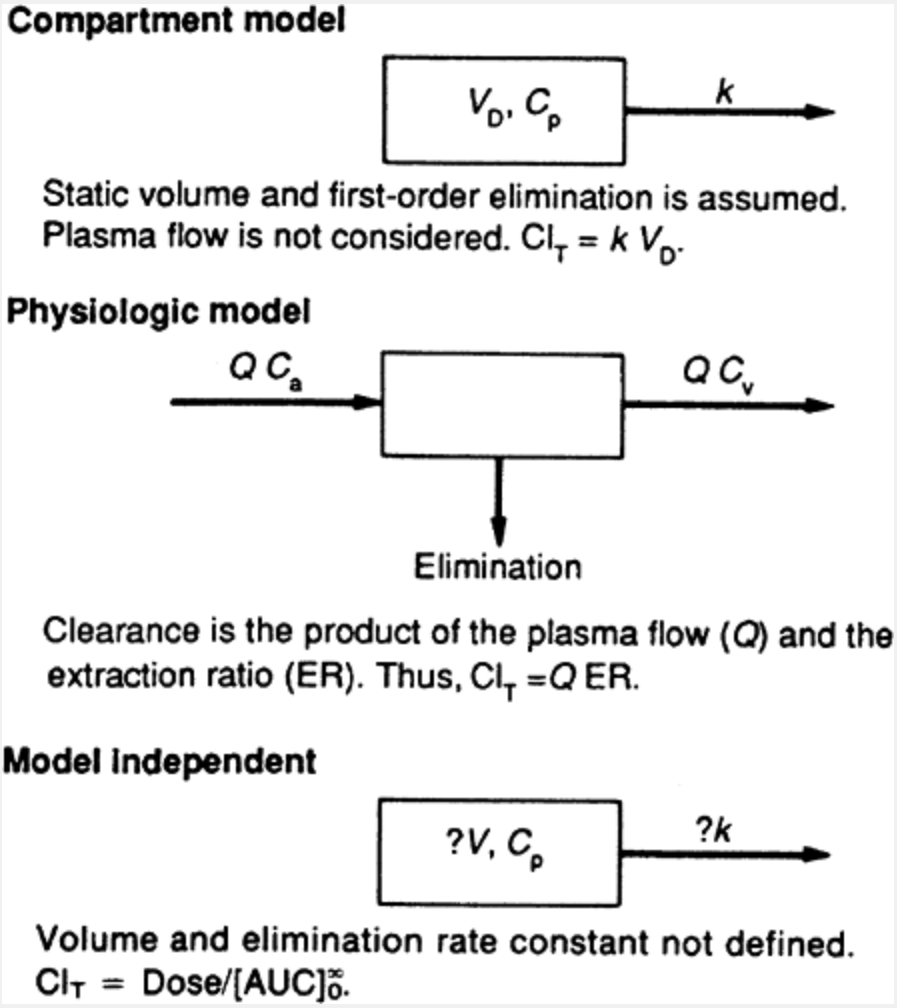

Figure 9-12. General approaches to clearance. *(Reprinted, with permission, from Shargel L, Yu A: Introduction to pharmacokinetics. In: Applied Biopharmaceutics and Pharmacokinetics, 3rd ed. Norwalk, CT, Appleton & Lange, 1993, p. 280.)*

Steady State

When exposure to a xenobiotic occurs at a fixed rate, the plasma concentration of the xenobiotic gradually achieves a plateau level at a concentration at which the rate of absorption equals the rate of elimination and is termed *steady state*. The time to achieve 95% of steady-state concentration for a first-order process is dependent on the half-life and usually necessitates 5 half-lives. The concentration achieved at steady state depends on the Vd, the rate of exposure, and the half-life.

Iatrogenic toxicity can occur in the therapeutic setting when dosing decisions are based on plasma concentrations determined prior to achieving a steady state. This adverse event is particularly common when using drugs with long half-lives such as digoxin[71] and phenytoin.

Peak Plasma Concentrations

Peak plasma concentrations (C_{max}) of a xenobiotic occur at the time of peak absorption. At this point in time, the absorption rate is at least equal to the elimination rate. Thereafter, the elimination rate predominates and plasma concentrations begin to decline. Whereas the C_{max} depends on the dose, the *rate of absorption* (k_a), and *the rate of elimination* (k_e), the *time to peak* (t_{max}) is independent of dose and only depends on the k_a and k_e. For the same dose of xenobiotic, if the k_e remains constant and the rate of absorption decreases, then the t_{max} will occur later and the C_{max} will be slightly lower. Controlled-release dosage forms and xenobiotics that form concretions and have a decreased rate of absorption may

not achieve peak concentrations until many hours after an immediate-release preparation with rapid absorption. The AUC will remain the same. However if the k_a remains constant and the k_e is increased, then the t_{max} occurs sooner, the C_{max} decreases, and the

AUC decreases (Table 9-9).[46]

TABLE 9-9. Pharmacokinetic Effects of the Absorption Rate Constant and Elimination Rate Constant[a]

Absorption Rate Constant k_a (h^{-1})	Elimination Rate Constant k_e (h^{-1})	t_{max} (h)	C_{max} (Âµg/mL)	AUC (ÂµgÂ·h/mL
0.1	0.2	6.93	2.50	50
0.2	0.1	6.93	5.00	100
0.3	0.1	5.49	5.77	100
0.4	0.1	4.62	6.26	100
0.5	0.1	4.02	6.69	100
0.6	0.1	3.58	6.69	100
0.3	0.1	5.49	5.77	100
0.3	0.2	4.05	4.44	50
0.3	0.3	3.33	3.68	33.3
0.3	0.4	2.88	3.16	25

0.3	0.5	2.55	2.79	20

t_{max} = time to peak plasma concentration; C_{max} = peak xenobiotic concentration; AUC = area under the (plasma drug concentration versus time) curve.
Values are based on a single oral dose (100 mg) that is 100% bioavailable (F = 1) and has an apparent Vd of 10 L. The drug follows a one-compartment open model. The AUC is calculated by the trapezoidal rule from 0 to 24 h.
Reprinted, with permission, from Shargel L, Yu A: Pharmacokinetics of drug absorption. In: Applied Biopharmaceutics and Pharmacokinetics, 3rd ed. Norwalk, CT: Appleton & Lange, 1993, p. 183.

In the overdose setting, gastric emptying, single-dose activated charcoal, and whole-bowel irrigation decrease k_a. Multiple-dose activated charcoal, manipulation of pH to promote ion trapping to facilitate elimination, and certain chelators (ie, succimer, deferoxamine) increase k_e and are likely to decrease C_{max}, t_{max}, and AUC.

Interpretation of Plasma Concentrations

For plasma concentrations to have significance, there must be an established relationship between effect and plasma concentration. For many medications, such as phenytoin, digoxin, carbamazepine, and theophylline, there is an established therapeutic range. However, there are also many drugs for which there is no established therapeutic range (diazepam, propranolol, verapamil). Some xenobiotics exhibit *hysteresis* in which the effect increases as the plasma concentration decreases (eg, physostigmine). For many xenobiotics, there is very little information on toxicodynamics. Sequential plasma concentrations often are collected for

retrospective analysis in an attempt to correlate plasma concentrations and toxicity. Tolerance to drugs, such as ethanol, also influences the interpretation of plasma concentrations. *Tolerance* is an example of a pharmacodynamic or toxicodynamic effect as a result of cellular adaptation, and it occurs when larger doses of a xenobiotic are necessary to achieve the same clinical or pharmacologic result.

Other factors that influence the interpretation of plasma concentrations include chronicity of dosing (a single dose vs. multiple doses); whether absorption is still ongoing and therefore concentrations are still rising; whether distribution is still ongoing and therefore concentrations are uninterpretable (Figure 9-13); or whether the value is a peak, trough, or steady-state concentration. Clinical examples where interpretation is dependent on the dosing pattern of a single dose versus multiple doses include theophylline, digoxin, lithium, and acetaminophen. Controlled-release preparations and those xenobiotics that delay gastric emptying or form concretions are expected to have prolonged absorptive phases and require serial plasma concentrations to obtain a meaningful analysis of plasma concentrations (Chap. 7). A combination of trough, peak and minimum inhibitory concentrations are often consequential for monitoring antibiotics such as gentamicin.[8,38]

Pitfalls in interpretation arise when the units for a particular plasma concentration are not obtained or are unfamiliar (eg, mmol/L) to the clinician. In the overdose setting, the type of analysis used is not generally applied to such large concentrations, and the laboratory may make errors in dilution, or errors can be inherent in the assay (Chap. 7). In those cases, the director of the laboratory should be consulted for advice with regard to the need for a reference laboratory. The type of collection tube (eg, plasma or serum instead of whole-blood for certain metals), or receptacle, or the conditions during delivery of the sample may give rise to inaccurate or inadequate information. When in doubt, the laboratory should be called prior to sample collection. The laboratory usually measures

total xenobiotic (free plus bound), and for agents that are highly plasma protein bound, reductions in albumin increase free

concentrations and alter the interpretation of the reported value (see Eq. 9-7). Active metabolites may contribute to toxicity and may not be measured.[33] Collection of accurate data for analysis requires at least 4 data points during 1 elimination half-life. During extracorporeal methods of elimination, ideal criteria for determining the amount removed require assay of the dialysate or charcoal cartridge or multiple simultaneous serum concentrations going into and out of the device and not random serum concentrations. Clearance calculations for drugs such as lithium that partition significantly into the red cell are more accurate when measurements are taken on whole blood.[11,17] Patient weight and height and, when indicated, hemoglobin, creatinine, albumin, and other parameters to assess elimination pathways, may be helpful.

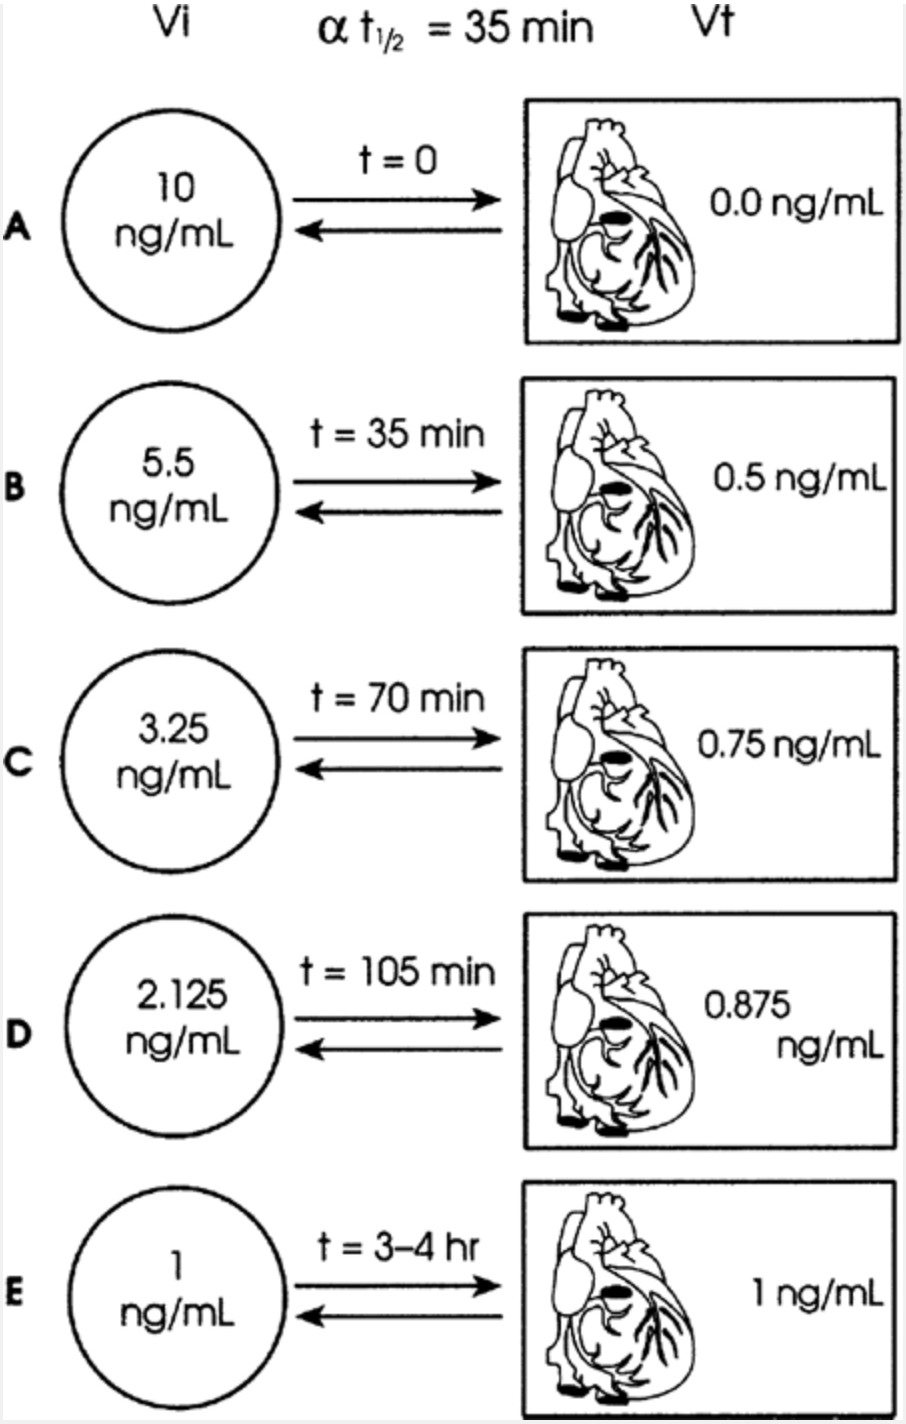

Figure 9-13. A theoretical two-compartment model for digoxin. *(Reprinted, with permission, from Winter ME: Digoxin. In: Koda-Kimble MA, Young LY, eds: Basic Clinical Pharmacokinetics, 3rd*

ed. Vancouver, WA, Applied Therapeutics, 1994, pp. 198â€“235.)

Case Illustrations

The following cases are designed to illustrate a number of pharmacokinetic and toxicokinetic principles. The cases demonstrate the applications of many of the mathematical models explained above.

Case 1

A 23-year-old, 90-kg female is seen in the emergency department 2 hours after the ingestion of 50 of her brother's Theo-Dur (300 mg) tablets. She is alert and oriented. Her vital signs are a blood pressure of 130/75 mm Hg; a heart rate of 110 beats/min; a respiratory rate of 20 breaths/min; and a temperature of 99.7Â°F (37.6Â°C) rectally. Her initial theophylline serum concentration is 40 mg/L.

- Estimate a peak serum concentration knowing that theophylline has a Vd of 0.5 L/kg, an *S* = 1 (not a salt form), and an *F* = 1 (100% bioavailable). Rearrange Equation 9-6.

$$C_0 = \frac{S \times F \times \text{dose (mg)}}{Vd}$$

$$C_0 = \frac{1 \times 1 \times 50 \times 300\ \text{mg}}{0.5\ \text{L/kg} \times 90\ \text{kg}} = 333\ \text{mg/L}$$

- If the history were correct what would prevent the patient from achieving this serum concentration?

  Increasing the number of tablets of sustained-release dosage forms may alter release characteristics, delay absorption, and

reduce k_a (absorption rate constant). Elimination (k_e) occurs during the absorptive phase, so C_{max} and AUC are reduced. Vomiting typically occurs following theophylline ingestion and will decrease bioavailability.

- How would treatment strategies affect the toxicokinetics of theophylline?

  Activated charcoal and whole-bowel irrigation decrease bioavailability. Multiple-dose activated charcoal, charcoal hemoperfusion, and hemodialysis enhance elimination.

- Can the patient be considered medically clear at this time?

  No. Serum concentrations may continue to rise and may not achieve peak levels for 12â€“24 hours. Therefore, sequential serum concentrations should be analyzed frequently until concentrations start to fall, and then less frequent determinations are necessary as the concentration approaches the therapeutic range (Chap. 63).

Case 2

A 63-year-old, 60-kg female is brought to the emergency department by her family 30 minutes after ingesting twenty-five 0.25-mg digoxin tablets. The patient complains of nausea, but is otherwise asymptomatic. Her physical examination is normal. Her vital signs are a blood pressure of 130/85 mm Hg; a heart rate of 76 beats/min and irregular; a respiratory rate of 17 breaths/min; and a temperature of 98Â°F (36.6Â°C) rectally. The ECG shows controlled atrial fibrillation at a rate of 76.

- Estimate this patient's plasma digoxin concentration. Assume Vd = 5 L/kg, S = 1, and F = 0.7 (70%).

$$C_0 = \frac{S \times F \times dose}{Vd}$$

$$C_0 = \frac{1 \times 0.7 \times 25 \times 0.25\ mg \times 1{,}000{,}000\ ng/1\ mg}{5\ L/kg \times 1000\ mL/L \times 60\ kg} = 14.6\ ng/mL$$

- Her serum digoxin concentration is reported to be 15 ng/mL (therapeutic = 0.8â€“2 ng/mL). Why doesn't this patient show more severe signs of digoxin toxicity?

  This patient does not show serious signs and symptoms of toxicity from digoxin because digoxin fits a two-compartment model with a long distribution half-life. Toxicity is related to the concentration in the peripheral (heart) compartment. However, in several hours she may demonstrate severe signs of toxicity (see Fig. 9-13).

- How do digoxin-specific antibody fragments (DSFab) alter the toxicokinetics of digoxin?

  Digoxin-specific antibody fragments reduce the Vd of digoxin by binding digoxin in the plasma, thereby establishing a concentration gradient to remove digoxin from reversible myocardial binding sites. All digoxin bound to digoxin-specific antibody fragments is inactive. The digoxin-specific antibody fragmentsâ€“digoxin complex is eliminated slightly faster than digoxin alone because of a reduced Vd.

- How would you calculate the appropriate dose of Digoxin-specific antibody fragments?

  If the ingested dose is known:

$$\text{Total body load (TBL)} = S \times F \times \text{dose}$$
$$= 1 \times 0.7 \times 25 \times 0.25 \text{ mg} = 4.375$$
1 vial of DSFab binds 0.5 mg of digoxin

$$\text{No. vials DSFab} = \frac{\text{TBL (4.375 mg)}}{\text{0.5 mg digoxin/vial DSFab}}$$
$$= 8.75 \text{ (Round up to 9 vials) vials}$$

If serum concentration is known:

$$\text{TBL (mg)} = C \text{ (ng/mL)} \times (1 \text{ mg}/1{,}000{,}000 \text{ ng}) \times V_d \text{ (L/kg)}(1000 \text{ mL/L}) \times \text{weight of patient (kg)}$$

$$= \frac{15 \text{ ng/mL} \times 5 \text{ L/kg} \times 60 \text{ kg}}{1000} = 4.5 \text{ mg}$$

$$\text{No. vials DSFab} = \frac{\text{TBL(4.5 mg) of digoxin}}{\text{0.5 mg digoxin/vial DSFab}}$$
$$= 9 \text{ vials DSFab}$$

OR a simplified version:

$$\text{No. vials DSFab} = \frac{C\text{(ng/mL)} \times \text{weight per patient (kg)}}{100}$$
$$= 9 \text{ vials DSFab}$$

The numbers of vials of digoxin-specific antibody fragments calculated either by using the history of the amount ingested or based on the serum concentration are usually different because each formula has independent inherent errors.

Case 3

A patient receives a continuous infusion of pentobarbital for 3 days. The infusion is terminated, but the patient has not awakened after 6 hours. The reported duration of hypnotic action after a single IV dose

is 1â€“4 hours. Is there a toxicokinetic explanation for the persistent somnolence?

Yes. The short duration of action after a single dose of IV pentobarbital is attributed to redistribution. With chronic dosing, accumulation occurs and the elimination half-life becomes 15â€“48 hours. This patient may require several days to awaken.

Case 4

A 70-kg man with no history of alcoholism ingests methanol and is found to have a serum concentration of 100 mg/dL (1 g/L). The following information is available:

- Methanol: molecular weight 32 daltons; water soluble
- Specific gravity (sp gr) of absolute ethanol and methanol: 0.8 g/mL
- Vd of ethanol and methanol = 0.6 L/kg
- Protein binding of ethanol and methanol = negligible
- Bioavailability for ethanol and methanol = 100%
- Hemodialysis clearance of ethanol and methanol = 150 mL/min; assume hemodialysis is a first-order process
- Hemodialysis extraction ratio of ethanol and methanol = 100%
- V_{max} = 0.13 g/kg/h for ethanol for a naive person
- How much methanol did the patient drink if he drank gas-line antifreeze which is 95% methanol?

$$C_0 = \frac{S \times F \times \text{dose}}{V_d} \quad \text{Rearranging: } S \times F \times \text{dose} = C_0 \times V_d$$

$$1 \times 1 \times \text{dose} = 1\text{g/L} \times 0.6\ \text{L/kg} \times 70\ \text{kg}$$
$$= 42\ \text{g of 100\% concentration}$$
$$(S = 1; \text{there is no salt form of an alcohol})$$
$$42\ \text{g} \times 1\ \text{mL}/0.95\ \text{g (95\% conc)} \times 1\ \text{mL}/0.8\ \text{g (sp gr)}$$
$$= 55\ \text{mL of 95\% methanol}$$

- How much ethanol as vodka (80 proof = 40%) should be given to the patient as a loading dose to achieve a serum ethanol concentration of 100 mg% (100 mg/dL or 1 g/L)?

$$C_0 = \frac{S \times F \times \text{dose}}{Vd} \quad \text{Rearranging: } S \times F \times \text{dose} = C_0 \times Vd$$

$$1 \times 1 \times \text{dose} = 1\text{g/L} \times 0.6\ \text{L/kg} \times 70\ \text{kg} = 42\ \text{g}$$
$$42\ \text{g} \times 1\ \text{mL}/0.4\ \text{g (40\% conc)} \times 1\ \text{mL}/0.8\ \text{g (sp gr)}$$
$$= 131\ \text{mL of 40\% ethanol}$$

- What maintenance dose of ethanol should be given to the patient to maintain an ethanol serum concentration of 100 mg/dL (1 g/L)?

  The V_{max} of 0.13 g/kg/h is the maximum rate of elimination for a patient not tolerant to ethanol. The maintenance dose is designed to replace the amount of ethanol eliminated. Therefore:

  0.13 g/kg/h Ã— 70 kg = 9.1 g/h Ã— 1 mL/0.1(10%) Ã— 1 mL /0.8 (sp gr) = 113.75 mL/h of 10% ethanol (can be given P0 or IV)

- How many hours of hemodialysis are necessary to reduce the methanol serum concentration to 10 mg/dL (0.1 g/L)?

  k_e = Cl/Vd; $Cl_{\text{total body}} = Cl_{HD} + Cl_{\text{endogenous}}$

  $= Cl_{HD} + 0$ (minimal endogenous clearance when methanol metabolism is blocked with ethanol)

$$\frac{150\ \text{mL/min} \times 60\ \text{min/h} \times 1\ \text{L}/1000\ \text{mL}}{0.6\ \text{L/kg} \times 70\ \text{kg}}$$

$$= 0.214\ \text{h}^{-1} = 21.4\%\ \text{per hour eliminated}$$

$$t_{1/2} = 0.693/k_e = 0.693/0.214\ \text{h}^{-1} = 3.22\ \text{h}$$

$$t_1 - t_2 = \frac{\ln C_1 - \ln C_2}{k_e} = \frac{\ln 100 - \ln 10}{0.214\ \text{h}^{-1}}$$

$$= 10.74\ \text{hours to go from 100 mg/dL to 10 mg/dL}$$

Case 5

A 70-kg male is brought to the hospital with a serum phenytoin concentration of 80 Âµg/mL (mg/L). Assume the ingestion occurred 2 days earlier and there is no ongoing absorption. Estimate how long it might take this patient to reach 20 Âµg/mL. The following information is available:

$$Vd = 0.7\ \text{L/kg}$$

V_m (maximum metabolic capacity) $= 7$ mg/kg/d

K_m (serum concentration at which the metabolic rate is at one-half the maximum metabolic rate) $= 4$ mg/L

$$v = \frac{V_{max} \times C}{K_m + C} = \frac{7\ \text{mg/kg/d} \times 70\ \text{kg} \times 80\ \text{mg/L}}{4\ \text{mg/L} + 80\ \text{mg/L}}$$

$$= 466.6\ \text{mg/day eliminated at zero order}$$

Estimate the initial amount of phenytoin in body:

Dose = C Ã— Vd 80 mg/L Ã— 0.7 L/kg Ã— 70 kg = 3920 mg

Estimate the amount of phenytoin in body at 20 mg/L:

Dose = C Ã— Vd = 20 mg/L Ã— 0.7 L/kg Ã— 70 kg = 980 mg

3920 mg - 980 mg = 2940 mg as the amount that needs to be eliminated

At an elimination rate of 466.6 mg/d, it takes about 6.3 days for the

serum phenytoin concentration of 80 mg/dL to fall to 20 mg/dL assuming neither ongoing absorption nor enhanced elimination from repeat dose activated charcoal occurs.

A similar result is found using the following formula:

$$t = \frac{[(K_m)(\ln Cp_1/\ln Cp_2)] + (C_1 - C_2)}{V_m/Vd}$$

$$= \frac{(4\ \text{mg/L}) \times (4.38 - 3) + (80 - 20)}{(7\ \text{mg/kg/d} \times 70\ \text{kg})/(0.7\ \text{L/kg} \times 70\ \text{kg})}$$

$$= 6.55\ \text{days}$$

Case 6

Compare the utility of exchange transfusion, peritoneal dialysis, hemodialysis, and hemoperfusion for the ingestion of 2 g of either amitriptyline or theophylline in a 15-kg child.

The following information is available:

Vd of amitriptyline = 30 L/kg; protein binding = high

Vd of theophylline = 0.5 L/kg; protein binding = moderate

Blood volume = 85 mL/kg: a double volume exchange

= 85 mL/kg Ã— 2

Estimate that 300 mL of peritoneal fluid is administered over 10 min, that the equilibration time is 20 min, and that 300 mL is removed over 30 min for a total time of 60 min.

Assume HP clearance of 200 mL/min for theophylline.

- Would exchange transfusion be reasonable for amitriptyline or theophylline removal?

Double volume exchange = 85 mL/kg Ã— 2

In this child = 85 mL/kg Ã— 15 kg Ã— 2 = 2550 mL = 2.55L

Vd for amitriptyline in this child = 30 L/kg Ã— 15 kg = 450 L

450 L/ 2.55 L = 176 double-exchange transfusions, an unrealistic number!

Vd for theophylline in this child = 0.5 L/kg Ã— 15 kg = 7.5 mL

7.5 L/2.55 L = about 3 double-exchanges, a reasonable number!

- Would peritoneal dialysis be reasonable for amitriptyline or theophylline removal? (For peritoneal dialysis, assume a 300-mL/h exchange which equals 7.2 L/d.)

  No for both amitriptyline and theophylline.

  For amitriptyline, 450 L/7.2 L/d = 62.5 days

  for theophylline, 7.5 L/7.2 L/d = 25 hours

  which is too long in a life-threatening situation.

- Would hemodialysis be reasonable for amitriptyline or theophylline removal?

  No, for amitriptyline; yes, for theophylline.

  For hemodialysis, there is unlikely to be any benefit for amitriptyline removal because of the high protein binding and large Vd. Moderate protein binding of theophylline would be a limiting factor but a small Vd would be advantageous. The result would be acceptable for theophylline.

- Would activated charcoal hemoperfusion be reasonable for amitriptyline or theophylline removal?

  No, for amitriptyline; yes, for theophylline.

  For hemoperfusion, protein binding may be of less importance if binding to activated charcoal is more substantial than protein binding.

k_e = Cl/Vd

Assume HP Cl = 200 mL/min Ã— 60 min/h = 12 L/h and the endogenous clearance is minimal.

For amitriptyline:

12 L/h/30 L/kg Ã— 15 kg = 0.0266 h^{-1}

$t_{Â½}$ = 0.693/k_e = 0.693/0.0266 = 26 hours, which is clinically unreasonable.

For theophylline:

12 L/h/0.5 L/kg Ã— 15 kg = 1.6 h^{-1}

$t_{Â½}$ = 0.693/k_e = 0.693/1.6 = 0.433 hours, which is clinically reasonable.

Acknowledgment

Christine Stork, PharmD, contributed to the development of some of these cases which also were used at workshops given at the NYCPCC.

Chapter 10

Principles and Techniques Applied to Elimination

David S. Goldfarb

Daniel Matalon

Enhancement of the elimination of a xenobiotic from a poisoned patient is techniques to inhibit absorption such as orogastric lavage, multiple-dose whole-bowel irrigation are initiated. Table 10-1 lists methods that might elimination. Some of these techniques are described in more detail in cha specific xenobiotics. In this chapter, hemodialysis, hemoperfusion, and h considered *extracorporeal therapies* because xenobiotic removal occurs in the body. These methods are used infrequently because current methods care keep the overall mortality rate low in poisoned patients who reach t these elimination techniques are not without adverse effects and complica in only a relatively small proportion of patients. Although undoubtedly an use, enhancement of elimination was used relatively infrequently in a coh patients reported by the American Association of Poison Control Centers Surveillance System (TESS) in 2004 (Chap. 130). Alkalinization of the u 8654 times; multiple-dose activated charcoal 5031 times; hemodialysis 1 29 times; and â€œother extracorporeal proceduresâ€• (most likely cont

hemofiltration [CVVH]) 33 times. Recent annual reports from the AAPCC c regarding the specific poisonings treated with the various modalities of e the past, when these data were reported, there were many instances of t therapies that would today be considered inappropriate, such as in the tr antidepressant overdose.

In comparing these most recent data to past reports, and recognizing tha is imperfect (Table 10-2), there is a continued increase in the reported paralleling a decline in reports of charcoal hemoperfusion (Chap. 130). T this decline are described in the â€œCharcoal Hemoperfusionâ€• section, and other sorbents once used for hemoperfusion are not currently availab Peritoneal dialysis (PD), a slower modality that should have little or no ro longer separately reported (Chap. 130). â€œOther extracorporeal proced reports may include some cases in which PD was used. In the later data, includes fewer reports of PD use and more reports of the more recently venovenous hemo(dia)filtration,â€• or CVVH(D). There are very few pro controlled clinical trials to determine which groups of patients actually be elimination of various xenobiotics, and which modalities are most efficaci it is unlikely that such studies will ever be performed, given the relative cases of sufficient severity and because of the many variables that would comparisons. Thus, anecdotal evidence predominates. We must still rely o principles of these methods to identify the individual patients for whom e indicated. Isolated case reports in which the kinetics are studied before, enhanced elimination are also very useful in establishing the efficacy of a

Indications for Enhanced Elimination

Enhanced elimination may be indicated in several types of patients:

- *Patients who fail to respond adequately to full supportive care.* Such intractable hypotension, heart failure, seizures, metabolic acidosis, o Hemodialysis or hemoperfusion are much better tolerated than in the potentially life-saving opportunities for patients with life-threatening t theophylline, lithium, salicylates, or toxic alcohols.
- *Patients in whom the normal route of elimination of the xenobiotic is*

may have renal or hepatic dysfunction, either preexisting or caused b example, a patient with chronic renal insufficiency associated with lon more likely to develop lithium toxicity and to require hemodialysis as

- *Patients in whom the amount of xenobiotic absorbed or its high conce indicates that serious morbidity or mortality is likely.* Such patients m on presentation. Xenobiotics in this group may include ethylene glyco paraquat, salicylate, and theophylline.

- *Patients with concurrent disease or in an age group (very young or o increased risk of morbidity or mortality from the overdose.* Such pati prolonged coma, immobility, and hemodynamic instability. An example severe underlying respiratory disease and chronic theophylline poison
- *Patients with concomitant electrolyte disorders that could be addresse* example is the lactic acidosis associated with metformin toxicity discu â€œHemodialysis â€• section of this chapter.

Xenobiotic-specific antibody fragments
Whole bowel irrigation

TABLE 10-1. Potential Methods of Enhancing Elimination of Xenol

Ideally, these techniques will be applied to poisonings for which studies s outcome in treated patients as compared to patients not treated with ex previously mentioned, these data are rarely available.

The need for extracorporeal elimination is less clear for patients who are that are known to be removed by the various modalities of treatment, bu morbidity if supportive care is provided. Relatively high rates of endogen make extracorporeal elimination redundant. Examples of such xenobiotics barbiturates. Both are subject to substantial rates of hepatic metabolism, expected to lead to significant morbidity after the affected patient has b intubated and is mechanically ventilated. There may be instances of sever substances in which enhanced elimination will reduce the length of ICU st nosocomial risks; extracorporeal elimination may then be a reasonable o

TABLE 10-2. Changes in Use of Extracorporeal Therapies [a]

Characteristics of Xenobiotics Appropriate Extracorporeal Therapy

The appropriateness of any modality for increasing the elimination of a g
on various properties of the molecules in question. Effective removal by
procedures and other methods listed in Table 10-1 is limited by a large v
volume of distribution (Vd) relates the concentration of the xenobiotic in t
total body burden. The Vd can be envisioned as the apparent volume in w
of drug is distributed before metabolism and excretion occur:

Vd(L/kg) = dose (mg)/concentration (mg/L)

The larger the Vd, the less the xenobiotic is available to the blood compa
drug with a relatively small Vd, considered amenable to extracorporeal e
distribute in an apparent volume not much larger than total body water. T
approximately 60% of total body weight, so that a Vd equal to total body

0.6 L/kg body weight.

Ethanol is an example of a xenobiotic with a small Vd approximately equa substantial fraction of a dose of ethanol could be removed by hemodialysi insignificant fraction of digoxin, with a large volume of distribution (Vd = weight), would be removed by this therapy. Lipid-soluble xenobiotics, and protein bound, have large volumes of distribution, which can exceed total body weight. These high apparent volumes of distribution imply that the to extracorporeal removal because only a small portion would be in the b extracorporeal circuit. In addition to the alcohols, other xenobiotics with phenobarbital, lithium, salicylates, bromide and fluoride ions,[10] and theo those with a high Vd (up to 40 L/kg of body weight), which would not be hemodialysis, include many Î²-adrenergic antagonists (with the possible e diazepam, organic phosphorus compounds, phenothiazines, quinidine, and antidepressants.

Whether a xenobiotic can be removed is also determined by the pharmac compound. Kinetic parameters after an overdose may differ from those a experimental doses. For instance, carrier or enzyme-mediated elimination overwhelmed by higher levels of the xenobiotic in question, making extr potentially more useful. Similarly, plasma protein- and tissue-binding sites higher concentrations, making extracorporeal removal feasible in instances role in less significant overdoses. An example is valproic acid, which may nontoxic levels associated with high rates of protein binding. Higher, pot concentrations saturate protein-binding sites and lead to a higher proportio serum and amenable to being removed at a clinically relevant rate by he the expected endogenous rates of elimination of a xenobiotic in the settin

should be made, where possible, from knowledge of the toxicokinetics ob of toxicity, not after therapeutic doses.

When assessing the efficacy of any technique of enhanced elimination, a principle is that the intervention is worthwhile only if the total body clear increased by at least 30%.[17] This substantial increase is easier to achieve a low endogenous clearance. Examples of xenobiotics with low endogenou mL/min/kg) include the toxic alcohols (particularly when their metabolism

sotalol, lithium, paraquat, phenytoin, salicylate, and theophylline. Xenobic endogenous clearances include many Î²-adrenergic antagonists, lidocaine, tricyclic antidepressants. Enhancement of elimination is expected to contri group than to the latter.

The efficacy of any technique of elimination can be directly assessed by c plasma concentrations of the substance at the beginning and at the end c example, a xenobiotic like theophylline, with one-compartment kinetics, is extracellular space. The difference between the theophylline concentration minus the concentration at the end of the procedure, divided by the conc beginning, is the fraction of the body burden of the xenobiotic that is eli

Certain xenobiotics like lithium distribute in part to the intracellular comp equilibrium is established for the drug between the intracellular and ext The latter compartment includes the blood from which xenobiotic eliminat the elimination rate from the extracellular compartment, such as by hem equilibrium. The rate of redistribution of the xenobiotic from the intracell now-dialyzed extracellular compartment may be slower than the rate of c dialysis membrane. In that case, the plasma concentration may become r substantial intracellular burden. This low plasma concentration reduces t for diffusion from plasma to dialysate so that dialysance, the dialysis clea although plasma or blood concentrations may fall precipitously during the body burden of the xenobiotic may not be affected significantly. An examp ingests one hundred 25-mg amitriptyline tablets, a tricyclic antidepressar fully absorbed, the 2500 mg distributes in an apparent volume of 40 L/kg achieve a plasma concentration of 1000 ng/mL, a potentially toxic level. is performed with a blood flow rate of 350 mL/min (plasma flow rate of 2 hematocrit of approximately 43%), and the extraction ratio is 100% (see Hemoperfusion ,â€• below), the clearance of drug is 200 mL/min or 200 minutes) of treatment, only 48 mg (48,000 Âµg), or less than 2% of the removed, which will have no effect on toxicity.

Further evidence that a xenobiotic is in a slowly equilibrating compartmen monitoring the blood concentrations after discontinuation of the procedur rebounding serum levels. This rebound indicates postdialysis redistribution magnitude of the rebound depends on total-body stores of the xenobiotic,

there is ongoing absorption from the gastrointestinal tract.

When assessing efficacy, the evidence of enhanced elimination must be c the clinical response. In some instances, improvement is observed that w based on the kinetics of the parent compound. For example, in severe ca antidepressant poisoning, unexpected improvement during hemoperfusion because the toxicity is manifested early and ameliorates rapidly during t phase.

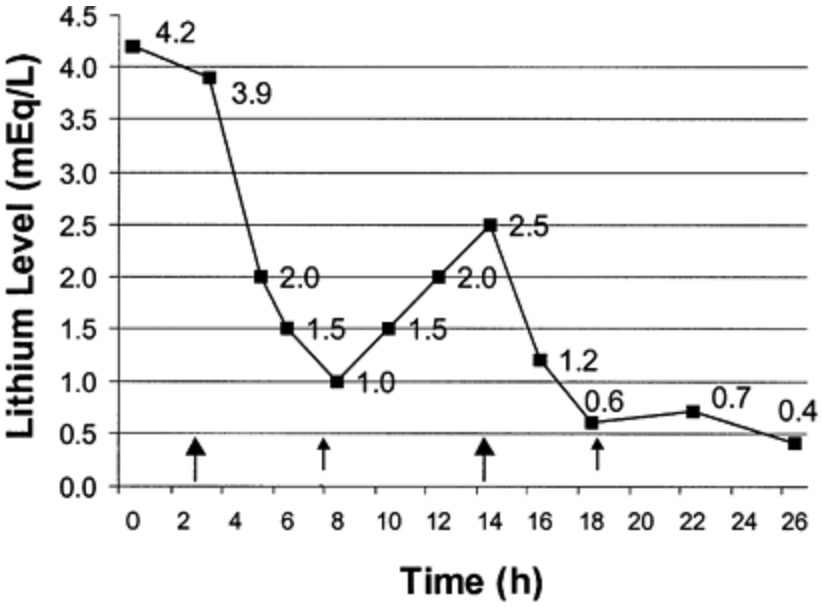

Figure 10-1. Repeated serum lithium concentrations after an acute inge beginning (large arrows) and end (small arrows) of hemodialysis. Followi treatment, a significant rebound in serum concentration occurred, with r impairment. An additional 4-hour hemodialysis treatment was then begur

Beginning a procedure during the initial distribution phase may increase t burden that can be removed. Later, after the xenobiotic has distributed in by plasma or tissue proteins, administration of extracorporeal treatment r clearance rates and benefits. Poisonings with paraquat and hepatotoxic m examples in which only early extracorporeal therapy *may* have benefit. A for unanticipated evidence of improvement is the removal of small amoun active metabolites from a shallow â€œtoxic effectâ€• compartment. This advanced to explain the response to hemodialysis of patients overdosed

chlorprothixene,[40] or with a combination of diltiazem and metoprolol.[3] Su transient improvements that are not sustained as drug redistributes from leading to early benefit but eventual recurrence of symptoms. Much of th to provide long-term followup to demonstrate prolongation of benefits af is completed and xenobiotics have redistributed.

Other examples also demonstrate that removal of a xenobiotic is a poor benefit. Enhanced elimination of phenobarbital[3,53] or carbamazepine[73] b charcoal did not affect clinical outcomes as compared to those of overdo despite a fall in their serum concentrations. In another study, no differer patients with lithium poisoning for whom hemodialysis was done and those recommended by a poison control center but not done.[8] The conclusion w should be considered appropriate only for the more severe cases. In ace efficacy of administration of *N* -acetylcysteine makes extracorporeal

removal unnecessary and not part of the recommended treatment strateg

Techniques Available to Enhance Removal

Although controversies remain about the efficacy of, or need for, removal consensus regarding the indications for a number of procedures has deve led to consistent application of several techniques of enhanced eliminatior exposures that occur relatively more frequently. The techniques to enha most commonly applied over the last decade have been alkalinization of hemodialysis for methanol, ethylene glycol, lithium, and salicylates; and theophylline.

Forced Diuresis and Manipulation of Urinary

Forced diuresis by volume expansion with isotonic sodium-containing solut or lactated Ringer solution, may increase renal clearance of some molecu theoretically be most true for xenobiotics such as lithium for which the g (GFR), the volume of plasma filtered across the glomerular basement mer important determinant of excretion. In people with normal extracellular flu had loss of sodium via renal, gastrointestinal, or other routes of excretion

expected with plasma volume expansion is variable and unpredictable and significant increases. The effect is potentially more important in patients of the extracellular fluid volume because of sodium loss. Loss of extracellu reduction of GFR partly as a result of decreased cardiac preload and card reduces renal plasma flow. This circumstance is also accompanied by acti small peptide that acts as a pressor and stimulates sodium reabsorption i Because small molecules like lithium are both filtered at the glomerulus a proximal tubule, especially when sodium depletion has occurred and angio activated, repletion of extracellular fluid volume with isotonic saline will i sodium reabsorption. The result is an increase in excretion of low-molec lithium. After the extracellular fluid volume is restored, continued infusion urine volume proportionally more than GFR, which may increase excretion such as urea, but which has marginal efficacy in the case of most poisoni not a significant determinant of excretion.

The significant risk of this therapy is extracellular fluid volume overload, and cerebral edema. This complication may be particularly likely in patie lithium use in whom chronic tubulointerstitial disease can lead to renal ir improve with fluid therapy. Other patients with acute renal failure not m fluid volume depletion are also at risk. Knowing the result of past serum may help distinguish acute from chronic renal insufficiency in such cases diuretics such as furosemide along with saline may diminish the risk of e overload, but complicate the therapy, confuse the assessment of extracel increase the risk of metabolic alkalosis and hypokalemia. The unproven e in the management of *any* overdose has led most experts to abandon its the repletion of extracellular fluid volume when it is contracted, as deterr physical examination, is, of course, appropriate.

Many xenobiotics are weak acids or bases that are ionized in aqueous solu depends on the pK_a of the compound and the pH of the solution. Knowing Henderson-Hasselbalch equation (Chap. 9) can be used to determine th the acids, bases, and buffer pairs. Cell membranes are relatively imperme molecules (such as an unprotonated salicylate anion), whereas nonionized the protonated, noncharged salicylic acid) can cross more easily. As xeno kidney, they may be filtered, secreted, and reabsorbed. If the urinary pH the formation of the ionized form in the tubular lumen, the xenobiotic is

fluid and not passively reabsorbed into the bloodstream (â€œion trapping
extent of its elimination can be increased. To make manipulation of urina
renal excretion of the compound must be a major route of elimination. A
American Academy of Clinical Toxicology (AACT) and the European Associ
and Clinical Toxicologists (EAPCCT) emphasizes that, as discussed above
therapies, enhanced removal does not necessarily translate into a clinical
outcomes.[55]

Acidification of the urine by systemic administration of HCl or NH_4 Cl to
weak bases, such as phencyclidine or the amphetamines, is not useful ar
The technique has been abandoned because it does not significantly enha
xenobiotics and is complicated by systemic metabolic acidosis.

Alkalinization of the urine to enhance elimination of weak acids has a lim
such as salicylates,[48] phenobarbital, chlorpropamide, formate, diflunisal,
and the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). These weak aci
urine pH and tubular reabsorption is thereby greatly reduced. Alkalinizatio
intravenous administration of sodium bicarbonate, 1â€“2 mEq/kg infused
goal is to increase urinary pH to 7â€“8.

This degree of alkalinization may be difficult, if not impossible, if metabo
are present, as often is the case with salicylate poisoning. In this situati
(administered as the sodium salt) is consumed by titration of plasma prot
in the urine. On the other hand, salicylate poisoning often causes respirat
that case, where PCO_2 is low, raising serum bicarbonate, equivalent to th
alkalosis, may lead to profound, life-threatening alkalemia. Finally, the ri
volume overload with sodium bicarbonate administration is the same as v
0.9% NaCl. Hypernatremia may also ensue after administration of hyper
Bicarbonaturia will also be associated with urinary potassium losses, so s
concentration should be monitored frequently and KCl given liberally as lo
impaired. A further complication of alkalemia is a decrease of ionized cal
bound by albumin as protons are titrated off serum proteins; if this occur
these complications can be identified and dealt with judiciously and safely

salicylate can increase 4-fold as urine pH increases from 6.5 to 7.5 with

Increasing urine pH by decreasing proximal tubular bicarbonate reabsorpt

carbonic anhydrase inhibitors such as acetazolamide is not recommended. xenobiotic may be increased, metabolic acidosis will ensue unless ample administered. In the case of salicylates, metabolic acidosis with acidemia distribution of drug into the central nervous system. As with $NaHCO_3$ ad bicarbonaturia is accompanied by urinary potassium losses; hypokalemia c of urinary alkalinization in the management of salicylate poisoning is disc .

Alkalinization is also used to increase the solubility of methotrexate and precipitation in tubules when patients are given high-dose folinic acid res Precipitation of sulfonamide antibiotics with renal stones or renal failure c alkalinization. Extracellular fluid volume expansion with 0.9% NaCl and N protects the kidneys from the toxic effects of myoglobinuria in patients w rhabdomyolysis. However, because patients with rhabdomyolysis may hav $NaHCO_3$ administration must be used before renal injury occurs and may volume overload if its administration continues once renal failure is estal

Peritoneal Dialysis

Theoretically, peritoneal dialysis enhances the elimination of a few wate weight, poorly protein-bound xenobiotics with a low volume of distribution lithium, salicylate, and theophylline. Clearance of xenobiotics in the aqueo dialysate flow rate, the surface area of the peritoneum, and the molecular compound. The highest clearances are achieved for molecules with MW < of peritoneal dialysis is markedly decreased when the patient is hypotens

Although peritoneal dialysis is a relatively simple method to enhance xen too slow to be clinically useful. Consequently, peritoneal dialysis is never unless hemodialysis and hemoperfusion are unavailable and transfer to a these techniques is not feasible. Besides exchange transfusion, it may be in small children if experience with extracorporeal techniques in younger a until a child can be transported to an appropriate center.

Hemodialysis

The utility of hemodialysis for the treatment of toxicity caused by lithium

salicylates, and theophylline is unquestionable and is not dealt with here these xenobiotics has its own chapter in which the toxicity and indicatior therapies are reviewed. Instead, this section describes the hemodialysis p its application to some newer situations.

Prompt consultation with a nephrologist is always indicated in the case of xenobiotic that might benefit from extracorporeal removal. The most rece that a number of deaths related to salicylate poisoning could have been had been instituted earlier (Chap. 130). The nephrologist has to call in a dialysis machine requires preparation, and the vascular access catheter ha of several hours before hemodialysis can be instituted should be anticipa modalities of treatment such as ethanol or fomepizole should be adminis to enhance elimination, such as urinary alkalinization or oral multiple-dos (MDAC), should be used where appropriate.

The technical details of the performance of hemodialysis for treatment of markedly from those used in the treatment of acute renal failure. Vascula via the femoral vein. The subclavian and internal jugular veins are also a slightly higher rates of such complications as pneumothorax and arterial after catheter removal is also more easily achieved at the femoral site. H hemoperfusion (see these sections below) are usually performed using a manufactured for dialysis that is made of silicon, polyethylene, polyuretha pumped through one lumen, passed through the machine, and returned t through the second lumen. Blood flow rates with these catheters can be a mL/min, although 350 mL/min may sometimes be the maximum rate ach

The blood lines and artificial kidney (the dialysis membrane) should be p volume of fluid to reduce or avoid hypotension when the procedure is sta efficiencyâ€• or â€œhigh-fluxâ€• artificial kidneys should be selected. H heparin is usually required. A typical adult heparin dose is 4000â€“5000 u by 400â€“500 units hourly. Alternatively, periodic flushes of the dialysis heparinized saline exposes the patient to very low doses of heparin and l anticoagulation. Regional anticoagulation of the dialysis circuit with citrate if heparin is absolutely contraindicated, although these agents complicate dialysate which contains citrate may be adequate for anticoagulation and avoided.[2]

In poisoned patients, hemodialysis is usually performed for 4â€“8 hours. patient's serum potassium concentration is normal, a standard bicarbonat potassium concentration of 3 or 4 mEq/L and a calcium concentration of 3 600â€“800 mL/min, is sufficient. If dialysis is performed in a dialysis unit, a concentrate with $NaHCO_3$ and highly purified water, usually derived by deionization. Dialysis procedures done in intensive care units should use generate the water for mixing, but in the past tap water has been period

During conventional hemodialysis, blood flows through hollow fibers whic membranes. The hollow fibers are bathed by a dialysis solution, or dialy across the membrane from blood into the dialysate down their concentrat Table 10-3 lists the characteristics of xenobiotics that make them amena requirements greatly reduce the number of substances that can be expect dialysis. During hemodialysis, clearance of a xenobiotic (Cl_H) can be cal

$$CI_H = [Q_{in} (C_{in} - C_{out}]/C_{in}$$

where Q_{in} is the blood flow entering the dialyzer, C_{in} is the concentration entering the system, and C_{out} is the concentration in blood leaving the s (ER) is a measure of the percentage of xenobiotic passing through

the artificial kidney, or charcoal hemoperfusion cartridge. This can be cal

$$ER = \frac{C_{in} - C_{out}}{C_{in}} \times 100$$

Charcoal hem movement of blood through a sorbent-containing cartridge and does not hemofiltration.

For All Three Techniques
- Low volume of distribution (<1 L/kg)
- Single-compartment kinetics
- Low endogenous clearance (<4 mL/min/kg)

For Hemodialysis
- MW <500 daltons
- Water soluble
- Not bound to plasma proteins

For Hemoperfusion
- Adsorption by activated charcoal
- Binding by plasma proteins does not preclude

For Hemofiltration
- MW <10,000 or <40,000 daltons, depending on filter used

TABLE 10-3. Characteristics of Xenobiotics That Allow Clearan Hemoperfusion, and Hemofiltration

Several technologic advances enable patients to tolerate dialysis with bet Clearance rates reported in the literature of the 1970s and 1980s may currently achievable clearance rates.[50] Patients undergoing hemodialysis

much less hemodynamic instability than in the past. For instance, the sou routinely is now $NaHCO_3$ rather than sodium acetate; the latter caused h cardiac output. Computerized machines allow fine control of ultrafiltration losses; in the past, imprecise calculations and manipulations led to freque hypotension. The sodium concentration of the dialysate can be programme course of the procedure, a technique called *sodium modeling* , which ma stability as well. Better hemodynamic stability and larger dual-lumen cath blood flows, up to 400â€“500 mL/min. As a result of such innovations, tr in more instances than was previously possible. Hypotension may still occ Saline, colloid, vasopressors, or inotropic agents may also be required in dialysis seems to offer the best chance for the patient's survival, it shoul

Dialysis membrane composition has continued to evolve. The hollow-fiber thousands of blood-filled capillary tubes held together in a bundle and ba generated dialysate. Conventional dialyzers, which are less frequently en made of cellulose-derived polymers, most commonly called cuprophane. have larger surface areas and therefore larger clearances. Hemodialysis with low-molecular-weight substances should improve with the use of lar larger clearances. The prototypical â€œmiddle molecule,â€• the clearance express a dialyzer's high-flux dialysance, is $Î²_2$ -microglobulin (MW 11,80

â€œHigh-flux,â€• synthetic dialyzers have larger pores that allow more molecules. Because these membranes also have higher water permeabili ultrafiltration control is necessary. These membranes, composed of polys polyacrylonitrile (PAN), and other polymers have better biocompatibility t derived membranes. Biocompatibility is measured by the rate of activation exposure to the membrane, of inflammatory mediators that include white complement, and cytokines. Better biocompatibility means less activation

damaging mechanisms as compared with more bioincompatible membrane biocompatibility on the outcomes of patients receiving long-term hemodia failure is still being assessed. Patients with chronic renal failure are expo materials during at least 3 treatments a week for many years. It is unlike biocompatibility will affect outcomes for dialysis of poisoned patients who treatments.

There are some instances in which high-flux dialyzers might be important larger molecules, such as vancomycin, which are not readily removed by membranes.[25] However, the indications for performing hemodialysis to en vancomycin and other xenobiotics with higher molecular weights have no Nonetheless, a sound pharmacologic basis for the efficacy of dialysis must amount of increased clearance will eliminate a xenobiotic with a large vol significant tissue binding.

With that proviso, recent experience suggests a role for high-flux hemodia certain xenobiotics that were previously thought to be effectively removed hemoperfusion. As valproic acid is increasingly prescribed for neurologic the incidence of both intentional and unintentional overdoses of this drug discussed previously, valproic acid is largely protein bound at therapeuti Toxic concentrations saturate protein binding sites leading to a higher pr in the serum and a lower apparent volume of distribution, thereby making dialyzable. Indeed, several case reports have demonstrated that the clear high flux hemodialysis is at least equivalent to, if not greater than, that hemoperfusion.[29, 34, 36, 38, 39] Although carbamazepine has a low mole volume of distribution that would allow for clearance by hemodialysis, its lack of water solubility would be expected to impede the efficacy of hem carbamazepine is also effectively cleared with high-flux hemodialysis.[61], underwent high-flux hemodialysis followed by charcoal hemoperfusion for removal rates were similar for the two modalities.[70] Unlike the case for v for these anecdotal reports for enhanced carbamazepine elimination is no pharmacokinetics of the drug are altered at toxic serum concentrations, a acid, is not known. Because of its potential efficacy and availability, and cost and adverse events, high-flux hemodialysis should probably replace as the treatment modality of choice when extracorporeal elimination of va carbamazepine is to be performed. As stated above, however, effective c a surrogate for improved outcomes.[73] The availability of more effective c reassessment of the utility of these therapies worthwhile.

In addition to removing xenobiotics, hemodialysis can correct acidâ€“base abnormalities such as metabolic acidosis or alkalosis, hyperkalemia, and overload. Consequently, hemodialysis is preferred for poisonings characte if clearance rates resulting from hemoperfusion and hemodialysis are rel

include salicylate poisoning which is often associated with metabolic acid glycol toxicity, which is often associated with lactic acidosis, especially in hepatic impairment.[52]

A more controversial question is the role of dialysis in the treatment of acidosis. Metformin may not always be primarily responsible for the lactic drug by hemodialysis would then be less likely to affect the outcome. An between serum metformin concentrations and mortality in patients with lactic acidosis.[42] This finding may indicate that many of those with lower concentrations and metformin-associated lactic acidosis have another, pri production other than metformin such as sepsis or bowel ischemia. These worse outcomes. In cases of metformin-associated lactic acidosis in patie function, extracorporeal removal is generally not indicated, as endogenou is quite high and prognosis is good without dialysis.[9]

The more important role for hemodialysis is in cases of metformin-associ involving acute renal failure without other causes of lactic acidosis such or in patients with chronic renal failure who are inappropriately treated w small molecular weight and negligible plasma protein binding of metformir drug removal despite a relatively large volume of distribution.[41] In additi correct acidosis via administration of bicarbonate. Clinical improvement w result as much or more from correction of the acidosis as from removal o

Complications of acute hemodialysis are relatively rare. Bleeding or throm vascular access, usually the femoral vein, is infrequent with normal hemo postprocedure tamponade of the catheter site. Bleeding in the gastrointe caused by systemic anticoagulation with heparin, can be avoided if low do Low-dose heparin is an appropriate choice when dialyzing patients for to are at risk for intracerebral bleeding. Nosocomial bacteremia can occur if place for prolonged periods; central lines should be removed after 5 days lines should always be removed in patients who are out of bed.

In addition, hemodialysis increases the elimination of some drugs admir such as folic acid and other water-soluble vitamins and antibiotics. Doses increased during dialysis or administered immediately afterwards. Similarly infusions used in the treatment of toxic alcohol ingestions must be increa a low molecular weight (MW 82.1) and a low volume of distribution (0.6â€

be dialyzed, but it is not significantly removed by hemofiltration.[60] If nec redosed after dialysis (see Antidotes in Depth: Ethanol and Fomepizole). limited in such cases by enriching the dialysate with ethanol to a concent Similarly, hypophosphatemia after more prolonged high-flux hemodialysis adding sodium phosphate salts, in the form of Fleet Phospho-Soda, to th administering phosphate intravenously. Angiotensin-converting enzyme inh used if dialysis is performed with PAN membranes as the combination is angioedema.[13]

Charcoal Hemoperfusion

In general, if a xenobiotic is adsorbed by activated charcoal, charcoal he exceed that of hemodialysis.

During hemoperfusion, blood is pumped through a cartridge containing a sorbent, either activated charcoal or carbon (see Fig. 10-2). The sorbent layer of polymer membrane such as cellulose acetate (Adsorba, made by hydrogel (Biocompatible Hemoperfusion Systems, made by Clark) or poly methacrylate; Hemosorba, made by Asahi). The membrane prevents direc and sorbent, improves biocompatibility, and helps to prevent charcoal em a further theoretical advantage to the heparin-hydrogel coating to dimini The adsorptive capacity of the cartridge is reduced with use because of and blood proteins, and saturation of active sites by the xenobiotic in qu residual adsorptive capacity by serial serum levels is usually not practical obtaining results. The cartridge should therefore be changed after 2 hours hemodialysis, patients must be anticoagulated with heparin, and regional cartridge is possible if full anticoagulation is undesirable. The technique ca [74] or children.[16 , 51] Hemoperfusion is usually performed for 4â€“6 hours 250â€“400 mL/min.

The characteristics of xenobiotics that make them amenable to hemoperf Table 10-3) differ from those for hemodialysis in the important respect limited by plasma protein binding. This is exemplified in a report in which hemodialysis increased the elimination of the avidly protein-bound oral h chlorpropamide.[43] Some xenobiotics are poorly adsorbed by activated ch

alcohols, lithium, and many metals (see Antidotes in Depth: Activated Ch hemoperfusion inappropriate in their management. Hemoperfusion clearanc manner similar to that for hemodialysis. Although hemoperfusion has his the preferred method to enhance the elimination of carbamazepine, phen theophylline (Table 10-4), recent improvements in hemodialysis technolo membranes, may make older comparisons of hemodialysis and hemoperfu obsolete.[50] Hemodialysis and hemoperfusion have been performed in ser thallium, theophylline, and carbamazepine overdoses, with greater appare with either procedure alone.[11 , 21 , 37] In this technique, blood circulates hemodialysis membrane, and then through the charcoal cartridge. If bloo membrane first, some of the xenobiotic is dialyzed, and the activated cha drug to adsorb.[30] The activated charcoal cartridge is exhausted more slo ratios are maintained in a patient who ingested 2 g of propranolol. A he has been inserted into an extracorporeal membrane oxygenation (ECMO) flow rate was >3 L/min.[66] The plasma concentrations of propranolol decre ECMO than after it was discontinued. The high flow rate through the cartr substantial clearance of the drug. Hemoperfusion does not correct acidâ€ disorders, another reason why the combination of the two modalities is and salicylate poisoning.

A practical problem limiting the use of charcoal hemoperfusion is the ava Many dialysis units do not routinely have them in stock. The cartridges a ($350â€“$425 as compared to the maximal cost for a high-flux dialysis m $20â€“$23). Some have expiration dates, limiting shelf life. Others, such have an indefinite shelf life but must be autoclaved before use, which ma in an emergency. Charcoal cartridges were more available in chronic hem were more frequently needed for the treatment of chronic aluminum toxic aluminum-associated dementia and osteodystrophy were once more preva hemodialysis patients, but aluminum carbonate has been supplanted as a calcium salts (carbonate and acetate) and sevelamer (Renagel), a phospl addition, the most frequent indication for acute charcoal hemoperfusion in theophylline toxicity. Theophylline is now less popular in the treatment o and asthma. Its lower rate of prescription today in asthmatic teenagers m frequently used drug for suicide attempts. In turn, the low incidence of currently contributes to poor stocking of the cartridges. All of these facto

diminished availability of charcoal cartridges and the relative infrequency is performed. In our recent survey of New York City hospital dialysis units of 34 units had cartridges (unpublished data).

The complications of hemoperfusion are similar to those of hemodialysis. develop thrombocytopenia, leukopenia, and hypocalcemia. Better membr techniques have made embolization of charcoal particles extremely rare. A hemodialysis, doses of drugs used therapeutically may need to be increase hemoperfusion.

Other Sorbents for Hemoperfusion

Other adsorptive resins have been used for hemoperfusion, such as the and XAD-4 and anion exchange resins such as Dow 1X-2. None of these approved or available for use in the United States. The literature regardir and relatively anecdotal. Though there is in vitro evidence that these resi adsorptive capacities than activated charcoal, there are few, if any, mear clinical setting.

A new concept in sorbents for poisonings is that of albumin dialysis. The available in the United States only for investigational use. The patient's b hollow-fiber hemodialyzer. The dialysate bathing the fibers contains huma serves as a sorbent to bind the xenobiotic of interest and maintain levels zero. A steep concentration gradient from blood to dialysate is established protein-bound xenobiotics can be removed from the plasma. The membra albumin which remains in the dialysate. The albumin is reprocessed by pa activated charcoal cartridge as well as an anion exchanger so that it can current proprietary version of this procedure is called Molecular Adsorber (MARS), manufactured in Germany by Teraklin. The procedure was used the mortality associated with hepatic encephalopathy and liver failure.[47] procedure includes a conventional hemodialysis treatment as well as an membrane. The mechanism of the significant benefit of the procedure is understood, although it does remove both water-soluble and protein-bound known which protein-bound molecules are being removed from the blood,

as bile salts and aromatic amino acids to account for the therapeutic adv

The MARS system increases removal of fentanyl and midazolam in an ani report suggests potential benefit in a patient treated for toxicity with phe significant protein-binding and therefore not expected to be removed by hemoperfusion.[64] Whether this relatively expensive, complicated and nor offer benefit in a handful of instances where protein-binding limits remova known. A similar device, using a powdered sorbent and called HemoClean shortly in the United States. The report of its initial use in 10 cases of t overdoses claimed benefit, although the limitations of extracorporeal ther class of drugs is discussed above.[5]

TABLE 10-4. Properties of Xenobiotics Grouped by Benefit of Ex for Elimination

Multiple-Dose Activated Charcoal: â€œGa Dialysisâ€•

Oral administration of multiple doses of activated charcoal increases elim xenobiotics present in the blood. This modality is dealt with in more detai Activated Charcoal .

Continuous Hemofiltration and Hemodiafil

Continuous, as opposed to intermittent, modalities of dialytic therapy are for the treatment of poisoning. These techniques find relatively widesprea of acute renal failure in the intensive care unit, and in this context are r modalities of *continuous renal replacement therapies* (CRRTs). The cleara xenobiotics that are achieved with these techniques are significantly lowe with hemodialysis. But as continuous modalities, what they lack in clearan in time.

There are several possible advantages of continuous modalities. One is th therapy for 24 hours each day, permitting hemofiltration to be instituted hemoperfusion to further remove a xenobiotic after it redistributes from t an attractive modality for slow, continuous removal of drugs such as lith slowly from tissue-binding sites or from the intracellular compartment (s xenobiotics with volumes of distribution that are large enough to preclude hemoperfusion might also be eliminated with longer courses.

Hemofiltration, or ultrafiltration, refers to the movement of plasma acros

membrane in response to hydrostatic pressure gradients. Table 10-3 sum
xenobiotics that make them amenable to hemofiltration. However, the rate
form of therapy may be insufficient to benefit critically ill patients. Patien
slower clearance rates may not require this enhanced elimination therapy
treatment to avoid redistribution of intracellularly

distributed lithium, for example, is preferable to repeating conventional h
clear.[45, 71] Rebound of serum levels indicates that the drug is moving ou
compartment where it is toxic, into the extracellular compartment where
removal by hemodialysis. Despite many anecdotal reports demonstrating
clearance, there are no data demonstrating that these continuous technic
mortality in treatment of xenobiotic toxicity. In most cases, hemodialysis
preferred initial mode of therapy.

The continuous modalities may be best suited for patients with hypotensi
conventional hemodialysis or hemoperfusion.[12] They may have a slight a
conventional hemodialysis membranes, but not high-flux membranes, in b
molecules such as methotrexate (MW 454.4).[26] There is growing evidence
the clearance of many molecules occurs because of adsorption of the mo
membranes.[20] Another practical advantage is that the procedure is usuall
care units by ICU nurses, and, where available in such units, might not
Familiarity of ICU staff with the procedure is critical to having it available
likely to be used effectively then, in hospitals with higher incidence rates

technique can be done intermittently using a hemodialysis machine, it has
intensive care units as a continuous form of treatment, particularly where
fluid is indicated. The clearance of low-molecular-weight solutes such as

Solute clearance can be significantly enhanced by adding a diffusive mec

permitting a dialysate solution to bathe the blood-filled capillaries running blood flow. The combination of hemofiltration with dialysis is known as *he* of dialysis also usually suffices to treat supervening acute renal failure o failure. Hemodiafiltration, like hemodialysis, requires that blood perfuse membranes made of synthetic plastics such as polysulfone or polyamide.[2] procedures, the patient must be fully anticoagulated, but some hemofilter not require anticoagulation. Anticoagulation can be achieved either with h The hydrostatic pressure required for hemofiltration can be derived either a blood pump. In continuous arteriovenous hemofiltration (CAVH), blood i filter by the patient's arterial pressure via a single-lumen femoral artery femoral vein catheter. Arteriovenous modalities are less favored now beca at least 16-French, catheter in the femoral artery while heparin is admini CAVH because a blood pump is required to maintain adequate flow rates, large-bore catheters is avoided. However, the need for a blood pump also experienced ICU team to be continuously present for more than the 4â€“6 hemodialysis or hemoperfusion. Both the expense and the complexity of procedure are thereby increased. One large case series found hemodialysi complicated than CVVH.[65] The addition of a dialysate bathing solution to apparatus changes CAVH and CVVH to the augmented CAVHD (CAVH with (CVVH with dialysis), respectively (see Fig. 10-2).

Ultrafiltrate flows of 100â€“6000 mL/h across the membrane can be achi losses must be replaced carefully. Depending on the filter, xenobiotics wit <10,000 or <40,000 daltons, as well as water, urea, creatinine, and sodiu ultrafiltrate. Heparin, myoglobin, insulin, and vancomycin are examples o with relative efficiency.[22] CVVH seems to be quite effective in the elimin clearance rates comparable to those of charcoal hemoperfusion.[28] For pr theophylline, continuous removal of the free unbound drug from the plasm equilibrium so that some drug is always moving from plasma protein to p components and molecules larger than the pore size of the membrane ret the venous line. For instance, a hemofilter with a molecular weight cutoff remove digoxin-antibody complexes (MW 45,000â€“50,000).[56] Essential e ultrafiltrate are replaced by balanced IV fluids.

Attention must be paid to the undesirable removal of therapeutic drugs s these continuous modalities. Drug clearances with different synthetic mer

the literature; the doses necessary to maintain therapeutic drug levels ca [20, 57]

Plasmapheresis and Exchange Transfusion

Plasmapheresis and exchange transfusion are intended to eliminate xenob molecular weights that are not dialyzable. This would include xenobiotics molecules with molecular weights greater than 150,000 daltons, typified substance should also have limited endogenous metabolism to make pher worthwhile. By removing plasma proteins, both techniques offer the cons removal of protein-bound molecules such as *Amanita* toxins,[32] thyroxine, of digoxin and antidigoxin antibodies. However, there is little evidence th the clinical course and prognosis. Thyroxine or carbamazepine removal a example, is followed by significant rebound from tissue stores, so that re only transient.[27, 35]

Pheresis is particularly expensive, and both pheresis and exchange transf to the risks of infection with plasma- or blood-borne diseases. Replaceme during plasmapheresis can be accomplished with fresh frozen plasma, alb both. The former is associated with manifestations of hypersensitivity, su wheezing, and hypotension, in as many as 21% of cases.[35]

A different setting in which exchange transfusion may be an appropriate t management of small infants or neonates in whom dialysis or hemoperfus difficult or impossible. Anticoagulation and MDAC may be hazardous and in the neonatal nursery where the risk of intracerebral bleeding and nec high. In premature neonates, a single volume exchange appears to

alleviate manifestations of theophylline toxicity.[6, 49] The therapy has be treat other pediatric poisonings, including severe salicylism.[44]

Toxicology of Hemodialysis

Unlike patients who receive acute hemodialysis once or twice in the man patients with chronic renal failure are repeatedly exposed to large volume municipal reservoirs during the course of their hemodialysis treatments.

regimen consists of 3 treatments of 4 hours each week, with dialysate flo patients will be exposed to more than 400 L of water separated from them semipermeable membrane designed to allow solute passage in either dire dialysate generation therefore have the potential to be lethal to this popu to significant quantities of toxins. Two potential sites of dialysate contam municipality's reservoirs and water treatment plants and in the dialysis u used for dialysate generation is regulated in the United States by the Ass Advancement of Medical Instrumentation (AAMI).[1] This organization regul to incorporate new technology and data.

Contamination of dialysate at the municipal water supply can occur as a r chemicals into reservoirs or as a result of the municipality's addition of s inadvertently or intentionally. Chlorine and chloramine are frequently add supplies to control bacterial populations. Chlorine can combine with nitro form chloramine, which can cause nausea, vomiting, methemoglobinemia, Recently, chloramine was blamed for decreased bone marrow sensitivity Aluminum is present in some municipal water supplies, and before it was aluminum led to encephalopathy characterized by seizures, myoclonus, ar osteomalacia; and to microcytic anemia.

Water from the municipal supply entering the dialysis unit is first treated remove calcium and magnesium. It is then run through an activated charc chloramine. The potential toxicity (hemolysis and death) from this compou mandates a redundancy in the carbon beds; when the active sites in one exhausted, a second will ensure that no toxicity will occur. Most commonl then generated by reverse osmosis, a process that requires that water, ir hydrostatic pressure (and against the osmotic gradient), cross a membran impermeable to solutes, leaving them behind. Alternatively, but less comn purified using deionization, a technique that runs water over an exchang ions in exchange for charged species in the water. Deionization is inferior removal of aluminum, and may be associated with release of lethal levels exchange sites are exhausted.[4] General water chemistry testing is manda testing for chlorine and chloramine is done daily.

Current requirements are that water be highly purified, but not sterile, b cross from the dialysate into the blood. However, small quantities of end

5â€“15,000 daltons) can cross, particularly in situations that include the membranes. Endotoxin is suspected of being responsible for activation of malnutrition, fever, and other syndromes such as carpal tunnel syndrome with chronic inflammation. Recommendations for the frequency of testing maximum amounts of endotoxin are continually debated and recently hav Water distribution systems are cleaned at least monthly with bleach, pera sterilants. Care must be taken that all of these potential toxins are thoro system before dialysis is restarted. Other products of bacterial metabolism containing compounds, generated on the dialysate side of the membrane, symptoms in hemodialysis patients.[62]

Unusual microbes have also been associated with serious toxicity. Untreate Brazil demonstrated growth of Cyanobacteria (blue-green algae) and pro cyclic peptides that cause serious hepatic toxicity; patients dialyzed with had a dramatic rate of death from liver failure.[33] Water contamination sho suspected when multiple patients experience similar symptoms nearly si distribution systems are always made of PVC (polyvinyl chloride) or other than copper, which also can leach into the water and cause hemolytic an

Besides water for dialysate, another potential source of poisoning in hemo process of reusing dialysis membranes. Until recently, up to 70% of dialys States reused membranes because of cost considerations. Each dialysis m peracetic acid, formaldehyde, or glutaraldehyde. Careful quality assurance there is no significant exposure of the patients to these molecules during Nonetheless, reuse programs are associated with a variety of syndromes reactions attributed to patient exposure to germicides or endotoxin due procedures.[58] Controversial data over the years have suggested, but not rates with reuse. Occupational exposure of dialysis personnel to the relev been monitored closely.

Summary

Further discussions of some of the techniques to enhance elimination, not found in Chaps. 30 (exchange transfusion), 52 (cerebrospinal fluid draina (toxin-specific antibodies), and 91 (chelation). All of these techniques ha indications, and the effect of these interventions on the overall body burd

usually small.

Urinary alkalinization, and many of the other techniques listed in Table 1 quickly in the emergency department. In contrast, the extracorporeal me removal, including hemodialysis, sorbent hemoperfusion, and continuous consultation with a nephrologist or intensivist. Timely use of these techr of a competent team and preparation of the requisite equipment. Rapid i exposure for which these techniques are appropriate, and the presence o features, should lead to prompt notification of the appropriate consult se of these techniques can proceed in an expeditious manner.

The applicability of these techniques to new xenobiotics should be conside principles discussed here so that these and newer treatment modalities ar indiscriminately. The relative infrequency of toxicity with individual xenol

continue to hinder accumulation of useful data and limit the numbers of trials performed. The literature regarding these techniques in general, and specific exposures to xenobiotics in particular should be read critically an

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 11
Use of the Intensive Care Unit

Mark A. Kirk

J. Samuel Pope

Over the past several decades, use of the ICU and its attendant resources has led to improved survival from many serious conditions. This is the direct result of the ability to continuously monitor physiologic parameters, pay meticulous attention to supportive care, and use the most modern medical technology and treatment. Most critically ill poisoned patients have acutely reversible conditions that will clearly benefit from intensive care intervention.[83]

Unlike many patients with diseases managed in the ICU, poisoned patients often do not have a well-recognized clinical course or predictable complications. More than almost any other disease managed in the ICU, uncertainties typify toxicologic emergencies. A patient's history is often unreliable with regard to the kind of xenobiotic ingested, time of ingestion, and amount ingested. The xenobiotic may have unknown or unpredictable toxic effects. The therapies, antidotes, and complications of acute poisoning may be unfamiliar to the ICU staff. These uncertainties challenge

healthcare providers and influence decisions about admitting patients to the ICU.

Often a patient is admitted to the ICU for observation and monitoring, not for intervention.[101] Of the 11.4 million reported xenobiotic exposures reported in the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) data from 1999 to 2003, only 5% were admitted to the hospital (Chap. 130). In addition, fewer than 25% of those hospitalized required specific treatments or antidotes other than GI decontamination.[11,101] Many physicians elect to observe poisoned patients in an ICU in anticipation of possible delayed, unrecognized life-threatening toxicity. The ICU provides necessary monitoring and individual nursing care that can help in the early recognition of developing toxicity. Intensive care units give healthcare providers the best opportunity to minimize morbidity and decrease mortality. However, ICU care is very expensive and has contributed significantly to the escalation of healthcare costs.

The ICU admission guidelines presented in this chapter are intended to encourage effective use of ICU resources without compromising patient care. Effective guidelines must consider the unique characteristics of a xenobiotic, the capabilities of the hospital, and all realistic alternatives for managing and observing poisoned patients without compromising care. Current medical literature allows us to develop only very general guidelines. Future clinical studies addressing the use of healthcare resources for the poisoned patient will allow refinement of these guidelines. Although it is impossible to be all-inclusive, this chapter provides a decision-making strategy for most xenobiotics discussed in this text.

Are There Nontoxicologic Criteria to Help Select Those Poisoned Patients

Needing ICU Admission?

Severity of Illness Models and ICU Admission

Overcrowded ICUs and escalating healthcare costs have been incentives to develop severity-of-illness models that predict the benefits of ICU care. The Acute Physiology and Chronic Health Evaluation (APACHE II/III), the Mortality Probability Model (MPM II), and the Pediatric Risk of Mortality (PRISM II/III) models are widely studied and generally accepted severity-of-illness models that score certain physiologic parameters and other factors in order to estimate risks and predict outcomes in critically ill individuals.[17,47â€“49,57,58] Additional acute clinical assessment tools such as the Simplified Acute Physiology Score (SAPS II) and the Glasgow Coma Score (GCS) are commonly used â€œbedsideâ€• methods of quickly assessing the severity of physiologic derangement and altered neurologic status, respectively.[54] Both the SAPS II and the GCS are included in the more comprehensive APACHE severity of illness models. These models are most effective for stratifying risks in clinical research trials and comparing quality of care among ICUs. Clinical studies to validate such scoring systems included patients with a variety of medical and surgical conditions, although few trials have validated these scoring systems in large cohorts of poisoned patients. The original APACHE II cohort of 5815 intensive care admissions from 13 hospitals included only 153 patients admitted to the ICU with a diagnosis of â€œdrug overdose.â€•[47] APACHE II is limited by its failure to distinguish between traumatic and nontraumatic causes of altered mental status, a fact of potentially vital import in cases of xenobiotic overdose. The development of APACHE III addressed this shortcoming of its predecessor. However, even this very complicated scoring system with proprietary mathematical modeling has limited value when applied to a wide range of

poisoned patients. In fact, when APACHE III was used by its authors to screen a large independent database of almost 40,000 ICU admissions including 1032 patients admitted with â€œdrug overdose,â€• predicted and actual mortality statistics

for these patients were vastly different.[102] Seven deaths (0.7%) were predicted in this cohort, although the actual number turned out to be 25 (2.4%). The difference was highly statistically significant. Additional articles addressing the usage of severity of illness scoring systems to identify high-risk overdose patients are lacking, although one review of 216 consecutive ICU admissions for intentional overdose found that admission APACHE II and GCS scores were equally strong predictors of morbidity and mortality.[37] Specifically, a GCS of â‰¤ 12 was 88% sensitive and 92% specific in identifying patients at risk of developing ICU requiring morbidity.

Given the unique characteristics of individual xenobiotics, other authors have attempted to apply severity of illness models in specific xenobiotic overdosages. APACHE II scores within 24 hours of presentation, showed promise as a predictor of mortality when studied prospectively in acetaminophen-induced acute liver failure, revealing similar power to predict a poor outcome when compared against the widely accepted King's College Criteria.[68] A second xenobiotic-specific study including 23 organic phosphorus compound poisoned adults found that an APACHE II score â‰¥ 26 was 95% sensitive and 100% specific in predicting mortality.[56] However, some clinical outcome predictors used in these scoring systems, such as neurologic outcome following cardiac arrest, are unreliable in the poisoned patient.[23,81] A patient with severe poisoning may have clinical characteristics that mimic brain death yet have a complete neurologic recovery. Case reports of poisoning from barbiturates, cyclic antidepressants, baclofen, ethylene glycol, botulism, solvents, and sedative hypnotics provide specific examples of this observation.[5,74,77,94,97,100] In addition,

many toxicologic emergencies occur in young patients who are free of underlying disease. This increases the likelihood of surviving significant insults such as prolonged hypotension or hypoxia. Indeed, one prospective trial involving 286 patients admitted to the ICU with nontraumatic coma found that 91% of the 101 xenobiotic-induced coma patients survived, a much higher rate than those patients whose cause of coma was hypoxia (33%), sepsis (28%), focal cerebral (26%), or a general cerebral insult (17%).[33] Despite negative predictors of outcome, aggressive resuscitation efforts may be justified for poisoned patients. Specifically, prolonged cardiac resuscitation should be provided for the victim of a cardiac arrest resulting from cyclic antidepressant overdoses, Î²-adrenergic antagonists, calcium channel blockers, or severe hypothermia.[25,42,66,73,86]

Few studies have evaluated the use of the ICU for poisoned patients.[11,23,35,39,41,44,52,88,90] Prospective studies have focused on mortality rates, use of resources, or types of xenobiotics ingested, whereas others, mostly retrospective, have focused on patients exposed to a specific xenobiotic. More study is needed before any severity of illness model can be considered reliable in predicting which patients are at the highest risk of developing ICU-requiring morbidity or mortality.

Other Criteria for ICU Admission

A set of criteria was established to determine whether initial clinical assessment could identify those poisoned patients who were at risk of developing serious toxicity, thus needing ICU admission.[11] The specific xenobiotic ingested was not considered in defining risks. Criteria defining high-risk patients were; need for intubation, unresponsiveness to verbal stimuli, seizures, PCO_2 >45 mm Hg, systolic blood pressure <80 mm Hg, QRS duration >0.12 seconds, or any cardiac rhythm except normal sinus rhythm, sinus tachycardia, or sinus bradycardia. Patients were classified as low

risk when none of the above criteria were present in the emergency department (ED). Retrospectively, 209 cases were analyzed using the above parameters. The most commonly ingested xenobiotics in both the high- and low-risk groups were barbiturates, benzodiazepines, cyclic antidepressants, ethanol, opioids, phenothiazines, and salicylates. None of the 151 patients who were considered low risk developed complications or required ICU interventions after admission. Of the 58 patients deemed high risk, 35 required ICU interventions such as intubation, treatment of dysrhythmias, the treatment of seizures, intravenous vasopressors, or hemodialysis/hemoperfusion. Seven patients developed high-risk complications such as hypoxia, respiratory failure, hypotension, or seizures after admission, but all had other high-risk criteria in the ED. Although the authors concluded that the clinical course of poisoned patients can be predicted during the initial 2 to 3 hours of observation, xenobiotics with delayed or prolonged toxic effects, such as sustained-release products, lithium, and oral hypoglycemic agents, were not prominent in their study population.

In this study population, 70% of the low-risk patients were admitted to the ICU for observation. Because none of these patients developed complications or required ICU intervention, the authors postulated that applying these criteria would have eliminated 50% of the ICU days without compromising care. The limitations of this study are its retrospective design, relatively small study population, and limited variety of xenobiotic exposures. However, it does suggest that with some clinical judgment, many poisoned patients will not require ICU admission.

Ideally, clinical indicators for ICU care should be established for each xenobiotic. Universal criteria cannot be applied to all poisoned patients because of the unique clinical course of some xenobiotics and the uncertainty regarding which xenobiotics were ingested. Until more specific predictors of outcome are developed for individual xenobiotics, nothing will be more useful than

experience and good clinical judgment in predicting who may benefit from ICU admission. At present, withholding ICU care from poisoned patients based solely on a nonspecific â€œscoreâ€• will not result in significant cost savings in the ICU but may increase the risk of morbidity and mortality.[14,50,91]

End-Organ Toxicity as the Basis for ICU Admission

It seems reasonable to assume that a patient's signs and symptoms can be used to decide the need for ICU admission. The presence of certain signs, symptoms, or abnormal diagnostic tests requires ICU observation or intervention, whatever the toxic exposure. This approach is most consistent with the philosophy of â€œtreating the patient and not the poisonâ€• and may prove most helpful for patients with polydrug ingestions.

CNS manifestations are common to many poisonings. Xenobiotic-induced acute delirium or coma often requires ICU admission because these findings will not resolve quickly. Many comatose or delirious patients without identifiable causes require continued investigation in the ICU. Likewise, xenobiotic-induced status epilepticus is best managed in the ICU.

Poisoned patients with signs of respiratory compromise may need ICU admission, regardless of whether the respiratory compromise is caused by CNS depression, hypoventilation, or acute lung injury. In addition, ICU admission is required when impaired

oxygen-carrying capacity or tissue hypoxia is evident from poisons such as hydrogen sulfide, cyanide, carbon monoxide, or methemoglobin inducers.

Xenobiotics can cause cardiac dysrhythmias, hypotension, hypertension, and tissue ischemia.

Gastrointestinal symptoms, particularly vomiting and diarrhea, are an early manifestation of poisoning by many xenobiotics. When symptoms are severe or persistent, significant fluid and electrolyte losses can occur. For example, a patient with a significant iron ingestion can have a GI mucosal injury, leading to vomiting, diarrhea, profound volume loss, and significant hypotension. Hepatotoxicity from poisoning or overdose usually occurs days after xenobiotic exposure, meaning there is no need for expectant admission to the ICU. If hepatotoxicity is evident at the time of admission (especially with hepatic encephalopathy), ICU management is strongly suggested.

Renal toxicity may be a direct effect of the xenobiotic or a complication of other toxic manifestations, such as hypotension or rhabdomyolysis. Severe xenobiotic-induced metabolic acidosis is best managed in an ICU. Metabolic acidosis is an important clue to the presence of xenobiotics such as ethylene glycol, methanol, and salicylates. Persistent or refractory hypoglycemia, resulting from an oral antidiabetic agent, insulin overdose, or other xenobiotics, is also best managed in an ICU. In addition, severe xenobiotic-induced alterations in temperature regulation or electrolyte disturbances merit close monitoring and intervention in the ICU.

The complications of chemical burns of the skin are similar to those of thermal burns. The injured dermis may be unable to prevent significant fluid losses, regulate core body temperature, and prevent infection. Besides these complications, systemic toxic effects may occur through dermal absorption of the xenobiotic that caused the injury.

Diagnostic tests such as routine laboratory analysis, electrocardiography, and diagnostic imaging are used as indicators of end-organ toxicity. Diagnostic tests may demonstrate definite end-organ toxicity or provide early warning signs of impending serious toxic effects. These diagnostic tests may suggest the need for aggressive management or more careful monitoring. Elevated

serum levels of some xenobiotics indicate that serious toxicity is likely. Although diagnostic tests are extremely useful for deciding about using the ICU, relatively few patients should be admitted to the ICU based on the results of a single diagnostic test.

Additional Information Influencing ICU Admission of the Poisoned Patient

End-organ toxicity is the most important reason to admit poisoned patients to the ICU. However, restricting ICU admission to those with only end-organ toxicity is inappropriate. Minimally symptomatic or asymptomatic patients may require ICU admission because other factors must be considered. In addition to end-organ toxicity, the xenobiotic, its treatment, and specific patient characteristics should influence ICU admission decisions.

Xenobiotic Characteristics as Basis for ICU Admission

Both the known and unknown characteristics of a xenobiotic will assist with ICU admission decisions. Some xenobiotics have proven their capability to cause harm or death to humans. Well-described, expected toxic effects assist in early recognition of poisoning. For other xenobiotics, the consequences after human exposure are not yet reported.

ICU admission is warranted for patients with expected serious toxic effects from an ingested xenobiotic. This is especially true for those xenobiotics known to be deadly, such as calcium channel blockers, cyanide, cyclic antidepressants, and salicylates. For example, patients with calcium channel blocker poisoning who exhibit hemodynamic compromise require close attention and aggressive treatment available only in the ICU.

Indicators of toxicity should be identified for individual xenobiotics

so that high-risk patients may be closely monitored and aggressively treated. Because cyclic antidepressants are some of the most common and potentially lethal overdoses reported, they have been studied in great detail to determine indicators of toxicity and safe disposition.[2,12,13,24,44,70,76,92] Cyclic antidepressants have accounted for up to 25% of drug overdoses admitted to adult ICUs, yet many admissions are for trivial ingestions.[19] Research efforts have focused on identifying those patients at risk for serious toxicity. These studies suggest that patients may be safely discharged if they remain asymptomatic for a 6-hour observation period after presentation.[2,13,44,75,92] Prolonged QRS duration on a 12-lead ECG is predictive of serious complications such as seizures and dysrhythmias.[6,70,98] Any patient manifesting persistent tachycardia, ECG abnormalities (including QRS â‰¤0.10 seconds), hypotension, anticholinergic signs, or neurologic signs or symptoms, requires ICU monitoring.[13,27] Unlike cyclic antidepressants, most xenobiotics do not have such an extensive literature to define high-risk patients.

Most acetaminophen poisoned patients can be safely managed outside of the ICU because they exhibit no end-organ toxicity and their hospital management entails only laboratory monitoring and antidotal therapy with *N*-acetylcysteine. However, acetaminophen poisoning can be lethal and at some point in the clinical course, manifestations of toxicity require close monitoring and treatments available only in the ICU. Predictors of poor outcome have been studied and can be useful guides for selecting patients who need ICU care. The King's College Criteria are well established indicators of impending hepatic failure and the need for transplantation. A pH <7.30 after adequate fluid resuscitation, a serum creatinine â‰¤3.3 mg/dL, a prothrombin time >100 seconds, and a grade III or higher encephalopathy are all predictive of poor outcome.[72] A serum lactate level greater than 3 mmol/L 12 hours after admission can be used in conjunction with the traditional King's College Hospital criteria to improve the

sensitivity of the criteria when attempting to identify patients who are likely to require liver transplantation.[3] Patients with abnormal clinical and laboratory data approaching these criteria are candidates for ICU admission or transfer to a specialized center with advanced ICU resources and transplantation services.

The natural history of many xenobiotics is unknown. New pharmaceutical and industrial products are introduced each year with little data on toxic exposure doses or human health effects in overdose. Sometimes animal studies provide the only known toxicologic data, and preclinical trials for new drugs may have excluded the populations at risk, such as infants, children, or the elderly. In these cases, the clinician must often make therapeutic decisions and anticipate potential toxicity with little or no reliable data. Because early recognition of serious toxicity may prevent an adverse outcome, expectant observation may be the only rational

approach. For example, intentional and unintentional ingestions followed the introduction of fluoxetine. Because, at that time, clinicians lacked experience treating overdoses of this drug and had no data regarding the natural course and toxic dose, many patients were admitted to the ICU to observe for toxic effects. Now that clinicians have experience with this drug and studies are available demonstrating few severe manifestations, ICU resources are seldom needed to treat such patients.[8]

Failure to appreciate the potential for serious, delayed toxic effects is a major pitfall in managing poisoned patients. An asymptomatic patient may be a â€œtime bombâ€• with the potential to deteriorate rapidly. Delayed or continued absorption, slow tissue distribution, interference with cellular function, production of toxic metabolites, or depletion of target organ reserve capacity are causes of delayed onset of clinical effects.[9]

Certain xenobiotics prolong gastrointestinal absorption, delaying onset of toxicity.[64] Sustained-release pharmaceutical preparations

and those with enteric coatings enhance patient compliance but, in overdose, may delay absorption and, in turn, make the onset of toxicity unpredictable.[67] Published cases of overdoses with sustained-release theophylline, verapamil, bupropion, and enteric-coated aspirin report delayed onset of toxicity (more than 16 hours), and peak serum levels were measured more than 24 hours after ingestion.[7,26,82,87,99]

Serial xenobiotic level measurements are necessary to verify peaks and ensure decreasing levels. Serial levels may, if available, warn of increasing potential for serious toxic effects. When serum levels are unobtainable, admission and observation are required for many patients with overdoses of sustained-release and enteric-coated agents, including patients smuggling (â€œbody-packingâ€•) or hiding (â€œbody-stuffingâ€•) contraband drugs in the gastrointestinal tract, which has resulted in delayed onset of serious toxicity from ruptured bags.[93]

Clinical effects may be delayed when toxicity is dependent upon alteration of enzyme functions, cellular reproduction, or metabolic function. For example, toxicity of a monoamine oxidase inhibitor (MAOI) may not be apparent for more than 12 hours after an overdose but then may progress rapidly to cardiovascular collapse.[60] Because of the delay in onset of severe toxicity, even if the patient is asymptomatic, a history of MAOI ingestion mandates ICU monitoring for 24 hours. When there is potential for serious delayed toxicity, the patient necesitates prolonged close monitoring.

Physiologic Monitoring and Specialized Treatment as Requirements for ICU Admission

The ICU setting offers the most highly skilled staff and modern technology available to manage complex medical problems. It also

provides a nurse-to-patient ratio that allows for frequent or continuous monitoring of basic physiologic parameters. Invasive monitoring is routinely used in the ICU and may be beneficial to some poisoned patients. Hemodynamic parameters are valuable for managing the patient with hypotension, intravascular volume depletion, or respiratory failure from acute lung injury (ALI). Intraarterial monitoring provides a more accurate and continuous record of actual blood pressure in a patient with cardiovascular compromise. A pulmonary artery catheter assists in the management of fluid and inotropic therapy for patients with complex hemodynamic abnormalities. Both invasive and noninvasive measurements of vital signs, neurologic status, and intake/output measurements, along with continuous cardiac monitoring, make possible early detection of toxicity, recognition of conditions needing active intervention, and prevention of complications.

Most critically ill poisoned patients have acute reversible conditions requiring supportive care measures (ie, ventilator support, vasopressor support, and close monitoring) that ICUs are most equipped to provide. Most often, supportive care measures improve the outcome of critically ill poisoned patients more than antidotes and specialized treatments. Focus on supportive care measures such as maintaining a patent airway, preventing hypoxia with the administration of oxygen, and treatment of shock decreased the mortality for patients with barbiturate overdoses from 20% in the 1930s to less than 2% in the 1950s.[15] Both adult and pediatric studies report good outcomes in most critically ill overdosed patients treated with only mechanical ventilation, vasopressor support, and careful monitoring.[23,52]

Antidotes and specific treatments should be administered in the emergency and ICU settings. Although possibly lifesaving, these treatments may have inherent risks. For example, antivenom administration for black widow spider envenomations can cause anaphylaxis, and rapid intravenous infusion of deferoxamine for

iron poisoning can cause hypotension. Because these treatments may be unfamiliar to staff and have their own inherent risks, the ICU is the most prudent environment to administer such treatments. In toxicologic emergencies, a familiar medication may be an antidotal therapy that requires doses that far exceed conventional regimens or indications that deviate from common treatment protocols. High doses of atropine (hundreds of milligrams) may be necessary for the treatment of organic phosphorus insecticide poisoning.[21,30,55] Also, intravenous calcium, which is no longer a routine part of advanced cardiac life support (ACLS) protocols, is commonly used to reverse toxicity from calcium channel blockers[79] and (by intraarterial infusion) from hydrofluoric acid burns of the extremities.[95] Sodium bicarbonate as a bolus and infusion is the treatment of choice for cyclic antidepressant and type IA antidysrhythmic agent cardiac toxicity.[75] Instead of the usual first-line vasopressor dopamine, direct vasopressors such as norepinephrine or phenylephrine may be more appropriate for the treatment of xenobiotic-induced hypotension. Some drugs are administered in unconventional doses, whereas other familiar drugs should be avoided in treating toxic emergencies. For example, type IA antidysrhythmic agents, such as procainamide, must not be used in patients with overdoses of cardiac sodium channel antagonists, such as cyclic antidepressants, phenothiazines, and propoxyphene.

A false sense of security can result when an antidote reverses toxicity but has a shorter duration of effect than the xenobiotic. An example is a patient, comatose from an opioid overdose, who responds to naloxone, awakens, and refuses further treatment. Toxicity may recur when naloxone's short duration of effect allows opioid toxicity to recur. These patients must be closely observed for the possible need to readminister the antidote. In a retrospective review of patients presenting with opioid overdosage, 31% of 84 naloxone responders experienced resedation necessitating readministration.[96] Resedation is

particularly problematic with long-acting opioids such as methadone and oxycodone controlled release preparations.[40]

Extracorporeal methods of eliminating xenobiotics, such as hemodialysis or hemoperfusion, are ideally performed in the ICU. Invasive procedures such as extracorporeal membrane oxygenation, cardiopulmonary bypass, and intraaortic balloon pump-assisted perfusion are used successfully in resuscitating critically ill poisoned

patients.[16,22,38,42,53] A bioartificial liver support system and a Molecular Adsorbents Recirculating System (MARS) using albumin dialysis, including a charcoal filter shows promise as a treatment in patients presenting with liver failure, including acetaminophen poisoning.[10,71]

Toxicologic emergencies, where the need for surgical intervention or specialized wound care is anticipated, are ideally managed in the ICU. Although transplantation becomes necessary in a minority of critically ill acetaminophen-poisoned patients, this treatment can improve survival to discharge by as much as 75%.[4] Compartment syndrome complicating crotaline envenomation is a rare but limb-threatening occurrence, sometimes resulting in the need for fasciotomy.[36] Any poisoned patient with significant rhabdomyolysis, whether localized or more widespread, is at risk for the development of compartment syndrome. If contemplating fasciotomy, monitoring and specialized postoperative care in an intensive care unit is warranted. Plasmapheresis and specialized wound care in an ICU are necessary in cases of toxic epidermal necrolysis (TEN) secondary to xenobiotics. Early referral to a specialized burn center reduces mortality in this condition.[65]

Patient Factors as Criteria for ICU Admission

Preexisting medical conditions increase a patient's risk for developing toxicity. Many patients who have chronic medical problems do not tolerate major physiologic stressors without significant compromise. For example, a patient with underlying cardiac disease could develop severe myocardial ischemia from a modest carbon monoxide exposure. An elderly or infirm patient with chronic salicylism is more likely to have major respiratory and CNS complications than a younger or healthier patient.[1] Conditions that alter drug metabolism or elimination, such as renal or hepatic disease, may prolong toxicity or produce toxicity after lesser amounts are ingested.

Patients with physical dependency on ethanol, benzodiazepines, or barbiturates may be admitted to the hospital for acute withdrawal or, during hospitalization, go through a period of abstinence that results in an acute withdrawal syndrome. Withdrawal from ethanol and sedative-hypnotics can have serious consequences and complications. ICU management is frequently indicated because large doses of medications with respiratory depressant effects may be required for treatment.

Eighty percent of recognized suicide attempts involve an overdose of medications.[69] Acute complications of poisoning make it difficult to adequately assess suicidal risks. Patients have an increased rate of suicide following discharge from an ICU for drug overdose.[88] Until suicidal risks are adequately assessed, it must be assumed that an overdosed patient needs close observation. Institutions differ on monitoring policies for suicidal patients not admitted on a psychiatric unit. The ultimate goal of treatment for any suicidal patient is to provide a secure and safe environment. In many hospitals, the ICU is the safest place, (but also the most expensive place) to observe a patient with suicidal risks until it is medically safe to transfer the patient to the psychiatric service.

Complications That Prolong ICU care

Poisoning produces both anticipated and unanticipated complications that can prolong ICU care and decrease survival. Serious complications of poisoning include pulmonary compromise, rhabdomyolysis, compartment syndrome, and anoxic brain injury. Complications such as acute renal or hepatic failure also might prolong an ICU course.

Pulmonary compromise following toxic exposures often develops after several hours or days in the ICU. Pulmonary complications following a toxic exposure include aspiration pneumonitis, ALI, and adult respiratory distress syndrome (ARDS). Aspiration of gastric contents is a common complication following poisoning, especially when a patient's mental status is altered and protective airway reflexes are lost.[31,46,85] Poisoned patients may aspirate spontaneously while lying unresponsive before being discovered, from stomach dilation secondary to bag-valve-mask ventilation, from GI decontamination procedures such as orogastric lavage, or during insertion of endotracheal or nasogastric tubes.[51] In a review of 4562 poisoning admissions, 71 clearly suffered from aspiration pneumonitis, giving a rate of 1.6%.[45] Older age, a GCS <15, spontaneous emesis, delayed presentation to the hospital, and ingestion of cyclic antidepressants were associated with aspiration pneumonitis in logistic regression analysis. Not only were the rates of ICU admission and length of stay increased in the patients with aspiration pneumonitis, but mortality was also higher, with a rate of 8.5% compared to 0.4% for those without.

Poisoning causes global cerebral anoxia from prolonged shock, respiratory failure, or direct toxic/metabolic effects. Distinguishing anoxic cerebral injury from reversible encephalopathy can be difficult in poisoned patients. Coma and loss of brainstem reflexes after prolonged, severe cerebral hypoxia indicates a poor prognosis.[59] Although poorly studied in toxicologic patients, new diagnostic technologies, including computer tomography, cerebral angiography, brain radionuclide perfusion imaging techniques, and the use of multimodality evoked potentials, may prove useful in

confirming brain death.[1,18,78] Electroencephalography can be particularly misleading in certain overdoses, such as those involving benzodiazepines or barbiturates, where the lack of brain electrical activity is a direct effect of the ingested xenobiotic. Angiographic imaging via computer tomography or direct arteriography may prove particularly useful in such cases, although such tests can reveal continued blood flow when intracranial hypertension is absent, despite severe axonal injury and brain death.[62] Further study is necessary before these modalities obtain widespread acceptance as diagnostic aids in toxicologic cases where the diagnosis of brain death is in question.[62] Because clinical predictors of outcome may be unreliable when applied to poisoned patients, the diagnosis of brain death should be made cautiously. Cerebral edema often is a secondary effect of global cerebral anoxia, although some xenobiotics have direct cellular effects. Cerebral edema can be a complication of acetaminophen-induced fulminant hepatic failure and the result of direct neuronal injury from salicylate and lead poisoning.[61,80,89] Aggressive ICU care is preferred to treat xenobiotic-induced cerebral injuries.

Criteria for Safe Disposition from the ICU

Once the acute toxic effects have resolved, most patients are safe to transfer out of the ICU. Patients with cyclic antidepressant overdoses were studied to determine when it was safe to discontinue

monitoring. Concerns arose from case reports of patients developing sudden death as late as several days following a cyclic antidepressant overdose.[12,63,84] In most cases, delayed complications developed in the setting of continued toxicity evidenced by lethargy or sinus tachycardia. More recent studies

demonstrate that dysrhythmias do not occur after signs of toxicity have resolved (ie, CNS and cardiac manifestations).[13,29,75] Current recommendations based on these studies suggest cardiac monitoring for an additional 24 hours after normalization of the ECG and resolution of other signs of continued toxicity.[12] This additional period of monitoring should occur after discontinuation of all specific forms of therapy, such as serum alkalinization.

Most xenobiotics have not received the level of attention given to cyclic antidepressants, making clinical judgments the only basis for deciding when to discharge a patient from the ICU, pending further research and experience. For example, drug-induced QTc interval prolongation may increase the risk of developing torsade de pointes.[28] Cardiac monitoring may be required until other clinical signs of toxicity resolve and the QTc interval returns to normal.

The same issues previously mentioned may be pitfalls to a patient's safe discharge from an ICU. GI decontamination should be completed before discharge from the ICU because it may cause prolonged or worsening clinical effects. Carefully consider discharge decisions about patients exposed to xenobiotics with serious delayed clinical effects, such as colchicine. Also be mindful that the duration of action of the xenobiotic may be longer than the duration of action of the specific treatment or antidote.

Finally, the patient's suicidal intent must be considered before transfer to a less closely monitored hospital unit. Transfer from the ICU should occur following assessment of suicide risk or other important psychosocial issues. Early involvement of psychiatric services, chemical dependency counseling, and social services can expedite ICU disposition. Disposition and treatment options can be considered at a time when the patient is still medically unstable by interviewing family, friends, and outpatient counselors.

Alternatives to ICU Admission

Placing patients in the ICU solely for observation often is an ineffective use of this expensive resource. Until further clinical studies are available to define those patients who are at risk for serious toxicity or life-threatening complications, many poisoned patients will be admitted to the ICU for observation. When information about the xenobiotic, the patient, and the capabilities of the medical unit are all considered, many patients can be safely observed outside the ICU. Table 11-1 presents some items to consider when making disposition decisions.

Alternatives to the ICU include a medical or pediatric floor bed, an intermediate care unit, a telemetry-monitored bed, a medical psychiatric unit, or an ED observation unit. Capabilities for managing poisoned patients may vary considerably between institutions and in different types of patient care areas. It is essential to understand the capabilities of the unit where a patient is being considered for admission. If the nursing staff is unfamiliar with the potential for rapid deterioration of the patient, or the staffing pattern does not allow for close observation, the results could be disastrous. For example, it is unrealistic to expect a nurse to manage intravenous fluids, record hourly intake and output measurements, record frequent vital signs, and check hourly urine pH measurements for a salicylate-poisoned patient while caring for 8 other patients. Emergency department observation may be an alternative for the care of select poisoned patients.[20,34,43] These units are capable of frequent monitoring of vital signs, continuous cardiac monitoring, and maintaining a safe environment for suicidal patients.[32] Patients with a low risk of serious toxicity or life-threatening complications who require only observation may be ideal candidates for ED observation units.

TABLE 11-1. Considerations for Intensive Care Unit Admission

Xenobiotic characteristics

Are there known serious sequelae (eg, cyclic antidepressant cardiotoxicity)?

Can the patient deteriorate rapidly from its toxic effects?

Is the onset of toxicity likely to be delayed (eg, sustained-release preparation, slowed GI motility, or delayed toxic effects)?

Does the xenobiotic have cardiac effects that will require cardiac monitoring?

Is the amount ingested a potentially serious or potentially lethal dose?

Is the required or planned therapy unconventional (eg, large doses of atropine for treating overdoses of organic phosphorus insecticides)?

Does the therapy have potentially serious adverse effects?

Is there insufficient literature to describe the potential human toxic effects?

Are potentially serious coingestants likely (must take into account the reliability of the history)?

Patient characteristics

Does the patient have any signs of serious end-organ toxicity?

Is there progression of the end-organ effects?

Are laboratory data suggestive of serious toxicity?

Are drug concentrations rising?

Is the patient a high risk for complications requiring ICU intervention?

Seizures

Unresponsive to verbal stimuli

Level of consciousness impaired to the point of potential airway compromise

PCO_2 >45 mm Hg

Systolic blood pressure <80 mm Hg

Cardiac dysrhythmias

Prolonged ECG complexes and intervals (QRS duration â‰¥ 0.10 seconds; QT prolongation)

Does the patient have preexisting medical conditions that could predispose to complications?

Chronic alcohol or drug dependence

Chronic liver disease

Chronic renal failure or insufficiency

Heart disease

Pregnancy

Is the patient suicidal?

Assessing the capabilities of the inpatient unit/observation unit

Does the admitting team (attending, house staff, students) appreciate the potential seriousness of a toxicologic emergency?

Is the nursing staff:

Familiar with this toxicologic emergency?

Familiar with the potential for serious complications?

Is the staffing adequate to monitor the patient?

What is the ratio of nurses to patients?

Are time-consuming nursing activities required? (eg, hourly urine pH assessments or whole-bowel irrigation)

Can a safe environment be provided for a suicidal patient?

Can a patient have suicide precautions and monitoring with a medical floor bed?

Can a one-to-one observer be present in the room with the patient?

Can the patient be restrained?

Many poisoned patients are placed in the ICU because they are suicide risks. Other than the ICU, many hospitals cannot provide an alternative for observing a high-risk suicidal patient. Less-

alternatives are available, but they must assure a safe environment for suicidal patients. An ED observation unit, an intermediate care unit, a medical psychiatric unit, or a one-on-one observer can safely monitor these patients.

Future studies must define prognostic factors for poisoning complications. Patients can then be stratified into high-risk or low-risk groups. The limitations of current studies prevent generalizing the results to individual patients or certain subgroups. Unfortunately, many current clinical guidelines now being used to ration care may be derived from poorly tested models with no scientific basis and may be motivated by financial concerns. Guidelines should be based on sound evidence so that they can provide the best care with less intensive use of health care resources.

Summary

Acute poisoning challenges medical and nursing staff because of its unpredictable clinical course and unfamiliar therapies. Poisoned patients are especially problematic because their clinical history is incomplete and the medical literature is often limited. These potential unknowns create many uncertainties in management. Because the ICU offers the highest level of skilled staff and modern technology available, most seriously poisoned patients should be admitted there. Whether this is clinically justified or is an effective use of resources for a given patient is always an issue because admission of the poisoned patient continues to be based mostly on clinical judgment and the best available information.

Chapter 12
Chemical Principles

Stephen J. Traub

Lewis S. Nelson

Chemistry is the science of matter; it encompasses the structure, physical properties, and reactivities of atoms and their compounds. In many respects, toxicology is the science of the interactions of matter with physiologic entities. Chemistry and toxicology are intimately linked. The study of the principles of inorganic, organic, and biologic chemistry offer important insight into the mechanisms and clinical manifestations of xenobiotics and poisoning, respectively. This chapter reviews many of these tenets and provides relevance to the current practice of medical toxicology.

The Structure of Matter

Basic Structure

Matter includes the substances of which everything is made. *Elements* are the foundation of matter, and all matter is made from one or more of the known elements. An *atom* is the smallest quantity

of a given element that retains the properties of that element. Atoms consist of a nucleus, incorporating protons and neutrons, coupled with its orbiting electrons. The *atomic number* is the number of protons in the nucleus of an atom, and is a whole number that is unique for each element. Thus, elements with 6 protons are always carbon, and all forms of carbon have exactly 6 protons. However, although the vast majority of carbon nuclei have 6 neutrons in addition to the protons, accounting for an *atomic mass* (ie, protons plus neutrons) of 12 (^{12}C), a small proportion of naturally occurring carbon nuclei, called *isotopes*, have 8 neutrons and a mass number of 14 (^{14}C). This is the reason that the *atomic weight* of carbon displayed on the periodic table is 12.011, and not 12, as it actually represents the average atomic masses of all isotopes found in nature weighted by their frequency of occurrence. Moreover, ^{14}C is actually a *radioisotope*, which is an isotope with an unstable nucleus that emits radiation (particles and/or rays), presumably in an effort to attain a stable state (Chap. 128). The atomic weight, measured in grams/mole (g/mol), also indicates the molar mass of the element. That is, in 1 atomic weight (12.011 g for carbon) there is 1 mole of atoms (6.023 Ã— 1023 atoms).

Elements combine chemically to form *compounds*, which generally have physical and chemical properties that differ from those of the constituent elements. The elements in a compound can only be separated by chemical means that destroy the original compound, as occurs during the burning (ie, oxidation) of a hydrocarbon which releases the carbon as carbon dioxide. This important property differentiates compounds from *mixtures*, which are combinations of elements or compounds that can be separated by physical means. For example, this occurs during the distillation of petroleum into its hydrocarbon components or the evaporation of sea water to leave sodium chloride. With notable exceptions, such as the elemental forms of many metals or halogens (eg, Cl_2), most xenobiotics are compounds or mixtures.

Dimitri Mendeleev, a Russian chemist in the mid-19th century,

recognized that when all of the known elements were arranged in order of atomic weight, certain patterns of reactivity became apparent. The result of his work was the Periodic Table of the Elements (Fig. 12-1), which, with some minor alterations, is still an essential tool today. All of the currently recognized elements are represented; those heavier than uranium are not known to occur in nature. Many of the symbols used to identify the elements refer to the Latin name of the element. For example, silver is Ag, for argentum, and mercury is Hg, for hydrargyrum, literally â€œsilver water.â€•

The reason for the periodicity of the table relates to the electrons that circle the nucleus in discrete orbitals. Although the details of quantum mechanics and electronic configuration are complex, it is important to review some aspects in order to predict chemical reactivity. Orbitals, or quantum shells, represent the energy levels in which electrons may exist around the nucleus. The orbitals are identified by various schemes, but the maximum number of electrons each orbital may contain is calculated as $2x^2$, where x represents the numerical rank order of the orbital. Thus, the first orbital may contain 2 electrons, the second orbital may contain 8, the third may contain 18, and so on. However, the outermost shell (designated by s, p, d nomenclature) of each orbital may only contain up to 8 electrons. This is irrelevant through element

20, calcium, because there is no need to fill the third-level or d shells. Even though the third orbital may contain 18 electrons, once 8 are present, the 4s electrons dip below the 3d electrons in energy and this shell begins to fill. This occurs at element 21, scandium, and accounts for its chemical properties and those of the other transition elements. Note that hydrogen and helium are unique in needing only 2 electrons to complete their valence shell; all other elements require 8 to be complete. Also, because the inert gas elements, which are also known as noble gases, have complete outermost

orbitals, they are unreactive under standard conditions. Transition elements are chemically defined as elements which form at least one ion with a partially filled subshell of d electrons.

Figure 12-1. The periodic table of the elements.

In general, only electrons in unfilled shells, or *valence shells*, are involved in chemical reactions. This property relates to the fact that the most stable form of an element occurs when the configuration of its valence shell resembles that of the nearest noble gas, found in group 0 on the periodic table. This state can be obtained through either the gaining, losing, or sharing of electrons with other elements and is the basis for virtually all chemical reactions.

Inorganic Chemistry

The Periodic Table

Chemical Reactivity

Broadly, the periodic table is divided into metals and nonmetals. Metals, in their pure form, are typically malleable solids that conduct electricity, whereas nonmetals are usually dull, fragile, nonconductive compounds (C, N, P, O, S, Se, halogens). The metals are found on the left side of the periodic table, and account for the majority of the elements, whereas the nonmetals are on the right side. Separating the two groups are the metalloids, which fall on a jagged line starting with boron (B, Si, Ge, As, Sb, Te, At). These agents have chemical properties that are intermediate between the metals and the nonmetals. Each column of elements is termed a family or group, and each row is a period. Although conceived and organized in periods, trends in the chemical reactivity, and therefore toxicity, typically exist within the groups.

The ability of any particular element to produce toxicologic effects relates directly to one or more of its many physicochemical properties, which may, to some extent, be predicted by their location

on the periodic table. For example, the substitution of arsenate for phosphate in the mitochondrial production of adenosine triphosphate (ATP) creates adenosine diphosphate monoarsenate (Chap. 13). Because this compound is unstable and not useful as an energy source, energy production by the cell fails; in this manner arsenic â€œuncouplesâ€• oxidative phosphorylation. Similarly, the existence of an interrelationship between Ca^{2+} and either Mg^{2+} or Ba^{2+} is predictable, although the actual effects are not. That is, under most circumstances, Mg^{2+} is a Ca^{2+} antagonist, and patients with hypermagnesemia present with neuromuscular weakness caused by blockade of myocyte calcium channels. Alternatively, Ba^{2+} mimics Ca^{2+} and closes Ca^{2+}-dependent K^{+} channels in myocytes, producing life-threatening hypokalemia. Additionally, the physiologic relationship between lithium (Li^{+}), potassium (K^{+}), and sodium (Na^{+}) are consistent with their chemical similarities (all alkali metals in Group IA). However, the clinical similarity between thallium (thallous) ion (Tl^{+}) and K^{+} is not predictable. Other than their monovalent nature (ie, +1 charge), it is difficult to predict the substitution of Tl^{+} (Group IIIA, Period 6) for K^{+} (Group IA, Period 4) in membrane ion channel functions, until the similarity of their ionic radii is known (Tl^{+}, 1.47Ã…; K^{+}, 1.33Ã…).

The Alkali (Group IA: Li, Na, K, Rb, Cs, Fr) and Alkaline Earth (Group IIA: Be, Mg, Ca, Sr, Ba, Ra) Metals

Alkali metals and hydrogen (not an alkali metal on earth) have a single outer valence electron and lose this electron easily to form compounds with a valence of 1+. The alkaline earth metals (between the alkali and rare earth, Group IIIB) readily lose 2 electrons, and their cations have a 2+ charge. In their metallic form, members of both of these groups react violently with water to liberate strongly basic solutions, accounting for their group names ($2Na^{0} + 2H_2O$ â†’ $2NaOH + H_2$). The soluble ionic forms of sodium, potassium, or

calcium, which are critical to survival, also produce life-threatening symptoms following excessive intake (Chap. 17). Toxins may interfere with the physiologic role of these key electrolytes. Li^+ may mimic potassium and enter neurons through K^+ channels, following which it serves as a poor substrate for the repolarizing Na^+-K^+-ATPase. Thus, lithium interferes with cellular potassium homeostasis and alters neuronal repolarization accounting for the neuroexcitability manifesting as tremor. Similarly, as noted previously, the molecular effects of Mg^{2+} and Ba^{2+} may supplant those of calcium. More commonly though, the consequential toxicities ascribed to alkali or alkaline earth salts actually relate to the anionic component. In the case of NaOH or $Ca(OH)_2$, it is a hydroxide anion (not the hydroxyl radical), while it is a CN^- anion in patients poisoned with potassium cyanide (KCN).

The Transition Metals (Group IB to VIIIB)

Unlike the alkali and alkaline earth metals, most other metallic elements are neither soluble nor reactive. This includes the transition metals, a large group that contains several ubiquitous metals such as iron (Fe) and copper (Cu). These elements, in their metallic form, are widely used both in industrial and household applications because of their high tensile strength, density, and melting point, which is partly a result of their ability to delocalize the electrons in the d orbital throughout the metallic lattice. Transition metals also form brightly colored salts that find widespread applications including pigments for paints or fireworks. However, the ionic forms, unlike the metallic form, of these elements are typically highly reactive and toxicologically important. Transition elements are chemically defined as elements which form at least one ion with a partially filled subshell of d electrons. Because the transition metals have partially filled valence shells, they are capable of obtaining several, usually positive, oxidation states. This important mechanism explains the role of transition metals in redox reactions generally as electron acceptors (see Oxidation-Reduction below). This reactivity is used by

living organisms in various physiologic catalytic and coordination roles, such as at the active sites of enzymes and in hemoglobin, respectively. Expectedly, the substantial reactivity of these transition metal elements is highly associated with cellular injury caused by the generation of reactive oxygen species. For example, manganese ion exposure is implicated in the free radical damage of the basal ganglia causing parkinsonism.

The Heavy Metals

Heavy metal is often loosely used to describe all metals of toxicologic significance, but in reality, the term should be reserved to describe only those metals in the lower period of the periodic table, particularly those with atomic masses greater than 200. The chemical properties and toxicologic predilection of this group vary among the agents, but their unifying toxicologic mechanism is electrophilic interference with nucleophilic sulfhydryl-containing enzymes. Some of the heavy metals also participate in the generation of free radicals through Fenton chemistry (Fig. 12-2). The likely determinant of the specific toxicologic

effects produced by each metal is the tropism for various physiologic systems, enzymes, or microenvironments; thus the lipophilicity, water solubility, ionic size, and other physicochemical parameters are undoubtedly critical. Also, because the chemistry of metals varies dramatically based on the chemical form (ie, organic, inorganic, or elemental), as well as the charge on the metal ion, prediction of the clinical effects of a particular metal is often difficult.

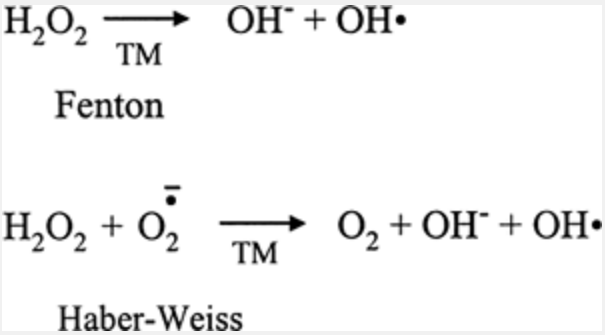

Figure 12-2. The Fenton and Haber-Weiss reactions which are the two most important mechanisms to generate hydroxyl radicals are both mediated by transition metals (TM). Iron (Fe^{2+}) and copper (Cu^{+}) are typical transition metals.

Mercury

Elemental mercury (Hg^0) is unique in that it is the only metal that exists in liquid form at room temperature, and as such is capable of creating solid solutions, or amalgams, with other metals. Although it is relatively innocuous if ingested as a liquid, it is readily volatilized (ie, high vapor pressure) transforming into a physical state that causes significant pulmonary mucosal irritation on inhalation. In addition, this change in the route of exposure raises its systemic bioavailability. Absorbed, or incorporated, Hg^0 undergoes biotransformation in the erythrocyte and brain to the mercuric (Hg^{2+}) form, which has a high affinity for sulfhydryl-containing molecules including proteins. This causes a depletion of glutathione in organs such as the kidney, and also initiates lipid peroxidation. The mercurous form (Hg^{+}) is considerably less toxic than the mercuric form, perhaps because of its reduced water solubility. Organic mercurial compounds, such as methylmercury and

dimethylmercury, are environmentally formed by anaerobic bacteria containing the methylating agent methylcobalamin, a vitamin B_{12} analog (Chap. 92).

Thallium

Another toxicologically important member of the heavy metal group is thallium. Metallic thallium is used in the production of electronic equipment and is itself minimally toxic. Thallium ions, however, have physicochemical properties that most closely mimic potassium, allowing it to participate in, and potentially alter, the various physiologic activities related to potassium. This property is clinically used during a thallium-stress test to assess for myocardial ischemia or infarction. Because ischemic myocardial cells lack adequate energy for normal Na^+-K^+-ATPase function, they cannot exchange sodium for potassium (or in this scenario radioactive thallium) producing a â€œcold spotâ€• in the ischemic areas on cardiac scintigraphy (Chap. 96).

Lead

Although lead is not very abundant in the earth's crust (only 0.002%), exposure may occur during the smelting process or from one of its diverse commercial applications. Most of the useful lead compounds are inorganic lead (II) (Pb^{2+}) salts, but lead (IV) (Pb^{4+}) compounds are also used. The Pb^{2+} compounds are typically ionizable, releasing Pb^{2+} when dissolved in a solvent, such as water. Lead (II) ions are absorbed in place of Ca^{2+} ions by the gastrointestinal tract and replace calcium in certain physiologic processes. This mechanism is implicated in the neurotoxic effect of lead ions. Lead (IV) compounds tend to be covalent compounds that do not ionize in water. However, some of the Pb^{4+} compounds are oxidants. Although elemental lead is not itself toxic, it rapidly develops a coating of toxic lead oxide or lead carbonate upon exposure to air or water (Chap. 91).

The Metalloids (B, Si, Ge, As, Sb, Te, At)

Although the metalloids share many physical properties with the metals, they are differentiated because of their propensity to form compounds with both metals and the nonmetals carbon, nitrogen, or oxygen. Thus, metalloids may be either oxidized or reduced in chemical reactions.

Arsenic

Toxicologically important inorganic arsenic compounds exist in either the pentavalent arsenite (As^{5+}) form or the trivalent arsenate (As^{3+}) form. The reduced water solubility of the arsenate compounds, such as arsenic pentoxide, accounts for its limited clinical toxicity when compared to trivalent arsenic trioxide. The trivalent form of arsenic is primarily a nucleophilic toxin, binding sulfhydryl groups and interfering with enzymatic function (Chaps. 13 and 85).

The Nonmetals (C, N, P, O, S, Se, Halogens)

The nonmetals are highly electronegative and, unlike the metals, may be toxic in either their compounded or their elemental form. The nonmetals with large electronegativity, such as O_2 or Cl_2, generally oxidize other elements in chemical reactions. Those with smaller electronegativity, such as C, behave as reducing agents.

The Halogens (F, Cl, Br, I, At)

In their highly reactive elemental form, which contains a covalent dimer of halogen atoms, the halogens carry the suffix -ine (eg, Cl_2, chlorine). Halogens require the addition of one electron to complete their valence shell; thus, halogens are strong oxidizing agents. Because they are highly electronegative, they form halides (eg, Cl^-, chloride) by abstracting electrons from less electronegative elements. Thus, the halogen ions, in their stable ionic form, generally carry a charge of â€“1. The halides, although much less reactive than

their respective elemental forms, are reducing agents. The hydrogen halides (eg, HCl, hydrogen chloride) are gases under standard conditions, but they ionize when dissolved in aqueous solution to form the hydrohalidic acids (eg, HCl, hydrochloric acid). All hydrogen halides except HF (hydrogen fluoride) ionize completely in water to release H^+ and are considered *strong acids*. Because of its small ionic radius, lack of charge dispersion, and intense electronegativity, HF ionizes poorly and is a *weak acid*. This specific property of HF has important toxicologic implications (Chap. 101).

Group 0: The Inert Gases (He, Ne, Ar, Kr, Xe, Rn)

Inert gases, also known as noble gases, maintain completed valence shells and are thus entirely unreactive except under extreme experimental conditions. However, despite their lack of chemical reactivity, the inert gases are toxicologically important as simple asphyxiants. That is, because they displace ambient oxygen from a confined space, consequential hypoxia may occur, and the expected warning

signs may be completely absent (Chap. 119). During high-concentration exposure, inert gases may produce anesthesia, and xenon is used as an anesthetic agent. Radon, although a chemically unreactive gas, is radioactive, and prolonged exposure is associated with the development of lung cancer.

Bonds

Electrons are not generally shared evenly between atoms when they form a compound. Instead, unless the bond is between the same elements, as in Cl_2, one of the elements exerts a larger attraction for the shared electrons. The degree to which an element draws the shared electron is determined by the element's *electronegativity* (Fig. 12-3). The electronegativity of each element was catalogued by Linus

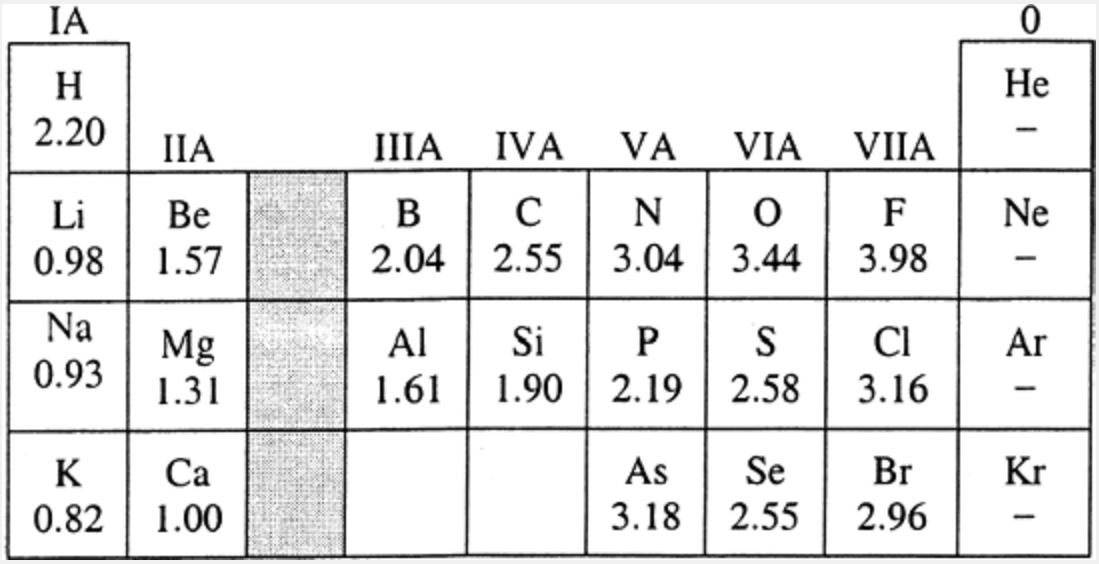
Pauling and relates to the ionic radius, or the distance between the orbiting electron and the nucleus, and the shielding effects of the inner electrons. The electronegativity rises toward the right of the periodic table, corresponding with the expected charge obtained on an element when it forms a bond. Fluoride ion has the highest electronegativity of all elements, which explains many of its serious toxicologic properties.

Several types of bonds exist between elements when they form compounds. When one element gains valence electrons and another loses them, the resulting elements are charged and attract one another in an *ionic*, or *electrovalent*, bond. An example is NaCl, or table salt, in which the electronegativity difference between the elements is 1.9, or greater than the electronegativity of the sodium (see text below and Fig. 12-3). Thus, the chloride wrests control of the electrons in this bond. In solid form, ionic compounds exist in a crystalline lattice, but when put into solution, as in the serum, the elements may separate and form charged particles, or *ions* (Na^+ and Cl_2). The ions are stable in solution, however, because their valence shells contain 8 electrons and are complete. The properties of ions differ from both the original atom from which the ion is derived and the noble gas with which it shares electronic structure.

It is important to recognize that when a mole of a salt, such as NaCl (molecular weight 58.45 g/mol), is put in aqueous solution, 2 moles of particles result. This is because NaCl essentially ionizes fully in water; that is, it produces 1 mole of Na^+ (23 g/mol) and 1 mole of Cl^- (35.45 g/mol). For salts that do not ionize completely, less than the intrinsic number of moles are released and the actual quantity liberated can be predicted based on the defined solubility of the compound, or the solubility product constant (K_{sp}). For ions that carry more than a single charge, the term *equivalent* is often used to denote number of moles of other particles to which one mole of the substance will bind. Thus, an equivalent of calcium ion will typically bind 2 moles (or equivalents) of chloride ions (which are monovalent) because calcium ions are divalent. Alternatively stated, a 10%

calcium chloride ($CaCl_2$) aqueous solution contains approximately 1.4 mEq/mL or 0.7 mmol/mL of Ca^{2+}.

Compounds formed by two elements of similar electronegativity have little ionic character because there is little impetus for separation of charge. Instead, these elements share pairs of valence electrons, a process known as *covalence*. The resultant molecule contains a *covalent bond*, which is typically very strong and generally requires a high-energy chemical reaction to disrupt it. There is wide variation in the extent to which the electrons are shared between the participants of a covalent bond, and the physicochemical and toxicologic properties of any particular molecule are in part determined by its nature. Rarely is sharing truly symmetric, as in oxygen (O_2) or chlorine (Cl_2). If sharing is asymmetric and the electrons thus exist to a greater degree around one of the component atoms, the bond is *polar*. However, the presence of a polar bond does not mean that the compound is polar. For example, methane contains a carbon atom that shares its valence electrons with 4 hydrogen atoms, in which there is a small charge separation between the elements (electronegativity [EN] difference = 0.40). Furthermore, because the molecule is configured in a tetrahedral formation, there is no notable polarity to the compound; this compound is *nonpolar*. The lack of polarity suggests that methane molecules have little affinity for other methane molecules and they are held together only by weak intermolecular bonds. This explains why methane is highly volatile under standard conditions.



IA							0

Figure 12-3. Electronegativity of the common elements. Note that the inert gases are not reactive and thus do not have electronegativity.

Because the electronegativity differences between hydrogen (EN = 2.20) and oxygen (EN = 3.44) are greater (EN difference = 1.24), the electrons in the HO bonds in water are drawn toward the oxygen atom, giving it a partial negative charge and the hydrogens a partial positive charge. Furthermore, because H_2O is angular, not linear or symmetric, water is a polar molecule. Water molecules are held together by hydrogen bonds, which are stronger than intermolecular bonds (also called van der Waals forces, see below). These hydrogen bonds have sufficient energy to open many ionic bonds and *solvate* the ions. In this process, the polar ends of the water molecule surround the charged particles of the dissolved salt. Thus, because there is little similarity between the nonpolar methane and the polar water molecules, methane is not water soluble. Similarly, salts cannot be solvated by nonpolar compounds, and thus a salt, such as sodium chloride, cannot dissolve in a nonpolar solvent, such as

carbon tetrachloride.

Alternatively, the stability and irreversibility of the bond between an organic phosphorus insecticide and the cholinesterase enzyme are a result of covalent phosphorylation of an amino acid at the active site of the enzyme. The resulting bond is essentially irreversible in the absence of another chemical reaction.

Compounds may share multiple pairs of electrons. For example, the two carbon atoms in acetylene (HC[triple bond]CH) share three pairs of double bonds between them, and each shares one pair with its own hydrogen. Carbon and nitrogen share three pairs of electrons in forming cyanide (C[triple bond]N^-) making this bond very stable and accounting for the large number of xenobiotics capable of liberating cyanide.

Complex ions are covalently bonded groups of elements that behave as a single element. For example, the hydroxide ion (OH^-) and sulfate (SO_4^{2-}) form sodium salts as if they were simply a chloride ion.

Noncovalent bonds, such as hydrogen or ionic bonds, are important in the interaction between ligands and receptors, and between ion channels and enzymes. These are low-energy bonds and easily reversible. Van der Waals forces, also known as London dispersion forces, are intermolecular forces that arise from induced dipoles as a consequence of nonuniform distribution of the molecular electron cloud. These forces become stronger as the atom (or molecule) becomes larger because of the increased polarizability of the larger, more dispersed electron clouds. This accounts for the fact that under standard temperature and pressure, fluorine and chlorine are gases, whereas bromine is a liquid, and iodine is a solid.

Oxidation-Reduction

Reduction-oxidation (*redox*) reactions involve the movement of

electrons from one atom or molecule to another, and actually comprise two dependent reactions: reduction and oxidation. *Reduction* is the gain of electrons by an atom that is thereby *reduced*. The electrons derive from a *reducing agent*, which in the process becomes *oxidized*. *Oxidation* is the loss of electrons from an agent, which is, accordingly, *oxidized*. An *oxidizing agent* accepts electrons, and in the process, is reduced. By definition, these chemical reactions involve a change in the valence of an atom. It is also important to note that acid/base and electrolyte chemical reactions involve electrical charge interactions but no change in valence of any of the involved components. The implications of redox chemistry for medical toxicology are profound. For example, the oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron within the hemoglobin molecule creates dysfunctional methemoglobin.

Also, metallic lead and elemental mercury are both intrinsically harmless metals, but when oxidized to their cationic forms both produce devastating clinical effects. Additionally, the oxidation of methanol to formic acid involves a change in the oxidation state of the molecule. In this case, an enzyme, alcohol dehydrogenase, acting as a catalyst, oxidizes (ie, removes electrons from) the C-O bond and delivers the electrons to oxidized nicotinamide adenine dinucleotide (NAD^+), reducing it to the reduced form (NADH). As in this last example, *oxidation* is occasionally used to signify the gain of oxygen by a substance. That is, when elemental iron (Fe^0) undergoes rusting to iron oxide (Fe_2O_3), it is said to oxidize. The use of this term is consistent because in the process of oxidation, oxygen derives electrons from the atom to which it is binding.

Reactive Oxygen Species

Free radicals are reactive molecules that contain one or more unpaired electrons, and are typically neutral but may be anionic or cationic. However, because certain toxicologically important reactive molecules do not contain unpaired electrons, such as hydrogen

peroxide (H_2O_2) and ozone (O_3), the term *reactive species* is preferred. The reactivity of these molecules directly relates to their desire to fill their outermost orbitals by receiving an electron; the result is *oxidative stress* on the biologic system. Molecular oxygen is actually a diradical with two unpaired electrons in the outer orbitals. However, its reactivity is less than that of the other radicals because the unpaired electrons have parallel spins, so catalysts (ie, enzymes or metals) are typically involved in the use of oxygen in biologic processes.

Reactive species are continually generated as a consequence of endogenous metabolism and there is an efficient system for their control. Under conditions of either excessive endogenous generation or exposure to exogenous reactive species, the physiologic defense against these toxic products is overwhelmed. When this occurs, reactive species induce direct cellular damage as well as initiate a cascade of oxidative reactions that perpetuate the toxic damage.

Intracellular organelles, particularly the mitochondria, may also be disrupted by various reactive oxygen species. This causes further injury to the cell as energy failure occurs. This initial damage is compounded by the activation of the host inflammatory response by chemokines that are released from cells in response to reactive oxygen species-induced damage. This inflammatory response aggravates cellular damage. The resultant membrane dysfunction or damage causes cellular apoptosis or necrosis (Chap. 13).

The most important reactive oxygen species in medical toxicology are derived from oxygen, although those derived from nitrogen are also important. Table 12-1 lists some of the important reactive oxygen and nitrogen species.

This biradical nature of oxygen explains both the physiologic and toxicologic importance of oxygen in biologic systems. Physiologically, the majority of oxygen is used by the body to serve as the ultimate electron acceptor in the mitochondrial electron transport chain (Fig. 13-3). In this situation, four electrons are added to each molecule of

oxygen to form two water molecules (O_2 + 4 H^+ + 4 e^- â†' 2 H_2O).

Superoxide is generated within neutrophil and macrophage lysosomes as part of the oxidative burst, a method of eliminating infectious agents and damaged cells. Superoxide may subsequently be enzymatically converted, or dismutated, into hydrogen peroxide by superoxide dismutase (SOD). Hydrogen peroxide may be subsequently converted into hypochlorous acid by the enzymatic addition of chloride by myeloperoxidase. Both hydrogen peroxide and hypochlorite ion are more potent reactive oxygen species than superoxide. However, this lysosomal protective system may also be responsible for tissue damage following poisoning as the innate inflammatory response attacks toxin-damaged cells. Examples include acetaminophen-induced hepatotoxicity (Chap. 34), carbon monoxide neurotoxicity (Chap. 120), and chlorine-induced

pulmonary toxicity (Chap. 119), each of which may be altered, at least in experimental systems, by the addition of scavengers of reactive oxygen species.

	Structure
Reactive Oxygen Species	
Free radicals	
Hydroxyl radical	OH·
Alcoxyl radical	RO·
Singlet oxygen (Σ)	[O] or $^1O_2$
Peroxyl radical	ROO·
Superoxide radical	O_2^- or O_2^-
Nonradicals	
Hydrogen peroxide	H_2O_2
Hypochlorous acid	HOCl
Singlet oxygen (Δ)	[O] or $^1O_2$
Ozone	O_3
Reactive Nitrogen Species	
Free radicals	
Nitric oxide	NO·
Nitrogen dioxide	NO_2·
Nonradicals	
Peroxynitrite anion	$ONOO^-$
Nitronium cation	NO_2^+

TABLE 12-1. Structure of Important Reactive Oxygen and Nitrogen Species

Although superoxide and hydrogen peroxide are reactive oxygen species, it is their conversion into the hydroxyl radical (OHÂ·) that accounts for their most consequential effects. The hydroxyl radical is generated by the Fenton reaction (Fig. 12-2), in which hydrogen peroxide is decomposed in the presence of a transition metal. This catalysis typically involves Fe^{2+}, Cu^+, Cd^{2+}, Cr^{5-}, Ni^{2+}, or Mn^{2+}. The Haber-Weiss reaction (Fig. 12-2), in which a transition metal catalyzes the combination of superoxide and hydrogen peroxide, is the other important means of generating the hydroxyl radical. Superoxide dismutase, within the erythrocyte, contains an atom of Cu^{2+} that participates in the catalytic dismutation (reduction) of superoxide to hydrogen peroxide (SOD was originally called

erythrocuprein) and the subsequent detoxification of hydrogen peroxide by glutathione peroxidase or catalase.

Transition metal cations may bind to the cellular nucleus where they locally generate reactive oxygen species, most importantly hydroxyl radical. This results in DNA strand breaks and modification, accounting for the promutagenic effects of many transition metals.[2] In addition to the important role that transition metal chemistry plays following iron or copper salt poisoning, the long-term consequences of chronic transition metal poisoning are exemplified by asbestos. The iron contained in asbestos is the origin of the Fenton-generated hydroxyl radicals that are responsible for the pulmonary fibrosis and cancers associated with long-term exposure.[2]

The most consequential toxicologic effects of reactive oxygen species occur on the cell membrane, and are caused by the initiation by hydroxyl radical of the lipid peroxidative cascade. The alteration of these lipid membranes ultimately causes membrane destruction. Identification of released oxidative products such as malondialdehyde is a common method of assessing lipid peroxidation.

Under normal conditions, there is a delicate balance between the formation and immediate endogenous detoxification of reactive oxygen species. For example, the conversion of superoxide radical to hydrogen peroxide via SOD is rapidly followed by the transformation of hydrogen peroxide to water by glutathione peroxidase or catalase. Furthermore, transition metals cannot be unattended in biologic systems and exist in â€œfreeâ€• form in only minute quantities, presumably to minimize the formation of hydroxyl radicals through Fenton reactions. Thus, cells have developed extensive systems by which transition metal ions can be sequestered and rendered harmless. Ferritin (binds iron), ceruloplasmin (binds copper), and metallothionein (binds cadmium) are specialized proteins that safely sequester transition metal ions. Certain proteins and enzymes that contain transition metals at their active sites, such as hemoglobin or SOD, harness the activity of transition metal ions in a controlled

fashion.

Detoxification of certain reactive species is difficult because of their extreme reactivity. Widespread antioxidant systems exist to trap reactive species before they can damage tissues. An example is the availability of glutathione, a reducing agent and nucleophile, to prevent both exogenous oxidants from producing hemolysis and the acetaminophen metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI) from damaging the hepatocyte.

The key reactive nitrogen species is nitric oxide. At typical physiologic concentrations, this radical is responsible for vascular endothelial relaxation through stimulation of guanylate cyclase. However, during oxidative burst, high concentrations of nitric oxide are formed from L-arginine. At these concentrations, nitric oxide has primarily both damaging effects and reacts with superoxide radical to generate the peroxynitrite anion. This is particularly important because peroxynitrite may spontaneously degrade to form the hydroxyl radical. Peroxynitrite ion is implicated in both the delayed neurologic effects of carbon monoxide poisoning and the hepatic injury from acetaminophen.

Redox Cycling

Although transition metals are an important source of reactive species, certain xenobiotics are also capable of independently generating reactive species. Most do so through a process called *redox cycling*, in which a molecule accepts an electron from a reducing agent and subsequently transfers that electron to oxygen, generating the superoxide radical. At the same time, this second reaction regenerates the parent molecule, which itself can gain another electron and restart the process. The toxicity of paraquat is selectively localized to pulmonary endothelial cells. Its pulmonary toxicity results from redox cycling generation of reactive oxygen species (Fig. 111-1). A similar process, localized to the heart, occurs with anthracycline antineoplastic agents such as doxorubicin.

Acidâ€“Base Chemistry

Water is *amphoteric*, which implies that water can function as either an acid or a base, much the same way as the bicarbonate ion (HCO_3^-). In fact, because of the amphoteric nature of water, H^+, despite the nomenclature, does not ever actually exist in aqueous solution; rather, it is covalently bound to a molecule of water to form the hydronium ion (H_3O^+). However, the term H^+, or proton, is used for convenience.

Even in neutral solution, a tiny proportion of water is always undergoing ionization to form both H^+ and OH^+ in exactly equal amounts. It is, however, the quantity of H^+ that is of concern, and this is the basis of using the pH to characterize a solution. In a perfect system at equilibrium, the concentration of H^+ ions in water is precisely 0.0000001, or 10^{-7}, moles per liter and that of OH^- is the same. The number of H^+ ions increases when an acid is added to the solution and falls when an alkali is added. In an attempt to make this quantity more practical, the negative log of the H^+ concentration is calculated, which defines the *pH*. Thus, the negative log of 10^{-7} is 7, and the pH of a neutral aqueous solution is 7. In actuality, the pH of water is approximately 6 because of dissolution of ambient carbon dioxide to form carbonic acid ($H_2O + CO_2$ â†' H_2CO_3), which ionizes to form H^+ and bicarbonate (HCO_3^-).

There are many definitions of acid and base. The three commonly used definitions are those advanced by (a) Arrhenius, (b) BrÃ¸nsted-Lowry, and (c) Lewis. Because the focus is on physiologic systems, which are aqueous, the original definition by the Swedish chemist Arrhenius is the most practical. In this view, an acid is any xenobiotic that releases hydrogen ions, or protons (H^+), in water. Similarly, a base is a xenobiotic that produces hydroxyl ions (OH^-) in water. Thus, hydrogen chloride (HCl), a neutral gas under standard conditions, dissolves in water to liberate H^+, and is therefore an acid.

For nonaqueous solutions the BrÃ¸nsted-Lowry definition is preferable. An acid, in this schema, is a substance that donates a proton and a base is one that accepts a proton. Thus, any molecule that has a hydrogen in the 1+ oxidation state is technically an acid, and any molecule with an unbound pair of valence electrons is a base. Because most of the acids or bases of toxicologic interest

have ionizable protons or available electrons, respectively, the BrÃ¸nsted-Lowry definition is most often considered when discussing acid-base chemistry (ie, $HA + H_2O$ â†' $H_3O^+ + A^-$; $B^- + H_2O$ â†' $HB + OH^-$). However, this is not a defining property of all acids or bases. Thus, Lewis offered the least-restrictive definition of such substances. A Lewis acid is an electron acceptor and a Lewis base is an electron donor. Simplistically, acids are sour and turn litmus paper red, whereas bases are slippery and bitter and turn litmus paper blue.

Because acidity and alkalinity are determined by the number of available H^+ ions, it is useful to classify chemicals by their effect on the H^+ concentration. Strong acids ionize completely in aqueous solution and very little of the parent compound remains. Thus, 0.001 (or 10^{-3}) mole of HCl, a strong acid, added to 1 L of water produces a solution with a pH of 3. Weak acids, on the other hand, obtain an equilibrium between parent and ionized forms, and thus do not alter the pH to the same degree as a similar quantity of a strong acid. This chemical notation defines the strength or weakness of an acid and should not be confused with the concentration of the acid. Thus, the pH of a dilute strong acid solution may be substantially less than that of a concentrated weak acid (Table 12-2).

The degree of ionization of a weak acid is determined by the pK_a, or the negative log of the *ionization constant*, which represents the pH at which an acid is half dissociated in solution. The same relationship applies to the pK_b of an alkali, although by convention the pK_b is expressed as the pK_a ($pK_a = 14$ â€“ pK_b). The lower the pK_a, the stronger the acid; the converse is true for bases. Knowledge of the

pK_a does not itself denote whether a substance is an acid or an alkali. To some extent, this quality may be predicted by its chemical structure or reactivity, or obtained through direct measurement or from a reference source. The pK of a strong acid is clinically irrelevant because it is fully ionized under all but the most extreme acid conditions.

Because only uncharged compounds cross lipid membranes spontaneously, the pK_a has clinical relevance. Salicylic acid, a weak acid with a pK_a of 3, is nonionized in the stomach (pH 2) and passive absorption occurs (Fig. 9-4). Because it is predominantly in the ionized form (ie, salicylate) in blood, which has a pH of 7.4, little of the ionized bloodborne salicylate passively enters the tissues. However, because in overdose the serum salicylate rises considerably, enough enters the tissue to have devastating clinical effects. Salicylate, a conjugate base of a weak acid and thus a strong base, equilibrates within the various tissues across the outer mitochondrial membrane. In this intermembrane space (between the inner and outer mitochondrial membrane) abundant protons exist, which are transported there via the electron transport chain of this organelle (Chap. 13). Because salicylate is a strong base, it protonates easily in this environment. In this nonionized form, some of the salicylic acid may pass through the inner mitochondrial membrane, into the mitochondrial matrix, and again establish equilibrium by losing a proton. The process just described uncouples oxidative phosphorylation, by dispersing the highly concentrated protons in the intermembrane space that are normally used to generate adenosine triphosphate (Chap. 13). Uncoupling in the skeletal muscle, for example, produces a metabolic acidosis, and this shifts the blood equilibrium of salicylate toward the nonionized, protonated form, enabling salicylic acid to cross the bloodâ€“brain barrier. Presumably, once in the brain, the salicylate uncouples the metabolic activity of neurons with the subsequent development of cerebral edema. This is the rationale for serum alkalinization in patients with aspirin overdose (Chap. 35).

TABLE 12-2. pH of 0.10 M Solutions of Common Acids and Bases Represents the Strength of the Acid or Base

Acid Base	pH
HCl (hydrochloric acid)	1.1
H_2SO_4 (sulfuric acid)	1.2
H_2SO_3 (sulfurous acid)	1.5
H_3PO_4 (phosphoric acid)	1.5
HF (hydrofluoric acid)	2.1
CH_3CO_2H (acetic acid)	2.9
H_2CO_3 (carbonic acid)	3.8
H_2S (hydrogen sulfide)	4.1
NH_4Cl (ammonium chloride)	4.6
HCN (hydrocyanic acid)	5.1
$NaHCO_3$ (sodium bicarbonate)	8.3
$NaCH_3CO_2$ (sodium acetate)	8.9

Na_2HPO_4 (sodium hydrogen phosphate)	9.3
Na_2SO_3 (sodium sulfite)	9.8
NaCN (sodium cyanide)	11.0
NH_4OH (aqueous ammonia)	11.1
Na_2CO_3 (sodium carbonate)	11.6
Na_3PO_4 (sodium phosphate)	12.0
NaOH (sodium hydroxide)	13.0

In a similar manner, alkalinization of the patient's urine prevents reabsorption by ionization of the urinary salicylate. Conversely, because tricyclic antidepressants are organic bases, alkalinization of the urine reduces their ionization and actually decreases the drug's urinary elimination. However, in the management of cyclic antidepressant poisoning, because the other beneficial effects of sodium bicarbonate on the sodium channel outweigh the negative effect on drug elimination, serum alkalinization is recommended.

Organic Chemistry

The study of carbon-based chemistry and the interaction of inorganic molecules with carbon-containing compounds is called *organic chemistry*, because the chemistry of living organisms is carbon based. *Biochemistry* (Chap. 13) is a subdivision of organic chemistry; it is the study of organic chemistry within biologic systems. This section reviews many of the salient points of organic chemistry,

focusing on those with the most applicability to medicine and the study of toxicology: nomenclature, bonding, nucleophiles and electrophiles, stereochemistry, and functional groups.

Chemical Properties of Carbon

Carbon, atomic number 6, has a molecular weight of 12.011 g/mol. With few exceptions (notably cyanide ion and carbon monoxide), carbon forms 4 bonds in stable organic molecules. In organic compounds, carbon is commonly bonded to other carbon atoms, as well as to hydrogen, oxygen, nitrogen, or halide (ie, fluorine, bromine, or iodine) atoms. Under certain circumstances, carbon can be bonded to metals, as is the case with methylmercury.

Nomenclature

The most rigorous method to name organic compounds is in accordance with standards adopted by the International Union of

Pure and Applied Chemistry (IUPAC); these names are infrequently used, especially for larger molecules, and *alternative chemical names* are common. Alternative chemical names are those based on the structure of a molecule, but which do not adhere completely to IUPAC rules. The complete details of the IUPAC naming system are beyond the scope of this text and can be reviewed elsewhere (http://www.iupac.org), but a brief description of the fundamentals of this system is included here.

The carbon backbone serves as the basis of the chemical name. Once the carbon backbone has been identified and named, *substituents* (atoms or groups of atoms that substitute for hydrogen atoms) are identified, named, and numbered. The number refers to the carbon to which the substituent is attached. Some of the common substituents in organic chemistry are â€“OH (hydroxy), â€“NH_2 (amino), â€“Br (bromo), â€“Cl (chloro), and â€“F (fluoro). Substituents are then

alphabetized and placed as prefixes to the carbon chain.

As an example, consider the molecule 2-bromo-2-chloro-1,1,1-trifluoroethane. The molecule has a 2-carbon backbone (ethane), 3 fluoride atoms on the first carbon, a bromine atom on the second carbon, and a chlorine atom on the second carbon (Fig. 12-4A). A basic understanding of a few simple rules of nomenclature thus allows one to quickly generate the molecular structure of a familiar compound, halothane, from what initially appeared to be an intimidating name.

Although the above-mentioned rules suffice to name simple structures, they are inadequate to describe many others, such as molecules with complex branching or ring structures. The IUPAC rules for naming compounds such as [1R-(exo,exo)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]octane-2-carboxylic acid methyl ester, for example, are too complex to include here. Fortunately, many compounds with complex chemical names have simpler names for day-to-day use; as an example, this molecule is commonly referred to as cocaine (Fig. 12-4B).

Cocaine is an example of a *common* or *trivial* name, that is, one without a rigorous scientific basis, but which is generally accepted as an alternative to frequently unwieldy proper chemical names. Common names may refer to the origin of the substance; for example, cocaine is derived from the coca leaf, and wood alcohol (methanol) can be prepared from wood. Alternatively, a common name may refer to the way in which a compound is used; â€œrubbing alcoholâ€• is a common name for isopropanol. Common names are often imprecise and may generate some confusion, however, as evidenced by the fact that â€œrubbing alcohol,â€• when commercially marketed, may be ethanol or isopropanol.

An even less precise system of nomenclature is the use of *street* names. A street name is a slang term for a drug of abuse, such as â€œblowâ€• (cocaine), â€œweedâ€• (marijuana), or â€œsmackâ€• (heroin). The street name *ecstasy* refers to the stimulant 3,4-

methylenedioxymethamphetamine (MDMA), which is most frequently consumed in pill form. It would stand to reason that *liquid ecstasy* might refer to a solution of MDMA, but street names are not necessarily logical. Instead, liquid ecstasy refers to the drug Î³-hydroxybutyrate (GHB), a sedative-hypnotic agent with a completely different pharmacologic and toxicologic profile. Furthermore, there are no standards for the content of ecstasy and many street pills contain other chemicals or no chemicals at all.

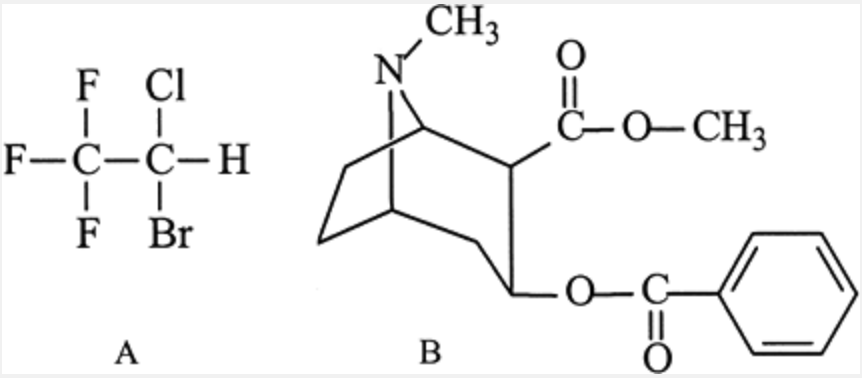

Figure 12-4. Nomenclature. A. 2-Bromo-2-chloro-1,1,1-trifluoroethane, or halothane. B. [1R-(exo,exo)]-3-(Benzoyloxy)-8-methyl-8-azabicyclo-[3,2,1]-octane-2-carboxylic acid methyl ester, or cocaine.

A final consideration must be given to *product names.* Product names are â€œtrade namesâ€• under which a given compound might be marketed, and are frequently different from both the chemical name and common name. Thus, the inhalational anesthetic in Figure 12-4A with the chemical name *2-bromo-2-chloro-1,1,1-trifluoroethane* has the common name *halothane* and the trade name *Fluothane*.

Bonding in Organic Chemistry

Whereas much of the bonding in inorganic chemistry is ionic or electrovalent, the vast majority of bonding in organic molecules is *covalent*. Whereas electrons in ionic bonds are described as â€œbelongingâ€• to one atom or another, electrons in covalent bonds are shared between two atoms; this type of bonding occurs when the difference in electronegativity between two atoms is insufficient for one atom to wrest control of an electron from another. Single bonds are represented by 1, double bonds by 2, and triple bonds by 3 lines between the atoms.

Nucleophiles and Electrophiles

Many organic reactions of toxicologic importance can be described as the reactions of *nucleophiles* with *electrophiles*. *Nucleophiles* (literally, nucleus-loving) are species with increased electron density, frequently in the form of a lone pair of electrons (as in the cases of cyanide ion and carbon monoxide). Nucleophiles, by virtue of this increased electron density, have an affinity for atoms or molecules which are electron deficient; such moieties are called *electrophiles* (literally, electron-loving). The electron deficiency of electrophiles can be described as absolute or relative. Absolute electron deficiency occurs when an electrophile is charged, as is the case with cations such as Pb^{2+} and Hg^{2+}. Relative electron deficiency occurs when one atom or group of atoms shifts electrons away from a second atom, making the second atom relatively electron deficient. This is the case for the neurotoxin 2,5-hexanedione (Fig. 12-5); the electronegative oxygen of the carbon-oxygen double bond pulls electron density away from the second and fifth carbon atoms of this molecule, making these carbon atoms electrophilic.

The reaction of a nucleophile with an electrophile involves the movement of electrons, by forming and/or breaking bonds. This movement of electrons is frequently denoted by the use of curved arrows, which better demonstrates how the nucleophile and electrophile

interact. The interaction of acetylcholinesterase with acetylcholine, organic phosphorus pesticides, and pralidoxime hydrochloride provides an excellent example of the way in which nucleophiles and electrophiles interact, and of how the use of curved arrow notation can lead to better understanding of the reactions involved.

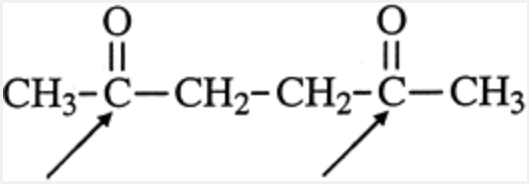

Figure 12-5. Chemical properties of 2,5-hexanedione. *Arrows* designate the electrophilic carbon atoms.

Under normal circumstances, the action of acetylcholine is terminated when the serine residue in the active site of acetylcholinesterase attacks this neurotransmitter, forming a transient serineâ€“acetyl complex and liberating choline; this serineâ€“acetyl complex is then rapidly hydrolyzed, producing an acetic acid molecule and regenerating the serine residue for another round of the reaction (Fig. 12-6A). In the presence of an organic phosphorus agent, however, this serine residue attacks the electrophilic phosphate atom, forming a stable serineâ€“phosphate bond, which is not hydrolyzed (Fig. 12-6B). The enzyme, thus inactivated, can no longer break down acetylcholine, leading to an increase of this neurotransmitter in the synapse, and possibly to a

cholinergic crisis.

The enzyme can be reactivated, however, by the use of another nucleophile. Pralidoxime hydrochloride (2-PAM) is referred to as a *site-directed nucleophile.* Because part of its chemical structure (the charged nitrogen atom) is similar to the choline portion of acetylcholine, this antidote is directed to the active site of acetylcholinesterase. Once in position, the nucleophilic oxime moiety (â€“NOH) of 2-PAM attacks the electrophilic phosphate atom; this displaces the serine residue, regenerating the enzyme (Fig. 12-6C). For a further discussion of organic phosphorus compound toxicity and the use of 2-PAM, see Chap. 109 and Antidotes in Depth: Pralidoxime.

A second toxicologically important electrophile is NAPQI (Fig. 12-7). NAPQI is formed when the endogenous detoxification pathways of acetaminophen metabolism (glucuronidation and sulfation) are overwhelmed (Chap. 34). As a result of the electron configuration of NAPQI, the carbon atoms adjacent to the *carbonyl carbon* (a carbonyl carbon is one that is double-bonded to an oxygen) are very electrophilic; the sulfur groups of cysteine residues of hepatocyte proteins react with NAPQI to form a characteristic *adduct*, 3-(cystein-*S*-yl)acetaminophen in a multistep process (an adduct is formed when one compound is added to another). These adducts are released as hepatocytes die, and can be found in the blood of patients with acetaminophen-related liver toxicity. Figure 12-7 diagrams the mechanism of the proteinâ€“NAPQI reaction (Chap. 34).

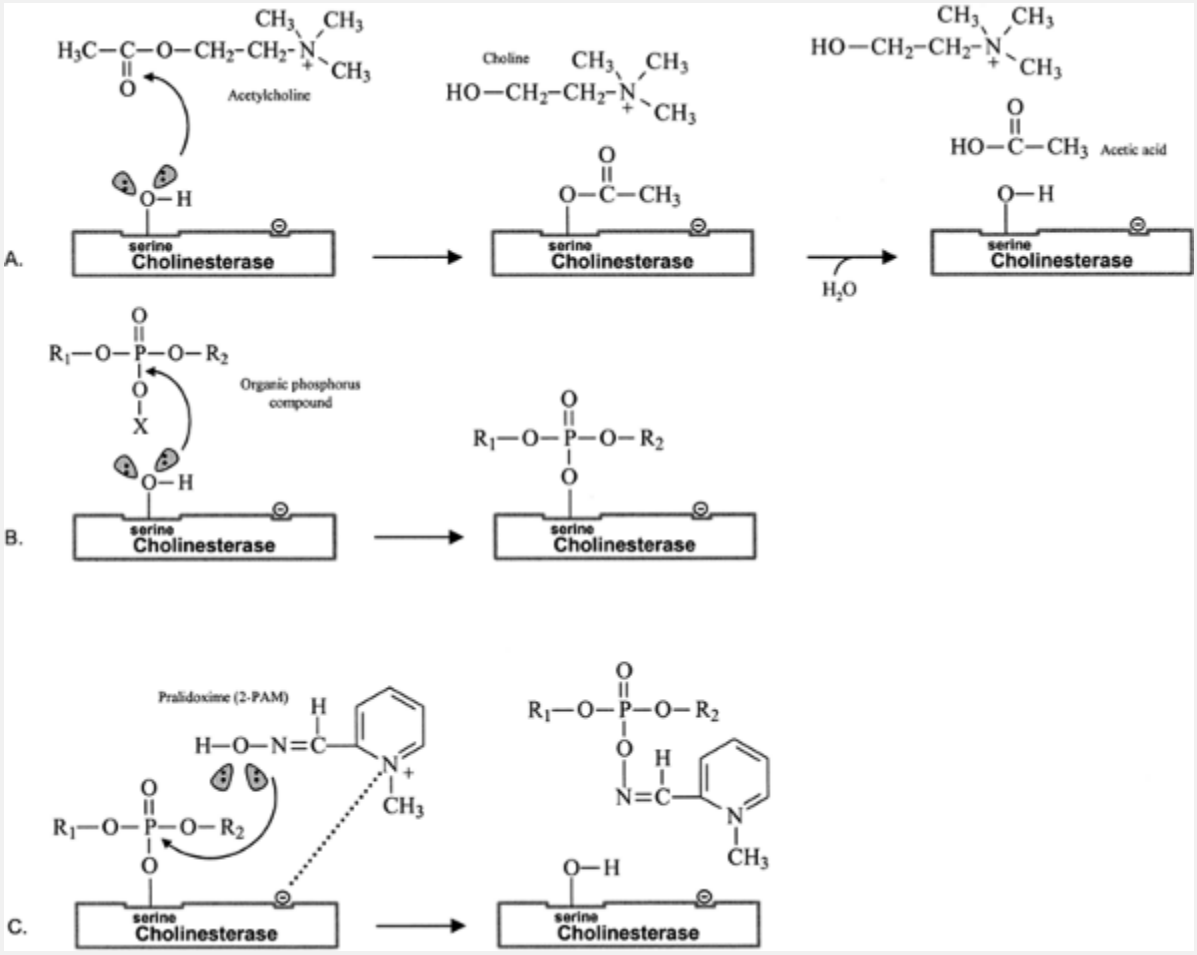

Figure 12-6. The reactions of acetylcholinesterase (AChE), organic phosphorus compounds, and pralidoxime hydrochloride (2-PAM). Curved arrows represent the movement of electrons as bonds are formed or broken. A. Normal hydrolysis of acetylcholine by acetylcholinesterase. B. Inactivation (phosphorylation) of acetylcholinesterase by organic phosphorus compound. C. Reactivation by 2-PAM of functional acetylcholinesterase.

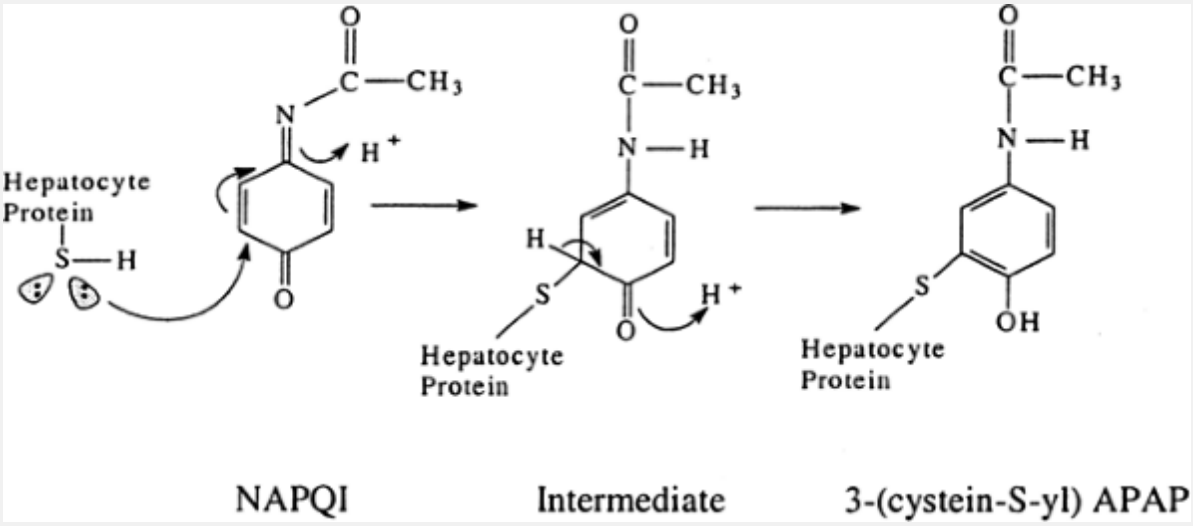

Figure 12-7. The reaction of cysteine residues on hepatocyte proteins with NAPQI to form the characteristic adducts 3-(cystein-S-yl) APAP.

Nucleophiles can be described by their strength; strength is related to the rate at which they react with a reference electrophile CH_3I. Of more use in pharmacology and toxicology, however, are the descriptive terms â€œhardâ€• and â€œsoft.â€• Although imprecise, the designations â€œhardâ€• and â€œsoftâ€• help to predict, on a qualitative level, how nucleophiles and electrophiles interact with one another.

â€œHardâ€• species have a charge (or partial charge) that is highly localized; that is, their charge to radius ratio is high. Hard nucleophiles are molecules in which the electron density or lone pair is tightly held; fluoride, a small atom that cannot spread its electron density over a large area, is an example. Similarly, hard electrophiles are species in which the positive charge cannot be spread over a large area; ionized calcium, a small ion, is a hard electrophile.

â€œSoftâ€• nucleophiles and electrophiles, on the other hand, are capable of delocalizing their charge over a larger area. In this case the charge to mass ratio is low, either because the atom is large or because the charge can be spread over a number of atoms within a given molecule. Sulfur is the prototypical example of a soft nucleophile and the lead ion, Pb^{2+}, is a typical soft electrophile.

The utility of this classification lies in the observation that hard nucleophiles tend to react with hard electrophiles, and soft nucleophiles with soft electrophiles. For example, a principal toxicity of fluoride ion poisoning (Chap. 101) is hypocalcemia; this is because the fluoride ions (hard nucleophiles) readily react with calcium ions (hard electrophiles). On the other hand, the soft nucleophile lead is effectively chelated by soft electrophiles such as the sulfur atoms in the chelating agents dimercaprol (Antidotes in Depth: Dimercaprol [British Anti-Lewisite or BAL]) and succimer (Antidotes in depth: Succimer [2,3-Dimercaptosuccinic Acid]).

Isomerism

Isomerism describes the different ways in which molecules with the same chemical formula (ie, the same number and types of atoms) can be arranged to form different compounds. These different compounds are called *isomers.* Isomers always have the same chemical formula, but differ either in the way that atoms are bonded to each other (*constitutional isomers*) or in the spatial arrangement of these atoms (*geometric isomers* or *stereoisomers*).

Figure 12-8. Two molecules with chemical formula C_2H_6O. A. Dimethylether. B. Ethanol (ethyl alcohol).

Constitutional isomers are conceptually the easiest to understand, because a quick glance shows them to be very different molecules. The chemical formula C_2H_6O, for example, can refer to either dimethyl ether or ethanol (Fig. 12-8). These molecules have very different physical and chemical characteristics, and have little in common other than the number and type of their atomic constituents.

Stereoisomerism, also referred to as *geometric isomerism*, refers to the different ways in which atoms of a given molecule, with the same number and types of bonds, might be arranged. The most important type of stereoisomerism in pharmacology and toxicology is the stereochemistry around a *chiral carbon*, a carbon atom to which four different substituents are bonded.

Consider the two representations of halothane shown in Figure 12-9. In this figure the straight solid lines and the atoms to which they are bonded exist in the plane of the paper, the solid triangle and the atom to which it is bonded are coming out of the paper, and the dashed triangle and the atom to which it is bonded are receding into

the paper. It is clear that, for the molecules in Figure 12-9A and B, no amount of rotation or manipulation will make these molecules superimposable. They are, therefore, different compounds.

The molecules in Figure 12-9A and B are *enantiomers* or *optical isomers.* They differ only in the way in which their atoms are bonded to the chiral carbon. It is important to define the stereochemical configuration of these two molecules, which can be done in one of two ways. In the first classificationâ€”the D(+)/L(â€“) systemâ€”molecules are named empirically based on the direction in which they rotate plane-polarized light. Each enantiomer will rotate plane-polarized light in one direction; the enantiomer that rotates light clockwise (to the right) is referred to as D(+), or

dextrorotatory; the L(â€“), or *levorotatory* enantiomer rotates plane-polarized light in a counterclockwise fashion (to the left).

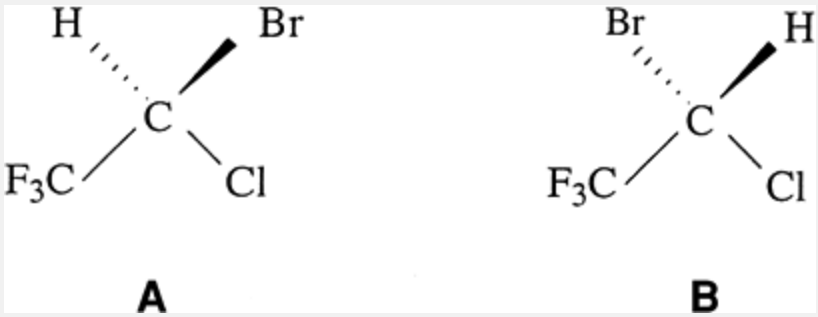

Figure 12-9. The graphic representation of the enantiomers of halothane.

Alternatively, enantiomers can be named using an elaborate and formal set of rules known as *Cahn-Ingold-Prelog.* These rules establish priority for substituents, based primarily upon molecular

weight, and then use the arrangement of substituents to assign a configuration. To correctly assign configuration in this system, the molecule is rotated into a projection in which the chiral carbon is in the plane of the page, the lowest priority substituent is directly behind the chiral carbon (and therefore behind the plane of the page), and the other three substituents are arranged around the chiral carbon. Figure 12-10 assigns Cahn-Ingold-Prelog priority to the halothane enantiomers of Figure 12-9, and rearranges the molecules in the appropriate projections.

If the priority of the substituents increases as one moves clockwise (to the right), the enantiomer is named *R* (Latin, *rectus* = right); if it increases as one moves counterclockwise, the enantiomer is named *S* (Latin, *sinister* = left). Thus, Figure 12-10A is the *R* enantiomer of halothane and Figure 12-10B is the *S* enantiomer.

Enantiomers have identical physical properties, such as boiling point, melting point, and solubility in different solvents; they differ from each other in only two significant ways. The first, as mentioned above, is that enantiomers rotate plane-polarized light in opposite directions; this point has no practical toxicologic importance. The second is that enantiomers may interact in very different ways with other three-dimensional structures (such as proteins and other cell receptors), which is of both pharmacologic and toxicologic significance.

Perhaps the best analogy to explain the toxicologic and pharmacologic importance of stereochemistry is that of the way a hand (analogous to a molecule of drug or toxin) fits into a glove (analogous to the biologic site of activity). Consider the left hand as the *S* enantiomer and the right hand as the *R* enantiomer. There are, qualitatively, three different ways in which the hand can fit into (interact with) a glove.

First, if the glove is very pliable (such as a disposable latex glove), it can accept either the left hand or the right hand without difficulty; this is the case for halothane, whose *R* and *S* enantiomers possess

equal activity. Second, if a glove is constructed with greater (but imperfect) specificity, one hand will fit well and the other poorly; this is the case for many substances, such as epinephrine and norepinephrine, whose naturally occurring levorotatory enantiomers are 10-fold more potent than the synthetic dextrorotatory enantiomers. Finally, a glove can be made with exquisite precision, such that one hand fits perfectly, while the other hand does not fit at all. This is the case for physostigmine, in which the (â€“) enantiomer is biologically active, whereas the (+) enantiomer is inactive.

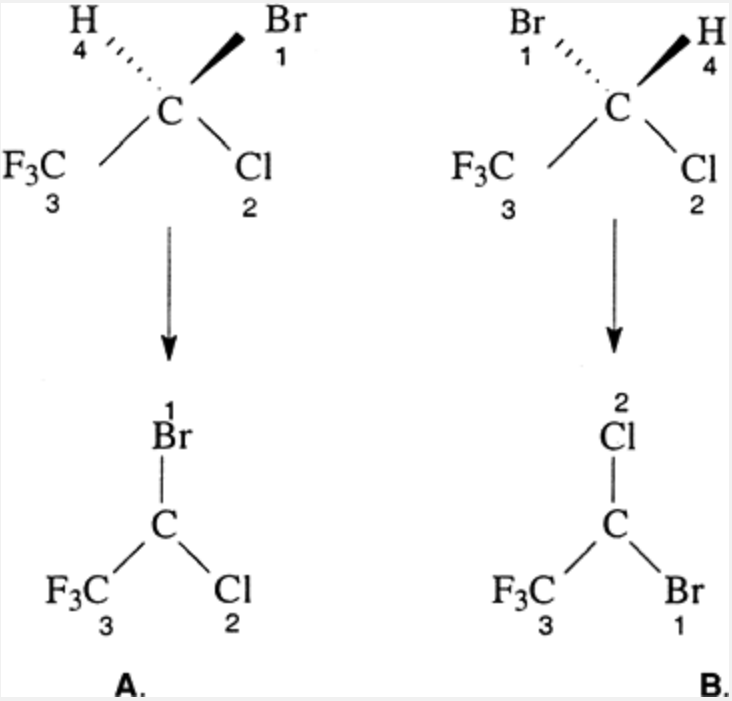

Figure 12-10. R and S enantiomers of halothane. A. The substituents increase in a clockwise fashion, so the configuration is R. B. The substituents increase in a counterclockwise fashion, so the configuration is S. In this projection, hydrogen atoms are directly behind the carbon atoms.

The above analogy is oversimplified, however, as one enantiomer of

a drug can be an agonist, while the other enantiomer is an antagonist. Dobutamine, for example, has one chiral carbon and thus two enantiomers. At the Î±$_1$ receptor, *l*-dobutamine is a potent agonist and *d*-dobutamine is a potent antagonist. Because dobutamine is marketed as a *racemic mixture* (a racemic mixture is a 1:1 mixture of enantiomers), however, these effects cancel each other out. Interestingly, at the Î²$_1$ receptor, *d*- and *l*-dobutamine have unequal agonist effects, with *d*-dobutamine approximately 10 times more potent than *l*-dobutamine.

Functional Groups

There is perhaps no concept in organic chemistry as powerful as that of the *functional group*. Functional groups are atoms or groups of atoms that confer similar reactivity on a molecule; of less importance is the molecule to which it is attached. Some representative functional groups in organic chemistry and toxicology are the *hydrocarbons* (*alkanes* and *alkenes*), *alcohols*, *carboxylic acids*, and *thiols.* These groups are discussed here because they illustrate important principles, not because this represents an exhaustive list of important functional groups in toxicology.

Hydrocarbons, as their name implies, consist of only carbon and hydrogen. *Alkanes* are hydrocarbons that contain no multiple bonds; they may be straight chain, usually designated by the prefix *n*- (Fig. 12-11A), or branched (isobutane, Fig. 12-11B). *Alkenes* contain carbon-carbon double bonds. *Alkynes*, which contain carbon-carbon triple bonds, are of limited toxicologic importance. Butane (lighter fluid) is an alkane, and gasoline is a mixture of alkanes.

Hydrocarbons are of toxicologic importance for two reasons: they are widely abused as inhalational drugs for their central nervous system depressant effects, and they can cause profound toxicity when aspirated. Although these effects are physiologically disparate, they are readily understood in the context of the chemical characteristics of the hydrocarbon functional group.

Hydrocarbons do not contain *polar groups*, or groups that introduce full or partial charges into the molecule; as such, they interact readily with other nonpolar substances, such as lipids or lipophilic substances. Hydrocarbons readily interact with the myelin of the CNS, disrupting normal ion channel function and

causing CNS depression. When aspirated, hydrocarbons interact with the fatty acid tail of surfactant, dissolving this protective substance and contributing to acute lung injury (Chaps. 79 and 102).

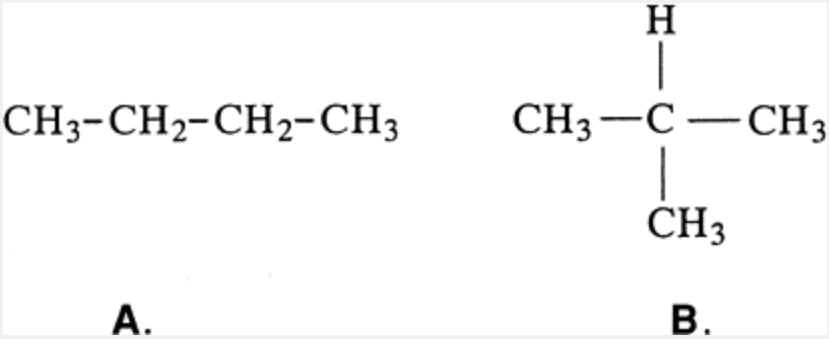

Figure 12-11. Two isomers of the 4 carbon alkane, butane. A. *n*-Butane. B. Isobutane.

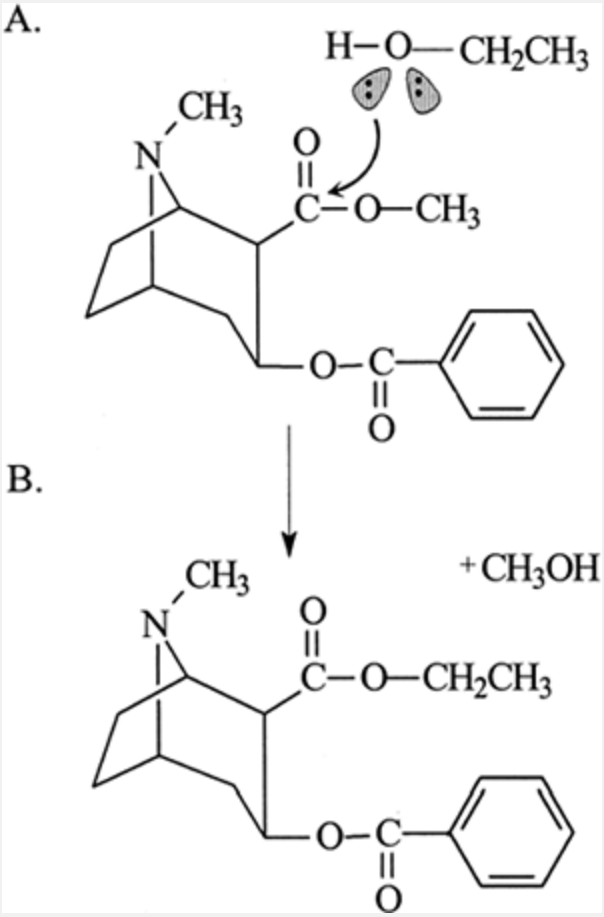

Figure 12-12. Reaction of cocaine with ethanol (A) to form cocaethylene and methanol (B).

Alcohols possess the hydroxyl (â€“OH) functional group, which adds polarity to the molecule and makes alcohols highly soluble in other polar substances, such as water. For example, ethane gas (CH_3CH_3) has negligible solubility in water, whereas ethanol (CH_3CH_2OH) is *miscible*, or infinitely soluble, in water. In biologic systems, alcohols are generally CNS depressants, but they can also act as nucleophiles. Ethanol may react with cocaine to form cocaethylene, a longer-acting and more vasoactive substance than cocaine itself (Fig. 12-12; see Chap. 74 for clinical details).

Alcohols can be primary, secondary, or tertiary, in which the reference carbon is bonded to 1, 2, or 3 carbons in addition to the hydroxyl group. Methanol, in which the reference carbon is bonded to no other carbons, is also a primary alcohol. The difference between primary, secondary, and tertiary structures is important, because although the alcohol functional group imparts many qualities to the molecule, the degree of substitution can affect the chemical reactivity. Primary alcohols can undergo multistep oxidation to form carboxylic acids, whereas secondary alcohols generally undergo one-step metabolism to form ketones, and tertiary alcohols do not readily undergo oxidation. This is a point of significant toxicologic importance, and is discussed in more detail later.

Alcohols can be named in many ways; the most common is to add *-ol* or *-yl alcohol* to the appropriate prefix. If the alcohol group is bonded to an interior carbon, the number to which the carbon is bonded precedes the suffix.

Carboxylic acids contain the functional group â€“COOH. As their name implies, they are acidic, and the pK_a of carboxylic acids are generally 4 or 5, depending on the substitution of the molecule. Carboxylic acids are capable of producing a significant anion gap metabolic acidosis, which is true whether the acids are endogenous or exogenous. Examples of endogenous acids are Î²-hydroxybutyric acid and lactic acid; examples of exogenous acids are formic acid (produced by the metabolism of methanol) and glycolic, glyoxylic, and oxalic acids (produced by the metabolism of ethylene glycol). Carboxylic acids are named by adding *-oic acid* to the appropriate prefix; the four-carbon straight-chain carboxylic acid is thus butanoic acid.

Thiols contain a sulfur atom, which usually functions as a nucleophile. The sulfur atom of *N*-acetylcysteine can regenerate glutathione reductase, and can also react directly with NAPQI to detoxify this electrophile. The sulfur atom of many chelating agents, such as dimercaprol and succimer, are nucleophiles that are very

effective at chelating electrophiles such as heavy metals. Thiols are generally named by adding the word *thiol* to the appropriate base. Thus, a 2-carbon thiol is ethane thiol.

As noted above, molecules with a given functional group often have more in common with molecules within the same functional group than they have in common with the molecules from which they were derived. The alkanes methane, ethane, and propane are straight chain hydrocarbons with similar properties. All are gases at room temperature, have almost no solubility in water, and have similar melting and boiling points. When these molecules are substituted with one or more hydroxide functional groups, they become alcohols: examples are methanol, ethanol, ethylene glycol (a *glycol* is a molecule that contains two alcohol functional groups), the primary alcohol 1-propanol, and the secondary alcohol 2-propanol (isopropanol). Each of these alcohols is a liquid at room temperature, and all are very water soluble. All have boiling points that are markedly different from the alkane from which they were derived, and quite close to each other.

In addition to conferring different physical properties on the molecule, the addition of the alcohol functional group also confers different chemical properties and reactivities. For example, methane, ethane, and propane are virtually incapable of undergoing oxidation in biologic systems. The alcohols formed by the addition of one or more hydroxyl groups, however, are readily oxidized by alcohol dehydrogenase (Fig. 12-13).

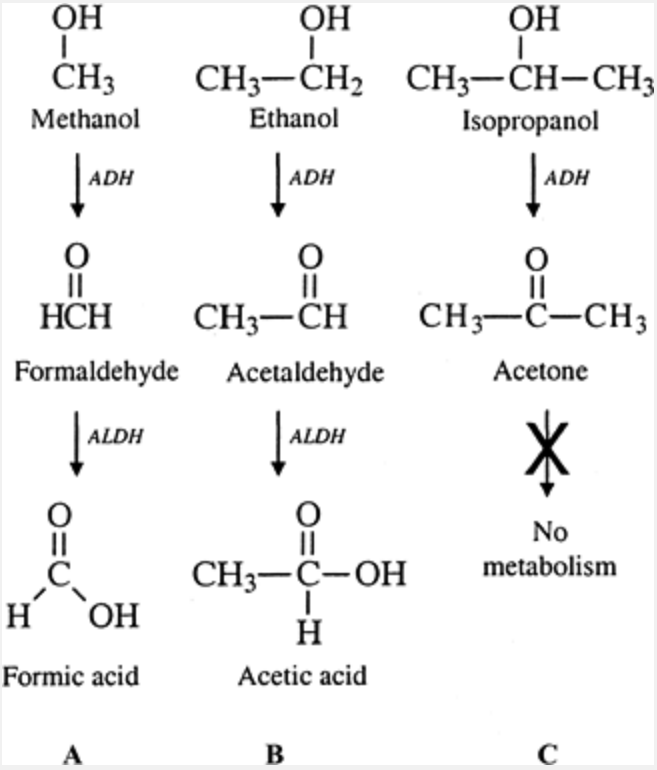

Figure 12-13. Oxidative metabolism of (A) methanol, (B) ethanol, and (C) isopropanol. Note that acetone does not undergo further oxidation in vivo. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase.

As Figure 12-13 indicates, the oxidation of the primary alcohols methanol and ethanol results in the formation of *aldehydes* (an aldehyde is a functional group in which a carbon atom contains a double bond to oxygen and a single bond to hydrogen), whereas the oxidation of the secondary alcohol isopropanol resulted in the formation of a *ketone* (a ketone is a functional group in which a carbon is double-bonded to an oxygen atom and single-bonded to two separate carbon atoms). Although both aldehydes and ketones contain the *carbonyl group* (a carbon-oxygen double bond),

aldehydes and ketones are distinctly different functional groups, and have different reactivity patterns. For instance, aldehydes can undergo enzymatic oxidation to carboxylic acids (Fig. 12-13A and B), whereas ketones cannot (Fig. 12-13C).

It is here that recognition of functional groups helps to understand the potential toxicity of an alcohol. Methanol, ethanol, and isopropanol are all alcohols; as such, their toxicity before metabolism is expected to be (and in fact is) similar to that of ethanol, producing CNS sedation.

Because these toxins are primary and secondary alcohols, all three can be metabolized to a carbonyl compound, either an aldehyde or a ketone. Here, however, the functional groups on the molecules have changed; whereas aldehydes can be metabolized to carboxylic acids (which can, in turn, cause an anion gap acidosis), ketones cannot. It is for this reason that methanol and ethylene glycol can cause an anion gap acidosis, and isopropanol cannot (Chap. 103).

The concept of functional groups, however useful, has limitations. For example, although both formic acid and oxalic acid are organic acids, they cause different patterns of organ system toxicity. Formic acid is a mitochondrial toxin, and exerts effects primarily in areas (such as the retina or basal ganglia) that poorly tolerate an interruption in the energy supplied by oxidative phosphorylation. Conversely, oxalic acid readily precipitates calcium and is toxic to renal tubular cells, which accounts for the hypocalcemia and nephrotoxicity that are characteristic of severe ethylene glycol poisoning. The concept of the functional group is thus an aid to understanding chemical reactivity, but not a substitute for a working knowledge of the toxicokinetic or toxicodynamic effects of xenobiotics in living systems.

Summary

Understanding key principles in inorganic and organic chemistry

provides insight into the mechanisms by which xenobiotics act. The periodic table forms the basis for inorganic chemistry and provides insight into the expected reactivity, and to a large extent the clinical effects, of any element. A growing understanding of how reactive species are formed and how they interfere with physiologic processes has led to new insights in the pathogenesis and treatment of toxin-mediated diseases. Organic chemistry forms the basis of life, and is essential to an understanding of biochemistry and pharmacology. Because many xenobiotics are organic compounds there is direct relevance to medical toxicology.

Chapter 13

Biochemical and Metabolic Principles

Kathleen A. Delaney

Xenobiotics are compounds that are foreign to a living system. Xenobiotic toxins injure living organisms by interfering with critical metabolic processes, by causing structural damage to cells, or by altering the cellular genetic material. The specific biochemical sites of actions that disrupt metabolic processes are well characterized for many xenobiotics although mechanisms of cellular injury are not. This chapter focuses on those general biochemical principles that are relevant to an understanding of the injurious effects of toxic xenobiotics. It also reviews the current understanding of the biotransformation enzymes and their clinical implications.

The capacity of a xenobiotic to produce injury in a living organism is affected by many factors that include its absorption, distribution, elimination, site of activation or detoxification, site of action, and capability to cross membranes to access a particular organ. Sites of action include the active sites of enzymes or receptor binding sites, DNA, and lipid membranes. The route of

exposure to a toxin may confine damage primarily to one organ: for example pulmonary injury that follows inhalation; GI injury that follows a caustic ingestion; or injury to the skin following dermal exposure. Hepatocellular injury results when a toxic xenobiotic is delivered to the liver, either by the portal venous system following ingestion, or by the hepatic artery that carries blood with xenobiotics absorbed from other sites of exposure. Various factors affect the ability of a toxin to access a particular organ. For example, many potentially toxic xenobiotics fail to produce injury because they cannot cross the bloodâ€“brain barrier. The negligible CNS effects of the mercuric salts when compared with organic mercury compounds are related to their inability to penetrate the CNS. Two potent biologic toxinsâ€”ricin (from *Ricinus communis*) and Î±-amanitin (from *Amanita phalloides*)â€”block protein synthesis through the inhibition of RNA polymerase. Their very different clinical effects are related to tissue accessibility. Ricin has a special binding protein that enables it to gain access to the endoplasmic reticulum in GI mucosal cells, where it inhibits cellular protein synthesis and causes severe diarrhea.[48] Î±-Amanitin is transported into hepatocytes by bile salt transport systems, where inhibition of protein synthesis results in cell death.[43 , 50] The electrical charge on a toxin also affects its ability to enter a cell. Unlike the ionized (charged) form of a xenobiotic, the uncharged form is lipophilic and passes easily through lipid cell membranes to enter the systemic circulation. The pK_a of an acidic xenobiotic (HA â† A^- + H^+) is the pH at which 50% of the molecules are charged (A^- form) and 50% are uncharged (HA form). A xenobiotic with a high pK_a is more likely to be absorbed in an acidic environment where the uncharged form predominates. Hence, the site of absorption of a toxin in the gastrointestinal tract; the acidic environment of the stomach or the alkaline environment of the small intestine; is affected by its pK_a . See Chap. 9 for a more extensive discussion of basic principles of pharmacokinetics.

General Enzyme Concepts

The capability to detoxify and eliminate both endogenous toxins and exogenous xenobiotics is crucial to the maintenance of physiologic homeostasis and normal metabolic functions for all organisms. A simple example is the detoxification of cyanide, a potent cellular poison that is ubiquitous in the environment and is also a product of normal metabolism. Mammals have evolved the enzyme rhodanese, which combines cyanide with thiosulfate to create the less toxic, renally excreted compound thiocyanate.[85]

The majority of xenobiotics have lipophilic properties that facilitate absorption across cell membranes in organs that are portals of entry to the body: the skin, GI tract, and lungs. The liver has the highest concentration of enzymes that metabolize xenobiotics. Enzymes found in the liquid matrix of hepatocytes that are specific for alcohols, aldehydes, esters, or amines act on many different substrates within these broad classes. Enzymes that act on more lipophilic xenobiotics, including the CYP (formerly cytochrome P450) enzymes, are embedded in the lipid membranes of the endoplasmic reticulum. When cells are mechanically disrupted and centrifuged, these membrane-bound enzymes are found in the pellet, or microsomal fraction; hence, they are called microsomal enzymes. Enzymes located in the liquid matrix of cells are called cytosolic enzymes and are found in the supernatant when disrupted cells are centrifuged. Cytosolic enzymes are present in all tissues.[42]

Biotransformation Overview

The term *biotransformation* refers to the alteration of a xenobiotic as a result of enzyme action.[51] Biotransformation usually results in â€œdetoxification,â€• a reduction in the toxicity of a substance and its removal from the body. In some cases, however, the metabolites produced may be more toxic than the parent

xenobiotic. In this case, the biotransformation results in â€œtoxicationâ€• or â€œmetabolic activation.â€•[82] A single xenobiotic may be a substrate for biotransformation by

several metabolic pathways, some resulting in detoxification and others in metabolic activation. The predominant pathway for the biotransformation of an individual toxin is determined by many factors that include the availability of cofactors, the effect of substrate concentration on the rate of substrate metabolism (reflected by the K_m [Michaelis-Menten dissociation constant] of the biotransformation enzyme and by saturation effects), changes in the concentration of the enzyme caused by induction, and the presence of inhibitors.[82] The production of toxic metabolites by a given biotransformation process is also affected by the concentration of protective agents such as glutathione.

The likelihood that a xenobiotic will undergo biotransformation depends on its chemical nature. Ionized compounds such as carboxylic acids are less likely to cross a lipid membrane to enter the body. When they do, the kidneys rapidly eliminate them. Very volatile compounds, such as dichloromethane, are expelled promptly via the lungs. Neither of these groups of xenobiotics undergo significant enzymatic metabolism. Nonpolar, lipophilic xenobiotics that are less soluble in aqueous fluids require biotransformation to more water-soluble compounds before they can be excreted.[51]

Most biotransformation reactions have two sequential phases. Phase I reactions add functional groups to lipophilic xenobiotics, converting them into more chemically reactive metabolites. This is usually followed by phase II reactions that conjugate the reactive products of phase I with other molecules that render them more water soluble, detoxifying the xenobiotic and facilitating its elimination. Some xenobiotics undergo only a phase I or a phase II reaction.

Oxidation Overview

Much of the activity that occurs during biotransformation or within critical metabolic pathways results in the oxidation or reduction of carbon. Oxidation involves the transfer of electrons from a substrate molecule to an electron-seeking (electrophilic) molecule, leading to reduction of the electrophilic molecule and oxidation of the substrate. These oxidation-reduction reactions are often coupled to the cyclical oxidation and reduction of a cofactor, such as the pyridine nucleotides, NADPH/$NADP^+$ (nicotinamide adenine dinucleotide phosphate) or NADH/NAD^+ (nicotinamide adenine dinucleotide). These nucleotides alternate between their reduced (NADPH, NADH) and oxidized ($NADP^+$, $NADH^+$) forms. The terminal transfer of electrons to oxygen also provides a mechanism for oxidation of substrates.

Electrons resulting from the catabolism of energy sources are extracted by NAD^+ , forming NADH. NADH transports the electrons into the mitochondria where they enter the cytochrome-mediated electron transport system. This results in the production of adenosine triphosphate (ATP), the reduction of molecular oxygen, and the regeneration of NAD^+ , a process that is critical to the maintenance of oxidative metabolism. NADPH serves primarily to carry electrons from the oxidative reactions of catabolism to the synthetic (anabolic) reactions of biosynthesis. NADPH is also coupled to the reduction of glutathione, which plays an important role in the protection of cells from oxidative damage. The main source of NADPH is the pentose phosphate pathway (also called the hexose-monophosphate shunt), an alternative pathway for the oxidation of glucose.

The oxidation state of a specific carbon atom can be determined by counting the number of carbon and hydrogen atoms to which the carbon atom is connected. The more reduced a carbon, the higher the number of carbon-hydrogen bonds. For example, the carbon in methanol (CH_3 OH) has three carbon-hydrogen bonds

and is more reduced than the carbon in formaldehyde (H_2 C = O), which has two. Carbon-carbon double bonds count as one bond.

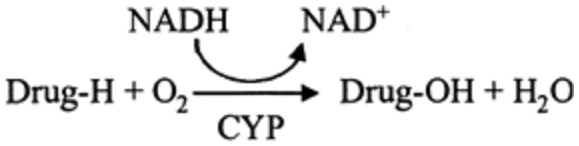

Figure 13-1. A common oxidation reaction catalyzed by CYP enzymes: the hydroxylation of Drug-H to Drug-OH.

Phase I Biotransformation Reactions

Phase I reactions are predominantly oxidation reactions that add functional groups suitable for conjugation during phase II. These include hydroxyl (-OH), sulfhydryl (-SH), amino (-NH_2), aldehyde (-COH), or carboxyl (-COOH) moieties.[42] Elements such as nitrogen, sulfur, and phosphorus that do not contain carbon are also oxidized in phase I reactions. Other phase I reactions result in hydrolysis, hydration, and dehalogenation.[82]

The CYP enzymes are cytochromes bound to the lipid membranes of the endoplasmic reticulum that use a cyclical transfer of electrons between oxidized (Fe^{3+}) or reduced (Fe^{2+}) forms of iron. They are responsible for the majority of phase I oxidative biotransformation reactions. Membrane-bound flavin monooxygenase (FMO), another NADPH-dependent oxidase located in the endoplasmic reticulum, makes an important contribution to the oxidation of amines and other compounds containing nitrogen, sulfur, or phosphorus.[51] A common oxidation reaction catalyzed by CYP enzymes is illustrated by the hydroxylation or monooxidation of a foreign compound R-H to R-OH (Fig. 13-1).[46]

The alcohol, aldehyde, and ketone oxidation systems are predominantly cytosolic enzymes that catalyze phase I oxidation-reduction reactions using NADH/NAD^+ .[30 , 44 , 49 , 82] Two classic phase I oxidation reactions are the metabolism of ethanol to

acetaldehyde by alcohol dehydrogenase (ADH) followed by the metabolism of acetaldehyde to acetic acid by aldehyde dehydrogenase (ALDH) (Fig. 13-2). Alcohol dehydrogenase, which oxidizes many different alcohols, is found in the liver, lungs, kidney, and gastric mucosa.[2 , 49] Females have less ADH in their gastric mucosa than males. This results in decreased first-pass metabolism of alcohol and increased alcohol absorption. Some populations, particularly Asians, are deficient in ALDH, resulting in increased acetaldehyde levels and symptoms of the acetaldehyde syndrome.[2 , 49]

$$CH_3CH_2OH + NADPH + H^+ + O_2 \xrightarrow{CYP2E1} CH_3CHO + NADP^+ + 2\,H_2O$$

$$CH_3CH_2OH + NAD^+ \xrightarrow{\text{Alcohol dehydrogenase}} CH_3CHO + NADH + H^+$$

Figure 13-2. Conversion of ethanol to acetaldehyde by CYP2E1 that uses reduced NADPH and oxygen and by alcohol dehydrogenase that uses oxidized NAD^- . This illustrates how NAD and NADP can function in oxidation reactions in both their oxidized and reduced forms. Alcohol dehydrogenase has a low K_m for ethanol and is the predominant metabolic enzyme in moderate drinkers.

Overview of the CYP Enzymes

The most numerous and important of the enzymes involved in phase I oxidation reactions are the CYP enzymes. This nomenclature derives from the complex cytochrome protein structure that is the basic unit of the enzyme and the spectrophotometric characteristics of its associated heme molecule. When bound to carbon monoxide, the maximal absorption spectrum of the reduced CYP (Fe^{2+}) enzyme occurs at 450 nm.[59 , 62] CYP enzymes, which incorporate 1 atom of oxygen

into the substrate and 1 atom into water, were once called â€œmixed-function oxidases.â€• This activity is now referred to as a â€œmicrosomal monooxygenation reaction.â€• [59, 82] These biotransformation CYP enzymes, bound to the lipid membranes of the smooth endoplasmic reticulum, are distinct from the cytochromes that comprise the mitochondrial electron transport chain.[59]

Although most of the CYP isozymes are found in the liver, high levels can be found in extrahepatic tissues, particularly the gastrointestinal tract.[19] The lungs,[54, 59] heart,[63] and brain[63] also have discernible amounts of CYP isozymes. Each tissue has a unique profile of CYP enzymes that determines its sensitivity to different xenobiotics.[19] The CYP enzymes in the enterocytes of the small intestine actually contribute significantly to â€œfirst-passâ€• metabolism of some xenobiotics.[41, 59] Corrected for tissue mass, the CYP enzyme system in the kidneys is as active as that in the liver. The activity of the renal CYP enzymes is decreased in patients with chronic renal failure, with relative sparing of CYP1A2, 2C19, and 2D6 compared with 3A4 and 2C9.[13]

More than 2500 different genes coding for CYP enzymes have been identified.[59, 60] CYP enzymes are categorized according to the similarities of their amino acid sequences. They are in the same â€œfamilyâ€• if they are more than 40% similar, and same â€œsubfamilyâ€• if they are more than 55% similar. Families are designated by an Arabic numeral, subfamilies by a capital letter, and each individual enzyme (or isozyme) by another numeral, resulting in the nomenclature CYPnXm for each isozyme. For example, CYP3A4 is an isozyme of the CYP3 family and of the CYP3A subfamily.[27, 58] CYP enzymes catalyze a diverse number of reactions that include both biosynthetic and xenobiotic biotransformation. Most xenobiotic metabolism is done by the CYP1, CYP2, and CYP3 families, with a small amount done by the CYP4 family.[13, 84] It is estimated that the total number of exogenous CYP enzyme substrates may exceed 200,000

chemicals.[47]

Nearly 90% of oxidative transformation of xenobiotics is accomplished by 6 CYP enzymes: 1A2, 2C9, C19, 2D6, 2E1, and 34A (Table 13-1).[59 , 75] The approximate amounts of liver CYP enzymes are 3A4 (40â€“55%), 2D6 (30%), 2C9 and 2C19 (10â€“20%), 2E1 (7%), and 1A2 (2%).[46 , 62]

TABLE 13-1. Characteristics of Different CYP Isozymes[1,13,19,46,47,54,59,62,63]

Substrate and CYP Enzyme Specificity

In vitro models, which are relatively inexpensive and involve no human subjects, have been used to define the specificities of CYP enzymes for their substrates and inhibitors.[28] Unfortunately, the ability of an enzyme to metabolize a substrate in a test tube does not always predict its role in the cell. These models use substrate and inhibitor concentrations that are much higher than would be encountered in vivo, and the mathematical models that extrapolate to clinically relevant processes produce conflicting results.[28] This has resulted in discrepancies in reported substrates, inhibitors, and inducers of specific CYP enzymes. Discordance between genetic type and phenotypic expression is routinely observed.[6]

The substrate specificity of a CYP enzyme greatly affects its role in biotransformation.[29] Some CYP enzymes, particularly those involved in biosynthesis, are highly selective. This is the case for CYP21A2, a mitochondrial enzyme that specifically catalyzes the 21-hydroxylation of progesterone, an important step in steroid synthesis.[31] Most CYP enzymes involved in xenobiotic biotransformation have low substrate specificity and can metabolize many substances.[29] This lack of substrate specificity allows the ongoing biotransformation of a substance in spite of deficiency or inhibition of a specific enzyme. When a substrate can be biotransformed by more than one CYP enzyme, the enzyme that has the highest affinity for the substrate usually predominates at low substrate concentrations, while enzymes with lower affinity may predominate at high concentrations. This transition is usually

concomitant with, but is not dependent on, the saturation of the catalytic capacity of the primary enzyme as it reaches its maximum rate of activity.[29, 31] The K_m, which is defined as the concentration of enzyme that results in 50% of maximal enzyme activity, describes this property of enzymes. For example, ADH in the liver has a very low K_m for ethanol, making it the primary

metabolic enzyme for ethanol when concentrations are low.[49] Ethanol is also biotransformed by the CYP2E1 enzyme. CYP2E1 has a high K_m for ethanol and only functions when ethanol levels are high. It accounts for only a small fraction of ethanol metabolism in moderate drinkers, but accounts for significantly more biotransformation in alcoholics. As another example, diazepam is metabolized by both CYP2C19 and CYP3A4. However, the affinity of CYP3A4 for diazepam is so low (ie, the K_m is high) that the majority of diazepam is metabolized by CYP2C19.[37]

The CYP enzymes that biotransform a specific xenobiotic cannot be predicted by its drug class. Whereas fluoxetine and paroxetine are both major substrates and potent inhibitors of CYP2D6, sertraline is not extensively metabolized and exhibits minimal interaction with other antidepressants.[5] The majority of Î²-hydroxy-Î²-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors are metabolized by CYP3A4 (lovastatin, simvastatin, and atorvastatin); however, fluvastatin is metabolized by CYP2D6 and pravastatin undergoes virtually no CYP enzyme metabolism at all.[32] Among angiotensin-II receptor blockers, losartan and irbesartan are metabolized by CYP2C9, while valsartan, eprosartan, and candesartan are not substrates for any CYP enzyme. In addition, losartan is a prodrug whose active metabolite provides most of the pharmacologic activity, while irbesartan is the primary active compound. For these two drugs the inhibition of CYP2C9 is predicted to have opposite effects.[24]

The specificity of enzyme inhibition may be affected by the concentration of an inhibitor. Omeprazole is a potent inhibitor of CYP2C19, CYP2C9, and CYP3A4.[32, 40] At lower concentrations omeprazole selectively inhibits CYP2C19, a specificity that is lost at higher concentrations.[28] The induction of CYP3A4 by rifampin in HIV-positive patients is associated with decreases in blood concentrations of the protease inhibitors saquinavir and ritonavir by 80% and 35%, respectively.[27]

The substrate selectivity of some CYP enzymes is determined by molecular, electrical, and physicochemical properties of the substrates. The CYP1A subfamily has greater specificity for planar polyaromatic substrates such as benzo[*a*]pyrene. The CYP2E subfamily targets low-molecular-weight, hydrophilic xenobiotics, whereas CYP3A4 has increased affinity for lipophilic compounds. Substrates of CYP2C9 are usually weakly acidic, whereas those of CYP2D6 are more basic.[47] High specificity can also result from key structural considerations such as stereoselectivity. Some xenobiotics are racemic mixtures of stereoisomers. These may be substrates for different CYP enzymes and have distinct affinities for the enzymes, resulting in different rates of metabolism. For example, R-warfarin is biotransformed by CYP3A4 and CYP1A2, whereas S-warfarin is metabolized by CYP2C9.[13 , 82]

Genetic Polymorphism

A simple model of the human genome has a DNA sequence for each gene, with a corresponding allele on each chromosome.[89] For enzymes, the translation of these DNA sequences into proteins results in the functionally defined phenotypic expression of the genes. When a genetic variation occurs, the result is either a rare defect or a polymorphism. A polymorphism is a genetic change that occurs in at least 1% of the human population.[89] A genetic change in a biotransformation enzyme may result in an alteration of the activity rate of that enzyme.[6 , 89]

The genetic polymorphism of human populations results in very significant differences in the abilities of individuals to biotransform specific xenobiotics. Differences in biotransformation capacity that lead to toxicity, once thought to be â€œidiosyncratic,â€• are likely caused by these inherited, unmeasured differences in the genetic complement of the individual. A familiar consequence of genetic polymorphism is the inheritance of rapid or slow â€œacetylatorâ€• phenotypes. Acetylation is a phase II

biotransformation that is especially important for the biotransformation of amines (R-NH_2) or hydrazines (NH_2 â€“NH_2). Slow acetylators may be at increased risk of toxicity associated with the slower biotransformation of nitrogen-containing xenobiotics such as isoniazid (INH), procainamide, hydralazine, and sulfonamides.[22 , 66]

Three major metabolizer phenotypes are recognized: extensive (normal), poor (slow), and ultraextensive (rapid).[46 , 58 , 89] The CYP2C19 and CYP2D6 genes are highly polymorphic (Table 13-1).[36] The CYP2D6 gene, which has 76 different alleles, is associated with ultraextensive metabolism in 30% of Ethiopians, 10% of Southern Europeans, and 1â€“2% of Northern Europeans.[36 , 46] It is associated with poor metabolism in 5â€“10% of whites, 2â€“8% of African Americans, and fewer than 1% of Asians.[13] The poor metabolizer phenotype of the CYP2C19 gene is found in 3â€“5% of whites, 15â€“20% of Asians, and 20% of African Americans. The CYP2C9 gene exhibits only mild polymorphism; poor metabolism occurs in 1â€–3% of whites and in 1â€–2% of Asians or African Americans.[13 , 59] Other CYP genes have varied degrees of polymorphism. In some cases there is discordance between the genetically determined biotransformation capacity and its phenotypic expression. This creates confusion when genotype alone is used to model expressions of human biotransformation capability.[6]

Inherited variations in the genes that code for enzymes in important metabolic pathways affect the toxicity of a xenobiotic by altering the response to or the disposition of the xenobiotic. A classic example of altered response to a xenobiotic is seen in glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD is a critical enzyme in the pentose phosphate shunt, a metabolic pathway located in the red blood cell (RBC) that produces NADPH, which is required to maintain RBC glutathione in a reduced state. In turn, reduced glutathione prevents hemolysis during oxidative stress.[82] In patients deficient in G6PD, oxidative stress produced

by electrophilic or oxidative xenobiotics results in hemolysis.

Besides being substrates, xenobiotics may induce or inhibit the activity of different CYP enzymes.[89] A xenobiotic may inhibit or induce the activity of an enzyme even though it is not a substrate at that CYP site. For example, quinidine is biotransformed by CYP3A4, but it is a potent inhibitor of CYP2D6.[54]

Heterogeneity of CYP enzymes results in differences in metabolic activity between individual patients. A prodrug may not be metabolized to its active form because the patient is a poor metabolizer or is taking a xenobiotic that inhibits the respective CYP enzyme.[27] Conversely, a drug may not reach a therapeutic level because the patient is an ultrarapid metabolizer or is taking a second drug that induces the respective CYP enzyme.[89]

Pharmacogenetics is the study of genetic variations that affect differences in individual responses to medications. This refers to the full spectrum of genes that determine drug efficacy and safety, including genetic factors that determine differences in drug distribution, target

proteins, and metabolism.[89] The goal of the study of pharmacogenetics is to characterize an individual patient's biotransformation enzyme genotype to allow prediction of toxicity and optimize the therapeutic effects of important drugs.[89]

Induction and Inhibition of CYP Enzymes

Enzyme induction is usually caused by increased expression of CYP genes, resulting in a net increase of enzyme protein synthesis. Induction of an enzyme results in more rapid biotransformation of a xenobiotic that is affected by the same enzyme. Inducer xenobiotics are often substrates for the affected CYP enzyme, amplifying the detoxification response during prolonged periods of

xenobiotic challenge.[86] Increased enzyme synthesis starts with the binding and activation of chromosomal â€œnuclear receptorsâ€• by inducer xenobiotics, which leads to increased transcription of gene specific messenger RNA.[46, 84] Nuclear receptors include PXR in the CYP3A family, CAR in the CYP family, and AhR in the CYP1A subfamily. The observation that the induction of CYP1A1 by omeprazole is not mediated by the AhR nuclear receptor suggests that there are other mechanisms of gene induction that do not use nuclear receptors.[58]

Because the clinical manifestations of enzyme induction rely on protein synthesis, there is a time delay in the onset and offset relative to starting and stopping the inducing xenobiotic. In addition, xenobiotics with long half-lives require longer periods to reach steady-state concentrations that maximize induction. CYP enzyme induction caused by xenobiotics with long half-lives, such as phenobarbital or fluoxetine, may fully manifest only after weeks of exposure. Conversely, xenobiotics with short half-lives, such as rifampin or venlafaxine, can reach maximum induction within days.[13, 27]

Similar pharmacokinetic considerations affect the clinical manifestations of enzyme inhibition. Competitive inhibition as a result of binding at substrate sites usually begins within hours.[13] Because the degree of inhibition correlates with the concentration of the involved xenobiotic, the time required to reach the maximal effect correlates with the half-life of the xenobiotic in question.[13] Although competitive inhibition is a common form of CYP enzyme function, it is the least likely mechanism of inhibition to be clinically relevant.[24]

Another mechanism of inhibition results from competition between one xenobiotic and a metabolite of a second xenobiotic at its CYP enzyme substrate binding site. For example, the metabolites of clarithromycin and erythromycin produced by CYP3A inhibit further CYP3A activity. The effect is reversible and usually increases with

repeated dosing. A relatively rare third mechanism is the irreversible inhibition of a CYP enzyme by the reactive metabolite of a second xenobiotic at its substrate binding site. This so-called suicide inhibition results in the destruction of the bound CYP enzyme. Biotransformation by the affected CYP enzyme does not resume until new enzyme is produced.[24 , 79]

Drugâ€“Drug and Drugâ€“Chemical Interactions with CYP Enzymes

Adverse reactions to medications, including drugâ€“drug interactions, are estimated to be one of the top 10 causes of death in hospitalized patients, the risk of which increases with the number of drugs taken. Fifty percent of adverse reactions are possibly related to pharmacogenetic factors.[89] The most significant interactions are mediated by CYP enzymes.[59]

Drugâ€“drug interactions that involve CYP enzymes can be either pharmacodynamic or pharmacokinetic in nature.[13] Pharmacodynamic interactions occur when the mechanism of action of one xenobiotic enhances or diminishes the effect produced by a second xenobiotic. Pharmacokinetic interactions occur when the effect of one xenobiotic alters the absorption, distribution, metabolism, and/or elimination of another, leading to a change in the effective concentration of the second xenobiotic at its site of action.[13] Drug interactions will be more significant if the xenobiotics have significant CYP enzyme specificity. For example, the potent and specific CYP3A inhibitor itraconazole prevents the metabolism of astemizole and simvastatin. Blockade of the biotransformation of these CYP3A-specific substrates has resulted in torsade de pointes dysrhythmias or rhabdomyolysis.[1]

Many drugâ€“drug interactions are not apparent in initial drug studies. Because of the overlapping substrate specificities of many CYP enzymes, drugâ€“drug interactions are not predictable even

when the specific enzyme responsible for the metabolism of a drug is known and can be quantitated. The life-threatening interactions between terfenadine and ketoconazole, both metabolized by CYP3A4, were not appreciated until 11 years after terfenadine was marketed.[59 , 75]

Many environmental and â€œnondrugâ€• xenobiotics interact with the CYP enzymes. St. John's wort, an herb marketed as a natural antidepressant, induces multiple CYP enzymes including 1A2, 2C9, and 3A4. The induction of CYP3A4 by St. John's wort is associated with a 57% decrease in effective serum levels of Indinavir when given comcomittantly.[65] Xenobiotics contained in grapefruit juice, such as naringin and furanocoumarins, are both substrates and inhibitors of CYP3A4. They inhibit the first-pass metabolism of CYP3A4 substrates by inhibiting CYP3A4 activity in both the gastrointestinal tract and the liver.[17] Polycyclic hydrocarbons found in charbroiled meats and in cigarette smoke induce CYP1A2. For smokers who drink coffee, levels of caffeine, a CYP1A2 substrate, will be increased following cessation of smoking.[46]

Specific CYP Enzymes

CYP1A2

This enzyme is involved in the metabolism of 15% of all pharmaceuticals used today.[13] As noted above, the CYP1 family is induced by polycyclic hydrocarbons found in cigarette smoke and charred food. This family bioactivates several procarcinogens including benzo[*a*]pyrene.[62] Xenobiotics activated by CYP1 enzyme in the gastrointestinal tract are linked to colon cancer.[59]

CYP3A4

CYP3A4 is the most abundant CYP in the human liver, comprising anywhere from 40â€“55% of the mass of hepatic CYP enzymes.[13 ,

[32, 46] The CYP3A4 enzyme is the most common one found in the intestinal mucosa and is responsible for much first-pass drug metabolism.[13]

More than 120 xenobiotics are metabolized by CYP3A4. It is involved in the biotransformation of 50â€“60% of all pharmaceuticals.[60, 86] Substrates include dihydropyridine calcium channel blockers, cyclosporine, cisapride, many opioids, and many HMG-CoA reductase inhibitors.[32] An excellent example of an adverse drug interaction related to this enzyme is the QT interval prolongation and spontaneous ventricular tachycardia that occurred in patients taking terfenadine or astemizole in combination with ketoconazole or erythromycin.[64, 75] Ketoconazole inhibits CYP3A4, causing a 15- to 72-fold increase in serum levels of terfenadine.[59]

Bioflavonoids in grapefruit juice decrease metabolism of some substrates by 5- to 12-fold.[13, 27, 59] The CYP3A4 enzyme does not exhibit genetic polymorphism; however, there are large interindividual variations in enzyme levels.[27]

CYP2D6

Approximately one-third of human CYP enzymes are in the CYP2 enzyme family, which, with 76 alleles, exhibits the greatest degree of genetic polymorphism.[46] Twenty-five percent of all drugs used today, including 50% of the commonly used antipsychotics, are substrates for CYP2D6. It is sometimes called debrisoquine hydrolase as it was first identified with studying the metabolism of the antihypertensive agent debrisoquine.[13, 36, 59]

Approximately 5â€“10% of whites and 2â€“8% of African Americans are poor metabolizers of CYP2D6 substrates.[13] Perhexiline, an antianginal agent marketed in Europe in the 1980s, caused severe liver disease and peripheral neuropathy in persons with a demonstrated inability to metabolize debrisoquine.[74]

Decreased activity of CYP2D6 was implicated in the development of severe lactic acidosis in some patients taking phenformin.[61]

CYP2E1

This enzyme comprises 7% of the total CYP enzyme content in the human liver.[62] Although not considered to demonstrate genetic polymorphism, genetic changes account for a 2-fold increase in nasopharyngeal cancer in Chinese persons who smoke. Besides CYP1A2, this is the only other CYP enzyme linked to cancer.[59] CYP2E1 is induced by a number of xenobiotics including ethanol, phenobarbital, isoniazid, phenytoin, and cigarette smoke.[45, 90] The induction of CYP2E1 is associated with increased liver injury by reactive metabolites of carbon tetrachloride and of bromobenzene (Chap. 26).[33] During the metabolism of substrates that include carbon tetrachloride, ethanol, acetaminophen, paranitrophenol, aniline, and *N* -nitrosomethylamine, CYP2E1 actively produces free radicals and other reactive metabolites associated with adduct formation and lipid peroxidation (Chap. 26).[20] CYP2E1 is inhibited by acute elevations of ethanol, an effect illustrated by the capacity of acute administration of ethanol to inhibit the metabolism of acetaminophen.[10] The chronic ingestion of ethanol hastens its own metabolism through enzyme induction.

CYP2C9

The CYP2C9 enzyme is the most abundant isozyme of the CYP2C enzyme family which, with CYP2C19, comprises approximately 10â€“20% of the CYP enzymes in the liver.[46] This enzyme is associated with polymorphism; poor metabolism occurs in 1â€“3% of whites and in 1â€–2% of Asians and African Americans.[13, 59] This enzyme biotransforms warfarin-S, the most active isomer of warfarin. There is an association between slow metabolism and an increased risk of bleeding in patients on warfarin.[3, 52]

Phase II Biotransformation Reactions

Phase II biotransformation reactions are synthetic reactions that catalyze rapid conjugation of the products of phase I reactions with endogenous molecules such as glucuronic acid, glutathione, sulfate, or some amino acids, such as glycine, glutamic acid, and taurine. This conjugation terminates the pharmacologic activity of the xenobiotic and greatly increases its water solubility and excretability.[51, 82] Most phase II reactions occur in the cytosol and are faster than phase I reactions.[51]

Glucuronides are the most common endogenous conjugating agents.[51] Glucuronyl transferase conjugates glucuronic acid donated by uridine diphosphate glucuronic acid (UDPG), with the nitrogen, sulfhydryl, hydroxyl, or carboxyl groups of foreign or endogenous compounds. The more polar conjugated xenobiotics are readily eliminated because of the ionized carboxyl group that is recognized by both biliary and renal organic acid active transport systems. Smaller conjugates usually undergo renal elimination, whereas larger ones undergo biliary elimination.[51]

Sulfate conjugates are highly ionized and very water soluble. The addition of sulfate donated by oxidized cysteine to the hydroxyl group of alcohols and aryl amines is a common mechanism for phase II detoxification.[51] The biotransformation of phenol is an interesting example of the effect of pharmacokinetics of biotransformation enzymes on the metabolism of an individual substrate. The affinity of sulfate for phenol is very high (the K_m is low), so that when low doses of phenol are administered, the predominant excretion product is the sulfate ester. Because the capacity of this reaction is readily saturated, when high doses of phenol are administered glucuronidation becomes the main method of detoxification.

Glutathione-S transferases catalyze the conjugation of the tripeptide glutathione (glycine-glutamate-cysteine, or GSH) with a

diverse group of reactive, electrophilic metabolites of phase I CYP enzymes. The reactive compounds initiate an attack on the sulfur group of cysteine, resulting in conjugation with GSH that detoxifies the reactive metabolite. Some GSH-conjugates are directly excreted. More commonly, the glycine and glutamate residues are cleaved and the remaining cysteine is acetylated to form an *N* -acetylcysteine (mercapturic acid) conjugate that is readily excreted in the urine. A familiar example of this detoxification is the avid binding of *N* -acetyl-*p* -benzoquinoneimine (NAPQI), the toxic metabolite of acetaminophen, by glutathione.[8, 11]

Mechanisms of Cellular Injury

Ideally, potentially toxic metabolites produced by phase I reactions are detoxified during the phase II reactions. When detoxification goes awry because of overproduction of a reactive intermediate or a deficiency of phase II substrates, toxic intermediates can cause cellular injury. The following sections review mechanisms of cellular injury related to xenobiotic biotransformation.

Synthesis of Toxins or â€œMistakenâ€• Toxins

Sometimes a xenobiotic is mistaken for a natural substrate by synthetic enzymes that act on the xenobiotic and facilitate its injurious effects. The incorporation of the rodenticide fluoroacetate into the tricarboxylic acid cycle is an example of this mechanism of toxic injury (Fig. 13-3). Another example is illustrated by analogs of purine or pyrimidine bases that are phosphorylated and inserted into growing DNA or RNA chains, resulting in mutations and disruption of cell division. This mechanism is used therapeutically with 5-fluorouracil (5-FU), an antitumor, pyrimidine base analog. When phosphorylated to 5-fluoro-dUTP and incorporated into

growing DNA chains, it causes structural instability of the cellular DNA and inhibits tumor growth.[72]

Injury by Metabolites at Distant Sites

Toxic metabolites may be synthesized at one site and transported to other target sites where they cause injury. Cyanide formed by the hepatic metabolism of acetonitrile nail removers produces toxicity

at distant sites.[15] Benzene is biotransformed in the liver to benzoquinone and dihydroxybenzene intermediates, which subsequently injure the bone marrow.[88] 2,5-Hexanedione, the neurotoxic metabolite of *n* -hexane and methyl-*n* -butyl ketone, is also produced in the liver, far from the site where injury occurs.[20]

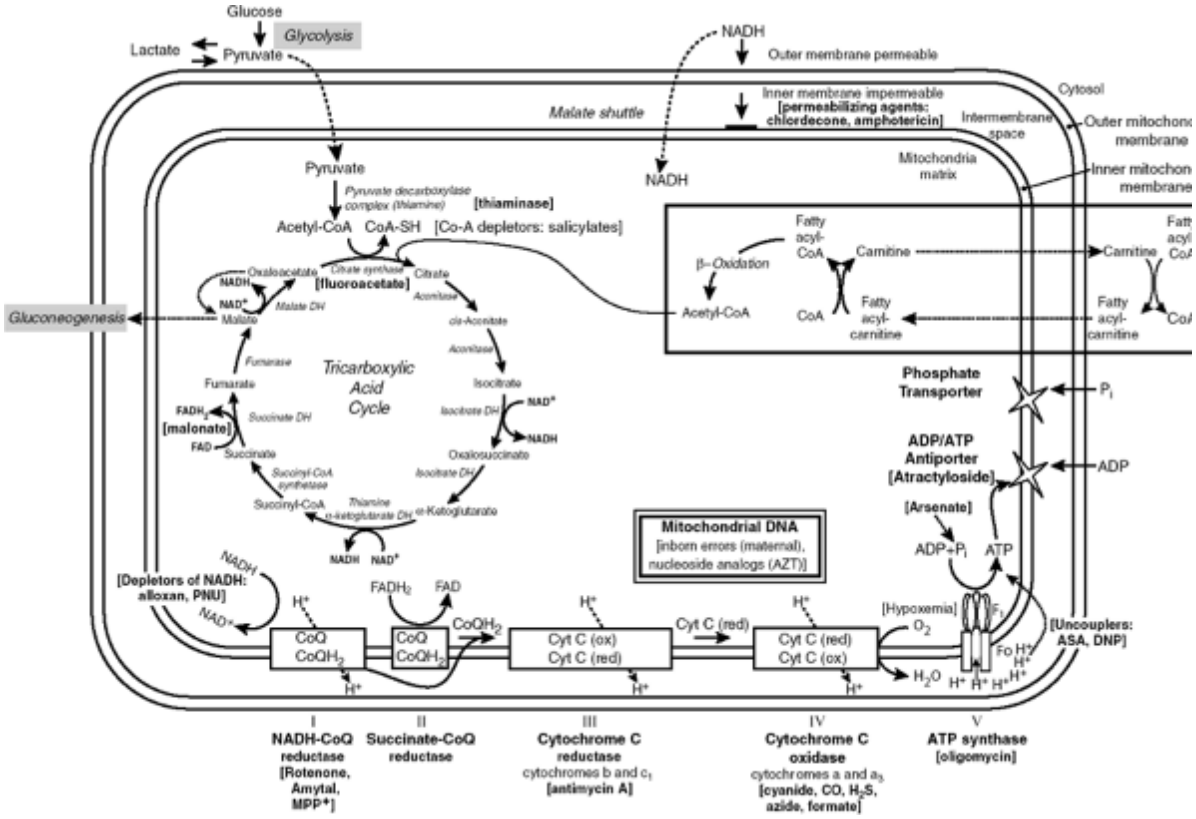

Figure 13-3. Pyruvate is converted to acetylcoenzyme A (acetyl-

CoA), which enters the Krebs cycle as shown. Reducing equivalents, in the form of NADH, and FADH, donate electrons to a chain of cytochromes beginning with NADH dehydrogenase. These reactions â€œcoupleâ€• the energy released during electron transport to the production of ATP. Ultimately, electrons combine with oxygen to form water. The sites of action of toxins that inhibit oxidative metabolism are shown. The sites where thiamine functions as a coenzyme are also illustrated. DH = dehydrogenase.

The toxicity of ingested xenobiotics may be altered by endogenous enzymatic activity or by the enzymatic activity of bacterial flora in the gastrointestinal tract. Laetrile (amygdalin) was used as an alternative treatment for cancer but caused deaths because of its biotransformation to cyanide. Amygdalin must be hydrolyzed in the gut to cyanide to exert its toxicity. When administered intravenously, amygdalin is not toxic.[34] Nitrates present in well water in farming communities are converted to nitrites by gut bacteria, leading to methemoglobinemia. A high gastric pH in very young infants allows the growth of enteric organisms in the stomach, making infants particularly susceptible to the toxic effects of ingested nitrates. Infants also have a reduced ability to detoxify nitrites.[69]

Injury by Metabolites of Biotransformation

The capacity of a tissue to biotransform certain toxins may be essential to the production of injury in that tissue. Highly reactive metabolites exert damage at the site where they are synthesized. Tissue injury by reactive metabolites occurs commonly in the liver, the major site of biotransformation of xenobiotics, but occurs in other organs as well (Chap. 26).[29 , 77] The lungs, skin, kidneys, gastrointestinal tract, and the nasal mucosa have the ability to biotransform xenobiotics to metabolites that result in local

injury.[12, 42] Overdoses of acetaminophen lead to excessive hepatic production of the highly reactive electrophile NAPQI, which initiates a damaging covalent bond with hepatocytes (Chap. 34).[8, 11] Acute renal tubular necrosis also occurs in patients with overdose of acetaminophen.[39] This is attributed to its biotransformation by prostaglandin H synthase within renal tubular cells to a highly reactive semiquinoneimine.[21]

Monoamine oxidases (MAOs) are mitochondrial enzymes present in many tissues. They oxidize a large number of different amines; including dopamine, epinephrine, and serotonin; and toxins such as primaquine and haloperidol. The metabolic activity of MAOs was responsible for the outbreak of parkinsonism associated with the use of methylphenyltetrahydropyridine (MPTP), an unintended byproduct of attempts to synthesize a â€œdesignerâ€• analog of meperidine, methylphenylpropionoxypiperidine (MPPP). After crossing the bloodâ€“brain barrier, MPTP is biotransformed by MAO in glial cells to methylphenyldihydropyridine ($MPDP^+$),

which is nonenzymatically converted to MPP^+ . The MPP^+ is subsequently taken up by specific dopamine transport systems into dopaminergic neurons in the substantia nigra, resulting in inhibition of oxidative phosphorylation and subsequent neuronal death.[26]

Free Radical Formation

Free radicals are compounds that have an unpaired electron and are very reactive with other species because they seek to obtain another electron. They include the superoxide anion O_2 Â·$^-$, which is produced by adding an electron to O_2 , and the highly reactive hydroxyl radical HOÂ·, which is produced by splitting (homolytic cleavage) the H_2 O_2 molecule. The H_2 O_2 molecule itself is reactive and is also associated with injury. The superoxide and hydroxyl radicals react with other molecules to generate other free radical

species. Some toxins promote the formation of reactive oxidizing species to the extent that defensive mechanisms against oxidants are overwhelmed, a condition called oxidative stress. Oxidative stress may result in oxidative damage to lipids, nucleic acids, and proteins. Free radicals are most destructive when they initiate chain reactions, such as when a free radical attacks polyunsaturated fatty acids in cellular membranes resulting in lipid peroxidation. This attack removes a hydrogen atom from a methylene carbon and leaves an unpaired electron, causing the formation of a lipid radical. This lipid free radical attacks other unsaturated fatty acid chains, causing a chain reaction that destroys the cellular membrane. Membrane degradation products initiate inflammatory reactions in the cells, resulting in further damage.[77]

Molecular oxygen (O_2) has two unpaired electrons in its orbits. Because oxygen is a relatively weak univalent electron acceptor (and most organic molecules are weak univalent electron donors), oxygen cannot efficiently oxidize amino acids and nucleic acids. However, the unpaired electrons of O_2 readily interact with the unpaired electrons of transition metals and organic radicals. Metals frequently catalyze the creation of oxygen free radicals. The following is an example of hydroxyl radical formation: (A) A first step is the addition of an electron to O_2 to create the superoxide ion. (B) The very reactive superoxide combines with hydrogen and another electron to produce hydrogen peroxide. (C) In the presence of a metal ion catalyst such as iron, hydrogen peroxide undergoes various reactions to produce the hydroxyl radical. The dot in these formulas represents an unpaired electron, the hallmark of a free radical.[35 , 51]

(A) $O_2 + e^- \longrightarrow O_2^{\bullet -}$

(B) $O_2^{\bullet -} + 2H^+ + e^- \longrightarrow H_2O_2$

(C) $H_2O_2 \xrightarrow[Fe^{2+}]{} OH^- + OH\bullet$ (Fenton)

$H_2O_2 + O_2^{\bullet -} \xrightarrow[Fe^{2+}]{} O_2 + OH^- + OH\bullet$ (Haber-Weiss)

The damaging effects of the free radicals can be minimized by reaction with antioxidants such as ascorbate, tocopherols, and glutathione.[51] Deficiencies of antioxidants, especially glutathione, are associated with increased oxidative damage. Free radicals are also neutralized by several enzymes, including peroxidase, superoxide dismutase, and catalase.

The ethanol-inducible CYP2E1 isozyme produces significant amounts of superoxide and peroxide free radicals, and, in the presence of iron, hydroxyl free radicals that readily initiate lipid peroxidation. This has been studied extensively in models of the metabolism of carbon tetrachloride, ethanol, and acetaminophen.[18] The formation of free radicals is implicated in the pulmonary injury caused by paraquat, the myocardial injury caused by doxorubicin, and the liver injury caused by carbon tetrachloride.[57 , 67] Paraquat reacts with NADPH to form a pyridinyl free radical, which, in turn, reacts with oxygen to generate the superoxide anion radical. Adriamycin is metabolized to a semiquinone free radical in the cardiac mitochondria, which, in the presence of oxygen, forms a superoxide anion radical that initiates myocardial lipid peroxidation.[57] Carbon tetrachloride (CCl_4) is metabolized to the trichloromethyl radical ($Â·CCl_3$) that binds covalently to cellular macromolecules. In the presence of oxygen, this is converted to the trichloromethylperoxyl radical ($Â·CCl_3\ O_2$) that can initiate lipid peroxidation (Fig. 13-4).[68] See Chap. 26 for a more extensive discussion.

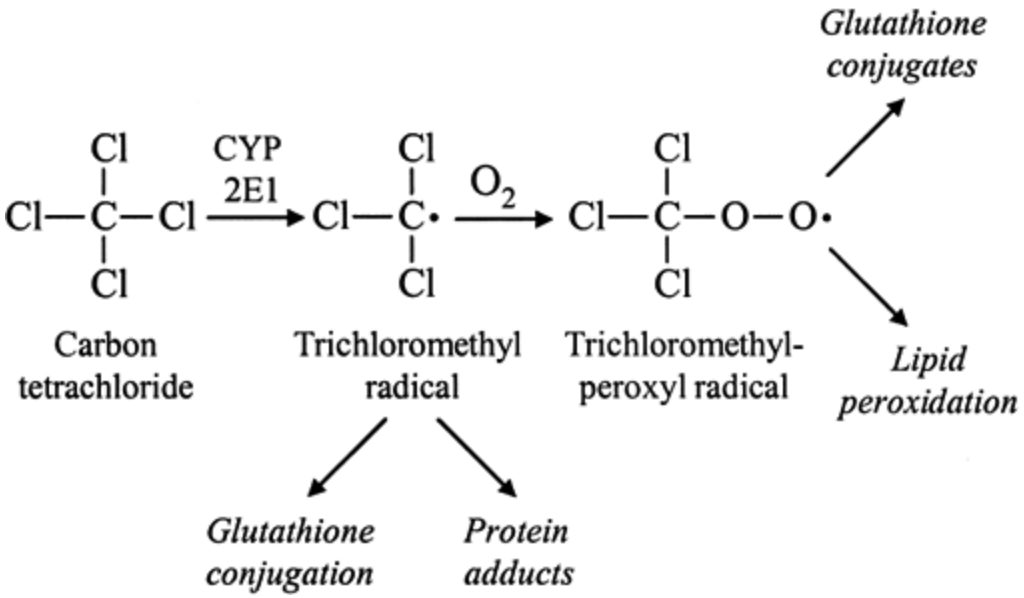

Figure 13-4. Carbon tetrachloride metabolism by the hepatocyte. Under hypoxic conditions, the CCl_3 radical is the predominant species formed. At higher oxygen tensions, CCl_3 radical is oxidized to the CCl_3 OO radical, which is more readily detoxified by glutathione. Both free radicals bind to hepatocytes and cause cellular injury.

Critical Biochemical Pathways and Toxins that Affect them

High-energy phosphate bonds, predominantly in the form of ATP, fuel all energy-dependent cellular processes such as synthesis, active transport, and maintenance of electrolyte balance and membrane integrity. When the production or use of ATP is inhibited, rapid cell death occurs. The ultimate goal of many metabolic processes is the production and mobilization of cellular energy. Numerous pathways interconnect glycogen, fat, and protein reserves in many tissues that store and retrieve ATP and glucose. The brain and red blood cells are entirely dependent on glucose for energy production, while other tissues can also use

ketone bodies and fatty acids to synthesize ATP.

Catabolic pathways that produce cellular energy include glycolysis, the tricarboxylic acid (TCA, or Krebs) cycle, and oxidative phosphorylation, which are mediated by the electron transport chain. Glycolysis occurs in the cytosol, while the TCA cycle and the electron transport chain are located within the mitochondria. Glycolysis produces small amounts of ATP through the anaerobic metabolism of glucose. Pyruvate, the end product of glycolysis, yields far more ATP when it is converted to acetylcoenzyme A (acetyl-CoA) and â€œprocessedâ€• aerobically by the oxygen-dependent TCA cycle. The TCA cycle and oxidative phosphorylation, which function only in the presence of oxygen, are the major pathways of oxidative metabolism and the synthesis of ATP (Fig. 13-3). Oxidative phosphorylation disposes of electrons or â€œreducing equivalentsâ€•

generated by the oxidative metabolism of cellular fuels, such as sugars and lipids, and converts their energy to ATP. Oxidative metabolism is highly energy efficient, producing 36 moles of ATP for each mole of glucose metabolized, compared to the 2 moles of ATP produced by glycolysis. The following sections review the basics of cellular energy metabolism and several important xenobiotics that affect these critical metabolic functions (Table 13-2).[38 , 56]

Glycolysis

Glycolysis is the first biochemical pathway in the metabolism of glucose. Other sugars enter the glycolytic pathway after conversion to glycolytic intermediates (Fig. 13-5). The glycolytic process converts one molecule of glucose to 2 pyruvate molecules + 2 ATP + 2 NADH. Pyruvate may follow many paths. Under anaerobic conditions, the 2 pyruvates produced from 1 glucose molecule are reduced by lactate dehydrogenase to 2 lactate

molecules in an NADH-requiring step that regenerates NAD+. Thus, anaerobic glycolysis yields 2 molecules of lactate + 2 ATP. When NAD^+ and oxygen are available, pyruvate is converted by pyruvate decarboxylase to acetyl-CoA, which is transported from the cytosol into the mitochondrion and condenses with oxaloacetate within the TCA cycle to form citrate (Fig. 13-3).[38, 56] In energy replete conditions, pyruvate molecules are used for fatty acid synthesis.

General
Oxygen becomes unavailable
Xenobiotics â†’respiratory paralysis
Xenobiotics â†’ischemia
Xenobiotics â†’ â†“hemoglobin oxygenation
Glycolysis
Inhibits NADH production
Iodoacetate (at GAPDH)
NO+ (at GAPDH)
Gluconeogenesis
Inhibits NADH production
4-(Dimethylamino)phenol *p* -benzoquinone
Hypoglycin
Fatty acid metabolism
Inhibits NADH production
Aflatoxin Protease inhibitors
Amiodarone Salicylates
Hypoglycin Tetracycline
Perhexiline Valproic acid
Pyruvate dehydrogenase
Inhibits NADH production
Arsenite
p -Benzoquinone
Tricarboxylic acid cycle
Inhibits NADH production
Fluoroacetate (at aconitase)

Electron-transport chain complex I
Inhibits electron transport at complex I
Rotenone, amytal, MPP+, paraquat
Electron-transport chain complex III
Inhibits electron transport at complex III
Antimycin-A, funiculosin, myxothiazole
Substituted phenols (are also uncouplers)
Di- and trivalent metal cations (Zn^{2+} , Hg^{2+} , Cu^{2+} , and Cd^{2+})
Electron-transport chain complex IV
Inhibits electron transport at complex IV
Cyanide H_2S
Azide Formate
Nitric oxide Carbon monoxide
Phosphine Protamine
Electron-transport chain at ATP synthase
Inhibits ATP production from ADP at ATP synthase
Mycotoxins (numerous, including oligomycin)
Organic chlorines (DDT and chlordecone)
Organotin agents (cyhexatin)
Propranolol
Paraquat
Mitochondria ADP/ATP antiporter
Disrupts the movement of ADP into and ATP out of the mitochondria at the ADP/ATP antiporter
Atractyloside
DDT
Free fatty acids and some compounds with similar structure
Mitochondria inner membrane
Uncouples oxidative phosphorylation by disrupting the proton gradient â†’ stops proton flow at ATP synthase â†’ stops ATP synthesis
Substituted phenols (pentachlorophenol, dinitrophenol)
Lipophilic amines (amiodarone, perhexiline, buprenorphine)
Benzonitrile

Thiadiazole herbicides
NSAIDs with ionizable groups (salicylates, diclofenac, indomethacin, piroxicam)
Valinomycin
Gramicidin
Calcimycin
Chlordecone
Mitochondria inner membrane
Diverts electrons to alternate pathways (vs. to the electron-transport chain)
Adriamycin
MPP^+
Naphthoquinones (menadione)
N -nitrosoamines
Paraquat
GAPDH = glyceraldehyde 3-phosphate dehydrogenase; MPP+ = 1-methyl-4-phenylpyridinium.

Step/Location Action Examples

TABLE 13-2. Inhibitors of Glucose Metabolism and ATP Synthesis

Arsenate has a toxic effect at the glycolytic step where 3-phosphoglyceraldehyde dehydrogenase (3-PGA) catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate; a reaction that preserves a high-energy phosphate bond used to synthesize ATP in the next step of glycolysis (Fig. 13-5).[14] As an analog of phosphate, arsenate acts as a substrate at this step. The resultant unstable intermediate is rapidly hydrolyzed, preventing the subsequent synthesis of ATP and interrupting glycolysis.[14]

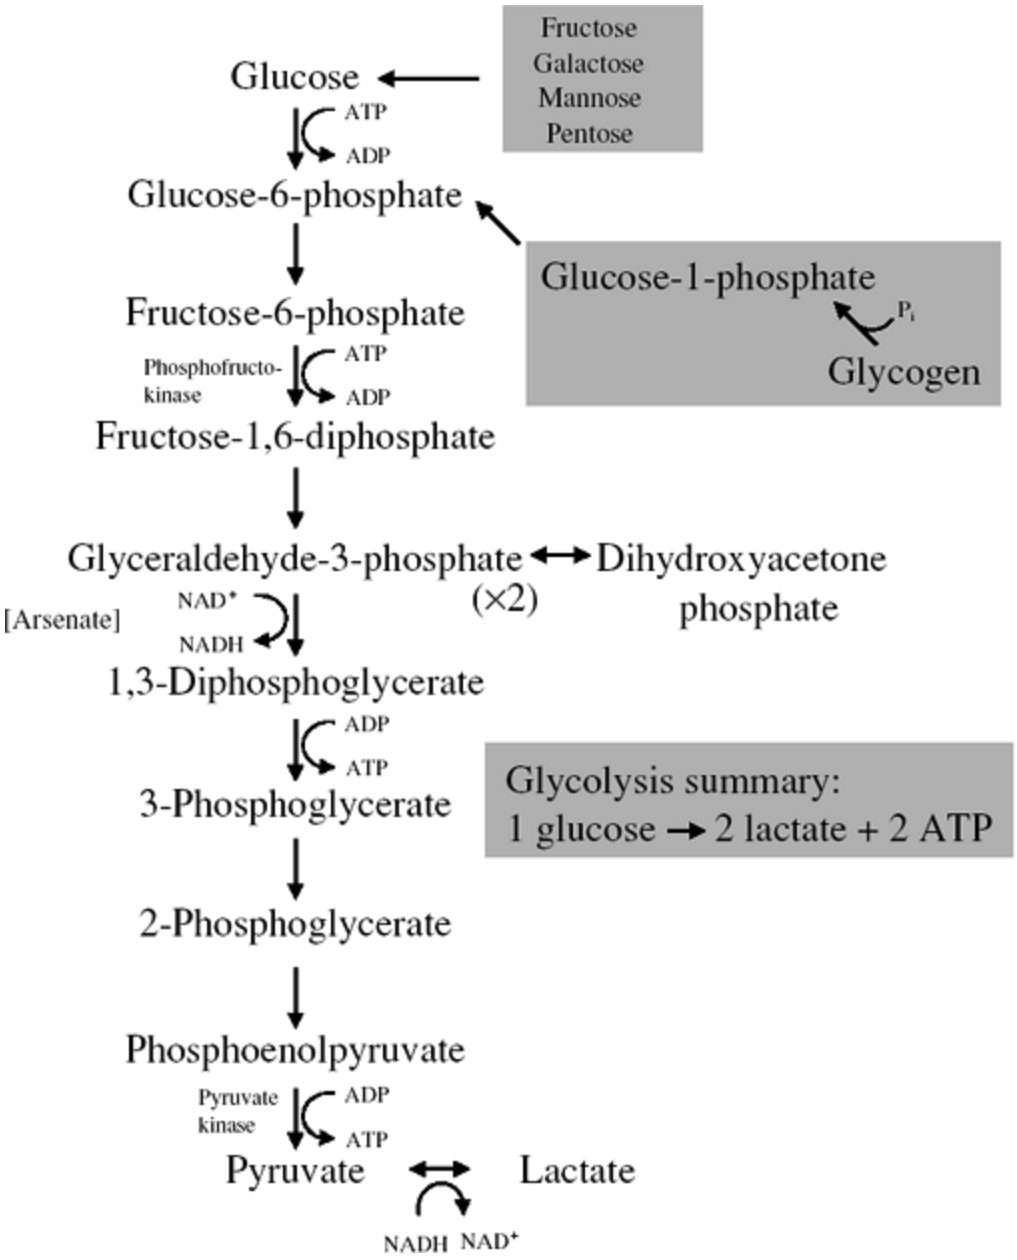

Figure 13-5. During glycolysis, the anaerobic metabolism of 1 mole of glucose to 2 moles of lactate results in the net production of 2 moles of ATP. Arsenic inhibits 3-phosphoglycerate dehydrogenase, which catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate.

Tricarboxylic Acid Cycle

The TCA cycle uses acetyl-CoA derived from glycolysis, fat, or protein to regenerate NADH from NAD^+ . The cycle is a major source of electrons (in the form of NADH) and is critical to the aerobic production of ATP (Fig. 13-3). Each acetyl-CoA molecule that is oxidized within the TCA cycle ultimately forms 1 molecule each of CO_2 and GTP (guanosine triphosphate), and, more importantly, 3 molecules of NADH and 1 molecule of flavin adenine dinucleotide (reduced form) ($FADH_2$), which enter the electron transport chain, and produce 15 molecules of ATP. In addition, the TCA cycle provides important intermediates for amino acid synthesis and for gluconeogenesis.[38]

Inhibitors of the TCA cycle are powerful toxins. Two highly toxic rodenticides, sodium fluoroacetate and fluoroacetamide, are incorporated as fluoroacetyl coenzyme A and enter the TCA cycle by condensation with oxaloacetate to form fluorocitrate. This blocks the conversion of citrate to isocitrate, which results in the accumulation of large amounts of citrate in the mitochondria, inhibition of the cycle, and termination of oxidative metabolism (Fig. 13-3) (Chap. 106).[82]

Thiamine is an important cofactor for two TCA cycle enzymes. It is required for the conversion of pyruvate to acetyl-CoA by pyruvate decarboxylase and for the conversion of (Î±-ketoglutarate to succinyl-CoA by (Î±-ketoglutarate dehydrogenase.[56] The life-threatening effects of thiamine deficiency are likely related to impairment of these enzyme functions (see Antidotes in Depth: Thiamine Hydrochloride).

The Electron Transport Chain

The success of aerobic metabolism requires disposal of electrons generated by oxidative metabolism so that new electrons can enter the pathway. The oxidative phosphorylation of adenosine

diphosphate (ADP) to ATP captures energy generated by the oxidative reactions of the TCA cycle in the high-energy phosphate bond of ATP (see Fig. 13-3). Oxidative phosphorylation of ADP to ATP occurs in the electron transport chain, which consists of a series of cytochrome-enzyme complexes within the inner mitochondrial membrane. Within these complexes, NADH is split into $NAD^+ + H^+ + 2$ electrons at two locations and $FADH_2$ is split into $FAD + H^+ + 2$ electrons at one position. These splits have two results. First, the regenerated NAD^+ and FAD are recycled back to the TCA cycle, enabling oxidative metabolism to continue. Second, these actions provide the energy required to pump protons (H^+) from the mitochondrial matrix into the intermembrane space. This action causes the matrix to become relatively alkaline compared to the now acidified intermembrane space; resulting in a proton gradient across the inner mitochondrial membrane. This gradient provides the energy needed to create the high-energy bonds of ATP. The final step in oxidative phosphorylation is the reduction of molecular oxygen to water by cytochrome a-a_3 (Fig. 13-3).[38 , 56]

Mitochondria oxidize substrates, consume oxygen, and make ATP. Toxins that interrupt oxidative phosphorylation impair ATP production by either inhibiting specific electron chain complexes or by acting as â€œuncouplers.â€• Both of these mechanisms result in rapid depletion of cellular energy stores, followed by failure of ATP-dependent active transport pumps, loss of essential electrolyte gradients, and increases in cell volume.[55]

â€œInhibitorsâ€• of specific cytochromes block electron transport and cause an accumulation of reduced intermediates proximal to the site of inhibition. This stops the use of oxygen and substrate. Failure to regenerate oxidized substrates for the TCA cycle, particularly NAD^+ and flavin adenine dinucleotide (FAD), further impairs oxidative metabolism. Cyanide, carbon monoxide, and hydrogen sulfide block the cytochrome a-a_3 -mediated reduction of O_2 to H_2 O. The very dramatic clinical effects of a significant cyanide exposure illustrate the importance of aerobic metabolism

(Chap. 121). Other xenobiotics have been less commonly associated with inhibition of the electron transport chain (Table 13-2).[83]

Severe metabolic acidosis is an unavoidable clinical manifestation of toxins that inhibit aerobic respiration. This metabolic acidosis is caused by the accumulation of protons in the mitochondrial matrix that are not used in the production of ATP, and not by the accumulation of lactic acid, which is only a marker for metabolic acidosis associated with the impairment of oxidative metabolism.[73]

Toxins that uncouple oxidative phosphorylation stop ATP synthesis by destroying the pH gradient across the mitochondrial

inner membrane. Protons continue to be pumped into the intermembrane space while oxygen and substrate consumption continue. Uncoupling agents allow the protons to cross back into the mitochondrial matrix, causing the loss of the proton gradient across the inner mitochondria membrane, which results in the loss of further ATP production. Thus, oxygen consumption is â€œuncoupledâ€• from ATP production. Energy created by electron transport that cannot be coupled to ATP synthesis is released as heat. Various xenobiotics â€œuncoupleâ€• ATP synthesis (Table 13-2). A classic one is dinitrophenol, used in the past as an herbicide and as a weight-loss product (Chaps. 39 and 111). Compounds that are capable of carrying hydrogen ions across membranes are generally lipophilic weak acids. These agents must have an acid-dissociable group to carry the proton, and a bulky lipophilic group to cross a membrane.[83] Dinitrophenol is able to carry its proton from the cytosol into the more alkaline mitochondrial matrix where it dissociates, acidifying the matrix and destroying the proton gradient across the inner mitochondrial membrane. Interestingly, the phenolate anion of dinitrophenol is relatively lipophilic and can cross back out to the cytosol where it gains a new proton and starts the process over again. Long-chain fatty acids uncouple oxidative phosphorylation by a similar

mechanism.[83] Fatal exposures to dinitrophenol and to pentachlorophenol, a wood preservative, are associated with severe hyperthermia attributed to heat generation by uncoupled oxidative phosphorylation.[53] Rats develop fatal hyperthermia following oral ingestion of dinitrophenol.[78] The hyperthermia and acidosis associated with severe salicylate poisoning are also attributed to its uncoupling of oxidative phosphorylation.[76]

Pentose Phosphate (Hexose Monophosphate) Shunt

The hexose monophosphate (HMP) shunt provides the only source of cellular NADPH. NADPH is used in biosynthetic reactions, particularly fatty acid synthesis, and is an important source of reducing power for the maintenance of sulfhydryl groups that protect the cell from free radical injury.[9, 35] As discussed earlier, G6PD is a key enzyme in the pathway (Fig. 13-6). Reduced glutathione, which is quantitatively the most important general antioxidant in cells, depends on the availability of NADPH. RBCs are especially vulnerable to deficiency of NADPH, which results in hemolysis during oxidative stress.

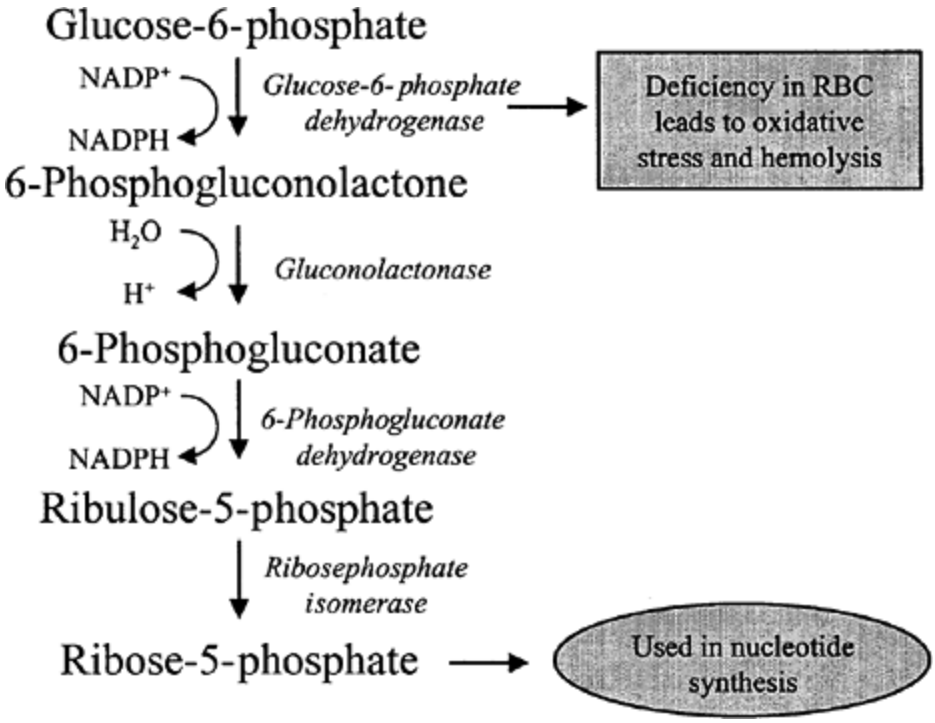

Figure 13-6. The oxidation reactions of the pentose phosphate pathway are an important source of NADPH for reductive biosynthesis and for protection of cells against oxidative stress. Deficiency of G6PD, the first enzyme in the pathway, may result in RBC hemolysis during oxidative stress.

Another manifestation of oxidative stress in RBCs is the oxidation of the iron in hemoglobin from Fe^{2+} to Fe^{3+}, producing methemoglobin that occurs both spontaneously and as a response to xenobiotics such as nitrites and aminophenols. Because most reduction of methemoglobin is done by NADH-dependent methemoglobin reductase, which is not deficient in persons who lack G6PD, such persons do not develop methemoglobinemia under normal circumstances. However, when oxidative stress is severe and methemoglobinemia develops, people who have G6PD deficiency have limited ability to use the alternative NADPH-dependent methemoglobin reductase (Chap. 122).[87]

Gluconeogenesis

Gluconeogenesis is a biochemical pathway localized predominantly in the liver that facilitates the conversion of amino acids and intermediates of the TCA cycle to glucose. It is an important source of glucose during fasting and enables maintenance of glycogen stores. Most of the steps in the synthesis of glucose from pyruvate are simply the reverse of glycolysis, with three irreversible exceptions: (a) the conversion of glucose-6-phosphate to glucose; (b) the conversion of fructose-1,6-diphosphate to fructose-6-phosphate; and (c) the synthesis of phosphoenolpyruvate from pyruvate. The synthesis of phosphoenolpyruvate from pyruvate is especially complex. Pyruvate is first converted to oxaloacetate within the mitochondria, then to malate, which is transported out of the mitochondria and converted in the cytosol back to oxaloacetate, and then to phosphoenolpyruvate (Fig. 13-7). Certain amino acids, notably alanine, glutamate, and aspartate, are readily converted to TCA cycle intermediates and can be used in the synthesis of glucose through this cycle.[38] Glycerol, produced by the breakdown of triglycerides in adipose tissue, is another substrate for gluconeogenesis.

The regulation of gluconeogenesis is opposite to that of glycolysis. Both glucagon and catecholamines stimulate gluconeogenesis, whereas insulin and hyperglycemia turn it off. Gluconeogenesis requires the presence of NAD^+ in the cytosol, which is necessary to oxidize lactate to pyruvate. It also requires the presence of NADH in the mitochondria. It is impaired by processes that increase the cytosol reducing potential as measured by the cytosol $NADH/NAD^+$ ratio (see discussion below).

A number of xenobiotics impair gluconeogenesis, resulting in hypoglycemia when glycogen stores are depleted (Table 13-2). Hypoglycin A, an unusual amino acid found in unripe ackee fruit that is the cause of Jamaican vomiting sickness, produces

profound hypoglycemia.[23, 76, 80] Its metabolite methylenecyclopropylacetic acid (MCPA) indirectly inhibits gluconeogenesis by blocking the oxidation of long-chain fatty acids, an important source of NADH in mitochondria. It also inhibits the metabolism of several glycogenic amino acids including leucine, isoleucine, and tryptophan, and blocks their entrance into the TCA cycle. MCPA may also prevent the transport of malate out of the mitochondria.[71, 80, 81] Significant hypoglycemia occurs in fasting patients with elevated ethanol levels.[7, 25, 49] This is likely a result of the impairment of gluconeogenesis by the increased cytosolic NADH:NAD^+ ratio associated with the metabolism of ethanol. This inhibits the two steps that require NAD^+ : the conversion of lactate to pyruvate and the conversion in the cytosol of malate to oxaloacetate.[4, 49, 68]

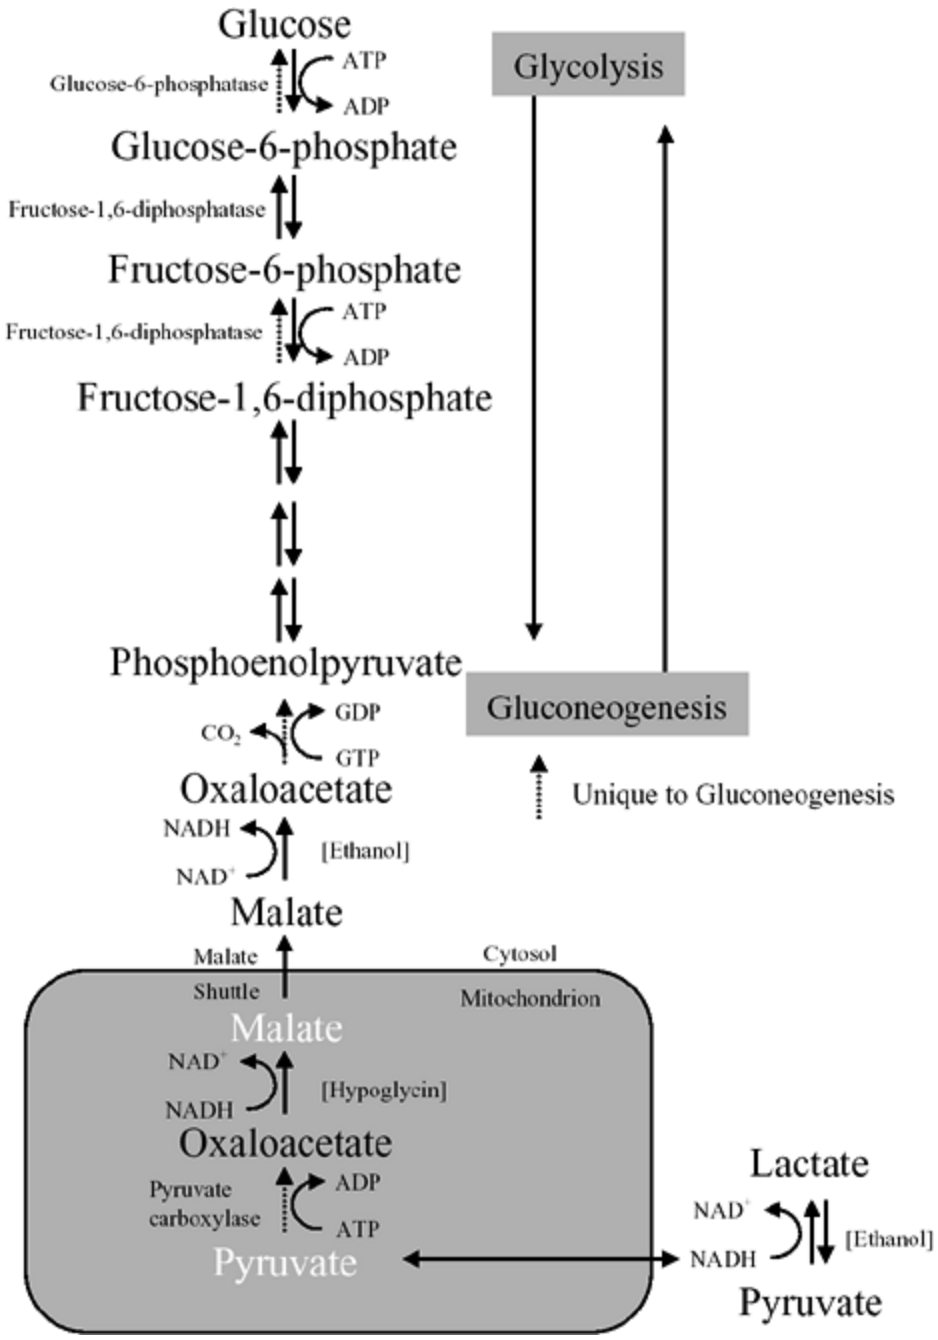

Figure 13-7. Gluconeogenesis reverses the steps of glycolysis, with the exception of the bypass of the three irreversible steps shown. The step from pyruvate to phosphoenolpyruvate involves both cytosolic and mitochondrial reactions that use ATP. Hypoglycin A inhibits the intramitochondrial conversion of oxaloacetate to malate by depleting NADH through interference

with Î²-oxidation of fatty acids. Ethanol decreases cytosolic supplies of NAD^+ . Pyruvate kinase (PK) and phosphofructokinase (PFK), the enzymes whose activities are regulated by glucagon via cyclic adenosine monophosphate (cAMP)-dependent phosphokinase, are shown.

Fatty Acid Metabolism

Fatty acid metabolism occurs primarily in hepatocytes. Fatty acids mobilized in adipose tissue enter hepatocytes by passive diffusion. Fatty acid synthesis is stimulated by insulin and inhibited by glucagon and epinephrine. Acetyl-CoA is the primary building block of free fatty acids (FFAs). In energy-repleted cells, fatty acids are combined with glycerol phosphate to form triacylglycerol (triglycerides), the first step in the synthesis of fat for storage. Hepatic triglycerides are bound to lipoprotein to form very-low-density lipoprotein (VLDL), then transported and stored in adipocytes. When hepatocytes are energy depleted, triglycerides are broken down to FFA and glycerol (Fig. 13-8). This process is suppressed by insulin, but supported by glucagon or epinephrine. FFAs undergo Î²-oxidation in the mitochondria, a process that breaks the FFA into acetyl-CoA molecules that can then enter the TCA cycle. FFAs require activation before transport into the mitochondria. This is accomplished by acylcoenzyme A (acyl-CoA) synthetase, which adds a CoA group to the FFA in an energy dependent synthetic reaction. These are transported into the mitochondria by a process that utilizes cyclical binding to carnitine, a â€œcarnitine shuttleâ€• (Fig. 13-3). Once inside the mitochondria, FFAs are converted to acetyl-CoA by Î²-oxidation, so-called because it involves the sequential removal of 2-carbon fragments, each time acting at the second carbon (the Î² carbon) position of the fatty acid. Each 2-carbon molecule removed from the FFA produces 1 NADH and 1 $FADH_2$, which enter oxidative

phosphorylation, and 1 mole of acetyl-CoA, which enters the TCA cycle. This process produces 1.3 times more ATP per molecule of carbon metabolized than does the oxidative metabolism of glucose or other carbohydrates.[38]

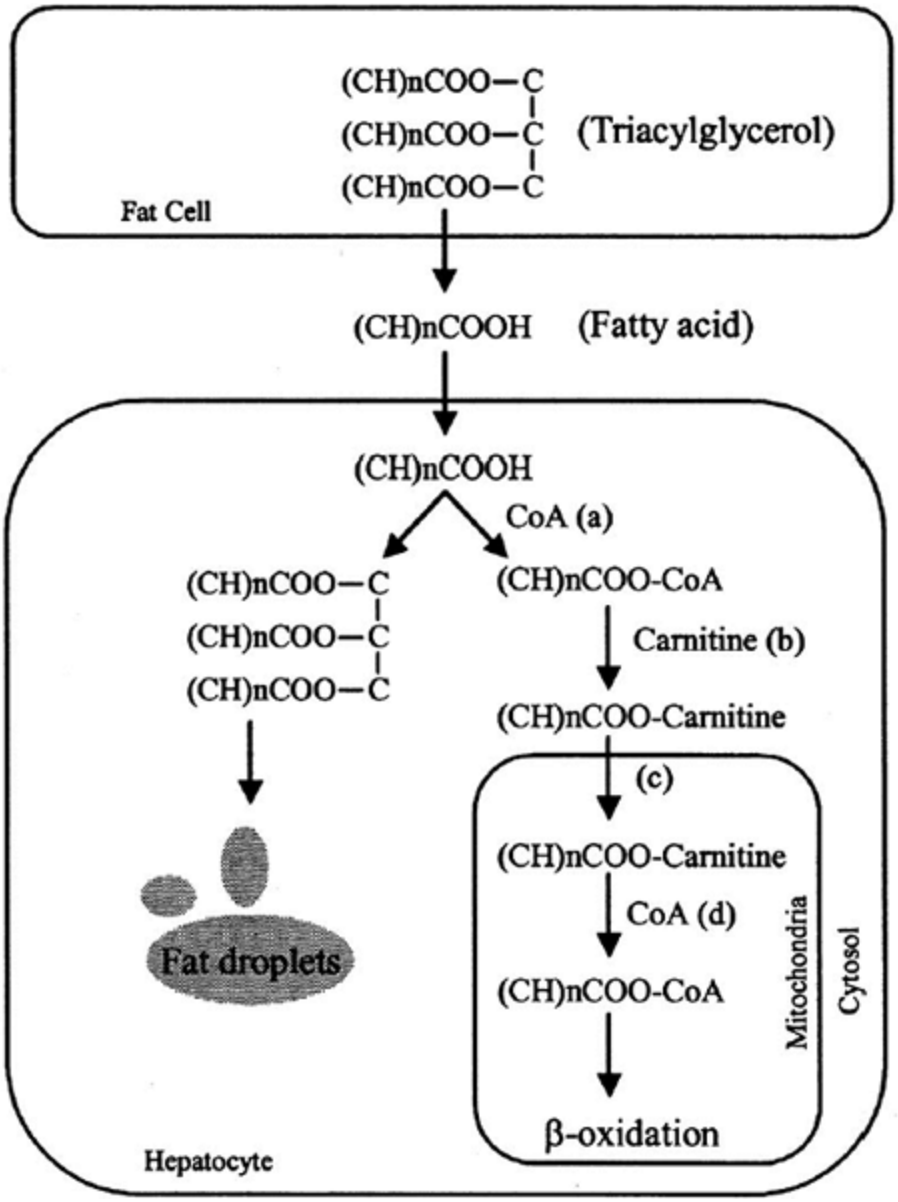

Figure 13-8. Steatosis, an accumulation of fat, results when toxins interfere with the oxidation of fatty acids. Other processes that may be associated with intracellular accumulation of fat include (a) impaired lipoprotein synthesis; (b) impaired lipoprotein

release; (c) increased mobilization of free fatty acids; (d) increased uptake of circulating lipids; and (e) increased production of triglycerides. Î²-Oxidation takes place in the mitochondria after transport of fatty acids from the cellular cytosol across the mitochondrial membrane. The enzymes involved are (a) acyl-CoA synthetase; (b) carnitine palmitoyltransferase I; (c) carnitine acylcarnitine translocase; and (d) carnitine palmitoyltransferase II. Acyl-CoA is the intramitochondrial substrate for Î²-oxidation. Potential mechanisms of inhibition of Î²-oxidation include induction of carnitine deficiency, inhibition of the transferase or translocase, and increased NADH:NAD^+ ratio via increased use of NAD^+ or by inhibition of NADH use. The specific site of action is not defined for many toxins that cause steatosis.

Many xenobiotics interrupt fatty acid metabolism at various steps, resulting in accumulation of triglycerides in the liver (Table 13-2). The mechanisms of disruption of fatty acid metabolism are poorly defined and numerous hypotheses are proposed.[16] Some agents, including ethanol, hypoglycin, and nucleoside analogs (Chap. 26), inhibit Î²-oxidation, at least indirectly, through effects on NADH concentrations. Protease inhibitors are associated with a syndrome of peripheral fat wasting, central adiposity, hyperlipidemia, and insulin resistance.

The condition of alcoholic ketoacidosis is related in part to inhibition of gluconeogenesis in the alcoholic patient and in part to an exuberant response to nutritional needs by the fatty acid machinery. Vomiting in the alcoholic patient leads to decreased intake of carbohydrate, which stimulates a starvation response with increases in serum glucagon, cortisol, growth hormone, and epinephrine concentrations, and decreases in serum insulin. When the need for carbohydrate is not met by gluconeogenesis, lipolysis, which is normally inhibited by insulin, is intensified and fatty acid mobilization progresses. Glucagon stimulates mitochondrial

carnitine acyltransferase, and Î²-oxidation of fatty acids is increased. The increased mitochondrial NADH:NAD^+ ratio favors the production of Î²-hydroxybutyrate over acetoacetate, its oxidized form. The administration of fluids, dextrose and thiamine to the alcoholic patient leads to correction of this process.[70]

Summary

Humans and other animals are exposed to a wide variety of xenobiotics. Some, including therapeutic drugs, are harmless at low doses and toxic only at high doses. The toxicity of those xenobiotics that interrupt important biologic functions or that result in cellular injury is dose-related and often rapidly evident. The diverse mechanisms of toxic injury have been discussed in general terms. The capacity of xenobiotics to cause injury is clearly a function of many factors specific to the xenobiotic, the tissue injured, and the individual animal or species.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 14

Neurotransmitters and Neuromodulators

Steven C. Curry

Kirk C. Mills

Anne-Michelle Ruha

Many poisonous substances produce their primary toxic effects by affecting neurotransmission. This chapter reviews the normal physiology of neurotransmission, the molecular action and biochemistry of several major neurotransmitters and their receptors, and the toxicologic mechanisms by which numerous substances act at the molecular level. Acetylcholine, norepinephrine, epinephrine, dopamine, serotonin, Î³-aminobutyric acid (GABA), Î³-hydroxybutyrate (GHB), glycine, glutamate, and adenosine are the neurotransmitters and neuromodulators of toxicologic interest that are discussed in this chapter.

When examining molecular actions of drugs and toxins on neurotransmitter systems, it is apparent that substances rarely possess single pharmacologic actions. For example, doxepin, in part, antagonizes voltage-gated sodium channels, histaminic H_1 and H_2

receptors, Î±-adrenoceptors, muscarinic acetylcholine receptors, dopamine D_2 receptors, and $GABA_A$ receptors; prevents potassium efflux; and inhibits norepinephrine, serotonin, and adenosine uptake. For obvious reasons, then, this chapter cannot include every action of every drug or toxin on the nervous system. Nor is it meant to be a complete discussion of toxic syndromes produced by various agents, as these are discussed in specific chapters. Rather, this chapter provides a general and basic understanding of the mechanisms of action of various toxic agents affecting neurotransmitter function and receptors, especially in the central nervous system. With this focus, the clinical effects produced by various toxins are more easily understood and predicted, and specific treatments aimed at reversing pharmacologic effects of the offending agents can be rationally undertaken.

Given the complexity of the nervous system and the numerous actions of a given drug, it is not always clear which neurotransmitter system is producing an observed effect during a particular toxicity. Therefore, pharmacologic agents discussed in this chapter may be found in several sections. An attempt is made to note what appears to be a drug or toxin's main mechanism of action, although other actions are noted when possible.

Neuron Physiology and Neurotransmission

Membrane Potentials, Ion Channels, and Nerve Conduction

Membrane-bound sodium-potassium adenosine triphosphatase (ATPase) moves three sodium ions (Na^+) from inside the cell to the interstitial space while pumping two potassium ions (K^+) into the cell. Because the cell membrane is not freely permeable to large, negatively charged molecules on the inside of the cell, such as

proteins, an equilibrium results in which the inside of the neuron is negative with respect to the outside. This typical neuronal resting membrane potential is â€“65 mV.

Sodium, calcium (Ca^{2+}), K^+, and chloride (Cl^-) ions move into and out of neurons through ion channels. Ions always move passively down electrochemical gradients through ion channels, which are long polypeptides comprising several subunits that span the plasma membrane several times. Many different ion channels are structurally comparable, sharing similar amino acid sequences.[17] Channels for a specific ion can also vary in structure, depending on the specific subunits that have combined to form the channel. Because of structural similarity of different channels, it is not surprising that many drugs or toxins are able to bind to more than one type of ion channel.

More than 40 different ion channels have been described in various nerve terminals,[99] and it is estimated that a human being contains hundreds of different varieties of ion channels for Na^+, Cl^-, Ca^{2+}, and K^+. Most ion channels fall into two general classes: voltage-gated (voltage-dependent) ion channels and ligand-gated ion channels.[99] Voltage-gated channels open or close in response to changes in membrane potential. Ligand-gated channels open or close when a ligand (eg, neurotransmitter) binds to the channel to change its configuration.

A commonly accepted model describes voltage-gated Na^+ channels and some other voltage-gated ion channels in three possible states. Using Na^+ channels as an example, the Na^+ channel is closed at rest and impermeable to sodium, preventing Na^+ from moving into the cell. When the channel undergoes activation, the channel opens, allowing Na^+ to move intracellularly, down its electrochemical gradient. The channel then undergoes a third conformational change by becoming inactivated, preventing further influx of Na^+. The term *recovery* describes the conversion of inactive channels back to the resting state, a process that requires repolarization of the cell

membrane.

Depolarization of a neuron usually results from an initial inward flux of cations (Na^+ or Ca^{2+}), or prevention of K^+ efflux. The fall in membrane potential (movement toward 0 mV) results in further activation of these voltage-dependent Na^+ channels, allowing yet a greater influx of cations. When the membrane

potential falls to threshold, Na^+ channels are activated en masse, and there is a large influx of Na^+.

Depolarization of a segment of the neurolemma causes the adjacent neuronal membrane to reach threshold, resulting in the propagation of an action potential down the neuron. Sodium channel activation is quickly followed by inactivation. Over the short-term, repolarization of the neuron occurring after inactivation of Na^+ channels mainly results from efflux of K^+ and some influx of Cl^-.

Neurotransmitter Release

Neurotransmitters are chemicals that are released from nerve endings into the synapse, where they produce effects by binding to receptors on postsynaptic and/or presynaptic cell membranes. The receptors may be on other neurons or effector organs such as smooth muscle. Concentrations of neurotransmitters in cytoplasm are usually low because of rapid degradation by various enzymes and because they diffuse out of the nerve ending. To provide a source of neurotransmitters that is protected from degradation and that can be rapidly released, neurotransmitters are concentrated and stored within vesicles in the axonal nerve terminal for release. As a wave of depolarization from Na^+ influx reaches the nerve ending, the membrane depolarization causes voltage-gated Ca^{2+} channels to open, allowing Ca^{2+} to move rapidly into the cell. This influx of Ca^{2+} triggers exocytosis of vesicle contents into the synapse. The voltage-gated Ca^{2+} channels responsible for inward Ca^{2+} currents that trigger neurotransmitter release are mainly of the N and P

subtypes.[103,121] Calcium channel blockers used in clinical practice (eg, verapamil, nifedipine) do not block these subtypes of voltage-dependent Ca^{2+} channels, but rather block the L-type. However, L-subtype Ca^{2+} channels reside elsewhere on neurons, which explains the ability of traditional Ca^{2+} channel blockers to affect some neurologic functions.

Vesicle Transport of Neurotransmitters

The pH inside neurotransmitter vesicles is about 5.5, lower than that in the cytoplasm. A vacuolar adenosine triphosphatase (V-ATPase) in the vesicular membrane is responsible for movement of protons into the vesicular lumen at the expense of adenosine triphosphate (ATP) hydrolysis. Vesicular uptake pumps that move neurotransmitters or their precursors from the cytoplasm into the vesicle lumen, in turn, are powered by the electrochemical H^+ gradient; that is, the movement of an H^+ out of the vesicle into the cytoplasm is coupled to the movement of a neurotransmitter from the cytoplasm into the vesicle. This is particularly true for vesicular transporters of GABA, glycine, dopamine, norepinephrine, and serotonin.

At least four unique *vesicular* transporters for neurotransmitters have been sequenced to date. VGAT transports GABA and glycine. VMAT2 transports all three monoamines, dopamine, norepinephrine, and serotonin (VMAT1 transports monoamines into nonneuronal vesicles). VAChT is responsible for acetylcholine (ACh) transport, and VGluT1 transports glutamate.

Neurotransmitters are confined within the vesicle, to a great extent, by ion trapping, as they are more ionized and less able to diffuse back out of the vesicle at the lower pH. Anything that causes a decrease in the pH gradient across the vesicle membrane results in the movement of neurotransmitters into the cytoplasm.[149] For example, amphetamines move into vesicles, where they buffer protons, causing the movement of monoamine neurotransmitters out of vesicles, and raising cytoplasmic concentrations of

neurotransmitters.[149,150]

Neurotransmitter Uptake

Although acetylcholine is inactivated in the synapse by enzymatic degradation, most neurotransmitters have their synaptic effects terminated by active uptake into neurons and/or glial cells. These plasma membrane neurotransmitter transporters are distinct from those transporters responsible for movement of neurotransmitters into vesicles within the cytoplasm. Cell membrane transporters (uptake pumps) for different neurotransmitters are Na^+-dependent transport proteins, during which the uptake of neurotransmitters is accompanied by the movement of Na^+ across the synaptic membrane.[2]

Neurotransmitter uptake transporters have been subdivided into two main families.[2] One family includes structurally similar uptake pumps for Î³-aminobutyric acid, glycine, norepinephrine, dopamine, and serotonin. They generally comprise 600â€“700 amino acids and form loops spanning the plasma membrane 12 times.

GAT-1 transports GABA into neurons, while GAT-2, GAT-3 and GAT-4 transport GABA into glial cells and, possibly, into postsynaptic neurons. DAT, SERT, and NET are responsible for uptake of dopamine, serotonin, and norepinephrine, respectively. GLYT-1 (at least three isoforms) transports glycine into neurons and astrocytes, while GLYT-2 transports glycine into glycinergic neurons.

The second family comprises 5 glutamate uptake transporters (excitatory amino acid transporters), which appear to traverse the plasma membrane 10 times. EAAT1 resides in cerebellar glial cells; EAAT2 in forebrain glia; EAAT3 in cortical neurons; EEAT4 in cerebellar Purkinje cells; and EAAT5 in the retina. Each time a glutamate moves into a neuron or glial cell, it is accompanied by 3 Na^+ and 1 proton. At the same time, a K^+ is extruded with each cycle.

Several properties make transporter proteins of particular toxicologic significance. First, they are capable of moving neurotransmitters in either direction; when cytoplasmic neurotransmitter concentrations are significantly elevated, neurotransmitters can be transported back into the synapse. Second, these transporters are not always completely specific for a particular substance. For instance, the uptake transporter for norepinephrine can pump dopamine and other biogenic amines into the neuron. Third, a drug or toxin that acts at the level of the membrane transporter may affect functions of several different neurotransmitters, depending on its specificity for a particular transporter. As an example, fluoxetine is fairly specific at inhibiting uptake of serotonin, whereas cocaine inhibits the uptake of serotonin, norepinephrine, and dopamine.

Neurotransmitter Receptors

Channel Receptors

The first general class of neurotransmitter receptors comprise ligand-gated ion channels (channel receptors or ionotropic receptors) in which the receptor for the neurotransmitter is part of an ion channel. These channels comprise multiple subunits which combine in various combinations to create channels that vary in their response to a given neurotransmitter or other agonist/antagonist. By binding to its receptor, the neurotransmitter allosterically changes the configuration of the ion channel so that ions can more easily traverse the channel and enter or leave the cell. As an example, the acetylcholine nicotinic receptor at the neuromuscular junction is a ligand-gated Na^+ channel. When

acetylcholine binds to the nicotinic receptor, the channel's configuration changes, allowing Na^+ to move into the cell and trigger an action potential. (The action potential then propagates down muscle via voltage-gated Na^+ channels.) Table 14-1 lists other

examples of channel receptors.

TABLE 14-1. Types of Neurotransmitter and Neuromodulator Receptors

Ion Channel	Linked to G Protein
ACh nicotinic	ACh muscarinic
$GABA_A$, $GABA_C$	$GABA_B$
Glycine (inhibitory)	Dopamine
Glutamate AMPA	Norepinephrine
Glutamate NMDA	$5\text{-}HT_{1,2,4â€“7}$
Glutamate kainate	Adenosine
$5\text{-}HT_3$	Glutamate metabotropic

ACh = acetylcholine; AMPA = amino-3-hydroxy-5-methyl-4-isoxazole propionate; GABA = Î³-aminobutyric acid; 5-HT = 5-hydroxytryptamine (serotonin); NMDA = *N*-methyl-D-aspartate.

G Protein Receptors

The second general class of neurotransmitter receptors are linked to

G proteins, which are part of a superfamily of proteins with guanosine triphosphatase (GTPase) activity responsible for signal transduction across plasma membranes.[140] G proteins comprise 3 polypeptide subunits: Î±, Î², and Î³ chains. These chains span the plasma membrane several times, and they associate with a separately transcribed neurotransmitter receptor that spans the cell membrane 7 times, with an external binding site for neurotransmitters. Some receptors (eg, $GABA_B$ receptor) coupled to G proteins are dimers comprising two separate proteins, both of which must be present for activity.

Both the Î± subunit and the Î²Î³ subunit of a G protein may account for activity resulting from a neurotransmitter binding to its receptor. The Î± chain normally binds guanosine diphosphate (GDP) in the cytoplasm and is inactive. When a neurotransmitter binds to its receptor on the outside of the cell membrane, GDP dissociates from the Î± chain and guanosine triphosphate (GTP) binds in its place, activating the Î± subunit. The activated Î± chain then dissociates from receptor and from the Î² and Î³ chains. Both the activated Î± subunit and Î²Î³ subunits modulate effectors in the plasma membrane.[140] The effector influenced by Î± or Î²Î³ subunits may be an enzyme that the subunits stimulate or inhibit (eg, adenylate cyclase) or an ion channel that is opened or closed directly or through other chemical reactions (eg, channel phosphorylation).[30] Intrinsic GTPase activity in the Î± chain eventually converts the GTP to GDP, inactivating the Î± subunit and allowing it to reassociate with the Î² and Î³ chains and the neurotransmitter receptor, terminating the action of the subunits.[140]

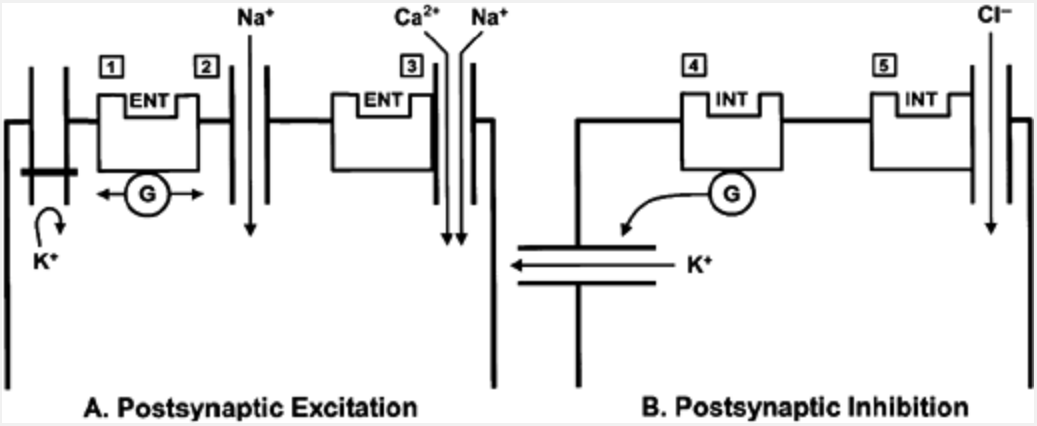

Figure 14-1. Common mechanisms of postsynaptic excitation and inhibition. A. An excitatory neurotransmitter (ENT) binds to receptors linked to G proteins to prevent K^+ efflux [1] or to allow Na^+ influx [2], producing membrane depolarization. An ENT may bind to and activate a cation channel [3] to allow Na^+ and/or Ca^{2+} influx with resultant membrane depolarization. B. An inhibitory neurotransmitter (INT) hyperpolarizes the membrane (makes membrane potential more negative) by binding to receptors linked to G proteins to enhance K^+ efflux [4], or to Cl^- channels to allow Cl^- influx [5]. Some chloride channels are regulated by G proteins as well. G = G protein.

G proteins are mainly categorized by the type of Î± chain they contain. The three main families of G proteins coupled to neurotransmitter receptors are G_s (containing the Î± subunit $Î±_s$), $G_{i/o}$ (containing $Î±_i$ or $Î±_o$), and G_q (containing $Î±_q$). G_s is a positive allosteric effector of membrane-bound adenylate cyclase; activation of a neurotransmitter receptor coupled to G_s causes a rise in intracellular 3â€², 5â€²-cyclic adenosine monophosphate (cAMP) concentration.[89] Neurotransmitter receptors activating G_i may inhibit adenylate cyclase or modulate K^+ and Ca^{2+} channels. Receptors coupled to $G_{q/11}$ act through membrane-bound phospholipase C to

increase intracellular calcium concentrations.

Table 14-1 lists the neurotransmitter receptors coupled to G proteins. A given neurotransmitter can activate different classes of receptors (eg, channel and G protein) or different types of receptors in the same class. For example, $GABA_A$ receptors are Cl^- channels, whereas $GABA_B$ receptors are coupled to G proteins. Dopamine D_1 receptors are linked to G_s, whereas D_2 receptors are linked to G_i or G_o.

Neuronal Excitation and Inhibition

Excitatory neurotransmitters usually act postsynaptically by causing Na^+ or Ca^{2+} influx, or by preventing K^+ efflux, triggering depolarization and an action potential (Fig. 14-1). These effects may be mediated by channel or G protein-coupled receptors.

Postsynaptic inhibition can be mediated by channel receptors or by receptors coupled to G proteins (Fig. 14-1). Inhibition is usually accomplished by movement of Cl^- into the neuron or by movement of K^+ out of the neuron. Both processes hyperpolarize the neuron and move membrane potential farther away from

threshold, making it more difficult for a given stimulus to depolarize the membrane to threshold voltage.

Presynaptic inhibition, the prevention of neurotransmitter release, is usually mediated by receptors coupled to G proteins. When a neurotransmitter released from a neuron binds to a receptor on that same neuron to limit further neurotransmitter release, the receptor is termed an *autoreceptor*.[133] Autoreceptors reside on dendrites, cell bodies, axons, and presynaptic terminals. Autoreceptors on dendrites and cell bodies (somatodendritic autoreceptors) usually inhibit further neurotransmitter release by increasing K^+ efflux, hyperpolarizing the neuron away from threshold (Fig. 14-2). However, activation of autoreceptors found on presynaptic terminals

(terminal autoreceptors) usually limits increases in intracellular Ca^{2+} concentration by limiting Ca^{2+} influx or preventing release from intracellular Ca^{2+} stores, impairing exocytosis of neurotransmitter vesicles (Fig. 14-2). Types of neurotransmitter receptors that serve as autoreceptors also usually reside postsynaptically, where they may mediate different physiologic effects.

Presynaptic nerve terminal inhibition of neurotransmitter release is not limited to actions by autoreceptors. Presynaptic terminal inhibitory receptors for various neurotransmitters may be found on a single neuron (heteroreceptors). For example, not only does stimulation of an $Î±_2$ autoreceptor on a noradrenergic nerve limit norepinephrine release, but stimulation of presynaptic $Î±_2$ receptors found on postganglionic parasympathetic nerve terminals prevents acetylcholine release.

Finally, stimulation of receptors on presynaptic nerve endings may enhance, rather than inhibit, neurotransmitter release. Such receptors also are usually coupled to G proteins. For example, stimulation of a $Î²_2$ receptor on an adrenergic nerve terminal enhances norepinephrine release.

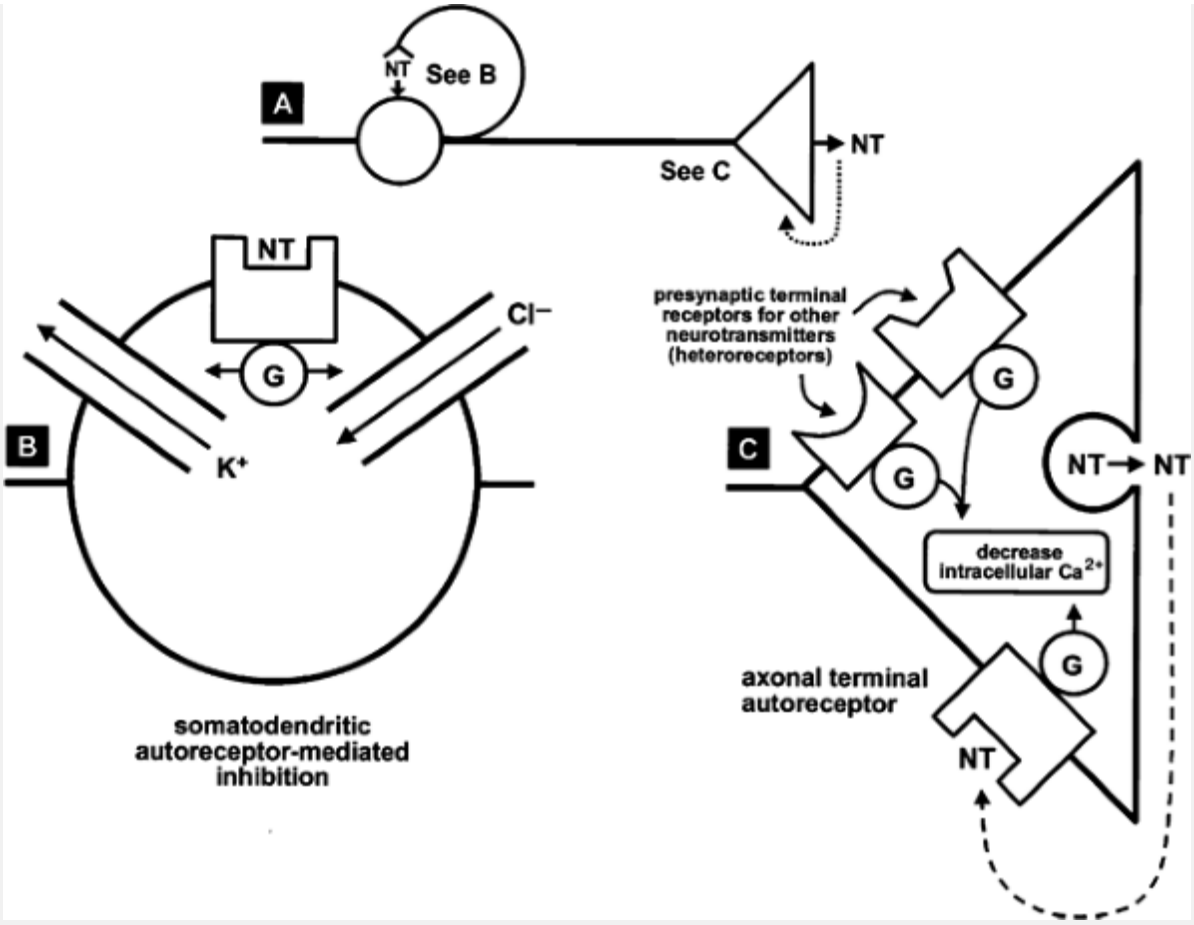

Figure 14-2. Common mechanisms of presynaptic inhibition (the inhibition of neurotransmitter [NT] release). A. Neuron A releases NT, which returns to activate receptors on the cell body or dendrites (somatodendritic autoreceptors), or on the axonal terminal (terminal autoreceptors). Such activation limits further release of NT by completing a negative feedback loop. B. At somatodendritic autoreceptors, NT binding produces activation of G proteins, which promote either K^+ efflux or Cl^- influx; both processes hyperpolarize the neuron away from threshold. C. At terminal autoreceptors, NT binding activates G proteins, which, through various mechanisms, lower intracellular Ca^{2+} concentrations to prevent exocytosis of NT vesicles, despite depolarization. Presynaptic inhibitory receptors for other types of

NTs (heteroreceptors) are illustrated in C. Excitatory axonal terminal autoreceptors and heteroreceptors that serve to enhance (not inhibit) neurotransmitter release are not shown. G = G protein.

Acetylcholine

ACh is a neurotransmitter of the central and peripheral nervous system. Centrally, it is found in both brain and spinal cord; cholinergic fibers project diffusely to the cerebral cortex. Peripherally, ACh serves as a neurotransmitter in autonomic and somatic motor fibers (Fig. 14-3).

Synthesis, Release, and Inactivation

Acetylcholine is synthesized from acetylcoenzyme A and choline. Acetylcholine moves into synaptic vesicles via the vesicular membrane transporter VAChT, where it is stored before release into the synapse by Ca^{2+}-dependent exocytosis. Acetylcholine undergoes degradation in the synapse to choline and acetic acid by acetylcholinesterase. An Na^{+}-dependent transporter in the neuronal membrane then pumps choline back into the cytoplasm to be used again as a substrate for ACh synthesis (Fig. 14-4). Pseudocholinesterase (plasma cholinesterase) is made in the liver and

plays no role in the degradation of synaptic ACh. However, it does metabolize some drugs, including cocaine and succinylcholine.

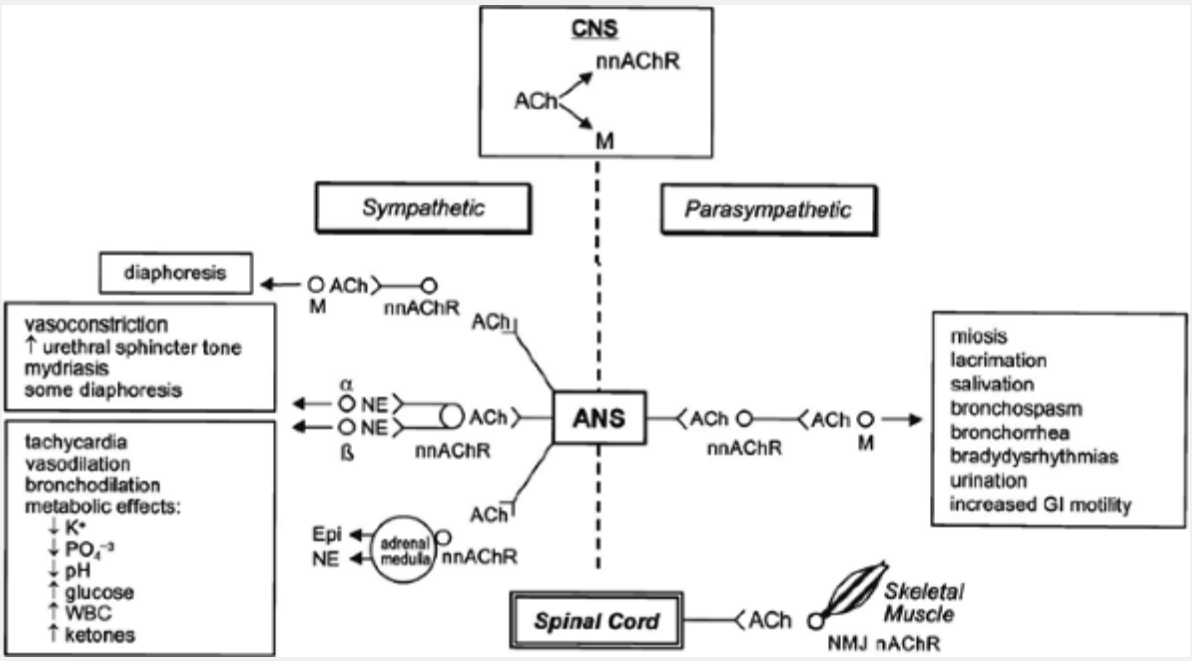

Figure 14-3. Diagram of the cholinergic nervous system, including adrenergic involvement in the autonomic nervous system. ACh binds to CNS, ganglionic, and adrenal neuronal nicotinic receptors (nnAChRs) and to neuromuscular junction nicotinic receptors (NMJ nAChRs). ACh also binds to various subtypes of muscarinic (M) receptors in the CNS and on effector organs innervated by postsynaptic parasympathetic neurons and to most sweat glands. NE and/or EPI released in response to ganglionic ACh stimulation of nnAChRs activates Î±- and Î²-adrenoceptors. ACh =acetylcholine; ANS = autonomic nervous system; CNS =central nervous system; EPI =epinephrine; NE =norepinephrine.

Acetylcholine Receptors

Nicotinic Receptors

After release from cholinergic nerve endings, ACh activates two main types of receptors: nicotinic and muscarinic.[85] Nicotinic receptors (nAChRs) reside in CNS (mainly in spinal cord), on postganglionic autonomic neurons (both sympathetic and parasympathetic), and at skeletal neuromuscular junctions, where they mediate muscle contraction (Fig. 14-3).

Nicotinic receptors at neuromuscular junctions (NMJ nAChRs) are part of an Na^+ channel made of five protein subunits and are thus channel receptors. Stimulation of these receptors by ACh results mainly in Na^+ influx, depolarization of the endplate, and triggering of an action potential that is propagated down muscle by voltage-gated Na^+ channels.

Nicotinic receptors on central or peripheral neurons or in the adrenal gland are termed neuronal nAChRs. Neuronal nAChRs are also ion channels, although in some cases Ca^{2+} influx through the receptor may be more important than Na^+ influx. Neuronal nAChRs also comprise five protein subunits.

Muscarinic Receptors

Muscarinic receptors reside in the CNS (mainly in the brain), on end organs innervated by postganglionic parasympathetic nerve endings, and at most postganglionic sympathetically innervated sweat glands (Fig. 14-4). At least five subtypes of muscarinic receptors, $M_{1â€“5}$, are recognized and linked to several G proteins. For example, in the heart, ACh released from the vagus nerve binds to M_2 receptors linked to G_i. G_i opens K^+ channels, allowing efflux of K^+ down its concentration gradient, which makes the inside of the cell more negative and more difficult to depolarize, slowing heart rate. Different subtypes of muscarinic receptors also act as autoreceptors in various locations, M_1 being the most common.

Chemical Agents

Table 14-2 provides examples of agents that affect cholinergic neurotransmission.

Modulators of Acetylcholine Release

Figure 14-4 illustrates sites of actions of numerous agents that influence the cholinergic nervous system. Botulinum toxins, some neurotoxins from pit vipers, and elapid Î²-neurotoxins prevent release of ACh from peripheral nerve endings.[61] This results in ptosis, other cranial nerve signs, weakness, and respiratory failure. Hypermagnesemia also inhibits acetylcholine release, probably by inhibiting Ca^{2+} influx into the nerve endings.[85]

Guanidine, aminopyridines, and black widow spider venom enhance the release of ACh from nerve endings. Guanidine has been unsuccessfully tried as a treatment for botulism. Aminopyridines block voltage-gated K^+ channels to prevent K^+ efflux; the resultant action potential widening (delayed repolarization) causes prolongation of Ca^{2+} channel activation, enhancing influx of Ca^{2+} and promoting neurotransmitter release. Aminopyridines have been used therapeutically in Lambert-Eaton syndrome, myasthenia gravis, and multiple sclerosis, and experimentally in calcium channel blocker overdose.

Black widow spider venom causes acetylcholine release with resultant muscle cramping and diaphoresis.[6] Carbachol, a nicotinic and muscarinic agonist, also probably causes ACh release.

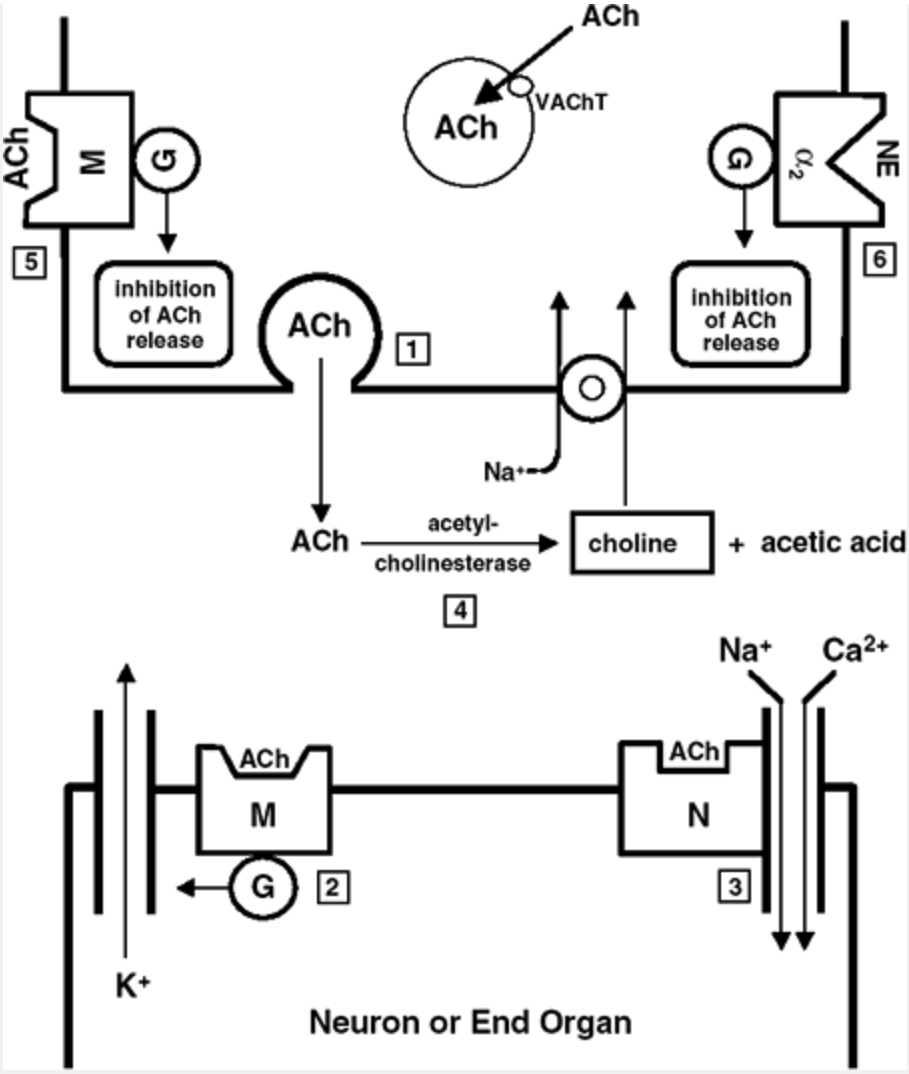

Figure 14-4. Cholinergic nerve ending. Activation of postsynaptic muscarinic receptors hyperpolarizes the postsynaptic membrane through G-protein-mediated enhancement of K^+ efflux. Several subtypes of muscarinic receptors coupled to various G proteins existâ€”a muscarinic receptor coupled to a G protein that opens K^+ channels is shown only as an example. Postsynaptic nicotinic receptor activation causes Na^+ influx and membrane depolarization. Importantly, Ca^{2+} influx appears to be the main cation involved with some neuronal nicotinic receptors. Presynaptic muscarinic and Î±$_2$-

adrenoceptor activation prevents ACh release through lowering of intracellular Ca^{2+} concentrations. The agents listed in Table 14-2 may act to enhance or prevent release of ACh [1]; activate or antagonize postsynaptic muscarinic (M) receptors [2]; activate or antagonize nicotinic (N) receptors [3]; inhibit acetylcholinesterase [4]; prevent ACh release by stimulating presynaptic muscarinic autoreceptors [5] or Î±$_2$-adrenergic heteroreceptors [6]; or enhance ACh release by antagonizing presynaptic autoreceptors [5] or by antagonizing presynaptic Î±$_2$-adrenergic heteroreceptors [6] (on parasympathetic postganglionic terminals). ACh =acetylcholine; G = G protein; NE =norepinephrine; VAChT = vesicular transporter for ACh.

Nicotinic Receptor Agonists and Antagonists

Agents that bind to and activate nicotinic receptors may stimulate postganglionic sympathetic and parasympathetic neurons, skeletal muscle endplates, and neurons within the CNS (Fig. 14-3). Prolonged depolarization at the receptor eventually causes blockade of nicotinic receptors.[113] For example, poisoning by nicotine, both a neuronal and NMJ nAChR agonist, produces hypertension, tachycardia, vomiting, diarrhea, muscle fasciculations, and convulsions (excitation), followed by hypotension, bradydysrhythmias, paralysis, and coma (blockade). Nicotinic agonists include nicotine alkaloids (eg, nicotine, coniine, lobeline), carbachol (mainly muscarinic effects), and methacholine (slight effect). Succinylcholine is a neuromuscular blocking agent that initially stimulates and then blocks NMJ nAChRs.

TABLE 14-2. Examples of Xenobiotics That Affect Cholinergic Neurotransmission

Cholinomimetics	Cholinolytics
Cause ACH release	Direct nicotinic antagonists
Î±$_2$-Adrenergic antagonists[a]	Î±-Bungarotoxin[c]
Aminopyridines	Coniine
Black widow spider venom	Cytisine
Carbachol	Gallamine
Guanidine	Hexamethonium
	Lobeline
Anticholinesterases	Mecamylamine
Echothiophate iodide	Nicotine
Edrophonium	Nondepolarizing neuro-
Galantamine	muscular blocking agents

N-methylcarbamate insecticides	Succinylcholine[b]
Metrifonate	Trimethaphan
Neostigmine	
Organic phosphorus insecticides	Indirect neuronal nicotinic
Physostigmine	antagonists
Pyridostigmine	Physostigmine
Rivastigmine	Tacrine
Tacrine	Galantamine
Direct nicotinic agonists	Direct muscarinic antagonists
Carbachol	Amantadine
Coniine	Antihistamines
Cytisine	Atropine
Lobeline	Benztropine

Nicotine	Carbamazepine
Succinylcholine (initial)[b]	Clozapine
	Cyclobenzaprine
Indirect neuronal nicotinic agonists	Disopyramide
Chlorpromazine	Glutethimide
Corticosteroids	Orphenadrine
Ethanol	Phenothiazines
Ketamine	Procainamide
Local anesthetics	Quinidine
Phencyclidine	Scopolamine
Volatile anesthetics	Tricyclic antidepressants
	Trihexyphenidyl
Direct muscarinic agonists	
Arecoline	Inhibit ACh release

Bethanechol	Î±2-Adrenergic agonists[d]
Carbachol	Botulinum toxins
Methacholine	Crotalidae venoms
Muscarine	Elapidae Î²-neurotoxins
Pilocarpine	Hypermagnesemia

ACh = acetylcholine
[a]Antagonism of Î±2-adrenoceptors enhances ACh release from parasympathetic nerve endings.
[b]Depolarizing neuromuscular blocking agent.
[c]Î±-Bungarotoxin exemplifies many elapid Î±-neurotoxins that produce paralysis and death from respiratory failure.
[d]Stimulation of presynaptic Î±2-adrenoceptors on parasympathetic nerve endings prevents ACh release.

Agents that block NMJ nAChRs without stimulation at skeletal neuromuscular junctions produce weakness and paralysis. Examples include curare and atracurium. Î±-Neurotoxins from elapids (eg, Î±-bungarotoxin) directly antagonize NMJ nAChRs,

producing ptosis, weakness, and respiratory failure from paralysis.[164]

Chemicals blocking peripheral neuronal nAChRs produce autonomic ganglionic blockade. Trimethaphan is used as a pharmacologic ganglionic blocker; however, trimethaphan is not entirely specific for neuronal nAChRs. Occasional patients develop weakness and

paralysis from NMJ nAChR blockade.

Recent studies demonstrate that the function of neuronal nAChRs can be modulated by a variety of compounds that do not bind to the ACh binding site, but bind instead to a number of distinct allosteric sites on the neuronal nAChR. For example, aside from their ability to inhibit acetylcholinesterase, physostigmine, tacrine, and galantamine bind to a noncompetitive allosteric activator site on neuronal nAChRs to enhance channel opening and ion conductance (there is evidence suggesting that serotonin may bind here as well). Furthermore, a diverse range of compounds, including chlorpromazine, phencyclidine, ketamine, local anesthetics, and ethanol bind to a noncompetitive negative allosteric site(s) to inhibit inward ion fluxes without directly affecting ACh binding. Steroids can desensitize neuronal nAChRs by binding to yet an additional allosteric site. Finally, a dihydropyridine calcium channel blocker binding site has been described, but remains poorly understood.[115]

Muscarinic Receptor Agonists and Antagonists

Peripheral muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic agonists produce sedation, extrapyramidal dystonias and rigidity, coma, and convulsions. Examples of direct muscarinic agonists include muscarine (from mushrooms), bethanechol, pilocarpine, carbachol, arecoline, and methacholine.

Anticholinergic poisoning syndrome results from blockade of muscarinic receptors and is more appropriately referred to as antimuscarinic poisoning syndrome.[136] Central nervous system muscarinic blockade produces confusion, agitation, myoclonus, tremor, picking movements, abnormal speech, hallucinations, and coma. Peripheral antimuscarinic effects include mydriasis, anhidrosis, tachycardia, and urinary retention. Muscarinic antagonists number in

the hundreds; Table 14-2 lists examples.

Acetylcholinesterase Inhibition

Agents inhibiting acetylcholinesterase raise ACh concentrations at both nicotinic and muscarinic receptors, producing a variety of CNS, sympathetic, parasympathetic, and skeletal muscle signs and symptoms.[32] Anticholinesterases include organic phosphorus compounds and *N*-methylcarbamates. Organic phosphorus compounds are usually encountered as insecticides, although topical medicinal organic phosphorus compounds are used for the treatment of glaucoma and lice. *N*-methylcarbamates are found as insecticides and pharmaceutics. Medicinal *N*-methylcarbamates include physostigmine, pyridostigmine, rivastigmine, and neostigmine. Edrophonium, galantamine, tacrine, and metrifonate are noncarbamate, reversible anticholinesterases.

Î ±$_2$-Adrenoceptor Agonists and Antagonists

Agonists and antagonists of Î±$_2$-adrenoceptors are discussed in detail below. Briefly, stimulation of presynaptic Î±$_2$-adrenoceptors on postganglionic parasympathetic nerve endings decreases ACh release. Conversely, presynaptic Î±$_2$ antagonism increases ACh release (Fig. 14-4).

Norepinephrine and Epinephrine

Norepinephrine (NE), epinephrine (EPI), dopamine (DA), and serotonin (5-hydroxytryptamine; 5-HT) have historically been referred to as biogenic amines, and their neurotransmitter systems are similar in many respects. Neurotransmitter synthesis, vesicle transport and storage, uptake, and degradation share many enzymes and structurally similar transport proteins. Cocaine, reserpine, amphetamines, and monoamine oxidase inhibitors (MAOIs) affect all four types of neurons. In addition, these agents produce several

different effects in the same system. For example, in the noradrenergic neuron, amphetamines work mainly by causing the release of cytoplasmic norepinephrine, but they also inhibit norepinephrine uptake, and their metabolites inhibit monoamine oxidase. Actions of drugs that affect all biogenic amine neurotransmitters are described in the most detail for noradrenergic neurons. For the sake of brevity, similar mechanisms of action are simply noted in discussions of dopaminergic and serotonergic neurotransmission.

Norepinephrine is released from postganglionic sympathetic fibers (Fig. 14-3) and is also found in the CNS. The adrenal gland, acting as a modified sympathetic ganglion, releases epinephrine and lesser amounts of norepinephrine in response to stimulation of neuronal nAChRs. Epinephrine-containing neurons also reside in the brainstem.

The locus ceruleus is the main noradrenergic nucleus in the brain, comprising about 12,500 neurons in the floor of the fourth ventricle on each side of the pons. Axons radiate from this nucleus out to all layers of the cerebral cortex, to the cerebellum, and to other structures. Norepinephrine demonstrates both excitatory and inhibitory actions in the CNS. Norepinephrine released from locus ceruleus projections in the hippocampus increases cortical neuron activity through Î²-adrenoceptor activation and G protein-mediated inhibition of K^+ efflux. Norepinephrine released in outer cortical areas produces inhibitory effects mediated by Î±-adrenoceptor agonism. At this level, norepinephrine produces slow cortical neuron hyperpolarization and decreased rates of spontaneous firing. Consistent with this, norepinephrine demonstrates anticonvulsant actions in animals. Carbamazepine's anticonvulsant action may be partly a result of inhibition of norepinephrine uptake.[45] Despite antagonistic actions on different cortical neurons, electrical stimulation of the locus ceruleus produces widespread cortical activation and excitation. This overall effect probably explains a great deal of the hyperattentiveness and lack of fatigue that

accompanies use of agents that mimic or increase noradrenergic activity in the brain. Locus ceruleus neuronal firing increases during waking and dramatically falls during sleep.

Synthesis, Release, and Uptake

Figure 14-5 is a representation of a noradrenergic neuron. Tyrosine hydroxylase is the rate-limiting enzyme in norepinephrine synthesis and is sensitive to negative feedback by norepinephrine. This enzyme requires Fe^{2+} as a cofactor and exists as a homotetramer and is upregulated by chronic exposure to caffeine and nicotine. Under normal dietary conditions tyrosine hydroxylase is completely saturated by tyrosine, and increasing dietary tyrosine intake does not appreciably increase dopa synthesis. Dopa undergoes decarboxylation by L-amino acid decarboxylase to dopamine. L-Amino acid decarboxylase (dopa decarboxylase) is not specific for dopa. For example, it also catalyzes the formation of serotonin from 5-hydroxytryptophan.

About one-half of cytoplasmic dopa is actively pumped into vesicles containing the enzyme dopamine-Î²-hydroxylase by VMAT2. The remaining dopamine is quickly deaminated.

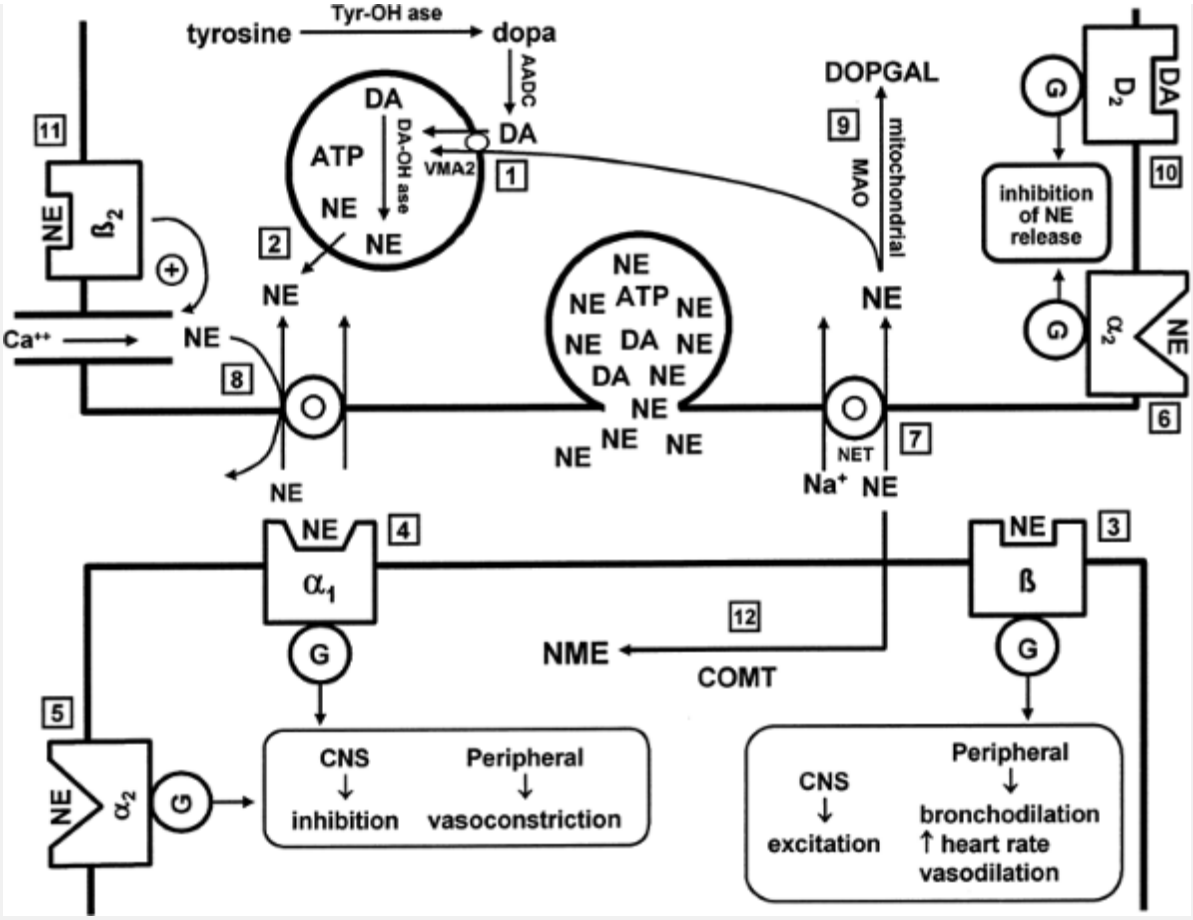

Figure 14-5. Noradrenergic nerve ending. The postsynaptic membrane may represent an end organ or another neuron in the CNS. Brief examples of effects resulting from postsynaptic receptor activation are shown. Agents in Tables 14-4 and 14-5 produce effects by inhibiting transport of dopamine (DA) or norepinephrine (NE) into vesicles through VMA2 [1]; causing movement of NE from vesicles into the cytoplasm [2]; activating or antagonizing postsynaptic Î±- and Î²-adrenoceptors [3â€“5]; modulating NE release by activating or antagonizing presynaptic $Î±_2$-autoreceptors [6], $dopamine_2$ (D_2) heteroreceptors [10], or $Î²_2$-autoreceptors [11]; blocking uptake of NE (NET inhibition) [7]; causing reverse transport of NE from the cytoplasm into the synapse via NET by raising cytoplasmic NE concentrations [8]; inhibiting monoamine oxidase (MAO) to prevent NE degradation

[9]; or inhibiting COMT to prevent NE degradation [12]. COMT is not found in neurons in large amounts. AADC =aromatic L-amino acid decarboxylase; ATP =adenosine triphosphate; DA-OHase = dopamine-Î²-hydroxylase; COMT = catechol-*O*-methyltransferase; CNS =central nervous system; DOPGAL = 3,4-dihydroxyphenylglycoaldehyde; G = G protein; NET =membrane NE uptake transporter; NME = normetanephrine; Tyr-OHase = tyrosine hydroxylase; VMA2 =vesicle uptake transporter for NE.

In the vesicle, dopamine is converted to norepinephrine by dopamine-Î²-hydroxylase, an enzyme requiring Cu^{2+} and ascorbic acid. Vesicles isolated from peripheral nerve endings contain dopamine, norepinephrine, dopamine-Î²-hydroxylase, and ATP, and all of these substances are released into the synapse during Ca^{2+}-dependent exocytosis triggered by neuronal firing. (Whether dopamine-Î²-hydroxylase is released into CNS synapses has not been determined.) In neurons containing epinephrine as a neurotransmitter, norepinephrine is released from vesicles into the cytoplasm, where it is converted to epinephrine by phenylethanolamine-*N*-methyl-transferase. Epinephrine is then transported back into vesicles before synaptic release.[85]

Norepinephrine is removed from the synapse mainly by uptake into the presynaptic neuron by the norepinephrine transporter (NET). Although this transporter has great affinity for norepinephrine, it also transports other amines, including dopamine, tyramine, MAOIs, and amphetamines. Once pumped back into the cytoplasm, norepinephrine can either be transported back into vesicles for further storage and release, or can be quickly enzymatically degraded by monoamine oxidase (MAO), an enzyme expressed on the outer mitochondrial membrane.

MAO resides in sympathetic postganglionic neurons, intestinal mucosa, liver, kidney, lung, and brain, but also extracellularly. It

exists as two isozymes, MAO-A and MAO-B,[98] each with relatively separate affinities for various substrates (Table 14-3). Neuronal MAO degrades cytoplasmic amines, including neurotransmitters, to

prevent elevated cytoplasmic concentrations of biogenic amines. Hepatic and intestinal MAO prevent large quantities of dietary bioactive amines from entering the circulation and producing systemic effects.

TABLE 14-3. Characteristics of Monoamine Oxidase (MAO) Isozymes

	MAO Isozymes	
	MAO-A	MAO-B
Location		
Brain	+	+++
Intestine	+++	+
Liver	++	++
Platelets	0	++++
Placenta	++++	0
Substrates		

Norepinephrine	+ + + +	+
Epinephrine	+ +	+ +
Dopamine	+ +	+ +
Serotonin	+ + + +	+
Tyramine	+ +	+ + +

Catechol-*O*-methyltransferase (COMT), found in the synaptic cleft, also metabolizes norepinephrine and epinephrine. In other tissue, COMT metabolizes catecholamines, including those that have entered the systemic circulation.

Adrenergic Receptors

The two main types of adrenoceptors are Î±-adrenoceptors and Î²-adrenoceptors. All adrenoceptors are linked to G proteins.

Î²-Adrenoceptors

Î²-Adrenoceptors are divided into three major subtypes ($Î²_1$, $Î²_2$, and $Î²_3$), depending on their affinity for various agonists and antagonists.[28,66,68,89] $Î²_1$- and $Î²_2$-adrenoceptors are linked to G_s, and their stimulation raises cAMP concentration and/or activates protein kinase A, which, in turn, produces several effects, including regulation of ion channels. At least some $Î²_3$-adrenoceptors may be coupled not only to G_s, but also to receptors for $G_{i/o}$ proteins.

The Î²-adrenoceptors are polymorphic, with genetic variation in the human population.[26] Polymorphism influences response to medications, regulation of receptors, and clinical course of

disease.[26,68,89] In general, peripheral Î²$_1$-adrenoceptors are found mainly in the heart (along with Î²$_2$ receptors), whereas peripheral Î²$_2$-adrenoceptors also mediate additional adrenergic effects.[68] Presynaptic Î²$_2$-adrenoceptor activation causes release of norepinephrine from nerve endings (positive feedback). Î²$_3$-Adrenoceptors reside mainly in fat, but they also reside in skeletal muscle, gallbladder, and colon where they regulate metabolic processes. Activation of cardiac Î²$_3$-adrenoceptors might produce negative inotropic effects in some circumstances. Î²$_3$-Adrenoceptors' polymorphism may contribute to clinical expressions of nonâ€“insulin-dependent diabetes and obesity.[26,148,165]

Î±-Adrenoceptors

Î±-Adrenoceptors are linked to G proteins that inhibit adenylate cyclase and lower cAMP levels, affect ion channels, increase intracellular calcium through inositol triphosphate and diacylglycerol production, or produce other actions. These receptors are divided into two main types, Î±$_1$ and Î±$_2$, and at least six subtypes, Î±$_{1A}$, Î±$_{1B}$, Î±$_{1D}$, Î±$_{2A}$, Î±$_{2B}$, and Î±$_{2C}$.[39,66] Most Î±$_1$ adrenoceptors are coupled to G_q, whereas most Î±$_2$ adrenoceptors are coupled to G_i.

In peripheral tissue, Î±$_1$-adrenoceptors reside on the postsynaptic membrane in continuity with the synaptic cleft. Stimulation of these receptors on blood vessels commonly results in vasoconstriction. Most Î±$_1$ receptors are coupled to G_q.

Î±$_2$-Adrenoceptors reside on both sides of the synapse. Presynaptic Î±$_2$-adrenoceptor activation mediates negative feedback, limiting further release of norepinephrine (Fig. 14-5). Postganglionic parasympathetic neurons (cholinergic) also contain presynaptic Î±$_2$-adrenoceptors that, when stimulated, prevent release of ACh (Fig. 14-4).

Postsynaptic Î±$_2$-adrenoceptors on vasculature also can mediate vasoconstriction. Initially, it was suggested that postsynaptic Î±$_2$-adrenoceptors resided mainly outside of the synapse and mediated

vasoconstrictive responses to circulating Î± agonists such as norepinephrine, whereas postsynaptic $Î±_1$-adrenoceptors responded to norepinephrine released from nerve endings. However, it has been demonstrated that in at least some tissues (eg, saphenous vein), norepinephrine released following nerve stimulation produces vasoconstriction through action at $Î±_2$-adrenoceptors, making the previous differentiation not as distinct.[39,74] Because both $Î±_1$- and $Î±_2$-adrenoceptors on noncerebral vasculature mediate vasoconstriction, a patient with hypertension from high concentrations of circulating catecholamine (eg, pheochromocytoma or clonidine withdrawal) or from extravasation of norepinephrine from an intravenous line commonly needs both $Î±_1$- and $Î±_2$-adrenoceptor blockade to vasodilate adequately (eg, phentolamine). Stimulation of postsynaptic $Î±_2$-adrenoceptors in the brainstem inhibits sympathetic output and produces sedation (Fig. 14-6). In fact, dexmedetomidine, an imidazole and potent $Î±_{2A}$-adrenergic agonist, is used for sedation in intensive care patients, although hypotension and bradycardia occur as expected side effects.[13]

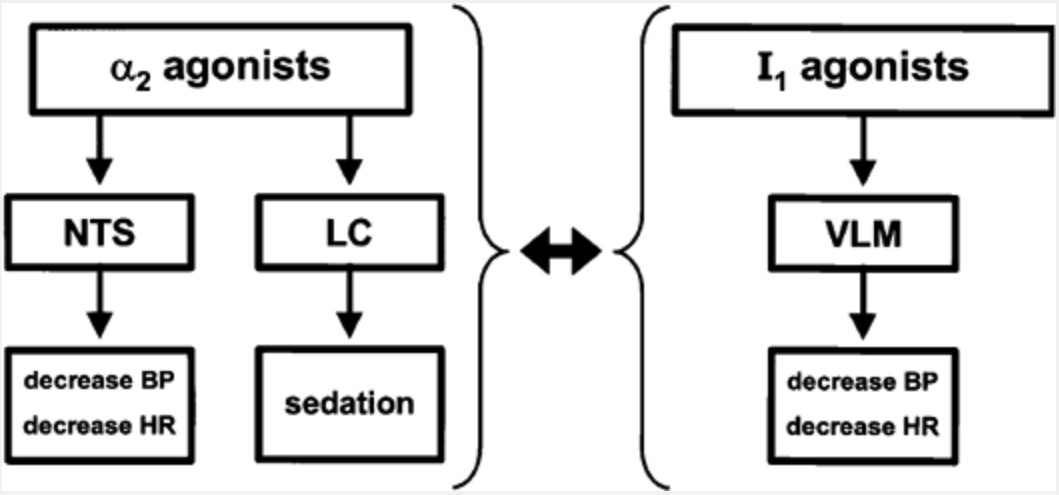

Figure 14-6. Central action of agents that activate $Î±_2$-adrenoceptors or that bind to type 1 imidazoline binding sites (I_1). There are poorly understood interactions between

imidazoline binding sites and Î±$_2$-adrenoceptors that make delineation of specific effects difficult to attribute to specific receptor activation. BP = blood pressure; HR = heart rate; LC =locus ceruleus; NTS = nucleus tractus solitarius; VLM =ventrolateral medulla.

Chemical Agents

Chemicals producing pharmacologic effects that result in or mimic increased activity of the adrenergic nervous system are *sympathomimetics* (Table 14-4). Those with the opposite effect are *sympatholytics* (Table 14-5).

Sympathomimetics

Direct-Acting Agents

Drugs or chemicals whose sympathomimetic actions result from direct binding to Î±- or Î²-adrenoceptors are called direct-acting sympathomimetics. Most of these drugs do not cross the bloodâ€“brain barrier in significant quantities.

Indirect-Acting Agents

Agents that produce sympathomimetic effects by causing the release of cytoplasmic norepinephrine from the nerve ending in the absence of vesicle exocytosis are called indirect-acting sympathomimetics. Amphetamine is the prototype of indirect-acting agents and is used for the discussion of what is known about their mechanism of action. In general, mechanisms of indirect release of norepinephrine by amphetamines, cocaine, phencyclidine, MAOIs, and mixed-acting agents noted in Table 14-4 are similar in that their actions depend on their ability to produce elevated cytoplasmic norepinephrine concentrations.

Amphetamine and structurally similar indirect-acting agents move into the neuron mainly by the membrane transporter that pumps norepinephrine into the neuron. (Lipophilic indirect-acting

agents move into the neuron by diffusion.) From the cytoplasm, amphetamines are transported into neurotransmitter vesicles, where they buffer hydrogen ions to raise intravesicle pH. As noted earlier, much of the vesicle's ability to concentrate norepinephrine (and other neurotransmitters) is a result of ion trapping of norepinephrine at the lower pH. The rise in intravesicle pH produced by amphetamines causes norepinephrine to leave the vesicle and move into the cytoplasm.[149,150] Such movement may be caused by diffusion and/or reverse transport of norepinephrine by VMAT2. In the cytoplasm, amphetamines also compete with norepinephrine and dopamine for transport into vesicles, which further contributes to elevated cytoplasmic norepinephrine concentrations. In the case of amphetamine, the rise in cytoplasmic concentrations of norepinephrine may be enhanced by the ability of amphetamine metabolites to inhibit MAO, which impairs norepinephrine degradation.

TABLE 14-4. Examples of Sympathomimetics

Venlafaxine

MAOIs = monoamine oxidase inhibitors; NE = norepinephrine.
[a] Mainly inhibit MAO-A at low doses.
[b] Mainly inhibit MAO-B at low doses.

Every time the Na^+-dependent uptake transporter, NET, moves, a bioactive amine (eg, tyramine) into the neuron where it is released, a binding site for norepinephrine on NET transiently faces inward and becomes available for reverse transport of norepinephrine out of the neuron. The normally low concentration of cytoplasmic norepinephrine prevents significant reverse transport. In the face of

elevated cytoplasmic norepinephrine concentrations produced by indirect-acting agents as described earlier, NET moves norepinephrine out of the neuron and back into the synapse, where the neurotransmitter stimulates adrenoceptors (indirect action). This process is sometimes referred to as facilitated exchange diffusion, or displacement, of norepinephrine from the nerve ending. Evidence supporting reverse transport produced by amphetamines is that inhibitors of the transporter (eg, tricyclic antidepressants) prevent amphetamine-induced norepinephrine release.

While all indirect-acting agents cause reverse norepinephrine transport by increasing cytoplasmic norepinephrine concentrations, those that move into the neuron by the membrane transporter (eg, amphetamines, MAOIs, dopamine, tyramine) further enhance reverse transport because their uptake may cause more norepinephrine binding sites on NET to face inward per unit time.

Although cocaine does inhibit NET, it also causes some norepinephrine release. In fact, cocaine similarly lessens pH gradients across vesicle membranes[150] to raise cytoplasmic concentrations of

norepinephrine. That cocaine produces less norepinephrine release than amphetamines is partly explained by cocaine-induced inhibition of the membrane transporter and by the fact that cocaine does not move into the neuron by active uptake (ie, does not increase the number of norepinephrine binding sites facing inward), but diffuses into the neuron. (Most of cocaine's severe sympathomimetic effects probably result from cocaine's action on the brain rather than peripheral nerve endings.[155])

TABLE 14-5. Examples of Sympatholytics

Î±-Adrenoceptor antagonists	Penbutolol[a]
Clozapine	Pindolol[a]
Doxazosin	Practolol[a]

Alprenolol[a]	Imidazoline binding-site agonists[d]
Atenolol	Clonidine

Betaxolol	Guanabenz
Bisoprolol	Guanfacine
Carteolol	Moxonidine
Carvedilol	Naphazoline
Esmolol	Oxymetazoline
Labetalol	Rilmenidine
Metipranolol[a]	
Metoprolol	Inhibitors of vesicle uptake
Nadolol	Reserpine[b]
Oxprenolol[a]	Tetrabenazine

NE = norepinephrine; MAOIs = monoamine oxidase inhibitors.
[a] Partial Î²-agonist.
[b] Causes transient NE release after initial dose.
[c] Metabolized to Î±-methylnorepinephrine, which activates Î±$_2$-receptors.
[d] Agents in these categories vary in their relative selectivity for Î±$_2$-adrenoceptors or imidazoline binding sites.

Phencyclidine (PCP) is a hallucinogen that possesses multiple pharmacologic actions. Like toxicity from many hallucinogens, PCP

toxicity is accompanied by increased adrenergic activity, which results, in part, from PCP-induced decreases in pH gradients across the vesicle membrane[150] and indirect release of norepinephrine. Like cocaine, PCP moves into the neuron by diffusion rather than uptake through the membrane transporter, at least partly explaining less PCP-induced norepinephrine release than is typically seen in amphetamine poisoning.

Reserpine, guanethidine, and bretylium cause neurotransmitter release either with initial doses or early in overdose before their primary sympatholytic effects are observed. Presumably this is a result of transient rises in cytoplasmic norepinephrine concentrations.

In addition to causing ACh release, black widow spider venom causes vesicle exocytosis of norepinephrine, producing hypertension and diaphoresis over the palms, soles, upper lip, and nose. All of the aforementioned indirectly acting agents, except black widow spider venom, enter the CNS.

Mixed-Acting Agents

Mixed-acting sympathomimetics act directly and indirectly. For example, large doses of phenylpropanolamine indirectly cause norepinephrine release and act directly as Î±-adrenoceptor agonists. Intravenously administered dopamine indirectly causes norepinephrine release, explaining most of its vasoconstricting activity, but also directly stimulates dopaminergic and Î²-adrenoceptors. Direct Î±-agonism occurs at high doses. Except for dopamine, these agents also cross the bloodâ€“brain barrier to produce central effects.

Uptake Inhibitors

Inhibitors of norepinephrine uptake raise concentrations of norepinephrine in the synapse to produce excessive stimulation of

adrenoceptors.

There are two main mechanisms of action for inhibitors of biogenic amine uptake: competitive and noncompetitive. Noncompetitive inhibitors, such as cyclic antidepressants, carbamazepine, venlafaxine, methylphenidate, and cocaine, bind at or near the carrier site on NET to prevent NET from moving norepinephrine and other agents into or out of the neuron. These inhibitors are not transported into the neuron by this mechanism; lipophilic agents diffuse into the neuron. Various drugs used for their antimuscarinic effects also block NET noncompetitively. These include benztropine, diphenhydramine, trihexyphenidyl, atomoxetine, and orphenadrine.[105]

The second mechanism, competitive inhibition of NET, characterizes most indirect-acting agents, including amphetamines and structurally similar compounds (eg, mixed-acting agents, MAOIs). These agents prevent norepinephrine uptake by competing with synaptic norepinephrine for binding to the carrier site on NET, the mechanism by which these agents move into the neuron. In fact, an additional adrenergic action of amphetamines, mixed-acting agents, MAOIs, and tyramine is to raise synaptic norepinephrine concentrations by competing with norepinephrine for uptake, thereby compounding their indirect and/or direct actions.

MAOIs

MAOIs are transported by NET into the neuron, where they act through several mechanisms.[98] Inhibition of MAO, their main pharmacologic effect, results in increased cytoplasmic concentrations of norepinephrine and some indirect release of neurotransmitter into the synapse. As a minor effect they also may displace norepinephrine from vesicles by raising pH in a manner similar to amphetamines. These actions explain the initial hyperadrenergic findings following MAOI overdose and probably also account for occasional and unpredictable adrenergic crises in patients taking these agents,

despite the patients' compliance with diet.

Nonspecific MAOIs inhibit both isozymes of MAO, preventing intestinal and hepatic degradation of bioactive amines as well. A person taking such an MAOI who then ingests food or receives drugs containing indirect-acting sympathomimetics (eg, tyramine, phenylpropanolamine, dopamine, amphetamines) has a much larger cytoplasmic concentration of norepinephrine to transport into the synapse and may therefore develop central and peripheral hyperadrenergic findings. Although MAOIs specific for the MAO-B isozyme are less likely to predispose to food or drug interactions by maintaining significant hepatic MAO activity, isozyme specificity is lost as the dose of the MAOI is increased. In fact, selegiline, currently marketed as a selective MAO-B inhibitor, partially inhibits MAO-A activity at therapeutic doses. Specificity may lack importance when indirect-acting agents are administered systemically (eg, intravenous dopamine or amphetamines). Several amphetamine metabolites are capable of inhibiting MAO, contributing to their sympathomimetic activity. Linezolid is an antibiotic that produces weak MAO inhibition.

Occasionally, patients suffering from refractory depression respond to a combination of MAOIs and tricyclic antidepressants. This combination therapy is usually unaccompanied by excessive adrenergic activity because the inhibition of the membrane uptake transporter by the tricyclic antidepressant attenuates excessive reverse transport of elevated cytoplasmic norepinephrine concentrations produced by MAOIs. In animals, tricyclic antidepressants that prevent norepinephrine uptake or cocaine, also an norepinephrine uptake inhibitor, protect against drug and food interactions with MAOIs by inhibiting the uptake transporter, thus inhibiting reverse transport.

COMT Inhibitors

Inhibitors of COMT are administered in the treatment of Parkinson

disease to prevent the catabolism of concomitantly administered L-dopa. Entacapone only acts peripherally, whereas tolcapone also crosses the bloodâ€“brain barrier.

Î ±$_2$-Adrenoceptor Antagonists

Yohimbine blocks Î±$_2$-adrenoceptors to produce a mixed clinical picture. Peripheral postsynaptic Î±$_2$ blockade produces vasodilatation. Blockade of presynaptic Î±$_2$-adrenoceptors on cholinergic nerve endings (Fig. 14-4) enhances ACh release, occasionally producing bronchospasm[82] and contributing to diaphoresis. Similar presynaptic actions on peripheral noradrenergic nerves enhance catecholamine release (Fig. 14-5). Blockade of central Î±$_2$-adrenoceptors in the locus ceruleus results in CNS stimulation, whereas blockade of postsynaptic Î±$_2$-adrenoceptors in the nucleus tractus solitarius may enhance sympathetic output (Fig. 14-6). The final result includes hypertension, tachycardia, anxiety, fear, agitation, mania, mydriasis, diaphoresis, and bronchospasm.[90] Yohimbine does not block

imidazoline receptors (see Imidazoline and Î±$_2$-Adrenoceptor Agonists below). One action of the antidepressant mirtazapine is Î±$_2$-adrenoceptor blockade.

Sympatholytics

Direct Antagonists

Direct Î±- and Î²-adrenoceptor antagonists are noted in Table 14-5. In overdose, and sometimes at therapeutic doses, any Î²-adrenoceptor selectivity becomes insignificant. Some Î²-adrenoceptor antagonists also are partial agonists.

Drugs That Prevent Norepinephrine Release

Drugs that prevent the release of norepinephrine, despite membrane depolarization, include guanethidine and bretylium. Both drugs initially cause release of norepinephrine and can produce transient sympathomimetic effects. Drugs that block the vesicle uptake transporter prevent the movement of norepinephrine into vesicles and deplete the nerve ending of this neurotransmitter, also preventing norepinephrine release after depolarization. Examples include rauwolfia alkaloids (reserpine), tetrabenazine, and guanethidine (in part). Reserpine and ketanserin inhibit both VMAT1 and VMAT2, whereas tetrabenazine only inhibits VMAT2. Like guanethidine, reserpine causes transient norepinephrine release with initial dose or early in overdose. Î²-Adrenoceptor antagonists block presynaptic $Î²_2$-adrenoceptors to limit catecholamine release from nerve endings, although this does not appear to be their main mechanism of action.

Imidazoline and $Î±_2$-Adrenoceptor Agonists

Numerous imidazoline derivatives (eg, clonidine) and structurally similar compounds are used as centrally acting antihypertensive agents or long-acting topical vasoconstrictors. These agents are currently divided into first-generation agents (eg, clonidine) that are thought to act at both $Î±_{2A}$-adrenoceptor and imidazoline binding sites, and second-generation agents (eg, rilmenidine) that express much greater affinity for imidazoline binding sites than for $Î±_{2A}$-adrenergic receptors.

The ventromedial (depressor) and the rostral-ventrolateral (pressor) areas of the ventrolateral medulla (VLM) are responsible for the central regulation of cardiovascular tone and blood pressure. They receive afferent fibers from the carotid and aortic baroreceptors, which form the tractus solitarius via the nucleus tractus solitarius (NTS).[73]

The hypotensive actions of $Î±_2$-adrenoceptor agonists were previously attributed entirely to brainstem $Î±_2$-adrenoceptor

activation, because stimulation of postsynaptic Î±$_2$-adrenoceptors in the NTS decreased sympathetic output (Fig. 14-6).[22] The discovery of imidazoline binding sites, however, led to a more complicated analysis. It was discovered that imidazolines and related substances produced hypotension when applied to the VLM, whereas catecholamines capable of activating Î±$_2$-adrenoceptors were claimed to be incapable of producing effects at this site. This led to the hypothesis that receptors specific for imidazoline-like compounds, different from Î±$_{2A}$-adrenoceptors, must exist. Decreased sympathetic output could result from activation of imidazoline binding sites in the VLM and from Î±$_2$-adrenoceptor activation in the NTS; sedation and respiratory depression were attributed to Î±$_2$-adrenoceptor activation in the locus ceruleus.[47]

Imidazoline binding sites have been characterized and subdivided into I_1, I_2 (with subtypes), and I_3.[42] I_1 binding sites reside on neuronal plasma membranes and are involved in controlling systemic blood pressure. I_2 sites are allosteric sites found on the external membrane of mitochondria and modulate MAO-A and MAO-B.[22,42] The putative I_3 sites are thought to modulate insulin secretion via ATP-sensitive potassium channels in Î²-islet cells.

The molecular structure of the imidazoline binding sites has not been identified and it is unclear whether these sites act through ion channels, through G proteins, or through some other mechanism. An endogenous ligand for these binding sites has been discovered. Agmatine, originally identified as a *clonidine-displacing substance*, is synthesized by decarboxylation of arginine. It appears to function as a neurotransmitter, and it binds all subclasses of both Î±$_2$-adrenoreceptors and I-binding sites, as well as block *N*-methyl-D-aspartate (NMDA) glutamate receptors. Other physiologic functions of agmatine continue to be investigated.[10,124]

Functional studies suggested that the hypotensive effects of clonidine-like drugs involved imidazoline binding sites, while most of the side effects involved Î±$_{2A}$-adrenoceptors.[47] Consequently, drugs

such as rilmenidine, possessing much greater activity at imidazoline binding sites than at Î±$_{2A}$-adrenoceptors, were developed. However, functional evidence suggests that there is significant interaction between the imidazoline sites and Î±$_{2A}$-adrenoceptors, and that this interaction is necessary to trigger hypotensive effects.[21,47] As examples, there appears to be a close relationship between â€œpresynapticâ€• imidazoline sites and â€œdownstreamâ€• Î±$_{2A}$-adrenoceptors in the VLM mediating hypotension;[62] Î±$_{2A}$-adrenoceptors in the VLM appear to be activated as a consequence of imidazoline site activation. Although second-generation agents (rilmenidine and moxonidine) preferentially act via imidazoline binding sites, and although Î±$_{2A}$-adrenoceptors are important for the hypotension produced by first-generation agents (clonidine and Î±-methyldopa), hypotension produced by all of these agents is dependent on central noradrenergic pathways.[21,62] Some studies report that yohimbine, an Î±$_2$-adrenoceptor antagonist, reverses the hypotensive effect of both clonidine and rilmenidine-like drugs, when given at high doses. Thus, it appears that there is significant interaction between imidazoline sites and Î±$_{2A}$-adrenoceptors, and that centrally acting antihypertensive agents with relatively high affinity for imidazoline binding sites may require both imidazoline-specific sites and functional Î±$_{2A}$-adrenoceptors to produce their hypotensive actions.

Ingestions of agents that activate Î±$_{2A}$-adrenoceptors and imidazoline binding sites (Table 14-5) produce a mixed picture. Peripheral postsynaptic Î±$_2$-adrenoceptor stimulation produces vasoconstriction, pallor, and hypertension, often with reflex bradycardia (Fig. 14-5). Peripheral presynaptic Î±$_2$-adrenoceptor stimulation prevents norepinephrine release (Fig. 14-5), whereas central Î±$_2$-adrenoceptor stimulation in the locus ceruleus accounts for CNS and respiratory depression (Fig. 14-6). Stimulation of postsynaptic Î±$_2$-adrenoceptors in the NTS and, with some agents, of central I_1 receptors in the VLM are thought to inhibit sympathetic output and enhance parasympathetic tone, explaining hypotension

with bradycardia (Fig. 14-6).[73] Both first- and second-generation agents produce dry mouth.[22,42]

Dopamine-Î²-Hydroxylase Inhibition

Inhibition of dopamine-Î²-hydroxylase (Fig. 14-5) prevents the conversion of dopamine to norepinephrine, resulting in less norepinephrine release and less Î±- and Î²-adrenoceptor stimulation with neuronal firing. Disulfiram produces such inhibition.[44] Because norepinephrine release mediates most of dopamine's ability to cause vasoconstriction, norepinephrine is the vasopressor of choice in a hypotensive patient taking disulfiram. Diethyldithiocarbamate, used in metal

chelation and by some AIDS patients, is a disulfiram metabolite that produces similar actions. MAOIs and Î±-methyldopa also inhibit dopamine-Î²-hydroxylase, although this is not their main mechanism of action.[98]

Dopamine is relatively contraindicated in hypotensive patients who have overdosed on MAOIs. First, dopamine acts indirectly and its administration might produce excessive adrenergic activity and exaggerated rises in blood pressure. Second, even if an adrenergic storm does not occur, most of dopamine's Î±-mediated vasoconstriction is secondary to norepinephrine release. In the presence of MAOIs, norepinephrine synthesis may be impaired from concomitant dopamine-Î²-hydroxylase inhibition, and dopamine may not reliably raise blood pressure if cytoplasmic and vesicular stores have been depleted. In the presence of impaired norepinephrine release or Î±-adrenoceptor blockade by any cause, unopposed dopamine-induced vasodilatation from action on peripheral dopamine and Î²-adrenoceptors may paradoxically lower blood pressure further. Norepinephrine and epinephrine can be used to support blood pressure relatively safely in patients taking MAOIs, because these vasopressors have little or no indirect action and are

metabolized by COMT when given intravenously.

Dopamine

Because dopamine is the direct precursor of norepinephrine, noradrenergic vesicles contain dopamine. The release of norepinephrine from peripheral sympathetic nerves, therefore, always results in release of some dopamine (Fig. 14-5), as does the release of norepinephrine and epinephrine from the adrenal gland, explaining the normal presence of dopamine in blood. In peripheral tissues, activation of dopamine receptors cause vasodilatation of mesenteric, and coronary vascular beds. Dopamine can also stimulate Î²-adrenoceptors and, at high doses, can directly stimulate Î±-adrenoceptors. When dopamine is administered intravenously, most vasoconstriction is caused by dopamine-induced norepinephrine release.

Dopamine accounts for about one-half of all catecholamines in the brain and is present in greater quantities than norepinephrine or 5-HT. In contrast to the diffuse projections of noradrenergic neurons, dopaminergic neurons and receptors are highly organized and concentrated in several areas, especially in the basal ganglia and limbic system.[81,135]

Excessive dopaminergic activity in the neostriatum and/or other areas from any cause (eg, increased release, impaired uptake, increased receptor sensitivity) can produce acute choreoathetosis[75] and acute Gilles de la Tourette syndrome, with tics, spitting, and cursing. Excessive dopaminergic activity in the limbic system and, perhaps, in other areas, produces paranoid psychosis that is indistinguishable from paranoid schizophrenia and is thought responsible for much of the drug craving and addictive behavior in patients abusing sympathomimetic drugs. Diminished dopaminergic tone (eg, impaired release, receptor blockade) in the neostriatum produces various extrapyramidal disorders such as acute dystonias and parkinsonism.[123,145,158]

Synthesis, Release, and Uptake

The steps of dopamine synthesis and vesicle storage are the same as those for norepinephrine, except that dopamine is not converted to norepinephrine after transport into vesicles (Fig. 14-7). Dopamine is removed from the synapse via uptake by DAT, the membrane-bound dopamine transporter. DAT and NET exhibit 66% homology in their amino acid sequences. Like NET, DAT is not completely specific for dopamine, but transports drugs such as amphetamines and other structurally similar sympathomimetics.

Cytoplasmic dopamine has a fate similar to norepinephrine. It is pumped back into vesicles by VMAT2 (brain) and VMAT1 (neuroendocrine tissue, adrenal glands) or degraded by MAO and COMT.

Dopamine Receptors

All dopamine receptors are coupled to G proteins and are divided into two main groups, depending on whether they raise or lower cAMP concentrations. Dopamine D_1-like receptors (D_1 and D_5) are expressed as various subtypes and are linked to G_s to stimulate adenylate cyclase and to raise cAMP concentrations.[81] Dopamine is 5â€“10 times more potent at D_5 receptors than it is at D_1 receptors.

D_2-like receptors (D_2, D_3, D_4) are linked to $G_{i/o}$, to produce several actions, including inhibition of adenylate cyclase and the lowering of cAMP levels. Again, numerous subtypes of receptors exist (eg, D_{2S}, D_{2L}). D_2 receptors are concentrated in the basal ganglia and limbic system. Some D_2 receptors also reside on presynaptic membranes, where their activation limits neurotransmitter release, including the peripheral release of norepinephrine (Figs. 14-5 and 14-7). D_3 receptors are concentrated in the hypothalamic and limbic nuclei, whereas D_4 receptors are concentrated in the frontal cortex and limbic nuclei (rather than basal ganglia nuclei). Most agonists bind to

the D_3 receptors with higher affinity than to D_2 receptors, whereas most antagonists bind preferentially to D_2 receptors.[81,135] Most agonists and antagonists express a lower affinity for D_4 receptors than they express for D_2 receptors; a notable exception is clozapine.

Chemical Agents

Table 14-6 provides examples of chemical agents that affect dopaminergic neurotransmission.

Dopamine Agonism

Indirect- and Mixed-Acting Agents

Most indirect- and mixed-acting sympathomimetics cause dopamine release. The mechanism of action is similar to that causing norepinephrine release. These agents diffuse into the neuron or undergo uptake by DAT before being transported into vesicles by VMAT2 where they buffer protons and displace dopamine into the cytoplasm for reverse transport by DAT into the synapse. Benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine also cause dopamine release, perhaps contributing to their abuse potential, which is noted below.[105] Excessive dopaminergic activity following therapeutic doses or overdoses of decongestants (eg, pseudoephedrine), amphetamines, methylphenidate, and pemoline can produce acute choreoathetosis and Tourette syndrome.[24,91] Parkinsonian patients ingesting excessive doses of L-dopa (which is converted to dopamine) may present with similar symptoms.

Direct Agonists

Bromocriptine is an ergot derivative that directly activates dopamine receptors (mainly D_2). Toxic effects include those described above for indirect-acting agents. Apomorphine directly activates D_2 receptors. Such action at the chemoreceptive triggering zone

produces vomiting, whereas agonism in the basal ganglia explains apomorphine's use in the treatment of Parkinson disease. Fenoldopam is a D_1 agonist used as a vasodilator in the treatment of hypertensive emergencies.

D_1 and D_2-like receptor activation is the predominant mediator of locomotor effects from dopamine agonists. Activation of either D_1- or D_2-like receptors produces antiparkinsonian effects.[63,135] Cabergoline, ropinirole, and pramipexole are D_2-like agonists used to treat Parkinson disease.[8,42,60] Dihydrexidine is a D_1-like agonist that has been used for the same purpose.

Uptake Inhibition

Agents inhibiting DAT prevent dopamine uptake and include cocaine, amphetamines, methylphenidate, and probably amantadine. Increased dopaminergic activity from cocaine toxicity may produce choreoathetosis (â€œcrack dancingâ€•) and Tourette syndrome. In general, antidepressants are not strong dopamine uptake blockers. However, bupropion appears to be more active in this regard.[131]

As noted earlier, much of the drug craving and addiction produced by sympathomimetics probably results from excessive dopaminergic activity in the mesolimbic system.[145] Interestingly, the anticholinergic drugs benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine are also dopamine uptake inhibitors, possibly explaining their abuse.[105,141] In fact, benztropine is one of the most potent dopamine uptake inhibitors known. Amantadine, an antiparkinsonian agent that causes dopamine release and some inhibition of dopamine uptake (as well as being anticholinergic), is also abused.

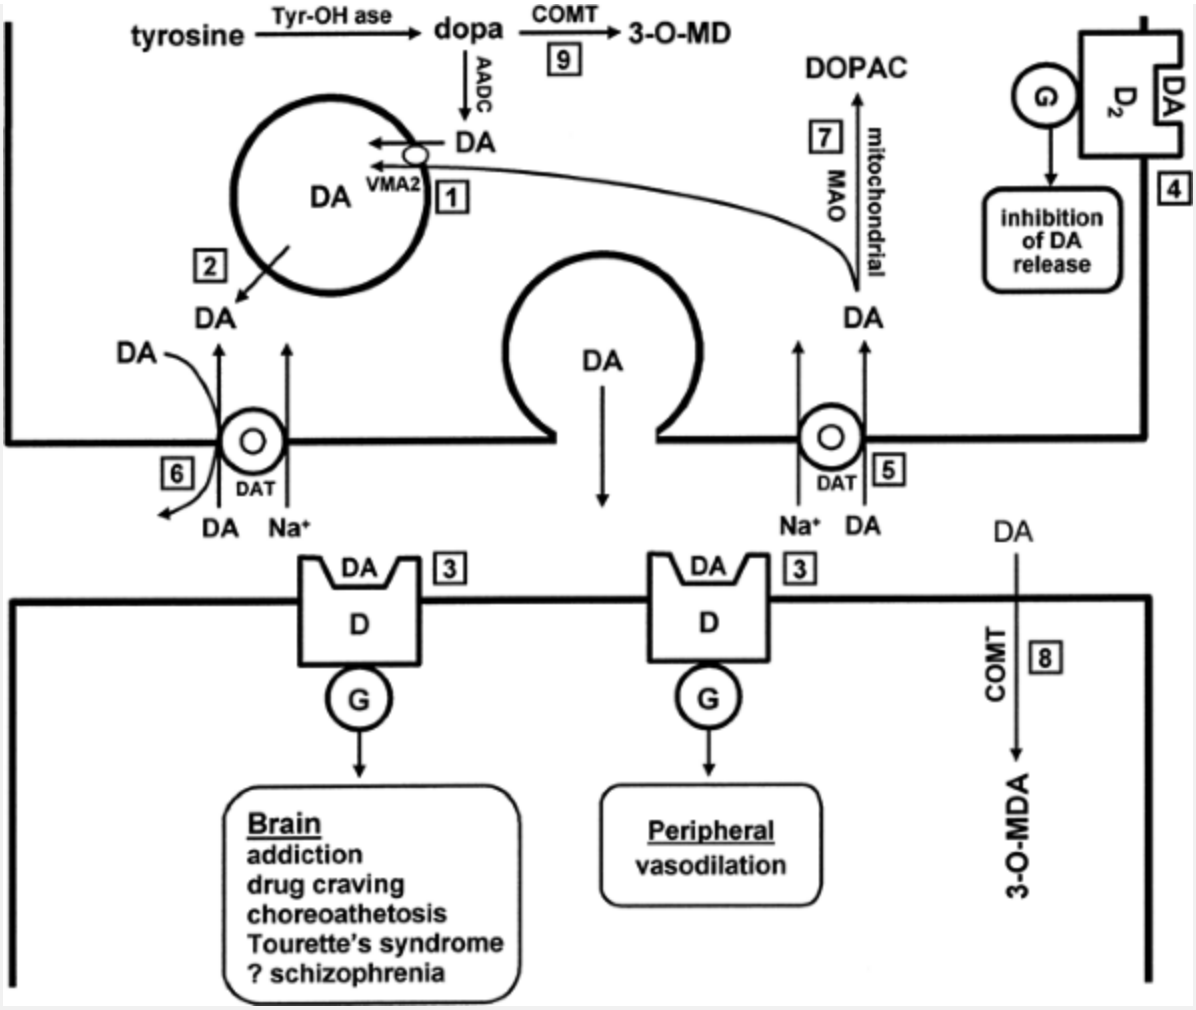

Figure 14-7. A dopaminergic nerve ending and postsynaptic membrane. Dopamine (DA) released from nerve endings binds to various postsynaptic DA receptors (D) on neurons or peripheral end organs. Stimulation of presynaptic D_2 receptors [4] lessens DA release. Agents in Table 14-6 may act to inhibit vesicle uptake [1]; cause DA to leave the vesicle and move into the cytoplasm [2]; activate or antagonize DA receptors [3,4]; inhibit DAT to prevent DA uptake [5]; cause reverse transport of cytoplasmic DA (via DAT) into the synapse by raising cytoplasmic DA concentrations [6]; prevent DA degradation by inhibiting monoamine oxidase (MAO) [7]; prevent DA degradation by inhibiting catechol-*O*-methyltransferase (COMT) [8]; or prevent

dopa metabolism by inhibiting COMT [9]. Both DA and dopa are substrates for COMT. For purposes of illustration, dopa metabolism is shown presynaptically, and DA metabolism is shown postsynaptically. 3-*O*-MD =3-*O*-methyldopa; 3-*O*-MDA =3-*O*-methyldopamine; AADC = L-aromatic amino acid decarboxylase; DAT =membrane DA uptake transporter; DOPAC =3,4-dihydroxyphenylacetic acid; Tyr-OHase =tyrosine hydroxylase; VMA2 = vesicle membrane uptake transporter.

Increase of Receptor Sensitivity

Several drugs are thought to increase sensitivity of dopamine receptors, resulting in choreoathetosis, even with therapeutic doses (eg, phenytoin). Evidence exists that increased dopamine receptor sensitivity may be responsible for movement disorders resulting from amphetamines.[29] Tardive dyskinesia (discussed below) may also result from increased dopamine receptor sensitivity.

MAO Inhibition

MAOIs inhibit the breakdown of cytoplasmic dopamine. Part of the food and drug interactions with MAOIs results from excessive release of dopamine from nerve endings.

COMT Inhibition

Peripheral COMT inhibitors (eg, entacapone, tolcapone) are given with levodopa to patients with Parkinson disease to prevent peripheral degradation of levodopa to 3-*O*-methyldopa. This allows more levodopa to traverse the bloodâ€“brain barrier and to be converted to dopamine by neuronal dopa decarboxylase. Tolcapone also inhibits COMT in the brain.[71] Other substrates of COMT include dopa, dopamine, norepinephrine, epinephrine, and

their hydroxylated metabolites. COMT inhibitors might potentiate the effects of these drugs when administered intravenously.[71]

TABLE 14-6. Examples of Xenobiotics That Affect Dopaminergic Neurotransmission

Dopamine agonism	Bupropion
Direct stimulation of dopamine receptors	Cocaine
Apomorphine	Diphenhydramine
Bromocriptine	Methylphenidate
Cabergoline	Orphenadrine
L-Dopa[a]	Pemoline
Fenoldopam	Trihexyphenidyl
Lisuride	
Pergolide	Increase dopamine receptor sensitivity
Pramipexole	
Ropinirole	Amphetamines

	Antipsychotics
Inhibit dopamine metabolismâ€”MAOIs	Metoclopramide
Clorgyline	Phenytoin
Isocarboxazid	
Linezolid	Dopamine antagonism
Moclobemide	Block dopamine receptors
Pargyline	Amoxapine
Phenelzine	Buspirone
Selegiline	Clozapine
Tranylcypromine	Droperidol
	Haloperidol
Inhibit dopamine metabolismâ€”COMTs	Loxapine
Entacapone	Metoclopramide
Tolcapone	Molindone

	Olanzapine
Indirect acting	Phenothiazines
Amantadine	Pimozide
Amphetamines	Quetiapine
Benztropine	Risperidone
Decongestants	Thioxanthenes
Diphenhydramine	Trazodone
MAOIs	Tricyclic antidepressants[b]
Methylphenidate	Ziprasidone
Orphenadrine	
Pemoline	Destroy dopaminergic neurons
Phencyclidine	
Trihexyphenidyl	MPTP

Inhibit dopamine uptake	Prevent vesicle dopamine uptake
Amantadine	
Amphetamines	Reserpine
Benztropine	Tetrabenazine

COMTs = catechol-*o*-methyltransferase inhibitors; MAOIs 5 monoamine oxidase inhibitors; MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

[a] Metabolized to dopamine, which acts as an agonist.

[b] Relatively weak D_2 receptor antagonists.

Dopamine Antagonism

Direct Receptor Blockade

Blockade of dopamine receptors is the specific aim when using many therapeutic agents. The neuroleptic actions of butyrophenones, phenothiazines, and other antipsychotics mainly correlate with their ability to block D_2-like receptors, probably in the mesolimbic system. Many phenothi-azines block both D_1-like and D_2-like receptors, whereas haloperidol mainly blocks D_2-like receptors. Unfortunately, antipsychotics and metoclopramide also block dopamine receptors in the striatum, producing various extrapyramidal symptoms, including acute parkinsonism and dystonias.

In the last decade, several â€œatypicalâ€• antipsychotics have been marketed that produce fewer extrapyramidal effects and are thought to carry less risk of producing tardive dyskinesia.[127] The relative

affinity of an antipsychotic for 5-HT_{2A} receptors over D_2 receptors has predictive value for atypical agents with a lower risk of extrapyramidal symptoms.[118] Such agents include clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.

The ratio of muscarinic (M_1) blockade to D_2-receptor blockade is also important in limiting extrapyramidal symptoms. Antipsychotic agents exhibiting strong antimuscarinic effects (eg, olanzapine, clozapine, thioridazine) are also less likely to induce extrapyramidal symptoms.[127]

Buspirone, an antianxiety agent, antagonizes D_2 receptors, which explains occasional extrapyramidal reactions. Various cyclic antidepressants, especially amoxapine, block D_2 receptors to some extent.

The chronic use of dopamine-blocking agents causes upregulation of dopamine receptors. The continued use or, especially, withdrawal of dopamine antagonists (antipsychotics, metoclopramide, and occasionally antidepressants) might result in excessive dopaminergic activity and tardive dyskinesia, characterized by choreiform movements typical of excessive dopaminergic influence in the neostriatum.

The blockade of dopamine receptors by numerous agents, including butyrophenones, phenothiazines, and metoclopramide, can produce a poorly understood disorder called *neuroleptic malignant syndrome*. Neuroleptic malignant syndrome also follows acute withdrawal of dopamine agonists (eg, stopping L-dopa or bromocriptine in a patient prior to surgery). Neuroleptic malignant syndrome is characterized, in part, by mental status changes, autonomic instability, rigidity, and hyperthermia.

Indirect Antagonism

Reserpine and tetrabenazine inhibit VMAT to prevent transport of dopamine into storage vesicles and deplete nerve endings of

dopamine. In fact, reserpine was used as an antipsychotic agent before the introduction of phenothiazines. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analog, undergoes activation by MAO to a metabolite that causes death of dopaminergic neurons. Both MPTP and its metabolite undergo uptake not only by DAT, but also by NET and SET, making their way into all biogenic amine neurons. The reasons that dopaminergic neurons are selectively damaged remains unknown. Both MAOIs and inhibitors of dopamine transporters prevent MPTP-induced destruction of dopaminergic neurons.

Serotonin

Serotonin (5-HT, 5-OH-tryptamine) is a ubiquitous indole alkyl-amine found in nature (animals, plants, venoms) that acts as a neurotransmitter centrally, but is also found peripherally. In fact, less than 2% of the body's 5-HT is found within the CNS.

In the CNS, several hundred thousand serotonergic neurons lie in or in juxtaposition to numerous midline nuclei in the brainstem (9 raphe nuclei), from which they project to virtually all areas of the brain, including the basal ganglia. Serotonin is involved with mood, personality, affect, appetite, motor function, temperature regulation, sexual activity, pain perception, sleep induction, and other basic functions. Serotonin is not essential for any of these processes but modulates their quality and extent. The serotonergic system is extremely diverse, with 14 types of receptors that act to stimulate or inhibit neurons, including those

of other neurotransmitter systems. Serotonin is also the precursor for the pineal hormone melatonin.[50]

Peripherally, 5-HT is produced mainly in the enterochromaffin cells of the intestine. Local release contributes to peristalsis. Platelets take up 5-HT while passing through the enteric circulation. Serotonin is released from activated platelets to interact with other platelet

membranes (promote aggregation) and with vascular smooth muscle (vasoconstriction in most vascular beds).

Experimentally, 5-HT exhibits diverse effects on the cardiovascular and peripheral nervous systems, although the importance of these actions remains uncertain in the normal physiologic state. Serotonin vasoconstricts (stimulation of 5-HT_2, 5-HT_{1B}, and 5-HT_{1D} receptors) most vascular beds except for coronary arteries and skeletal muscle, where it produces vasodilatation in the presence of intact endothelium. 5-HT_{1B} and 5-HT_{1D} agonists (eg, sumatriptan) might produce coronary vasoconstriction as an adverse effect to their desired actions on cranial vasculature.[59]

Centrally, it is particularly difficult to ascribe a specific symptom or physical finding to serotonergic neurons because of the diversity of their physiologic actions. However, 5-HT definitely plays an important role in the action of many hallucinogenic or illusionogenic drugs, which act as partial agonists at cortical 5-HT_2 receptors.[88] Proserotonergic agents are used to treat depression, whereas agents that antagonize 5-HT receptors (5-HT_2) have greater importance in the management of schizophrenia.

Generally, 5-HT acts in opposition to dopamine. For example, 5-HT serves to increase prolactin, adrenocorticotropic hormone (ACTH), and growth hormone secretion, whereas dopamine decreases prolactin secretion. As another example, activation of basal ganglial 5-HT_{2A} receptors inhibits dopamine release. However, well-known exceptions exist, such as cortical 5-HT_3 receptors, whose activation promotes dopamine release.[88]

Synthesis, Release, and Uptake

Figure 14-8 illustrates 5-HT synthesis. Tryptophan-5-hydroxylase is the rate-limiting enzyme of 5-HT synthesis and is free from negative feedback influences by the end product, 5-HT. Thus, increases in tryptophan are predictably accompanied by increased 5-HT

production. L-Amino acid decarboxylase (dopa decarboxylase) converts 5-hydroxytryptophan to 5-HT. Cytoplasmic 5-HT is transported into vesicles by VMAT2, where it is concentrated by ion trapping before release by Ca^{2+}-dependent exocytosis. In contrast to vesicles containing dopamine or norepinephrine, 5-HT vesicles contain almost no ATP. After release into the synapse, a transporter (SERT) in the neuronal membrane transfers 5-HT back into the neuron, where it reenters vesicles or is degraded by MAO.

Serotonin is preferentially metabolized by the MAO-A isozyme. Paradoxically, the serotonergic nerve terminal is almost devoid of MAO-A but contains abundant amounts of MAO-B. It has been hypothesized that the large amounts of MAO-B metabolize other agents that might inappropriately promote serotonin release (eg, dopa). However, the small amount of MAO-A found in serotonergic neurons provides adequate degradation of 5-HT.[50]

Serotonin Receptors

Most authors identify seven major functioning receptors ($5\text{-}HT_1$ through $5\text{-}HT_7$) and numerous subtypes.[9]

$5\text{-}HT_1$ Receptors

Receptors in the $5\text{-}HT_1$ class are coupled to G proteins and commonly increase K^+ efflux and decrease cAMP concentrations. Members of the $5\text{-}HT_1$ receptor class express greatest affinity for 5-HT and are thus biologically active under normal physiologic conditions. $5\text{-}HT_{1A}$ receptors reside predominantly on raphe nuclei, where they act as somatodendritic autoreceptors. Hippocampal $5\text{-}HT_{1A}$ receptors reside postsynaptically, where they also inhibit through similar mechanisms.[83]

Central $5\text{-}HT_{1D}$ and $5\text{-}HT_{1B}$ receptors primarily act as inhibitory terminal autoreceptors and heteroreceptors. They are found less commonly on postsynaptic membranes. Originally $5\text{-}HT_{1B}$ receptors

were not believed to exist in humans. However, most of the actions described in older literature regarding 5-HT_{1D} receptors can now be attributed to 5-HT_{1B} receptors. Unfortunately, this distinction will continue to lead to confusion for some years to come. Cranial blood vessels (eg, meninges) possess 5-HT_{1D} and 5-HT_{1B} receptors, whose activation produces vasoconstriction and decreased inflammation.[57,59]

5-HT_{1E} and 5-HT_{1F} receptors are more recently discovered members of the 5-HT_1 receptor class. 5-HT_{1F} receptors reside on presynaptic membranes and may act in a similar fashion to 5-HT_{1D} and 5-HT_{1B} receptors.[9]

5-HT_2 Receptors

The three subtypes of 5-HT_2 receptors are coupled to G proteins, thus serving to decrease K^+ efflux and/or increase intracellular Ca^{2+} concentration by raising concentrations of inositol triphosphate and diacylglycerol.[130] The three subtypes of 5-HT_2 receptors are so similar in characterization that investigational agents have great difficulty in distinguishing the subtypes. 5-HT_{2A} receptors are most concentrated in the cerebral cortex, where they serve as excitatory postsynaptic receptors. Their activation increases glutamate release from pyramidal cells, but also can lead to release of GABA.[1,86] 5-HT_{2A} receptors also reside on platelets, where their activation produces platelet aggregation. 5-HT_{2C} receptors (previously 5-HT_{1C}) reside on the choroid plexus, where they regulate cerebrospinal fluid production. Peripherally, 5-HT_{2C} activation also promotes penile erection. Activation of 5-HT_{2B} receptors in the GI tract promotes colonic contraction.[86]

5-HT_3 Receptors

5-HT_3 receptors are isopentameric ligand-gated cation channels that are structurally similar to ACh nicotinic receptors, $GABA_A$ Cl^- channels, and NMDA glutamate receptors.[3] They have been localized

to both presynaptic and postsynaptic membranes. Upon activation, they stimulate the neuron by opening the channel to cause depolarization through Na^+ and/or Ca^{2+} influx. In addition, these channels are normally blocked by Mg^{2+} in a voltage-dependent manner similar to glutamatergic NMDA receptors (see Glutamate below). Centrally, 5-HT_3 receptors are expressed diffusely, but are especially concentrated in the chemoreceptive triggering zone, where their activation induces emesis. In the cerebral cortex, their activation leads to increased release of dopamine and decreased release of ACh. Cortical 5-HT_3 receptors are frequently identified on GABA interneurons where they increase inhibitory, GABAergic tone. In contrast to cerebral actions, activation of peripheral 5-HT_3 receptors on cholinergic nerves in the gut enhances ACh release to increase gastrointestinal motility.[9,18]

5-HT_4 Receptors

5-HT_4 receptors are coupled to G proteins (G_s). Their activation leads to increased cAMP concentrations. 5-HT_4 receptors are scattered diffusely throughout the brain, and their exact role remains undefined. Peripheral 5-HT_4 receptors reside in the heart, intestines, and adrenal gland where their activation can be demonstrated to produce tachycardia, aldosterone and cortisol release, and contraction of gut and bladder smooth muscle. Again,

whether these actions are important under normal physiologic conditions is not clear. Both central and peripheral 5-HT_4 receptors promote the release of acetylcholine.[41]

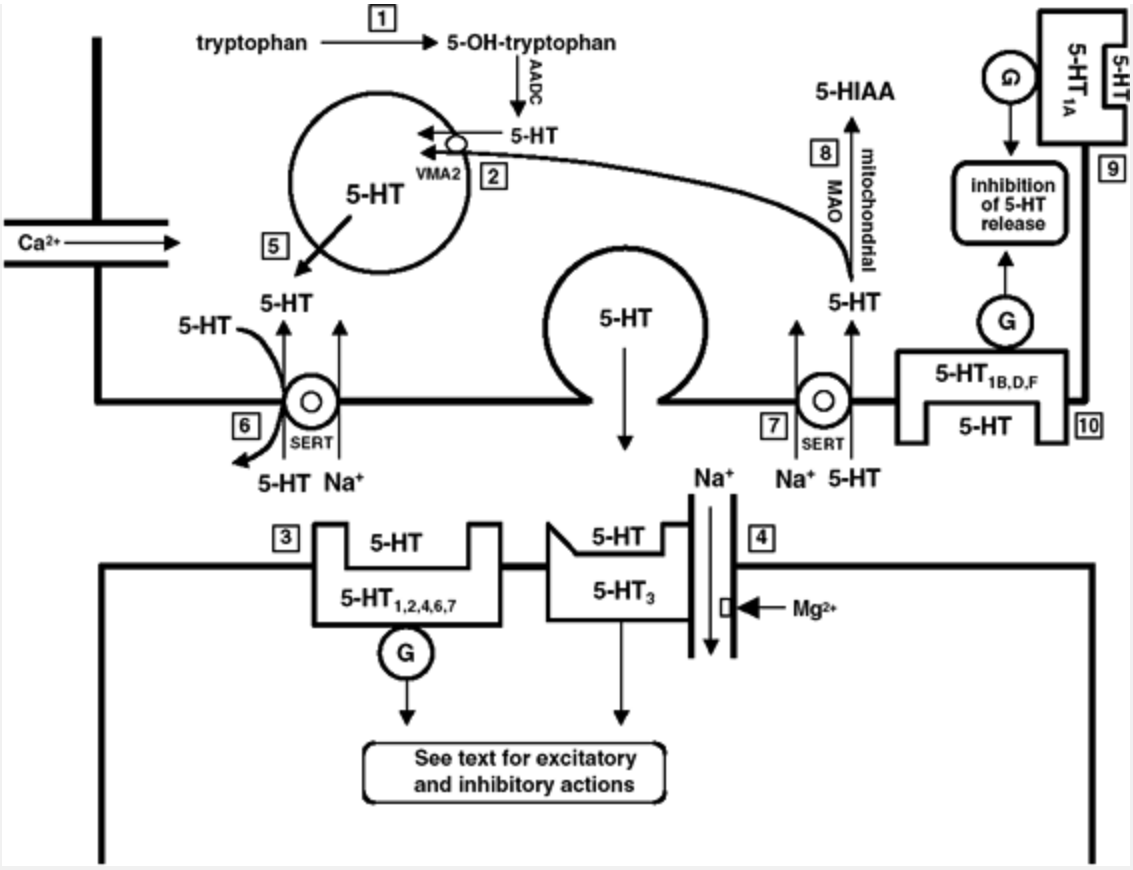

Figure 14-8. A serotonergic nerve ending and postsynaptic membrane. Tryptophan hydroxylase [1] converts tryptophan to 5-hydroxytryptophan (5-OH-tryptophan). Aromatic L-amino acid decarboxylase (AADC) then metabolizes 5-OH-tryptophan to serotonin (5-HT). Serotonin is concentrated within vesicles through uptake by VMA2 before exocytosis [2]. After uptake into the neuron by SERT [7], 5-HT is transported back into vesicles or undergoes degradation by monoamine oxidase (MAO) to an intermediate compound, which is converted to 5-hydroxyindoleacetic acid (5-HIAA) [8]. $5\text{-HT}_{1,2,4,6,7}$ receptors [3,9,10] are coupled to G proteins, while 5-HT_3 receptors [4] are ligand-gated cation channels that may conduct Na^+ and/or Ca^{2+}. 5-HT_3 cation channels also appear to be blocked by Mg^{2+} until the cell is depolarized, allowing Mg^{2+} to dissociateâ€”a mechanism similar to that found at NMDA glutamate receptors. In

addition to residing on postsynaptic membranes, 5-HT_{1A}, 5-HT_{1B}, 5HT_{1D}, and 5-HT_{1F} receptors serve as presynaptic autoreceptors that, when stimulated, decrease further release of 5-HT [9,10]. Presynaptic 5-HT_{1A} receptors mainly serve as somatodendritic autoreceptors, whereas presynaptic 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors serve as terminal autoreceptors. Agents in Table 14-7 act to enhance 5-HT synthesis [1]; inhibit VMA2 to prevent vesicle uptake of 5-HT [2]; raise cytoplasmic concentrations of 5-HT, resulting in reverse transport of 5-HT into the synapse by SERT [6] by displacing 5-HT from vesicles [5] or inhibiting MAO [8]; activate or antagonize 5-HT receptors [3,4,9,10]; or by inhibiting 5-HT uptake [7]. G =G protein; SERT =membrane 5-HT uptake transporter; VMA2 =vesicle membrane uptake transporter.

5-HT_5 Receptors

5-HT_5 receptors exist in the form of at least two subtypes, one of which may be coupled to G_s. Their mechanism of activation remains unknown. 5-HT_5 receptor agonists or antagonists are not readily available.[9]

5-HT_6 and 5-HT_7 Receptors

5-HT_6 and 5-HT_7 receptors are positively coupled to cAMP formation through G proteins. Their distribution is poorly defined. However, many antidepressant and antipsychotic agents antagonize these receptors. They are currently a source of great interest because of the possibility of avoiding dopamine blockade to achieve antipsychotic activity. The 5-HT_7 receptor may be particularly important in regulating circadian rhythms.[78]

Chemical Agents

Table 14-7 provides examples of chemical agents that affect serotonergic neurotransmission.

Serotonin Agonists

The ingestion of tryptophan is thought to increase 5-HT production and was commonly used as an unproved sleep aid until it was associated with the eosinophilia myalgia syndrome. 5-Hydroxytryptophan (5-HTP) is the immediate precursor to 5-HT. 5-HTP is commonly available without a prescription. The antianxiety agents buspirone, gepirone, and ipsapirone act as partial agonists at somatodendritic and postsynaptic 5-HT_{1A} receptors.[9] Sumatriptan, an antimigraine agent, mainly activates 5-HT_{1D} and 5-HT_{1B} receptors. Sumatriptan's action may result from vasoconstriction of meningeal and other cranial, extracerebral vasculature; no impairment of cerebral blood flow follows the use of this agent. Other members of the triptan class of drugs include rizatriptan, zolmitriptan, and naratriptan.[59]

Metoclopramide, cisapride, zacopride, renzapride, and tegaserod are prokinetic drugs that activate 5-HT_4 receptors to increase gut motility.[41,60,84] Because 5-HT_4 receptors are also found in the heart and urinary bladder detrusor muscle, 5-HT_4 agonists occasionally produce bladder incontinence and tachycardia.

Numerous indoles and phenylalkylamines, including ergot alkaloids, lysergic acid diethylamide (LSD), psilocybin, and mescaline, exhibit both agonistic and antagonistic properties at multiple 5-HT receptors. Their hallucinogenic/illusionogenic action is best

explained by partial agonism at 5-HT_{2A} receptors. Some substituted amphetamines (eg, methylenedioxymethamphetamine) directly stimulate serotonin receptors.[1,88]

TABLE 14-7. Examples of Xenobiotics That Affect Serotonergic Neurotransmission

Serotonin agonism	Citalopram
Enhance 5-HT synthesis	Cocaine
L-Tryptophan	Dextromethorphan
5-Hydroxytryptophan	Duloxetine
	Escitalopram
Direct 5-HT agonists	Fluoxetine
Buspirone	Fluvoxamine
Cisapride	Lamotrigine
Ergots and indoles[a]	Meperidine
Flesinoxan	Milnacipran
Gepirone	Nefazodone
Hallucinogenic substituted	Reboxetine
amphetamines	Sertraline

Ipsapirone	Tramadol
mCPP	Trazodone
Mescaline[a]	Tricyclic antidepressants[b]
Metoclopramide	Venlafaxine
Naratriptan	
Renzapride	Serotonin Antagonism
Rizatriptan	Direct 5-HT antagonists
Sulpiride	Alosetron
Sumatriptan	Amisulpride
Tandospirone	Clozapine
Tegaserod	Cyproheptadine
Urapidil	Dolasetron
Zacopride	Ergots and indoles (eg,
Zolmitriptan	LSD)[a]

	Granisetron
Increase 5-HT release	Haloperidol
Amphetamines	Ketanserin
Cocaine	Mianserin
Codeine derivatives	Mescaline[a]
Dexfenfluramine	Methysergide
Dextromethorphan	Metoclopramide
L-Dopa	Mirtazapine
Fenfluramine	Nefazodone
MDMA	Olanzapine
Mirtazapine	Ondansetron
Reserpine (initial)	Phenothiazines
	Phentolamine
Increase 5-HT tone by unknown	Pindolol

mechanism	Propranolol
Lithium	Quetiapine
	Risperidone
Inhibit 5-HT breakdown (MAOIs)	Ritanserin
Clorgyline	Sertindole
Isocarboxazid	Trazodone
Linezolid	Tricyclic antidepressants
Moclobemide	Tropisetron
Pargyline	Ziprasidone
Phenelzine	Zotepine
Tranylcypromine	
Selegiline	Enhance 5-HT uptake
	Tianeptine
Inhibit 5-HT uptake	

Amoxapine	Inhibit vesicle uptake
Amphetamines	Reserpine
Atomoxetine	Ketanserin
Carbamazepine	Tetrabenazine

5-HT = serotonin; LSD = lysergic acid diethylamide; MAOIs = monoamine oxidase inhibitors; *m*CPP = *m*-chlorophenylpiperazine (metabolite of trazodone and nefazodone); MDMA = methylenedioxymethamphetamine.
[a] Indoles and phenylalkylamines activate and antagonize various 5-HT receptors. Their hallucinogenic/illusionogenic effects mainly result from partial agonism at 5-HT_2 receptors.
[b] Clomipramine is the most potent 5-HT uptake inhibitor of the tricyclic antidepressants.

Cocaine and indirect-acting sympathomimetics, especially amphetamines, cause serotonin release as previously described. Other releasing agents are dextromethorphan and codeine derivatives. Centrally, dopamine undergoes uptake into serotonergic neurons to displace 5-HT from the neuron. Ingestion of L-dopa or other agents that increase CNS dopamine concentrations can cause 5-HT release.[104]

Inhibitors of 5-HT uptake include amphetamines, cocaine, various antidepressants, meperidine, and dextromethorphan.[104] Several antidepressants specifically inhibit 5-HT uptake. Examples of selective serotonin reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram. The use of SSRIs sometimes produces extrapyramidal side effects[5] for reasons that

remain unclear because of the numerous actions of 5-HT in the basal ganglia. Two anticonvulsants, carbamazepine and lamotrigine, appear to inhibit 5-HT uptake.[144] Again, reserpine and tetrabenazine prevent 5-HT uptake into vesicles.

MAO-A accounts for most 5-HT degradation, and nonspecific MAOIs and MAO-A inhibitors (clorgyline, moclobemide) both raise 5-HT concentrations and, through indirect action, probably cause 5-HT release.[53,104]

Serotonin Antagonists

Trazodone and nefazodone act mainly as antagonists at 5-HT_2 receptors, but are also weak uptake inhibitors. Both undergo metabolism to *m*-chlorophenylpiperazine (mCPP), which activates most 5-HT receptors, but is especially active at 5-HT_{2C} receptors. Ketanserin and ritanserin specifically antagonize 5-HT_{1D} receptors while methysergide and cyproheptadine antagonize 5-HT_1 and 5-HT_2 receptors.[53,104]

Mirtazapine exhibits complex actions, including antagonism of 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors.[86] Mirtazapine also indirectly increases 5-HT_{1A} activity and enhances release of norepinephrine through antagonism of Î±$_2$-adrenoceptors. Mirtazapine also demonstrates potent antagonism of histaminic, muscarinic, and Î±-adrenoceptors.[53]

Most antipsychotics and tricyclic antidepressants antagonize 5-HT_{2A} and, to a lesser extent, 5-HT_{2C} receptors. In fact, investigators are interested in developing antipsychotic agents similar to risperidone that possess potent antagonistic properties at 5-HT_2 receptors without accompanying dopamine receptor antagonism in order to limit extrapyramidal side effects. These investigations have resulted in the introduction of olanzapine, sertindole, ziprasidone, zotepine, quetiapine, and amisulpride.[16]

Ondansetron, granisetron, tropisetron, dolasetron, and alosetron

antagonize 5-HT_3 receptors. Their antiemetic action is thought to be explained by several mechanisms. Central antagonism at the chemoreceptor triggering zone lessens vomiting. Peripheral 5-HT_3 receptor antagonism in the gut prevents ACh release, decreasing gut motility. Finally, antagonism of vagal 5-HT_3 receptors decreases afferent stimulatory signals to the vomiting center in the brainstem.[9] Ondansetron and other experimental 5-HT_3 antagonists are being studied in the treatment of schizophrenia because of their ability to prevent dopamine release. Metoclopramide antagonizes 5-HT_3 and D_2 receptors.

Tianeptine is an antidepressant that enhances 5-HT uptake, thus lowering synaptic 5-HT concentrations.[112]

Serotonin Syndrome

Excessive stimulation of 5-HT_{1A} receptors and, to a lesser extent, 5-HT_2 receptors, causes serotonin

syndrome.[104] Briefly, this disorder is characterized by shivering, myoclonus, tremor, and rigidity (especially of legs), along with hyperthermia, tachycardia, diaphoresis, confusion, agitation, convulsions, and coma. This iatrogenic, idiosyncratic syndrome results most commonly from the combined use of two serotonergic drugs (eg, SSRI and lithium, SSRI and MAOI, MAOI and clomipramine). Reports indicate that serotonin syndrome may occur following the isolated use or overdose of a single seroto-nergic agent (eg, venlafaxine or fluvoxamine). Drugs that act to increase CNS dopamine concentrations, such as levodopa and bromocriptine, have potential to precipitate serotonin syndrome by indirect serotonin release.[104] Adverse effects (eg, rigidity, hyperthermia) resulting from interactions between MAOIs and meperidine, dextromethorphan, or codeine may result from excessive serotonergic activity, as well, because all of these agents enhance serotonergic tone (Table 14-7).

Î³-Aminobutyric Acid

GABA is one of two main inhibitory neurotransmitters of the central nervous system (glycine is discussed below; see Glycine as an Inhibitory Neurotransmitter). Drugs that enhance GABA activity are generally used as anticonvulsants, sedative-hypnotics, and general anesthetics. Agents that antagonize GABA activity typically produce CNS excitation and convulsions. GABA is synthesized from glutamate, the brain's main excitatory neurotransmitter.

In general, GABA inhibition predominates in the brain. In the spinal cord, through mono- and polysynaptic reflex pathways, GABA mediates a number of physiologically minor peripheral effects outside the CNS (eg, vasodilatation, bladder relaxation). Spinal cord GABA is important in attenuating skeletal muscle reflex arcs.[96]

Synthesis, Release, and Uptake

Figure 14-9 illustrates GABA synthesis. Glutamic acid decarboxylase (GAD) requires pyridoxal phosphate (PLP) as a cofactor. Pyridoxal phosphate is synthesized from pyridoxine (vitamin B_6) by the enzyme pyridoxine kinase (PK).[102] VGAT, a vesicle-bound transporter comprising about 130 amino acids and crossing the vesicle membrane about 10 times, transports GABA into vesicles from where it is released through Ca^{2+}-dependent exocytosis into the synapse.[96] Uptake of GABA from the synapse back into the presynaptic neurons is mediated by the Na^+-dependent transporter, GAT-1, whereas uptake into glial cells and possibly postsynaptic neurons is mediated by GAT-2, GAT-3, and GAT-4. Evidence also suggests that GABA is released into the synapse from cytoplasm by reverse transport under some conditions. In glial cells, cytoplasmic GABA can undergo degradation by GABA-transaminase (GABA-T) to succinic semialdehyde (SSA), part of which then undergoes oxidation to succinate. GABA-T also requires PLP as a cofactor.[109] The transamination of GABA to SSA by GABA-T results in the conversion of Î±-ketoglutarate to glutamate, which then moves back into

neurons to be used for resynthesis of GABA.

GABA Receptors

There are three main types of GABA receptors (Table 14-8).[20] $GABA_A$ receptors are Cl^- channels that mediate postsynaptic inhibition by allowing Cl^- to move into and hyperpolarize the postsynaptic neuron. Situated at various sites in relation to the GABA recognition site on the Cl^- channel are sites for exogenous and endogenous modulatory agents (Fig. 14-10) where numerous excitatory and depressant drugs bind, and through which $GABA_A$ receptor responsiveness is regulated under normal physiologic conditions. The common denominator for modulation at the $GABA_A$ complex is an increase or decrease in inward Cl^- current.

Throughout the CNS there are regional variations in expressions of multiple subunit genes for the $GABA_A$ complex. $GABA_A$ receptors exist as pentamers, composed most commonly of 1 to 3 Î± subunits, 1 to 3 Î² subunits, and either a Î³ or Î´ subunit. The most common combination appears to be 2Î±-2Î²-1Î³. Multiple subtypes of subunits exist (eg, $Î±_1$â€“$Î±_6$), but within a single receptor, the subtypes of individual subunits appear to be identical. Nevertheless, given the large numbers of subtypes and different combinations of subunits, more than 2000 different $GABA_A$ Cl^- channels theoretically could form, with different pharmacologic affinities for certain ligands, including anesthetics, benzodiazepines, barbiturates, and for GABA itself.[8,139] It appears highly unlikely, however, that this many different types of $GABA_A$ receptors are found in mammalian brains.

The second type of GABA receptor, $GABA_B$, is found on both pre- and postsynaptic membranes. The $GABA_B$ receptors are heterodimers, with companion proteins linked to the receptors, and are coupled to G proteins (probably $G_{i/o}$) that mediate both presynaptic and postsynaptic inhibition.[23] Presynaptic inhibition results from preventing Ca^{2+} influx so as to impair exocytosis of neurotransmitter vesicles, including those containing excitatory amino acids (eg,

glutamate). Postsynaptic inhibition is mediated by increasing K^+ efflux through K^+ channels, resulting in hyperpolarization of the membrane away from threshold. Through presynaptic actions, $GABA_B$ receptors also serve as autoreceptors, where their activation in response to synaptic GABA provides feedback inhibition of further neurotransmitter release (Fig. 14-9).

A third GABA receptor, $GABA_C$, is a Cl^- channel that, when activated, allows increased Cl^- influx. The $GABA_C$ receptors are thought to comprise 5 ligand-binding sites, whereas $GABA_A$ receptors have 2 ligand-binding sites.[20] $GABA_C$ receptors are composed of Ï• subunits (Ï•$_1$â€“Ï•$_3$). Ï•$_1$ subunits are located in the mammalian retina, Ï•$_2$ subunits are present in most brain regions, and Ï•$_3$ subunits are found in the hippocampus. Ï•$_1$ and Ï•$_2$ receptors have also been found outside the CNS.[69] $GABA_C$ receptors are sensitive to *cis*-4-aminocrotonic acid (CACA), are insensitive to baclofen, bicuculline, benzodiazepines, and barbiturates, and are less sensitive to neuroactive steroids and to picrotoxin (Table 14-8).[69] $GABA_C$ receptors are activated at 40-fold lower GABA concentrations than $GABA_A$ receptors, are less liable to desensitization, and remain open longer than $GABA_A$ Cl^- channels.

Chemical Agents

Table 14-9 provides examples of chemical agents that affect GABAergic neurotransmission.

Modulation of GABA Production and Degradation

Isoniazid (INH) and other hydrazines (eg, monomethylhydrazine from mushrooms) lower CNS GABA concentrations by several mechanisms. Most important, they compete with pyridoxine for binding to PK, impairing PLP production.[102] Pyridoxal phosphate binding to the GAD complex is easily reversible.[109] The acute decrease in PLP

concentration, then, is rapidly accompanied by impaired GABA synthesis and a decrease in GABA concentration. Lack of normal GABA inhibition produces seizures typical of hydrazine intoxications. Although PLP is also required for GABA degradation by GABA-T, acute decreases in PLP do not affect this enzyme nearly as much, because PLP is more

tightly bound to the GABA-T complex and remains associated with the enzyme.[109] To a lesser extent, isoniazid binds to the GAD-PLP complex to prevent GABA formation.

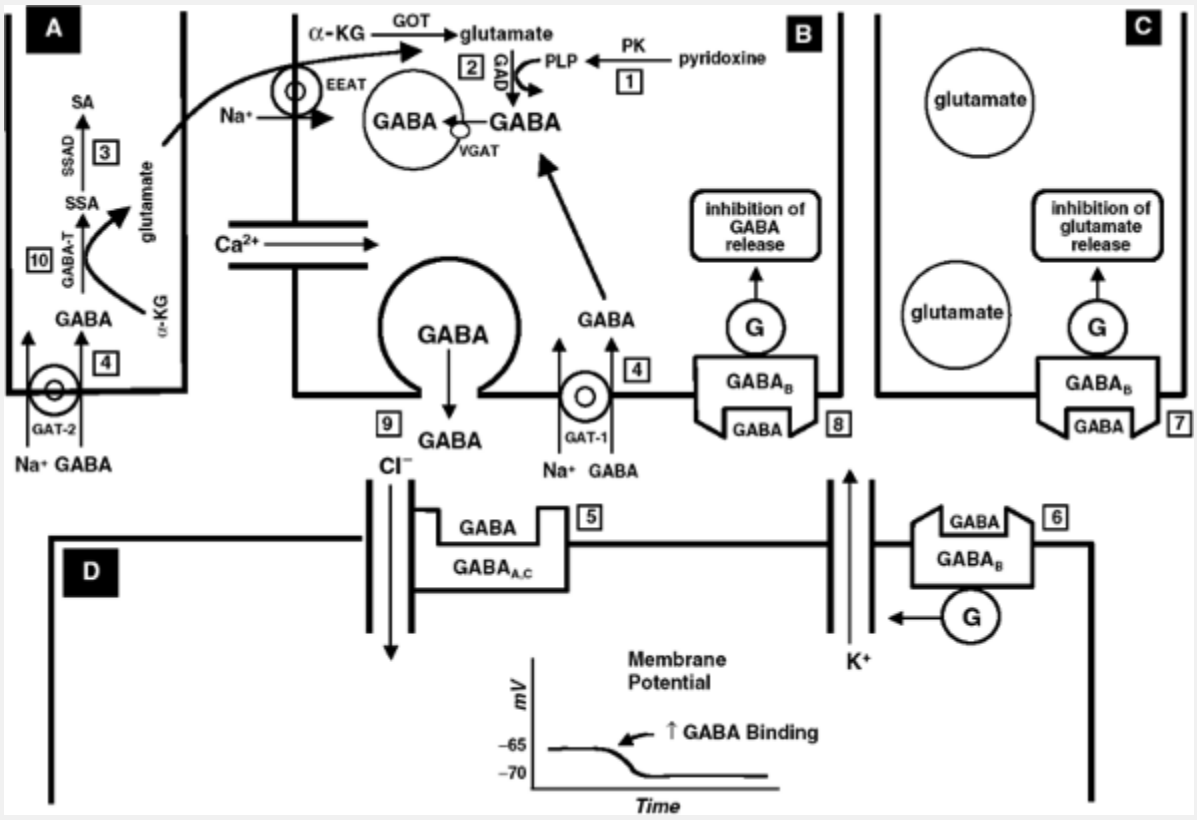

Figure 14-9. GABAergic neurotransmission. GABA (Î³-aminobutyric acid) released from a presynaptic neuron (B) binds to postsynaptic $GABA_A$, $GABA_B$, or $GABA_C$ receptors to hyperpolarize and inhibit neuron D [5,6] or to presynaptic $GABA_B$

heteroreceptors on neuron C [7] to inhibit neurotransmitter release by blocking Ca^{2+} influx (an excitatory glutamatergic neuron is shown as an example). Stimulation of $GABA_B$ autoreceptors on neuron B [8] also reduces further release of GABA. Synaptic GABA undergoes uptake into the presynaptic neuron by GAT-1, and uptake into glial cells and possibly postsynaptic neurons by GAT-2, GAT-3, and GAT-4 (GAT-2 is shown mediating uptake into glial cell A as an example.) Acute falls in pyridoxal phosphate (PLP) lead to impaired glutamic acid decarboxylase (GAD) activity and low GABA concentrations. Although GABA-transaminase (GABA-T) also requires PLP, acute falls in PLP do not affect this enzyme as dramatically because of tight PLP binding to the GABA-T complex. Agents in Table 14-9 act to impair PLP formation by inhibiting pyridoxine kinase (PK) [1]; to increase GABA concentrations by either stimulating GAD [2] or inhibiting SSAD [3]; to inhibit GABA uptake [4]; to stimulate or block GABA receptors [5â€“8]; to cause GABA release [9]; or to inhibit GABA-T [10]. Glutamic-oxaloacetic transaminase (GOT), GABA-T, and SSAD are mitochondrial enzymes. Î±-KG = Î±-keto-glutarate; G = G protein; GAT = membrane GABA uptake transporter; SA = succinic acid; SSA = succinic semialdehyde; SSAD = SSA dehydrogenase; VGAT = vesicle membrane GABA uptake transporter.

Cyanide inhibits numerous enzymes besides cytochrome oxidase. Inhibition of GAD with a resultant fall in GABA concentration may partly explain seizures that occur in cyanide-poisoned patients. Domoic acid (see Glutamate below) may inhibit GAD.[35]

TABLE 14-8. GABA Receptors and Their Characteristics

	$GABA_A$	$GABA_B$	$GABA_C$
Receptor	Cl^- channel	G-protein-coupled	Cl^- channel
Bicuculline antagonism	Yes	No	No
Baclofen agonism	No	Yes	No
Benzodiazepine agonism	Yes	No	No
Barbiturate agonism	Yes	No	No
Picrotoxin antagonism	Yes	No	Slight

The most important mechanism for valproate's anticonvulsant action is unknown. In vitro studies demonstrate its ability to increase brain GABA concentrations either by inhibition of succinic semialdehyde dehydrogenase or by activation of GAD.[70] Gabapentin's ability to increase the rate of GABA synthesis in the brain also may result from stimulation of GAD.[153] Vigabatrin, an anticonvulsant, acts by irreversibly inhibiting GABA-T.[147]

$GABA_A$ Agonism

Figure 14-10 schematically illustrates the $GABA_A$ receptor complex. In general, substances that increase $GABA_A$ complex activity cause CNS depression, ranging from mild sedation and nystagmus to ataxia, stupor, coma, and even general anesthesia. Most indirect agonists that bind to the $GABA_A$ complex have no activity in the absence of GABA. With some exceptions,

their pharmacologic actions require the binding of GABA to its receptor and do not result from a direct effect on Cl^- conductance exclusive of GABA binding. Many of these drugs demonstrate additional actions that are not mediated through the $GABA_A$ complex.

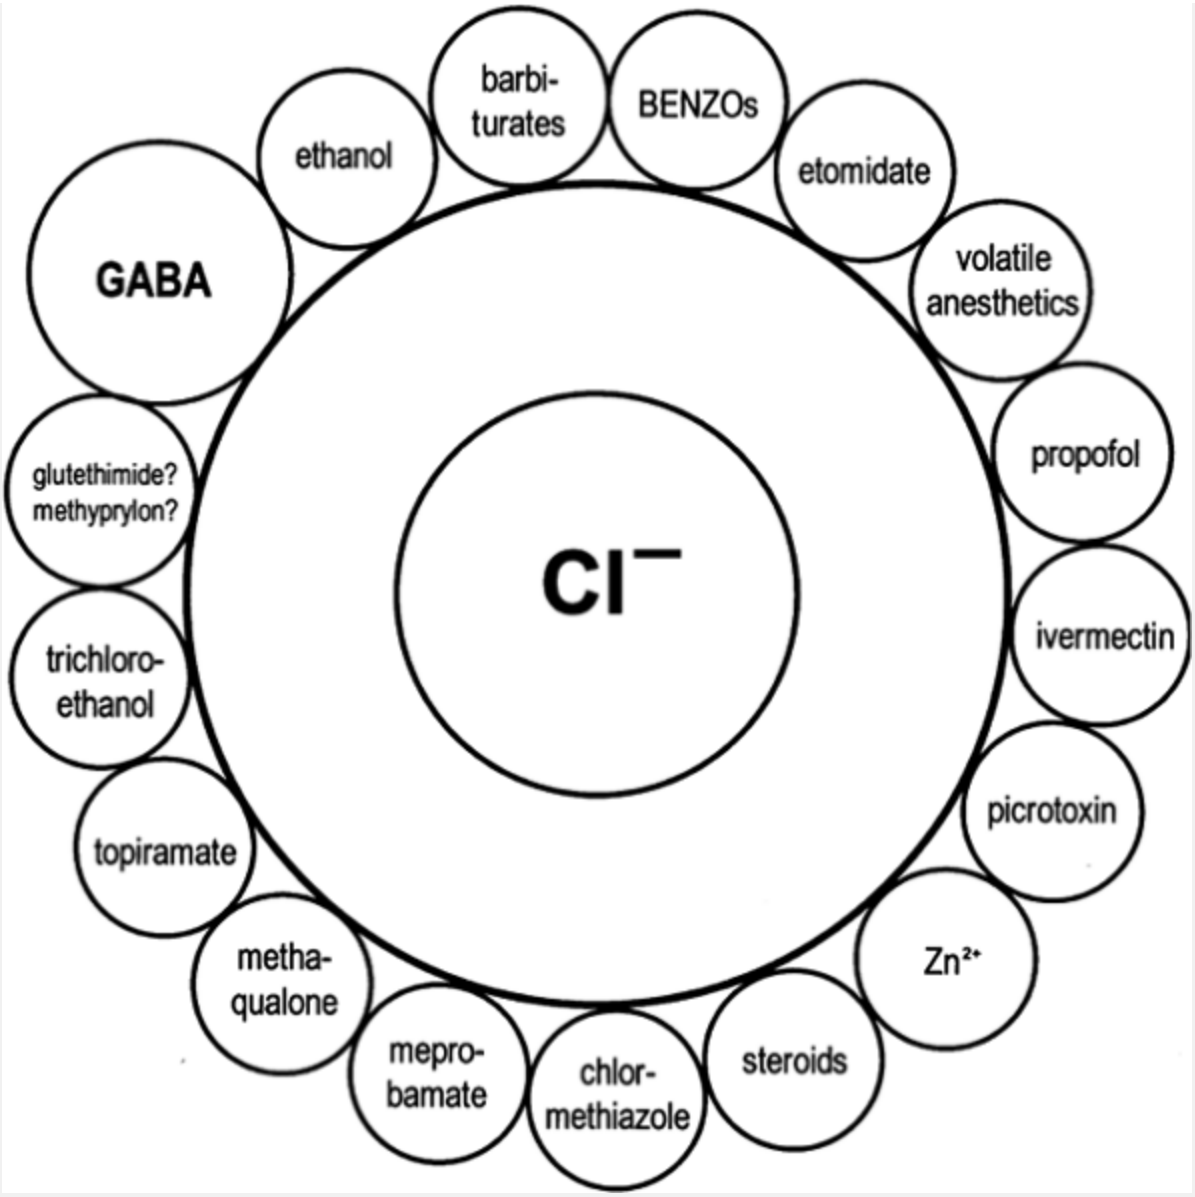

Figure 14-10. Representation of the $GABA_A$ Cl^- channel receptor complex. Benzodiazepines (BENZOs), barbiturates, picrotoxin, steroids, and GABA (Î³-aminobutyric acid) clearly bind to different sites on the channel. Although separate circles represent different agents capable of binding to and of modulating Cl^- influx through the $GABA_A$ receptor complex, it is not always apparent where these agents bind on the channel. For example, general anesthetics and ethanol may produce their

effects by interacting with the steroid binding site. Chloral hydrate undergoes metabolism to trichloroethanol, which interacts with the $GABA_A$ receptor complex. Zolpidem, zopiclone, and zaleplon are nonbenzodiazepines that bind to the benzodiazepine site. Given the structural similarity of glutethimide and methyprylon to barbiturates, it is speculated that their action may be mediated at $GABA_A$ receptors.

Direct GABA Agonists

The main direct GABA agonist of toxicologic interest is muscimol, found in some poisonous mushrooms. Muscimol binds to the GABA receptor on the $GABA_A$ complex to mimic the action of GABA.[110] Ibotenic acid, a direct glutamate agonist found in the same mushrooms, is decarboxylated to muscimol just as glutamate is decarboxylated to GABA.

Indirect GABA Agonists

Benzodiazepines bind to benzodiazepine receptors on $GABA_A$ complexes to increase the affinity of GABA for its receptor and to increase the frequency of Cl^- channel opening in response to GABA binding.[138] The benzodiazepine binding site on the $GABA_A$ receptor is located in a pocket between an Î± subunit and a Î³ subunit.[161] Benzodiazepines also inhibit adenosine uptake apart from $GABA_A$ activity (see Adenosine below).

Various isoforms of $GABA_A$ Cl^- channels differ in their affinity for different benzodiazepines. $GABA_A$ receptors containing $Î³_2$ subunits are more sensitive to benzodiazepines than are $GABA_A$ receptors containing $Î³_1$ and $Î³_3$ subunits. Sensitivity and response to benzodiazepine binding is also highly dependent on the specific Î± subunit composition of the $GABA_A$ receptor. $GABA_A$ receptors containing an $Î±_4$ or $Î±_6$ subunit are completely insensitive to and

will not bind benzodiazepines, whereas $GABA_A$ receptors containing $Î±_1$, $Î±_2$, $Î±_3$, or $Î±_5$ subunits are sensitive to benzodiazepine binding. In addition, specific Î± subunits may mediate different effects of benzodiazepines. For example, sedative effects are mediated through binding to $Î±_1$ subunits while anxiolytic effects appear to be mediated by binding to $Î±_2$ subunits.[49]

Zolpidem, an imidazopyridine, and zaleplon, a pyrazolopyrimidine, are nonbenzodiazepine agents that act as agonists at the

benzodiazepine binding site on the $GABA_A$ receptor. These agents exhibit a high selectivity for the $Î±_1$ subunit and low selectivity for $Î±_2$, $Î±_3$, and $Î±_5$ subunits.[142,161] This selective binding to $Î±_1$ subunits is thought to account for relatively selective sedative properties of zaleplon and zolpidem at therapeutic doses, as compared to benzodiazepines.

TABLE 14-9. Examples of Xenobiotics That Affect GABAergic Neurotransmission

GABA agonism	GABA antagonism
Stimulate GAD	Direct $GABA_A$ antagonists
Valproate	Bicuculline
Gabapentin	Cephalosporins
	Ciprofloxacin
Direct $GABA_A$ agonists	Enoxacin

Muscimol	Imipenem
Progabide[a]	Nalidixic acid
	Norfloxacin
Indirect $GABA_A$ agonists	Ofloxacin
Avermectin	Penicillins
Barbiturates	
Benzodiazepines	Indirect $GABA_A$ antagonists
Chloral hydrate	Aztreonam
Clomethiazole	Clozapine
Ethanol	Flumazenil
Etomidate	Lindane
Felbamate	MAOIs
Ivermectin	Maprotiline
Meprobamate	Organochlorine insecticides

Methaqualone	Penicillins
Propofol	Pentylenetetrazol
Steroids	Picrotoxin
Topiramate	Tricyclic antidepressants
Trichloroethanol	
Volatile anesthetics	Inhibit GAD
Zaleplon	Cyanide
Zolpidem	Domoic acid
Zopiclone	Hydrazines
	Isoniazid
Direct $GABA_B$ agonists	
Baclofen	Direct $GABA_B$ antagonists
GHB	Phaclofen[b]
Progabide[a]	Saclofen[b]

Inhibit GABA-T	Inhibit PK
Vigabatrin	Hydrazines[c]
	Isoniazid[c]
Inhibit GABA uptake	
Guvacine	
Tiagabine	
Valproate	

GABA = Î³-aminobutyric acid; GABA-T = GABA transaminase; GAD = glutamic acid decarboxylase; GHB = Î³-hydroxybutyric acid; PK = pyridoxine kinase; MAOIs = monoamine oxidase inhibitors.

[a] Directly activate $GABA_A$ and $GABA_B$ receptors as well as being metabolized to GABA.

[b] Thought not to cross bloodâ€“brain barrier in meaningful amounts.

[c] Major site of action is PK inhibition, though some direct GAD inhibition occurs.

Numerous steroids, such as alphaxalone and naturally occurring analogs, bind to more than one site on the $GABA_A$ complex to inhibit or enhance the action of GABA.[55,138]

The synthesis of neuroactive steroids is partly regulated by benzodiazepine binding to mitochondrial benzodiazepine receptors

(MBRs) apart from the $GABA_A$ complex.[80,138] These mitochondrial benzodiazepine binding sites are found both within and outside the CNS and were originally called peripheral benzodiazepine receptors. Mitochondrial benzodiazepine binding sites comprise three subunits: a voltage-dependent anion channel; an adenine nucleotide carrier; and a binding site for PK 11195, an isoquinoline carboxamide derivative.[54] Benzodiazepines vary in their affinity for mitochondrial binding. On binding, benzodiazepines appear to enhance the movement of cholesterol into mitochondria to begin steroid synthesis. Some of carbamazepine's action may be a result of binding at mitochondrial benzodiazepine receptors.[45]

Barbiturates bind to the $GABA_A$ complex to produce several effects.[77,138] All barbiturates enhance the action of GABA by producing more Cl^- influx for a given amount of GABA binding by increasing the duration of Cl^- channel opening. Whereas phenobarbital does not change the affinity of GABA or benzodiazepines for their binding sites, depressant barbiturates, such as pentobarbital, do increase GABA and benzodiazepine receptor affinities for their ligands, further enhancing inward Cl^- currents. At high concentrations, at least some barbiturates directly open Cl^- channels to cause Cl^- influx.[77] In addition, barbiturates possess other actions that depress all excitable membranes, including cardiac and smooth muscle.

The intravenous anesthetics propofol and etomidate enhance inward $GABA_A$ Cl^- currents, and at high concentrations they directly open chloride channels in the absence of GABA.[7] The anesthetic effects of etomidate are mediated by $Î²_3$ subunits, while agonism at $Î²_2$ subunits may contribute to etomidate's sedative effect.[111,125,142] Volatile general anesthetics also directly activate $GABA_A$ Cl^- channels.

Some of ethanol's action is mediated through binding to the $GABA_A$ complex. The degree to which ethanol enhances the effect of GABA on Cl^- influx depends on the $GABA_A$ receptor subunit composition. For

example, receptors with an Î±4 or Î±6 subunit and a Î´ subunit respond to very low concentrations of ethanol.[151,163]

Methaqualone produces at least part of its pharmacologic effect through indirect $GABA_A$ activity. Little is known of glutethimide's and methyprylon's mechanism of action. Their structural similarities to barbiturates suggest that much or most of them reside at the $GABA_A$ receptor. Trichloroethanol, a metabolite of chloral hydrate, and clomethiazole interact at the $GABA_A$ complex in a manner similar to barbiturates, although it is not clear whether they are binding to an identical site on the Cl^- channel.[166] Ivermectin, an antihelminthic, activates $GABA_A$ Cl^- channels by increasing GABA binding. Meprobamate displays barbiturate-like action at the $GABA_A$ receptor, and, at high concentrations, is able to cause Cl^- influx in the absence of GABA.[126] High concentrations of felbamate also cause inward Cl^- currents in the presence of GABA, although this seems unimportant at therapeutic doses.[126] Part of topiramate's anticonvulsant action may result from enhanced Cl^- influx through binding to $GABA_A$ receptors.[137]

Inhibition of GABA Uptake

Valproate and the anticonvulsants guvacine and tiagabine work, in part, by inhibiting GABA uptake. Although valproate is structurally similar to GABA, its inhibition of the GABA transporter does not appear to be competitive.[108]

$GABA_A$ Antagonism

Direct $GABA_A$ Antagonists

Substances that act by any mechanism to decrease $GABA_A$ activity can cause CNS excitation and convulsions by preventing inhibitory inward Cl^- currents. Direct antagonists bind to the same site as GABA to prevent GABA binding, the prototype being the convulsant bicuculline. Various antibiotics interact with the $GABA_A$ receptor to

antagonize the action of GABA. In a dose-dependent manner, both imipenem and cephalosporins appear to directly antagonize GABA binding and can produce seizures at high doses or at therapeutic doses in susceptible individuals.[162] Evidence suggests that penicillin may also directly antagonize GABA binding. Electrophysiologic and radioligand binding studies indicate that norfloxacin, ciprofloxacin, ofloxacin, and enoxacin all combine with the GABA binding site to prevent GABA binding.[162] Theophylline and at least some nonsteroidal antiinflammatory agents markedly enhance GABA antagonism by some fluoroquinolones in vitro.[162] Virol A, from *Cicuta virosa*, appears to directly antagonize binding of GABA to its receptor on the $GABA_A$ complex.[156]

Indirect $GABA_A$ Antagonists

Penicillin is well known for producing convulsions at high doses (eg, >20 million units of penicillin per day with renal insufficiency), and both penicillin and aztreonam, a monobactam, appear to block the Cl^- channel to prevent GABA-mediated inward Cl^- currents.[162]

Picrotoxin, from *Anamirta cocculus* (fish berries), and the experimental convulsant pentylenetetrazol bind to the picrotoxin site of the $GABA_A$ receptor complex to inhibit the action of GABA. Excessive doses produce CNS excitation and convulsions. Some organochlorine insecticides (eg, lindane) also inhibit the action of GABA by binding to what appears to be the picrotoxin site.[92] Convulsions characterize acute poisonings by these agents. Both Î±-thujone, the active component in wormwood oil, and cicutoxin from the water hemlock noncompetitively antagonize $GABA_A$ activity.[64,157]

Flumazenil competitively antagonizes benzodiazepines, zolpidem, zaleplon, and zopiclone at their receptors to reverse their pharmacologic effects.[20,139] Paradoxically, large doses of flumazenil exhibit anticonvulsant activity in animals. This is explained by flumazenil's ability to inhibit adenosine uptake, not by partial agonism at the benzodiazepine receptor.[117]

Cyclic antidepressants, including amoxapine and maprotiline, and at least two MAOIs (isocarboxazid and tranylcypromine) inhibit GABA-mediated Cl^- influx at $GABA_A$ receptors.[95,146] Their potency at inhibiting Cl^- influx correlates with the frequency of seizures that occur in patients taking therapeutic doses of these medications. Impaired $GABA_A$ activity may contribute to or be primarily responsible for seizures seen in patients who overdose on these agents. The exact binding site of these drugs on the $GABA_A$ receptor complex is not yet known, although some evidence suggests at least indirect activity at the picrotoxin binding site.

Some subtypes of $GABA_A$ receptors are susceptible to inhibition by zinc ions.[138] What role this plays in normal physiology or toxicology is not established.

$GABA_A$ Withdrawal

Acute withdrawal from all $GABA_A$ direct and indirect agonists appears almost identical except for time course; in all cases, a common denominator is impaired Cl^- influx. Withdrawal of all $GABA_A$ agonists can cause tremor, hypertension, tachycardia, respiratory alkalosis, diaphoresis, agitation, hallucinations, and convulsions. When $GABA_A$ receptors are chronically exposed to an agonist, changes in gene expression of receptor subunits occur which lessens Cl^- influx in response to GABA or drug binding, producing tolerance. Importantly, withdrawal of the agonist produces yet further changes in subunit expression. For example, benzodiazepine-insensitive $Î±_4$-subunit expression is increased following withdrawal of many GABA agonists, including benzodiazepines, zolpidem, zaleplon, neuro-steroids, and ethanol. (Expression of other subunits, including $Î±_1$, $Î³_2$, $Î²_2$, and $Î²_1$ also change in response to exposure and/or withdrawal of $GABA_A$ agonists.[49]) Alterations in $GABA_A$ receptor subunit composition following chronic exposure to and withdrawal of an agonist can, therefore, affect the ability to successfully treat withdrawal

symptoms. While any $GABA_A$ receptor agonist may be used to treat withdrawal from another, some agents work better than others in different clinical settings. For example, patients experiencing severe alcohol withdrawal may have an increased proportion of $GABA_A$ receptors containing benzodiazepine-insensitive Î±4 subunits, and contain fewer $GABA_A$ receptors with benzodiazepine-sensitive Î±1 subunits.[27] Even extremely high doses of benzodiazepines in these patients may not effectively control severe alcohol withdrawal. A better treatment option in such a setting would be $GABA_A$ agonists such as propofol or phenobarbital that act either on a different site on the $GABA_A$ receptor or directly open the Cl^- channel.[7,27] Phenytoin and carbamazepine do not stop $GABA_A$ withdrawal seizures because their pharmacologic effects are independent of $GABA_A$ agonism.

$GABA_B$ Agonists

The main $GABA_B$ receptor agonist of toxicologic significance is baclofen. Coma, hypothermia, hypotension, bradydysrhythmias, and seizures characterize its toxicity. The convulsions that occur in patients with baclofen overdose are thought to result from disinhibition (inhibition of inhibitory neurons). Carbamazepine's activation of $GABA_B$ receptors has been demonstrated, although this is not thought to explain most of its anticonvulsant action. Some of Î³-hydroxybutyrate's actions following pharmacologic doses may be mediated through activation of $GABA_B$ receptors.

$GABA_B$ Withdrawal

Baclofen withdrawal is similar clinically to $GABA_A$ withdrawal. Hallucinations, agitation, tremor, increased sympathetic activity, and convulsions are the main characteristics of baclofen withdrawal. Withdrawal from chronic intrathecal baclofen administration may also be accompanied by large swings in autonomic tone (hypotension, hypertension, tachycardia, bradycardia) and transient cardiomyopathy and shock. Reinstitution of oral baclofen therapy

following oral withdrawal, or intrathecal baclofen following intrathecal withdrawal is the definitive treatment of choice.[96]

Î³-Hydroxybutyrate

Î³-Hydroxybutyrate (GHB; Î³-hydroxybutyric acid) exists endogenously but toxicologic interest stems from its use as a drug of abuse and as a treatment for narcolepsy.[11,46,87] GHB is rapidly absorbed and freely crosses the blood-brain barrier. Toxicity resulting from ingestion of GHB is explained by GHB receptor and $GABA_B$ receptor activation, and comprises agitation, tremor, rapid onset of coma, vomiting, bradycardia, hypotension, hypotonia, and apnea that usually resolve within several hours. Although seizure activity has been noted in experimental animals, it is debated whether GHB causes true convulsive activity in human beings. Human experiments with â€œtherapeuticâ€• doses of GHB have not found EEG changes consistent with seizure activity.[87] Some authors have reported â€œgeneralized seizuresâ€• occurring in patients presenting after GHB overdose. Interestingly, patients with the rare inborn error of metabolism, succinic semialdehyde dehydrogenase (SSAD) deficiency, have elevated GHB concentrations and tend to experience seizures.[56] Valproate similarly elevates endogenous GHB concentrations by inhibiting SSAD.

Controversy exists as to whether GHB should be considered a neurotransmitter or simply a neuromodulator because it is unclear whether this substance is concentrated within vesicles for synaptic release. There is evidence demonstrating a sodium-dependent uptake transporter for GHB.

GHB receptors appear to be heterogeneously distributed throughout the brain, with highest concentrations in the hippocampus, cortex, limbic areas, and thalamus, as well as in regions innervated by dopaminergic terminals and dopaminergic nuclei. GHB receptors exist on neurons, mainly at the synaptic level, but are absent from glial or peripheral cells.

At least two general GHB receptors have been described thus far, based on binding affinity for GHB and other ligands. High-affinity receptors for GHB do not respond to GABA, GABAergic agonists, Î³-butyrolactone, or dopamine. Similarly, GHB does not activate $GABA_A$ Cl^- channels. Flumazenil and baclofen fail to antagonize GHB binding to its binding site.[11]

Although Î³-butyrolactone (GBL) does not express affinity for GHB binding sites, GBL rapidly undergoes hydrolysis to form GHB by peripheral Î³-lactonase.[11,94] 1,4-Butanediol undergoes conversion to GHB via alcohol dehydrogenase and aldehyde dehydrogenase.

Several proposed pathways for endogenous GHB formation exist (Fig. 14-11).[11] Evidence exists for GHB's metabolism back to GABA, although this appears minimal at physiologic GHB concentrations.[46] However, effects resulting from pharmacologic doses of GHB may result, in part, from secondary GABA formation.

Although normal endogenous GHB concentrations are probably not high enough to activate $GABA_B$ receptors, such receptor activation may occur with exogenous administration of GHB. Furthermore, there appears to be functional interplay between GHB and $GABA_B$ receptors.[11]

Specific interactions between GHB and dopamine are complex and not fully delineated. Treatment with GHB appears to inhibit dopamine release, probably via stimulation of $GABA_B$ receptors.[168] GHB also affects the firing rates of dopaminergic neurons, dopamine synthesis, and levels of dopamine and its major metabolites. GHB is thought to affect sleep cycles, temperature regulation, cerebral glucose metabolism and blood flow, memory, and emotional control, and it may be neuroprotective.

Although GHB can suppress alcohol withdrawal, GHB is also addictive, and both tolerance and a withdrawal syndrome have been described. Withdrawal is characterized, in part, by insomnia, cramps, paranoia, hallucinations, tremor, and anxiety.

Glycine as an Inhibitory Neurotransmitter

Glycine acts as a postsynaptic inhibitory neurotransmitter in the spinal cord and lower brainstem. In the CNS, serine is converted to glycine by serine hydroxymethyltransferase (SHMT).

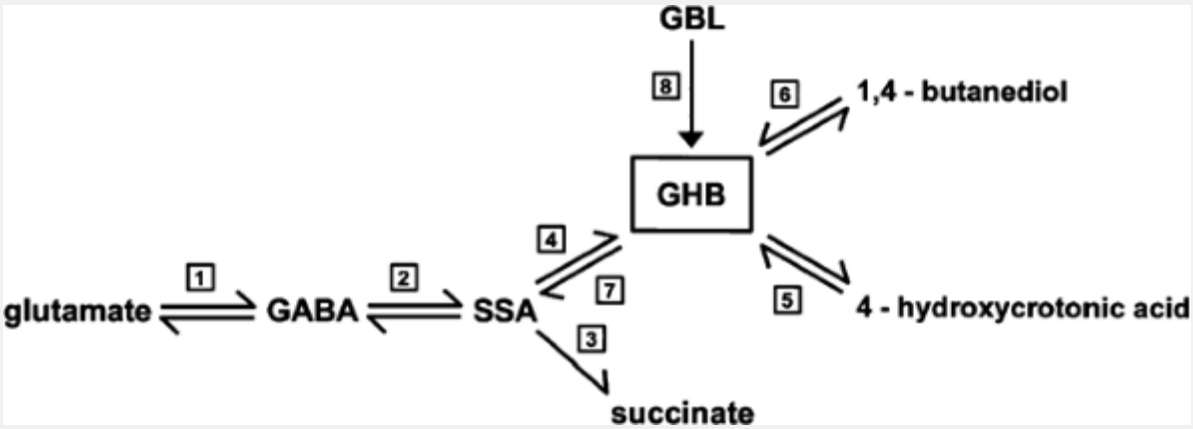

Figure 14-11. Potential pathways of GHB (Î³-hydroxybutyrate) synthesis and degradation. GABA = Î³-aminobutyric acid; GBL = Î³-butyrolactone; SSA =succinic semialdehyde; [1] =glutamic acid decarboxylase; [2] = GABA-transaminase; [3] =succinic semialdehyde dehydrogenase; [4] =specific succinic semialdehyde reductase and/or nicotinamide adenine dinucleotide phosphate (NADPH)-dependent aldehyde reductase 2; [5] = mitochondrial Î² oxidation; [6] =alcohol dehydrogenase and aldehyde dehydrogenase; [7] =GHB dehydrogenase; [8] = Î³-lactonase.

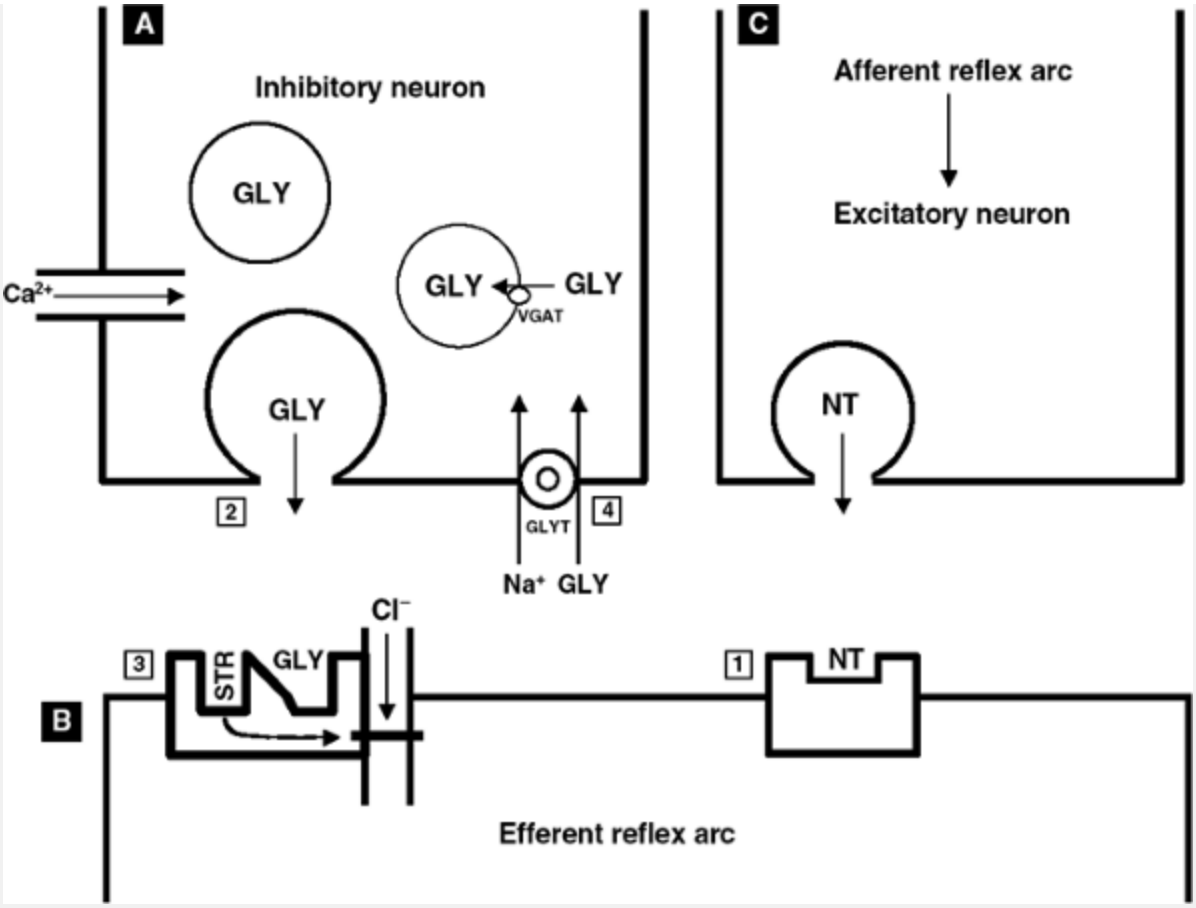

Figure 14-12. Inhibitory glycinergic neurotransmission. Glycine is concentrated within vesicles by uptake via VGAT, the vesicle membrane transporter. Signals from the afferent limb of a reflex arc (neuron C) cause the release of an excitatory neurotransmitter (NT) that crosses the synapse to bind to neuron B in the efferent limb of the reflex arc [1]. To prevent excessive neuronal firing and motor activity, glycine (GLY) released from inhibitory neuron A [2] binds to glycine Cl^- channel receptors on neuron B [3] and causes inhibition by hyperpolarization through Cl^- influx. Synaptic glycine is transported back into the neuron by at least two subtypes of membrane glycine transporters, GLYT-1 and GLYT-2 [4]. Strychnine (STR) binds to the glycinergic Cl^- channel to decrease glycine's binding, which prevents Cl^- influx. Although strychnine is shown to bind to a separate site from

glycine, there is evidence that these sites may overlap.

Release and Uptake

Glycine is transported into storage vesicles by VGAT and undergoes Ca^{2+}-dependent exocytosis upon neuronal depolarization (Fig. 14-12). Glycine is removed from the synapse through uptake by a Na^{+}-dependent transporter into presynaptic neurons and into glial cells. Two glycine membrane transporters have been cloned,

and share homology with GABA uptake transporters. GLYT-1 is found both in astrocytes and neurons, whereas GLYT-2 is localized on axons and terminal boutons of neurons that contain vesicular glycine. Although both transporters are found associated with glycinergic neurons in the brainstem and spinal cord, GLYT-1 is also found in the forebrain in regions devoid of glycinergic neurotransmission. At the latter location, GLYT-1 may regulate extracellular glycine that is available for NMDA receptor activation, and GLYT-1 inhibitors, then, could enhance NMDA responses (see NMDA Receptor Antagonists below). Glycine transporters can also function in reverse, pumping glycine out of the cell when the intracellular sodium concentrations rise.[4]

Glycine Receptors

Like $GABA_A$, the glycine receptor is a Cl^- channel on the postsynaptic membrane. $GABA_A$ Cl^- channels and glycinergic Cl^- channels share significant amino acid homology. Glycine receptors are pentameric proteins made up of Î± and Î² subunits. Four isoforms of the Î± subunit and one isoform of the Î² subunit have been described.[101]

Glycine receptor activation causes an inward Cl^- current that hyperpolarizes the membrane. It appears that three glycine molecules must bind to sites on the Cl^- channel to produce inhibitory

Cl^- influx.

Chemical Agents

Table 14-10 provides examples of chemical agents that affect inhibitory glycine Cl^- channels. The amino acids D-alanine, taurine, L-alanine, L-serine, and proline can activate glycinergic Cl^- channels. Both ethanol and propofol potentiate glycine-mediated inward Cl^- currents through action at the Î± subunit of the glycine receptor, just as they do at $GABA_A$ Cl^- channels.[97,101] Clozapine inhibits glycine uptake.[67]

Strychnine is the main toxicologic agent affecting glycinergic transmission. Strychnine binds to the Î± subunit of the glycine receptor to prevent glycine's action on Cl^- influx,[3] at least in part by decreasing glycine's binding to its receptors. This physiologic antagonism of glycine's action produces increased muscle tone, rigidity, opisthotonus, trismus, and death from respiratory failure and rhabdomyolysis. Given the similarity in Cl^- channels, it is not surprising that strychnine binds to the $GABA_A$ complex in vitro. However, strychnine's affinity for this complex is less than that for glycine receptors, and most of its toxicologic action is a result of physiologic antagonism of glycine's inhibitory action.

Picrotoxin binds to the glycine receptor to impair Cl^- influx.[93] Tetanus toxin produces rigidity and trismus by preventing glycine release from nerve endings in the spinal cord and brainstem.

TABLE 14-10. Examples of Xenobiotics That Affect Inhibitory Glycine Chloride Channels

Glycine agonists	Glycine antagonists
Ethanol	Strychnine
Propofol	Picrotoxin
D-Serine	Glycine uptake inhibitor
	Clozapine

Ethanol and propofol enhance Cl^- influx through glycine Cl^- channels, although they do not appear to act as direct agonists. Evidence exists for picrotoxin's direct antagonism at the glycine binding site(s) in contrast to $GABA_A$ Cl^- channels, where it acts at a site separate from where GABA (Î³-aminobutyric acid) binds.

Glutamate

Glutamate is the main excitatory neurotransmitter in the CNS. Up to 66% of all brain energy expenditure is attributed to uptake and recycling of glutamate.[67] Aspartate displays similar actions although its exact role as a neurotransmitter is not as well defined because it is only active at certain types of glutamate receptors. Glutamate and aspartate are commonly referred to as excitatory amino acid (EAA) neurotransmitters. Glutamate is essential for memory, learning, perception, and locomotion.[38,76]

Glutamatergic neurotransmission has been a subject of intense research because of its role in mediating neuronal damage in degenerative neurologic diseases and during times of trauma, ischemia, hypoglycemia, and status epilepticus. Although glutamate receptor stimulation is necessary for normal brain activity, excessive glutamate receptor activation endogenously or by glutamate agonists can produce convulsions, neuronal damage, and death. Conversely, glutamate antagonists demonstrate anticonvulsant activity and neuroprotective action in animal models of brain and spinal cord injury. Glutamate may also play an important role in the development of drug abuse and subsequent withdrawal symptoms. Glutamate antagonists decrease drug craving and withdrawal symptoms in patients addicted to ethanol, benzodiazepines, and opioids.[14]

Synthesis, Release, and Uptake

Glutamate is a nonessential amino acid that does not cross the bloodâ€“brain barrier. It must, therefore, be synthesized from products of glucose metabolism or other precursors that enter neurons. Glutamate is primarily synthesized from glutamine by the enzyme glutaminase located within the mitochondrial compartment. Other amino acids, such as aspartate, also serve as sources for glutamate production. Glutamate stored within vesicles is released into the synapse by Ca^{-2}-dependent exocytosis.[38] Five different EAA uptake transporters have been identified, and glutamate undergoes uptake both by neuronal and glial cells.[134] Synaptic glutamate transported into glial cells undergoes conversion back to glutamine by the enzyme glutamine synthase. Glial cells then release glutamine back into the synapse for uptake by neurons and recycling back to glutamate and then into storage vesicles (Fig. 14-13). Reverse transport of glutamate from the cytoplasm into the synapse by the membrane transporter may occur under some circumstances.[38] Glutamate also serves as the precursor for GABA's synthesis.

Glutamate Receptors

The EAA receptor system is the most complex of all neurotransmitters. This complexity is necessary for protection against the devastating effects of uncontrolled excitatory neurotransmission. At present, 11 different glutamate receptors are recognized. Three ionotropic glutamate receptors are cation channels, and 8 metabotropic receptors are linked to G proteins.[38]

A single neuron may express numerous types of glutamate receptors. Postsynaptic glutamate receptors are usually excitatory, although some inhibitory actions have been demonstrated. Presynaptic terminal glutamate receptors appear mainly to inhibit release of various neurotransmitters, including glutamate (Fig. 14-13).[118]

Ionotropic Glutamate Receptors

Three ionotropic glutamate receptors have been identified. All allow for excitation through cation

influx. These receptors are further categorized and named by their abilities to be activated or antagonized by various substances: kainate, AMPA (Î±-amino-3-hydroxy-5-methyl-4-isoxazole propionate), and NMDA (*N*-methyl-D-aspartate).

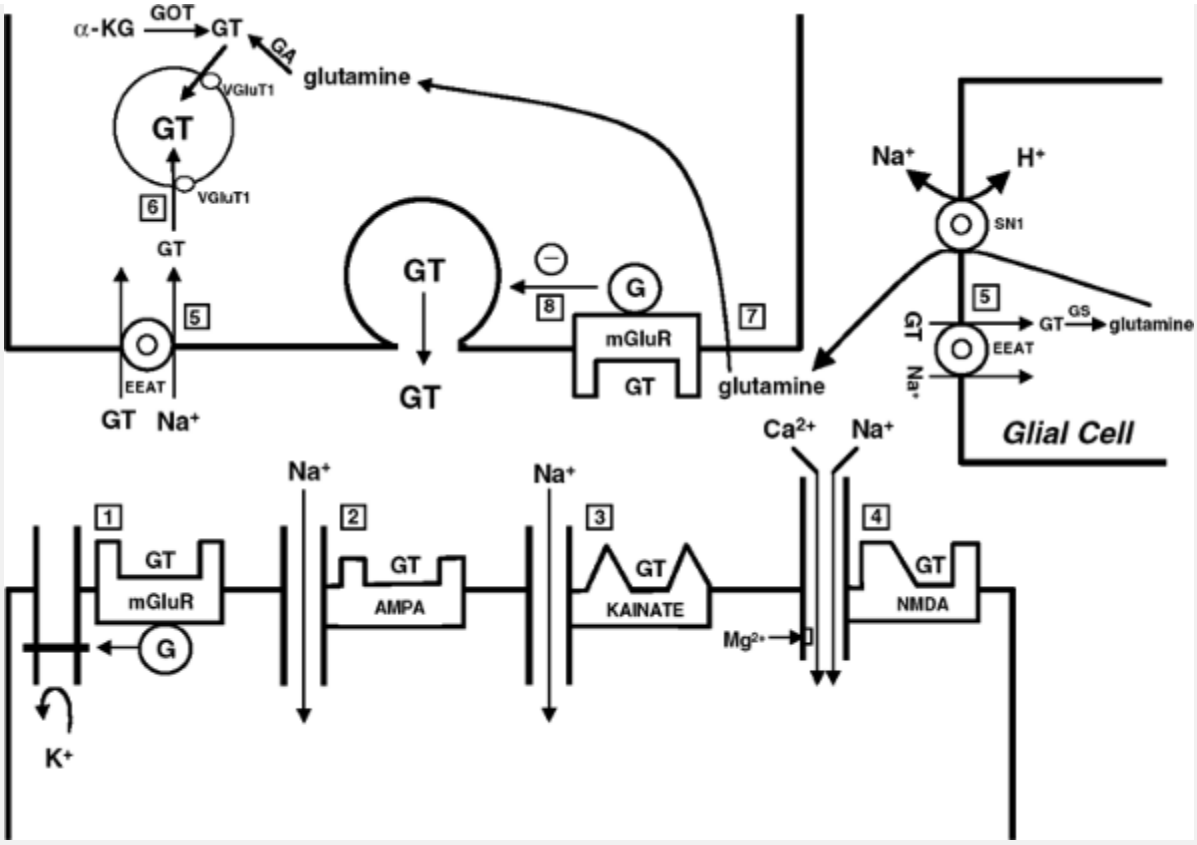

Figure 14-13. Glutamatergic neurotransmission. Glutamic-oxaloacetic transaminase (GOT) converts Î±-ketoglutarate (Î±-KG) to glutamate (GT) in mitochondria. GT also forms from glutamine via mitochondrial glutaminase (GA). Glutamate is transported into vesicles [6] by VGlut1 (or possibly other subtypes) for exocytotic release into the synapse. Synaptic glutamate activates four main types of receptors. AMPA [2], kainate [3], and NMDA [4] receptors are cation channels. Membrane depolarization in response to their activation causes neuronal excitation through cation influx. Metabotropic receptors (mGluR) [1,8] are coupled to G proteins and are expressed on pre- and postsynaptic membranes. In addition, some mGluRs reside outside of the synapse. Postsynaptic mGluR excitation in this example [1] results from preventing K^+ efflux, but other mechanisms of excitation exist. Presynaptic mGluRs act to inhibit

[8] glutamate (and other neurotransmitter) release through modulating intracellular Ca^{2+} concentrations. Figure 14-14 provides a more detailed illustration of the NMDA receptor. Excessive influx of Ca^{2+} through NMDA receptors (and through some AMPA and kainate receptors) causes neuronal damage and cell death. An Mg^{2+} ion normally blocks the NMDA receptor channel to prevent Ca^{2+} influx despite glutamate binding. However, depolarization of the neuronal membrane by cation influx resulting from activation of any of the other receptor types causes Mg^{2+} to dissociate from the NMDA receptor and to allow potentially damaging inward Ca^{2+} currents. Glutamate undergoes uptake by neurons and glial cells by various subtypes of EEAT, the membrane bound glutamate transporter [5]. In glial cells, GT is converted to glutamine by glutamine synthase (GS), and glutamine is transported out of glial cells by system N-1 (SN1), a Na^{+}- and H^{+}-dependent pump that is structurally similar to VGAT, the vesicle membrane GABA transporter. Glutamine then moves back into neurons [7] where it undergoes conversion back to glutamate. Various agents in Table 14-11 affect glutamatergic neurotransmission, in part, by stimulating or blocking the various glutamate receptors [1â€“4,8] or by preventing glutamate uptake [5]. G =G protein.

Kainate receptors are named for their affinity for kainic acid found in seaweed and comprise GluR5â€“7, KA1, and KA2 subunits.[72] Activation allows Na^{+} influx and a small amount of K^{+} efflux, resulting in neuronal depolarization. Some kainate receptors in the hippocampus also appear to allow Ca^{2+} influx following activation. Kainate receptors are the only ionotropic glutamate receptors, to date, found presynaptically, although they are much more prevalent on postsynaptic neuronal membranes.[52]

The AMPA receptor is an ion channel structurally similar to the kainate receptor that also mediates Na^{+} influx (and lesser amounts

of K^+ efflux) on postsynaptic membranes, triggering neuronal depolarization.[12] AMPA receptors are composed of GluR1â€“3 subunits.[72] The AMPA receptor is the most common ionotropic glutamate receptor found in the brain and appears to account for most glutamatergic excitation under normal conditions. A subtype of AMPA receptors in the hippocampus may also allow Ca^{2+} influx after activation.[129]

The NMDA receptor, the most studied of all glutamate receptors, is a Ca^{2+} channel whose activation allows for inward Ca^{2+} and Na^+ currents (and some K^+ efflux), resulting in neuronal depolarization

and excitation (Fig. 14-14). NMDA receptors comprise NR1, $NR2_{Aâ€“D}$, and $NR3_{Aâ€“B}$ subunits.[72] Excessive stimulation of NMDA receptors by glutamate released during times of ischemia, trauma, hypoglycemia, or convulsions triggers damaging rises in intracellular Ca^{2+} concentrations, activation of numerous enzymes, and free radical formation, all of which incite cell death.[76] Antagonists of NMDA Ca^{2+} channels demonstrate anticonvulsant and neuroprotective activity during times of neuronal insult.

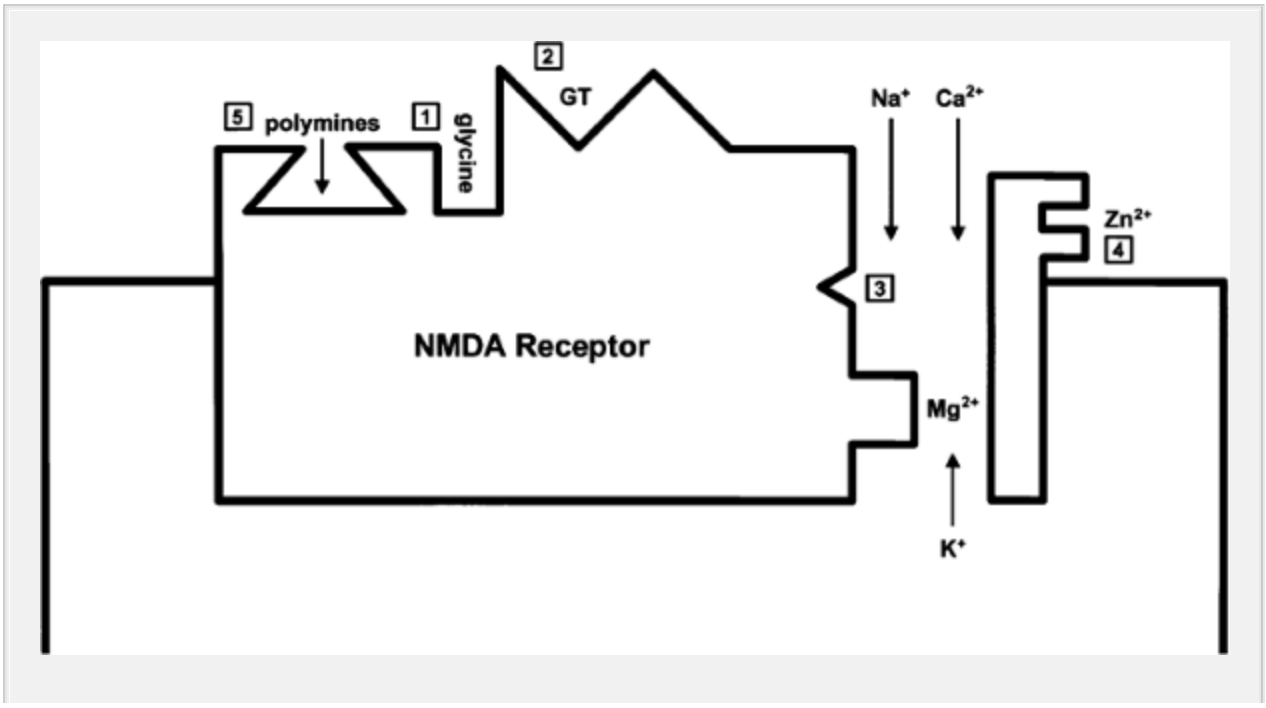

Figure 14-14. Representation of the NMDA glutamate receptor. The NMDA receptor is a voltage-gated and ligand-gated Ca^{2+} channel. Glutamate (GT) binds to its receptor on the channel [2] to open the Ca^{2+} channel and to allow Ca^{2+} and Na^{+} influx and lesser amounts of K^{+} efflux. Mg^{2+} normally blocks the Ca^{2+} channel, preventing cation influx in response to glutamate binding. Mg^{2+} leaves the channel when the membrane is depolarized by 20â€“30 mV. Glycine must also bind to its site on the NMDA receptor complex for successful glutamate agonism. Polyamines bind on the extracellular surface of the receptor [5]. Zn^{2+} binds [4] to inhibit Ca^{2+} influx. The phencyclidine (PCP) binding site [3] lies within the channel. Agents in Table 14-11 may antagonize glycine binding [1]; block the Ca^{2+} channel by binding to the PCP binding site [3]; bind to the polyamine binding site [5]; or directly stimulate the glutamate binding site [2].

The NMDA Ca^{2+} channel is normally blocked by Mg^{2+} in a voltage-dependent manner, preventing Ca^{2+} influx despite glutamate binding (Fig. 14-14).[128] Only when the neuronal membrane is depolarized by at least 20â€“30 mV through some other mechanism (eg, activation of another type of glutamate receptor) will Mg^{2+} leave the channel and allow Ca^{2+} influx in response to glutamate binding. Thus, the NMDA glutamate receptor is both a ligand-gated and voltage-gated ion channel. Many neurons express both NMDA and non-NMDA receptors for glutamate. Excessive stimulation of kainate or AMPA receptors by glutamate causes cell damage through Na^{-} (and in some instance, Ca^{2+}) influx, because the membrane depolarization they produce causes Mg^{2+} to leave the NMDA receptor and allows for potentially damaging inward Ca^{2+} currents.[38] Calcium ion influx through voltage-gated ion channels (including the L subtype) on cell bodies that open in response to depolarization also contributes to accumulation of intracellular calcium and cell damage. Consequently, excessive activation of any excitatory glutamate receptor has the

potential to produce neuronal cytotoxicity.[76] Glutamate alone is incapable of activating NMDA receptors, even after Mg^{2+} has dissociated from the ion channel. Glycine also must bind to its specific receptor on the NMDA receptor complex for successful glutamate agonism (Fig. 14-14), making glycine an indirect agonist of excitatory neurotransmission.[38] Strychnine does not antagonize glycine's excitatory action at NMDA receptors, explaining why glycine NMDA receptors are also known as strychnine-insensitive glycine receptors.

Zinc ions normally bind to the NMDA receptor complex to antagonize the action of glutamate. Binding of spermine or spermidine to a polyamine binding site on the extracellular side of the NMDA receptor results in increased affinity of glycine and glutamate for their binding sites. However, polyamine agonism is not essential for glutamate activation of NMDA receptors.[65]

Metabotropic Glutamate Receptors

Metabotropic glutamate receptors (mGluRs) are linked to various G proteins on post- and presynaptic membranes (Fig. 14-13). Eight different receptors have been isolated. In contrast to ionotropic glutamate receptors, mGluRs may excite or inhibit at postsynaptic membranes, and appear mainly to inhibit at presynaptic locations. Postsynaptic excitation most commonly results from prevention of K^+ efflux or activation of phospholipase C, which serves to raise intracellular Ca^{2+} concentration. Postsynaptic inhibition usually results from enhanced K^+ efflux.[100]

Metabotropic glutamate receptors are commonly subdivided into three main groups based on their sequence homology, intracellular signaling mechanisms and response to specific experimental agonists.[106] As a general rule, group I receptors (mGlu1, mGlu5) reside postsynaptically; activation produces excitation through blockade of K^+ efflux or by activating phospholipase C, producing rises in intracellular Ca^{2+}.[152] In animal experiments, agonists of

group I receptors produce convulsions, while antagonists display anticonvulsant effects.[106]

Groups II (mGlu2, mGlu3) and III (mGlu4, mGlu6, mGlu7, mGlu8) receptors most commonly serve as presynaptic autoreceptors and heteroreceptors and, when activated, inhibit adenylate cyclase activity. This, in turn, prevents Ca^{2+} influx and serves to inhibit release of neurotransmitters, including glutamate, GABA, dopamine, and adenosine. Group II presynaptic autoreceptors may play an especially important role in decreasing further glutamate release during pathologic conditions when the extracellular

concentration of glutamate exceeds normal physiologic levels.[152] Agonists of groups II and III metabotropic receptors produce anticonvulsant effects in animals.[106]

TABLE 14-11. Examples of Xenobiotics That Affect Glutamatergic Neurotransmission

Glutamate agonism	NMDA receptor antagonists
Direct glutamate receptor agonists	Amantadine
BMAA	Dextrorphan
BOAA	Dizocilpine (MK801)
Domoic acid	Ketamine

Ibotenic acid	Memantine
Willardine	Orphenadrine
	Pentamidine
Glycine NMDA receptor agonists	Phencyclidine
D-Cycloserine	Ethanol[a]
Milacemide	
	NMDA glycine antagonists
Glutamate uptake inhibitor	Felbamate
Clozapine	Kynurenic acid
	Meprobamate
Glutamate antagonism	
Prevent glutamate release	Polyamine antagonists
Lamotrigine	Ifenprodil
Nimodipine	Eliprodil

Riluzole	

BMAA = Î±-amino-Î²-methylaminopropionic acid; BOAA = Î²-*N*-oxalylamino-L-alanine; NMDA 5 *N*-methyl-D-aspartate.
[a] Ethanol antagonizes glutamate's action at NMDA receptors through an unknown mechanism.

Chemical Agents

Table 14-11 provides examples of chemical agents that affect glutamatergic neurotransmission.

Glutamate Agonism

Domoic acid produces amnestic shellfish poisoning, partly characterized by confusion, agitation, convulsions, memory disturbance, neuronal damage, and death.[58] The structural similarity between domoic acid and glutamate is thought to explain excessive activation of kainate receptors with secondary NMDA receptor activation and neuronal damage.

Investigators hypothesize that other naturally occurring glutamate receptor agonists produce additional neurologic diseases. The neurogenic form of lathyrism results from using chickling peas (*Lathyrus sativus*) as a food staple. Chickling peas contain Î²-*N*-oxalylamino-L-alanine (BOAA), an agonist of AMPA receptors.[38,79] Neurogenic lathyrism was common in German concentration and prisoner of war camps during World War II and still occurs regularly in some parts of the world. Ibotenic acid, from poisonous mushrooms, activates NMDA and some metabotropic glutamate receptors.[38,79] It undergoes decarboxylation to muscimol, a direct agonist at $GABA_A$ receptors. Clozapine inhibits glutamate uptake.[67]

Because noncompetitive NMDA receptor antagonism reproduces many

signs and symptoms of schizophrenia, investigators are directing efforts at increasing glutamate's activity at NMDA channels in an effort to treat the disease. After crossing the bloodâ€“brain barrier, milacemide undergoes conversion to glycine, which is required for NMDA receptor activation. D-Cycloserine also crosses the bloodâ€“brain barrier to stimulate glycine receptors on NMDA calcium channels.[38]

Glutamate Antagonism

Prevention of Glutamate Release

Riluzole, used for the treatment of amyotrophic lateral sclerosis, indirectly prevents release of glutamate. Lamotrigine diminishes glutamate release through blockade of voltage-gated Na^+ channels. Blockade of voltage-gated Ca^{2+} channels by nimodipine also appears to impair glutamate release.[154]

NMDA Receptor Antagonists

Although some experimental agents and pharmaceutics antagonize the action of glutamate, most of our knowledge concerns antagonism at NMDA receptors. Phencyclidine and ketamine appear to bind within the ion channel (PCP binding site) to block Ca^{2+} influx following glutamate binding (Fig. 14-14).[76] Both agents possess other pharmacologic actions and can produce convulsions in overdose. However, in animal models of seizures and neuronal insult, both drugs are neuroprotective and anticonvulsant.

Dextromethorphan and its first-pass metabolite, dextrorphan, exhibit anticonvulsant activity in animals. Dextrorphan's anticonvulsant activity results, in part, from blockade of NMDA receptor Ca^{2+} channels by binding to the PCP binding site. Dextromethorphan does not bind to the NMDA complex but, like dextrorphan, can directly block N- and L-type voltage-dependent Ca^{2+} channels.[29]

Dizocilpine (MK-801) is an NMDA receptor antagonist that binds to the PCP binding site in the NMDA Ca^{2+} channel. Human trials of dizocilpine resulted in adverse effects similar to those produced by phencyclidine, preventing further use in humans as a neuroprotective agent. Amantadine, memantine, and orphenadrine act as low-affinity antagonists at the PCP site but are not associated with psychotomimetic adverse effects. Part of amantadine's effectiveness in the treatment of Parkinson disease may be related to NMDA antagonism. Pentamidine also antagonizes glutamate binding at NMDA channels.[154]

Ethanol competitively inhibits NMDA receptor stimulation by an unknown mechanism, resulting in upregulation of this glutamatergic system. It does not appear to act through currently recognized binding sites.[167] In some animal models of ethanol withdrawal seizures, NMDA receptor antagonists demonstrate better anticonvulsant action than $GABA_A$ agonists.

Glycine Antagonists

Felbamate's anticonvulsant activity may result, in part, from antagonism of glycine at NMDA receptors.[100] Kynurenic acid, a metabolite of L-tryptophan, prevents NMDA activation through glycine antagonism. Meprobamate also antagonizes NMDA glutamate receptors by a yet-to-be-determined mechanism. However, given the structural similarity to felbamate, meprobamate may act by antagonizing the action of glycine.[126]

Polyamine Antagonism

Ifenprodil and eliprodil antagonize glutamate's action at NMDA channels by preventing polyamine binding.[100]

Adenosine

The overall action of adenosine throughout the body is to lessen

oxygen requirements and to increase oxygen and substrate delivery. In keeping with the paradigm, adenosine functions in the CNS as an extremely important inhibitory neuromodulator and vasodilator.

Synthesis, Release, and Uptake

Normal intracellular concentrations of adenosine range from 50 to 300 nM. An Na^+-dependent purine uptake transporter moves

adenosine into the neuron (Fig. 14-15). During times of adequate oxygen delivery and oxidative phosphorylation, intracellular ATP concentrations are normally many fold greater than those of adenosine. Adenosine begins conversion to ATP by adenosine kinase, but adenosine can also be metabolized to inosine by adenosine deaminase, a less important pathway.[25,120]

ATP is commonly coreleased with other neurotransmitters (eg, norepinephrine, ACh, glutamate) into the synapse where it can be degraded to adenosine monophosphate (AMP) (Fig. 14-15). When oxygen delivery remains adequate to meet metabolic demands, most synaptic adenosine arises from the extracellular dephosphorylation of AMP by ectosolic 5-nucleotidase.[25]

During increased cellular catabolism, especially during inadequate oxygen delivery, intracellular adenosine concentrations rapidly rise as phosphorylated adenosine species are degraded to adenosine. The rise in intracellular adenosine concentration results in reverse transport of adenosine into the synapse by the purine uptake transporter (Fig. 14-15). Synaptic adenosine, then, activates adenosine receptors on neuronal and nonneuronal tissue (eg, vasculature). Adenosine's actions are terminated by uptake into glial cells and neurons (Fig. 14-15).[25]

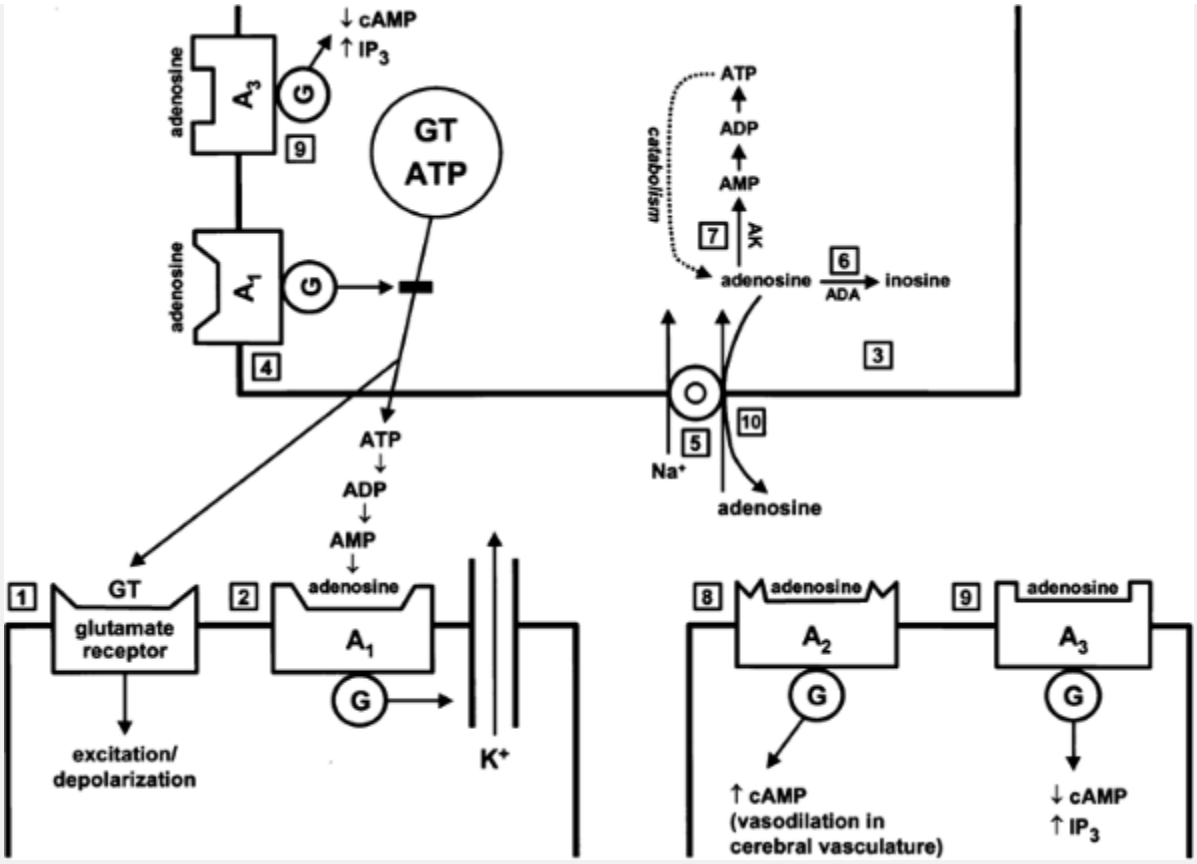

Figure 14-15. Adenosine's role in regulating excitatory neurotransmission, using glutamate as an example. In this example, glutamate (GT) excites a postsynaptic neuron by activating glutamate receptors [1]. Adenosine triphosphate (ATP) enters the synapse when glutamate is released. Adenosine formed from metabolism of ATP within the synapse binds to postsynaptic A_1 receptors [2], which open K^+ channels to inhibit the neuron through hyperpolarization. Adenosine also activates presynaptic A_1 receptors [4] to lower intracellular Ca^{2+} concentrations, thereby impairing further glutamate release. After uptake [5], adenosine is acted upon either by adenosine kinase (AK) [7] to form adenosine monophosphate (AMP), or by adenosine deaminase (ADA) [6] to form inosine. Adenosine also binds to neuronal A_2 receptors (especially in the striatum) and to vascular A_2 receptors to cause vasodilatation [8]. A_3 receptors

[9] are not activated by normal concentrations of adenosine. During times of excessive catabolism (eg, seizures, hypoglycemia, stroke) when intracellular adenosine concentrations rise markedly, adenosine moves into the synapse through reverse transport via the purine uptake transporter [10]. Resultant stimulation of A_1 and A_2 receptors results in inhibitory actions to decrease oxygen requirements and to increase substrate delivery through vasodilatation as described above. However, the resultant stimulation of A_3 receptors [9] may contribute to neuronal damage and death. Agents in Table 14-12 act to inhibit adenosine uptake [5]; to inhibit ADA [6]; to inhibit AK [7]; to increase adenosine release; and to antagonize A_1 [2,4] and A_2 [8] receptors. ADP = adenosine diphosphate; ATP =adenosine triphosphate; cAMP =cyclic adenosine monophosphate; G =G protein; IP_3 =inositol triphosphate.

Exogenously administered adenosine used in the treatment of supraventricular tachycardia does not cross the bloodâ€“brain barrier and therefore is centrally inactive. The half-life of adenosine in the blood is less than 10 seconds.

Adenosine Receptors

The purine P_1 receptor family comprises four adenosine receptor subtypes linked to G proteins: A_1, A_{2A}, A_{2B}, and A_3.[122] Postsynaptic A_1

stimulation results in K^+ channel opening and K^+ efflux with subsequent hyperpolarization of the neuron (Fig. 14-15). Evidence suggests that G protein-mediated Cl^- influx may explain postsynaptic hyperpolarization by A_1 activation in some cases. Presynaptic A_1 stimulation modifies voltage-dependent Ca^{2+} channels, lessening Ca^{2+} influx during depolarization, which limits exocytosis of neurotransmitter. Therefore, activation of A_1 receptors prevents

release of neurotransmitters presynaptically and inhibits their response postsynaptically.[122,159]

In the central and autonomic nervous systems, A_1 receptors reside on presynaptic and postsynaptic membranes, where they serve as inhibitory modulators for numerous neurotransmitter systems; they are particularly prevalent in association with glutamatergic neurons in the CNS.[159] A_1 receptor stimulation also produces sedation and is important in sleep regulation.[120] Other functions attributed to A_1 receptors include neuroprotection, anxiolysis, temperature reduction, anticonvulsant activity, and spinal analgesia.

Peripheral A_1 receptor activation produces bronchoconstriction, decreased glomerular filtration, decreased heart rate, slowed atrioventricular conduction, and decreased atrial myocardial contractility.[36] In the heart, almost all A_1 receptors reside in the atria.[19]

In the CNS, A_{2A} receptors demonstrate limited distribution. They are concentrated on cerebral vasculature and produce vasodilatation when stimulated.[122,159] Additionally, A_{2A} receptors are especially prevalent on neurons in the striatum where they inhibit the activity of D_2 receptors.[48] Striatal A_{2A} receptors decrease GABA effects while enhancing cholinergic, glycinergic, and glutamatergic neurotransmission.[40] Some A_2 receptors are found presynaptically where they serve to increase glutamate release upon activation.[19]

A_{2B} receptors are expressed diffusely throughout the brain, and are most commonly identified on glial cells. A_{2B} receptors demonstrate low affinity for adenosine, and little is known of their physiologic role.[22] Both A_{2A} and A_{2B} receptors are coupled to G_s. The rise in cAMP concentration resulting from A_{2A} activation on cerebral vasculature and elsewhere explains vasodilatation.[122] For example, peripheral A_2 receptor activation also results in coronary artery vasodilation.[33]

A_3 receptors reside diffusely throughout the CNS and express low

affinity for adenosine. A_3 receptors act through G proteins to decrease adenylate cyclase activity and increase phospholipase C activity.[160] The low concentrations of adenosine found during normal metabolism minimally activate A_3 receptors to produce inhibitory effects. During times of excessive adenosine accumulation (eg, hypoxia, seizures), adenosine accumulates at and activates A_3 receptors to produce complex responses that appear to enhance ischemic cellular injury and death, at least in part through disinhibition of presynaptic metabotropic glutamate receptor responses. Thus, A_3 receptor antagonists are being examined for neuroprotective actions.[160]

Adenosine and Seizure Termination

In humans and in animal models of status epilepticus, including those from drugs and toxins, there are two alternating phases of electrical activity noted on electroencephalography. Periods of high-frequency spike activity accompanied by marked increases in cerebral oxygen consumption and metabolic requirements alternate with interictal periods of isolated spike waves during which metabolic demands are less. The high-frequency phase lasts only a few minutes before suddenly terminating, sometimes with a few seconds of electrocerebral silence. A gradual increase in electrical activity during the interictal phase eventually leads to a recurrence of high-frequency spike activity.

These periodic spontaneous self-terminations of high-frequency electrical activity initially occur before neurons exhaust oxygen and energy supplies. These punctuations result from adenosine release from depolarizing neurons (and probably glial cells).[43] Adenosine acts on presynaptic receptors to prevent further release of excitatory neurotransmitters and acts on postsynaptic receptors to inhibit their actions.

Any agent that directly or indirectly enhances adenosine's action at A_1 receptors in the brain will usually exhibit anticonvulsant activity.

Conversely, A_1 receptor antagonists lower the seizure threshold and make seizure termination more difficult and less likely to respond to anticonvulsants.

Agents that antagonize A_{2A} receptors produce cerebral vasoconstriction and may limit oxygen delivery during times of increased demand. Antagonism of A_{2A} receptors in the striatum increases dopamine-mediated motor activity.

Chemical Agents

Table 14-12 provides examples of chemical agents that affect adenosine receptors.

Direct Adenosine Agonists

ADAC (adenosine amine congener) is a direct A_1 receptor agonist used in the treatment of Huntington disease.[19] Tecadenoson is a selective A_1 receptor agonist that is used for treatment of supraventricular tachycardia.[19]

Indirect Adenosine Agonists

Papaverine and dipyridamole inhibit adenosine uptake.[116] Like other adenosine agonists, papaverine and dipyridamole demonstrate anticonvulsant activity when injected into the CNS. Such actions are not achievable with safe systemic doses.

In addition to their actions at $GABA_A$ receptors, benzodiazepines inhibit adenosine uptake.[34,117] This may explain observations that methylxanthines, potent adenosine receptor antagonists, reverse benzodiazepine-induced sedation in humans. The potencies of benzodiazepines as inhibitors of adenosine uptake show

good correlation with clinical anxiolytic and anticonflict potencies, suggesting that such inhibition contributes to their action. The anticonvulsant effect of large doses of flumazenil also results from

inhibition of adenosine uptake. Carbamazepine inhibits adenosine uptake, although this is not thought to account for most anticonvulsive action.

TABLE 14-12. Examples of Xenobiotics That Affect Adenosine Receptors

Adenosine agonism	Inhibit ADA
Direct agonists	Acadesine
Adenosine	Dipyridamole
ADAC (adenosine amine congener)	Pentostatin
Tecadenoson	
	Inhibit AK
Inhibit uptake	Acadesine
Acadesine	
Acetate[a]	Increase adenosine release
Benzodiazepines	Opioids

Calcium channel blockers	
Carbamazepine	Adenosine antagonism
Dipyridamole	A_1 blockade
Ethanol[a]	Caffeine
Flumazenil	Carbamazepine
Indomethacin	Theophylline
Papaverine	
Propentofylline	A_2 blockade
Tricyclic antidepressants	Caffeine
	Theophylline

ADA = adenosine deaminase; AK = adenosine kinase.
[a] Ethanol is metabolized to acetate, which inhibits adenosine uptake.

Adenosine may mediate many of the acute and chronic motor effects of ethanol on the brain. Ethanol, probably through its metabolite, acetate, prevents adenosine uptake, raising synaptic adenosine concentrations.[28] Excessive stimulation of several adenosine receptors in the cerebellum may explain much of the motor impairment from low ethanol concentrations. In fact, animals made

tolerant to ethanol develop cross-tolerance to adenosine agonists. In mice, adenosine receptor agonists increase ethanol-induced incoordination while adenosine antagonists decrease this intoxicating response.[37]

Numerous other agents are inhibitors of adenosine uptake, including propentofylline, nimodipine, tricyclic antidepressants, and other calcium channel blockers.[114,116]

A_1 receptors located at the spinal cord level are important modulators of pain transmission by limiting release of substance P.[132] Tricyclic antidepressants-induced inhibition of adenosine uptake may explain some of their effectiveness in treating neuropathic pain.[132] The analgesic effectiveness of opioids can be partially attributed to their ability to increase the release of adenosine within the spinal cord.[143]

Dipyridamole inhibits adenosine deaminase, raising adenosine concentrations. During times of elevated adenosine levels that occur with cardiac or cerebral ischemia, acadesine further enhances adenosine's beneficial actions by three mechanisms: inhibition of adenosine kinase (AK), inhibition of adenosine deaminase (ADA), and inhibition of adenosine uptake.[107]

Adenosine Antagonists

The main adenosine antagonists of toxicologic concern are methylxanthines. Theophylline and caffeine are selective P_1 antagonists, blocking both A_1 and A_2 receptors.[159] The response to methylxanthines by A_3 receptors varies widely depending on the species. Human A_3 receptors demonstrate very low affinity for methylxanthines.[160]

Peripherally, methylxanthines produce excessive release of catecholamines from peripheral nerve endings (and probably the adrenal gland) by blocking presynaptic A_1 receptors. In turn, catecholamine-mediated responses are exaggerated by blockade of

inhibitory postsynaptic A_1 receptors on end organs.[51]

Centrally, enhanced release and actions of excitatory neurotransmitters (eg, glutamate) and resultant lack of periodicity probably explain convulsions that are frequently refractory to anticonvulsants in methylxanthine poisoning. The reasons why theophylline convulsions carry such a high mortality stem from a lack of self-termination (continual high-frequency spike activity and large metabolic demands) that has resulted from A_1 antagonism, compounded by vasoconstriction caused by blockade of A_2 receptors.[119] $GABA_A$ receptor agonism, especially by barbiturates, most effectively prevents and terminates methylxanthine-induced seizures. Phenytoin not only is ineffective in treating theophylline-induced seizures, but may actually increase the likelihood of seizures and mortality.[15]

Like phenytoin, carbamazepine's major anticonvulsant effect results from Na^+ channel blockade. Unlike phenytoin, carbamazepine appears to antagonize A_1 receptors.[31,34] This may explain the higher frequency of seizures after carbamazepine overdose than after phenytoin overdose. The absence of A_2 blockade by carbamazepine theoretically allows for increases in cerebral blood flow to meet metabolic demands of the seizing brain.

Summary

Neurotransmitter systems share common physiologic features, including neurotransmitter uptake, vesicle membrane pumps, ion trapping of neurotransmitters within vesicles, calcium-dependent exocytosis, and receptors coupled to either G proteins or to ion channels. It is not surprising, then, that a single pharmacologic agent frequently produces effects on several different neurotransmitter systems.

As the number of new drugs and toxins encountered by man continues to grow, an understanding of their molecular actions in the

nervous system helps the physician to anticipate and better understand various pharmacologic and adverse effects resulting from therapeutic or toxic doses.

Chapter 15
Withdrawal Principles

Richard J. Hamilton

In the central nervous system, excitatory neurons fire regularly, and inhibitory neurons inhibit the transmission of these impulses. Whenever action is required, the inhibitory tone diminishes, permitting the excitatory nerve impulses to travel to their end organs. Thus, all action in human neurophysiology is disinhibition.[50,95,100]

Tonic activity of a xenobiotic produces an adaptive change in the neuron. For example, tonic stimulation of an inhibitory neuron reduces the activity of that neuron so that the baseline level of function is again attained. A withdrawal syndrome occurs when the constant presence of this xenobiotic is removed or reduced and the adaptive changes persist. This produces a dysfunctional state in which there is significantly reduced inhibitory neurotransmission, essentially producing excitation (Fig. 15-1). Every withdrawal syndrome has two characteristics: (a) a preexisting physiologic adaptation to a xenobiotic, the continuous presence of which prevents withdrawal, and (b) decreasing concentrations of that

xenobiotic. In contrast, simple tolerance to a drug is characterized as a physiologic adaptation that shifts the doseâ€“response curve to the right; that is, greater amounts of xenobiotic are required to achieve a given effect. Patients with withdrawal syndromes have often developed tolerance, but tolerance does not require the continued presence of the xenobiotic to prevent withdrawal.[38,86]

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) provides a helpful and descriptive set of criteria that mesh with our understanding of the pathophysiology of withdrawal syndromes.[30] According to DSM-IV, withdrawal is manifested by either of the following: (a) a characteristic withdrawal syndrome for the substance or (b) the same (or a closely related) substance is taken to relieve withdrawal symptoms. Note that either criterion fulfills this definition. Logically, all syndromes have the first criterion, and so it is the presence of the second criterion that is critical to understanding physiology and therapy.

For the purposes of defining a unifying pathophysiology of withdrawal syndromes, this chapter considers syndromes in which both features are present. An analysis from this perspective distinguishes xenobiotics that affect the inhibitory neuronal pathways from the effects of those agents that stimulate the excitatory neuronal pathways, such as cocaine. Cocaine does not produce a withdrawal syndrome using this definition, but rather a postintoxication syndrome that often results in lethargy, hypersomnolence, movement disorders, and irritability. This syndrome does not meet the second of the DSM-IV criteria for a withdrawal syndrome because the same (or a closely related) substance is not taken to relieve or avoid withdrawal symptoms. This postintoxication syndrome, the so-called â€œcrack crashâ€• or â€œwashed-out syndrome,â€• is caused by prolonged use of the drug, and patients return to their premorbid function without intervention.[74,87,98] This distinction is important for toxicologists, because (a) withdrawal syndromes that demonstrate both features of the DSM-IV criteria are treated with reinstatement and gradual withdrawal of a xenobiotic that has an effect on the

receptor and (b) withdrawal syndromes that do not demonstrate the second feature require only supportive care and resolve spontaneously.

Finally, withdrawal syndromes are best described and treated based on the class of receptors that are affected because this concept also organizes the approach to patient care. For each receptor and its agonists, research has identified genomic and nongenomic effects that produce neuroadaptation and withdrawal syndromes. There appear to be six mechanisms involved: (a) genomic mechanisms via mRNA; (b) second messenger effects via protein kinases, cyclic adenosine monophosphate (cAMP),[43] and calcium ions; (c) receptor endocytosis; (d) expression of various receptor subtypes depending on location within the synapse (synaptic localization); (e) intracellular signaling via effects on other receptors; and (f) neurosteroid modulation. All or some of these mechanisms are already demonstrated in each of the known withdrawal states.[51] These mechanisms develop in a surprisingly rapid fashion and modify the receptor and its function in such complex ways as to depend on the continued presence of the substance to prevent dysfunction.[49,63,67,69,85,99,103]

$GABA_A$ Receptors (Barbiturates, Benzodiazepines, Ethanol, Volatile Solvents)

Î³-Aminobutyric acid type A ($GABA_A$) receptors have separate binding sites for GABA, barbiturates, benzodiazepines, and picrotoxin, to name only a few xenobiotics (Chap. 14). Barbiturates and benzodiazepines bind to separate receptor sites and enhance the affinity for $GABA_A$ at its receptor site. $GABA_A$ receptors are part of a superfamily of ligand-gated ion channels, including nicotinic acetylcholine receptors and glycine receptors, that exist as pentamers arranged around a central ion channel.[89] When activated,

they hyperpolarize the postsynaptic neuron by facilitating an inward chloride current (without a G protein messenger), decreasing the likelihood of the neuron firing an action potential.[50,80]

The GABA receptor is a pentamer comprised of two Î± subunits, two Î² subunits and an additional subunit, most commonly Î³, which

is a key element in the benzodiazepine binding site. The two GABA-binding sites per receptor are located in a homologous position to the benzodiazepine site between the Î± and Î² subunits. Although the mechanism is unclear, benzodiazepines have no direct functional effect without the presence of GABA. Conversely, certain barbiturates, or perhaps all in a dose-dependent manner, can increase the frequency of channel opening producing a net increase in current flow without GABA binding.[36,67]

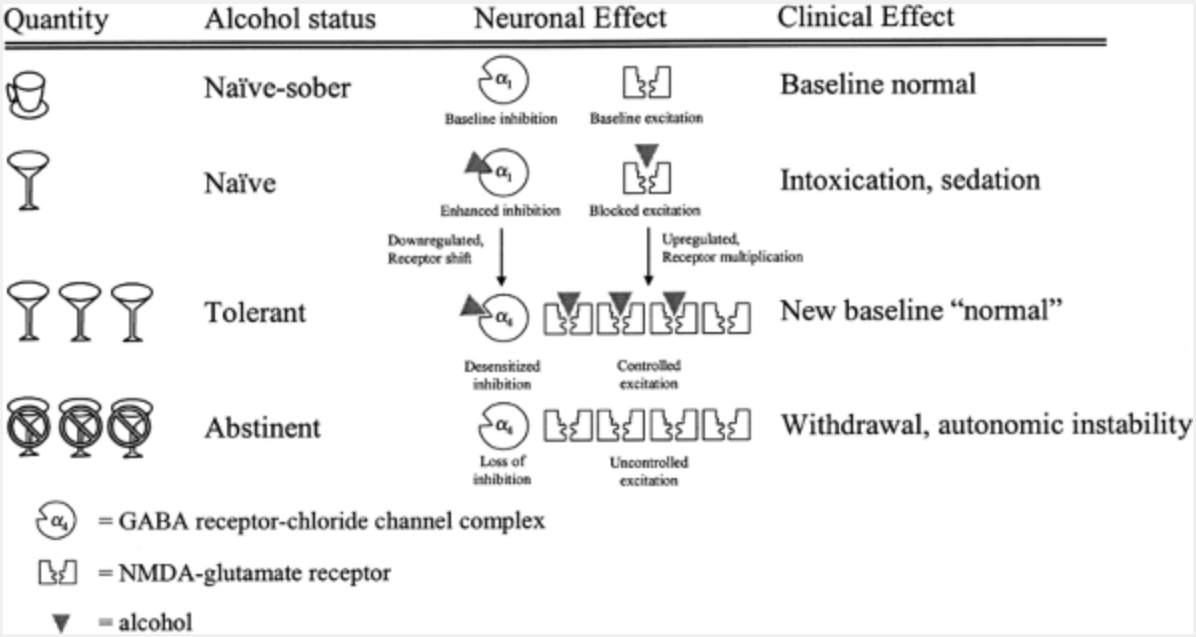

Figure 15-1. Alcohol intoxication, tolerance, and withdrawal. Alcohol consumption in alcohol-naive persons produces intoxication and sedation by simultaneous agonism at the Î³-

aminobutyric acid (GABA) receptor-chloride channel complex and antagonism at the *N*-methyl-D-aspartate (NMDA)-glutamate receptor. Continuous alcohol consumption leads to the development of tolerance through changes in both the GABA receptor-chloride channel complex (a subunit shift from Î±$_1$ to Î±$_4$, results in reduced sensitivity to the sedating effects of alcohol) and the NMDA subtype of glutamate receptor (upregulation in number, resulting in enhanced wakefulness). There is conceptually a level at which the tolerant patient may appear clinically normal despite having an elevated blood alcohol concentration. Tolerant patients who are abstinent lose the tonic effects of alcohol on these receptors, resulting in withdrawal.

Recent evidence demonstrates that this prototypical pentameric $GABA_A$ receptor assembly is derived from a permutation and combination of two, three, four, or even five different subunits. The subtypes of GABA receptors can even vary on the same cell.[67] In fact, GABA receptors are heterogeneous receptors with different subunits and distinct regional distribution. Although the preponderance of subtypes Î±$_1$Î²$_2$Î³$_2$, Î±$_2$Î²$_3$Î³$_2$, and Î±$_3$Î²$_3$Î³$_2$ account for 75% of GABA receptors, there are at least 16 others of import.[103] The recognition of additional subunits of $GABA_A$ receptors, such as Ï‰, has permitted the development of targeted pharmaceuticals.[7] For example, the drug zolpidem achieves its effect of hastened onset of sleep by targeting the Ï‰$_1$ receptor subunit of $GABA_A$.[84]

Previously, ethanol was thought to have GABA-receptor activity, although a clearly identified binding site was not evident (Chap. 75). Traditional explanations for this effect included (a) enhanced membrane fluidity and allosteric potentiation (so-called cross-coupling) of the 5 proteins that construct the $GABA_A$ receptor; (b) interaction with a portion of the receptor; and/or (c) enhanced GABA release.[18,50,52,83] Research with chimeric reconstruction of $GABA_A$

and *N*-methyl-D-aspartate (NMDA) channels demonstrates highly specific binding sites for high doses of ethanol which enhance $GABA_A$ and inhibit NMDA receptor-mediated glutamate neurotransmission.[68] However, research has not clarified whether ethanol at low doses is a direct agonist of $GABA_A$ receptors or a potentiator of $GABA_A$ receptor binding.[53,67,73,76]

Ethanol exhibits all 6 mechanisms of adaptation to chronic exposure, and is the prototypical substance for studying neuroadaptation and withdrawal.[51] These 6 mechanisms appear to apply to benzodiazepines as well.[3,48,73,76] The mechanisms are (a) altered $GABA_A$ receptor gene expression via alterations in mRNA and peptide concentrations of $GABA_A$ receptor subunits in numerous regions of the brain (genomic mechanisms); (b) posttranslational modification through phosphorylation of receptor subunits with protein kinase C (second-messenger effects); (c) subcellular localization by an increased internalization of $GABA_A$ receptor $Î±_1$-subunit receptors (receptor endocytosis); (d) modification of receptor subtypes with differing affinities for agonists to the synaptic or nonsynaptic sites (synaptic localization); (e) regulation via intracellular signaling by the NMDA, acetylcholine, serotonin, and $Î²$-adrenergic receptors; and (f) neurosteroid modulation of GABA-receptor sensitivity and expression.[17,31,34,46,52,53,78,101]

Intracellular signaling via NMDA subtype of the glutamate receptor appears to explain the â€œkindlingâ€• hypothesis, in which successive withdrawal events become progressively more severe.[8,10,12,15,33,55,102] The activity of an excitatory neurotransmission increases the more it fires, a phenomenon known as long-term potentiation, and is the result of increased activity of mRNA and receptor protein expression, a genomic effect of intracellular signaling.[38] As

NMDA receptors increase in number and function (upregulation)[42] and $GABA_A$ receptor activity diminishes, withdrawal becomes more severe.[28,55,65,78] The dizocilpine (MK-801) binding site of the NMDA

receptor appears to be the major contributor, and this effect is recognized in neurons that express both NMDA and $GABA_A$ receptors.[4,101,105] Interestingly, animal models suggest that chronic ethanol use induces alterations in the receptor subunit composition of the $GABA_A$ receptor, which may be partly responsible for the development of ethanol tolerance, withdrawal, and kindling.[20,55]

In summary, it is an over simplification to view $GABA_A$ receptors as a homogenous and static collection of cell-surface proteins that are stimulated by sedatives. $GABA_A$ agonists induce modulatory changes in the receptors through genomic and nongenomic mechanisms that ultimately alter their function. In this way, withdrawal symptoms represent the clinical manifestation of a change in GABA-receptor-complex characteristics.[19,44] When alcohol or any xenobiotic with GABA agonist activity is withdrawn, inhibitory control of excitatory neurotransmission, such as that mediated by the now upregulated NMDA receptors, is lost.[34,63,81] This results in the clinical syndrome of withdrawal: CNS excitation (tremor, hallucinations, seizures), and autonomic stimulation (tachycardia, hypertension, hyperthermia, diaphoresis) (Chap. 76).[39,50,85]

Volatile solvents, such as gasoline, ether, and toluene, are widespread substances of abuse whose effects appear to be mediated by the GABA receptor; all of these solvents have a well-established abuse potential, especially in adolescents. These solvents can produce CNS inhibition and anesthesia at escalating doses via the $GABA_A$ receptor. Elaboration of the mechanism specific for solvent abuse awaits further study, although it is logical to assume that they act in a similar fashion as ethanol and other xenobiotics with the $GABA_A$ receptor.[9] They also appear to initiate the same dopamine reward system as other drugs of abuse.[77,91]

$GABA_B$ Receptors (GHB and Baclofen)

$GABA_B$ agonists such as Î³-hydroxybutyric (GHB) acid and baclofen have similar clinical characteristics with regard to adaptation and

withdrawal.[11,24,37,104] The $GABA_B$ receptor is a heterodimer of the $GABA_{B(1)}$ and $GABA_{B(2)}$ receptor. Unlike $GABA_A$, the $GABA_B$ receptor couples to various effector systems through a signal-transducing G protein. $GABA_B$ receptors mediate presynaptic inhibition (by preventing Ca^{2+} influx) and postsynaptic inhibition (by increasing K^+ efflux). The postsynaptic receptors appear to have a similar inhibitory effect as the $GABA_A$ receptors. The presynaptic receptors provide feedback inhibition of GABA release. Unlike $GABA_A$ receptors, these are mediated through G protein messengers.[13,62,104]

GHB is a naturally occurring inhibitory neurotransmitter with its own distinct receptor. Physiologic concentrations of GHB activate at least two subtypes of a distinct GHB receptor (antagonist-sensitive and antagonist-insensitive). However, at supraphysiologic concentrations, such as those that occur after overdose and abuse, GHB also binds directly to the $GABA_B$ receptor and is also metabolized to GABA (which then activates the $GABA_B$ receptor). Endogenous GHB activates a presynaptic GHB receptor to modulate GABA and glutamate release and inhibits dopamine release by the $GABA_B$ receptor.[6] The GHB withdrawal syndrome clinically resembles the withdrawal syndrome noted from ethanol and benzodiazepines. Distinctive clinical features of GHB withdrawal are the relatively mild and brief autonomic instability with the persistence of psychotic symptoms.[97]

Baclofen is also a $GABA_B$ agonist. The pre- and postsynaptic inhibitory properties of baclofen allow it, paradoxically, to cause seizures in both acute overdose (because of decreased release of presynaptic GABA via autoreceptor stimulation) and withdrawal. Withdrawal is probably a result of the loss of chronic inhibitory effect of baclofen on postsynaptic $GABA_B$ receptors. On discontinuation, this produces hyperactivity of neuronal Ca^{2+} channels (N, P/Q type),[27] leading to seizures, hypertension, hallucinations, psychosis, and coma. However, these manifestations may not differ from the withdrawal symptoms of $GABA_A$ agonists.[79,92]

Typically, the development of a baclofen withdrawal syndrome occurs 24â€“48 hours after discontinuation of baclofen. Case reports highlight the development of seizures, hallucinations, psychosis, dyskinesias, and visual disturbances. The intrathecal baclofen pump has become an effective replacement for oral dosing, but withdrawal can occur following use of this modality as well. Reinstatement of the prior baclofen-dosing schedule appears to resolve these symptoms within 24â€“48 hours. Benzodiazepines and $GABA_A$ agonists (not phenytoin) are the appropriate treatment for seizures induced by baclofen withdrawal.[72]

Opioid Receptors (Opiates and Opioids)

Similar to ethanol and $GABA_A$ receptors, opioid binding to the opioid receptors result in a series of genomic and nongenomic neuroadaptations, especially via second-messenger effects. When opioids bind to opioid receptors they alleviate pain by inhibiting neurons. They also activate G_S proteins, and stimulate K^+ efflux currents. The opioid receptors are also linked to the $G_{i/o}$ proteins. These act through adenyl cyclase and activate inward Na^+ current, thus enhancing the intrinsic excitability of a neuron (Chap. 38).[23]

Chronic exposure to opiates and opioids (all drugs with opioid-receptor affinity) results in a decreased efficacy of the receptor to open potassium channels by genomic mechanisms and second-messenger effects. Following chronic opioid exposure, the expression of adenyl cyclase increases through activation of the transcription factor known as cAMP response element-binding protein (CREB).[64,70] (Fig. 15-2) This results in an upregulation of cAMP-mediated responses such as

the inward Na^+ channels responsible for intrinsic excitability. The net effect is that, only higher levels of opioids result in analgesia and other opioid effects. In the dependent patient, when opioid levels drop, inward Na^+ flux occurs unchecked, and the patient experiences

the opioid withdrawal syndrome. The clinical findings associated with this syndrome are largely a result of uninhibited activity at the locus caeruleus.[21,49,64,66,70]

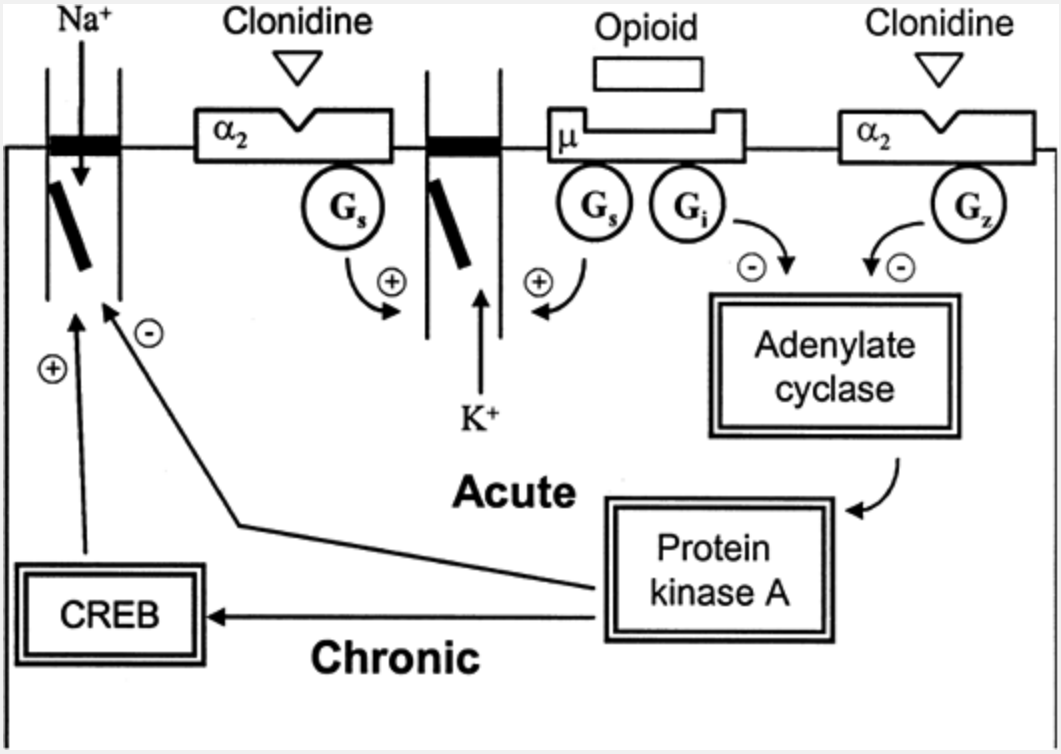

Figure 15-2. Immediate and long-term effects of opioids. The acute effects of both opioids and Î±2-adrenergic agonists are to increase inhibition through enhanced potassium efflux and inhibited sodium influx. Chronic effects alter gene expression to enhance sodium influx and restore hemeostasis. CREB (cAMP response element-binding protein).

Furthermore, opioid receptors and central Î±2-adrenergic receptors both exert a similar effect on the potassium channel in the locus ceruleus. Clonidine binds to the central Î±2-adrenergic receptor and stimulates potassium efflux, as do opioids, and produces similar

clinical findings.[2] This explains why clonidine has some efficacy in treating the opioid withdrawal syndrome. In addition, the antagonistic effect of naloxone at the opioid receptor seems to reverse the effect of clonidine on this shared potassium efflux channel.[2,35,40]

Rapid opioid detoxification is a form of iatrogenic withdrawal that uses drugs with antagonist activity to accelerate a return to premorbid receptor states. In theory, inducing opioid withdrawal under general anesthesia with high-dose opioid antagonists permits the transition from drug dependency to naltrexone maintenance without drug withdrawal symptoms.[56,57,58] Naltrexone blocks the euphoric effects of continued opioid use and discourages recidivism by blunting drug craving.[47,59,60,61] Although the mechanism by which naltrexone blocks drug craving is not entirely clear, the speculation is that mere receptor occupancy by an antagonist is sufficient to blunt cravings. However, withdrawal symptoms may still be intense and persist for up to 1 week after rapid detoxification, suggesting that clinical recovery from the changes induced by chronic opioid use is slow.[22,41,84,90,94]

Î ±$_2$-Adrenergic Receptors (Clonidine)

Î ±$_2$-Adrenergic receptors are located in the central and peripheral nervous system. Clonidine is a central and peripheral Î ±$_2$-adrenergic agonist. Stimulation of central presynaptic Î ±$_2$-adrenergic receptors inhibits sympathomimetic output and results in bradycardia, and hypotension.[32] Within 24 hours after the discontinuation of clonidine, norepinephrine concentrations rise as a result of enhanced efferent sympathetic activity.[82] This results in hypertension, tachycardia, anxiety, diaphoresis, and hallucinations.[16]

Adenosine (A) Receptors (Caffeine)

The release of neurotransmitters is accompanied by passive release

of adenosine as a by-product of adenosine triphosphate (ATP) breakdown. The released adenosine binds to postsynaptic A_1 receptors where it typically has inhibitory effects on the postsynaptic neuron. It also binds to presynaptic A_1 autoreceptors to limit further release of neurotransmitters. A_2 receptors are found on the cerebral vasculature and peripheral vasculature where stimulation promotes vasodilation.[26,45] Caffeine and other methylxanthines, such as theophylline, antagonize the inhibitory effect of adenosine, primarily on postsynaptic A_1 receptors. As a result, acute exposure results in increases in heart rate, ventilation, gastrointestinal motility, gastric acid secretion, and motor activity. Chronic caffeine exposure results in tolerance to the clinical effects of large, acute doses of caffeine. Chronic caffeine exposure regulates A_1 receptors by a variety of mechanisms, including increases in receptor number, increases in receptor affinity, enhancing receptor coupling to the G protein, and increases in G protein-stimulated adenyl cyclase.[54] An animal study demonstrates that the adenosine receptor has a 3-fold increase in affinity for adenosine at the height of withdrawal symptoms. This model suggests that chronic caffeine administration results in increase in receptor affinity for adenosine, thus restoring a state of physiologic balance (normal motor inhibitory tone). When caffeine is withdrawn, the enhanced receptor affinity results in a strong adenosine effect and clinical symptoms of withdrawal: headache (cerebral vasodilation), fatigue, and hypersomnia (motor inhibition).[69,93,96]

Acetylcholine Receptors (Nicotine)

Nicotinic receptors are a type of acetylcholine receptors located in the autonomic ganglia, adrenal medulla, CNS, spinal cord, neuromuscular junction, and carotid and aortic bodies. Nicotinic receptors are fast-response cation channels that are not coupled to G proteins, distinguishing them from muscarinic receptors, which are coupled to G proteins. Nicotinic acetylcholine receptors have both excitatory and inhibitory effects. As in other withdrawal syndromes,

changes brought on by chronic use of nicotinic agonists, such as nicotine in cigarettes, appear to be related to selective upregulation of cAMP. Much remains unknown about these receptors and how they affect addiction and withdrawal.[71,99]

SSRI Discontinuation Syndrome

Upon discontinuation of chronic selective serotonin reuptake inhibitor (SSRI) therapy, patients develop a characteristic syndrome. This syndrome complies with the definition of withdrawal syndromes in that symptoms begin when drug concentrations drop, and the syndrome abates when the drug is reinstated. Headache, nausea, fatigue, dizziness, and dysphoria are commonly described symptoms. The condition appears to be uncomfortable but not life-threatening, rapidly resolves with reinstatement of a drug of the same class, and slowly resolves when the drug is discontinued after a more gradual taper (Chap. 70).[14,24,75]

Chapter 16 Thermoregulatory Principles

Susi U. Vassallo

Kathleen A. Delaney

Despite exposure to wide fluctuations of environmental temperatures, human body temperature is maintained within a narrow range.[20,130] Elevation or depression of body temperature occurs when (a) thermoregulatory mechanisms are overwhelmed by exposure to extremes of environmental heat or cold; (b) endogenous heat production is either inadequate, resulting in hypothermia, or exceeds the physiologic capacity for dissipation, resulting in hyperthermia; or (c) disease processes or drug effects interfere with normal thermoregulatory responses to heat or cold exposure.

Methods of Heat Transfer

Heat is transferred to or away from the body through radiation, conduction, convection, and evaporation. *Radiation* involves the transfer of heat from a body to the environment, and from warm objects in the environment, for example, from the sun to a body.

Conduction involves the transfer of heat to solid or liquid media in direct contact with the body. Water immersion or wet clothing in contact with the body conducts significant amounts of heat away from the body. This effect facilitates cooling in a swimming pool on a hot summer day, or may lead to hypothermia despite moderate ambient temperatures on a rainy day. The amount of heat lost through conduction and radiation depends on the temperature gradient between skin and surroundings, cutaneous blood flow, and insulation such as subcutaneous fat, hair, clothing, or fur in lower animals.[144] In the respiratory tract, heat is lost by conduction to water vapor or gas. In animals unable to sweat, this represents the primary method of heat loss. The amount of heat lost through the respiratory tract depends on the temperature gradient between inspired air and the environment, as well as the rate and depth of breathing.[144] *Convection* is the transfer of heat to the air surrounding the body. Wind velocity and ambient air temperature are the major determinants of convective heat loss. *Evaporation* is the process of vaporization of water, or sweat. Large amounts of heat are dissipated from the skin during this process, resulting in cooling. Ambient temperature, rate of sweating, air velocity, and relative humidity are important factors in determining how much heat is lost through evaporation. On a very humid day, sweat may pour off, rather than evaporate from a person exercising in a hot environment, thereby accomplishing little heat loss. In very warm environments, thermal gradients may be reversed, leading to transfer of heat to the body by radiation, conduction, or convection.[159,190]

Physiology of Thermoregulation

In the normal human, stimulation of peripheral and hypothalamic temperature-sensitive neurons results in autonomic, somatic, and behavioral responses that lead to the dissipation or conservation of heat. Thermoregulation is the complex physiologic process that serves to maintain hypothalamic temperature within a narrow

range of 98.6 Â± 0.8Â°F (37 Â± 0.4Â°C) known as the set point.[308] This hypothalamic set point is influenced by factors such as diurnal variation, the menstrual cycle and others. Maintaining, raising, or lowering the set point results in many outwardly visible physiologic manifestations of thermoregulation such as sweating, shivering, flushing, or panting. In the central nervous system, thermosensitive neurons are located predominantly in the preoptic area of the anterior hypothalamus, although some are found in the posterior hypothalamus. These neurons may be divided into those that are warm-sensitive, cold-sensitive, or temperature-insensitive. Approximately 30% of preoptic neurons are warm-sensitive. These increase their firing rate during warming and decrease their firing rate during cooling.[32] Warming of the hypothalamus in conscious animals results in vasodilation, hyperventilation, salivation, and increases in evaporative water loss, as well as a reduction of cold-induced shivering and vasoconstriction.[128] Cooling of the hypothalamus in conscious animals causes shivering, vasoconstriction, and increased metabolic rate, even if the environment is hot.[119] How these temperature-sensitive neurons of the hypothalamus detect temperature changes and effect neuronal transmission is unclear. Altered action potential initiation and propagation caused by temperature-dependent changes in membrane potential, changes in

the ratios of Na^+ to Ca^{2+} ions which alter neuronal excitability and neurotransmitter release, or effects on the Na^+K^+-ATPase (adenosine triphosphatase) pump, may be involved.[144] Drugs that increase intracellular cyclic adenosine monophosphate (cAMP) increase the thermosensitivity of warm-sensitive neurons.[32] In the brainstem, warm- and cold-sensitive neurons are located in the medullary reticular formation, where information from cutaneous receptors, spinal cord, and preoptic area of the anterior hypothalamus is integrated.[24,106,130,134]

The spinal cord also manifests thermosensitivity. Heat- and cold-sensitive ascending spinal impulses are conducted in the spinothalamic tract. As in the hypothalamus, local heating or cooling of the spinal cord results in thermoregulatory responses.[128] In addition to the hypothalamus, brainstem, and spinal cord, there is evidence of thermosensitivity in the deep abdominal viscera.[115,128,242] Intra-abdominal heating or cooling results in thermoregulatory responses. Cold- and warm-sensitive afferent impulses can be recorded from the splanchnic nerves in animals.[115,244] Finally, the skin also contains heat and cold thermosensitive neurons. Cold receptors are free nerve endings that protrude into the basal epidermis, whereas warm-sensitive receptors protrude into the dermis.[127,129] Cutaneous thermoreceptor output is affected by the absolute temperature of the skin, rate of temperature change, and area of stimulation.[128] Cutaneous cold receptors are AÎ´ and C nociceptor afferent fibers. AÎ´ fibers are small-diameter thinly myelinated fibers that conduct at 5â€“30 m/sec, and C-fibers are small-diameter unmyelinated fibers that conduct at 0.5â€“2 m/sec.[122] Afferents from heat receptors are primarily C fibers. Cutaneous thermoreceptive neurons respond to external temperature change as well as rate of temperature change, sending early warning to the central nervous system (CNS) via afferent impulses, allowing rapid and transient thermoregulatory responses before brain temperature changes (Fig. 16-1).

Vasomotor and Sweat Gland Function

Vasomotor responses to thermoregulatory input differ according to location. The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body-core temperature results in active vasodilation in the extremities and is under noradrenergic control; increasing sympathetic stimulation results in vasoconstriction, and decreasing sympathetic control results in vasodilation. Vasodilation in the

head, trunk, and proximal limbs is not a result of decreased sympathetic tone; instead, it is a result of an active process that is under the influence of cholinergic sudomotor nerves and local effects of temperature on venomotor tone. Sweat glands release local transmitters, such as vasoactive intestinal polypeptide (VIP) or bradykinins, and vasodilation results. Areas of the body such as the forehead, where sweating is most prominent during heat stress, correspond to areas where active vasodilation is greatest. The neurotransmitters involved in the regulation of relationships between vasodilation and sweating as a response to heat stress are not fully elucidated, but animal evidence suggests the presence of specific vasodilator nerves.[128]

Sweat glands are controlled by sympathetic postganglionic nerve fibers, which are cholinergic, and large amounts of acetylcholinesterase as well as other peptides involved in neural transmission.[127,128]

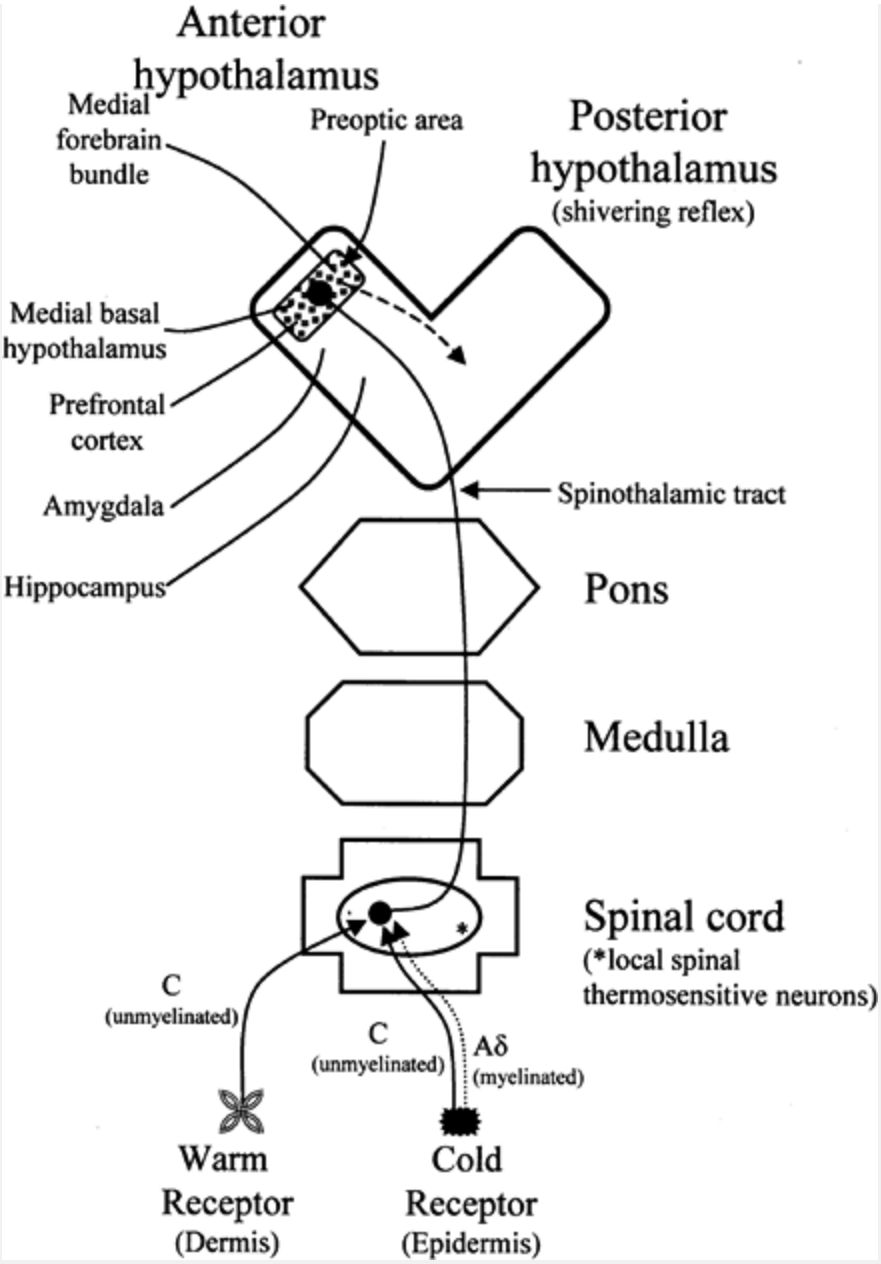

Figure 16-1. A representation of the response of cutaneous thermoreceptive neurons to external temperature change as an early warning to the central nervous system.

Neurotransmitters and Thermoregulation

The neurotransmitters involved in thermoregulation include serotonin, norepinephrine, acetylcholine, dopamine, prostaglandins, Î²-endorphins, and intrinsic hypothalamic peptides such as arginine vasopressin, adrenocorticotropic hormone, thyrotropin-releasing hormone, and Î±-melanocyteâ€“stimulating hormone.[52,230] Studies on the effects of individual neurotransmitters in thermoregulation yield contradictory results, depending on the animal species and the route of administration of the exogenous neurotransmitter. Refinements in techniques of microinjection of neurotransmitters into the hypothalamus of animals, rather than intraventricular instillation, have elucidated microanatomic sites where neurotransmitters are active. More research is needed, however, as interspecies variations and theoretical differences in response to exogenous versus endogenous peptides makes this area of study complex.

Apomorphine is a mixed dopamine agonist that has been shown to cause hypothermia in animals; studies using selective D_1- and D_2-receptor agonists and antagonists suggest that the hypothermic effect of apomorphine is a result of its effects on D_2 receptors, with some modulation by D_1 receptors in the hypothalamus.[205] Stimulation of D_2 receptors appears to mediate the hypothermia induced

by the peptide sauvagine.[35] Dopamine D_3 receptors undoubtedly play a role, as well; stimulation of D_3 by specific agonists caused hypothermia in an animal model.[206,207] There appears to be a link between dopamine D_2 receptors and norepinephrine receptors in the hypothalamus, perhaps leading to vasodilation and hypothermia. The effect of clozapine in producing hypothermia in the rat was demonstrated to be caused by D_1 and D_3 stimulation.[206,255] Lesser-known peptides appear to be involved in

thermoregulation. For example, neuropeptide Y is an amino acid neurotransmitter that occurs in high concentrations in the preoptic area of the anterior hypothalamus. Administration of neuropeptide Y caused a reduction in core temperature when administered with adrenoceptor antagonists such as prazosin, an Î±$_1$-adrenergic antagonist, propranolol, a Î²-adrenergic antagonist, and clonidine, a central Î±$_2$-adrenergic agonist.[87,253] The administration of synthetic cannabinoids induces hypothermia in animals, an effect that is antagonized by adrenergic agonists and enhanced by adrenergic antagonists.[237] Finally, studies on muscarinic receptors suggest the involvement of muscarinic M_2 and M_3 receptors in the production of hypothermia when agonists to these receptors are administered centrally.[256] Blockers of adenosine triphosphate (ATP)-sensitive K^+ channels can reverse the effect of cholinomimetic drugs in producing hypothermia.[239]

Drug effects on Thermoregulation

Many drugs and toxins have pharmacologic effects that interfere with thermoregulatory responses (Tables 16-1 and 16-2).[187,191,292] Î±-Adrenergic agonist agents prevent vasodilation in response to heat stress. Increased endogenous heat production in the setting of increased motor activity also occurs in patients poisoned with cocaine or amphetamines. Life-threatening hyperthermia has been associated with the use of these agents. Î²-Adrenergic antagonists and calcium channel blockers diminish the cardiac reserve available to compensate for heat-induced vasodilation, whereas diuretics decrease cardiac reserve through their effects on intravascular volume.[67] Î²-Adrenergic antagonists also interfere with the capacity to maintain normothermia under conditions of cold stress, possibly related to their interference with the mobilization of substrates required for thermogenesis.[128,191] Opioids, and diverse sedative-hypnotics, depress hypothalamic function and predispose to hypothermia in the overdose setting.[89] Carbon monoxide poisoning must also be considered in the

hypothermic patient. Organic phosphorous insecticides and other agents that cause cholinergic stimulation cause hypothermia by stimulation of inappropriate sweating and possibly through depression of the endogenous use of calorigenic substrates.[191] Drugs with anticholinergic effects decrease sweating and predispose to hyperthermia during environmental heat exposure or exercise. Phenothiazines appear to interfere with normal response to both heat and cold. Severe hyperthermia associated with the absence of sweating is frequently described in patients using phenothiazines and may be a consequence of their anticholinergic effects.[257,310] Effects on cold tolerance are attributed to their Î²-adrenergic antagonist effects, which prevent vasoconstriction in response to cold stress.[189] In addition, hyperthermia associated with severe extrapyramidal rigidity may occur in patients on antipsychotic agents.[178] This rigidity is attributed to the dopamine-blocking effects of this class of drugs.

TABLE 16-1. Effects of Xenobiotics that Predispose to Hyperthermia

I. Impaired cutaneous heat loss
A. Vasoconstriction through Î±-adrenergic stimulation
Amphetamine and derivatives
Cocaine
Ephedrine
Phenylpropanolamine
Pseudoephedrine
B. Sweat gland dysfunction by anticholinergic effects
Antihistamines
Belladonna alkaloids
Cyclic antidepressants
Phenothiazines
II. Myocardial depression

A. Decreased cardiac output
Antidysrhythmics
Î²-Adrenergic antagonists
Calcium channel blockers
B. Reduced cardiac filling by dehydration
Diuretics
Ethanol

III. Hypothalamic depression
Antipsychotics

IV. Impaired behavioral response
Ethanol
Opioids
Phencyclidine
Sedative-hypnotics
Cocaine

V. Uncoupling of oxidative phosphorylation
Pentachlorophenol
Dinitrophenol
Salicylates

VI. Increased muscle activity through agitation, seizures, or rigidity
Amphetamine derivatives
Caffeine
Cocaine
Isoniazid
Lithium
Monoamine oxidase inhibitors
Phencyclidine
Strychnine
Sympathomimetics

VII. Dystonia
Butyrophenones
Phenothiazines

VIII. Withdrawal

Dopamine agonists
Ethanol
Sedative-hypnotics

Ethanol

Ethanol is the most common xenobiotic related to the occurrence of hypothermia in an urban setting.[64,301] The mechanism by which ethanol predisposes to hypothermia is said to be by virtue of its effects on CNS depression, vasodilation, and blunting of behavioral

responses to cold. However, thermoregulatory dysfunction associated with ethanol intoxication is undoubtedly more complex.

TABLE 16-2. Effects of Xenobiotics that Predispose to Hypothermia

Sedative-hypnotics

Impaired vasoconstriction
Î±-Adrenergic antagonists
Ethanol
Phenothiazines

In animal models, ethanol leads to hypothermia, the extent of which is partly dependent on ambient temperature.[224,245,246] In mice, as the dose of ethanol increased, body temperature decreased and the rate of this decline in body temperature was faster at higher ethanol doses.[219] The decline in body temperature could be reversed by increasing ambient temperature; increasing ambient temperature to 96.8Â°F (36Â°C) caused an immediate rise in the body temperature.[219] The poikilothermic effect of ethanol was not a result of hypoglycemia. Poikilothermia is the variation in body temperature greater than Â±3.6Â°F (Â±2Â°C) on exposure to environmental temperature changes. Rats treated with equipotent amounts of sodium pentobarbital showed the same effects on body temperature as rats treated with ethanol, suggesting a similar central mechanism of central nervous system depression resulting in altered thermoregulation.[219]

Numerous mechanisms are involved in the â€œethanol-induced depression of central nervous system function.â€•[250] Genetic factors influence the role of ethanol in the production of hypothermia. Mouse strains bred for sleep times differed in sensitivity to the effect of ethanol on temperature.[103,210,219] Mice can be selectively bred for genetic sensitivity or insensitivity to acute ethanol-induced hypothermia, and the differences appear to

be mediated by the serotonergic systems.[90] Histidyl-proline diketopiperazine (cyclo His-Pro or CHP), another neurotransmitter that is found in many animal species, acts at the preoptic-anterior hypothalamus to modulate body temperature.[42,137] Exogenous administration of this neuropeptide produced a dose-dependent decrease in ethanol-induced hypothermia. Attenuation of hypothermia resulted from passive immunization with CHP antibody.[42,137] Ethanol effects may be mediated through modulation of endogenous opioid peptides, as high-dose (10 mg/kg) naloxone reverses ethanol-induced hypothermia in animals.[234]

Pharmacokinetic characteristics of ethanol metabolism change in the presence of hypothermia. Hypothermic piglets infused with ethanol showed slower ethanol metabolism and a smaller volume of distribution and, as a result, higher ethanol levels than normothermic controls. Ethanol elimination and metabolism decreased as temperature fell.[165]

Tolerance develops to the effect of ethanol in producing hypothermia in all species.[92,224] The degree of tolerance is proportional to the dose and duration of treatment with ethanol and is not explained by the increased rate of metabolism with chronic exposure.[144] Age is a factor in the development of tolerance; older animals do not display the same degree of tolerance to the hypothermic effects of chronic ethanol administration as do younger animals.[216,233,307] The development of tolerance to ethanol-induced hypothermia is affected by genetic factors. Experimentally, tolerance to ethanol-induced hypothermia increases the incorporation of certain amino acids into proteins in the rat brain. The formation of new proteins in ethanol-tolerant rats suggests stimulation of gene expression related to the tolerant state.[144,295] Deficits in *N*-methyl-D-aspartate (NMDA) receptor systems may also be implicated in the development of ethanol tolerance. In addition, altered nicotinamide adenine dinucleotide (NADH) oxidation to NAD^+, diminished blood flow to

the liver, or slowing of metabolism through the microsomal enzyme system may be involved.[250]

Hypothermia alters the breathâ€”ethanol partition in the alveolus, and the temperature of expired breath alters breath-alcohol analysis results. In patients with mild hypothermia, ethanol breath analysis results in lower values by 7.3% per degree centigrade (or 1.8Â°F) decrease in body temperature.[95] Whether breath-alcohol analysis is also affected by hyperthermia in the test subject remains to be studied.[95]

Disease Processes and Thermoregulation

Many disease processes interfere with normal thermoregulation, limiting an individual's capacity to prevent hypothermia or hyperthermia. Extensive dermatologic disease or cutaneous burns impair sweating and vasomotor responses to heat stress.[37] Patients with autonomic disturbances such as diabetes or peripheral vascular disease also have altered vasomotor responses that impair vasodilation and sweating.[243] Extensive surgical dressings may preclude the evaporation of sweat in an otherwise normal patient. Heat-stressed persons with poor cardiac reserve may not be able to sustain a skin blood flow high enough to maintain normothermia.[77,276] Intense motor activity may lead to excessive endogenous heat production in patients with Parkinson disease or hyperthyroidism. Patients with agitated delirium or seizures also have significantly elevated rates of endogenous heat production. Hypothalamic injury caused by cerebrovascular accidents, trauma, or infection may disturb thermoregulation.[76,183] Hypothalamic dysfunction can lead to high, unremitting fevers and insufficient stimulation of heat loss mechanisms such as sweating. Hypothalamic damage may predispose to hypothermia by interference with centrally mediated heat conservation.[76,183,258,259] Fever, the normal response to

stimulation of the hypothalamus by pyrogens, results in an elevated physiologic temperature set point and is a disadvantage in the heat-stressed individual.[128]

Hypothermia

Epidemiology

Hypothermia is defined as an unintentional lowering of the core body temperature to <95Â°F (<35Â°C). Between 1979 and 2002, 16,555 people died of hypothermia in the United States, an average of 689 per year.[48] In 2002, 646 hypothermia-related deaths were reported,[48] 66% of which were in males. The majority of deaths were in individuals 65 years of age or older.

Medical factors increase the risk in the frail elderly, including limited mobility, impaired shivering, chronic illness, confusion, decreased protective fat, and slower metabolic rates. Social isolation and deprivation, poor nutrition, and inadequate access to or use of indoor heating, often because of financial concerns, are additional factors associated with the development of hypothermia.[46,132,153] Other risks associated with hypothermia in all groups are ethanol use, mental illness, use of antipsychotic medication, hypothyroidism, starvation, immobilization, dehydration, poverty, and homelessness (Table 16-3).[45]

Most hypothermic deaths occur in the winter months; however, mildly cool environments and windy wet conditions are also frequently associated with hypothermia. In 2002, Alaska, New Mexico, North Dakota, and Montana had the greatest overall death rates from hypothermia. States with milder climates, such as North and South Carolina, and western states, such as Arizona, with high elevations and cold nighttime temperatures, also reported hypothermia-related deaths.[48]

Response to Cold

The normal physiologic response to cold is initiated by stimulation of cold-sensitive neurons in the skin, so that the onset of the body's response to cold occurs prior to cooling of central blood. Cold-sensitive neurons in the skin send afferent impulses to the hypothalamus, resulting in shivering and piloerection. Shivering is the main thermoregulatory response to cold in humans, except in neonates, where nonshivering thermogenesis prevails. Shivering is initiated in the posterior hypothalamus when impulses from cold-sensitive thermoreceptors are integrated in the anterior hypothalamus and communicated to the posterior hypothalamus, or when cold-sensitive neurons in the posterior hypothalamus are activated directly. Efferent stimuli from the posterior hypothalamus travel through the midbrain tegmentum, pons, and lateral medullary reticular formation to the motor pathways of the tectospinal and rubrospinal tracts, resulting in shivering.[25] A mechanism of stimulation of shivering that usually occurs later when core temperature drops is the local cooling of the spinal cord, which leads to shivering by increasing excitability of motor neurons.

Heat produced without muscle contraction is known as nonshivering thermogenesis.[36,128] Nonshivering thermogenesis is mediated by the sympathetic nervous system.[58] Catecholamines activate adenylate cyclase, increasing cAMP, resulting in mobilization of fat and glucose stores (Î²-adrenergic receptors).[191,252] Nonshivering thermogenesis is blocked by Î²-adrenergic receptor antagonism and increased by administration of norepinephrine. Brown adipose tissue is the most important site of nonshivering thermogenesis. In humans, brown fat is found primarily in neonates, although in cold-acclimatized people there may be small amounts found on autopsy.[36] Brown adipose tissue functions as a thermoregulatory effector organ, producing heat by the oxidation of fatty acids when the tissue is stimulated by

norepinephrine.[41]

TABLE 16-3. Factors Predisposing to Hypothermia

Advanced age
Decreased metabolic rate
Decreased temperature discrimination
Decreased ability to shiver
Reduced peripheral blood flow
Central nervous system depression
Ethanol
Hypothalamic dysfunction
Infection
Intracranial bleeding
Stroke
Xenobiotics

Homelessness
Unintentional
Hepatic failure
Immobilization
Central nervous system dysfunction
Illness
Spinal cord injury

Trauma

Nutritional
Hypoglycemia
Glycogen depletion
Starvation
Thiamine deficiency

Sepsis

Social
Failure to use indoor heating
Homelessness
Inadequate indoor heating
Poverty
Social isolation

Uremia

In addition to shivering and nonshivering thermogenesis, efferent sympathetic fibers from the hypothalamus stimulate peripheral vasoconstriction (Î±-adrenergic receptors). Piloerection and vasoconstriction result in decreased heat loss from the body. Intense vasoconstriction shunts blood away from the periphery to the core and antidiuretic hormone antagonism results in increased urine output and hemoconcentration.

Disease Processes and Hypothermia

Several disease processes commonly result in an inability to maintain a normal body temperature in a cool environment. Hypothermia may develop in association with sepsis,[180] hypothyroidism, hypoglycemia, uremia, hepatic failure, or poor nutrition.[240,243] Hypothalamic injury

may result in chronic poikilothermia.[189] Thiamine deficiency adversely affects the hypothalamus, perhaps because of inefficient glucose metabolism, and leads to hypothermia.[164] Spinal cord transections above the first thoracic segment interrupt hypothalamic-sympathetic outflow pathways, resulting in hypothermia.[243] The frail elderly are at greater risk of hypothermia because of decreased vasomotor responses and decreased capacity to shiver.[58,61] Mentally and physically compromised patients may be unable to make appropriate behavioral responses to hot or cold environments.

Evaluations to determine the presence of underlying diseases are often difficult in the hypothermic patient.[93,180] The mental status may be markedly altered by hypothermia but is not usually abnormal until the temperature falls below 90Â°F (32.2Â°C). If normal mental status is not regained when the temperature reaches 90Â°F (32.2Â°C) during rewarming, underlying CNS structural, toxic, or metabolic problems must be considered.[93,240] Failure of the patient to rewarm quickly suggests the presence of underlying disease. In one study, hypothermic patients without underlying disease are reported to rewarm at a rate of 1.0â€“3.7Â°F/h (0.6â€“2.1Â°C/h) (average, 2.1Â°F/h; 1.2Â°C/h), whereas patients with significant underlying disease (sepsis, gastrointestinal hemorrhage, diabetic ketoacidosis, pulmonary embolus, myocardial infarction) warmed at a rate of 0.25â€“1.8Â°F/h (0.1â€“1.0Â°C/h) (average, 1Â°F/h; 0.6Â°C/h).[300]

Alteration of Drug Metabolism in Hypothermia

Metabolism of drugs is altered in the setting of hypothermia. In hypothermic piglets, the volume of distribution and the clearance of fentanyl are decreased.[166] Similarly, in piglets given

gentamicin, the volume of distribution and clearance rate decreased in direct proportion to the decrease in cardiac output and glomerular filtration rate.[165] Hypothermic puppies given intravenous lidocaine showed slower rates of disappearance of the drug than when normothermic.[211] Humans and animals given propranolol showed a reduced volume of distribution and decreased total body clearance, resulting in higher than expected propranolol levels.[197,198,222] Decreased hepatic metabolism of propranolol during hypothermia has been shown in vitro.[198] Hypothermia prolongs neuromuscular blockade with *d*-tubocurarine,[117] and increases neuromuscular blockade with suxamethonium.[304] Phenobarbital metabolism and volume of distribution decreased with hypothermia in children.[143] The lethal dose of digoxin was doubled in hypothermic dogs.[21] Digoxin-like substances are present during hypothermia.[99,131]

Reasons for altered metabolism in hypothermia include delayed distribution of the drug and altered enzyme function with temperature and pH changes. Volume of distribution changes, in part, because of peripheral vasoconstriction. Cardiac output decreases, leading to decreased liver perfusion and decreased delivery of drug to hepatic microsomal enzymes.[117,146,147 and 148,231] Plasma volume decreases as free water moves intracellularly, causing hemoconcentration and further decreasing organ perfusion.[306] Biliary excretion of atropine, procaine, and sulfanilamide decreases in vitro.[146,147 and 148] The glomerular filtration rate decreases in hypothermia.[33] In vitro, the activity of metabolic pathways, including acetylation and hydrolysis, decrease with cooling.[146,147]

Clinical Findings

The clinical effects of hypothermia are related to the membrane-depressant effects of cold, which result in ionic and electrical conduction disturbances in the brain, heart, peripheral nerves, and

other major organs (Table 16-4).[133] Cold tissues are protected by decreases in tissue oxygen requirements. As body temperature decreases, metabolic activity declines at a rate of approximately 7% per 1.8Â°F (1Â°C).[306] This effect provides significant protection to vital organs despite the potentially deleterious effects of membrane suppression.

TABLE 16-4. Physiologic and Clinical Manifestations of Hypothermia

Cardiovascular
Normal, decreased, or increased cardiac output
Normal heart rate or tachycardia, then bradycardia
Vasoconstriction and central shunting of blood
ECG
Prolongation of intervals
Atrial fibrillation
Increased ventricular irritability
J-point elevation â€œOsborn wavesâ€•
Central nervous system
Mild: 90â€“95Â°F (32â€“35Â°C)
Normal mentation or slightly slowed
Moderate: 80â€“90Â°F (27â€“32Â°C)
Lethargic but verbally responsive
Severe: 68â€“80Â°F (20â€“27Â°C)
Unlikely to respond verbally, purposefully to noxious stimuli
Profound: <68Â°F (<20Â°C)
Unresponsive, may appear dead
Gastrointestinal tract

Decreased motility
Depressed hepatic metabolism

Hematologic
Hemoconcentration
Left shift of oxyhemoglobin dissociation curve

Kidneys
Cold-induced diuresis
Antidiuretic hormone antagonism

Lungs
Respiratory rate variable
Bronchorrhea

Metabolic
Metabolic acidosis
Increased glycogenolysis
Increased serum free fatty acids
Normal thyroid and adrenal function

Effects on the central nervous system are temperature-dependent and predictable. Mild hypothermia (90â€“95Â°F; 32.2â€“35Â°C) usually results in relatively benign clinical manifestations. Ataxia, slight clumsiness, slowed response to stimuli, and dysarthria are common.[93] As cooling continues, the mental status slowly deteriorates. In moderate hypothermia (80â€“90Â°F; 27â€“32.2Â°C), the patient is usually lethargic but still likely to respond verbally. In severe hypothermia (68â€“80Â°F; 20â€“26.6Â°C) the patient is unlikely to respond verbally, but will react purposefully to noxious stimuli.[93,124] In profound hypothermia (<68Â°F; <20Â°C), the patient is unresponsive to stimuli. Pupils may be fixed and dilated and the patient may appear dead.[124] However, standard criteria of brain death do not

apply to hypothermic patients. The hypothermia itself protects

against cerebral hypoxic damage.[133] Temperature drop inhibits the release of the excitatory neurotransmitter glutamate and attenuates the release of dopamine in brain ischemia animal models, suggesting a protective effect of hypothermia in brain injury.[40] Ventricular cerebrospinal fluid glutamate concentrations were lower in patients showing benefit from mild induced hypothermia after brain injury when compared to brain-injured patients kept normothermic.[194] However, a subsequent report of 392 patients failed to detect a benefit of induced hypothermia after acute brain injury.[5,54,123]

Figure 16-2. A characteristic electrocardiographic finding in the patient with profound hypothermia. The terminal phase of the QRS complex shows a typical elevation of the J-point Osborn wave (â†‘).

Under controlled circumstances patients have survived with body temperatures as low as 48.2Â°F (9Â°C).[96] Vigorous resuscitation is required for these patients. In particular, cardiac resuscitation should not be terminated in the field, where temperatures are

seldom taken. The adage that a patient cannot be considered dead until the patient is warm and dead is critical to providing appropriate management. This approach may lead to hours of cardiopulmonary resuscitation of hypothermic patients with ventricular fibrillation, ventricular tachycardia, or asystole, but may be ultimately successful in resuscitating patients initially presumed to be dead.[274]

The cardiac and hemodynamic effects of cold correlate closely with body temperature. As cooling begins there is a transient increase in cardiac output. Tachycardia develops secondary to shivering and sympathetic stimulation. At about 81Â°F (27.2Â°C) shivering ceases. Bradycardia develops with maintenance of a normal cardiac stroke volume.[38] This bradycardia is responsible for the decreased myocardial oxygen demand which may be protective in the setting of hypothermia.[38] In profound hypothermia, bradycardia may progress to asystole and death.

Unlike cerebral circulation, where autoregulation is preserved during cooling, coronary autoregulation is disturbed during hypothermia, and myocardial injury may ensue.[38] Attempts to maximize myocardial oxygenation through administration of oxygen and volume replacement to increase diastolic filling pressure are appropriate. Pharmacologic or electrical attempts to increase heart rate may dangerously increase myocardial oxygen demand.

The initial respiratory response to hypothermia is hyperventilation. As temperature continues to decrease, hypoventilation develops, which may progress to apnea and death. In animal models, this has been attributed to cold-induced failure of phrenic nerve conduction.[156]

The Electrocardiogram

The most common ECG abnormality in hypothermia is generalized,

progressive depression of myocardial conduction. Because myocardial oxygen demand remains unchanged in spite of cooling, and stroke volume is preserved, the number of beats per minute decreases as a means of decreasing myocardial oxygen requirements. PR, QRS, and QTc intervals are all prolonged, and increasingly profound hypothermia may lead to gradual progression to asystole.[74,288] Ventricular fibrillation occurs in an irritable myocardium most commonly at temperatures less than 86Â°F (30Â°C) resulting in a high O_2 consumption dysrhythmia. Atrial fibrillation is the most common dysrhythmia occurring in the presence of hypothermia.[94,232] Shivering may not be clinically evident, but a fine muscular tremor frequently produces a mechanical artifact in the baseline of the electrocardiogram.[80] A deflection occurring at the junction of the QRS and ST segment is invariably present in patients with temperatures <86Â°F (<30Â°C) (Fig. 16-2). First described in a single patient in 1938, the J-point deflection is commonly known as the *Osborn wave*.[81,235,284] The J-point deflection, thought to be a â€œcurrent of injuryâ€• associated with CO_2 retention under hypothermic conditions, was believed to be a poor prognostic sign.[235] Subsequent study has refuted its prognostic significance, as the J-point deflection is invariably found in the hypothermic patient when multiple electrocardiographic leads are obtained.[79,81,286,293] The size of the J-point deflection increases as body temperature decreases.[232,293] Atrial dysrhythmias that occur in the absence of underlying heart disease invariably disappear solely with rewarming.

Management

After blood specimens have been drawn, the hypothermic patient should be given 0.5â€“1.0 g dextrose/kg of body weight as $D_{50}W$ (50% dextrose in water) and 100 mg of thiamine IV. If hypoglycemia is the cause of the hypothermia, the response to dextrose may be dramatic, heralded by the onset of shivering and

rapid return to normal body temperature. Wernicke encephalopathy is uncommon, but may be associated with mild hypothermia; thermoregulation and normal ocular motion may return after the initiation of thiamine therapy.[164]

Hypothermia shifts the oxygen dissociation curve to the left (Chap. 22), resulting in decreased oxygen unloading to tissues; therefore, oxygen administration may be of benefit.[69] If clinically indicated for airway protection or inadequate ventilation or oxygenation, endotracheal intubation should be performed and can be done without complication.[64,173,208] However, there are case reports of ventricular fibrillation occurring during endotracheal intubation.[17,102,124,236,302] Every effort should be made to limit patient

activity and stimulation during the acute rewarming period, as activity may increase myocardial oxygen demand or alter myocardial temperature gradients, increasing the risk of iatrogenic ventricular fibrillation. Although pulmonary artery catheters and central venous lines have been inserted without complications, they should be avoided unless absolutely essential, so as not to precipitate ventricular dysrhythmias.[121,174,285] If a central venous catheter is considered necessary, it should not be allowed to touch the endocardium.[287] Patients who develop ventricular fibrillation are difficult to manage. In these instances, cardiopulmonary resuscitation (CPR) should be initiated, and the patient intubated and ventilated to maintain a pH of 7.40, uncorrected for temperature. Active internal rewarming should be instituted because standard therapy for ventricular fibrillation is often unsuccessful until rewarming is achieved. Patients should be supported, then defibrillated; if unsuccessful, defibrillation should not be attempted again until the patient has been warmed several degrees centigrade. Defibrillation may not be successful until the temperature exceeds 86Â°F (30Â°C); however, defibrillation can be successfully accomplished in animals and patients with

temperatures of less than 86Â°F (30Â°C).[7,17,66,215] The pneumatically powered â€œthumperâ€• and cardiopulmonary bypass devices are used successfully during prolonged hypothermic cardiopulmonary arrests.[17,57,177,275,285] Transesophageal echocardiographic examination of 7 hypothermic patients demonstrated that the thoracic pump mechanism is important for forward blood flow during CPR. The thoracic pump theory states that forward blood flow is caused by blood forced out of the heart and thoracic aorta by a general increase in intrathoracic pressure. Doppler studies demonstrate forward blood flow across the open mitral valve during external chest compression.[192]

Arterial Blood-Gas Physiochemistry

Assessment of the adequacy of ventilation and oxygenation in the hypothermic patient often poses a dilemma to clinicians, as chemical effects of cold on arterial pH and blood gases lead to confusion in the interpretation of arterial blood-gas values. Cold inhibits the dissociation of water molecules, causing pH to increase as cooling occurs. In vitro, the pH change of blood as it is cooled increases parallel to the pH change of neutral water. The partial pressures of CO_2 and O_2 decrease as cooling occurs, even as the blood content of those gases remains unchanged. Blood in a syringe taken from a patient whose body temperature is 98.6Â°F (37Â°C) yields a pH of 7.40 and a PCO_2 of 40 mm Hg in the blood-gas machine at 98.6Â°F (37Â°C), but yields a pH of 7.72 and a PCO_2 of 14 mm Hg if the blood is cooled to 61Â°F (16Â°C) and the values are measured at that temperature. Specially calibrated laboratory equipment, not routinely available, is required to measure blood-gas values directly at other than normal body temperature. A patient whose body temperature is 61Â°F (16Â°C) and whose actual in vivo blood-gas values are pH 7.72 and PCO_2 14 mm Hg will have values of pH 7.40 and PCO_2 40 mm Hg when the blood is warmed to 98.6Â°F (37Â°C) and measured in the

standard laboratory blood-gas machine. Because the machine measures pH and blood-gas pressures only in blood warmed to 98.6Â°F (37Â°C) (the uncorrected values), the actual in vivo values in hypothermic patients can be approximated using mathematically derived corrected values. Because the pH of neutrality has also increased, it is unclear what clinical meanings these corrected values have. The uncorrected values indicate what the pH and PCO_2 would be if the patient were normothermic. At first glance, the clinician might be content to learn that a hypothermic patient at 61Â°F (16Â°C) has a corrected pH of 7.47 and PCO_2 of 40 mm Hg. However, the uncorrected values of pH 7.18 and PCO_2 111 mm Hg indicate that the patient has a significant respiratory acidosis. Attempts to maintain a corrected pH of 7.40 may lead to hypoventilation and risk alveolar collapse and impairment of oxygenation. The preponderance of evidence in the anesthesia and cardiovascular surgery literature suggests that maintenance of ventilation is associated with a decreased incidence of myocardial injury and a decreased incidence of ventricular fibrillation.[69] pH and PCO_2 blood-gas values should be left uncorrected after the blood sample is warmed in the blood-gas machine and interpreted in the same way as in the normothermic patient.[69] In a study of hemodynamically stable hypothermic pigs, intraosseous blood-gas values of PCO_2 and pH correlated well with mixed venous blood samples.

Hypotension

When hypotension occurs in hypothermia, it is usually a result of the presence of bradycardia and the commonly associated volume depletion. Fluid depletion in hypothermia occurs as a result of a variety of mechanisms, including central shunting of blood by vasoconstriction and cold-induced diuresis. Cold diuresis occurs when increases in central blood volume result in inhibition of antidiuretic hormone. Impairment of renal enzyme activity and decreased renal tubular reabsorption contribute to the large

quantities of dilute urine known as cold diuresis.[118,122,174,306] Normal saline should be given to expand intravascular volume. Urine output is an important indicator of organ perfusion and the adequacy of intravascular volume in the hypothermic patient, although the initial cold diuresis may lead to underestimation of fluid needs.[306]

Pharmacologic Interventions

The best means to effect resuscitation of the hypothermic victim in ventricular fibrillation is controversial. The most recent recommendations for the treatment of cardiac arrest when the body core temperature is <86Â°F (<30Â°C) does not include the administration of a vasopressor drug or antidysrhythmic.[8] There is no data to support this recommendation. There is data, however, that suggests the possibility of improved chance of resuscitation with the use of antidysrhythmics.

Epinephrine and Vasopressin

The administration of vasopressin to pigs in hypothermic cardiac arrest increased coronary perfusion pressure and improved defibrillation success.[266] However, because of defibrillation, there was no difference in the 1-hour return in spontaneous circulation.[266] When using warmed thoracic lavage, vasopressin increased coronary perfusion pressure and increased the 1-hour survival.[265] Compared with the administration of saline that resulted in zero episodes of successful defibrillation, 8 of 8 vasopressin-treated pigs had restoration of spontaneous circulation after electrical defibrillation and improved short-term survival. The whole-body temperature was not increased, but the authors postulated there may be myocardial warming.[265] In another study in which epinephrine was given to one group of pigs and vasopressin to another, increased coronary perfusion pressure and return of spontaneous circulation (ROSC) resulted in both

groups.[169] In contrast, body temperature significantly increased during CPR with thoracic lavage, and epinephrine increased coronary perfusion pressure, but no improvement in ROSC occurred.[167] The length of time of cardiac arrest, the doses of drug, and the efforts

to rewarm differed in these studies. In one 19-year-old patient with prolonged hypothermic cardiopulmonary arrest who had received epinephrine 2 mg with no improvement, the administration of vasopressin was followed by immediate restoration of spontaneous circulation.[280] Interactions with epinephrine, vasopressin, and ischemia during CPR are complex and incompletely understood.[170] In normothermic patients with asystolic cardiac arrest, vasopressin followed by epinephrine was more effective in restoring spontaneous cardiac activity than epinephrine alone.[299]

Amiodarone

Amiodarone is recommended in the current for ventricular fibrillation in normothermia. In one study comparing the use of amiodarone, bretylium, and placebo in a hypothermic dog model, amiodarone showed no statistical improvement in causing ROSC. There was no significant difference between the groups; only 1 of 10 amiodarone-treated dogs demonstrated ROSC, versus 3 of 10 in the placebo group and 4 of 10 in the bretylium-treated dogs.[279]

Bretylium

Bretylium tosylate is a benzyl quaternary ammonium compound with a biphasic action, initially causing release of norepinephrine and then blocking its release. This may cause transient hypertension, but hypotension is the most common result.[215,234] Hypothermic dogs given bretylium had significantly lower mean arterial pressures and systemic and pulmonary vascular resistance

as compared to controls.[234] The mechanism of the antidysrhythmic effect of bretylium in normothermia may be related to its ability to increase the myocardial refractory period.[234]

Bretylium may be of benefit in the treatment of ventricular fibrillation in the hypothermic patient. The antidysrhythmic effect of bretylium is poorly understood. It prolongs the cardiac action potential and reduces heterogeneity of repolarization times.[248] The net effect seems to be stabilization of the cardiac rhythm. Bretylium is found to increase the fibrillation threshold in hypothermic cats given bretylium 50 mg/kg,[223] and in hypothermic dogs given bretylium 15 mg/kg,[39] whereas bretylium 7.5 mg/kg was found to increase the threshold prior to cooling.[234] In a canine study,[215] cooling occurred and either a 0.9% NaCl solution placebo or bretylium 40 mg/kg was administered prior to an attempt to induce ventricular fibrillation. Six of 11 dogs given placebo developed ventricular fibrillation, whereas only 1 of the 11 dogs pretreated with bretylium developed ventricular fibrillation following attempted induction. In this study, 3 dogs receiving pretreatment with bretylium fibrillated during the infusion, prior to maneuvers. Of the 6 dogs given placebo that developed ventricular fibrillation, all were successfully resuscitated, although 4 required bretylium to do so. This study did not attain statistical significance, and bretylium infusion both resulted in ventricular fibrillation and was effective in chemical defibrillation of ventricular fibrillation.[215] A single case of successful chemical defibrillation with bretylium is reported in an environmentally exposed patient with a core temperature of 85.1Â°F (29.5Â°C).[65] Given the difficulty of treating ventricular fibrillation once it occurs during hypothermia, the preponderance of evidence suggests a role for the use of bretylium. However, bretylium has been removed from the American Heart Association guidelines for advanced cardiac life support and may no longer be available in some institiutions.[8]

Dopamine

Dopamine increases cardiac output, mean arterial pressure, heart rate, and stroke volume in dogs cooled to 77Â°F (25Â°C), and stabilizes pulmonary arterial wedge pressure.[221] In a canine hypothermia model, dopamine infusions provided some protection from ventricular fibrillation. Dopamine lowered the temperature at which ventricular fibrillation occurred and reduced the incidence of ventricular fibrillation, as did infusion of norepinephrine.[11] The added benefit of dopamine in hypothermia may be a result of its renal and splanchnic vasodilating properties, increasing renal perfusion and supporting urine output.[106] Dopamine increases myocardial oxygen demand and decreases peripheral perfusion, potentially detrimental effects in the hypothermic patient.[11] Nevertheless, after the administration of intravenous fluids, dopamine infusion during hypothermia is indicated in the patient requiring blood pressure support.

Rewarming

Three types of rewarming modalities are used in the management of hypothermic patients.[60,181] *Passive external rewarming* involves covering the patient with blankets and protecting the patient from further heat loss. Passive external rewarming uses the patient's own endogenous heat production for rewarming and is most successful in healthy patients with mild to moderate hypothermia whose capacity for endogenous heat production is intact.[122] Passive external rewarming is reported to be successful in hypothermic patients with temperatures as low as 69Â°F (20.6Â°C).[283,293,301] Advocates of passive external rewarming argue that it allows vasoconstriction to persist and it decreases the afterdrop and shock from vasodilation associated with active skin rewarming.[122,208,283]

Active external rewarming involves the external application of heat to the patient. There is disagreement about the possible

detrimental effects of active external rewarming. For example, skin warming may lead to a physiologically detrimental suppression of shivering.[122] Acute vasodilation of peripheral vessels could cause hypotension and an increased peripheral demand on the persistently cold myocardium. The return of cold blood from the extremities to the heart is suggested to exacerbate intramyocardial temperature gradients, which could cause ventricular irritability during hypothermia.[186] However, in pigs, blood returning to the heart was found to be warm before warming of central organs occurred.[107]

Afterdrop is the continuing decrease in temperature once rewarming begins. Some authors (including the American Heart Association Advanced Cardiac Life Support [ACLS] guidelines)[8] recommend that rewarming of the extremities should be delayed by application of heat to the trunk only, rather than to the trunk and extremities, in an attempt to avoid the complications of afterdrop and intramyocardial temperature gradients.[171] However, there is no scientific evidence to suggest that this drop in temperature is more dangerous than the very temperature that had existed originally.[185] In addition, there is no evidence of pooling of blood in the periphery, nor of increased flow during surface rewarming.[185,260] Flow studies in the hand, arm, calf, and foot demonstrate that afterdrop has already occurred and is completed before any increase in blood flow occurs in the limbs.[185,297] Initial experiments demonstrating afterdrop were done in inanimate objects and reflected continued cooling of central structures before heat from external sources reached the core.[107,185,297]

Treatment including complete submersion is available in some institutions. Eighteen patients with temperatures of 78.8â€“91.4Â°F (26â€“33Â°C) were successfully warmed in a Hubbard tank, although one fatality not associated with rewarming occurred.[309] Submersion must be used with caution, however, because of the inherent

difficulties of controlling agitated patients and monitoring and resuscitating patients in water.

Mortality rates for active external rewarming are frequently reported to be higher than for passive external rewarming,[243] but case selection is not controlled in these series. It is possible that sicker patients who fail to rewarm passively are then actively rewarmed and have a higher mortality rate caused by their underlying disease, rather than by the method of therapy selected. The published series and case reports do not allow for an analysis of this hypothesis. Selection of either passive or active external rewarming in treatment of mild to moderate hypothermia does not appear to influence the prognosis as much as the presence or absence of underlying disease.[136,208,300] In our experience, active external rewarming has not resulted in mortality, except in those patients with severe underlying disease.[293]

Active internal rewarming involves attempts to increase central core temperature directly, by warming the heart prior to the extremities or periphery. The administration of heated, humidified oxygen delivered by face mask is considered part of active internal rewarming. Additional minimally invasive modalities of active internal rewarming include endotracheal intubation with warmed, humidified oxygen,[125] and gastric lavage with warmed fluids. Transcutaneous pacing was successful in improving hemodynamic parameters and speeding rewarming in an animal model.[76] More invasive modalities, those procedures that are fundamental to the rewarming controversy, include peritoneal lavage with warmed dialysate,[141,226] and the rerouting of blood through external blood rewarming equipment via cardiopulmonary or femoral-femoral bypass and hemodialysis.[43,130,217] Heparin-coated bypass systems are available, which avoids systemic anticoagulation, thus decreasing the risk of bleeding complications. It is suggested that extracorporeal venovenous rewarming and continuous arteriovenous rewarming show improved rewarming rates when

compared to standard techniques such as saline lavage of the bladder, stomach, or peritoneal cavity.[100] Extracorporeal methods of active internal rewarming should be reserved for severely hypothermic patients (<80Â°F or <27Â°F) or those with unstable cardiac rhythms (ventricular fibrillation or tachycardia, or asystole) attributed to hypothermia.[7,68,119] The evidence for the benefit of extracorporeal methods in those patients with stable rhythms is not yet available. In patients with stable rhythms, studies are essential to resolve the debate over the merits of passive or active external rewarming versus active internal rewarming.

Unfortunately, current ACLS guidelines for the management of hypothermia make several recommendations that are not supported by the literature. The most glaring area of controversy is the recommendation of extracorporeal rewarming for stable patients based on a temperature of 86Â°F (30Â°C) or less. ACLS guidelines assert that passive rewarming is ineffective in the stable patient with severe hypothermia, which is defined as a temperature below 86Â°F (30Â°C). However, many patients with temperatures below 86Â°F (30Â°C) have been successfully treated with passive external rewarming with, at most, the addition of warm, humidified oxygen.[293,301] Patient temperature correlates poorly with outcome.[7,66,173,285,288] Treatment recommendations should not be based solely on temperature. Stability of the vital signs and cardiac rhythm, and the underlying cause of hypothermia, are much more critical considerations in management. It is hard to imagine a patient with a stable cardiac rhythm and core temperature of 80â€“86Â°F (26.6â€“30Â°C) in whom extracorporeal rewarming with cardiopulmonary bypass is indicated.

Additionally, ACLS guidelines state that significant hyperkalemia may develop during rewarming, suggesting that this is a complication of rewarming. Hyperkalemia is not described as a consequence of rewarming.[64] In all of the evidence collected with

regard to hyperkalemia, this abnormality was present as a consequence of the hypothermia and not the rewarming.[124,192,262]

These are ideal subjects for intensive evidence-based investigations to resolve the science versus myth in hypothermia resuscitation.

Prognosis in Hypothermia

Except in cases of profound hypothermia,[124] the prognosis is most closely correlated with the presence or absence of underlying disease.[136,208,229,300,301] In patients with hypothermia alone, in the absence of underlying disease, mortality is 0â€“10%. In the presence of an underlying disease, mortality rises to 75â€“90%. Morbidity results from associated frostbite and trauma.

Prolonged cardiopulmonary arrest and absolute temperature are not predictive of poor outcome.[7,66,173,285,288] In severely hypothermic patients, profound hyperkalemia (K^+>10 mEq/L) is associated with unsuccessful resuscitation.[124,192,262]

Frostbite

Hypothermia may be accompanied by frostbite when patients are exposed to environmental temperatures that are less than 20Â°F (6.7Â°C).[209] Frostbite should be managed by rapid rewarming. The extremity involved may be placed in a large, soft basin of warm water (100â€“108Â°F; 38â€“43Â°C) for 30 minutes. The water temperature must be frequently adjusted, as the frozen extremity will have the effect of ice cubes, and with time, will cool the water in the basin. Parenteral analgesics may be necessary, as the rewarming process is often painful. Frostbitten areas should never be rubbed, as the tissue is particularly sensitive to trauma. Dextran, alcohol, vasodilators, and anticoagulants have not proven useful. Sympathectomy in this situation is also of unproven benefit and remains highly controversial.[157,172,200]

Prevention

Because many patients may not wear (and may not possess) adequate clothing, it is essential that they be assessed for social services support after the acute episode is resolved. In addition, many of these patients live in substandard, inadequately heated (often unheated) housing. Patients should be advised to wear comfortable, warm clothing to prevent future episodes of hypothermia. Adequate clothing is particularly important for patients traveling by automobile during inclement weather conditions. The importance of adequate nutrition should also be stressed.

Hyperthermia

Definition of Heatstroke

Heatstroke is defined by a rectal temperature greater than 106Â°F (41.1Â°C) in the setting of a neurologic disturbance manifested by psychosis, delirium, stupor, coma, and/or convulsions.[159] Temperature criteria cannot be absolute, as information regarding the patient's temperature is rarely available at the time of onset of heatstroke. In some instances the temperature may not be measured for several hours, during which time cooling may have been instituted or occurred spontaneously.[151,152] When appropriate environmental conditions prevail, the diagnosis of heatstroke should be made liberally. Although the absence of sweating was once thought to be an essential component of the definition of heatstroke,[55,227]

many patients with heatstroke have been noted to maintain the ability to sweat on presentation.[63,193,270,294]

Epidemiology of Heatstroke

Hundreds of people die annually of heatstroke in the United States, and 80% of the victims are older than age 50 years. Several studies show mortality rates from heatstroke to be 5.6â€“80%. Thousands of other victims survive with significant heat-related morbidity.[10,30,75,142,155,276] The high morbidity and mortality of heatstroke markedly contrast with those of profound hypothermia, in which the prognosis is related not to the temperature itself, but to the underlying etiology. The overall prognosis in heatstroke depends primarily on how long the temperature has been elevated prior to cooling, the maximum temperature reached, and the affected individual's premorbid health.

Heat-related deaths are preventable, and the public health preparedness of cities and healthcare workers is essential.[19,44] Mortality during heat waves is increased in urban areas where a heat wave has not occurred for several years.[53,78,142,264] Mortality is decreased when public health interventions improve preparedness. The city of Milwaukee experienced a heat wave in 1995 that resulted in numerous public health and preparedness responses; this may have led to the number of heat-related deaths and emergency medical service runs in the heat wave of 1999 being 49% lower than predicted.[298] After the Chicago heat wave of 1995, public policies targeting the elderly of Chicago may have contributed to a change in the demographics of those who succumbed during a subsequent heat wave in Chicago in 1999. The dead in 1999 were younger; more that 50% of those who died were younger than age 65 years. More than half of the dead were seen or spoken to on either the day of or the day before their death. Psychiatric illness was almost twice as prevalent in the younger victims, compared to those older than 65 years of age.[220]

Heat waves are meteorologic events characterized by air temperatures that are â‰¥90Â°F (â‰¥32.2Â°C) for 3 or more consecutive days.[47] During the summer of 2003, Europe experienced record high temperatures for many consecutive days.

The prolonged heat caused extreme increases in mortality across Europe. In France, there were 14,800 excess deaths caused by heat. This is equivalent to a total mortality increase of 60% between August 1 and August 20, 2003.[175,290] Italy reported 1094 excess deaths from June to August 2003, a 23% increase compared with the average annual number of deaths from 1995â€“2002.[44] Increased mortality was associated with risk factors previously reported, including old age, limited access to care, poor living conditions and social isolation.[267,291]

Socially isolated individuals or those with preexisting illness, as well as the physically compromised and frail elderly, are at greatest risk of death during heat waves. Confinement to bed was the strongest predictor of death in the Chicago heat wave of 1995, and living alone doubled the risk of death. There were fewer deaths among people with working air conditioners or who had access to an air-conditioned environment.[249,267] A working air conditioner was found to be the strongest protective factor against heat-related death 4 years later in the next deadliest heat wave in Chicago in a decade.[220] Although fans may seem to improve comfort, they do not prevent heat-related illness and may contribute to heat stress when temperatures and humidity exceed approximately 100Â°F (37.8Â°C)[149,154,155,220,267,305] In times of heat waves, preventive public health programs should encourage visiting nurses, housekeepers, and community service programs, such as Meals-on-Wheels, to increase the awareness of the danger of heat and identify those individuals most at risk.[267] A decreased risk of death was found among people with contacts from these agencies during the Chicago heat wave.[267] The media must alert the public and provide information on avoiding heat illness, as well as encourage individuals to help others to stay cool by assuring access to cooling measures.

The number of deaths from exposure-related illness has increased 3-fold in foreign transients attempting to enter the United States from Mexico. Because urban areas are more tightly patrolled,

individuals attempting to cross into the United States illegally have turned to the harsh deserts and mountain ranges of the southwestern United States, increasing prolonged exposure and resulting in death from heat, cold and dehydration. Although many more bodies remain undiscovered, 99 individuals' deaths were attributed to environmental causes in the year 2000.[84]

From 1995â€“2002, 233 children died from heatstroke when left unattended in cars, 75% of whom were either forgotten or left by caretakers who did not expect the temperature to rise dangerously within the automobile. In 25% of the incidents, children were trapped inadvertently while playing. Most of these deaths occurred during the summer months.[113]

Infants may suffer heatstroke under environmental conditions that would not be expected to place the child in danger. Well-meaning parents sometimes overinsulate children with clothing and blankets, inhibiting their cutaneous heat loss and placing them at risk.[16,138,139]

During 2002, the United States military reported 1816 heat-related injuries of active duty soldiers.[14] During Operation Iraqi Freedom, 6 soldiers died from heat-related causes. There were 30 other cases of heatstroke and many other heat-related casualties. During the period 1997â€“2002, 8084 soldiers were treated as outpatients for heat injuries.[14] The United States military actively promotes heat illness prevention and exhorts its personnel to not repeat history.[289] In comparison, in 1917, 425 British soldiers on active duty in the area on the Persian Gulf formerly known as Mesopotamia, presently known as Iraq, died of heatstroke during 1 month, and 524 died in 1 year.[303]

There were 104 heatstroke deaths among football players from 1960 to 2004. In the past 10 years, 24 football players have died of heatstroke, 19 of these in high school, 3 in college, and 2 professional. Three heatstroke deaths occurred in high school football players in 2004.[160,213]

High ambient temperature is associated with an increase in mortality from cocaine overdose. The mean daily number of deaths from cocaine overdose was 33% higher when the ambient temperature exceeded 88Â°F (31Â°C).[195]

Thermoregulation and Heat Stress

The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body-core temperature results in active dilation of cutaneous vessels and skin blood flow increases.[128,252] Because increased skin blood flow is attained primarily by an increase in heart rate and stroke volume, the capacity to increase cardiac output is critical to cooling. Compensatory shifting of blood flow from the splanchnic and renal vessels to the skin further increases skin blood flow.[135,252] Sweat-gland function is activated by parasympathetic stimulation, and the combination of vasodilation, increased skin blood flow, and increased sweating results in heat loss through convection and

evaporation. Dehydration after profuse sweating increases plasma osmolarity. Heat-sensitive neurons in the preoptic anterior hypothalamus are inhibited by locally increased osmolarity and by input from distal hepatoportal osmoreceptors. The inhibition of heat-sensitive neurons results in decreased heat dissipation response.[52,230]

Types of Heatstroke

Heatstroke is commonly divided into two types: exertional and nonexertional. Nonexertional, or classic, heatstroke describes heatstroke occurring in the absence of extreme exertion. Nonexertional heatstroke is most commonly described during heat waves, and the victims are predominantly those persons least able to tolerate heat: infants,[16] the aged,[59] those with psychiatric

disorders, and the chronically ill.

Exertional heatstroke occurs as a result of increased motor activity. It may occur in young, healthy individuals who are exercising, or in individuals whose increased motor activity results from other causes, such as seizures or agitation. Often a period of significant heat stress in exercising individuals precedes the development of heatstroke. Military recruits who develop heatstroke may sometimes present to the camp infirmary with vague complaints prior to collapse.[270] Published studies of heatstroke in miners, athletes, and military recruits describe several precipitating factors in heatstroke: fatigue associated with a recent deficit in sleep; poor physical conditioning; a recent febrile illness; recent heat-related symptoms such as thirst or weakness; relative volume depletion; failure to allow for acclimatization; and obesity. Symptoms of nausea, weakness, headache, diarrhea, or irritability often precede the development of heatstroke. Although rapid onset of symptoms and acute loss of consciousness are frequently reported in exertional heatstroke, the preceding period of heat stress and insidious symptoms may go unrecognized. Although exertional heatstroke is more likely to occur during intense exertion in a hot, humid environment, it may also occur with moderately intense exercise early in the morning, when environmental conditions do not usually represent a thermoregulatory stress.[13]

Differential Diagnosis of Hyperthermia

In addition to exposure and exertion, conditions that predispose to severe hyperthermia include primary hypothalamic lesions; intracranial hemorrhage; agitation; alcohol and sedative-hypnotic withdrawal; seizures; and the use of therapeutic and illicit drugs (Table 16-5).[104,109,110 and 111,168,196,281] Included in the differential diagnosis of severe hyperthermia are the serotonin syndrome, malignant hyperthermia, and neuroleptic malignant

syndrome, all of which may result in high temperature, altered mental status, and increased muscle tone.

Serotonin Syndrome

The serotonin syndrome results from excess stimulation of the serotonin receptor, primarily the 5-HT_{1A} subtype.[278] Drug interactions are most commonly the cause of the syndrome. Monoamine oxidase inhibitors used in conjunction with tricyclic antidepressants,[18] selective serotonin reuptake inhibitors,[88] L-tryptophan,[88,282] meperidine,[120] dextromethorphan,[247] amphetamines,[168] and sumatriptan are reported to lead to serotonergic hyperstimulation and severe symptoms.[105,278] The clinical condition resulting from excess serotonin includes alterations in consciousness, restlessness, increased muscle tone, tremor, gastrointestinal disturbances, and hyperthermia. Treatment of the syndrome focuses on control of hyperthermia by using aggressive cooling; muscle relaxation primarily by using benzodiazepines; or, in severe cases, endotracheal intubation and paralysis (Chap. 70).

TABLE 16-5. Differential Diagnosis of Hyperthermia

I. Increased heat production
- *Increased muscle activity*
  - Agitation
  - Catatonia
  - Ethanol withdrawal
  - Exercise
  - Infectious diseases
  - Malignant hyperthermia
  - Monoamine oxidase inhibitor drug interactions
  - Neuroleptic malignant syndrome

Parkinson disease
Sedative-hypnotic withdrawal
Seizures
Serotonin syndrome
Xenobiotics
- *Increased metabolic rate*
  Hyperthyroidism
  Pheochromocytoma
  Sympathomimetics

II. Impaired heat loss
- *Environmental*
  Heat
  Humidity
  Lack of acclimatization
- *Social disadvantage*
  Isolation
  Poverty
  Lack of air conditioning
  Confinement to bed
- *Medical illness*
  Cardiac insufficiency
  Diabetes
  Hypertension
  Pulmonary
  CNS dysfunction
- *Dehydration*
- *Fatigue*
- *Limited behavioral response*
  Extremes of age
  Psychiatric impairment
  Mental retardation
  Xenobiotics

Malignant Hyperthermia

Malignant hyperthermia is a very rare disorder that is associated with a congenital disturbance of calcium regulation in striated muscle. Malignant hyperthermia was first reported in 1960. Ten deaths occurred in a single family following general anesthesia.[73] Exposure to anesthetics, depolarizing muscle relaxants, or, rarely, severe exertion, precipitates uncontrolled calcium influx into the sarcoplasmic reticulum, leading to severe muscle rigidity and hyperthermia.[112,140] The clinical setting of severe muscle rigidity and hyperthermia following general anesthesia usually is adequate to define the syndrome (Chap. 66).

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome, a severe extrapyramidal syndrome associated with muscle rigidity, autonomic dysfunction, and altered mental status, was first

described in 1968.[70] This disorder develops during the administration of antipsychotic drugs or the withdrawal of dopaminergic agents. Increased muscle tone, because of dopaminergic blockade of the striatum, as well as central altered hypothalamic thermoregulation, leads to hyperthermia.[126] Temperature elevation and alteration of mental status occur after the onset of â€œlead pipeâ€• muscle rigidity.[24,116] Laboratory findings are not specific and include marked elevation of creatine phosphokinase (CPK) in some patients and leukocytosis with a left shift. Neuroleptic malignant syndrome must be distinguished from the much more common cases of heatstroke in psychiatric patients that are caused by heat intolerance resulting from the anticholinergic effects of antipsychotic drugs or antihistamines prescribed to control extrapyramidal symptoms (Chap. 67).[257,310]

Acute Phase Response and Heat Shock

Proteins

The response to heat stress is a coordinated interplay between the mediators of inflammation, including endothelial cells, leukocytes, inflammatory cytokines, and endotoxins. These are important mediators of the systemic immune response. However, in heatstroke, they are responsible for systemic inflammation, similar to the sepsis syndrome. Many proinflammatory cytokines are identified in heatstroke, including tumor necrosis factor; interleukins-2, 6, 8, 10, and 12; interferon-Î± and -Î³; and granulocyte colony-stimulating factors.[31] Hypothermia delays the release of interleukin-1B, interleukin-6, and tumor necrosis factor in vitro.[158]

Heat stress causes increased gene transcription of heat shock proteins, which render the organism more resistant to heat injury, protecting cells from injury and increasing cell survival. Heat shock protein 72 is protective against injury, from heat stress, and the extent of protection correlates with the level of heat shock protein.[188]

During exercise, splanchnic hypoperfusion may increase translocation of bacteria from the gut into the bloodstream, establishing the cascade of inflammation and injury which perpetuate tissue injury after normothermia is established.[85]

Pathophysiologic Characteristics of Heatstroke

Hypotension and tachycardia in heatstroke are caused by a number of factors. The patient with heatstroke may have a reduced plasma volume secondary to dehydration. There is peripheral pooling of blood associated with an increase in cutaneous blood flow from 0.5 L/min to 7â€“8 L/min.[135,252] In addition, patients may manifest primary myocardial insufficiency.[161] Clinically, patients exhibit either a hypo- or

hyperdynamic circulatory response. The observed circulatory response to heat stress is a function of the patient's cardiac reserve, volume status, and degree of myocardial heat injury. The hyperdynamic condition is characterized by increased cardiac index and decreased systemic vascular resistance.[228] These hemodynamic characteristics occur in patients who are able to maintain a significantly increased cardiac output in response to the circulatory demand of heat stress.

Volume-depleted patients, or those patients with primary myocardial insufficiency, may exhibit a hypodynamic response. These patients have a decreased cardiac index and increased systemic vascular resistance.[228,277] Whether pulmonary vascular resistance is affected is unclear. High central venous pressures have been found in some patients, with evidence of right-heart failure and right-heart dilation on autopsy.[193] This has led to the suggestion that pulmonary vascular resistance may be elevated.[228] In 22 (64%) of 34 patients with heatstroke, central venous pressures (CVPs) were greater than 3 cm H_2O. Twelve patients had a CVP â‰¤ 0, and 10 had a CVP that exceeded 10 cm H_2O. These authors cautioned against injudicious infusion of large quantities of intravenous fluids that can result in complications of congestive heart failure and fluid overload. In the study, only 3 patients required more than 2 L of 0.9% sodium chloride solution during cooling. Crystalloid infusion ranged from 500 to 2500 mL, and none of the patients developed problems associated with fluid overload.[268]

A study of compromised elderly patients with heatstroke, using pulmonary artery catheters, showed that pulmonary vascular resistance was low or normal. Pulmonary capillary wedge pressures were not elevated.[276] A study of 13 cases of heatstroke in pilgrims to Mecca, Saudia Arabia, monitored with pulmonary artery catheters, demonstrated a good correlation of CVP with pulmonary capillary wedge pressures.[2] Serial electrocardiograms in 51 of these pilgrims suffering from heatstroke showed normal

sinus rhythm in 25%, sinus tachycardia in 52%, atrial fibrillation in 16%, and sinus bradycardia in 6%. ST segment depression and other ST-T wave changes were reported. The QTc interval showed no abnormality.[3] ST changes suggestive of acute coronary syndrome may occur and normal coronary arteries are noted upon coronary catherization.[214] In some patients, echocardiography showed pericardial effusions and regional wall motion abnormalities, asymmetric septal hypertrophy, right ventricular dilation, and left ventricular dilation with impaired function.[3]

Autopsy studies of the heart demonstrate right-heart dilation, pericardial effusions, interstitial edema, degeneration and necrosis of myocardial fibers, and subendocardial hemorrhages.[152,193] Postmortem examination of the lungs revealed vascular congestion, pleural effusions, and parenchymal hemorrhages.[193,228]

Gastrointestinal hemorrhage, vomiting, and diarrhea occur frequently.[270] At autopsy, edema and hemorrhage of the bowel wall occur.[49] These changes may be partly a result of to regional ischemia of splanchnic blood vessels and resultant hypoperfusion and hypoxia. Increased bowel wall edema and bleeding predispose to the release of bacteria into the bloodstream from the gut, causing focal microvascular changes in the intestinal villi, leading to bowel wall anoxia and further injury.[86] Liver injury occurs commonly and is not clinically manifest until the second or third day following the temperature increase.[151,270] Centrilobular changes, such as widening of central veins and adjacent sinusoids and pooling of blood, and varying degrees of hepatocellular degeneration, are demonstrated on liver biopsy. Repeat biopsies demonstrated that these changes resolve as the patient recovers.[151] In other cases, only congestion and fatty infiltration are reported.[49]

Neuropsychiatric impairment is, by definition, present in all cases of heatstroke. Length of coma correlates significantly with

mortality.[15,270] Autopsy studies demonstrate a variety of structural and microscopic CNS injuries. Edema and venous congestion are evident. The number of cortical neurons is reduced, with concomitant glial proliferation. Cerebellar Purkinje cell deterioration is marked. The hypothalamus appears to be relatively spared, with limited edema of the neuronal nuclei. Hemorrhages occur throughout the brain.[49,193,270] Carotid artery vasoconstriction occurs in response to heating, in an in vitro model using the carotid arteries of rabbits as a possible mechanism of ischemia and injury, in heatstroke.[218] Heatstroke-induced cerebral ischemia is associated with increased glutamate release, activation of cerebral dopaminergic neurons causing dopamine overload, and gliosis. These changes are attenuated by induction of hypothermia in an animal model.[51]

Reports of MRI of brains of patients recovering from heatstroke describe radiographic findings, including hemorrhagic and ischemic abnormalities of the cerebrum and cerebellum, delayed cerebellar atrophy, central pontine myelinolysis, vascular infarcts, and medial thalamic lesions, which correspond anatomically to the paraventricular nucleus.[23,201,202] The paraventricular nucleus is involved with core temperature regulation via the hypothalamicâ€“pituitaryâ€“adrenal axis.[22] The clinical symptoms of dysphagia, quadriparesis, wasting extrapyramidal syndrome, and pancerebellar syndrome have corresponding MRI findings.[4] Persistent cerebellar dysfunction occurs, as does lower motor neuron damage, manifested by areflexia and muscle wasting.[71,176] Abnormal nerve conduction studies are documented.[145] Higher cortical functions may be spared in survivors, or may be reversible when they occur.[85,179,204] Permanent neurologic sequelae are correlated with the degree and duration of hyperthermia.

Acute renal failure was the major cause of death in heatstroke victims before the advent of hemodialysis.[263,294] In addition to the direct effects of heat, volume depletion, and hypotension,

myoglobinuria secondary to rhabdomyolysis results in further renal tubular injury. This is especially common in the agitated or exercising patient.[56,104,238] The mechanism by which myoglobin contributes to renal failure remains controversial. At autopsy the kidneys are enlarged, with numerous petechial hemorrhages.[193] Acute tubular necrosis is seen on biopsy. In exertional heatstroke with acute renal failure, renal hemodynamics are compromised because of increased vasoconstrictive hormones, such as catecholamines, renin, aldosterone, and endothelin-1, and decreased vasodilatory hormones, such as prostaglandin E_2.[182]

Bleeding is associated with significant morbidity and mortality in many cases of heatstroke. Coagulation disturbances seen in patients with heatstroke appear to be multifactorial. Elevation of the prothrombin time may occur within 30 minutes of temperature elevation and is attributed to direct heat injury of clotting factors.[18] Liver damage may significantly contribute to the coagulation disturbances, although this does not manifest as rapidly.[18,219,241] Two patients with severe liver failure secondary to heatstroke received liver transplantation; both died after chronic rejection.[254] A third patient with extensive liver cell necrosis as a consequence of heatstroke was referred for consideration of liver transplantation but recovered completely with supportive therapy.[101] Evidence of diffuse capillary basement-membrane injury has been demonstrated by electron microscopy and is thought to precipitate consumptive coagulopathy in severe cases of heatstroke.[49,273] Thrombocytopenia is very common and occurs within 30 minutes of onset of heatstroke, frequently in the absence of other evidence of disseminated intravascular coagulation. Direct thermal injury leading to decreased platelet survival and megakaryocyte damage may play a role (Table 16-6).[193,219]

Clinical Findings in Heatstroke

Clinical evaluation of the hyperthermic patient begins with careful assessment of the vital signs. Vital sign abnormalities commonly include heart rates greater than 130 beats/min, hypotension, and an elevation of the respiratory rate, often above 30 breaths/min. Most importantly, temperature is elevated. After cooling, there is often a secondary rise in temperature that suggests persistent disturbances of thermoregulation.[193]

Neurologic examination reveals a confused, delirious, comatose, or seizing patient. Pupils may be normal, fixed and dilated, or pinpoint. Decerebrate or decorticate posturing may be evident. Muscle tone is increased, normal, or flaccid. The skin may be hot and dry or diaphoretic. Nasal and oropharyngeal bleeding may be present as a consequence of the acute coagulopathy. Examination of the lungs is often nonspecific, although heatstroke victims are at risk of pulmonary edema as a primary event associated with capillary endothelial damage or following overly aggressive fluid resuscitation. Cardiac auscultation may reveal a flow murmur secondary

to high cardiac output or a right ventricular gallop. Neck vein distension indicates increased central venous pressure. Jaundice suggests hepatic injury and occurs on the second or third day following the onset of heatstroke.[50] Nasogastric aspiration or rectal examination may demonstrate gross bleeding. A petechial rash develops, probably secondary to capillary endothelial damage.

TABLE 16-6. Physiologic and Clinical Manifestations of Heatstroke

Cardiovascular
Hypodynamic states in elderly

- Hyperdynamic states in young healthy individuals
- Electrocardiogram
  - Nonspecific
  - Widening of QRS because of an underlying abnormality (cocaine toxicity, hyperkalemia associated with rhabdomyolysis)

Central nervous system

- Altered mental status
  - Irritability, confusion, ataxia, seizures, coma
  - Weakness, dizziness, headache
  - Plantar extension, pupillary abnormalities, decorticate posturing
- EEG
  - Normal or diffuse slowing
- CSF
  - Normal or increased protein
  - Lymphocytosis

Gastrointestinal

- Vomiting, diarrhea, hematemesis

Hematologic

- Bleeding diathesis
  - Prolonged PT and PTT
  - Disseminated intravascular coagulation
  - Thrombocytopenia
  - Petechiae
  - Purpura
- Leukocytosis

Hepatic

- Hepatic insufficiency at 12â€“36 h
- Elevated AST, ALT, LDH

Metabolic

- Metabolic acidosis and respiratory alkalosis
- Electrolyte disturbance
  - Hypernatremia

- Hypokalemia
- Hypocalcemia
- Hypophosphatemia

Muscle
- Rhabdomyolysis
- Elevated CPK

Renal
- Decreased renal perfusion
- Myoglobinuria
- Proteinuria
- Oliguria
- Acute tubular necrosis
- Interstitial necrosis

Laboratory Findings of Heatstroke

Lactic acid dehydrogenase (LDH) rises as a consequence of diffuse tissue injury. Early rises in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which peak at 48 hours, are indicators of the liver damage that occurs during heatstroke.[151] Muscle enzymes were elevated in all patients in a study of exertional heatstroke,[270] and in 86% of patients in one study of nonexertional heatstroke.[108] Nonspecific ST- and T-wave changes on ECG are common. Myocardial enzyme elevation occurs and correlates with ECG changes.[152] Results of lumbar puncture are nonspecific, are often normal, or may demonstrate elevated cerebrospinal fluid (CSF) protein and lymphocytosis.[270]

Other laboratory parameters are affected by heatstroke. Dehydration leads to hemoconcentration in patients exposed to elevated temperatures for a period of time. Hypokalemia is common, with potassium deficits as great as 500 mEq occurring during the early period of heat exposure. Arterial blood-gas analysis may show a respiratory alkalosis secondary to direct

stimulation of the respiratory center by heat, or a metabolic acidosis secondary to lactic acid production.[63,277] Metabolic acidosis is the most frequent acidâ€“base disturbance, either alone or part of a mixed picture. The prevalence of metabolic acidosis correlates with the degree of hyperthermia; 95% of patients demonstrated metabolic acidosis when the body temperature exceeded 107.6Â°F (42Â°C).[30]

Hypophosphatemia is common and is attributed to respiratory alkalosis, which causes intracellular shifts of phosphate. However, 8 of 10 heatstroke patients developed hypophosphatemia and none were alkalemic.[29] The hypophosphatemia in these cases was associated with increased phosphaturia and decreased tubular reabsorption of phosphorus, a finding which reversed after cooling.[162] Renal tubular damage may also lead to phosphate depletion.[114] Phosphate and potassium are elevated when significant muscle injury has occurred. Calcium is normal or low, the latter secondary to binding to damaged muscle tissue. Later, hypercalcemia occurs, possibly as a result of release of this bound calcium.[97,184]

Significant alterations occur in lymphocyte subsets in heatstroke victims. One study reported an increased ratio of T-suppressor to T-cytotoxic cells, as well as increased natural killer cells. There was a significant decrease in the percentages of T and B cells and T-helper cells. These changes correlated with the degree of hyperthermia.[27] Catecholamines are increased in heatstroke,[1] and may affect the distribution of the lymphocyte subsets.[27] It is possible that the increased susceptibility to infection described in heatstroke and the alterations in lymphocyte populations are related.[27]

Effects of Drugs in Heatstroke

Drugs predispose the individual to heatstroke by two primary mechanisms: increased production of heat as a result of drug

action and interference with the body's ability to dissipate heat because of pharmacologic effects on thermoregulatory centers (see Table 16-5). Drugâ€“drug interactions may cause life-threatening increases in temperature, such as the combination of monoamine oxidase inhibitors with meperidine or dextromethorphan resulting in the serotonin syndrome. The uncoupling of oxidative phosphorylation by salicylate, pentachlorophenol, or dinitrophenol leads to the release of metabolic energy as heat, rather than trapping that energy in the form of high-energy phosphate bonds in ATP. Increased heat production occurs as a result of the stimulation of hepatic metabolism by sympathomimetic drugs and, of course, by the increased physical activity often associated with sympathomimetic drug use.

During heat stress, vasodilation leads to increased cutaneous blood flow, resulting in an increased cardiac output. Parasympathetic stimulation results in increased sweating. Drugs that impair these physiologic mechanisms for heat dissipation predispose the individual to heatstroke. Drugs with anticholinergic effects, such as antihistamines, cyclic antidepressants, and antipsychotics interfere with sweating. Sympathomimetic drugs stimulate Î±-adrenergic receptors, impairing vasodilation. Antihypertensives and antianginal drugs (most notably calcium channel blockers and Î²-adrenergic antagonists) with negative inotropic and chronotropic effects impair the ability of the heart to meet the output requirements of increased skin blood flow. Diuretic induced volume depletion also limits cardiac output. Antipsychotics cause hypothalamic depression, altering the normal CNS response to heat stress. Finally, drugs such as ethanol, opioids, and sedative-hypnotics impair normal behavioral responses, and heat-related discomfort may go unnoticed.[292]

Heatstroke and Subsequent Heat

Intolerance

Whether heatstroke victims are subsequently unable to adapt to exercise in a hot environment remains unclear. Is the heatstroke victim genetically predisposed to heat intolerance, or does heatstroke occur as a result of environmental and host factors? Several studies suggest that heatstroke leads to persistent heat intolerance. These studies often use a single heat intolerance test.[83,269,271,272] A study of 10 previous heatstroke victims showed no difference in acclimatization responses, thermoregulation, whole-body sodium and potassium balance, sweat-gland function, and blood values when compared with controls.[13] The rate of recovery from exertional heatstroke probably differs among individuals. In this study, 1 of 10 patients was found to have recurrent heat intolerance 12 months after the study.[13] Resolution of heat intolerance was delayed for 5 months in an individual who had experienced heatstroke twice.[150]

Treatment of Heatstroke

Management must focus on the early recognition of hyperthermia. Body temperatures > 106Â°F (>41.1Â°C) place the patient at great risk for end-organ injury. Rapid cooling is the first priority, and is associated with improved outcomes. Cooling that is delayed allowing body temperatures to remain above 102.2Â°F (38.9Â°C) for more than 30 minutes is associated with a high morbidity and mortality. In one report of the Chicago heat wave of 1995, only 1 patient of 58 victims was cooled within 30 minutes, resulting in an in-hospital mortality of 21% and an additional 28% mortality within 1 year.[72] Cooling by covering in ice water was twice as rapid in lowering the core temperature as was cooling by using evaporative spray.[12] Ice water immersion results in faster cooling when compared with all of the evaporative cooling methods.[62,91,98] A recent report of endovascular cooling using a heat exchange balloon catheter demonstrated dangerously lengthy

cooling times and inadequate cooling measures.[203]

Successful treatment requires adequate preparation. Equipment needed for rapid cooling should always be readily available in the emergency department, and includes fans, ice, and tubs for submersion. En route to the hospital, the patient's clothes should be removed and the patient should be covered with ice and water-soaked sheets. Respiration and cardiovascular status should be stabilized and monitored. Oxygen should be administered. The cause of the heatstroke should be determined and appropriate measures initiated immediately. Pharmacologic agents, such as antihistamines, butyrophenones, and phenothiazines, and physical restraints that interfere with heat dissipation, such as camisoles and strait jackets, should not be used.[111] Light hand and foot restraints should be used to protect the patient from self harm. If light restraints are used, the patient should be monitored continuously. The patient who is hyperthermic in the setting of ethanol or sedative-hypnotic withdrawal should be treated with a benzodiazepine.[110] The patient should never be confined to a small, unventilated seclusion room. Adequate cooling, hydration, sedation, and electrolytes and substrate repletion should be ensured.[108]

In the emergency department, appropriate laboratory studies should be performed and an IV line inserted. Administration of 0.5â€“1.0 g/kg dextrose as $D_{50}W$ and 100 mg of thiamine should be considered. A rectal probe should be placed for continuous temperature monitoring. The patient should be immersed in an ice bath with a fan blowing over the patient if possible. In addition to the ice bath, iced gastric lavage may be effective.

Agitation, seizures, and cardiac dysrhythmias must be managed while cooling is accomplished. Benzodiazepines are the treatment of choice for agitation and seizures. Heatstroke patients may have significant volume needs, depending on the amount of fluid lost

prior to the onset of heatstroke. Hypotension should be treated with fluids and cooling. Volume repletion should be monitored carefully by parameters such as blood pressure, pulse, central venous pressure, pulmonary wedge pressure, and urine output. As the temperature returns to normal, the hypotension may resolve if significant volume deficits are not present.[55,161,163] In patients with myoglobinuria, an attempt should be made to increase renal blood flow and urine output. The use of sodium bicarbonate and mannitol in the prevention of acute tubular necrosis in these cases is controversial.[82,97,251]

Phenothiazines should not be used in the treatment of heatstroke. Phenothiazines depress an already altered mental status, may produce hepatotoxicity in a compromised liver, lower the seizure threshold,[26] cause acute dystonic reactions, exacerbate hypotension, and interfere with thermoregulation and cooling by affecting the hypothalamus. However, although phenothiazines may theoretically reduce shivering and the possibility of rebound hyperthermia, their onset of action is slow.[227] When shivering occurs during cooling, we recommend the judicious use of a benzodiazepine. In addition, benzodiazepines treat ethanol and sedative-hypnotic withdrawal and cocaine intoxication, common causes of hyperthermia.

There is no role for antipyretic agents in the management of heatstroke. Aspirin and acetaminophen lower temperature by reducing the hypothalamic set point, which is only altered in a patient febrile from inflammation or endogenous pyrogens.[73,128] Heatstroke, however, occurs when cooling mechanisms are overwhelmed, and the hypothalamic thermoregulatory set point is not disturbed.[20]

Dantrolene sodium is the preferred drug in the treatment of malignant hyperthermia (see Antidotes in Depth: Dantrolene Sodium).[140,296] It acts directly on skeletal muscle and either inhibits the release of calcium or increases calcium uptake through

the sarcoplasmic reticulum.[34] Its usefulness has not been demonstrated in other conditions associated with hyperthermia, and there is no evidence to support its administration for other conditions.[9] In a prospective, randomized, double-blind, placebo-controlled study of 52 patients with heatstroke, IV dantrolene sodium at 2 mg/kg of body weight did not alter cooling time.[28] There was no significant difference in the mean number of hospital days necessitated by heatstroke victims who received dantrolene and cooling versus those who received cooling alone. Dantrolene may influence central dopaminergic metabolism in patients with neuroleptic malignant syndrome by affecting calcium-triggered neurotransmitter release in the central nervous system; however, further study is required.[225] Anecdotal reports of the efficacy of dopamine agonist agents such as bromocriptine and amantadine have appeared in descriptions of neuroleptic malignant syndrome.[199] No drug therapy should delay the institution of aggressive external cooling (Table 16-7).

Prevention of Heatstroke

In the young, active population, prophylaxis should be accomplished by gradual acclimatization. Active persons should select the coolest and least humid time of day to be outdoors. Exposure should be increased slowly, and work paced. Breaks should be frequent initially and later may be decreased in number and length. Overweight and underconditioned persons require even longer periods of acclimatization. Airy and cool clothing should be chosen. The practice of exercising in unventilated plastic clothing to increase weight loss leads to the loss of fluid, not fat, and defeats the body's cooling mechanisms, resulting in hyperthermia.

Athletes performing during hot, humid weather should increase their fluid intake, although excessive consumption of fluids

may cause hyponatremia.[6,212,261] All individuals who fatigue easily

or manifest nausea, vomiting, cramps, weakness, dizziness, or collapse should limit their activity and must be carefully observed.

TABLE 16-7. Management of Heatstroke

Preparation
- Ice and cooling fans available in emergency department
- Monitor weather reports
- Alert media

On Arrival
- Rapid cooling
  - Clear airway and administer oxygen
  - Cover with ice and water-soaked sheets
  - Stabilize respiratory and cardiovascular status
  - Cool as rapidly as possible
- Intravenous access
  - 0.9% NaCl or Ringer lactate based on CVP or pulmonary artery catheter
  - Administration of dextrose 0.5â€“1.0 g/kg, and thiamine 100 mg
  - Benzodiazepines for agitation, shivering, seizures
- Continous monitoring
  - Remove from ice bath at 101Â°F (38.3Â°C)
  - Watch for rebound hyperthermia
- Cautions
  - Antipsychotics may have serious adverse effects
  - Antipyretics do not work
  - Cooling blankets alone are inadequate

Anyone who takes illicit drugs, who takes medications, or who has a medical condition that may interfere with thermoregulation

should be monitored closely for signs of heat intolerance or hyperthermia.

Summary

The thermoregulatory processes responsible for the maintenance of normothermia are complex. Pharmacologic agents may disturb normal thermoregulation and result in the abnormal conditions of hyperthermia or hypothermia. These disturbances of homeostasis present significant clinical management challenges. In particular, recommendations for the treatment of hypothermia perpetuate themselves in the literature with little supportive scientific evidence. Although greater understanding is gained through research and thoughtful analysis, emphasis must be placed on prevention. Hypothermia and heatstroke are largely preventable conditions. During heat waves, many socioeconomically disadvantaged and elderly individuals are affected, and it is essential that cities be prepared and that the public be aware of the dangers of heat waves, to themselves and to others. Similarly, hypothermia is preventable by prudent preparation for harsh environmental conditions, and by policies that provide for shelter for those at greatest riskâ€”the poor, the homeless and those with underlying medical and psychiatric illnesses.

Chapter 17

Fluid, Electrolyte, and Acidâ€“Base Principles

Alan N. Charney

Robert S. Hoffman

A meaningful analysis of fluid, electrolyte, and acidâ€“base abnormalities must be based on the clinical characteristics of each patient. Although a rigorous appraisal of laboratory parameters often yields the correct differential diagnosis, essential information concerning extracellular fluid volume (ECFV), pathophysiology, and treatment may only be gained from the history and physical examination. Thus, the evaluation always begins with an overall assessment of the patient's status.

Initial Patient Assessment

History

The history should include clinical complaints associated with fluid

and electrolyte abnormalities. Common manifestations of xenobiotic exposure result in fluid losses through the respiratory system (hyperpnea and tachypnea), gastrointestinal tract (vomiting and diarrhea), skin (diaphoresis), and kidneys (polyuria). Patients with ECFV depletion may complain of dizziness, thirst, and occasionally polydipsia, and usually the patients can identify the source of fluid loss.

A history of exposures to nonprescription and prescription medications, alternative therapies and other xenobiotics may suggest the most likely electrolyte or acidâ€“base abnormality. In addition, premorbid conditions and the ambient temperature and humidity should always be considered.

Physical Examination

The vital signs are invariably affected by gross alterations in ECFV. Whereas hypotension and tachycardia may herald life-threatening ECFV depletion, an initial increase of the heart rate and a narrowing of the pulse pressure may be earlier findings. Abnormalities may be recognized through an ongoing dynamic evaluation, realizing that the measurement of a single set of supine vital signs offers useful information only when grossly abnormal. The addition of orthostatic pulse and blood pressure measurements provides a more meaningful determination of functional ECFV status (Chaps. 3 and 23).

The respiratory rate and pattern can give clues to the patient's metabolic status. Hyperventilation (manifested by tachypnea, hyperpnea, or both) may be caused by a primary respiratory stimulus (a respiratory alkalosis) or may be a response to the presence of metabolic acidosis. Although hypoventilation (bradypnea or hypopnea or both) is present in patients with metabolic alkalosis, it is rarely clinically significant except in the presence of chronic lung disease. More commonly, it is associated with a primary depression of consciousness and respiration, and

respiratory acidosis. Unless the clinical scenario (eg, nature of the overdose or poisoning, presence of renal or pulmonary disease, findings on physical examination or laboratory testing) is diagnostic, arterial blood gas analysis is required to determine the acidâ€“base disorder associated with a change in ventilation.

The skin should be evaluated for turgor, moisture, and the presence or absence of edema. The moisture of the mucous membranes can also provide valuable information. These are nonspecific parameters and may not correlate perfectly with the status of hydration. This dissociation is especially true with xenobiotic exposure, as many xenobiotics alter skin and mucous membrane moisture without necessarily altering ECFV status. For example, antihistamines and anticholinergics commonly dry mucous membranes and skin without producing ECFV depletion. Conversely, patients exposed to sympathomimetic agents (eg, cocaine) or cholinergic agents (eg, organic phosphorus insecticides) may have moist skin and mucous membranes even in the setting of significant fluid losses. These dissociative characteristics further reinforce the need to assess patients meticulously.

The physical findings associated with electrolyte abnormalities also are nonspecific. Hyponatremia, hypernatremia, hypercalcemia, and hypermagnesemia all may produce a depressed mental status. Neuromuscular excitability such as tremor and hyperreflexia may occur with hypocalcemia, hypomagnesemia, hyponatremia, and hyperkalemia. Multiple, concurrent electrolyte disorders can produce confusing clinical presentations, or patients may appear normal. Rarer diagnostic findings, such as Chvostek and Trousseau signs (primarily found in hypocalcemia), may be useful in assessing patients with potential xenobiotics exposures.

Rapid Diagnostic Tools

The electrocardiogram (ECG) is a useful tool for screening of some

common electrolyte abnormalities (Chap. 5). It is easy to perform, rapid, inexpensive, and routinely available. Unfortunately,

because poor sensitivity (0.43) and moderate specificity (0.86) were demonstrated when ECGs were used to diagnose hyperkalemia, in actuality, the test is of limited diagnostic value.[173] However, the ECG is valuable for the evaluation of changes in serum potassium and calcium concentrations ($[K^+]$ and $[Ca^{2+}]$) in a single patient.

In many patients, bedside assessment of urine specific gravity by dipstick analysis may provide valuable information about ECFV status. A high urine specific gravity (>1.015) signifies concentrated urine and is often associated with ECFV depletion. However, urine specific gravity may be similarly elevated in states of ECFV excess, such as congestive heart failure or third spacing. Furthermore, when renal impairment is the source of the volume loss, the specific gravity is usually â‰¤1.010 (known as isosthenuria). Patients with lithium-induced diabetes insipidus excrete dilute urine (specific gravity <1.010) despite ongoing water depletion, and patients with methylenedioxymethamphetamine (MDMA)-induced antidiuretic hormone secretion excrete concentrated urine (specific gravity >1.015) in the presence of a normal to high ECFV status.

The urine dipstick is particularly useful for rapidly determining the presence of ketones, which are often associated with specific toxicologic problems and common causes of metabolic acidosis (eg, diabetic ketoacidosis, salicylate poisoning, alcoholic ketoacidosis). The urine ferric chloride test rapidly detects exposure to salicylates with a high sensitivity and specificity (Chap. 35).

Laboratory Studies

A simultaneous determination of the venous serum electrolytes,

blood urea nitrogen (BUN), and glucose, and arterial or venous blood gases is adequate to determine the nature of the most common acidâ€“base, fluid, and electrolyte abnormalities. More complex clinical problems may require determinations of urine and serum osmolalities, urine electrolytes, serum ketones, serum lactate and other tests. A systematic approach to common problems is discussed in the following sections.

Acidâ€“Base Abnormalities

Definitions

The terminology of acidâ€“base disorders often leads to confusion and error. The following definitions provide the appropriate frame of reference for the remainder of the chapter.

The terms *acidosis* and *alkalosis* refer to processes that tend to change pH in a given direction. By definition a patient is said to have:

- A *metabolic acidosis* if the patient's arterial pH is <7.40 and serum bicarbonate concentration ($[HCO_3^-]$) is <24 mEq/L. Because acidemia stimulates ventilation (respiratory compensation), metabolic acidosis is usually accompanied by a PCO_2 <40 mm Hg.
- A *metabolic alkalosis* if the patient's arterial pH is >7.40 and serum $[HCO_3^-]$ is >24 mEq/L. Because alkalemia inhibits ventilation (respiratory compensation), metabolic alkalosis is usually accompanied by a PCO_2 >40 mm Hg.
- A *respiratory acidosis* if the patient's arterial pH is <7.40 and partial pressure of carbon dioxide (PCO_2) is >40 mm Hg. Because an elevated PCO_2 stimulates renal acid excretion and the generation of $[HCO_3^-]$ (renal compensation), respiratory acidosis is usually accompanied by a serum $[HCO_3^-]$ >24

mEq/L.

- A *respiratory alkalosis* if the patient's arterial pH is >7.40 and PCO_2 is <40 mm Hg. Because a decreased PCO_2 decreases renal net acid excretion and increases the excretion of [HCO_3^-] (renal compensation), respiratory alkalosis is usually accompanied by a serum [HCO_3^-] <24 mEq/L.

It is important to note that under most circumstances a venous pH permits an approximation of arterial pH (see Chap. 22 for a further discussion of the relationship between arterial and venous pH). Any combination of acidoses and alkaloses can be present in any one patient at any given time. The terms *acidemia* and *alkalemia* refer only to the resultant arterial pH of blood (acidemia referring to a pH <7.40 and alkalemia referring to a pH >7.40). These terms do not describe the processes that led to the alteration in pH. Thus, a patient with acidemia must have a primary metabolic and/or respiratory acidosis, but may have an alkalosis present at the same time. Clues to the presence of more than one acidâ€“base abnormality include the clinical presentation, an apparent excess or insufficient â€œcompensationâ€• for the primary acidâ€“base abnormality, a delta (Î”) anion gap-to-Î” [HCO_3^-] gap ratio that significantly deviates from 1, and/or an electrolyte abnormality that is uncharacteristic of the primary acidâ€“base disorder.

The following case discussion illustrates an organized approach to acidâ€“base disorders.

Patient 1 A 27-year-old man was found unconscious at home with a suicide note and some empty pill containers. A history of injection drug use was assumed by the paramedics because of the presence of track marks on his skin. The initial assessment was notable for a blood pressure of 140/90 mm Hg, a pulse of 120 beats/min, and a respiratory rate of 18 breaths/min. The patient was placed on high-flow oxygen and transported to the emergency

department (ED). En route to the ED, an IV line was inserted and blood samples were obtained for later analysis at the hospital.

On arrival at the ED the patient was intermittently agitated and stuporous with a blood pressure of 120/90 mm Hg, a pulse rate of 110 beats/min, labored respirations of 18 breaths/min, and a rectal temperature of 100.6Â°F (38.1Â°C). His skin was slightly diaphoretic and was notable for multiple track marks of various ages. There were no signs of head trauma. Pupils were 4 mm in size, equal and round, but sluggishly reactive to light. His neck was supple, without signs of meningeal irritation. His chest was clear to auscultation and percussion, and heart sounds were normal. His abdomen was soft, without organomegaly, and with normal bowel sounds. Rectal tone was normal, and stool was negative for occult blood. Neurologic assessment revealed good motor strength, intact corneal and oculocephalic reflexes, and brisk but symmetric deep tendon reflexes. Plantar flexion was present.

The blood specimens obtained by the paramedics were sent to the laboratory for electrolytes, glucose, BUN, complete blood cell count (CBC), and a serum acetaminophen concentration. Two serum tubes were placed aside for future studies. An arterial blood-gas analysis was obtained on room air, and an ECG showed sinus tachycardia with no evidence of PR, QRS, QTc abnormalities, or ectopy.

The arterial blood gas analysis showed a pH of 7.30, PCO_2 of 15 mm Hg, and PO_2 of 120 mm Hg. The calculated arterial bicarbonate concentration ($[HCO_3^-]$) was 12 mEq/L.

Determining the Primary Acidâ€“Base Abnormality

It is helpful to begin by determining whether the patient is acidemic or alkalemic. In patient 1, the arterial pH of 7.30

signifies acidemia, and the [HCO_3^-] of 12 mEq/L and PCO_2 of 15 mm Hg indicate the presence of metabolic acidosis with respiratory compensation. Of

note, concomitant reductions in the arterial [HCO_3^-] and PCO_2 also are observed in respiratory alkalosis. However, under those circumstances the patient would be alkalemic; that is, the arterial pH would be increased above 7.40.

Next it is important to determine whether the compensation of the primary acidâ€“base disorder is appropriate or excessive. It is generally assumed that overcompensation cannot occur.[118] That is, if the primary process is metabolic acidosis, respiratory compensation tends to raise the pH toward normal, but never to greater than 7.40. If the primary process is respiratory alkalosis, compensatory renal excretion of HCO_3^- tends to lower the pH toward normal, but not to less than 7.40. The same is true for primary metabolic alkalosis and primary respiratory acidosis. As a rule, compensation for a primary acidâ€“base disorder that is inadequate or excessive suggests the presence of a second primary acidâ€“base disorder.

The Winters equation,[8] based on patient data, predicts the degree of the respiratory compensation (the decrease in PCO_2) in metabolic acidosis. As Equation 17-1 illustrates:

$$P_{CO_2} = [1.5 \times HCO_3^-] + 8 \pm 2 \qquad \text{(Eq. 17–1)}$$

Thus, in this patient with an arterial [HCO_3^-] of 12 mEq/L, the predicted PCO_2 may be calculated as in Equation 17-2:

(1.5 Ã— 12) + 8 Â± 2

or

$$26 \pm 2 \text{ mm Hg} \qquad \text{(Eq. 17–2)}$$

Because the PCO_2 of patient 1 is substantially lower than is predicted by the Winters equation, it can be concluded that both a

primary metabolic acidosis and a primary respiratory alkalosis are present.

An alternative to the Winters equation is the observation by Narins and Emmett that in compensated metabolic acidosis, the arterial PCO_2 is usually the same as the last two digits of the arterial pH.[118] For example, a pH of 7.26 predicts a PCO_2 of 26 mm Hg. In this case, the PCO_2 of 15 mm Hg is much lower than would be predicted from the last two digits of the arterial pH of 7.30. As was deduced from the Winters equation, this method also suggests that a second primary process (respiratory alkalosis) is present in patient 1.

Guidelines are also available to predict the compensation for metabolic alkalosis,[69] respiratory acidosis, and respiratory alkalosis.[89] Patients with metabolic alkalosis compensate by hypoventilating and increasing their PCO_2 above 40 mm Hg. However, the concomitant development of hypoxemia limits this compensation so that respiratory compensation in metabolic alkalosis usually results in a PCO_2 no greater than 55 mm Hg. It is difficult to be more precise about the expected respiratory compensation for metabolic alkalosis although the compensation, as in metabolic acidosis, is nearly complete within hours of onset.

By contrast, the degree of compensation in primary respiratory disorders depends on the length of time the disorder has been present. In a matter of minutes, primary respiratory acidosis results in an increase in the serum $[HCO_3^-]$ of 0.1 times the increase (Î”) in the PCO_2. This is a result of the production and dissociation of H_2CO_3. Over a period days, respiratory acidosis causes the compensatory renal excretion of acid. This compensation increases the serum $[HCO_3^-]$ by 0.3 times the Î”PCO_2. Primary respiratory alkalosis acutely decreases the serum $[HCO_3^-]$ by 0.2 times the Î”PCO_2. If respiratory alkalosis persists for several days, renal compensation, by the urinary excretion of HCO_3^-, decreases the serum $[HCO_3^-]$ by 0.4 times the Î”PCO_2.

Further assessment of patient 1, including calculating the anion gap, requires an evaluation of the serum electrolytes. The laboratory studies of patient 1 were as follows: serum sodium concentration ($[Na^+]$) 133 mEq/L; potassium ($[K^+]$) 3.6 mEq/L; chloride ($[Cl^-]$) 99 mEq/L; bicarbonate ($[HCO_3^-]$) 12 mEq/L; BUN 12 mg/dL; creatinine (Cr) 0.9 mg/dL; and glucose (Glu) 120 mg/dL.

Calculating the Anion Gap

The concept of the anion gap is said to have arisen from the â€œGamblegramâ€• originally described in 1939;[53] however, its use was not popularized until the determination of serum electrolytes became routinely available. The law of electroneutrality states that the net positive and negative charges of the serum must be equal. Thus, all of the negative charges present in the serum must equal all of the positive charges, and the sum of the positive charges minus the sum of the negative charges must equal zero. The problem that immediately arose (and produced an â€œanion gapâ€•) was that all charged species are not routinely measured.

Normally present but not routinely measured cations consist of calcium and magnesium, whereas normally present but not routinely measured anions consist of phosphate, sulfate, albumin, and organic acids.[42,51,121] Sodium and K^+ normally account for 95% of extracellular cations, whereas Cl^- and HCO_3^- account for 85% of extracellular anions.[42] Thus, because more cations than anions are measured, subtracting the anions from the cations normally yields a positive number, known as the anion gap. The anion gap is therefore derived as shown in Equation 17-3:

$$\mathrm{Na^+ + K^+ + unmeasured\ cations\ (U_c) = Cl^- + HCO_3^-} \\ \mathrm{+ unmeasured\ anions\ (U_a)} \\ \mathrm{Anion\ gap = U_a - U_c}$$

or

$$\text{Anion gap} = (Na^+ + K^+) - (Cl^- + HCO_3^-) \quad \text{(Eq. 17–3)}$$

Because K^+ is largely an intracellular cation and rarely alters the anion gap, it is often deleted from the equation for simplicity. Most prefer this approach, yielding Equation 17-4:

$$\text{Anion gap} = (Na^+) - (Cl^- + HCO_3^-) \quad \text{(Eq. 17–4)}$$

Using Equation 17-4, the normal anion gap was initially determined to be 12 Â± 4 mEq/L.[42,170] More recent data suggest that as a result of a change in laboratory instrumentation and higher serum [Cl^-] values than previously reported, the range for a normal anion gap may be lower: 7 Â± 4 mEq/L.[169]

A variety of pathologic conditions may result in a rise or fall of the anion gap. High anion gaps result from increased presence of unmeasured anions or decreased presence of unmeasured cations (Table 17-1).[42,51,100,144] Similarly, a low anion gap results from an increase in unmeasured cations or a decrease in unmeasured anions (Table 17-2).[42,51,65,143,154]

Anion Gap Reliability

Several authors have considered the usefulness of the anion gap determination.[21,52,78] When 57 hospitalized patients were studied to determine the cause of elevated anion gaps, in those patients whose anion gap was greater than 30 mEq/L the cause was always lactic acidosis or ketoacidosis.[52] In patients with smaller elevations of the anion gap, the ability to define the cause of the elevation

diminished; in only 14% of patients with anion gaps of 17â€“19 mEq/L could the etiology be defined. It should be noted that because of the small size of this study, there were no patients with toxic alcohol ingestion. Another study determined that although the anion gap is often used as a screening test for hyperlactacidemia (as a sign of poor perfusion), only those

patients with the highest serum lactate concentrations had elevated anion gaps.[78] Finally, in a sample of 571 patients, those with higher anion gaps tended to have increased severity of illness. This resulted in higher admission rates, a greater percentage of admissions to intensive care units, and a higher mortality.[21] Thus, although the absence of an increased anion gap does not exclude significant illness, a very elevated anion gap can generally be attributed to a specific cause and usually indicates a relatively severe illness.

TABLE 17-1. Xenobiotic and Other Causes of a High Anion Gap

Increased unmeasured anions
- Metabolic acidosis (see Table 17-3)
- Dehydration
- Therapy with sodium salts of unmeasured anions
  - Sodium citrate
  - Sodium lactate
  - Sodium acetate
- Therapy with certain antibiotics
  - Carbenicillin
  - Sodium penicillin
- Alkalosis

Decrease in unmeasured cations
- Simultaneous hypomagnesemia, hypocalcemia, and hypokalemia

Metabolic Acidosis

Once the diagnosis of metabolic acidosis has been made by finding an arterial pH <7.40, a [HCO_3^-] <24 mEq/L, and a PCO_2 <40 mm Hg (as in patient 1), the serum anion gap should be analyzed. Indeed, the popularity of the anion gap is primarily based on its usefulness in categorizing metabolic acidosis as being of the high-anion-gap or normal-anion-gap type. This determination should be made after correcting the anion gap for the effect of hypoalbuminemia, a common and important confounding factor in such patients. The anion gap decreases approximately 3 mEq/L per 1 g/dL decrease in the serum albumin.[48] In general, the electrolyte abnormalities that frequently accompany metabolic acidosis usually have only small and insignificant effects on the anion gap.

TABLE 17-3. Xenobiotic and Other Causes of a High Anion Gap Metabolic Acidosis

Carbon monoxide
Cyanide
Ethylene glycol
Hydrogen sulfide
Isoniazid
Iron
Ketoacidoses (diabetic, alcoholic, and starvation)
Lactate
Metformin
Methanol
Paraldehyde
Phenformin
Salicylates
Sulfur (inorganic)
Theophylline
Toluene

Uremia (acute or chronic renal failure)

Note: Many clinicians rely on the mnemonic MUDPILES to help remember this differential diagnosis where M represents methanol, U (uremia), D (diabetic ketoacidosis), P (paraldehyde), I (iron), L (lactic acidosis), E (ethylene glycol), and S (salicylates).

TABLE 17-2. Xenobiotic and Other Causes of a Low Anion Gap

Increase in unmeasured cations
Hypercalcemia
Hypermagnesemia
Hyperkalemia
Lithium poisoning
Multiple myeloma
Decrease in unmeasured anions
Hypoalbuminemia
Dilution
Overestimation of the chloride
Bromism
Iodism
Nitrate excess

A high-anion-gap metabolic acidosis results from the absorption or generation of an acid that dissociates into an anion other than Cl^- that is neither excreted nor metabolized. The retention of this

â€œunmeasuredâ€• anion (eg, lactate in lactic acidosis) increases the anion gap. Normal-anion-gap metabolic acidosis results from the absorption or generation of an acid that dissociates into H^+ and Cl^-. In this case, the â€œmeasuredâ€• Cl^- is retained as HCO_3^- is titrated and reduced during the acidosis, and no anion gap is produced. Normal-anion-gap acidosis, also referred to as hyperchloremic metabolic acidosis, may be caused by intestinal or renal bicarbonate losses as in diarrhea or renal tubular acidosis, respectively. Other causes of high- and normal-anion-gap metabolic acidoses are described elsewhere[2] and shown in Tables 17-3 and 17-4. Patient 1, described above, has an anion gap of 22 mEq/L [133 mEq/L (99 mEq/L + 12 mEq/L)], and thus is said to have a high-anion-gap metabolic acidosis.

Narrowing the Differential Diagnosis of a High-Anion-Gap Metabolic Acidosis

The ability to diagnose the etiology of a high-anion-gap metabolic acidosis is an essential skill in clinical medicine. The following

discussion provides a rapid and cost-effective approach to the problem. As always, the clinical history and physical examination may provide essential clues to the diagnosis. For example, iron poisoning is virtually always associated with significant gastrointestinal symptoms, the absence of which essentially excludes the diagnosis of this poisoning (Chap. 40). Furthermore, when iron overdose is suspected, an abdominal radiograph may show the presence of tablets. The acidosis associated with isoniazid (INH) toxicity results from seizures, the absence of which excludes INH as the cause of a metabolic acidosis (Chap. 55). Methanol toxicity may be associated with visual complaints or an abnormal funduscopic examination (Chap. 103). Methyl salicylate has a characteristic odor (Chap. 21). When these findings are absent, the laboratory analysis must be relied on, as follows:

- *Begin with the electrolytes and glucose:* A rapid glucose reagent test should be performed to help confirm or exclude the possibility of hyperglycemia. While hyperglycemia should raise the possibility of diabetic ketoacidosis, the absence of an elevated serum glucose does not exclude the possibility of euglycemic diabetic ketoacidosis,[80] or alcoholic or starvation ketoacidosis, which are often associated with normal or even low serum glucose concentrations. An elevated BUN and creatinine are essential to diagnose acute or chronic renal failure.
- *Proceed to the urinalysis:* Do not wait for the laboratory results, as all of these urinary studies are easily accomplished. In addition, if there is a suspicion of a high-anion-gap metabolic acidosis, and only the arterial or venous blood-gas analysis is completed, the evaluation may begin here, while the electrolyte determination is pending. A urine dipstick for glucose and ketones helps with the diagnosis of diabetic ketoacidosis and other ketoacidoses. However, the absence of urinary ketones does not exclude a diagnosis of alcoholic ketoacidosis (Chap. 75), and ketones are often present in severe salicylism (Chap. 35), and biguanide-associated metabolic acidosis (Chap 48). The urine of a patient who has ingested fluorescein-containing antifreeze (ethylene glycol) does not reliably fluoresce when exposed to a Wood lamp. Also, because ethylene glycol is metabolized to oxalate, calcium oxalate crystals may be present in the urine of a poisoned patient. Both fluorescent and calcium oxalate-containing urine are useful findings if present, but their absence does not exclude ethylene glycol poisoning (Chap. 103). When clinically available, a urine ferric chloride test should be performed. Although highly sensitive and specific for the presence of salicylate, this test is not specific for the diagnosis of salicylism, as small amounts of salicylate will be detected in the urine even days after its last use (Chap. 35).

Thus, a serum salicylate level must be obtained to quantify the findings of a positive ferric chloride test. A negative ferric chloride test essentially excludes a diagnosis of salicylism.

- An arterial or venous blood lactate level can be helpful. In theory, if the lactate (measured in mEq/L) can entirely account for the fall in serum [HCO_3^-], then the cause of the increased anion gap can be attributed to lactic acidosis. However, it is important to remember that glycolate (a metabolite of ethylene glycol) can produce a significant false-positive elevation of lactate with many current laboratory techniques.[112,129,171]

TABLE 17-4. Xenobiotic Causes of a Normal Anion Gap Metabolic Acidosis

Acetazolamide
Acidifying agents
Ammonium chloride
Arginine hydrochloride
Hydrochloric acid
Lysine hydrochloride
Cholestyramine
Sulfamylon
Toluene
Topiramate

When the above analysis is unproductive, the diagnosis is usually toxic alcohol ingestion, starvation, alcoholic ketoacidosis (with minimal urine ketones), or a multifactorial process involving small amounts of lactate and other anions. One approach is to provide the patient with 1â€“2 hours of intravenous hydration, dextrose,

and thiamine. If the acidosis improves, the etiology is either ketoacidosis or lactic acidosis. Alternatively, a more detailed search for the toxic alcohols, involving either the osmol gap or specific levels, should be initiated (discussed below).

In patient 1, urinalysis revealed trace amounts of protein, small ketones, and large glucose (after dextrose administration). There were no crystals or fluorescence, but a ferric chloride test was positive. A lactate level was not obtained.

Diagnosis of Patient 1

There are many causes of a concomitant high-anion-gap metabolic acidosis and respiratory alkalosis (as was observed in patient 1). Examples include pneumonia in the presence of renal failure; diabetic ketoacidosis or lactic acidosis in the presence of sepsis; renal failure in a patient with cirrhosis of the liver; and salicylate poisoning (Chap. 35). In patient 1, with the positive ferric chloride test, the presence of urinary ketones, and the acidâ€“base abnormalities noted, salicylate toxicity is strongly suggested. In fact, the patient's serum salicylate level was later reported as 97 mg/dL, and he underwent hemodialysis with complete metabolic recovery.

The Î” Anion Gap-to-Î”[HCO_3^2] Gap Ratio

Like patient 1, many patients have mixed acidâ€“base disorders such as metabolic acidosis and respiratory alkalosis. Depending on their relative effects, the patient may have significant acidemia or alkalemia, minor alterations in pH, or even a normal pH. Although the clinical presentation, degree of compensation for the primary acidâ€“base disorder, and the presence of unexpected electrolyte abnormalities may suggest whether more than one primary acidâ€“base disorder is present, sometimes comparing the Î” anion

gap (Î”AG) with the Î”[HCO_3^-] gap may be useful.

A typical example is the patient with diabetic ketoacidosis (DKA) and vomiting. Although DKA would be expected to produce a classic high-anion-gap metabolic acidosis, the vomiting could raise the [HCO_3^-] and pH to normal. The toxicologic clinical correlate of the patient with a mixed acidâ€“base disorder might be the iron-poisoned patient with refractory vomiting and a multifactorial high-anion-gap metabolic acidosis (Chap. 40). Another example is the patient with alcoholic ketoacidosis and vomiting. In these cases with two clinically obvious disorders, the arterial blood gas analysis could yield values of pH 7.40, PCO_2 40 mm Hg, and [HCO_3^-] 24 mEq/L. In most circumstances, of course, one process predominates, although its significance may be minimized by the presence of the second, undiagnosed primary acidâ€“base disorder.

In the patient with a simple high-anion-gap metabolic acidosis, each 1 mEq/L decrease in the serum [HCO_3^-] should (at least initially) be associated with a 1 mEq/L rise in the anion gap.[118] This occurs because the unmeasured anion is paired with the acid that is titrating the HCO_3^-. Any deviation from this direct relationship may be an indication of a mixed acidâ€“base disorder.[66,118,125] Thus, the ratio of the change in the anion gap (Î”AG) to the deviation of the serum [HCO_3^-] from normal (Equation 17-5) evolved:

$$\text{Anion gap ratio} = \Delta AG/\Delta HCO_3^- \qquad \text{(Eq. 17–5)}$$

A ratio close to 1 would suggest a pure high-anion-gap metabolic acidosis. When the ratio is >1, there is a relative increase in [HCO_3^-] (suggesting a mixed disorder) that can result only from a concomitant metabolic alkalosis or renal compensation (ie, renal

generation of HCO_3^-) for a respiratory acidosis. Alternatively, when the ratio is <1, the additional presence of either hyperchloremic (normal-anion-gap) metabolic acidosis or

compensated respiratory alkalosis is suggested.

One author[172] suggested calculating the â€œdelta gapâ€• or gap of the gap as shown in Equation 17-6:

$$\text{Gap of the gap} = \Delta AG - \Delta HCO_3^- \qquad \text{(Eq. 17–6)}$$

where a delta gap >6 mEq/L would suggest concomitant metabolic alkalosis and a delta gap <6 mEq/L would suggest concomitant hyperchloremic acidosis.

The usefulness of this relationship between the change in the anion gap and the change in the serum [HCO_3^-] has been evaluated by many authors. Although supported strongly by some authors,[122,125] others suggest that it is often flawed and frequently misleading.[35,139] The next section summarizes the discussion.

For the fall in the serum [HCO_3^-] to be either proportionally or linearly related to the rise in the anion gap, the following criteria should be met:

- All of the acid formed should be titrated by HCO_3^-. In fact, there are many non-HCO_3^- buffer systems, and the duration of acidosis alters the relative contributions of these systems.[145]
- The volumes of distribution of H^+, its associated anion, and HCO_3^- should be the same. This is not always true. For example, in the case of lactic acidosis, lactate remains extracellular while some of the lactic acid is buffered intracellularly. Thus, the increase in the anion gap (because of lactate) is usually less than the decrease in [HCO_3^-].
- The rates of elimination of the anion and regeneration of HCO_3^- should be equal. For example, in the patient with ketoacidosis, acetone and the anions acetoacetate and Î²-hydroxybutyrate are often cleared quickly when renal function is normal and poorly when renal function is impaired.

- Acidosis and alkalosis should not alter the anion gap themselves. As pH changes, the charges on serum proteins change, such that acidemia tends to decrease the anion gap and alkalemia tends to increase the gap.[1] This change is related to the generation of lactate and a change in the charges on albumin (an unmeasured anion).
- There must be no concurrent process other than the metabolic acidosis that is affecting the anion gap.

For these reasons, the statements of one author[35] appear to be correct in concluding that â€œthe exact relationship between the Î”AG and Î”[HCO_3^-] in a high-anion-gap metabolic acidosis is not readily predictable and deviation of the Î”AG/Î”[HCO_3^-] ratio from unity does not necessarily imply the diagnosis of a second acidâ€“base disorder.â€• However, very large deviations from a value of 1 usually are associated with the presence of a second acidâ€“base disorder. Indeed, in the first patient discussed above, the Î”AG-to-Î”[HCO_3^-] ratio was very high, 1.8 (Î”AG 22 mEq/L-to-Î”[HCO_3^-] 12 mEq/L), strongly suggesting the presence of two primary acidâ€“base disorders.

The Osmol Gap

The osmol gap is defined as the difference between the values for the measured osmolality and the calculated osmolarity.[154] Osmolarity is a measure of the total number of particles in 1 L of solution. Osmolality differs from osmolarity in that the number of particles is expressed per kilogram of solution. Thus, osmolarity and osmolality represent molar and molal concentrations of solutes, respectively.[58] In clinical medicine, osmolarity is usually calculated, whereas osmolality is usually measured.

Calculating osmolarity requires a summing of the known particles in solution. Because molarity and milliequivalents are particle-based measurements, unlike weight or concentration, the known

constituents of serum have to be converted to molar values. Assumptions are required based on the extent of dissociation of polar compounds (such as NaCl), the water content of serum, and the contributions of various other solutes such as Ca^{2+} and Mg^{2+}. The nature and limitations of these assumptions is beyond the scope of this chapter. The reader is referred to several reviews for more details.[61,72,123] Many equations have been used and evaluated for calculating osmolarity. One investigation that used 13 different methods to evaluate sera from 715 hospitalized patients[37] concluded that Equation 17-7 provided the most accurate calculation:

$$1.86(Na^{+} \text{ in mEq/L}) + (\text{glucose in mg/dL})/18 + (\text{BUN in mg/dL})/2.8 \qquad \text{(Eq. 17–7)}$$

Obvious sources of potential error in this calculation include laboratory error in determining the measured parameters, and the failure to account for a number of osmotically active particles.

The measurement of serum osmolality has the potential for error as well, stemming from the use of different laboratory techniques. A 1989 survey of clinical laboratory methodology demonstrated that while more than 80% of facilities studied offered osmometry, 11% used the vapor pressure method exclusively (as opposed to the freezing-point method).[41] Furthermore, 50% of the laboratory supervisors questioned failed to recognize that the vapor pressure technique was likely to produce an erroneously low serum osmolality for sera containing methanol, ethanol, or isopropanol. This error results from the fact that these alcohols will boil out of solution before the boiling point of water is reached.

The mathematical and theoretical errors in determining osmolarity and osmolality are potentially additive when the two values are mathematically combined to determine the osmol gap. In addition, a conceptual error is present. In methanol poisoning, the methanol particle has osmotic activity that is measured but not calculated, and no increase in the anion gap is present until it is metabolized

to formate. Although the metabolite also has osmotic activity, its activity is accounted for by Na^+ in the osmolarity calculation because it is largely dissociated, existing as Na^+ formate. Thus, at least in theory, an early methanol ingestion is marked by an elevated osmol gap and a normal anion gap, whereas later, the anion gap increases and the osmol gap decreases. This effect is highlighted by several case reports.[10,31,157] Despite these limitations, a determination of the osmol gap is commonly proposed as a diagnostic adjunct when considering ingestions of toxic alcohols.

To qualify as a good screening test, the osmol gap should predict toxic alcohol ingestion with a low frequency of false-negative results (high sensitivity). To exclude a diagnosis of toxic alcohol ingestion, the determination of an osmol gap should have a low frequency of false-positive results (high specificity). As a first step, the range of normal values (and its variability) must be known. Using Equation 17-7 to calculate osmolarity, the previously mentioned study determined that the â€œnormalâ€• osmol gap was 10 Â± 6 mOsm.[37] However, when more than 300 adult samples were studied with a more commonly used equation (Equation 17-8):

$$2(Na^+ \text{ in mEq/L}) + (\text{glucose in mg/dL})/18 + (\text{BUN in mg/dL})/2.8 \qquad \text{(Eq. 17–8)}$$

normal values were -2 Â± 6 mOsm. Other commonly used equations yield normal values that range from -5 to +15 mOsm.[72] Almost identical results are reported in children.[107] While the concept of a negative osmol gap might be disconcerting, the numerous assumptions and approximations used to calculate osmolarity may not be valid. Also, although ethanol is the most common cause of elevated osmolality in varied groups of patients,[22,28,124,135] a serum ethanol measurement was not included for any of the patients used in the reference that serves

as the standard to define osmol gaps.[37] The relatively recent inclusion of ethanol in the osmolarity formula in a systematic evaluation of normal values predictably increased the calculated osmolarity in patients in whom ethanol was present, making the osmol gap smaller than previously suggested, or even negative.[72] Furthermore, a slight rise in measured serum [Na^+] has occurred.[169] If this is related to changes in laboratory determination, it will also lead to a lowering of the osmol gap. In fact, other investigations have concluded that the mean osmol gap in control (presumably ethanol-free) populations was a negative value.[61,79,142] Thus, the commonly used â€œnormalâ€• value of <10 mOsm, often attributed to two earlier works,[58,154] is clearly arbitrary and erroneous in the authors' own words, and should be abandoned.

The largest limitation of the osmol gap calculation comes from the documented large standard deviation around a small â€œnormalâ€• number.[37,72,79,142] This variability may result from the heterogeneity of the control population and/or the imprecision of laboratory measurements. For example, an error of 1 mEq/L (<1.0%) in the determination of the serum [Na^+] may result in an error of 2 mOsm in the calculation of the osmol gap. Considering this variability, the molecular weights and relatively modest blood concentrations of the xenobiotics in question (eg, ethylene glycol, MW 62 daltons, at a concentration of 50 mg/dL contributes only 7.8 mOsm/L), and the predicted fall in osmol gap as metabolism occurs, small or even negative osmol gaps can never be used to exclude toxic alcohol ingestion.[60,72] This overall concept is illustrated by the case of a patient with an osmol gap of 7.2 mOsm (well within the normal range) who ultimately required hemodialysis for severe ethylene glycol poisoning.[157]

Finally, although large osmol gaps may be suggestive of toxic alcohol ingestions, common conditions such as alcoholic ketoacidosis, lactic acidosis, renal failure, and shock are all associated with elevated osmol gaps.[79,142,151] Because lactate,

acetoacetate, and Î²-hydroxybutyrate should not account for any increase in the osmol gap because they are charged (and accounted for in the osmolarity calculation), these conditions are probably associated with the accumulation of small uncharged molecules in the serum.

The above discussion suggests that the negative and positive predictive values of the osmol gap are too poor to recommend this test to screen for xenobiotic ingestion. However, in the presence of very high osmol gaps (>50â€“70 mOsm), the diagnosis of toxic alcohol ingestion is usually confirmed (Chap. 103).

Differential Diagnosis of a Normal-Anion-Gap Metabolic Acidosis

Although the differential diagnosis for a normal-anion-gap metabolic acidosis is extensive (Table 17-4), most cases result from either urinary or gastrointestinal HCO_3^- losses: renal tubular acidosis (RTA) or diarrhea, respectively. A number of xenobiotics can cause this disorder, including toluene,[26] which also may cause a high-anion-gap metabolic acidosis. When the findings of the history and physical examination cannot be used to narrow the differential diagnosis, the use of a urinary anion gap is suggested.[15,133]

The urinary anion gap can be calculated as shown in Equation 17-9:

$$(Na^+ + K^+) - (Cl^-) \qquad \text{(Eq. 17–9)}$$

The size of this gap is inversely correlated with urinary ammonium (NH_4^+) excretion.[64] As NH_4^+ elimination increases, the urinary anion gap narrows and may become negative, because NH_4^+ serves as an unmeasured urinary cation and is accompanied predominately by Cl^-.

The normal-anion-gap metabolic acidosis associated with diarrhea

results from HCO_3^- loss. During this process, the kidney's ability to eliminate NH_4^+ is undisturbed; in fact, it increases as a normal response to the acidemia. Thus, with gastrointestinal HCO_3^- losses the urinary anion gap should decrease and may become negative. Alternatively, the patient with RTA has lost the ability to either reabsorb HCO_3^- (type 2 RTA) or increase NH_4^+ excretion (types 1 and 4 RTA) in response to metabolic acidosis, and the urinary anion gap should become more positive. Indeed, when the urinary anion gap was calculated in patients with diarrhea or RTA, it was found that those patients with diarrhea had a mean negative gap (-20 Â± 5.7 mEq/L), as compared to a positive gap (23 Â± 4.1 mEq/L) in those with RTA.[64] Therefore, when evaluating the patient with a normal-anion-gap metabolic acidosis, the determination of a urinary anion gap may help to determine the source of the disorder.

Adverse Effects of Metabolic Acidosis

The acuity and severity of metabolic acidosis determine the consequences of the disorder. Acute metabolic acidosis is usually characterized by obvious hyperventilation (due to respiratory compensation). At arterial pH values <7.20, cardiac and central nervous system abnormalities also become evident. These may include decreases in blood pressure and cardiac output, cardiac dysrhythmias, and progressive obtundation.[2] Chronic metabolic acidosis is often asymptomatic. The symptoms of anorexia and fatigue may be the only manifestations of chronic acidosis, and compensatory hyperventilation may be undetectable. Because the consequences of even severe metabolic acidosis are not specific, the presence of metabolic acidosis is most often suggested by the clinical setting and the underlying cause.

Management Principles in Patients with Metabolic Acidosis

The treatment of metabolic acidosis depends on its severity and cause. In most cases of severe poisoning, a serum [HCO_3^-] concentration <8 mEq/L and arterial pH values <7.20 should probably be treated with HCO_3^- to increase the pH to >7.20, as described in detail elsewhere.[2] As an example, to raise the serum [HCO_3^-] by 4 mEq/L in a 70-kg person with an estimated HCO_3^- distribution space of 50% of body weight, approximately 140 mEq must be administered. When ECFV overload (caused by heart failure, renal failure and/or the sodium bicarbonate therapy) cannot be prevented or managed by administering loop diuretics, hemofiltration or dialysis may be necessary.

In patients with arterial pH values >7.20, the cause of the acidosis should guide therapy. Metabolic acidosis primarily caused by the overproduction of acid (eg, ketoacidosis, lactic acidosis) will require very large quantities of HCO_3^- and may not respond well to HCO_3^- therapy. Treatment in these patients should be directed

at the cause of acidosis (eg, insulin in diabetic ketoacidosis; fomepizole in methanol and ethylene glycol poisonings [see Antidotes in Depth: Fomepizole]; fluids, glucose, and thiamine in alcoholic ketoacidosis; antibiotics in sepsis-induced lactic acidosis). Metabolic acidosis primarily caused by underexcretion of acid (eg, acute or chronic renal failure, RTA), should be treated with a low-protein diet (if feasible) and oral sodium bicarbonate or substances that generate HCO_3^- during metabolism. Such patients can usually be managed with an oral citrate solution (eg, Shohl solution yields 1 mEq base/mL). The goal of therapy is to increase the [HCO_3^-] to >20 mEq/L and pH >7.30.

Metabolic Alkalosis

Patient 2 A 2-week-old boy was brought to the ED by his parents because of a 36-hour history of fever, diarrhea, and lethargy. The child was born at 39 weeks gestation via normal spontaneous

vaginal delivery and had Apgar scores of 9 and 10. The baby and the mother were discharged from the hospital at the usual time, and the baby remained well until 36 hours prior to presentation in the ED. Physical examination was remarkable for an irritable child who was inconsolable, even by his parents. Vital signs on arrival were as follows: blood pressure, 60/40 mm Hg; irregular pulse, 160 beats/min; respiratory rate, 28 breaths/min; rectal temperature, 100.9Â°F (38.3Â°C). His skin was dry and without a rash. His anterior fontanel was depressed, and his capillary refill was delayed. The remainder of the physical assessment was unremarkable.

The child was attached to a cardiac monitor that showed frequent premature ventricular contractions (confirmed by 12-lead ECG). An intravenous catheter was inserted, and blood was drawn for culture, electrolytes, glucose, and CBC. An arterial blood-gas sample was obtained on room air and supplemental oxygen was administered. The child was given dextrose (1 g/kg) and a 20-mL/kg bolus of 0.9% sodium chloride solution intravenously. A lumbar puncture was performed and the child was started on broad-spectrum antibiotics.

The laboratory studies revealed arterial pH 7.76; PCO_2 40 mm Hg; PO_2 96 mm Hg. Electrolytes were [Na^+], 154 mEq/L; [K^+], 3.1 mEq/L; [Cl^-], 86 mEq/L; and [HCO_3^-], 43 mEq/L. BUN, Cr, and glucose were normal. The lumbar puncture revealed a normal cell count and chemistry, with a negative Gram stain.

Adverse Effects of Metabolic Alkalosis

Life-threatening metabolic alkalosis is rare but can result in tetany (from decreased ionized [Ca^{2+}]),[97] weakness (from decreased serum [K^+]),[108] altered mental status leading to coma,[92] seizures,[62] and cardiac dysrhythmias.[85] In addition, metabolic alkalosis shifts the oxyhemoglobin dissociation curve to the left, impairing tissue oxygenation (Chap. 22). The expected

compensation for a metabolic alkalosis is hypoventilation and increased PCO_2. As discussed above, respiratory compensation is irregular and inadequate at best, invoking the teleologic argument that hypoxia is more undesirable than alkalemia.[118] Several authors, however, have reported that severe hypoventilation and respiratory failure can occur in response to metabolic alkalosis, suggesting a real, although uncommon risk.[108,126]

Approach to the Patient with Metabolic Alkalosis

Metabolic alkalosis results from gastrointestinal or urinary loss of acid, administration of exogenous base, and/or renal HCO_3^- retention (ie, impaired renal HCO_3^- excretion). Table 17-5 lists the causes of metabolic alkalosis. As compared to metabolic acidosis, metabolic alkalosis is less common and less frequently a consequence of poisonings.

TABLE 17-5. Xenobiotic and Other Causes ot Metabolic Alkalosis

Gastrointestinal acid loss
Nasogastric suction (protracted)
Vomiting (protracted)
Urinary acid loss
Common
Diuretics
Glucocorticoids
Rare

Hypokalemia
Volume contraction

The etiologies of metabolic alkalosis can be characterized from a therapeutic standpoint as chloride-responsive or chloride-resistant. Chloride-responsive etiologies such as diuretic use, vomiting, and nasogastric suction, or Cl^- diarrhea, are usually associated with a low urinary [Cl^-] <10 mEq/L.[69,85] These disorders respond rapidly to infusion of 0.9% NaCl solution when concomitant therapy addresses the underlying problem.[3] Chloride-resistant disorders exemplified by hyperaldosteronism and severe K^+ depletion are characterized by urinary [Cl^-] >10 mEq/L and tend to be resistant to 0.9% NaCl solution therapy.[55,69] These disorders often require K^+ repletion or agents that reduce mineralocorticoid effects, such as spironolactone, before correction can occur.[55] When 0.9% NaCl solution repletion is ineffective, or emergent correction of the alkalosis is required, some authors have suggested infusions of lysine or arginine HCl, or dilute HCl.[3,108] However, this technique is rarely necessary.

Diagnosis of Patient 2

Further history revealed that patient 2 was being fed oral baking soda several times per day as part of a folk remedy. Urinary [Cl^-] was 6 mEq/L. He was treated with intravenous 0.9% NaCl solution with subsequent resolution of clinical and laboratory abnormalities. The parents were educated about the risks of prescription and nonprescription medications, and complementary therapies.

Xenobiotic-Induced and other Alterations of Water Balance

Significant fluid abnormalities commonly occur in the setting of xenobiotic exposure. Gastrointestinal losses in the form of vomiting,

diarrhea, gastrointestinal hemorrhage, and third spacing (such as from gastrointestinal burns) result from a variety of xenobiotic exposures and their management, such as emetics and cathartics. Renal fluid losses result from the ability of many toxins to increase the glomerular filtration rate (inotropes), impair absorption (diuretics), or enhance urine volume in response to an obligate solute load (salicylates). Fluid losses also may occur through the skin as a result of sweating (sympathomimetics, cholinergics, and uncouplers of oxidative phosphorylation) or the lung as a result of increased minute ventilation (salicylates and sympathomimetics) or bronchorrhea (cholinergics). To the extent that these lost fluids contain Na^+, various signs, symptoms, and laboratory evidence of ECFV depletion will be present.

The diagnosis and treatment of abnormal serum electrolyte concentrations are usually addressed after repletion of the ECFV deficit with isotonic, Na^+-containing fluids (eg, blood products, 0.9% NaCl solution, lactated Ringer solution). Other fluid balance issues are discussed in Chaps. 25 and 27 and in chapters relating to individual toxins. This section focuses on body water balance (abnormalities of which manifest as hypernatremia and

hyponatremia) and specifically on the toxicologically relevant syndromes of diabetes insipidus (DI) and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Sodium concentration in the extracellular space is intrinsically related to and directly reflects total body water balance. This occurs because the sodium cation is largely restricted to the extracellular space, and its (serum) concentration is primarily, if indirectly, controlled by factors that control water balance. Thus, both the serum [Na^+] and plasma osmolality vary inversely with changes in the quantity of body water.

Plasma osmolality is maintained through a complex interaction between dietary water intake; the hypothalamus, pituitary gland, and kidney; and the effects of hormones such as antidiuretic hormone (ADH) and adrenal mineralocorticoids.[17,20,120,165] Briefly, changes in osmolality are caused by changes in water intake and insensible (dermal, respiratory, and stool) and sensible (urinary, sweat) water losses. Urinary water losses are controlled by the hormone arginine vasopressin (ADH). Increases in the osmolality in the extracellular fluid stimulate anterior hypothalamic osmoreceptors, thereby stimulating thirst and ADH synthesis and release by the posterior pituitary gland. ADH release reaches its maximum level at a serum osmolality of about 295 mOsm/kg. Antidiuretic hormone is transported to the kidney via the bloodstream, where it stimulates the synthesis of cyclic adenosine monophosphate (cAMP). cAMP increases the water permeability of the distal convoluted tubule and collecting duct (by stimulating the insertion of aquaporin channels in the apical membrane) increasing water reabsorption and urine concentration, and minimizing urinary water losses. Conversely, as plasma osmolality falls, thirst and ADH release are diminished. This results in decreased renal cAMP generation, decreased water permeability of the distal convoluted tubule and collecting duct, and the excretion of a relatively dilute urine that ultimately corrects the body water excess. Marked alterations in water intake combined with

perturbations of these various processes often lead to hypernatremia or hyponatremia.

Hypernatremia

Table 17-6 summarizes the xenobiotics that cause hypernatremia. Hypernatremia may be caused by the parenteral administration of sodium-containing drugs or rapid and excessive oral Na^+ intake.[4] Oral NaCl and oral sodium citrate have been used as emetics and antiemetics, respectively. As might be expected, both have produced severe hypernatremia.[20] One case of fatal hypernatremia resulted from gargling with a supersaturated salt solution.[111] Similarly, massive ingestion of sodium hypochlorite bleach was associated with hypernatremia.[70,137]

More commonly, xenobiotic induced hypernatremia results from relatively electrolyte-free (hypotonic) water losses, including xenobiotics or conditions that cause urinary, gastrointestinal, and dermal fluid losses.[4] Indeed, all fluid losses from the body, with the exceptions of bleeding and fistulous losses, are hypotonic (and have the potential to cause hypernatremia). The failure of patients to replace these losses is a key element in the development of hypernatremia because even the large losses caused by diabetes insipidus or cholera-induced diarrhea will not cause hypernatremia if the losses are adequately replaced. Thus, in patients with hypernatremia caused by fluid losses, the reason why the losses were not replaced by the patient should always be sought.

Agents that produce significant diarrhea, such as lactulose or cholestyramine, can cause hypernatremia through unreplaced stool water losses. A similar pathogenesis accounts for the hypernatremia caused by the polyethylene-containing solution used for bowel preparation for colonoscopy.[14] Of particular concern is the use of cathartics in the management of poisonings, especially when fluid losses are not anticipated. For example, multiple doses of sorbitol can produce severe hypernatremic

dehydration and death in both children and adults.[24,44,57,166]

TABLE 17-6. Xenobiotic Causes of Hypernatremia

Sodium gain

Opioid antagonists
Propoxyphene
Rifampin
Streptozotocin
Vasopressin V_2-receptor antagonists

Significant water loss also can occur through the skin. Although diffuse diaphoresis resulting from cocaine or organic phosphorus agent toxicity has the potential to produce hypernatremia, this rarely, if ever, occurs. However, application of a burn remedy containing hyperosmolar povidone-iodine to the skin of burn patients has been reported to produce significant water losses and hypernatremia.[146]

Diagnosis and Treatment

The symptoms of significant hypernatremia consist largely of altered mental status ranging from confusion to coma, and neuromuscular weakness that occasionally results in respiratory paralysis. If hypernatremia is associated with Na^+ losses and marked ECFV depletion, cardiovascular symptoms, tachycardia, and orthostatic hypotension may be present. Treatment consists of replacing the Na^+ deficit first, if necessary (with isotonic fluids such as 0.9% NaCl solution), and then replacing the water deficit. The water deficit may be estimated by assuming that the fractional increase in serum [Na^+] is equal to the fractional decrease in total body water. Thus, a serum [Na^+] that has increased by 10% (from 144 mEq/L to 158 mEq/L) indicates that the water deficit is 10% (3.6 L in a 60-kg person with 36 L of body water).

When the hypernatremia develops over several hours, for example, as occurs after ingestion or administration of a sodium salt, rapid correction is indicated. However, when hypernatremia

develops over several days or when the duration is unknown, slow correction of hypernatremia (over several days) is recommended.[4] The adaptation of brain cells to the water deficit (including the loss of intracellular solute) makes cerebral edema a frequent result of rapid water replacement. Although some sources suggest that 0.9% NaCl solution infusion is an appropriate replacement fluid regardless of the magnitude of the water deficit, recent emphasis has been on the use of hypotonic fluids in the absence of a significant sodium deficit.[4]

Diabetes Insipidus

The greatest water losses and, therefore the potentially most severe cases of hypernatremia, occur during DI, which is always characterized by greater or lesser degrees of hypotonic polyuria. DI may be neurogenic (resulting from failure to sense a rising osmolality, or from a failure to release ADH), or nephrogenic (resulting from failure of the kidney to respond appropriately to ADH). Although there are many nontoxicologic causes of DI (eg, trauma, tumor, sarcoidosis, vascular and congenital), drug-induced DI is not uncommon, and may interfere with ADH effects through both central and peripheral mechanisms.

Ethanol, opioid antagonists, and Î±-adrenergic agonists all suppress ADH release.[10,115] Lithium,[99,150] demeclocycline,[149] methoxyflurane,[103] propoxyphene, foscarnet,[119] mesalazine,[101] streptozotocin, amphotericin,[74] glufosinate,[160] lobenzarit,[138] rifampin,[130] and colchicine,[165] are associated with nephrogenic DI (see Table 17-6). In addition, nephrogenic DI may be caused by severe hypokalemia from diuretic use, and hypercalcemia from vitamin D poisoning.[165] Of all these agents, lithium has been the most extensively evaluated. Although polyuria is a common finding with lithium therapy (occurring in 20â€“70% of patients on maintenance therapy), the exact incidence of DI and hypernatremia is unclear. Estimates range from 10â€“20% to as

high as 80%.

Diagnosis

Patients with DI complain of polyuria and polydipsia. Urine volumes typically exceed 30 mL/kg/d[165] and may be as high as 9 L/d with nephrogenic DI[99] and 12â€“14 L/d with neurogenic (central) DI.[116] Nocturia, fatigue, and decreased work performance are noted.[165] Neurogenic DI resulting from hypothalamic or pituitary damage is typically associated with other signs of neuroendocrine dysfunction.[116]

Once polyuria is confirmed (eg, in adults, by measuring a urine output >200 mL over 1 hour), the urine osmolality or specific gravity should be measured. The diagnosis of DI is established by the occurrence of dilute urine (urine osmolality <300 mOsm/kg, urine specific gravity <1.010) in the presence of increased serum [Na^+] and serum osmolality >295 mOsm/kg.[165] Following this determination, a trial of desmopressin (DDAVP), an arginine vasopressin analog, helps to differentiate between neurogenic and nephrogenic DI. If the etiology of the DI is neurogenic, the patient promptly responds to DDAVP with a decrease in urine output and increase in urine osmolality. In nephrogenic DI, DDAVP will have no significant effect.

Treatment

The initial approach to the hypernatremic patient with DI involves the repletion of the water deficit (as described above) and the restoration of electrolyte balance, if necessary. If a reversible cause for the DI can be established, it should be corrected. Specifically, drugs implicated as the cause of DI should be discontinued or their dose reduced. Patients with neurogenic DI should be maintained on either vasopressin or DDAVP. The latter is preferred because of the lack of vasopressor effects and ease of administration. In the past, patients were occasionally treated with

oral agents known to produce SIADH (see below). Patients with nephrogenic DI can be treated with thiazide diuretics,[38] prostaglandin inhibitors,[34,74,94] and/or amiloride.[16]

Hyponatremia

Hyponatremia may be associated with a high, normal, or low plasma osmolality. Patients with myeloma or severe hyperlipidemia may exhibit artifactual hyponatremia whenever the measurement technique requires dilution of the serum sample rather than direct measurement by a sodium electrode. These patients have a normal serum osmolality, no symptoms related to their artifactual hyponatremia, and require no therapy. Hyperglycemic patients develop hyponatremia because the increase in plasma osmolality caused by hyperglycemia results in a water shift from the intracellular to the extracellular space. The reduction in serum $[Na^+]$, which may cause symptoms, is an approximately 2 mEq/L per 100 mg/dL increase in serum glucose concentration. The contribution of hyperglycemia to the hyponatremia should be calculated to determine if other causes of hyponatremia should also be sought. All other causes of hyponatremia are associated with a low plasma osmolality. In fact, in the absence of myeloma, hyperlipidemia and hyperglycemia, the plasma osmolality need not be measured in hyponatremic patients and may be assumed to be low.

Hyponatremia associated with a low plasma osmolality usually results from water intake in excess of the renal capacity to excrete it. When renal water excretion is normal, very large quantities are required to cause hyponatremia. Usually such quantities are ingested over a short period of time by people with psychiatric or neurologic disorders.[63,134] Xenobiotic-induced water excess comparable to psychogenic polydipsia is quite uncommon. An example occurs during urologic procedures, such as transurethral resection of the prostate (TURP), where large volumes of irrigation

solution are required. Because the wounds are electrically

cauterized, these fluids cannot contain conductive electrolytes such as sodium. Sorbitol, dextrose, and mannitol were tried in an attempt to maintain a normal osmolality in these irrigating solutions, but their optical characteristics were undesirable. Thus, irrigation during TURP is performed with glycine-containing solutions. When 1.5% glycine (osmolality 220 mOsm/Kg) is absorbed through the prostatic venous plexus, a rapid reduction in serum [Na^+] results and will persist until the glycine is metabolized.[71,110] Symptoms in these patients are probably a result of several factors: hyponatremia, the glycine itself, and NH_3, a glycine metabolite. A similar complication is also described during hysteroscopy.[127,147]

Rarely, hyponatremia results from the loss of a body fluid with a [Na^+] greater than the extracellular fluid (ECF) [Na^+] (of 154 mEq/L). This may occur in patients with adrenal insufficiency through hypertonic urinary losses (although increased ADH secretion as a consequence of ECF sodium depletion is probably a more important mechanism; see below). In burn patients, Na^+ may be lost directly from the ECF. When treated with the topical applications of silver nitrate cream, hyponatremia may develop from the diffusion of sodium through permeable skin into the hypotonic dressing.[29] Ingestion of licorice, which contains glycyrrhizic acid, produces a syndrome of hyponatremia, hypokalemia, and hypertension that resembles mineralocorticoid excess. Although the exact mechanism of hyponatremia is debated, one report suggested that a glycyrrhizic acid-induced reduction in 11-Î²-hydroxysteroid dehydrogenase activity could account for the findings.[40,43] Lithium, which is usually associated with diabetes insipidus and hypernatremia, has been reported to cause renal sodium-wasting and hyponatremia that seems to be unrelated to ADH effects.[109]

Most cases of hyponatremia are caused by water intake in excess

of a reduced renal excretory capacity. This reduction in urinary water excretion may be physiologic (as during ECF sodium depletion) or pathologic (in association with renal failure, heart failure, or cirrhosis of the liver).[5,14] Because these conditions are accompanied by alterations in renal sodium handling, signs and symptoms of ECFV depletion (eg, postural hypotension) or excess (eg, edema) usually accompany the hyponatremia. Other patients cannot excrete water normally because malignancy or various brain or pulmonary diseases cause ADH secretion.[5] In fact, in some cases the tumors are associated with paraneoplastic disease and directly secrete ADH. Xenobiotics may cause ECFV depletion (eg, diuretics), but most directly stimulate ADH secretion or augment the renal effects of ADH. Drugs such as the thiazide diuretics cause hyponatremia by several mechanisms, including interference with maximal urinary dilution, and by ADH-induced water retention in response to decreased ECFV.[5,47] Patients with excess secretion and/or action of ADH who have near-normal ECFV are said to have SIADH. Table 17-7 summarizes these and other causes of hyponatremia.

SIADH

SIADH is characterized by hyponatremia and plasma hypotonicity in the absence of abnormalities of ECFV, adrenal, thyroid, or renal function. Early reviews claimed that SIADH was a disorder of volume overload, based largely on evidence of weight gain.[115] The consistent absence of edema, however, and the fact that the decrease in serum [Na^+] cannot be accounted for by the fluid gain (weight gain), suggest that water retention is only part of the mechanism.[88] Urinary Na^+ loss and Na^+ redistribution from the extracellular to the intracellular space are apparently important as well.

TABLE 17-7. Xenobiotic and Other Causes of Hyponatremia

Arginine
Captopril and other angiotensin-converting enzyme inhibitors
Diuretics
Glycine (transurethral prostatectomy syndrome)
Lithium
Nonsteroidal antiinflammatory drugs
Primary polydipsia
Silver nitrate

SIADH
- Amiloride
- Amitriptyline (and other tricyclic antidepressants)
- Biguanides
- Carbamazepine (and oxcarbamazepine)
- Cisplatin
- Clofibrate
- Cyclophosphamide
- Desmopressin (DDAVP)
- Diazoxide
- Indapamide
- Indomethacin
- MDMA (methylenedioxymethamphetamine)
- Metformin
- Nicotine
- Opioids
- Oxytocin
- Selective serotonin reuptake inhibitors
- Sulfonylureas
- Thioridazine
- Tranylcypromine

Vasopressin
Vincristine and vinblastine

There are many nontoxicologic etiologies of SIADH, most of which involve pulmonary or intracranial processes. These causes include infections, malignancies, and surgery.[5,88,115,116] Table 17-7 summarizes xenobiotics known to produce SIADH. The oral hypoglycemics, including agents from both the sulfonylurea (eg, chlorpropamide) and biguanide (eg, metformin) classes, produce hyponatremia more commonly than other agents.[114] Their actions are multifactorial and can include both the potentiation of endogenous ADH and the stimulation of ADH release.[114] Many psychiatric medications, including the selective serotonin reuptake inhibitors, cyclic antidepressants, and antipsychotics are implicated in causing SIADH.[27,86,96,156,163] The effects of these drugs may be mediated by the complex interactions between the dopaminergic and noradrenergic systems that control ADH release.[156] Additional evidence supports a role of serotonin in drug-induced SIADH. Serotonin (specifically $5\text{-}HT_2$ and/or $5\text{-}HT_{1C}$) directly stimulates ADH release[11] and water intake.[77] An important role of serotonin is supported by the occurrence of SIADH with (methylenedioxymethamphetamine) MDMA use.[76,168]

Diagnosis

The clinical presentation of patients with hyponatremia depends on the cause, the absolute serum $[Na^+]$ and the rate of decline in serum $[Na^+]$. Patients with associated ECFV excess or depletion will present with evidence of altered ECFV, as well as signs and symptoms of the disease that caused the abnormality in ECFV, such as adrenal insufficiency and heart failure.[5] Rarely will these patients exhibit findings caused by the hyponatremia and hyposmolality of body fluids per se. This may be because of the moderate degree of hyponatremia (>130 mEq/L), the

moderate rate of decline in serum [Na^+], and/or because the loss of Na^+ and water limits the development of cerebral edema.[91] It is important to note that patients with hyponatremia and a low plasma osmolality (excluding those with primary polydipsia) all have a urinary osmolality that is relatively high, regardless of whether they have excess, diminished, or normal ECFV. Consequently, these disorders can only be differentiated by the history, physical examination, and other laboratory tests.

Patients with SIADH, if symptomatic, usually present with signs and symptoms of hyponatremia. As noted above, the clinical manifestations of hyponatremia are dependent on both the absolute serum [Na^+] and its rate of decline.[12,91,116] Chronic, slow depression of the serum [Na^+] is usually well tolerated, whereas rapid decreases may be associated with symptoms and sometimes catastrophic events. Symptoms include headache, nausea, vomiting, restlessness, disorientation, depression, apathy, irritability, lethargy, weakness, and muscle cramps. In more severe cases, respiratory depression, coma, and seizures develop.

The diagnosis of SIADH is based on establishing the presence of hyponatremia, a low plasma osmolality, and impaired urinary dilution in the absence of edema, hypotension, hypovolemia, and renal, adrenal, or thyroid dysfunction.[88] As discussed above, the presence of any of these clinical findings suggests that another cause of hyponatremia may be present. A serum uric acid concentration may be helpful in differentiating SIADH from other causes of hyponatremia. In the presence of hyponatremia and impaired urinary dilution, patients with SIADH have hypouricemia, whereas patients exhibiting ECFV excess or depletion characteristically have hyperuricemia.[32,155]

Treatment

Treatment of patients with demonstrable ECFV excess or depletion

should be directed at the abnormal ECFV and its cause, rather than the hyponatremia. In almost all cases, the hyponatremia will improve with correction of the ECFV.[5,91] In a similar way, correction of the serum glucose in hyperglycemic patients and the removal of glycine by hemodialysis in patients with the TURP syndrome will correct the serum [Na^+]. The rate of correction of the serum [Na^+] in these patients is generally not of concern.

In patients with SIADH, treatment begins with fluid restriction. Because the goal of this therapy is to establish a negative fluid balance, careful attention to intake and output is required. If an offending agent can be identified, it should be eliminated. Although most cases resolve in 1â€“2 weeks,[88,116] SIADH caused by chronic cerebral or pulmonary conditions or by malignancy often persists. If this occurs, therapy with demeclocycline or lithium may be helpful, because severe fluid restriction is often intolerable. One author suggested that demeclocycline was more efficacious than lithium when the two agents were compared in a small series of patients with SIADH.[50]

In all asymptomatic or mildly symptomatic patients (usually patients with chronic hyponatremia of more than 2 days duration), correction should proceed slowly, and certainly at a rate less than 0.5 mEq/L/h during the first 24 hours. This is because too rapid correction of hyponatremia may increase the risk of irreversible CNS damage known as central pontine myelinolysis.[5,13,158] Water restriction is usually sufficient, but occasionally demeclocycline may be appropriate in these patients in whom the rate of correction represents a greater risk for brain damage than the absolute serum [Na^+]. The anticipated availability of oral vasopressin V_2- and $V_{1/2}$-receptor antagonists will make the management of these asymptomatic patients much easier.[5,68]

When hyponatremia is associated with life-threatening clinical presentations, careful infusion of hypertonic (3%) saline (eg, 0.5â€“1 mEq/kg/h), with or without furosemide, is indicated.[5,88]

In these symptomatic patients, the goal is to increase the serum [Na^+] by 1â€“2 mEq/L/h, or by 10% over 12â€“24 hours, or until the symptoms abate.[5,91] After this initial correction and amelioration of symptoms, the serum [Na^+] should be increased at a rate <0.5 mEq/L/h, preferably by water restriction alone. Formulae are available to help calculate the rate of correction of hyponatremia.[5] Equation 17-10 might be helpful.

When one liter of fluid is infused:

$$\text{The change in the serum } Na^+ = \frac{\text{infusate } Na^+ - \text{serum } Na^+}{\text{total body water} + 1 \text{ liter}}$$

Where infusate Na^+ concentrations in mEq/L equal:

3% sodium chloride	513
0.9% sodium chloride	154
Lactated Ringer solution	130
0.45% sodium chloride	77
0.33% sodium chloride	51

(Eq. 17–10)

Xenobiotic-Induced Electrolyte Abnormalities

Potassium

Xenobiotic-induced alterations in serum [K^+] are potentially more serious than alterations in other electrolyte concentrations because of potassium's critical role in a variety of homeostatic processes. Potassium balance is complex.[23,128,141] The total body potassium content of an average adult is about 54 mEq/kg, of which only 2% is located in the intravascular space. The large intracellular store of potassium is maintained by a variety of systems, the most important of which is membrane Na^+-K^+-adenosine triphosphatase (ATPase). The relationship between total body stores and serum [K^+] is not linear, and small changes in the total body potassium may result in dramatic alterations in serum concentrations, and, more importantly, in the ratio of extracellular

to intracellular [K^+].

People eating a western diet ingest 50â€“150 mEq/d of potassium, approximately 90% of which is subsequently eliminated in the urine. The body has two major defenses against a potassium load: acutely, potassium is transferred into cells; chronically, potassium is excreted in the urine by decreased proximal tubular reabsorption and increased distal tubular secretion (to a maximum of 600â€“700 mEq/d).[23] Intracellular [K^+] is maintained through insulin and catecholamine-mediated uptake of potassium in liver and muscle cells.[98,136] Renal potassium excretion is primarily modulated by the reninâ€“angiotensinâ€“aldosterone system. In addition, the gastrointestinal absorption of potassium decreases as the serum [K^+] increases.

Hypokalemia results from decreased oral intake, gastrointestinal losses caused by repeated vomiting or diarrhea, urinary losses through increased secretion or decreased reabsorption, and processes that shift potassium into the intracellular compartment.[20,23,148,167] Table 17-8 summarizes the xenobiotics commonly associated with hypokalemia.

The neuromuscular manifestations of hypokalemia are reviewed elsewhere.[87] Patients with hypokalemia are often asymptomatic when the decrease in serum [K^+] is mild (serum concentrations of

3.0â€“3.5 mEq/L). Occasionally, hypokalemia interferes with renal concentrating mechanisms and polyuria is noted. More significant potassium deficits (serum concentrations of 2.0â€“3.0 mEq/L) cause generalized malaise and weakness. As the [K^+] fall to less than 2 mEq/L, weakness becomes prominent and areflexic paralysis and respiratory failure may occur, often necessitating intubation and mechanical ventilation.[87] Rhabdomyolysis is also likely. These neuromuscular manifestations are so prominent that they may be erroneously attributed to a primary neuromuscular syndrome such as Guillain-BarrÃ©. Other clinical findings

associated with hypokalemia may include gastrointestinal hypoperistalsis (ileus), manifestations of cardioactive steroid toxicity, worsening hyperglycemia in diabetic patients, and symptoms and signs of metabolic abnormalities that often accompany hypokalemia such as hyponatremia, metabolic acidosis, or alkalosis.[167]

TABLE 17-8. Xenobiotic Causes of Altered Serum Potassium

Hypokalemia	Hyperkalemia
Aminoglycosides	Amiloride
Amphotericin	Angiotensin-converting enzyme inhibitors
Barium (soluble salts)	
Î²-Adrenergic agonists	Angiotensin receptor blockers
Bicarbonate	Î±-Adrenergic agonists (phenylephrine)
Caffeine	
Carbonic anhydrase inhibitors	Î²-Adrenergic antagonists
Cathartics	Arginine hydrochloride

Chloroquine	Cardioactive steroids
Cisplatin	Fluoride
Dextrose	Heparin
Hydroxychloroquine	Nonsteroidal antiinflammatory drugs
Insulin	
Licorice (glycyrrhizic acid)	Penicillin (potassium)
Loop diuretics	Potassium salts
Metabolic alkalosis	Spironolactone
Oral hypoglycemics	Succinylcholine
Osmotic diuretics	Triamterene
Quinine	Trimethoprim
Salicylates	
Sodium penicillin and its analogs	
Sodium polystyrene sulfate	

Sympathomimetics	
Theophylline	
Thiazide diuretics	
Toluene	

Electrocardiographic changes also are common, even with mild potassium depletion, although the absence of ECG changes should never be used to exclude significant hypokalemia. Common ECG findings of hypokalemia include depression of the ST segment, decreased T-wave amplitude, and increased U-wave amplitude (Chap. 5). These findings may herald life-threatening rhythm disturbances.[75,95,167]

Treatment of hypokalemia involves discontinuing or removing the offending xenobiotic and correcting the potassium deficit. Potassium supplementation may be given orally and/or intravenously. The choice of potassium salt should be based on the associated acidâ€“base abnormality, if present. Thus, KCl should be administered when metabolic alkalosis is present, and another salt of potassium (eg, potassium citrate or $KHCO_3$) should be administered when metabolic acidosis is present.[167] Potassium phosphate should be part of the K^+ supplement when hypophosphatemia is present (as in many hypokalemic patients with diabetic ketoacidosis). Hypomagnesemia, which may cause or accompany hypokalemia (eg, in diuretic-induced hypokalemia), must be corrected because this abnormality may prevent successful potassium replacement.

The debate over the maximum safe infusion rate for intravenous potassium is summarized elsewhere.[90,167] Based on experience

with more than 1300 infusions, one group concluded that under intensive care monitoring, intravenous administrations of 20 mEq/h (by central or peripheral vein) were well tolerated. They also found that each 20 mEq of potassium administered resulted in an average increase in serum [K^+] of 0.25 mEq/L. Others have used significantly larger doses (up to 100 mEq/h) in life-threatening circumstances.[33]

Hyperkalemia results from decreased urinary elimination (renal insufficiency, potassium-sparing diuretics, hypoaldosteronism), increased intake (either orally or intravenously), or redistribution from tissue stores.[20,23] The last mechanism is of major toxicologic importance. Overdoses of both cardioactive steroids (Chap. 62) and Î²-adrenergic antagonists (Chap. 59) cause hyperkalemia by promoting net potassium release from its intracellular reservoir. Presumably because of other protective mechanisms, overdose with a Î²-adrenergic antagonist produces only a moderate rise in serum [K^+] (usually to 5.0â€“5.5 mEq/L). By contrast, a similar rise in serum [K^+] as a consequence of blockade of the Na^+-K^+-ATPase pump during cardioactive steroid toxicity may be lethal. This suggests that hyperkalemia per se is not the cause of the lethality of cardioactive steroid overdose. Thus, the focus of therapy should involve efforts to neutralize or eliminate the cardioactive steroid rather than reduce the serum [K^+].[18] Table 17-8 lists xenobiotics that cause hyperkalemia.

After oral overdoses of potassium salts, patients usually complain of nausea and vomiting. Ileus, and intestinal irritation, bleeding and perforation may complicate the clinical course.[141] In the absence of potassium ingestion, gastrointestinal symptoms of hyperkalemia are usually very mild. Neuromuscular manifestations include weakness with an ascending flaccid paralysis and respiratory compromise, with intact sensation and cognition.[87,105,128] The similarity of these signs and symptoms to those associated with hypokalemia is striking, suggesting that hyperkalemia may be diagnosed with certainty only by laboratory

measurement.

The cardiac manifestations of hyperkalemia are distinct, prominent and life-threatening. Electrocardiographic patterns progress through characteristic changes.[140,141] Although the progression of ECG changes is very reproducible, there is tremendous individual variation with respect to the serum $[K^+]$ at which these ECG findings occur. Initially, the only ECG finding may be the presence of tall, peaked T waves. As the serum $[K^+]$ concentration increases, the QRS complex tends to blend into the T waves, the P-wave amplitude decreases, and the PR interval becomes prolonged. Next, the P wave is lost and ST-segment depression occurs. Finally, the distinction between the S and T waves becomes blurred and the ECG takes on a sine wave configuration (Chap. 5). Hemodynamic instability and cardiac arrest can result. As the patient's serum $[K^+]$ falls with therapy, these ECG changes resolve in a reverse fashion.

The treatment of severe hyperkalemia includes standard airway management, methods to reverse the ECG effects, methods to transfer K^+ to the intracellular space, and methods to enhance K^+ elimination. Pharmacologic interventions, extensively discussed elsewhere,[141] are summarized here. Calcium (eg, $CaCl_2$ 10â€“20 mEq administered intravenously) works almost immediately to protect the myocardium against the effects of hyperkalemia although it does

not reduce the serum $[K^+]$. However, a potentially life-threatening interaction occurs when the patient with cardioactive steroid toxicity is given Ca^{2+} (Chap. 62); thus, this therapeutic modality is relatively contraindicated in such circumstances.

The administration of insulin (and dextrose to prevent hypoglycemia), sodium bicarbonate, and/or inhalation of a Î²-adrenergic agonist all stimulate potassium entry into cells.[9] They reduce the serum $[K^+]$ over approximately 30 minutes, but

potassium begins to reenter the extracellular space over the next several hours. Cationic exchange resins, such as Na^+ polystyrene sulfonate, take somewhat longer (about 45 minutes), but they enhance gastrointestinal potassium loss. Hemodialysis or peritoneal dialysis may be useful, especially when significant renal impairment is present.

Calcium

Calcium is the most abundant mineral in the body and 98â€“99% is located in bone. Approximately half of the remaining 1â€“2% of the body's calcium is bound to plasma proteins (mostly albumin) and most of the rest is complexed to various anions, with free, ionized calcium representing a very small fraction of extraosseous stores. The serum [Ca^{2+}] is maintained through interactions between dietary intake and renal elimination, modulated by vitamin D activity, parathyroid hormone, and calcitonin. More extensive discussions of calcium physiology are found elsewhere.[7,117]

Xenobiotic-induced hypercalcemia is uncommon and usually caused by an increased dietary calcium as a result of milk or antacid usage, or a decrease in its renal excretion such as occurs with thiazide use.[7,20] Cholecalciferol, available as a rodenticide, can increase the serum [Ca^{2+}] by increasing its release from bone, increasing gastrointestinal absorption, and decreasing renal elimination (Chap. 104). Vitamin D toxicity from excessive vitamin intake or supplementation of milk also can cause hypercalcemia.[49,82] Table 17-9 lists other causes of hypercalcemia.

Symptoms of hypercalcemia consist of lethargy, muscle weakness, nausea, vomiting, and constipation. Life-threatening manifestations include complications from altered mental status such as aspiration pneumonia and cardiac dysrhythmias (Chap. 5). Treatment of clinically significant hypercalcemia focuses on

removing the offending agent when possible, decreasing gastrointestinal absorption, increasing distribution into bone, and enhancing renal excretion through forced diuresis with intravenous 0.9% NaCl solution and furosemide.[7,159] Hemodialysis may be required when significant renal impairment is present.

TABLE 17-9. Xenobiotic Causes of Altered Serum Calcium

Hypocalcemia	Hypercalcemia
Aminoglycosides	Aluminum
Bicarbonate	Androgens
Bisphosphonates	Antacids (calcium containing)
Calcitonin	Antacids (magnesium containing)
Citrate	Cholecalciferol and other Vitamin D analogs
Ethanol	Glucocorticoids
Ethylene glycol	Lithium
Fluoride	Milkâ€“alkali syndrome
Furosemide	Tamoxifen

Mithramycin	Thiazide diuretics
Neomycin	Vitamin A
Phenobarbital	
Phenytoin	
Phosphate	
Theophylline	
Valproate	

Xenobiotic-induced hypocalcemia is more common than hypercalcemia. Minor, usually clinically insignificant decreases in serum [Ca^{2+}] can occur in association with anticonvulsant[93] and aminoglycoside therapy.[20] Severe, life-threatening hypocalcemia can occur, however, from ethylene glycol poisoning (Chap. 103) or as a manifestation of fluoride toxicity from either fluoride salts or hydrofluoric acid (Chap. 101).[39,161] Complex formation with fluoride or oxalate ions is responsible for the rapid development of hypocalcemia in these settings. Similar effects occur with excess phosphate[164] or citrate[104,162] intake or administration. This mechanism (calcium complex formation) decreases the ionized [Ca^{2+}], but may or may not reduce the measured total serum [Ca^{2+}]. Other drugs and toxins that produce hypocalcemia decrease absorption, enhance renal loss, and/or stimulate calcium entry into cells (Table 17-9).

Symptoms of hypocalcemia consist largely of neuromuscular

findings, including paresthesias, cramps, carpopedal spasm, tetany, and seizures. Although ECG abnormalities are common (Chap. 5), life-threatening dysrhythmias are rare. Treatment strategies focus on calcium replacement. When hypomagnesemia or hyperphosphatemia is present, these abnormalities should be corrected or calcium replacement may fail.

Magnesium

Magnesium is the fourth most abundant cation in the body (after Ca^{2+}, Na^{+}, and K^{+}), with a normal total body store of about 2000 mEq in a 70-kg human.[131] Approximately 50% of magnesium is stored in bone, with most of the remainder distributed in the soft tissues. Because only approximately 1â€“2% of magnesium is located in the extracellular fluid, serum concentrations correlate poorly with total body stores.[132] Magnesium homeostasis is maintained through dietary intake, and renal and gastrointestinal losses, modulated by hormonal effects.[7]

Clinically significant hypermagnesemia is uncommon in the absence of renal failure, except when massive parenteral infusions of magnesium salts overwhelm renal excretory mechanisms. This has been reported with inadvertent intravenous infusion,[19,25,73,113] urologic procedures involving irrigation with magnesium salts,[45,83] and ingestion of large quantities of magnesium-containing antacids[106] and cathartics.[46,54,59] Of concern is iatrogenic overdose from the use of magnesium-containing cathartics as part of routine poison management.[56,84,152] In a series of poisoned patients, a single-dose of a magnesium-containing cathartic failed to produce any demonstrable rise in serum $[Mg^{2+}]$.[153] However, patients who received three doses of magnesium sulfate over 8 hours had a statistically significant increase in their serum $[Mg^{2+}]$.[153] Thus, as with the cathartic sorbitol, the potential for iatrogenic toxicity exists, mandating cautious use of magnesium-containing

cathartics, especially in patients with renal insufficiency. Table 17-10 lists the causes of hypermagnesemia.

The symptoms of hypermagnesemia correlate roughly with serum concentrations but depend somewhat on the rate of increase and host factors. At serum [Mg^{2+}] of about 3â€“10 mEq/L, patients feel weak, nauseated, flushed, and thirsty. Bradycardia, a widened QRS complex on ECG, hypotension, and decreased deep tendon reflexes may be noted. As concentration increases, hypoventilation, muscle paralysis, and ventricular dysrhythmias occur. Serum [Mg^{2+}] greater than

10 mEq/L, and especially those greater than 15 mEq/L, often cause death.

TABLE 17-10. Xenobiotic Causes of Altered Serum Magnesium

Hypomagnesemia	Hypermagnesemia
Aminoglycosides	Antacids (magnesium containing)
Amphotericin	Cathartics (magnesium containing)
Cisplatin	Lithium
Citrate	Magnesium sulfate
Cyclosporine	
DDT	

Ethanol	
Fluoride	
Foscarnet	
Insulin	
Laxatives	
Loop diuretics	
Methylxanthines	
Osmotic diuretics	
Phosphates	
Strychnine	
Thiazide diuretics	

Hypermagnesemia should be considered a life-threatening disorder. When significant neuromuscular or ECG manifestations are noted, administration of $CaCl_2$ 5â€“20 mEq intravenously will reverse some of the toxicity.[7,67] Further therapy should focus on enhancing renal excretion by administering fluids and loop diuretics such as furosemide.[67] In the presence of renal failure or inadequate renal excretion, hemodialysis will rapidly correct hypermagnesemia.

Xenobiotic-induced hypomagnesemia is common, but rarely life-threatening. Renal losses (caused by diuretics), gastrointestinal losses (caused by ethanol), intracellular shifts from insulin[102] or Î²-adrenergic agonists, and complex formation (by fluoride or phosphate) are common.[7] Table 17-10 lists these and other causes of hypomagnesemia. Of note, many causes of hypomagnesemia also cause hypokalemia and hypocalcemia.[6] Therefore, when hypomagnesemia is suspected or discovered, the presence of other electrolyte abnormalities should be sought.

The symptoms of hypomagnesemia are lethargy, weakness, fatigue, neuromuscular excitation (tremor and hyperreflexia), nausea, and vomiting.[30,36] Dysrhythmias may occur, especially during therapy with cardioactive steroids. Signs and symptoms consistent with hypocalcemia and hypokalemia also may be present.

Treatment involves removing the offending agent (if it can be identified) and restoring magnesium balance. Although either oral or parenteral supplementation is usually acceptable for mild hypomagnesemia, parenteral therapy is required when significant clinical effects are present. When oral therapy is indicated, a normal diet or magnesium oxide, magnesium chloride, or magnesium lactate in divided doses (magnesium 20â€“100 mEq/d) will often correct the hypomagnesemia.[6,7] When hypomagnesemia is severe or symptomatic, several authors suggest that in the absence of renal insufficiency, the administration of magnesium sulfate 16 mEq (2 g) intravenously over several minutes to a maximum of 1 mEq/kg of magnesium in a 24-hour period.[7,30,81] During any substantial magnesium infusion, frequent serum [Mg^{2+}] determinations should be obtained and the presence of reflexes documented. If hyporeflexia occurs, the magnesium infusion should be discontinued.

Summary

The management of poisoned or overdosed patients must include an evaluation of their fluid, electrolyte, and acidâ€“base status. Abnormalities in acidâ€“base and water balance, and alterations in potassium, calcium, and magnesium metabolism are common in such patients, and often are life-threatening. Conversely, the possibility of xenobiotic ingestion or administration must always be considered when patients present with abnormalities of water, electrolyte, or acidâ€“base balance. This is because these abnormalities are frequently caused by therapeutic doses of many drugs. Clearly, an appreciation of the pathophysiology of these abnormalities and a rational approach to their correction are essential for reducing morbidity and mortality. Finally, fluid and electrolyte abnormalities may result from the therapy of poisoned patients. Thus, the poisoned or overdosed patient must be monitored and reevaluated as treatment progresses to insure that iatrogenic fluid, electrolyte, or acidâ€“base disorders do not complicate the clinical course.

Chapter 18
Psychiatric Principles

Mark R. Serper

Michael H. Allen

Psychiatric problems may be the cause or the effect of many toxicologic presentations. Suicide attempts and aggressive behaviors are commonly associated with intoxications and can be uniquely difficult to assess and manage. These patients are often viewed as either totally voluntary and deliberate or totally â€œout of controlâ€• and irrational. The truth is usually more complex, with some aspects occurring within the patient's awareness and control and other aspects either unknown or overwhelming to the patient. This chapter presents schemas for understanding suicide and violence, in order to enable the physician to adopt the appropriate role of both diagnostician and medical decision maker.

Suicide and Self-Injurious Behavior

Suicide and self-injurious behavior are among the most common and challenging emergency department (ED) presentations. It is estimated that there are 790,000 annual suicide attempts in the

United States; more than 30,000 people complete suicide every year.[15] Suicide is the 11th leading cause of death in America and third leading killer of young people. In 2002, for example, more than 124,000 visits to US emergency departments were made after attempted suicides or other self-harm incidents among persons between 10 and 24 years of age.[15] A recent population-based estimate of the 12-month prevalence of suicide attempts was 0.7%, suggesting that perhaps 10 times more attempts occur than present to EDs.[22] These statistics reveal that suicide is significantly underreported. One survey estimated a 12-month incidence of suicidal ideation at 5.6%, representing some 10.5 million people.[25] According to the latest available data males are 4 times more likely to die from suicide than females and of the 24,672 suicides reported among men in 2001, more than 60% involved the use of a firearm.[6] In contrast, women are 3 times more likely to attempt suicide than men and often use xenobiotics in their attempt.

Suicidal crises are heterogeneous, with suicide the final outcome of many possible psychiatric conditions and social circumstances. This distinction is rendered even more complex by the possibility or probability that suicidal ideation may be deliberately concealed, making it critical for healthcare providers to address this issue with all patients as part of their medical history. Consequently, early identification of the acutely suicidal patient places an extreme burden on the emergency physician to detect and intervene to prevent death.

Suicide is usually discussed in terms of attempts and completions. When the term *suicide* is used alone, it refers to completed suicide. The two are considered separately because those who attempt and those who complete suicide appear to constitute somewhat different groups.

Patients with self-inflicted injury are also common ED presentations. In 2000, for example, there were more than 40

million ED visits because of injuries. Of these, 3 million were the result of intentional injuries, and of this group, approximately 25â€“30% were intentionally self-inflicted.[48] A common method of injurious behavior takes the form of self-poisoning. A recent British study found that approximately 50% of patients who present to the ED with 2 or more episodes of self-poisoning were at increased risk of death by suicide in the future.[14] These investigators found that the factors associated with an increased risk of suicide from one self-poisoning episode to the next included an increase in the number of drugs ingested, an increase in the dose ingested, an increase in coma score and an increase in subsequent drug or alcohol abuse.[14] Additional factors associated with future death included patient consumption of 70 or more tablets or capsules, patients who had an increase of 2 or more in the number of different agents ingested from prior visits, and patients' who had an increase of 50 or more in the number of defined daily doses ingested. Self-poisoned males older than age 45 years who had a delay to toxicology consultation were also at increased risk for death.[11] In addition, Israeli investigators found that the large majority of self-poisoning patients were 15- to 20-year-old women who used pharmaceuticals and had neurologic impairment.[11] A group of Finnish investigators followed a cohort of 100 consecutive self-poisoned patients in Helsinki for 37 years.[70] They found suicides in this group continued to accrue throughout the 37 years after the initial suicide attempt. The authors' concluded that a history of a self-poisoning suicide attempt represents a high suicide risk throughout the adult life span.[70] These recent studies reveal that patients who attempted suicide by self-poisoning represent a group of people with persistent suicidality.[11 , 70]

However, it is difficult for the emergency physician to assess the patient's intention for self-injurious behavior. Self-injurious behavior may be caused by factors other than suicidal intent. The challenge for emergency physicians is determining which of those

among the patients presenting with self-injurious behaviors are seriously suicidal. Failure to do so is associated with some of the largest

damage awards in emergency medicine. Intentional self-poisoning is a common method of attempting suicide, but this must be differentiated from unintentional overdoses, particularly in the young, the developmentally challenged, those with dementia, and those who chronically abuse drugs.[30] In addition, self-injurious behavior may be the result of a patient's attempt to manipulate others or their environment, to cope with emotional lability, or as a reaction to delusions or hallucinations.

Self-poisoning to attempt suicide is also more common in younger women with depression or personality disorders. But the methods preferred by women have shifted over time. While self-poisoning remains common, since the 1960s and 1970s use of this method has decreased, perhaps in part because of changing prescription practices and, in part, because of other social changes. In 1970, 47.9% of suicides committed by women were by poisoning compared to 34.6% in 1993. In 2002 both women and men were most frequently the victims of self-inflicted gunshot wounds (54%), while self-poisoning accounted for only 17.3% of all suicides.[41]

The tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) are the most common drugs implicated in suicide because of their toxicity and frequent use in the populations at risk. The decline in self-poisoning may be related to decreased use of these potentially more lethal medications.[21, 37] Data from the Drug Abuse Warning Network suggest that newer antidepressants are significantly safer in overdose. Although the risk of an attempt is roughly similar, the risk of death is 8.5 times greater with desipramine than fluoxetine.[40]

Psychiatric Management of Self-Poisoning

Table 18-1 depicts a case of suspected self-poisoning from the starting point of prehospital care through the completion of a comprehensive assessment and treatment planning.

Focused Psychiatric Assessment

At a relatively early point in the patient's course, when the patient can be cooperative, a focused psychiatric assessment is critical to address specific clinical concerns. A thorough psychiatric consultation is warranted, once the patient is medically stable. The determination that the patient is stable is not solely established on the basis of blood concentrations of a xenobiotic or ancillary medical tests, but rather when the emergency physician or medical toxicologist with an understanding of pharmacokinetics deems it appropriate. Psychiatric examination is warranted when the altered mental status has cleared. There are several reasons for this approach.

Patient course
Patient found in the community unresponsive
Patient monitored in the ED; vital signs stable; still unresponsive
Patient lethargic but cooperative; answers simple questions
Patient fully awake and alert
Evaluation complete
Treatment course
Prehospital
Triage
Medical assessment
Observation and monitoring
Formal psychiatric evaluation
Treatment planning
Physician course

Patient identification
Search for prescription drugs, drug paraphernalia
Assessment of cardiac and respiratory functions
Orogastric lavage(?)
Activated charcoal
Diagnostic testing (blood studies, ECG, toxicology)
Contact collateral sources for history
Prior records
Focused psychiatric assessment: elopement, aggressive behavior, decisional capacity, addressing confidentiality, and immediate suicide risk
Comprehensive psychiatric assessment: diagnostic interviewing, risk factors, future risk
Treatments: medication, hospitalization, substance abuse, crisis intervention family therapy

Case Evolution Disposition

TABLE 18-1. Case Presentation: Suspected Self-Poisoning

The physician should not unequivocally attribute altered mental status to poisoning or intoxication until the signs of altered consciousness have resolved and cognitive functions have returned to normal. Until that time, other toxic metabolic and structural conditions that might coexist with, or masquerade as, intoxication cannot be excluded. If the patient's cognitive functioning is impaired by xenobiotics critical historical details may be unreliable. It should be understood that much of what the patient reports may be ephemeral, caused by the predictable temporary and reversible effects on mood of these xenobiotics.

A focused assessment is necessary to ascertain elopement risk or decisional capacity. Subacute residual CNS effects of ingestions such as confusion, fatigue, and fear can dispose patients to wander or elope. Additionally, the patient's intentions remain

unclear at this point, and the question of unintentional versus intentional exposure to a xenobiotic cannot be completely resolved. For these reasons, a high level of supervision should be maintained, and a patient should not be allowed to leave until an adequate assessment of the patient's mental status is completed. Depending on the architecture and organization of the ED and personnel, it may be sufficient to place the patient in an open area in the direct line of sight of nursing staff. If such an arrangement is not possible, or if the patient is agitated and disruptive, it may be necessary to separate the patient from the general population. Under these circumstances, an individual aide should be assigned to observe the patient on a â€œone-to-oneâ€• basis. Safe physical and/or chemical restraints may be necessary to prevent further injury both to patient and staff.

In general, patients are presumed competent and must consent to treatment, but the issue of decisional capacity frequently arises. Patients may request their discharge, refuse care, or become aggressive. Aggression may arise from lingering effects of a toxic ingestion, severe anxiety, fear, anger at the loss of autonomy, or the discomfort associated with unpleasant procedures. Although patients may respond to verbal limit setting and repeated explanations of

their care, they may also require chemical (pharmacologic) or physical restraint and involuntary treatment. Patients are not allowed to make poor healthcare decisions if their ability to weigh the risks and benefits of the proposed care is limited by cognitive deficits or mental illness. In the setting of intoxication, appropriate care may be provided under the doctrine of implied consent.

The emergency exception to the doctrine of informed consent may also apply in circumstances where self-injury is suspected. The emergency exception permits forcible detention, restraint, medication over objection, and necessary medical care until

psychiatric assessment can be accomplished. After the management of the immediate medical emergency and resolution of intoxication, suspected self-injury is sufficient evidence of impaired decisional capacity for the emergency physician to hold a patient for further psychiatric assessment. The emergency physician should note the patient's objections in the patient's medical record and indicate the basis for the determination of diminished capacity.

After the intentionally self-poisoned patient is stabilized, there may be a need for a more thorough assessment of decisional capacity. Psychiatric consultation is appropriate at this stage to help document the degree of impairment, determine the etiology, and predict the likely course.

Immediate Risk

After these safety considerations have been addressed, the aim of the focused psychiatric assessment moves toward a determination of immediate suicide risk. This examination should answer the following questions:

- What is the patient's attitude toward lifesaving care?
- What are the patient's current wishes with regard to living or dying?
- What are the patient's thoughts about his or her rescue and likely recovery?

These questions can only be answered in the course of a frank discussion between the patient and the emergency physician. The physician should not be concerned about â€œprovokingâ€• further self-injurious impulses by having this vital discussion; many patients will be relieved that the healthcare provider is speaking directly about their distress.

Reliability and Confidentiality

Mention should be made here about the difficult issues of reliability and confidentiality with regard to gathering history. Evasiveness, lack of detail, inconsistency, and improbability may lead to an unreliable history. It is appropriate to confront the patient with the implausible aspects of this history and offer an opportunity for the patient to rethink his or her history. This is often successful, although subsequent reports are, of course, equally suspect.

The most important step from the standpoint of both clinical care and risk management is to locate other sources of information to clarify the patient's situation. A careful review of any previous medical and psychiatric records is critical. Any pattern to a patient's presentations such as increasing frequency, more aggravated behavior, or disheveled appearance should be noted.

Collateral contacts are another important source of information, although the level of involvement, sophistication, and reliability of the collaterals must also be taken into account. In the interest of providing necessary medical and psychiatric care for a patient, the ED staff may make contacts that are limited to soliciting information without specific consent. An effort should be made to obtain consent for any broader discussion with family, friends, or other physicians. The patient may express concern about the ED staff contacting a family member or counselor. Any information to be imparted to third parties can be negotiated in advance with the patient. The patient may restrict consent to receiving information only and may withhold consent to impart certain information. More caution is indicated in contacting an employer. Although disclosing information about the patient without the patient's consent is a breach of confidentiality, a physician may do so in the interest of protecting the patient.[5]

Comprehensive Psychiatric Assessment

The comprehensive psychiatric assessment includes a characterization of the suicidal ideation present, exploration of certain so-called risk factors, and the formulation of a diagnostic impression. These three elements help to determine the attendant risk and guide treatment planning.

Stress Vulnerability Model

The best understanding of suicide at this time is that it results from intrinsic vulnerability factors interacting with extrinsic circumstances. Intrinsic vulnerability may be conferred by a variety of traits such as impulsivity or conditions such as depression, anxiety, and hopelessness. Extrinsic factors include stressful life events, access to lethal means, and a host of other factors, positive and negative.

Characterization of Suicidal Ideation

The core of the suicide risk assessment is a detailed discussion of the patient's suicidal thoughts and urges. This must be included in every mental status examination. It is important to establish rapport and introduce the topic in an appropriate context in order to improve the patient's candor. This evaluation requires significant time and skillful interviewing, for which there is no substitute. This approach will enhance the therapeutic quality of the interview as well as its reliability. For example, almost everyone has had some period in life when he or she was discouraged. The clinician may spend a few moments talking with the patient about the point in life when the patient was most disheartened. This is done by asking the patient if he or she has been feeling â€œdownâ€• lately; and if the patient has, by asking if this is the worst the patient has ever felt. If the patient denies recent depression altogether, or indicates that this is not the

worst, it is helpful, for several reasons, to ask the patient to describe the point in his or her life when the patient felt worst. Depression may fluctuate markedly, and characterizing the worst period assures that a prior history of major depression will not be overlooked.

At some point, the physician should ask if, during that worst period in the patient's life, the patient ever felt that perhaps things would never get better (hopelessness), that he or she could not go on (helplessness), or perhaps that he or she would be better off dead (passive suicidal ideation). If failing others was involved in the patient's demoralization (guilt), the physician should ask if the patient had ever felt that others would be better off without him or her. These are common thoughts that most people can endorse without much difficulty and lay the groundwork for discussing more troublesome ideas in the suicidal spectrum. Ultimately, the patient must be asked directly if he or she has ever felt like â€œkillingâ€• himself or herself (active suicidal ideation). Nothing else

will do. The more generic form, â€œhurtingâ€• himself or herself, which might seem to cover more, is in fact confusing to patientsâ€”even those who wish to die do not usually consciously intend to be hurt in the process. The latter is more typical of multiple suicide attempters than suicide completers.

For those patients who have felt like killing themselves at some point, the next step in this scenario might be to establish how the patient is currently and to compare this to a prior episode(s). One dimension to assess is the progression from passive to active suicidal ideation. Suicidal feelings may take the form of a relatively inchoate wish to die, perhaps from a fatal disease or injury, and then proceed to consideration of various active means of hastening death. Planning might range from fleeting thoughts or images of a variety of methods from which the patient recoils, to a more detailed consideration of a particular, realistic method of

choice, to serious planning concerning acquisition of the means, and so-called last acts. At some point the patient goes beyond thinking to acting by hoarding pills or completing his or her will. An astute family member may observe a series of odd conversations including phone calls to distant friends and family members as the suicidal individual begins to implement the plan with a series of vague farewells. In psychological autopsy studies, approximately 50â€“70% of those who completed suicides gave some warning of their intention and 30â€“40% of individuals who completed suicides disclosed a direct and specific intent to kill themselves.[8,63]

Other dimensions to assess include frequency, urgency, chronicity, reactivity to positive and negative external events, and subjective distress. Table 18-2 presents a schema for the detailed characterization of suicidal ideation.

The communication of suicidal ideas either directly or indirectly should not be misconstrued as a â€œcry for helpâ€• and hence evidence of lower risk. Communication is probably related to the degree of preoccupation with morbid thoughts and to personality characteristics that dispose individuals to revealing their thoughts to various degrees.[42]

The risk of suicide increases 50 to 100 times within the first 12 months after an episode of self-harm, compared to the general population risk. About half of all people who commit suicide have a history of self-harm and this ratio increases by 60% in juvenile age groups.[6]

TABLE 18-2. Characterization of Suicidal Ideation

While much is known about the risk of suicide for various groups over time, little can be said with certainty about an individual patient at a particular point in time. There is no one type of â€œtypicalâ€• suicidal patient or clinically useful test or rating scale at this time. Albeit, while one investigator was able to prospectively identify almost all of those who ultimately died by suicide (97% sensitivity), the investigator overpredicted suicide by almost half (56% specificity).[60] However, there is also no patient in distress for whom the risk of suicide is so remote that it need not be considered. Assessment of the potentially suicidal patient begins with a screen for psychiatric illness, substance abuse and history of self-harm.

Psychiatric Illness and Suicide

One major consideration in suicide risk assessment is the occurrence of severe mental illness. Suicide risk for individuals with severe mental illness is 20â€“40 times higher than it is for the general population.[41] Psychological autopsy studies in the United States and Europe over the years have consistently revealed major psychiatric illness to be a factor in suicide, present in 93% of adult suicide cases.[39, 41, 61, 64] This is also true of those who make medically serious suicide attempts.[10, 39] In particular, prospective cohort studies and retrospective case control investigations have revealed clinical depression and bipolar disorder to dramatically increase suicide risk.[16, 42, 75] For mood

disorders, factors correlated with acute suicidality have included current depression, severe anxiety, anhedonia, panic, insomnia, ambivalence, and acute alcohol abuse.[42] After mood disorders, chronic alcoholism is the most commonly reported disorder; it is present in approximately 20% of cases. Moreover, alcoholic patients who also suffer from periodic episodes of depression are at more risk for suicide than patients who present with either disorder separately. As a result, any assessment conducted on a patient with a substance abuse history must include an examination of symptoms of major depression or bipolar illness.[26, 76]

Schizophrenic patients are at risk for suicide at rates comparable to major depression and are 20 times more likely to attempt suicide than the general population.[74] Approximately 50% of schizophrenic patients will attempt suicide and 13% of schizophrenic patients will complete suicide.[13, 74] Additionally, between 5 and 18% of patients with severe borderline personality disorder (especially patients who are comorbid for depression) ultimately

kill themselves.[28, 69] Figure 18-1 shows the odds of suicide attendant to various conditions.[39]

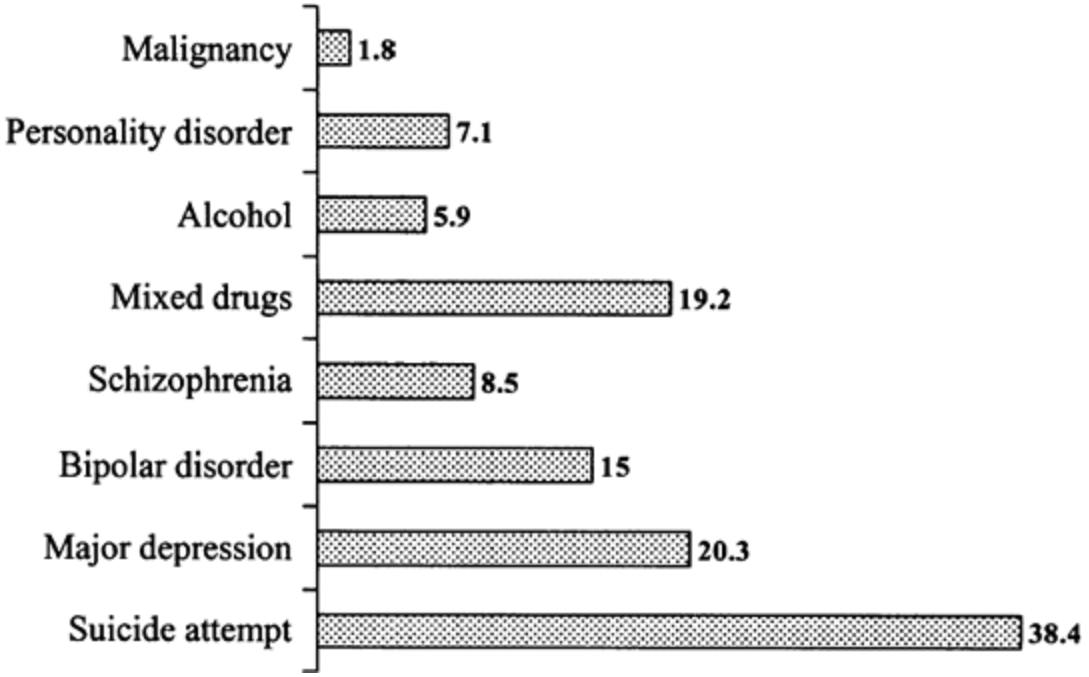

Figure 18-1. Increased likelihood of suicide for various conditions. *(Data adapted from Inskip HM, Harris EC, Barraclough B: Lifetime risk of suicide for affective disorder, alcoholism and schizophrenia. Br J Psychiatry 1998;172:35â€“37.)*

The ability to treat psychiatric disorders such as mood disorders, schizophrenia, and alcoholism suggests that most suicides are preventable. Intentional self-injury, consequently, represents a major, but preventable, US public health problem.

Indeed, a suicide prevention program directed at general practitioners in Sweden was able to demonstrate prevention based on the detection and treatment of depression.[62] The possibility of preventing suicide necessitates a comprehensive psychiatric assessment to identify contributory psychiatric disorders.

The Centers for Disease Control and Prevention (CDC) reported that psychiatric problems in US emergency departments represented approximately 3% of the visits, which is significantly lower than the national psychiatric rate of 20â€“28%.[15] This suggests significant psychiatric underdiagnosis is occurring in the

ED. Emergency physicians, consequently, must enhance the comprehensive nature of their psychiatric screens in order to pick up suicidality and concomitant mental disorders in presenting self-injurious patients.

Demographic Risk Factors

A complete assessment should also include an examination of demographic risk factors. Factors have been identified empirically that place groups of individuals at high risk for suicide. Although this level of prediction is actuarial and reflective of groups rather than individuals, knowledge of these risk factors is important.[50] Although not specifically predictive, suicide is statistically more common in men than women and in whites than in nonwhites. Younger black men, however, have approximately the same suicide rate as white men of the same age. Suicide rates for both black and white adolescents (15 to 19 years of age) have been increasing. In contrast, suicide rates in the those over 65 years of age have decreased 3-fold since 1940, but still occur in disproportionately high numbers.[41, 75]

Previous suicide attempts are an obvious risk factor. However, those who attempt suicide appear to be a somewhat different group demographically and diagnostically. Parasuicidal behavior is more common in 25- to 44-year-olds than in the elderly, and more common in women than men. Existing data also indicate that nonfatal suicide attempters are equally prevalent across racial and ethnic groups.[25, 54] Most individuals who kill themselves seem to do so on the first attempt. Although that suicide attempt is still the strongest predictor of suicidal outcome, only about 1 in 10 attempters is ultimately successful.[35, 60] Multiple attempters also appear to have higher risk than those who make a single attempt.[32, 70] Medically serious attempts may be a better marker of risk. Those who make serious attempts tend to share with completers a higher rate of serious mental illness.[9]

A number of avenues of inquiry suggest that violent suicide attempts are associated with a persistent deficiency in brain serotonin levels. Impulsive types of aggression and impulsive suicidal behavior have been linked to serotonergic dysfunction in prefrontal cortical regions of the brain.[23] This deficiency has been measured in postmortem brains and spinal fluid of suicide victims and survivors of violent attempts compared to nonviolent attempts and to other patients. Serotonergic deficiencies persist during periods of acute psychiatric illness as well as remission. Hopelessness has also received a significant amount of study as a potential predictor of suicide. However, hopelessness appears to have high sensitivity but low specificity.[10] Identifying hopelessness as a problem also suggests possible interventions.

Ultimately, most persons belonging to a high-risk group do not commit suicide, and some individuals with no apparent risk factors do. Many risk factors are not modifiable. This type of information, then, weighs most heavily in the assessment in the absence of other more specific data, early in the hospital course, or in the case of the uncooperative or hostile patient. The best foundation for treatment planning and clinical decision making is direct examination and clinical diagnosis.

Treatment

Following the comprehensive psychiatric assessment, the next step is deciding on treatment alternatives. Any patient who has made a suicide attempt must be considered to be at risk, and some further intervention is warranted. The risk of a subsequent lethal attempt is approximately 1% per year over the first 10 years. The risk is highest in the first 1 month to 1 year.

The treatment alternatives available will depend on the psychiatric sophistication of the staff available to the ED at any given time. This section describes the commonly used interventions in the ED; they can be used singly or in combination.

Medications can be used acutely in the treatment of severe anxiety or psychosis; however, in the case of antidepressants, a period of weeks is required for therapeutic effect, so their immediate use is not indicated in the ED. In fact, there are concerns about prescribing medications with relatively high potential for lethality in overdose, such as the cyclic antidepressants and nonselective monoamine oxidase inhibitors, to persons who have recently attempted suicide. However, newer antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs), can be used as first-line drugs for treatment of most depressions and are relatively safe in overdose. A marked drop in the number of deaths per million antidepressant prescriptions was observed between 1970 and 1974 in Europe.[37] Nonetheless, the initiation of antidepressant therapy by the nonpsychiatric physician is not recommended unless a tight linkage can be made between discharge and immediate (within days) aftercare by either a community outreach team or a crisis clinic.

Patients with depressive disorders may suffer from significant anxiety, as may patients with overwhelming situational stressors such as job loss, new financial hardship, bereavement, or divorce.

The prescription of a short course of a benzodiazepine may provide significant relief to the patient in crisis.

After the patient's immediate symptoms have been treated in the emergency department, the next treatment decision is determining the setting in which further treatment may safely be provided. Not all patients with suicidal ideation or even significant attempts necessarily require hospitalization, and there is still a substantial stigma attached to psychiatric hospitalization. In general, it should be the treatment used if less restrictive measures cannot insure the patient's safety. If significant doubt exists about the safety of outpatient treatment, the patient should be held in the ED for further evaluation, admitted to a general hospital with close

nursing supervision, or admitted to a psychiatric unit. â€œHolding bedsâ€• now available in some larger psychiatric emergency departments are ideal for this purpose. Some localities may also have crisis outreach services that follow the patient after discharge from the ED and improve appropriate monitoring and continuity of care.

Patients most likely to respond to interventions in the ED are individuals who until recently have been stable but who, as a result of some external event, find their way of life threatened. This acute change results in a painful state of anxiety and the mobilization of some combination of adaptive and maladaptive coping strategies. Finally, a second event, the precipitant, intensifies the anxiety to the point that the patient cannot tolerate the instability and is thrown into crisis. The patient then feels desperate and may be completely immobilized or vulnerable to various strong impulses including the impulse to run away, strike out at someone else, or kill himself or herself. Reality testing is preserved, and no major psychiatric syndrome is present. The patient accurately perceives his or her situation, understands that the current reaction is a psychological problem, and is highly motivated to obtain help. The crisis may last for a matter of hours or weeks prior to the ED presentation and will ultimately resolve. Such patients respond well to crisis intervention and may actually undergo some positive development in the course of treatment.

By contrast, patients whose condition has been deteriorating for some time in the absence of significant stressors, and who appear on examination to be suffering from severe depressive symptoms, are unlikely to benefit rapidly from supportive techniques. If such patients present with suicidal ideation or attempts, it will be difficult, though not impossible, to manage them outside the hospital.

Outpatient settings have the advantage of maintaining the patient's functioning as much as possible. Work and child care

responsibilities, financial obligations, and social relationships are not disrupted. Unnecessary regression is halted. The patient is able to assume more responsibility for his or her outcome, and independence helps preserve self-esteem. These individuals remain closer to and more engaged with the people and situations with whom and with which they must learn to cope. Their morale may be rapidly improved by the combination of support, planning, and modest early treatment successes.

In some cases, though, these same factors may be disadvantageous. Routine tasks may seem overwhelming. High levels of conflict may render major relationships at least temporarily unworkable. Inpatient settings offer the advantage of respite, high levels of structure, more intensive professional and peer support, constant supervision, and, usually, more rapid pharmacologic and psychosocial intervention. The physical plant also reduces, although it cannot eliminate, the possible means of suicide.

The choice of inpatient or outpatient setting will depend on the balance of strengths and weaknesses of the patient, the involvement and competence of family or friends, the availability of a therapist in the community, and the ongoing stresses in the patient's life and this decision is best made by a psychiatrist. Because a psychiatrist is not always present in many facilities, a trained mental health professional should be on call to every emergency department. This may be a psychiatric social worker, nurse clinician, or psychologist. When such services are not available, it is appropriate to detain patients in the ED until a practitioner with specific competence is available or to transfer the patient to another facility for evaluation. Every state has laws that provide for the involuntary commitment of the mentally ill under circumstances that vary from state to state. Any acute, deliberate self-injurious behavior would generally qualify. Chronic, repetitive dangerous behavior that is not â€œdeliberate,â€• such as frequent unintentional opioid, alcohol, sedative-hypnotic, or illicit

â€œrecreationalâ€• psychoactive drug overdoses warrant careful evaluation. In the absence of psychiatric illness, involuntary treatment is usually not necessary. The practitioner should be familiar with the criteria for commitment and the classes of healthcare providers so empowered under state law.

There are other treatment interventions that can be provided in the emergency setting, including crisis intervention, substance abuse counseling, and family therapy. A single session in the ED may be sufficient to defuse a crisis or to spur the drug-abusing patient to seek help. Alternatively, the intervention may be initiated in the ED and continued as an outpatient.

Crisis intervention is a brief, highly focused therapy that seeks to deconstruct how a crisis occurred, with an the intent of examining the patient's role. Often, patients have distorted perceptions of the crisis, and a gentle â€œcorrectionâ€• of catastrophic thinking can be extremely helpful. An example follows:

- Patient: â€œI'm going to be broke and unemployed the rest of my life.â€•
- Physician: â€œHow did you get your last job?â€•
- Patient: â€œWell, I interviewed a couple of times.â€•
- Physician: â€œSo people have hired you in the past, right?â€•

The crisis is presented to the patient as an unfortunate and perhaps tragic experience that the patient can overcome. Ideally, the patient should have a relief of symptoms and learn how crises may be avoided in the future. This insight intervention will likely fail for patients with severe depression because of the presence of profound hopelessness. It is best used for patients who give a history of high functioning just prior to the crisis.

Substance abuse treatment is ultimately an intermediate (weeks to months) to long-term (months to years) intervention. However,

there are powerful initial steps that the emergency physician can take. Chief among these is confronting the patient about the medical consequences of substance use. This can take the form of discussion only, or the physician can invite the patient to examine clinical laboratory results or view remarkable clinician/diagnostic findings (hepatomegaly, repeated fractures from falls, increased liver enzymes or evidence of â€œsilentâ€• past myocardial infarction). There is little to be lost from a respectful but blunt confrontation of the patient's deterioration, and he or she may listen to a physician rather than family or friends. Peer counseling is particularly useful in addictive disorders; if possible, patients should be referred to community 12-step programs such as Narcotics Anonymous and Alcoholics Anonymous. Family therapy can occur as a series of sessions over the long-term or can be useful in the emergency setting to defuse a crisis, reinstate social supports for the patient, or

educate families about mental illness. It is most important to respect a patient's request as to the level of family involvement, because in the emergency setting, a patient may be either too angry or ashamed to confront his or her family. It is prudent to defer to the patient's wishes, and to assure the family that the patient is safe and that you will keep them as informed as confidentiality and discretion allow at a later date.

Violence

Aggression also presents unique challenges to the emergency physician. Moreover, aggression is intimately related to suicidal behavior. Chronic aggression and impulsivity are risk factors for suicidal behavior. Also like suicidal patients, aggressive patients are difficult to treat and they tend to elicit strong negative reactions in ED personnel.[66] In one study of violence in the ED, directors of residency programs in emergency medicine were surveyed as to the frequency of verbal threats, physical attacks,

and the presence of weaponry in the area. Of the 127 institutions surveyed, 74.7% of the residency directors responded; 41 (32%) reported receiving at least one verbal threat each day; moreover, 23 (18%) reported that weapons were displayed as a threat at least once each month. Fifty-five program directors (43%) noted that a physical attack on medical staff occurred at least once a month.[45] In a second study, the authors conducted a retrospective review of university police log records and ED staff incident reports to examine the problem of violence in the ED setting. Almost 75% of the incidents occurred during the evening or night. Of the 686 episodes of violence in this study, more than 25% required physical restraint or removal from the premises. In addition, it was found that the police responded to the ED nearly twice daily.[59] These studies underscore the need for timely identification of the violent patient, as well as appropriate management for this diagnostically heterogeneous group. The assessment and management of the violent patient should include provisions for patient and staff safety as well as a thorough search for the cause of violent behavior.[66] This section addresses the differential diagnosis of violent behavior, the pharmacotherapy of aggressive and/or agitated behavior, and the use of seclusion and restraint. It also provides an overview of potential risk factors for violent behavior.

Stress-Vulnerability Model of Aggression

As in the case of suicide, there are many and varied causes of violent behavior, some more social and some more medical in nature. It is most helpful to think of violence as the outcome of a dynamic interaction among numerous factors both intrinsic and extrinsic to the individual, some of which promote and some of which ameliorate the potential for violent behavior at any given moment. This is the stress-vulnerability model. Education may

provide alternatives to violence, but delirium may cause an otherwise nonviolent person to misinterpret healthcare efforts, in which case, education is of no benefit at that time. Hence, the individual becomes violent under circumstances that would not normally be sufficient to provoke a violent outburst. Some patients, on the other hand, come from cultures in which aggressive behavior is more acceptable, and these patients require little stress or provocation before responding in what can be perceived as aggression by western cultural standards.

In the ED, likely medical sources of vulnerability include metabolic derangements, exposure to xenobioticsâ€”both licit and illicit, withdrawal syndromes, seizure disorders, head trauma, psychotic states, and personality disorders. Additionally, patients with severe pain, delirium, or extreme anxiety can respond to the efforts of emergency personnel with resistance, hostility, or frank aggression.

Prediction

Research on risk factors for community violence may not apply to the prediction of inpatient violence. Some researchers have postulated that violence committed outside the hospital may not be predictive of inpatient violence and that hospital violence may result from the interaction of patients with specific factors found in the hospital environment.[36 , 66] Other studies are contradictory.[58 , 68] Consequently, prior violence is not a perfect predictor of future violence. Other factors, such as mental illness and substance abuse, need to be examined in order to make meaningful predictions of inpatient violence for each individual case.[66] One study found that the most common types of hospital violence were incidents of aggression against objects in the hospital (56.7%), violence directed against the hospital staff (27.8%), and violence directed against other patients (14.4%).[67] In this study, men were not found to be committing significantly

greater incidents of violence than women. Other studies concur that male patients are not necessarily more of a risk for inpatient violence than female inpatients. For example, researchers examining inpatient violence found that close to half of the violent incidents were committed by female patients,[43, 61] and the number of violence-related injuries committed by male and female inpatients were almost proportional to the ratio of male and female inpatients on the unit. The conclusion was that gender should not be considered a risk factor for inpatient violence. Long hospitalization was not considered a factor predictive of violence for the majority of inpatients. As with outpatient violence, the correlation of violence with younger age appears to hold true in the inpatient setting.[53, 61, 62]

Substance Use

The association between substance use and violence is well established. Alcohol is found in the offender, the victim, or both in one-half to two-thirds of homicides and serious assaults.[17, 61] Substance abuse is seldom the sole cause, but it may contribute to violence in a number of ways. The direct pharmacologic effects include disinhibition and misinterpretation, suspiciousness, or paranoia. Psychological effects of substance use include cultural expectations of appropriate behavior under the influence and the ability to excuse or disavow inappropriate behavior that occurs while intoxicated. Substance use then interacts with other physiologic, cognitive, psychological, situational, and cultural factors including any underlying mental illness. A tripartite model has been described: (a) systemic violence related to drug distribution, (b) economic compulsive violence associated with the criminal activity necessary to sustain a drug habit, and (c) psychopharmacologic violence resulting from the direct effects of the particular xenobiotic.[30, 31]

Mental Illness

The relationship between mental illness and violence is also complex. Efforts made to destigmatize mental illness have confused the issue, but it seems clear that mental illness is associated with a greater risk for violence.[61] In one large epidemiologic study, the prevalence of violence for those with no disorder was 2%. Schizophrenia was associated with an 8% rate of violent behavior, and other mental disorders all had similar prevalences of approximately

12%. But of all respondents reporting violent behaviors, 42% had a substance use disorder. Substance use more than tripled the rate of violence for individuals with schizophrenia. Mental illness appears to reduce the threshold for aggression, and the more comorbid conditions present, the greater the risk.[71, 72]

Researchers are consistently finding a greater prevalence of personality disorders among violent inpatients than among nonviolent inpatients.[55] However, antisocial personality is the condition most strongly associated with both substance use and aggression. In one study, when the history of juvenile deviance was controlled, alcohol, the drug most commonly associated with violence, accounted for only 2% of the violent behavior.

In conclusion, some aggressive behavior is attributable to the direct pharmacologic effects of xenobiotics, but probably represents only a modest fraction. Substance use is also a part of the setting of violent behavior in the community, a coincidental part of the lifestyle of violent individuals and both substance use and violence are related to common underlying characteristics such as a character disorder.

Medication Noncompliance

Many research studies currently list medication noncompliance as

a risk factor for violence that is as serious as substance use or mental illness. One such study associated medication noncompliance and substance use with increased violence risk in the mentally ill.[73] It suggested that medication noncompliance may lead to self-medicating through the use of illicit xenobiotics, and substance use may lead to further medication noncompliance. These two factors together may then have the effect of increasing violence for the mentally ill. This study also suggested that low insight into their illness can be associated with greater violence. However, they found that poor insight was correlated with substance use and medication noncompliance, so it is unclear if poor insight is truly predictive. Other studies have replicated these findings.[72]

Patients entering the ED who did not adhere to their medications as outpatients may be more of a risk for inpatient violence. Furthermore, inpatients who refuse to adhere to medication prescribed in the hospital also are more of a risk for violence, especially when comorbid with substance abuse disorders.

Additional Factors in Aggressive Behavior

Many of the factors correlated with aggression are easy to observe and monitor in the hospital. However, some additional factors that influence violent behavior may not be as easy to detect. For example, one study examining violent behavior found that most violent incidents in the hospital occur on Mondays and Fridays, with very few incidents on weekends.[44] These violence research investigators suggested that the analysis was comparable in the general population as Mondays and Fridays have special significance in the workweek and weekends are usually less stressful. This finding illustrates the point that seemingly minor social stressors can be as conducive to violent behavior as any other factor.

Furthermore, researchers have postulated a seasonal variation of violence.[19] They reported finding an increase in the frequency of assaults by inpatients during the winter months and hypothesized that increased population density, cold temperature, and less sunlight during the day could account for the increased violence. This finding is in contrast to the literature on outpatient violence, which has reported greater incidence of violence during the warmer months.[7] However, this same review conceded that any extreme temperature could evoke aggressive feelings and frustration. Yet another study examined the relationship between temperature and violence and found that more aggressive acts occur during the summer months, both in the hospital and in the community.[27] They cited several explanations, one of which was that the high rate of staff turnover, as vacations are taken, disrupts the social networks that the patients have established, evoking aggressive feelings.

Although it is unclear whether the cold can provoke aggression as much as it has been established that heat can, it does seem clear that overcrowding and social stressors can lead to violent behavior. If the effects of temperature and social stressors (eg, holidays) correlate so drastically with violence in the community, it is likely that such effects would have even more impact when comorbid with severe mental illness, substance use, or any of the other risk factors of aggression.

Assessment

The comprehensive evaluation of the violent patient should include a complete physical examination. The examination may reveal the underlying cause of the violent behavior as well as insuring the treatment of any secondary patient injuries. Laboratory analysis may include blood chemistries (thyroid-stimulating hormone, glucose, electrolytes including calcium and liver enzymes), a complete blood count, lumbar puncture and neuroimaging as

guided by the examination and clinical history.

Illicit xenobiotic and alcohol use often present with symptoms of violence. Acute intoxication with cocaine can produce extreme psychomotor agitation, delirium, and transient psychosis characterized by paranoia and hallucinations; a clinically indistinguishable syndrome can be seen following the ingestion of amphetamines. Phencyclidine intoxication is manifested by assaultiveness, muscle rigidity, dysarthria, nystagmus, autonomic instability, and ataxia. Alcohol intoxication is characterized by typical signs of cerebellar dysfunction such as slurred speech, gait ataxia, and incoordination; however, patients who are intoxicated are also at risk for violent behavior. Cannabis does not typically produce violent or aggressive behavior but paranoia can occur with intoxication and can secondarily promote reactions of extreme fear associated with distorted perception, as can occur with lysergic acid diethylamide (LSD) and psilocybin, particularly in the naive user.

Withdrawal syndromes from specific xenobiotics can also promote aggressive behavior as a consequence of physical discomfort or anticipatory anxiety. Opioid withdrawal is characterized by myalgias, rhinorrhea, and piloerection with a clear sensorium, whereas alcohol, benzodiazepines, and barbiturates share a common syndrome of autonomic hyperreactivity, seizures, and subsequent delirium. Patients suffering from any of these signs and symptoms may become aggressive, verbally abusive, or threatening. Prompt recognition of these syndromes and immediate treatment can prevent some aggressive outbursts. Because drug use is often concealed, is difficult to ascertain on clinical grounds, and frequently contributes to violent behavior, urine and blood toxicologic studies may be useful to enhance the understanding and long-range treatment of some patients.[61]

Delirium can be a cause of aggression. Patients are often suddenly confused, frightened, or frankly psychotic as a result of impaired

perception. Patients may require sedation or physical restraint in order to prevent injury to themselves as well as staff.

Although persons suffering from psychotic disorders are not generally aggressive, there are aspects of the psychotic state that

place patients at risk for aggressive behavior. Paranoid ideation can serve to promote misperceptions of impending bodily harm (â€œThey're trying to kill meâ€•), sexual victimization (â€œMen and women are raping meâ€•), and humiliation (â€œEveryone is laughing at meâ€•). It follows that these fearful perceptions might provoke violent reactions in a patient. Hallucinations can cause aggression, either as a result of command hallucinations or in reaction to the anxiety and irritation that patients experience with loud or persistent auditory hallucinations (â€œhearing voicesâ€•). Patients with either borderline or antisocial personality disorder are at risk for violent acting out as a result of poor impulse control.

Violence risk has also been associated with cognitive dysfunction. Both acute mental illness and chronic substance use can result in neurologic impairment. Psychiatric patients with compromised cognitive abilities such as impaired attention, memory, or executive functioning such as reasoning and planning have been found to be at increased risk for violence.[61] Patients presenting with cognitive impairment may also be at increased risk for committing acts of violence in the ED.

Treatment

The acute pharmacotherapy of violent behavior is directed simply at reducing the level of arousal. A recent review of this issue proposed a model for the efficient use of medication for the control of episodic, as opposed to chronic, agitation and aggression.[3] In this model, agitation and violent outbursts are viewed as transient disturbances of the usual treatment

relationship between the physician and patient. Pharmacotherapy and seclusion or restraint are to be used only as needed to restore that relationship, for the benefit of the patient as well as other members in the environment. The restoration of the treatment relationship is necessary in order to take measures to understand and address the cause of the agitation, with the input and consent of the patient, thus preventing future incidents. For this reason, sleep is considered an undesirable use of medication. Sleep delays, rather than promotes, assessment, may further frighten or anger the patient, and does not even guarantee elimination of the agitated state on awakening.

As aggression derives from varied and multiple etiologies, it follows that there is much debate about the specific sedative that should be used, the route of administration, and the dosing interval. Studies examining the treatment of aggression and/or agitation have included such diverse populations as schizophrenics, acutely intoxicated patients (alcohol), trauma patients, postoperative patients, patients in alcohol withdrawal, and patients with presumed personality disorders. Treatment settings for these studies included psychiatric inpatient units, intensive care units, and the ED.[1,12,14,42,43 and 44] An excellent review examined a number of these studies, finding that both benzodiazepines and antipsychotics resulted in rapid control of agitation and aggression.[24]

It seems, however, that there are specific clinical situations when benzodiazepines and antipsychotic agents might be preferentially used. Haloperidol has been safely used in the treatment of agitation and aggression in patients with psychoses, acute alcohol intoxication, and delirium.[2,14,42,43] The drug can be administered orally, intravenously, or intramuscularly. Dosing intervals range from 30 minutes to 2 hours, with a usual regimen of haloperidol 5 mg given every 30 to 60 minutes; most patients respond after 1 to 3 doses. The dose of haloperidol needed to achieve sedation rarely exceeds a total of 50 mg in acute

management.

Benzodiazepines are also quite effective for sedation; their use has been examined in patients with psychoses, stimulant intoxication, sedative-hypnotic and alcohol withdrawal, and postoperative agitation.[1,29,52] Lorazepam 1 to 2 mg may be given orally or parenterally and repeated at 30- or 60-minute intervals, respectively, until the patient is calm. Because diazepam is poorly absorbed from intramuscular sites, its route of administration is either intravenous or oral. Diazepam may be given as 5 to 10 mg IV, with repeat dosing titrated to desired effect. Concerns regarding respiratory depression mandate careful observation of patients receiving sedation with these agents. Benzodiazepines may have a unique role in the treatment of agitation secondary to cocaine intoxication, as seizures may develop in this syndrome (Chap. 74). Antipsychotics, particularly low-potency antipsychotics, are known to lower the seizure threshold in animals, so their use for patients with cocaine intoxication should be avoided. Studies have examined the use of combinations of lorazepam with antipsychotics in patients with psychiatric illness and delirium and it appears that the combination of benzodiazepines and antipsychotics afforded relief of psychotic symptoms while allowing for a reduced dose of antipsychotic medications.[2,18,65]

Physical Restraint

Isolation and restraint are also used in the treatment of violent behavior. Isolation or seclusion can help to diminish environmental stimuli and thereby reduce hyperreactivity. However, a few aspects are worth mentioning: Because seclusion is defined by a condition of very limited interactive and environmental cues, it is not indicated for patients with unstable medical conditions, delirium, dementia, self-injurious behavior (cutting, head banging), or who are suffering extrapyramidal reactions as a

consequence of antipsychotic medication.[4] Restraint is used to prevent patient and staff injury. All facilities should have clear, written policy guidelines for restraint that address monitoring, provisions for patient comfort, and documentation.

Training

Finally, training in the management of aggression helps to reduce violence and injuries through the early identification of impending episodes of violence, use of verbal techniques to defuse incidents, and appropriate physical techniques to minimize injuries in those that occur. It is necessary for healthcare providers to maintain their skills through training and to advocate for continuing medical education on this topic at the workplace.[13]

Summary

Both violent and suicidal behavior in the ED may be the cause or the effect of many toxicologic presentations. Patients presenting with suicidal or aggressive behavior pose unique problems for the clinician who must make appropriate assessment and management decisions. It is incumbent on all emergency physicians to screen patients for psychiatric emergency presentations as part of a comprehensive screening for self-harm.

Identifying risk factors for suicide and aggression can aid the clinician in employing preventive or early intervention strategies in the ED. Important risk factors for both suicidal and violent behavior include past history of the behavior, comorbid mental illness,

drug and alcohol intoxication, and young age. Mental status examination for suicidality should focus on extrinsic factors such as current ideation, intent, lethality of plan, current life stressors, as well as intrinsic vulnerability factors such as comorbid mental

illness, feelings of hopelessness, and impulsivity. In terms of violence risk assessment, drug and alcohol intoxication, mental illness, and psychiatric medication noncompliance (alone or in combination) are robust predictors of aggressive behavior in the ED and other inpatient settings. Early detection and rapid intervention for patients at risk for suicide or violence is, to date, the best means for preventing injury or death.

Chapter 19
Neurologic Principles

Rama B. Rao

The central nervous system (CNS) coordinates responses to the fluctuating metabolic requirements of the body and modulates behavior, memory and higher levels of thinking. These functions require a diversity of cells: astrocytes, neurons, ependymal cells, and vascular endothelial cells. Disruption or death of any one cell type can cause critical changes in the function or viability of another. This cellular interdependence along with the high metabolic demands of the central nervous system, make neurons especially vulnerable to injury from both endogenous neurotoxins and xenobiotics. Endogenous neurotoxins like the metals iron, copper and manganese, are substances which may be critical to CNS function, but are harmful when their penetration into the CNS is poorly controlled.

The understanding of the normal chemical and molecular functions of the CNS is limited at best. Interestingly normal cellular mechanisms have sometimes been revealed by investigating xenobiotic induced neuronal injuries.[167] For example, the

pathophysiology of Parkinson disease, which affects movement and motor tone, was elucidated by the inadvertent exposure of individuals to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The mechanisms of axonal transport were elucidated by investigations of the effects of acrylamide exposures in human and animal models.[141] The neurodegenerative changes of amyotrophic lateral sclerosis has a promising xenobiotic model in Î²-methylamino-L-alanine (BMAA), a neurotoxin found in the cyanobacteria associated with cycad plants ingested by the Chamorro people of Guam.[69]

There are few minimally invasive methods available to investigate xenobiotic-induced CNS injury. Biomarkers are usually nonspecific and not readily available. Xenobiotic concentrations in blood and urine rarely reflect tissue concentrations of the central nervous system.[145] Cerebrospinal fluid may be useful in excluding CNS injury from infection, hemorrhage, and inflammatory processes, but is, with few exceptions, poorly reflective of the mechanisms of neuronal injuries.[224] Similarly, electroencephalograms and electromyelograms are useful in only a few types of xenobiotic exposures, and neuroimaging, while progressively evolving,[132] is a poor substitute for neuroanatomic evaluations that are usually only available on autopsy. Much of the current study to elucidate the mechanisms of CNS injury uses animal models, cultured astrocytes and other tissue, or postmortem investigations. Less commonly, occupational evaluations, such as the enzyme activity of cholinesterases in pesticide workers, are employed.

This is not a comprehensive chapter on all neurotoxic compounds and the status of their associated investigations. Instead, the concept of excitotoxicity is introduced, as are the common mechanisms by which xenobiotics exploit the functional and protective components of the CNS, with a few relevant examples. The multiple factors determining the clinical expression of neurotoxicity are reviewed. Finally, a special section on the delivery and complications of intrathecal xenobiotics is included.

Chap. 14 offers a detailed review of neurotransmitters.

Neurons: Classification, Infrastructure, and Functional Pathways

Neurons are the major route of cellular communication in the CNS. Having one of the highest metabolic rates in the body, these cells are especially sensitive to changes in the microenvironment and are dependent on astrocytes, choroidal epithelium, and capillary endothelium to confer protection and deliver glucose and other sources of energy.

Although each neuron is capable of receiving information through different neurotransmitters and receptor subtypes at the dendrite, neurons typically produce and release a single type of neurotransmitter at the axonal terminal. This specificity allows for cellular classification of neurons based on the neurotransmitter released, for example, serotonergic, cholinergic, and dopaminergic neurons (Chap. 14). Other substances that are less specific to the neuron type, such as adenosine, may also be produced and released.

The anatomic structure of neurons facilitates their function. Dendrites located on the cell body are lined with receptors that bind neurotransmitters and affect cellular changes via several mechanisms. The soma, or cell body is responsible for coordination and production of multiple proteins required to carry out normal physiologic functions. This synthesis occurs at a rate several times greater than the liver or kidney. These proteins, organelles, and substrates must then be transported across long distances to the terminal axon. This energy-dependent function is supported by a cytoskeleton comprised of neurofilaments, microfilaments, microtubules, and complex transport proteins. Fast anterograde transport of membrane-bound organelles occurs through kinesin at a rate of 200â€“400 mm per day. Channel proteins, synaptic

vesicles, mitochondria, Na^+ -K^+ -adenosine triphosphatase (ATPase), glycolipids, and other substances are transported by kinesin. Slow anterograde transport also occurs at a substantially slower rate (0.5â€“4 mm/d). The retrograde transport protein dynein is produced in the soma

and delivered to the nerve terminal for the movement of larger vesicles and reusable proteins back to the cell body.

In the CNS, groups of neurons are organized into complex functional pathways, with a single class of neuron regulating different functions and clinical effects depending on the brain region affected. As an example, dopaminergic neurons regulate cravings, movement, and resting muscle tone, each of which is determined not only by dopaminergic neurons and receptor subtype, but the part of the cortex or basal ganglia specifically affected (Chap. 14).

Neurons must be able to respond to changes in the local environment and alter the expression of different receptors in response to signaling from neurotrophic factors, variations in metabolic requirements, and xenobiotic interactions. This â€œneuroplasticityâ€• accounts for the diversity of clinical responses to substances that induce tolerance to xenobiotics such as ethanol (Chap. 15).

Glial Cells

Astrocytes, Oligodendrocytes, Microglia

Astrocytes comprise between 25% and 50% of the brain volume.[159] In addition to the anatomic contribution to the bloodâ€“brain barrier (BBB), astrocytes play a critical role in maintaining neuronal function.[4 , 5 , 209] They contribute to three

major areas: homeostasis of the extraneuronal environment, provision of energy substrates, and limitation in oxidative stress. In addition, astrocytes contribute to the â€œplasticityâ€• of cells and receptor expression in the CNS.

For cells of all types to function in the CNS, membrane potentials must be adequately maintained. Astrocytes contribute to this by closely regulating the extracellular pH, free water, and, like brain capillaries, the extracellular potassium concentration. Metallothioneins, which control the entry of heavy metals necessary for CNS function, are produced by astrocytes.[62 , 239] To further support CNS functions, astrocytes release energy substrates such as lactate, citrate, alanine, glutathione and Î±-ketoglutarate for use by neurons.[25]

Astrocytes metabolize glutamate, the main excitatory neurotransmitter in the CNS, and ammonia. These cells also produce superoxide dismutase and glutathione peroxidase to reduce free radical propagation. Glutathione, the major antioxidant for the brain, is predominantly located in the astrocytes. It can be released into the extracellular space or cleaved for neuronal uptake and intracellular reformulation.[25]

Through the release of complex trophic factors, astrocytes control the expression of endothelial transporters of the BBB and the production of tight junctions in both the bloodâ€“cerebrospinal fluid barrier (B-CSFB) and BBB. Angiogenesis is similarly astrocyte regulated, as is detection of neuronal injury, immune mediation, and neurotransmitter production. The growth of neurites, the branches of neuronal cell bodies that eventually become dendrites or axons, are similarly modulated by astrocytes.

Oligodendrocytes are a type of glial cell that provide anatomic support, protective insulation, and facilitate rapid neuronal depolarization by the production of myelin. Myelin is the primary constituent of white matter in the CNS. The production of myelin in the peripheral nervous system is performed by the Schwann

cells.

Finally, microglial cells, another type of glial cell, modulate immune response, inflammation, and tissue repair from a variety of CNS injuries. Like neurons, microglia are dependent on signaling from astrocytes.

Neuroprotective Mechanisms

The nervous system has multiple neuroprotective mechanisms. Xenobiotics are prevented from accessing the CNS by the bloodâ€“brain and bloodâ€“CSF barriers. For xenobiotics that enter the CNS, there are multiple cellular specializations to limit oxidant stress. These protective mechanisms are reviewed in the following sections.

Bloodâ€“Brain Barrier

The BBB confers an anatomic and enzymatic barrier to xenobiotic entry into the CNS. Brain capillaries are surrounded by the foot processes of adjacent astrocytes. The potential spaces between endothelial cells are limited by tight junctions, or zonulae occludens, which are between 50 and 100 times tighter than those found on peripheral capillaries.[3 , 4 and 5 , 126] This anatomic barrier prevents movement of substances between cells, also known as the paracellular aqueous pathway, as a result of osmotic and oncotic forces.[3 , 4 and 5 , 126 , 156]

Trans-endothelial movement of critical substrates and, potentially, xenobiotics, occurs through three major mechanisms: diffusion, transport proteins, and endocytosis.[3 , 4] These routes allow carefully controlled entry of critical substrates and cofactors while limiting the potential for injury from either endogenous or exogenous neurotoxins.

Lipophilic substances may move directly across the luminal and abluminal endothelial membranes abutting the central nervous

system. Other substances may enter the endothelium through bidirectional transport proteins on the luminal surface. These proteins may be specific, such as the GLUT-1 protein for uptake of glucose, or less-specific large neutral amino acid transporters (LNAAs) which move amino acids and xenobiotics, such as baclofen, intracellularly. These transporters also line the abluminal surface of the endothelial cell for movement of substrates and xenobiotics into the CNS. The third line of entry for larger proteins is via endocytosis. This can be either adsorptive or mediated through specific receptors such as insulin or transferrin.[3 , 4 and 5 , 126 , 156 , 239]

Endothelial cells have other protective properties including intracellular enzymes to metabolize xenobiotics, and efflux proteins to transport certain xenobiotics back into the capillary lumen. These efflux proteins include energy dependent P-glycoproteins which are adenosine triphosphate (ATP)-binding cassette transporters and are sometimes referred to as multidrug-resistant (MDR) proteins. Several hydrophobic xenobiotics are prevented from accumulating in the CNS through these transporters, including vinca alkaloids, digoxin, cyclosporine, and protease inhibitors. Nonsedating antihistamines may have limited sedative properties due, in part, to efflux though P-glyproteins.[58] Another type of saturable transporter, know as organic acid transport (OAT) protein, facilitates the efflux of hydrophilic xenobiotics such as valproic acid and baclofen. The expression of each of these transporters may be upregulated under certain conditions such as intermittent disruptions in the BBB from seizures. This expression upregulation is theorized to account for the resistance of anticonvulsant medications in patients with epilepsy. Comprehensive lists of xenobiotics that are substrates for these transporters are available elsewhere.[3 , 126]

Bloodâ€“CSF Barrier

The ventricles of the brain are lined by the epithelial cells of the choroid. These cells also have tight junctions, but they are not as extensive as those of the BBB. They are, however, rich in glutathione peroxidase and other xenobiotic

metabolizing enzymes in concentrations approximating that of the liver. Similar to brain capillary cells, the choroid contains efflux transporters for organic anions and cations, as well as MDR efflux proteins to limit entry of xenobiotics into the CSF.[3, 5, 126, 239]

Excitotoxicity

Neuronal function is strictly dependent on aerobic metabolism with an adequate supply of substrates and functioning mitochondria for the production of ATP. When energy expenditure exceeds production, cellular dysfunction and ultimately, cell death or apoptosis, results. The specific cascade of molecular events relating to this process is termed *excitoxicity*.[24, 187]

The initial event is traced to an oxidant stress and excessive stimulation of *N*-methyl-D-aspartate (NMDA) receptors by glutamate, an excitatory amino acid neurotransmitter. An influx of intracellular calcium changes membrane potentials across the cellular and mitochondrial membranes. The mitochondria become progressively more inefficient at ATP production and handling the resulting reactive oxygen species. As membrane damage is propagated, calcium further depolarizes the mitochondria, activating a permeability transition pore across the mitochondrial membrane. Gradients are further disrupted, precipitating more injury, energy failure, and ultimately, cell death.

Excitotoxicity is considered a common mechanism of cell death as a consequence of xenobiotic, ischemic, traumatic, infectious, neoplastic, or neurodegenerative injury. It is the subject of study for many therapeutic interventions in central nervous system injury.

Determinants of Neurotoxicity

The clinical expression of neurotoxicity is related to many factors, including the chemical properties of the xenobiotic; the dose and route of administration; xenobiotic interactions; and underlying patient characteristics including age, gender, and comorbid conditions (Table 19-1).

Chemical Properties of Xenobiotics

An important determinant of neurotoxicity is the capability of a xenobiotic to penetrate the BBB. Water-soluble molecules larger than M_r 200â€“400 (molecular weight ratio, or mass of a molecule relative to the mass of an atom) are unable to bypass the tight junctions.[3] Xenobiotics with a high octanol-to-water partition coefficient are more likely to passively penetrate the capillary endothelium, and potentially the BBB, whereas those with a low partition coefficient may require energy-dependent facilitated transport.[156] Xenobiotics that are substrates for capillary endothelial efflux mechanisms will have limited penetration regardless of the coefficient.[3 , 5 , 126 , 239]

Chemical properties of xenobiotics
Route of administration
Xenobiotic interactions
  Altered CNS penetration
  Clinical synergy
  Enhanced concentration
  Excessive neurotransmitter availability
Patient characteristics
  Age and gender
  Comorbidities
    Alterations in receptor function or expression
    Conditions affecting BBB integrity

Nutritional status
Extraaxial organ dysfunction
Enhanced sensitivity to xenobiotics
Production of endogenous neurotoxins
Undiagnosed diseases

TABLE 19-1. Determinants of Neurotoxicity

Route of Administration

The route of xenobiotic administration may also be consequential. Whereas most xenobiotics gain access to the nervous system through the circulatory system, aerosolized solvent and heavy metals in industrial and occupational exposures gain CNS access through inhalation, traveling via olfactory and circulatory routes. Alternatively, some agents may move from the peripheral nervous system via retrograde axonal transport to the CNS. Naturally occurring proteins such as tetanospasmin, rabies, polio, and herpes viruses use this mechanism to access the peripheral and central nervous system.[29 , 35 , 112] The toxalbumins ricin and abrin, as well as bismuth salts may also use this mechanism to a limited extent.[208 , 230] This understanding may prove beneficial from a therapeutic perspective. For example in one small series of patients experiencing severe pain, doxorubicin was injected into the involved peripheral nerves. Therapeutically, a chemical ganglionectomy occurred through retrograde â€œsuicideâ€• transport of doxorubicin, providing substantial relief in these patients in this experimental therapy.[122]

Some xenobiotics may be delivered directly into the CSF (intrathecally), the consequences of which are variable. See Special Considerations: Intrathecal Xenobiotic Administration.

Xenobiotic Interactions

Coadministration of xenobiotics may precipitate neurotoxicity by several mechanisms.[110] Extraaxially (outside of the CNS), xenobiotic interactions that increase the blood concentration of one or both agents may overwhelm the protective mechanisms of the BBB.[46] Similar effects may occur in the peripheral nervous system (PNS), where elevated blood concentrations may have enhanced clinical effects, resulting in peripheral neuropathies.[23]

Xenobiotic interactions can be synergistic, acting on the same neuroreceptor with additive effects. Benzodiazepines and ethanol, for example, both stimulate the Î³-aminobutyric acid type A ($GABA_A$) receptor.[31] The excessive neuroinhibition can result in deep coma and even respiratory depression when these agents are administered together.

In some circumstances, xenobiotic interactions result in excessive neurotransmitter availability. This is demonstrated in patients with the serotonin syndrome, the result, for example, of coadministration of a monoamine oxidase inhibitor and a serotonin reuptake inhibitor or other serotonergic agent (Chap. 70).

Access to the CNS may be altered by one of the xenobiotics, allowing the other to bypass the BBB. For example, mannitol causes transient opening of the BBB; as a result,[127] therapeutic use of mannitol is under investigation for the delivery of antineoplastic agents that might otherwise be unable to access the nervous system.[127] Similarly, some xenobiotics, such as verapamil, cyclosporine, and probenecid, are blockers of capillary endothelium efflux.[3 , 239] These theoretically limit efflux of other substrates of P-glycoprotein or OAT. The clinical usefulness of employing such efflux blockers

is under investigation as was done in a study in which primates received intrathecal methotrexate. The CSF clearance was reduced in animals administered intrathecal probenecid.[27 , 192]

Patient Characteristics

Age

Patient-specific variables may affect either the ability of a xenobiotic to penetrate the BBB and/or the clinical effects of a given exposure. For example, age of the patient at the time of exposure is critical, especially in the fetus and neonates.[194] The structural and enzymatic development of the bloodâ€“brain barrier is incomplete and synaptogenesis, or formation of intercellular relationships, is especially sensitive to impaired protein synthesis or other excitotoxic events. This is demonstrated classically by maternal exposure to methylmercury. The mother may be minimally affected, but the developing fetus suffers profound neurologic and developmental consequences (Chaps. 30 and 92).

In neonates, immature liver function may lead to the accumulation of circulating bilirubin. Because of incomplete formation of the bloodâ€“brain barrier, the bilirubin may access the central nervous system and produce a form of encephalopathy known as kernicterus.

Elderly patients may also have increased susceptibility to neurotoxins as a result of relatively impaired circulation or age-related changes in mitochondrial function that predispose to excitotoxicity.[201] Xenobiotic-induced parkinsonism, or the unmasking of subclinical idiopathic Parkinson disease may occur more readily in older than in younger patients. Animal models also suggest age-related sensitivity, with one study noting increased toxicity to manganese as the animals age.[83]

Gender

The role of gender in expression of xenobiotic-induced neurologic injury is potentially contributory. In animal models, the presence of estrogen- and progesterone-related compounds may be

neuroprotective for some xenobiotic injuries.[159, 179] In humans, females are more susceptible to some movement disorders, such as drug-induced parkinsonism and tardive dyskinesia, whereas dystonias and bruxism are more prevalent in young male patients.[188] The etiologies of these gender-related differences are incompletely understood.

Comorbidities

Conditions affecting the integrity of the bloodâ€“brain barrier can affect CNS penetration of xenobiotics and endogenous neurotoxins. For example, glutamate concentrations are normally higher in the circulatory system than the CNS.[140] Patients with trauma, ischemia, or lupus vasculitis[2] may experience neuropsychiatric disorders as a result of increased penetration of glutamate or sensitivity to additional xenobiotics. Similarly, meningitis and encephalitis cause openings in the BBB, which can be exploited to enhance therapy. Intravenous penicillin achieves a higher CSF concentration in animals with meningeal inflammation than in animals without meningitis.[193]

In some patients, previously undiagnosed diseases become evident on exposure to xenobiotics. This is especially true in patients with peripheral neuropathies. For example, patients being treated with therapeutic doses of vincristine suffered a severe polyneuropathy as a result of unmasking of a previously undiagnosed Charcot-Marie-Tooth disease.[54] Similarly, patients with diabetes mellitus, which is the most common cause of peripheral neuropathy, or HIV disease may have exacerbation of symptoms in the presence of antiretroviral agents.[56, 181] Patients with myasthenia gravis may have exacerbation of weakness with aminoglycoside administration, which can affect transmission at the neuromuscular junction.[235]

Chronic exposures to some neuroinhibitory xenobiotics such as ethanol may alter neuronal receptor expression and

â€œupregulateâ€• or increase the amount of receptors for excitatory amino acids. In addition to receptor augmentation, neurotransmitter concentrations of the excitatory neurotransmitters glutamate and aspartate are increased, as is homocysteine. These changes induce a tolerance to neuroinhibitory xenobiotics acting on the same receptor, and patients require escalating doses to achieve the same clinical effect. In such patients, cessation of ethanol intake results in a relative deficiency of exogenous inhibitory tone. The patient experiences neuroexcitability and the clinical syndrome of withdrawal (Chap. 15).[38 , 39]

Adequate nutritional status is important for the maintenance of normal neurologic function. The BBB may not be adequately maintained in patients with malnutrition. Deficiencies of heavy metal cofactors such as manganese, copper, zinc, and iron can affect neurologic function. In some cases, the deficiencies enhance absorption of other xenobiotics. For example, iron deficiency enhances lead and manganese absorption in the gastrointestinal tract, which can ultimately overwhelm neuroprotective mechanisms. Vitamins serve as enzymatic cofactors in modulating the production of glutamate, homocysteine, and other amino acids. Specific vitamin deficiencies can precipitate neurologic syndromes such as Wernicke encephalopathy in thiamine-depleted patients (see Antidotes in Depth: Thiamine Hydrochloride and Chap. 41). The toxicity of xenobiotics may also be enhanced. For example, a relative pyridoxine deficiency in patients with acute isoniazid overdose may result in seizures as a result of a relative excess of excitatory amino acids (see Antidotes in Depth: Pyridoxine and Chap. 55). Glucose is a critical energy substrate that can cause profound neurologic impairment when delivery is inadequate (see Antidotes in Depth: Dextrose and Chap. 48).

Extraaxial Organ Dysfunction

Renal failure may impair metabolism of xenobiotics or endogenous neurotoxins such as urea, rendering it more available to the central nervous system. Hyperglycemia in patients with diabetes mellitus may also increase formation of CNS-reactive oxygen species. Similarly, patients with liver failure may have elevations in CNS manganese.

Hepatic encephalopathy illustrates the concept of excitotoxicity from endogenous neurotoxins. Hyperammonemia increases oxidative stress and free radical formation in astrocytes. Ammonia potentially decreases critical metabolic enzymes such as catalases, superoxide dismutase, and glutathione peroxidase. Nitric oxide (NO) production is increased as a result of elevations in NO synthetase. Under these conditions, astrocytes upregulate the expression of the peripheral benzodiazepine receptor (PBR) on the outer mitochondrial membrane. The PBR modulates the production of neurosteroids and, in turn, the $GABA_A$ receptor. Continued CNS exposure to ammonia and other endogenous solutes propagates this oxidative and nitrosative stress to the mitochondrial membrane, potentially opening the mitochondrial permeability transition pore (channel). Osmotic swelling of the mitochondrial membrane followed by excitotoxicity results in cerebral edema, which produces hepatic encephalopathy.[160 , 161]

Mechanisms of Neurotoxicity

Alteration of Endogenous Neurotransmission

Xenobiotics can induce neurotoxicity by triggering changes in neurotransmission in either the central or peripheral nervous systems. In some cases, xenobiotics enhance neurotransmission through a specific receptor subtype. This enhanced transmission

can occur through inhibition of presynaptic metabolism (monoamine oxidase inhibitors), stimulation of neurotransmitter release (amphetamines), impairment of neurotransmitter reuptake (cocaine), or inhibition of synaptic degradation (acetylcholinesterase inhibitors).

Alternatively, synaptic neurotransmission may be impaired.[198] Xenobiotics may inhibit the presynaptic release of neurotransmitters (botulinum toxin), block receptors (antimuscarinics) or alter membrane potentials at the postsynaptic membrane (tetrodotoxin).[75, 78] Patients may present with a clinical syndrome of toxicity associated with altered neurotransmission of the specific receptor (Chap. 3).

Direct Receptor Interaction

Some xenobiotics are able to directly stimulate receptors. Both kainate and AMPA (Î±-amino-3-hydroxy-5-methyl-4-isoxazole propionate) are subclasses of the glutamate receptors that are targeted by some naturally occurring xenobiotics.[101] An example is Î²-*N* -oxalylamino-L-alanine (BOAA) found in the grass pea, *Lathyrus sativus.* BOAA stimulates the AMPA and inhibits specific mitochondrial enzymes resulting in the spastic paraparesis of lathyrism.[169] Domoic acid stimulates the kainate receptor and causes the neuroexcitation associated with neurotoxic shellfish poisoning.

Direct inhibition is also possible, as exemplified by phencyclidine, an NMDA (*N* -methyl-D-aspartate) receptor antagonist.

Enzyme and Transporter Exploitation

The classic example of xenobiotics that exploit endogenous enzymes and/or transporters is MPTP.[92] Once MPTP crosses the BBB, it is converted by monoamine oxidase to the neurotoxic compound MPP^+ (1-methyl-4-phenylpyridine) in astrocytes. MPP^+

is taken up by dopamine transporters into the neurons of the substantia nigra pars compacta. MPP^+ inhibits complex I of the mitochondrial electron transport chain resulting in dopaminergic excitotoxicity and the clinical syndrome similar to Parkinson disease (see Disorders of Movement and Tone below and Chap. 38).

Altered Conduction Along Membranes: Demyelinating Neurotoxins

Aside from xenobiotics that affect neurotransmission at the postsynaptic membrane, some affect the production or maintenance of myelin by oligodendrocytes and Schwann cells.[55, 79, 90, 115] In the central nervous system, these are often associated with white matter abnormalities and a leukoencephalopathy.[79] Agents such as hexachlorophene, arsenic, inhibitors of tumor necrosis factor-Î±, neural tissue-derived rabies vaccine, and the act of â€œchasing the dragonâ€• or inhaling volatilized heroin are associated with a demyelinating neurotoxicity.[55] In the peripheral nervous system, nitrous oxide, suramin, and tacrolimus are associated with peripheral demyelination (Table 19-2).[111]

Inhibition of Intracellular Functions

Some xenobiotics are nonspecific inhibitors of cellular function.[64] The neurotoxicity of substances such as carbon monoxide (CO) or cyanide can result in diffuse dysfunction or, depending upon the dose and specific vulnerabilities of an exposed patient, be more focal. For example, patients surviving CO exposure may experience delayed neurologic sequelae that is a diffuse impairment of neuropsychiatric function, or more focally, present with a xenobiotic induced Parkinson syndrome (see below and Chap. 120).

Alterations in endogenous neurotransmission
Alterations in membrane conduction
Direct receptor interactions
Exploitation of enzymes and transporters
Inhibition of intracellular function
  Inhibition of neuronal transport
  Inhibitors of protein production
  Mitochondrial inhibitors

TABLE 19-2. Mechanisms of Neurotoxicity

Chemotherapeutic agents can affect the production of critical proteins required for cellular maintenance. These can be very specific, such as the ability of vincristine to impair cytoskeletal transport in the peripheral nervous system (Chap. 52).

Clinically Relevant Xenobiotic Mediated Conditions

Alterations in Consciousness

The toxicologic differential diagnosis of xenobiotics that induce alterations in mental status or consciousness is expansive. These xenobiotics can be broadly divided into those agents that produce some form of neuroexcitation, and those that produce neuroinhibition. While some agents, such as phencyclidine, have elements of both, depending on dose, this categorization facilitates a general clinical understanding of neurotoxic alterations in mental status.

Xenobiotics resulting in neuroexcitation are agents that enhance neurotransmission of excitatory amino acids (EAAs), or diminish inhibitory input from GABAergic neurons. The clinical presentation of the patient can vary, therefore some patients may be alert and

confused, suffering from an agitated delirium, hallucinations or a seizure.

Neuroinhibitory xenobiotics typically enhance GABA-mediated neurotransmission. These patients may be somnolent or in deep coma. Benzodiazepines hyperpolarize cells by increasing inward movement of Cl^- ions through the chloride channel of the $GABA_A$ receptor complex. This hyperpolarization limits subsequent neurotransmission. Less commonly, neuroinhibition is a result of diminution of EAAs. Patients presenting the day after bingeing on cocaine may be sleepy but arousable and oriented in what is termed cocaine â€œwashout,â€• theoretically related to depletion of EAAs and dopamine. Xenobiotics that cause diffuse cortical dysfunction through impairment in the delivery or use of oxygen or glucose can also present with depressed or altered consciousness.

Clinical evaluation of patients with altered consciousness includes obtaining a complete history, including medications, comorbid conditions, occupation, and suicidal intent, when relevant or available. Patients should have a complete physical examination, with particular attention to vital sign abnormalities or findings that may indicate a toxic syndrome. Assessment and correction of hypoxia or hypoglycemia should be performed. An electrocardiogram may be useful in some circumstances (Chaps. 5 and 23).

Xenobiotic-Induced Seizures

Seizures are the most extreme form of neuroexcitation. As with alterations of consciousness, this may be a result of enhanced excitatory amino acid neurotransmission (domoic acid, sympathomimetics) or of inhibition of GABAergic tone (isoniazid). Unlike patients with traumatic or idiopathic seizure disorders who have an identifiable seizure focus, the initiation and propagation of xenobiotic-induced seizures is diffuse. It is for this reason that

most nonâ€“sedative-hypnotic anticonvulsants such as phenytoin, are unlikely to be effective in seizure termination.

Status epilepticus is variably defined, but involves 2 or more seizures without a lucid interval, or continuous seizure activity for greater than 15 minutes. True xenobiotic-induced status epilepticus is rare. Cicutoxin, the toxin in water hemlock (*Cicuta maculata*), is a potent inhibitor of $GABA_A$ neurotransmission and may cause status epilepticus.

TABLE 19-3. Xenobiotic-Induced Seizures

Theophylline toxicity precipitates seizures and status epilepticus through a different mechanism. Normally, endogenous termination of seizures is mediated through presynaptic release of adenosine during the release of the primary neurotransmitter at the terminal axon. Adenosine functions as a feedback inhibitor of the presynaptic neuron, disrupting propagation of excitatory neurotransmission. Theophylline is an adenosine antagonist. Adenosine administration is not a useful therapy for theophylline-induced seizures as adenosine is unable to cross the BBB. Generally high-dose sedative hypnotics, affecting $GABA_A$ receptors, are required for seizure control.

Some clinical conditions appear to be centrally mediated tonicâ€“clonic movements, but are caused by glycine inhibition in the spinal cord. Glycine is the major inhibitory neurotransmitter of motor neurons of the spinal cord. Under normal conditions glycine contributes to termination of reflex arcs. Glycine inhibition results in myoclonus, hyperreflexia and opisthotonos, often without alteration in consciousness. Presynaptic glycine inhibition is caused by tetanospasmin, the major neurotoxin from *Clostridium tetani.* Postsynaptic glycine inhibition is caused by strychnine, the

toxin in *Strychnos nux-vomica.* Patients with exposures to these agents are often treated in quiet environments where the stimuli to propagate hyperreflexia are minimized (Chap. 108 and Table 19-3).

Xenobiotic-Induced Mood Disorders

Certain xenobiotics are inconsistently associated with alterations in mood.[6 , 40] What predisposes individuals to xenobiotic-induced mood alterations is unclear. In some circumstances, patients with previously undiagnosed bipolar disorder are given a xenobiotic that unmasks their disease. Interestingly antibiotic-induced mania is found in some patients without a previous psychiatric history. The symptoms of mania are usually evident within the first week of therapy, and unlike the mania of purely psychiatric origin, readily abate within 48â€“72 hours of the last antibiotic dose. Some patients with clarithromycin-induced mania have documented reoccurrence on rechallenge of the antibiotic (Table 19-4).[6]

Disorders of Movement and Tone

Most movement disorders, including akathisia, bradykinesia, tics, dystonias, and chorea, are mediated by the complex dopaminergic pathways of the basal ganglia. Different dopamine receptor subtypes, modulated by GABAergic, glutaminergic, and cholinergic neurons are involved (Chap. 14).

TABLE 19-5. Xenobiotic-Induced Movement Disorders

Dopamine receptor antagonists can precipitate acute dystonic reactions. The D_2 -receptor antagonists, in conjunction with alterations in muscarinic cholinergic tone, are usually implicated. Animal models suggest possible mediation through Ïƒ receptors, the craniofacial distribution of which corresponds to the common clinical manifestations of acute dystonias.[116]

Chorea occurs in some cases of carbamazepine overdose, therapeutic oral contraceptive use,[74] and after cocaine use when the stimulant effects have subsided.[188]

Other centrally mediated disorders of tone include serotonin syndrome and neuroleptic malignant syndrome (NMS). Both of

these potentially life-threatening syndromes consist of altered consciousness, hyperthermia, rigidity, and autonomic insufficiency. NMS may occur in patients on dopamine-receptor antagonists such as antipsychotic medications, or in patients with idiopathic Parkinson disease who abruptly stop their dopaminergic therapy. Dopamine receptor agonists such as bromocriptine or restoration of antiparkinson medications are used therapeutically in these circumstances (Chap. 67).

Flaccid paralysis usually occurs as a result of impaired transmission at the neuromuscular junction (NMJ)[31 , 34] or from xenobiotics causing demyelination. Rarely, toxins can enhance transmission at the NMJ. Latrotoxin, the toxic compound in black widow spider (*Latrodectus* spp), causes enhanced release of acetylcholine at the NMJ with severe, painful muscle contractions (Tables 19-5 , 19-6 , and 19-7).

Xenobiotic-Induced Parkinson Syndrome

Similar to idiopathic Parkinson syndrome, xenobiotic-induced Parkinson syndrome is defined by the clinical syndrome of unstable posture, rigidity, gait disturbance, loss of facial expression and hypokinesis.[18] The common neuroanatomic target involves the dopaminergic neurons of the basal ganglia, specifically the substantia nigra.[60 , 214]

Resting Tremor Sustension Tremor Kinetic Tremor

TABLE 19-7. Xenobiotic-Induced Tremor

In some circumstances, the toxicity is transient and the mechanism inadequately understood. Some xenobiotics, such as MPTP, carbon disulfide, manganese, and the endogenous neurotoxin copper in patients with Wilson disease, produce predictable mitochondrial impairment of the basal ganglia neurons. Viscose rayon workers exposed to carbon disulfide may present with a Parkinson syndrome refractory to L-dopa administration.[106, 107] Manganese is a critical substrate for production and metabolism of several neurotransmitters including glutamate. Excessive manganese interferes with normal uptake of glutamate and is critical to the function of superoxide dismutase and glutamine synthetase.[72, 82] Patients with liver failure may accumulate manganese.[82] Although copper accumulation in the basal ganglia can produce parkinsonism, sometimes the syndrome is clinically silent until a xenobiotic with antidopaminergic properties is administered. Another example of subclinical Parkinson disease being unmasked occurs in patients with both AIDS and psychosis who are administered antipsychotic agents therapeutically.[59]

TABLE 19-8. Xenobiotic-Induced Parkinsonism [18,60,70,94,109,151,153,214]

Other xenobiotics, such as carbon monoxide and heroin, produce more diffuse tissue hypoxia, which occasionally results in xenobiotic-induced Parkinson syndrome. One study of patients with occupational exposure to pesticides suggested an increased risk of Parkinson disorder with long-term exposure. Specific agents were not clearly causative (Table 19-8).[80]

Cranial Neuropathies

Xenobiotics are a relatively rare cause of cranial nerve impairment. Some neuropathies are a result of direct delivery of the xenobiotic to the affected cranial nerve. For example, some patients may have optic nerve impairment from intraorbital

installation of silicone oil[9] or inadvertent deep space injection of a local anesthetic during dental anesthesia with a resultant abducens palsy.[146] In some cases, a xenobiotic is converted into a toxic substance such as formic acid in the retina.

The neuromuscular junction of the cranial nerves is sensitive to disruptions in neurotransmission and clinically noticed by the patient during disruptions of conjugate gaze. Botulinum toxin, elapid snake venom, and the cranial neuropathy associated with the organic phosphorus insecticide-induced intermediate syndrome are some examples.

Absence of critical substrates such as glucose or thiamine can result in an ophthalmoplegia. In most cases, however, the mechanisms underlying the cranial neuropathy are poorly understood, such as chemotherapeutic agents. Similarly, some patients who survive ethylene glycol poisoning experience transient ophthalmoplegia days after the initial exposure (Table 19-9 and Chaps. 20 and 21).[134 , 216]

Peripheral Neuropathies

Patients may complain of pain, paresthesias, numbness, or weakness of their extremities. This condition is clinically termed a neuropathy, but the mechanisms of its evolution are variable. Common to most xenobiotic-induced neuropathies is early bilateral involvement of the lower extremities. This may be partly a result of the patient's rapid recognition of impairment during an attempt to ambulate. Additionally, the axons serving the lower extremities are longer. Maintenance and transportation of substrates is more energy dependent and sensitive to xenobiotic-induced disruptions (Fig. 19-1).

In some cases, the anatomic structure of the nerve is maintained, but the xenobiotic affects neurotransmission. This may be a consequence of direct impairment of specific enzymes at the NMJ,

such as cholinesterase inhibitors.[61] Triorthocresyl phosphate (TOCP) is an inhibitor of neuropathic target esterase. Contamination of food and beverages with TOCP resulted in irreversible lower extremity paralysis in several epidemic exposures.[171, 217] Indirectly, the extracellular environment may be altered as in the case of hypermagnesemia, or hypokalemia which can be induced by multiple agents (Chap. 17). Ciguatoxin, a sodium channel opener, affects neurotransmission causing paresthesias and the unusual symptom of sensory reversal in which the perception of temperature is reversed to the stimulus.

TABLE 19-9. Xenobiotic-Induced Cranial Neuropathies[a 14, 16, 20, 26, 30, 36, 48, 51, 77, 88, 96, 133, 154, 178, 182, 196, 209, 212, 216, 232]

Xenobiotics such as amiodarone and tacrolimus induce peripheral demyelination. Patients present with weakness and flaccidity.

Nitrous oxide impairs the production of *S* -adenosyl-L-methionine essential to the production of myelin and is additive to the nitrous

oxide disruptions of vitamin B_{12} , which further impair axonal function.[222]

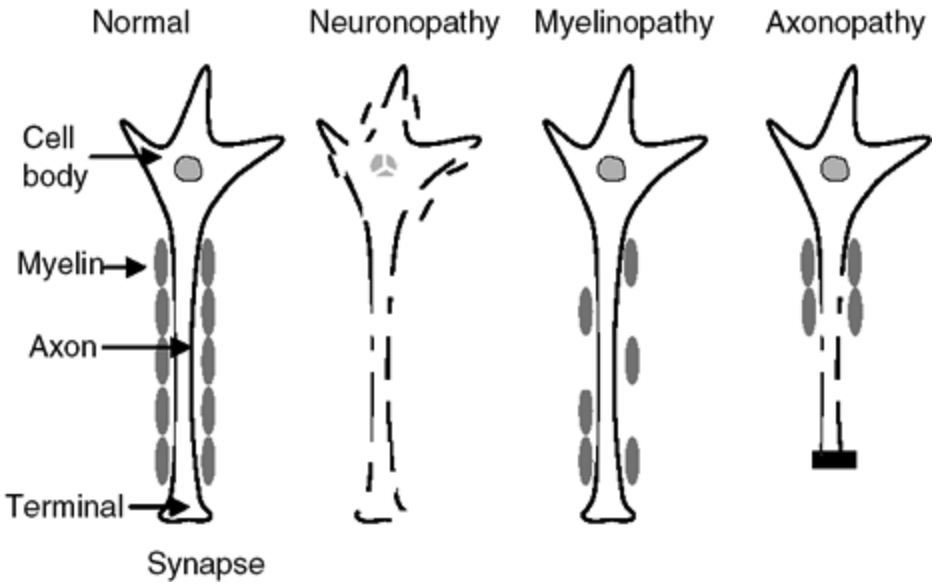

Figure 19-1. Schematic of a peripheral neuron and its three prototypic pathologic responses to toxic insults. Neuronopathies produce secondary axonopathic and myelinopathic changes, leading to degeneration of the entire peripheral nerve. Myelinopathies and axonopathies may occur separately or together. When the axon is involved, the prognosis is worse than with demyelination alone. Neuronopathies have the poorest prognosis of the three. *(Adapted from Chaudhry V: Multifocal motor neuropathy. Semin Neurol 1998;18:74; and Anthony DC, Montine TJ, Graham DG: Toxic responses of the nervous system. In: Klaassen CD, ed. Casarett and Doull's Toxicology, The Basic Science of Poisons, 5th ed. New York, McGraw Hill, 1996.)*

Other xenobiotics affect the structure or intracellular function of the peripheral nerves. Those that induce death of the cell body are termed *neuronopathies* and they may be clinically indistinguishable

from those that affect the axon, or *axonopathies* .

Peripheral nerve cell death is usually linked to injury at the spinal cord as was demonstrated by the doxorubicin injection of the peripheral nerves.[122] Pyridoxine overdose is another cause of neuronopathy. However, neuronopathies are an unusual mechanism of peripheral nerve toxicity.

Unlike neuronopathies, axonopathies are potentially reversible and are the most common mechanism of xenobiotic induced peripheral neuropathy. Xenobiotic-induced axonal injuries to the peripheral nerves are usually diffuse and bilateral, with preservation of the proximal cell body. These often target the cytoskeleton and impair the capacity for the microtubule system to deliver functional substrates.[52 , 100] Patients with occupational exposure to 2,5-hexanedione, a Î³ diketone metabolite of *n* -hexane present in certain glues, suffer from a sensorimotor axonopathy because of cross-linking of neurofilaments and impaired substrate transport.[164] Progressive neuropathy may occur long after the initial exposure. Vincristine similarly effects axonal transport. Acrylamide impairs fast anterograde and retrograde transport with animal models, suggesting effects on both kinesin and dynein.

Nucleoside reverse transcriptase inhibitors cause peripheral neuropathy by decreasing the production of mitochondrial DNA (Tables 19-10 , 19-11 , and 19-12).

TABLE 19-12. Classification of Selected Xenobiotic-Induced Peripheral Neuropathies

Most xenobiotic-induced muscle injuries or myopathies are more diffuse.[97,190,202,215] Î²-Hydroxy-Î²-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors can cause myalgias, cramping, myositis, or rhabdomyolysis. The incidence appears to be higher in patients taking other medications that share the same liver metabolic enzymes. The mechanism underlying the myopathy may be related to impaired cholesterol synthesis in myocytes, or diminished production of regulatory proteins such as ubiquinone and guanosine triphosphate (GTP)-binding proteins required for mitochondrial function.

Another myopathy that presents predominantly with weakness is the acute quadriplegic myopathy of intensive care patients. This syndrome was originally described in ventilated patients with asthma who received glucocorticoids and nondepolarizing neuromuscular blockers, but is also reported in other critically ill patients

(Chap. 66).[21] The mechanisms underlying quadriplegic myopathy, eosinophilia myalgia syndrome, and toxic oil syndrome are poorly described. Table 19-13 lists xenobiotics associated with muscle

injury.

TABLE 19-13. Xenobiotics Associated with Muscle Toxicity[19, 21, 43, 131]

Special Considerations: Cerebrospinal Fluid Administration of Xenobiotics

Cerebrospinal fluid (CSF) is produced by the choroid plexus lining the ventricles at a rate of between 15 and 30 mL/h, or roughly 500 mL/d in adults.[108] Cerebrospinal fluid flows in a rostral to caudal direction and is resorbed through the arachnoid villi directly into the venous circulation. The estimated total volume of CSF in a healthy adult is between 130 and 150 mL, and 35 mL in infants.[108, 142, 186]

For more than 100 years, a variety of experimental and therapeutic agents have been delivered directly into the CSF.[121, 223, 233] The most common current indications for intrathecal xenobiotic administration include analgesia, anesthesia, and treatment of spasticity or CNS neoplasms. The clinical advantages of this route of administration include targeted delivery and lower medication dosages with fewer systemic effects. Medications are usually administered via a spinal needle or an indwelling intrathecal catheter. Catheters may be attached to either an external or subcutaneous pump. Less commonly, substances are administered into a reservoir of an intraventricular shunt (Table 19-14).

The distribution of intrathecal xenobiotics is determined by a variety of factors. Baricity is the ratio of the specific gravity of the xenobiotic to the specific gravity of CSF at 98.6Â°F (37Â°C). Hyperbaric agents typically distribute in accordance with gravitational forces.[104] Patient position, baricity, and interindividual variations in lumbosacral CSF fluid volume may

affect xenobiotic distribution and may account for the differences in the level of spinal anesthesia among patients administered the same local anesthetic dosages.[104] In overdose or administration of agents unintended for intrathecal administration, however, distribution, resorption, and clinical effects might not follow predictable models.

Complications can occur from preparation and dosing errors or inadvertent puncture of the CSF during epidural anesthesia or analgesia.[67, 103] Medications intended for intrathecal delivery might

be administered into the wrong port of a pump delivery system, resulting in a massive overdose. Another potentially fatal error involves inadvertent administration of the wrong medication into the CSF.[117] This occurs with misidentification or mislabeling of medications during pharmacy preparation, or at the bedside. For patients with indwelling devices, medications intended for intravenous delivery can be misconnected to the intrathecal catheter, which also operates via the Luer-Lock system.

Adjuvants
- Dextrose
- Elliot B solution

Analgesics/anesthetics
- Anesthetics (local)
- Clonidine
- Ketamine
- Midazolam
- Neostigmine
- Octreotide
- Opioids
- Ziconotide

Antibiotics
- Amikacin
- Amphotericin B
- Cefotetan
- Ceftriaxone
- Gentamicin
- Penicillin
- Polymyxin E
- Vancomycin

Antiinflammatory
- Corticosteroids

Antispasmodic
- Baclofen

Chemotherapeutics
- Cytarabine
- Methotrexate

Vasoactive
- Epinephrine
- Papaverine
- Phenylephrine

Other Agents
- Bethanechol
- Colistin
- Leucovorin[b]
- Somatostatin
- Tetanus immunoglobulin

[a] very few of these are FDA approved and many are controversial applications at best.

[b] Intrathecal leucovorin is potentially fatal.

TABLE 19-14. Intrathecal Xenobiotics Administered Inadvertently or Therapeutically[a] [1,7,32,33,41,42,50,57,68,91,99,117,135,147,148,155,170,175,176,177,197,204,211,221,226,236]

Several factors affect the clinical toxicity of intrathecal medication errors. The properties of the xenobiotic are important. Ionized xenobiotics are likely to disrupt normal neurotransmission and cause toxicity, as may hyperosmolar or lipophilic substances. The site of administration also might be important. Patients administered the wrong xenobiotic into an Ommaya CSF reservoir may suffer more immediate alterations in mental status depending on the agent administered. Although intrathecal administration of preservatives and excipients are investigated in animal models, the characteristics of these adjuvants in medication errors is unlikely to be of value in predicting clinical effect.[105]

Patients may present with exaggerated symptoms that are typically associated with the xenobiotic. For example, patients with intrathecal morphine overdose may present with symptoms of opioid toxicity.[119] Other manifestations of intrathecal errors, regardless of the substance, include pain and paresthesias, often ascending in nature, autonomic instability, especially with extremes of blood pressure, and hyperreflexic myoclonic spasms similar to those seen in patients with tetanus. Seizures or depressed mental status may also occur. The time of onset of these life-threatening symptoms may be determined by the dose, and characteristics of the xenobiotic. For example, a woman inadvertently administered intrathecal potassium chloride complained immediately of severe back pain.[149] Myoclonic spasms, seizures, and coma followed, and the patient expired within 3 hours despite a normal serum potassium concentration. Patients with inadvertent vincristine exposures can be asymptomatic for many hours and expire within a few days to a few weeks.

Once a medication delivery error is identified, rapid intervention is mandatory, especially for ionic agents, chemotherapeutics, or iodinated water-soluble contrast agents. In cases in which outcome is uncertain or not previously described, the exposure should be treated as potentially fatal. Any existing access to the CSF, ideally of the lumbosacral area, should be maintained.[219] Immediate drainage by gravity of CSF, in volumes as high as 75 mL in adults, is indicated. This can be replaced with lactated Ringer solution or 0.9% sodium chloride solution. Some authors recommend that the initial large volume drainage be performed in 20â€“30-mL aliquots. For children, multiple aliquots of between 5 and 10 mL can be drained and replaced with isotonic fluid. If the patient can tolerate an upright position, cephalad movement of xenobiotics may be limited, but positioning for any critical life support measures should take precedence.

Delays to initial CSF drainage should be minimized as the interval between the exposure and CSF drainage may affect xenobiotic recovery. In the interim, a neurosurgical consultation should be obtained to consider the placement of ventricular access for the performance of continuous CSF lavage. This procedure, also known as ventriculolumbar perfusion, involves continuous ventricular instillation of an isotonic solution with CSF drainage through a lumbar site. Another intervention involves placement of an epidural catheter into the intrathecal space at a space above the lumbar drainage site. An isotonic solution can be perfused through the catheter and drained caudally. This serves as a readily available, rapid intervention for patients awaiting placement of an emergent ventriculostomy.[152]

The CSF replacement fluid is isotonic. Lactated Ringer solution, 0.9% sodium chloride solution, Plasma-Lyte, or a combination of those have been used. Some older cases used Elliot B solution. For ventriculolumbar perfusion, lavage flow rates can be as high as 150 mL/h. Fresh-frozen plasma can be added to the lavage fluid to increase the CSF protein content in accordance with intracranial

pressure monitoring. The ideal lavage fluid, protein components, and infusion rates are not known.[98] Table 19-15 describes some previously used protocols. Although artificial CSF formulations exist, their role in such medication errors has not been evaluated.[165]

Depending on the xenobiotic exposure, specific antidotes or rescue agents can be employed. With most intrathecal exposures, these rescue agents are administered via oral, intramuscular, or intravenous routes. Extreme caution should be used to avoid delivery of antidotes directly into the CSF, unless specific data supports their use.

Xenobiotic Recovery from CSF

Immediate, aggressive CSF removal and lavage resulted in nearly 95% recovery of vincristine in the lavage fluid of a patient with inadvertent exposure. Of the published cases in which xenobiotic recovery is reported, percentages relate to the both the lavage method and quantity of CSF drained. For example, drainage of 10 mL of CSF 45 minutes after a methotrexate overdose in a 4-year-old patient recovered 20% of the initial dose.[8] Drainage of 200 mL of CSF in aliquots, 45 minutes after methotrexate overdose in a 9-year-old recovered 78% of the initial dose.[85] Interestingly, the specific xenobiotic may affect recovery as well. For example a patient underwent drainage of 30 mL of CSF at 18 minutes after an overdose of simultaneously administered lidocaine, epinephrine, and fentanyl. Approximately 39% of lidocaine was recovered, whereas the recovery of fentanyl was only 7%.[205]

Specific Exposures

Ionic Contrast Media

Several different agents have been used historically for contrast

myelography. Many of these agents were abandoned because of their capacity to cause an adhesive arachnoiditis and chronic pain syndromes or other complications (eg, Thorotrast). Low osmolar, nonionic contrast media are currently used, but, unfortunately, other hyperosmolar ionic media are readily available in radiographic suites and sometimes inadvertently administered. Exposed patients become symptomatic between 30 minutes and 6 hours with hyperreflexia and myoclonic spasms on minimal stimulation.[189, 191, 213] Clinical symptoms typically begin in the lower extremities and move in a cephalad direction, sometimes progressing to opisthotonos. This is likely caused by alterations in inhibitory neurotransmission as seen in patients with tetanus, and has been termed ascending tonicâ€“clonic syndrome (ATCS). In one review, nearly one-third of patients died as a result of their exposures.[220] Immediate, large-volume CSF drainage should be performed in 20-mL aliquots with isotonic fluid replacement. Ventriculolumbar perfusion should be considered in severe cases.

Chemotherapeutics

Methotrexate is administered intrathecally for the prevention and treatment of leukemic meningitis and other CNS neoplasms. Errors are generally dose related.[8, 84, 85, 113] In most reported cases, aggressive drainage of CSF up to 250 mL in aliquots with isotonic fluid replacement was used without ventriculolumbar

perfusion. Experimental treatment of patients with intrathecal carboxypeptidase G2 without obvious adverse events has been described.[166, 229] Leucovorin can be administered intravenously, but intrathecal leucovorin is absolutely contraindicated because it can be fatal.[114, 130, 218]

TABLE 19-15. Table of Adverse Intrathecal Exposures

Vincristine is typically administered intravenously and does not cross the bloodâ€“brain barrier. There are no therapeutic indications for intrathecal vincristine, and such errors are almost always fatal.[11, 12, 13, 37, 71, 95, 128] As soon as the exposure is identified, immediate CSF drainage should be instituted and rapid neurosurgical consultation obtained. The few known survivors with cognitive function underwent early neurosurgical intervention for ventriculolumbar perfusion.[12, 152] One of these patients had an epidural catheter placed intrathecally above the drainage site for lumbolumbar perfusion while awaiting ventriculostomy. This method of intrathecal perfusion should be considered in all patients with intrathecal vincristine exposures until definitive ventriculolumbar perfusion can be established. Other rescue medications are covered in Chap. 52 .

Pump Malfunctions and Errors

Some implantable pumps contain two access sites, one of which is contiguous with the intrathecal space and allows for CSF withdrawal or injection of nonionic contrast media for imaging. The other is a depot port that is intermittently filled with concentrated amounts of drug (usually an opioid analgesic or baclofen) to be delivered through a programmable pump. In some cases, a template must be placed on the skin overlying subcutaneous pumps to ascertain the proper medication port. Errors occur when a concentrated bolus is inadvertently injected into the wrong port resulting in a massive, sometimes fatal, overdose.[117, 175, 234] Massive intrathecal morphine overdose can have severe rapid symptoms, including hypertensive crises. Either reaccessing the CSF port immediately or placing a spinal needle into the intrathecal space at another site is critical for the withdrawal of CSF. Large-volume drainage with isotonic fluid replacement is

required, along with other supportive measures, such as intravenous naloxone. These patients usually require intubation and care in an intensive care unit. The clinical service which placed the pump should be consulted to assist in further CSF access and perform interrogation of the pump in cases where malfunction is suspected.[73] If the consultant is not readily available, then emptying the deport port will automatically cause the pump motor to stop.

The other pump problem encountered is sudden, insufficient delivery of either baclofen or opioid pain medication.[184] This may occur because of pump malfunction. Alternatively, the intrathecal catheter may kink, migrate, or become obstructed by an inflammatory mass.[65, 66, 117, 174] Patients with chronic use of baclofen or morphine may suffer severe withdrawal symptoms when intrathecal delivery is disrupted. Intrathecal doses are between 100 and 1000 times more potent than the equivalent dose administered intravenously.[120] Consequently, these patients may require very high oral or intravenous doses to treat withdrawal until intrathecal delivery can be reestablished. The clinical service that implanted the pump should be consulted, and a thorough neurologic examination to evaluate for spinal cord compression symptoms should be performed.[117] An anteroposterior and lateral radiograph can be obtained to assess for kinking or fracture of the catheter.

Conclusions

The principles involving xenobiotic-induced neurologic injury are an area of ongoing intensive investigation. With improved understanding of these neurotoxic principles, therapeutic medications can be better delivered to the central nervous system while limiting the entry of potentially toxic substances. Toxicologic models for the investigation of neurodegenerative disorders can be

further developed as can new and creative therapies for mood disorders, hepatic encephalopathy, and injuries from infections, trauma, and ischemia. Elucidation of neurotoxicologic principles shows promise for the treatment of many nervous system disorders, and is an evolving field of investigation. The chemical properties of the xenobiotic and the characteristics of the patient exposed are critical to the clinical expression of neurotoxicity.

Chapter 20
Ophthalmic Principles

Adhi Sharma

Martin J. Smilkstein

Frederick W. Fraunfelder

Xenobiotics can affect the eyes in diverse manners. The eyes may be injured by direct contact with a number of xenobiotics, may provide a portal of entry for systemic toxicity, and may themselves be adversely affected by systemic exposures. The clinician must perform a thorough ophthalmic examination. Examination of the eye not only provides clues to the diagnosis of certain direct toxic exposures, but may also lead to timely detection of life-threatening indirect effects, such as intracranial hemorrhage. In addition to providing diagnostic clues, the visual system is the target of many xenobiotics that threaten normal vision. Understanding these principles can be lifesaving or sightsaving, and is essential to efficient, systematic patient care.

Ophthalmic Examination

As a matter of convention, the routine eye examination is

performed in the following sequence: visual acuity, pupillary response, extraocular muscle function, funduscopy, and when indicated, a slit-lamp examination. Examination of the pupillary size and response to light can help determine the presence of a toxic syndrome. Opioid and cholinergic agents may produce miosis, whereas anticholinergic agents may produce mydriasis. Assessment of the extraocular muscles can reveal xenobiotic-induced nystagmus. Funduscopy can reveal pink discs characteristic of poisoning by methanol or carbon monoxide. The slit-lamp examination allows for evaluation of toxic exposure to the lids, lacrimal systems, conjunctiva, sclera, cornea and anterior chamber. However, before considering specific toxic exposures in detail, it is important to review the anatomy and physiology of the visual pathways and how alteration of the normal physiology and anatomy correlate with clinical signs and symptoms.

Ocular Anatomy

The eye is a roughly spherical structure referred to as a globe. The globe is divided into anterior and posterior structures (Fig. 20-1). The most anterior structures are the cornea, conjunctiva, and sclera. Posterior to the cornea are the iris, the lens, and the ciliary body. The space between the cornea and the iris is the anterior chamber, and the space between the iris and the lens is the posterior chamber. Both chambers contain aqueous humor, which is produced by the ciliary bodies. The fundus is the most posterior structure and includes the retina, retinal vessels, and the head of the optic nerve or disc. The fundus is surrounded by gelatinous vitreous fluid, an important body fluid in forensic toxicology (Chap. 33). Xenobiotic-mediated injury to any of these structures can lead to symptoms as mild as chemical conjunctivitis or as severe as permanent blindness.

Visual Acuity and Color Perception

Normal vision is dependent on light transmission to intact neural elements. Appropriate light transmission requires a clear cornea and aqueous humor, proper pupil size, an unclouded lens and clear vitreous. The neural elements include the retina, optic nerve, and the optic cortex; all of these structures require intact blood circulation for proper function. Decreased acuity can result from abnormalities anywhere in the visual system that affect either light transmission or neural elements.[4,16,30] Corneal injury or edema may result in blurring of vision, characteristically described as â€œhalosâ€• around lights. Toxicologic causes of corneal abnormalities include direct exposure to chemicals, failure of corneal protective reflexes because of local anesthetic effects or a profoundly decreased level of consciousness, and incomplete eyelid closure during coma. Mydriasis, secondary to various xenobiotics (Table 20-1), may interfere with the pupillary constriction necessary for accommodation, thereby resulting in decreased acuity for near objects. Lens clouding or cataract formation causes blurred vision and decreased light perception, as does blood (hyphema) or other deposits in the aqueous humor or vitreous humors. Xenobiotic-induced lens abnormalities caused by chronic exposures are well described (Table 20-2),[23,30,39] but are unimportant in the evaluation of an acute toxicologic emergency. Even if light reaches the retina without distortion, abnormal reception or transmission can result from ischemia or injury to any neural element from the retina to the optic cortex. Direct, acute, visual neurotoxic injury is rare and is caused almost exclusively by methanol or quinine. Indirect injury following xenobiotic-induced central nervous system (CNS) ischemia or hypoxia is far more common. Alterations in color perception generally result from abnormalities in retinal or optic nerve function. Color-vision abnormalities are attributed to hundreds of agents, but unlike those caused by chronic xenobiotic exposure such abnormalities are rare and inconsistent features of acute toxicity.[23,30]

Pupil Size and Reactivity

Generally, pupils are round and symmetric with an average diameter of 3â€“4 mm under typical light conditions. Physiologic anisocoria (unequal pupils) is a normal variant and is defined as a difference in pupil size of 1 mm or less. However, in the absence

of a history of physiologic anisocoria, any asymmetry in pupil size should be considered an abnormal finding. Pupils react directly and consensually to light intensity by either constricting or dilating. Constriction is also a component of the near reflex (accommodation) that occurs when the eye focuses on near objects. The iris controls pupil size through a balance of cholinergic innervation of the sphincter (constrictor) muscle by cranial nerve III and sympathetic innervation of the radial (dilator) muscle.[16]

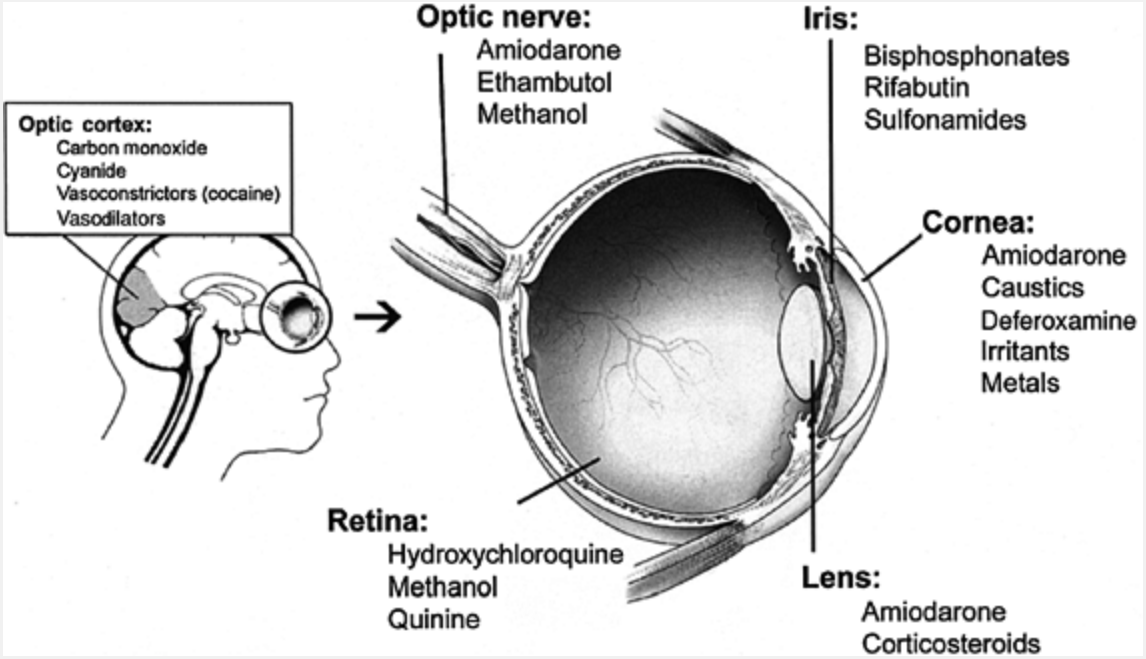

Figure 20-1. The major xenobiotics and their areas of ophthalmic injury. *(Courtesy of the National Eye Institute,*

National Institutes of Health, adapted by Joseph Lewey.)

Pupillary dilation (mydriasis) can result from increased sympathetic stimulation by endogenous catecholamines or, from xenobiotics such as cocaine, amphetamines, and other sympathomimetics as well as ophthalmic instillation of sympathomimetic agents such as phenylephrine. Mydriasis can also result from inhibition of muscarinic cholinergic-mediated pupillary constriction secondary to systemic or ophthalmic exposure to anticholinergic agents (Chap. 50). Because pupillary constriction in response to light is a major determinant of normal pupil size, blindness from ocular, retinal, or optic nerve disorders also leads to mydriasis as exemplified by methanol and quinine toxicity. Reactivity of mydriatic pupils to light varies with the etiology of the mydriasis.[30] Although often difficult to appreciate, constriction to light can usually be elicited after sympathomimetic exposures because constrictor function is preserved, whereas this is often not the case when mydriasis results from anticholinergic excess. Light reactivity is absent in cases of complete blindness caused by retinal or optic nerve damage, but may be preserved if there is some remaining light perception.

Miosis can result from increased cholinergic stimulation such as opioids, pilocarpine, and cholinesterase inhibitors such as organic phosphorus compounds, or inhibition of sympathetic dilation caused by clonidine. There are conflicting reports regarding the pupillary reactions to many xenobiotics. Depending on the stage and severity of toxicity, the presence of coingestants or coexistent hypoxemia, and numerous other factors, many individual substances (eg, phencyclidine and barbiturates) are reported to cause either mydriasis, miosis, or hippus, the fluctuation between miosis and mydriasis.[30,40] For some xenobiotics, the pupillary examination provides consistent information (Table 20-1), but many factors are involved and the significance of the pupil size

and reactivity must always be considered in the context of the remainder of the patient evaluation.

Extraocular Movement, Diplopia, and Nystagmus

Maintenance of normal eye position and movement requires a coordinated function of a complex circuit involving bilateral frontal and occipital cortices, multiple brainstem nuclei, cranial nerves, extraocular muscles, and connecting fibers between each.[2,16] Because of the many elements necessary for normal function, abnormalities of eye movement can result from several causes and are extremely common.[30] Probably the most common abnormality is reversible nystagmus or rhythmic oscillations of the globes (Table 20-1). Xenobiotic-induced nystagmus can take many forms, but is most commonly jerk nystagmus, as opposed to pendular, or horizontal and symmetric. The nystagmus may be evident at rest but is accentuated by visual pursuit and extreme lateral gaze. Although nystagmus with extreme lateral gaze is a normal finding, it extinguishes within 2â€“5 beats; if nystagmus persists, it is evidence of underlying pathology. Xenobiotic-induced vertical nystagmus occurs with phencyclidine, ketamine, dextromethorphan, or phenytoin toxicity; vertical nystagmus, however, is usually associated with a structural lesion of the CNS. Loss of conjugate gaze commonly results from CNS depression of any cause, typically after a sedative-hypnotic or ethanol overdose. Except after extremely rare exposures to neurotoxins (Table 20-1), diplopia without a decreased level of consciousness should not be attributed to an acute toxicologic etiology. In addition to the transient effects of some xenobiotics thallium, carbon disulfide, and carbon monoxide, may cause sustained gaze disorders as a consequence of residual cranial nerve and CNS injury.[30] Nystagmus and ophthalmoplegia caused by thiamine deficiency usually improves after therapy, but the nystagmus may not

completely resolve.[63]

Systemic Absorption and Toxicity from Ocular Exposures

Systemic absorption from ocular exposures has caused serious toxicity, morbidity, or death.[20,33] Although the patterns of toxicity are characteristic of the xenobiotics involved, recognition may be

delayed as a result of a failure to appreciate the eye as a significant route of absorption. Although transcorneal diffusion of xenobiotics are limited, there is substantial nasal mucosal absorption after nasolacrimal drainage, and absorption via conjunctival capillaries and lymphatics, which is markedly increased during conjunctival inflammation. Unlike the gastrointestinal route of absorption, there is no significant first-pass hepatic removal after ocular absorption; consequently, bioavailability is much greater.[20,33,57] If nasolacrimal outflow is normal, up to 80% of instilled drug may be absorbed systemically.[20] By the time toxicity is apparent, there is no role for ocular decontamination to prevent further absorption. After instillation of eye drops, absorption is generally complete within 7 minutes.

TABLE 20-1. Ophthalmic Findings Caused by Acute Xenobiotic Exposures

Miosis
Increased cholinergic tone
Carbachol
Cholinesterase inhibitors (carbamates, organic phosphorus compounds)

Muscarine
Nicotine
Pilocarpine
Decreased sympathetic tone (clonidine, guanabenz, methyldopa, opioids)
Coma from sedative-hypnotics (barbiturates, benzodiazepines, ethanol)
Mydriasis
Decreased cholinergic tone
Antihistamines
Belladonna alkaloids
Cyclic antidepressants (inconsistent finding)
Postanoxic encephalopathy
Increased sympathetic tone (amphetamines, cocaine, phenylephrine and other sympathomimetics, ethanol and sedative-hypnotic withdrawal)

Nystagmus
Carbamazepine
Dextromethorphan
Ethanol
Ketamine
Lithium
Monoamine oxidase inhibitors
Phencyclidine
Phenytoin
Sedative-hypnotics
Thiamine deficiency

Disconjugate gaze
Botulism
Elapid envenomation
Neuromuscular blockers
Paralytic shellfish poisoning

Tetrodotoxin
Thiamine deficiency
Secondary to decreased level of consciousness (many causes)

Funduscopic abnormalities
Carbon monoxide (red)
Cocaine (vasoconstriction)
Cyanide (retinal vein arteriolization)
Ergot alkaloids (vasoconstriction)
IV drug use (embolic)
Methanol (disc and retinal pallor or hyperemia)
Methemoglobin (cyanotic)

Papilledema
See causes of pseudotumor cerebri (Table 41-2)

Children appear to be at greatest risk, possibly because of the higher relative drug dose they experience when systemic absorption does occur.[20,47,57] Diligent attempts to comply with prescribed dosing in a struggling, crying infant may also result in excessive dosing. As eyedrop size (40â€“50 ÂµL) exceeds ocular cul-de-sac capacity (30 ÂµL), overflow often occurs and is assumed to represent a failed instillation, which leads to unnecessary reinstillation. Also, as doses of ocular medications are typically not adjusted based on patient weight, the consequences of equivalent degrees of systemic absorption are much greater for an infant than for an adult. Toxicity from eye drops is also a problem among the compromised, probably because of the combination of greater use of potentially toxic ophthalmic medications and the presence of comorbid conditions.

Prevention of systemic toxicity from topical ophthalmic medications requires recognition of the risk, a careful history, use

of the lowest effective concentration and dose, and patient education including proper administration instructions. To minimize inadvertent absorption, no more than one drop of any eyedrop solution should be instilled at one time in the superolateral corner of the eye while using gentle finger compression of the medial canthus to limit nasolacrimal drainage.[20,33]

Mydriatics

Mydriatics are used almost exclusively to dilate the pupils prior to diagnostic evaluation of the eyes. This common practice is not generally considered to be potentially dangerous; however, the risk may be substantial if the precautions outlined are not considered. Anticholinergic poisoning (Chap. 50), including substantial morbidity and mortality, is well described after ocular use of atropine, cyclopentolate, or scopolamine eyedrops, especially in infants.

The use of the Î±-adrenergic agonist phenylephrine eyedrops in a 10% solution may cause severe hypertension, subarachnoid hemorrhage, ventricular dysrhythmias, and myocardial infarction.[22] Fortunately, these effects are rare if the 2.5% ocular phenylephrine is used. Mydriatics can also precipitate acute angle closure glaucoma in susceptible individuals.

Miotics and Other Antiglaucoma Drugs

Maintaining miosis to prevent angle closure is an important part of glaucoma therapy. Cholinesterase inhibitors used for this purpose, such as echothiophate, can exacerbate asthma, parkinsonism, and cardiac disease. If neuromuscular blockade is required for patients using ocular cholinesterase inhibitors, an agent not metabolized by plasma cholinesterase (eg, atracurium, pancuronium, vecuronium, or tubocurarine) must be used. Succinylcholine and mivacurium

are cleared by plasma cholinesterase and have profoundly prolonged effects when a cholinesterase inhibitor is present.[33] Because of their long duration of action and resultant risk of accumulation after repeated dosing, cholinesterase inhibitors are associated with the highest incidence of adverse reactions among susceptible patients.

Miosis can also be produced by use of direct cholinergic agonists, such as pilocarpine, which have a much shorter duration of action. Although absorption is limited, nausea and abdominal cramps can occur at recommended doses. After excessive dosing, salivation, diaphoresis, bradycardia, and hypotension may occur.

Î²-Adrenergic antagonists, such as timolol, levobunolol, metipranolol, carteolol, and betaxolol, are used to lower intraocular pressure but cause a variety of adverse effects, including bradycardia, hypotension, myocardial infarction, syncope, transient ischemic attacks, congestive heart failure, exacerbation of asthma, status asthmaticus, and respiratory arrest. Timolol has exacerbated symptoms in patients with myasthenia gravis and is implicated in both causing and masking symptoms of hypoglycemia in diabetics.[61,62] Nonspecific complaints of anorexia, anxiety, depression, fatigue, hallucinations, headache, and nausea are also described after use of timolol eyedrops. Despite the cardioselectivity of betaxolol, respiratory toxicity has been reported.[20]

Dipivefrin, an esterified epinephrine derivative sometimes used to treat glaucoma, can cause adrenergic systemic effects, although much fewer than those caused by epinephrine. Ophthalmic formulations of highly selective $\hat{I}\pm_2$-adrenergic agonists, brimonidine (Alphagan) and apraclonidine (Iopidine) have been introduced to treat glaucoma.[20,65] Apraclonidine is expected to have a lower potential for toxicity because of limited CNS absorption. Systemic absorption of brimonidine eye drops in a

child has led to bradycardia, hypotension, and a decreased level of consciousness, similar to the central effects of other Î±$_2$-adrenoceptor agonists (eg, clonidine),[7] apparently mediated through both Î±$_2$-adrenoceptors and imidazoline receptors.[11]

Antimicrobials

Life-threatening reactions to ophthalmic antimicrobials are unusual but do occur. Episodes of aplastic anemia have occurred after prolonged use of chloramphenicol eye preparations,[21] and Stevens-Johnson syndrome was reported after short-term use of ophthalmic sulfacetamide in a patient with a history of allergy to sulfa drugs.[29]

Ocular Caustic Exposures: First AID and Initial Approach

The initial approach to all patients with ocular caustic exposures should be immediate decontamination by irrigating with copious amounts of fluids, water being the most often used.[12,64] Water, normal saline, lactated Ringer solution, and balanced salt solution (BSS) are all appropriate choices.[54] In theory, BSS is ideal, because it is both isotonic and buffered to physiologic pH. Lactated Ringer solution (pH 6â€“7.5) and 0.9% sodium chloride solution (pH 4.5â€“7) are also isotonic and therefore theoretically preferable to water.[32] The use of an ocular anesthetic is usually required to perform irrigation properly. Irrigation is intended to accomplish at least 4 objectives: immediate dilution of the offending agent; removal of the agent; removal of any foreign body; and in some cases, normalization of anterior chamber pH. As delays of even seconds can dramatically affect outcome,[30] there is no justification for waiting for any specific solution if water is the first available agent. Irrigation must include the external and internal palpebral surfaces, as well as the cornea and

bulbar conjunctiva and its recesses. Effective irrigation includes lid retraction and eversion or use of a scleral shell or other irrigating device. After irrigation, visual acuity testing, inspection of the eye, and slit-lamp examination should be performed.

Exposure-Specific Irrigating Solutions

Despite theoretical concern, there is probably no toxic exposure for which standard aqueous solutions are contraindicated. Of greatest concern are agents such as white or yellow phosphorus, metallic sodium, metallic potassium, and calcium oxide (cement) that may theoretically react violently in the presence of water, leading to heat or mechanical injury, or resulting in the generation of sodium hydroxide, potassium hydroxide, and calcium hydroxide.[30] Although not well-studied, irrigation with large amounts of water probably dissipates the heat of the initial hydration reaction with conjunctival moisture more than it initiates a thermochemical reaction. In addition to removing the offending material, irrigation serves to dilute and remove the alkaline byproducts formed by reaction with conjunctival water.

The use of special irrigating solutions for more uncommon exposures, including hydrofluoric acid and phenols, is also debated. A recent animal model of alkaline injury suggests irrigation with amphoteric or buffered solutions rapidly restores anterior chamber pH.[55] However, the majority of the published human data have been case reports. Therefore, at this time these solutions are probably best suited for first aid treatment at worksite eyewash stations and are neither practical nor proven in the emergency department setting for prolonged irrigation.

Hydrofluoric Acid

For hydrofluoric acid exposures (Chap. 101), experimental irrigation with calcium salt solutions was too irritating to the eye, but isotonic magnesium chloride solutions appear effective and not

irritating.[41,42] From a practical standpoint, however, 0.9% sodium chloride solution remains readily available, well studied and effective.

Phenol

For phenol exposure, topical low-molecular-weight polyethylene glycol (PEG) solutions are effective for treatment of experimental skin exposure; for eyes, copious water irrigation appears to be as effective as PEG.[10] There is, however, a report of superior efficacy of PEG-400 over water in treatment of actual phenol eye burns.[35] Although PEG-400 may be readily available at worksites where phenols are used, it is not a realistic option in the emergency department, and there should be no hesitation to use water, 0.9% sodium chloride solution, lactated Ringer solution, or BSS as lavage solutions.

Cyanoacrylate Adhesives

Ocular exposures to cyanoacrylate adhesives such as Dermabond and Krazy Glue occasionally result in rapid adherence between upper and lower eyelids that may persist for days. Such occurrences may be associated with corneal abrasions,[17] but are otherwise relatively harmless. In fact, cyanoacrylate has been safely used for decades to treat corneal perforations.[66] Solvents such as acetone or ethanol, which are often effective treatment for dermal-to-dermal adhesions caused by cyanoacrylates, should never be used in or around the eyes. Expectant management is the safest approach as spontaneous rejection of the glue will occur over time. Application of gauze pads soaked with antibiotic ophthalmic ointment may speed recovery.[34] A thorough eye examination should be performed once the eyelids can be fully opened.

Other xenobiotic-specific treatments have been tried experimentally or clinically,[32] but none should be considered prior

to or instead of copious irrigation, most are not advocated, and consideration of such agents should be vanishingly rare.

Duration of Irrigation

To accomplish the desired goals of irrigation, the appropriate duration varies with the exposure. Most solvents, for example, do not penetrate deeper than the superficial

cornea, and brief (10â€“20 minutes) irrigation is generally sufficient.[30] After exposure to acids or alkalis, normalization of the conjunctival pH is often suggested as a useful end point. Testing of pH should be done in every case of acid or alkali exposure, but the limitations of testing must be understood. When measured by sensitive experimental methods, normal pH of the conjunctival surface is 6.5â€“7.6.[1] This is highly method-dependent, however, and normal values in the literature range from 5.2 to 8.6.[14] When measured by touching pH-sensitive paper to the moist surface of the conjunctival cul-de-sac, normal pH is most often near 8.[3] Therefore, after irrigation following alkali burns, pH should not be expected to reach 7 and is more likely to stabilize near 8.[30] In this setting, lower pH values may indicate the pH of the irrigant rather than of the ocular surface. Waiting for an interval of several minutes between irrigation and pH testing allows washout of any residual irrigant.[15] Choice of testing paper is important, as some are intended for use at extremes of pH and lack sensitivity in the clinically useful range.

Despite these limitations, a logical role for pH assessment can be described: Probably a minimum of 500â€“1000 mL of irrigant should be used for each affected eye before any assessment of pH, and after 7â€“10 minutes, the pH of the lower fornix conjunctiva should be checked. Thereafter, cycles of 10â€“15 minutes of irrigation followed by rechecks should be continued until the pH is 7.5â€“8. This is certainly adequate for exposures to weak acids,

which do not penetrate well, and for alkaline exposures where the pH is less than 12.

For strong alkaline, concentrated acid, or for hydrofluoric acid exposures with apparent eye abnormalities, normal surface pH is not an adequate end point (see Alkalis below). After these burns, irrigation should be continued for at least 2â€“3 hours, regardless of surface pH, in an attempt to correct anterior chamber pH;[30,53,64] in addition, immediate ophthalmologic consultation is mandatory. Following this lengthy irrigation, it is important to verify that conjunctival pH has normalized. If not, irrigation must be continued, sometimes for 24â€“48 hours.

Other General Measures

There is a wide array of options for adjunctive therapy of chemical burns of the eye. In all cases in which serious injury is evident, the treatment plan must include consultation with an ophthalmologist. Generally, patients with corneal injury should be treated with an ocular topical antibiotic providing antistaphylococcal and antipseudomonal coverage. Cycloplegics not only reduce pain from ciliary spasm, but also decrease the likelihood of posterior synechiae (scar) formation. Topical NSAIDs and systemic analgesics also improve patient comfort. It is never appropriate to dispense topical ophthalmic anesthetic agents, because repeated use of these agents leads to further corneal disruption both by direct chemical effects and by eliminating corneal protective reflex sensation.

Ocular Caustic Exposures: specific xenobiotics

The effect of any xenobiotic on the eye depends on the inherent properties as a solvent or detergent; the amount, concentration, and pH of the xenobiotic; and the duration of exposure. The end

result of ocular exposure to these agents depends on the extent of damage to the cornea, particularly the integrity and function of the stroma; penetration into the anterior chamber and the resulting injury to its structures; and resultant inflammatory reaction.[30,64] Because similar xenobiotics tend to produce similar reactions, they can be conveniently grouped for discussion into acids, alkalis, and others.

Acids

Fortunately, weak acids do not penetrate the cornea well.[30,64] The hydrogen ion causes damage by lowering ocular pH, while the anion denatures ocular proteins on contact, causing precipitation and coagulation that actually limits the extent of penetration. The dehydrating effect of some acids, the heat of hydration, and the affinity of each anion for corneal tissues all affect the extent of injury. Intense pain usually results from stimulation of exposed nerve endings in the corneal epithelium. Corneal defects are common, but in many cases the damaged epithelium is swept away, revealing a healthy Bowman layer, over which epithelium resurfaces the cornea. Strong acids can penetrate the stroma, damage deeper tissue and structures of the anterior chamber, and lead to the more serious sequelae, such as those that often occur after alkali burns.[30,64] Prolonged exposure to weaker acids may result in significant extension of the injury, making immediate irrigation mandatory.

Hydrofluoric acid may cause unexpectedly severe injury because of its ability to penetrate deep into the eye.[41,42,52] Damage is generally concentration dependent, with severe injury expected after exposure to 20% solutions or higher, but even dilute formulations have led to persistent abnormalities. On the basis of anecdotal reports, some authors[60] advocate repeated instillation of calcium gluconate eye drops to bind free fluoride, but there is no evidence that this is beneficial.[5] At this time, we do not

advocate the use of calcium or magnesium solutions for irrigation or instillation after hydrofluoric acid eye exposure.

Alkalis

Alkali burns of the eye represent an ophthalmic emergency. A rational approach to care is based on an understanding of the complex pathophysiology of these injuries.[64] The hydroxyl ion saponifies lipid membranes, directly disrupting cells, whereas the penetration of the alkali is determined by the cation. Cations react with and hydrate stromal collagen and glycosaminoglycans, causing loss of clarity. For this reason, once the damaged epithelium is swept away, any haziness of the underlying stroma is evidence of alkali penetration and potential serious sequelae. If injury is limited only to destruction and lysis of corneal epithelium, with clear stroma, rapid and complete resolution is expected. Large amounts of concentrated strong bases such as sodium hydroxide, xenobiotics that penetrate rapidly such as ammonium hydroxide, and prolonged exposure all promote deeper injury.[30,51,64] Penetration into corneal stroma may destroy keratocytes, alter collagen structure, and damage the endothelium.[62] Paradoxically, more extensive burns may be less painful, because of destruction of corneal nerve endings and resultant anesthesia. In addition to indicating an increased depth of the burn, stromal and endothelial injuries often impair the ability of the cornea to regenerate later and to maintain an adequate epithelium. Further penetration can cause the pH of the anterior chamber to rise significantly within 2â€“3 minutes.[48,64] Ammonium hydroxide is especially destructive by this mechanism, as it penetrates far more rapidly than other alkalis. Experimentally, 8.5% ammonium hydroxide increases anterior chamber

pH within 15 seconds.[30] As a result, the sequelae of these exposures are severe and may be out of proportion to both pH and

the degree of surface injury.

The increase in intraocular pH is injurious to the trabecular meshwork, iris, lens, and ciliary body, and also triggers a sudden contraction of corneal and scleral collagen, leading to increased intraocular pressure and exacerbation of pain. A less dramatic but more sustained increase in intraocular pressure ensues, resulting from intraocular prostaglandin release.[64]

In addition to these direct effects, further injury results from the inflammatory response to the initial injury. Dysfunction of the normal bloodâ€“aqueous humor barrier results in exudation of protein and inflammatory cells into the anterior chamber, leading to a severe fibrinous reaction. Fibrosis, in turn, can lead to permanent angle closure with resultant glaucoma. At the opposite extreme, permanent dysfunction of the ciliary body, which produces the aqueous humor, can result in visual loss as a consequence of collapse of the eye (phthisis bulbi).[30,64]

The full extent of injury may not be evident for 48â€“72 hours. In the ensuing days to weeks, outcome is determined by the balance between degradation and repair of the stromal matrix, the quantity and quality of corneal reepithelialization, and the extent of inflammatory cell infiltration. After severe burns, normal repair is distinctly rare and extensive scarring is the rule. The goal of therapy is to prevent corneal ulceration, ocular perforation, and glaucoma while preserving the eye for possible secondary surgical revision or repair.

The mainstay of treatment is immediate and copious irrigation following the guidelines discussed. After exposures to calcium hydroxide (lime) from mortar or cement splashes, any adherent material must be found and removed. A sterile cotton-tipped applicator soaked in 0.05 mol/L edetate disodium (Na_2 EDTA) may aid this process.[30,51,64] Follow up is essential in all cases of alkali eye burns. Emergent consultation with an ophthalmologist should be obtained for all suspected severe burns. For isolated, very

superficial corneal defects this is not necessary; however, if there is pain unrelieved by topical anesthetics, evident corneal opacification, increased intraocular pressure, or any slit-lamp examination evidence of deep corneal burn, corneal edema, or anterior chamber cell or flare, immediate consultation is essential.

Not only is comprehensive early evaluation important, but the advisability of several adjunctive treatments should be determined in conjunction with the ophthalmologist. Emergent needle paracentesis and lavage of the anterior chamber removes alkali and returns pH to normal and also decreases intraocular pressure.[30,48,64] Animal studies suggest that this technique is useful if performed within minutes, but its benefit is not proven in human exposures, possibly because of delay in patient presentation and limited availability of expertise in the technique. In addition to topical antibiotics, cycloplegics, topical steroids, topical and systemic tetracyclines, and antiglaucoma medications may all be indicated. Early steroid treatment may decrease the inflammatory response, but continued use inhibits fibroblast function and healing.[18,64] Ophthalmologists therefore suggest steroids only for the first 7 days. Although well-controlled research in animal models of ocular alkali injury suggest that topical citrate and ascorbate improve healing, a recent long-term study showed no significant benefit in humans and demonstrated delayed healing when used in patients with mild to moderate injury.[9,49,50]

Tetracyclines, particularly doxycycline, inhibit collagenase activity by chelating zinc, and reduce corneal ulceration.[13,56] In addition, they also inhibit leukocyte activity. These treatments have supplanted less-effective earlier collagenase inhibitors (cysteine, acetylcysteine, penicillamine, EDTA), and many other previously used approaches. Investigational agents include fibronectin, epidermal growth factor, hyaluronate, and retinoic acid to promote regrowth of epithelium; and medroxyprogesterone and NSAIDs to limit inflammation without inhibiting stromal repair and collagen formation. Many surgical interventions are investigational and may

be indicated, including limbal stem cell and amniotic membrane transplantation.[58,65]

Others

Most solvents cause immediate pain and superficial injury because of dissolution of corneal epithelial lipid membranes, but do not penetrate or react significantly with deeper tissue.[30] The epithelial defect may be large or complete, but the limited depth of injury usually allows rapid regeneration of normal epithelium. Detergents and surfactants cause variable injury, ranging from minor irritation from soaps to extensive injury from cationic agents such as concentrated benzalkonium chloride.[30] Ocular exposure to A-200 Pyrinate pediculicide shampoo causes typical detergent-surfactant injury, leading to extensive loss of corneal epithelium but with normal underlying stroma, and therefore complete healing within days. Lacrimators (tear gases), such as chloroacetophenone, stimulate corneal nerve endings and cause pain, burning, and tearing, but produce no structural injury at low concentrations. At high concentrations, these agents can produce significant corneal injury.

Pepper spray, often used for self-protection by civilians or law enforcement agents, contains the active ingredient oleoresin capsicum (OC). OC results in rapid depolarization of nociceptors containing substance P, resulting in immediate pain, blepharospasm, tearing, and blurred vision. In general, ocular injury is uncommon, although corneal erosions can occur. The solvent used for the spray can be more injurious to the eye than the OC itself. Although most sprays use a water- or oil-based solvent, some use alcohol, which can result in significant corneal damage.[67] Management of pepper spray exposure consist of rapid irrigation and pain control. Corneal erosions can be treated with artificial tears but corneal abrasions should be treated with topical antistaphylococcal antibiotics. Specific information on thousands of

agents is readily available if needed.[30]

Disposition

Disposition of patients with chemical burns of the cornea can be challenging. Patients with extensive burns to other parts of the body should be evaluated for transfer to a burn center. Grading the degree of injury in patients with isolated ocular injury can guide disposition. The most commonly used grading system is the Roper-Hall modification of the Ballen classification system. Injury is graded on a 4-tier scale: Patients with mild conjunctival injection with corneal epithelial loss and minimal corneal haziness are classified as grades 1 and 2 (mild to moderate). These patients can be safely discharged from the emergency department with ophthalmology followup within 24â€“48 hours. Patients with severe corneal haziness or opacification with significant limbal ischemia are classified as grades 3 or 4 (moderate to severe) and should receive immediate consultation with an ophthalmologist and transfer to a burn unit should be considered.

Toxicity to Ocular Structures from Nonocular Exposures

Ocular toxicity from systemic xenobiotics is almost always the result of chronic exposure, and the manifestations develop over a prolonged period of time. Thousands of substances are implicated, affecting every element of the visual system from the cornea to the optic cortex. Thorough discussion of this topic is beyond the scope of this text, but Table 20-2 lists examples of causative xenobiotics.[23,30] Many topical and systemic medications are associated with inflammation of the eye, as well as uveitis.[24] Unlike many other ocular abnormalities caused by xenobiotics, uveitis should prompt immediate ophthalmologic consultation.

Because many etiologies are commonly prescribed medications, adverse drug effects should always be considered when patients present with visual abnormalities or unusual ocular findings on examination.

TABLE 20-2. Examples of Ocular Abnormalities Caused by Chronic Systemic Xenobiotic Exposures[a]

Corneal/conjunctival inflammation	Retrobulbar and optic neuropathy
Cytosine arabinoside (Ara-C)	Carbon disulfide[d]
Isotretinoin[b]	Chloramphenicol[d]
Mercury (acrodynia)	Dinitrobenzene[d]
Practolol[c]	Dinitrochlorobenzene[d]
	Dinitrotoluene[d]
Retinal injury	Disulfiram
Carmustine[c]	Ethambutol[b]
Carbon disulfide[d]	Isoniazid[c]
Chloramphenicol[c]	Lead[c]

Chloroquine	Thallium
Cinchona alkaloids (quinine)	Vincristine[c]
Deferoxamine[c]	
Digitalis[c]	Cataracts
Ethambutol	Busulfan[c]
Thallium	Corticosteroids[b]
Vigabatrin	Deferoxamine
Vincristine[c]	Dinitrophenol (internal use)[d]
	Trinitrotoluene[d]
Uveitis	
Bisphosphonates	Cortical blindness
Pamidronate	Cisplatin
Rifabutin	Cyclosporine
Sulfonamides	Interleukin[c]

	Tacrolimus
Corneal deposits	Methylmercury compounds[d]
Amiodarone[b]	
Chloroquine	Lens deposits
Chlorpromazine	Amiodarone[b]
Copper[d]	Chlorpromazine
Gold	Copper[d]
Mercury[d]	Iron
Retinoids	Mercury[d]
Silver (argyria)[d]	Silver[d]
Vitamin D	
	Myopia[c]
	Acetazolamide
	Diuretics (chlorthalidone, thiazides, spironolactone)

	Retinoids
	Sulfonamides

[a] This list includes only selected examples and is not intended to be comprehensive.
[b] Particularly important example.
[c] Reported, but extremely rare from this exposure.
[d] Mostly of historical interest; associated with patterns of use that are no longer common.

TABLE 20-3. Xenobiotics Reported to Cause Visual Loss After Acute Exposures

Direct causes
- Caustics
- Methanol
- Quinine
- Lead[a]
- Mercuric chloride[a]

Indirect causes[b]
- Amphetamines
- Cocaine
- Embolization of foreign material (parenteral injection)
- Cisplatinum
- Combined endocrine agents (thyrotropin-releasing hormone with gonadotropin-releasing hormone and glucagon)
- Ergot alkaloids

Hypotension (eg, calcium channel blockers)

[a] Distinctly rare with these poisonings.
[b] Distinctly rare with use of these agents; visual loss often instantaneous, secondary to sudden hypotension, vascular spasm, or embolization.
Adapted, with permission, from Smilkstein MJ, Kulig KW, Rumack BH: Acute toxic blindness: Unrecognized quinine poisoning. Ann Emerg Med 1987;16:98â€“101.

In the setting of emergency care, xenobiotic-induced disturbances of normal vision from systemic exposures take many forms. Impaired near-vision from mydriasis, and diplopia or nystagmus from interference with normal control of extraocular movements, are examples of common, usually harmless, visual effects. Serious effects generally result from injury or dysfunction of the neural elements from the retina to the cortex. Such toxicity can be direct (neurotoxic) or indirect (hypoxia, ischemia). Many xenobiotics historically reported to cause acute visual loss directly are no longer available.[30] Methanol and quinine are currently the most important xenobiotics that cause direct visual toxicity after acute oral poisoning. Many xenobiotics capable of causing vasospasm, hypotension, or embolization also cause acute visual loss (Table 20-3).[59] Blindness and other visual defects are described following recovery from severe toxicity with barbiturates and other sedative-hypnotics, opioids, carbon monoxide, and many others.[30]

Methanol

Formate, the byproduct of methanol metabolism (Chap. 103), is the cause of visual toxicity from methanol poisoning. Although interspecies differences complicate the analysis, it appears that the primary event in ocular toxicity is the metabolism of methanol

by retinal glial cells, which results in local elevation of formate concentration.[19,27,28,38,46] The exact effects of formate remain to be defined, but formate is postulated to interfere with mitochondrial cytochrome oxidase and succinate-cytochrome c reductase, and possibly with the Na^+-K^+-adenosine triphosphatase (ATPase) system in the fibers of the optic nerve head.[37] Although the retina is the likely primary site of toxicity,[19,27,28,38,45,46] injury to the retinal ganglion cells and the retrobulbar optic nerve are also described, possibly as secondary effects. The visual signs and symptoms of methanol-induced visual disturbance include blurred or misty vision, â€œsnowfieldâ€• vision, spots, central and peripheral scotomata, decreased light perception, and complete blindness.[6] The physical examination is consistent with the mechanism described: Although

in many patients with only mild visual impairment the examination may be normal, the most consistent finding in severe cases is initial hyperemia of the optic nerve head, which later becomes edematous. The extension of the edema to the surrounding retina correlates with central scotomata, which are common. In severe cases, the edema may extend to large areas of the retina. In the most severe cases, when light perception is lost, the pupils may be widely dilated and unreactive.

In severe cases, histopathologic examination reveals injury to the retinal ganglion cell layer and extension of the optic nerve injury to the retrobulbar nerve fibers.[28] Optic atrophy often follows, and although central scotomata and peripheral visual field constriction are common, more complete visual loss may then occur. Patients with prolonged metabolic acidosis show a tendency towards developing residual visual impairment.[36] Additionally, the constellation of severe initial impairment, dilated and unreactive pupils, and widespread retinal edema also implies a particularly poor visual prognosis.

The concentration and duration of formate exposure also appears

to be critical to the development of retinal toxicity, but there are not yet reliable estimates or practical methods of determining these variables after human poisoning. Therefore, any patient with acidemia after methanol poisoning is assumed to be at risk for retinal damage. As discussed in Chap. 103, the risk can be reduced by the administration of folate or folinic acid to enhance the elimination of formate and to prevent retinal folate depletion[27,28] (see Antidotes in Depth: Leucovorin [Folinic Acid] and Folic Acid and Antidotes in Depth: Sodium Bicarbonate).

Quinine

The mechanism of quinine-induced visual impairment is less-well understood, but it is known to involve neurotoxic injury to the optic nerve and perhaps retinal ganglion cells.[31] Visual symptoms can include blurred vision, central and peripheral scotomata, and complete blindness.[8] The onset of visual impairment varies, but sudden visual loss can occur as late as 14 hours or more after overdose.[59] Physical examination reveals pupils that are dilated and unreactive in proportion to the degree of visual impairment. Funduscopic examination is often completely normal but may show edema of the optic nerve, retina, or both, and retinal arteriolar constriction.[30] Retinal vasoconstriction was previously thought to be the cause of visual injury, and therapies such as vasodilators and stellate ganglion block were used in an attempt to reverse the vasospasm. Further study clearly shows both complete blindness with normal vessels, and recovery in patients with vasospasm.[26,59] Thus, retinal vasoconstriction is no longer thought to be of primary importance, although there is still speculation that vasospasm may have a modifying effect on outcome. Currently, there is no role for vasodilator therapy in these cases.

Recovery is often very rapid, but residual impairment is common in severe cases. In a study of 225 cases of quinine poisoning, 70 patients developed visual impairment. Of 31 patients whose worst

ocular manifestation was blurred vision, all had complete visual recovery. However, of 39 patients who developed complete blindness, only 17 had full recovery.[8] The most common residual effects are peripheral field defects and central scotomata. Impaired color vision and complete blindness may also persist, but this is less common. Varying degrees of visual impairment (quinine amblyopia) have resulted from diverse forms of quinine exposure, but complete blindness is reported only after oral ingestion of large amounts of quinine. It is difficult to predict which patients will develop quinine amblyopia, but it does appear to be dose related. Although it certainly occurs at lower levels, permanent blindness should be expected if quinine serum levels exceed 20 mg/mL in the first 10 hours after ingestion (Chap. 56).[8]

Ocular Complications of Drug Abuse

In addition to the well-known ocular pupillary signs of opioid, cocaine, amphetamine, and phencyclidine toxicity, a number of complications may result from short- or long-term use of these and other agents.[43] Quinine amblyopia (see Quinine above) caused by intravenous use of quinine-containing heroin is one of many ocular complications caused by injection of contaminants. Talc retinopathy was first described after prolonged intravenous use of adulterated methylphenidate,[25] but has subsequently been noted after intravenous use of heroin, methadone,[44] codeine, meperidine, and pentazocine. Talc retinopathy develops only after extensive intravenous drug use. In one study of intravenous methadone abusers, only patients who had injected more than 9000 tablets developed this complication.[44] Infectious complications, such as fungal (*Candida, Aspergillus*) or bacterial (*Staphylococcus* spp, *Bacillus cereus*) endophthalmitis, are well known as both direct effects of intravenous drug use and secondary complications of AIDS. In addition to AIDS-related ophthalmic infections such as cytomegalovirus, cryptococcus, toxoplasmosis retinitis, and choroidal *Mycobacterium avium-*

intracellulare complex (MAC), other disorders include retinal cotton-wool spots, conjunctival Kaposi sarcoma, and ocular motility disorders caused by infectious or neoplastic meningitis. Corneal defects have been noted after smoking cocaine alkaloid (â€œcrack eyeâ€•).[54] Cocaine that is either volatilized or inadvertently introduced by direct contact, probably results in corneal anesthesia and loss of corneal protective reflex sensation. Minor trauma, such as eye rubbing, then leads to corneal epithelial defects. In addition, there appears to be an increased incidence of infectious keratitis and corneal ulceration in these patients. The ability of local anesthetics to interfere with corneal epithelial adhesion may also play a role.

Summary

Both systemic and local toxicologic emergencies occur in the ophthalmic system. This discussion has focused on the research in the treatment of damage to the eye caused by xenobiotics. Although the obvious physical injuries are apparent to the clinician, the more subtle clues to toxicologic mechanisms that involve the ophthalmic and neurologic systems are only made by a meticulous examination of the eye. A careful ophthalmic examination often leads to early recognition of a toxicologic emergency.

Chapter 21
Otolaryngologic Principles

William K. Chiang

Many xenobiotics adversely affect the special senses of olfaction, gustation, and cochlear-vestibular functions. These toxic effects are not life-threatening and frequently are not considered to be important. Because of the lack of standardized diagnostic techniques and normal parameters, particularly for olfactory and gustatory functions, it is likely that such adverse effects will be overlooked and dismissed by healthcare providers, despite significant patient distress and dysfunction. This chapter reviews the anatomy and physiology related to these senses; delineates the effects of xenobiotics on these senses; and examines the significant diagnostic information these senses contribute to the detection of xenobiotics. Understanding the effects of xenobiotics on the senses may allow for early detection, which occasionally can be lifesaving.

Olfaction

Anatomy and Physiology

Olfactory receptors are bipolar neurons located in the superior nasal turbinates and the adjacent septum. There are 10â€“20 million cells per nasal chamber, and the receptor portion of the cell undergoes continuous renewal from the olfactory epithelium.[111 , 114] Renewed olfactory receptors regenerate neural connections to the olfactory bulb. Olfactory receptor neurons are distinctive in their ability to regenerate.[25] The axons of these cells form small bundles that traverse the fenestrations of the cribriform plate of the ethmoid bone to the dura. Within the dura, these bundles form connections with the olfactory bulb. Neural projections then connect to the olfactory cortex. There are extensive central interconnections to other parts of the brain, such as the hippocampus, thalamus, hypothalamus, and frontal lobe, suggesting effects on other biologic functions.[111] Although primary odor detection is a function of the olfactory cranial nerve (CN I), some irritant odors, such as ammonia and acetone, are transmitted through the trigeminal cranial nerve (CN V) and its receptors.[44 , 150]

The actual olfactory receptor sites are structurally similar to taste receptors of the mouth and photoreceptors of the retina. The receptor is a single polypeptide chain consisting of approximately 350 amino acids, which folds back and forth on itself to transverse the cellular membrane 7 times. The outer end of the polypeptide contains an amine group (N-terminal) and the cytosol end contains a carboxyl group (C-terminal). The transmembranous portions determine the receptor shape and characteristics of the binding site. When a molecule binds to a specific receptor site, the resultant conformational change leads to the activation of the G-protein system, and calcium and/or sodium channel activation and neurotransmission.[77]

Smelling is an extremely sensitive detector of certain substances. Olfactory receptors can detect as little as a few molecules of

certain xenobiotics with a sensitivity that is superior to some of the most sophisticated laboratory detection instruments.[69]

Limitations of the Olfactory Senses

A number of problems present the greatest utility of smell as a toxicologic warning system. Human olfaction is a variable trait.[5, 122, 179] For example, 40â€“45% of people have specific anosmia (inability or loss of smell) for the bitter almond odor of cyanide.[45, 91, 122] There are limited data on the inheritance characteristics or genetic basis of these specific forms of anosmia. While some studies suggest that the ability to detect the odor of cyanide is a sex-linked recessive trait,[59] other studies yield conflicting results.[5, 20, 93] Females have a greater ability to detect androsterone, which is also prominent in human underarm secretion.[69] Human olfaction usually can distinguish a mixture of no more than 4 xenobiotics,[97] and therefore specific odors may be masked by other stimuli.

Olfactory fatigue is the process of olfactory adaptation following exposure to a stimulus for a variable period of time. This leads to a temporal diminution of the smell. Unfortunately, this adaptation may lead to a false sense of security with continued exposure to a xenobiotic. For example, hydrogen sulfide, which inhibits cytochrome oxidase, is readily detectable as distinct and offensive at the very low concentration of 0.025 ppm. At the higher and potentially toxic concentration of 50 ppm, the odor is less offensive, and recognition may disappear after 2â€“15 minutes of exposure.[8, 154] At an even higher concentration, when toxicity is likely, the onset of olfactory fatigue is even more rapid. The combination of the rapid onset of olfactory fatigue and toxicity at high concentrations of hydrogen sulfide exposure has contributed to numerous fatalities (Chap. 121).[1, 27]

In industrial settings, it is important to be aware of impaired olfactory function in any worker who may be exposed to chemical

vapors or gases.[75, 159] Such workers are at increased risk for toxic injury. The National Institute for Occupational Safety and Health (NIOSH) requires that an individual using an air-purifying respirator be capable of detecting the odor of a xenobiotic at levels below those producing toxicity.[6, 159] Sensory perception at this level ensures that the individual can detect filter cartridge â€œbreakthroughâ€• or failure at a safe level.[159] The odor safety factor refers to the ratio of the time-weighted average (TWA) threshold limit value (TLV)

to the odor threshold for a given xenobiotic. A xenobiotic with a high odor safety factor can be detected despite prolonged exposure.[6] Nontoxic xenobiotics, such as ethyl mercaptan, with a very high odor safety factor, can be added to xenobiotics that are odorless with lower safety factors, so that olfactory detection is predictable. This enhanced sensory awareness is the basis for the addition of mercaptans to the odorless natural gases used in the home so as to limit the potential for unrecognized hazardous exposure.

Clinical Use of Odor Recognition

The recognition of odors has traditionally been considered an important diagnostic skill in clinical medicine. Diseases can be diagnosed solely by recognizable associated odors: diabetic ketoacidosis as fruity; diphtheria as sweet; scurvy as putrid; typhoid fever as fresh-baked brown bread; and scrofula as stale beer.[38] Odors are also described for disorders of amino acid and fatty acid metabolism, such as phenylketonuria, maple syrup urine disease, hypermethioninemia, and isovaleric acidemia.[38]

The recognition of odors continues to be an important diagnostic skill for the rapid detection of xenobiotics (Table 21-1). To increase the awareness of odors of toxic xenobiotics, a â€œsniffing barâ€• of commonly available odors may be prepared (Table 21-2

).[64] Nontoxic xenobiotics that simulate the odors of toxic xenobiotics are placed in test tubes, numbered, and inserted in a test tube rack for circulation among staff. The sniffing bar, brief descriptions of clinical presentations, and a table of diagnostic odors (Table 21-1), may be used to teach the recognition of odors in medical toxicology.[64]

Etiology of Olfactory Impairment

There are different types of olfactory dysfunction. Anosmia, the inability to detect certain odors, and hyposmia, a decrease in the perception of certain odors, are the most common forms of olfactory impairment. The etiology of olfactory impairment may be classified as conductive, from anatomic obstruction of inspired air, or perceptive, from dysfunction of the olfactory receptors or signal transmission. Most conductive olfactory dysfunction results in hyposmia, because the obstruction is usually incomplete.[111 , 147]

Acetone (sweet, fruity)
Lacquer, ethanol, isopropanol, chloroform, trichloroethane, paraldehyde, chloral hydrate, methylbromide
Bitter almond
Cyanide
Carrots
Cicutoxin (water hemlock)
Disinfectants
Phenol, creosote
Eggs (rotten)
Hydrogen sulfide, carbon disulfide, mercaptans, disulfiram, *N* -acetylcysteine
Fish or raw liver (musty)
Zinc phosphide, aluminum phosphide
Fruit
Nitrites (amyl, butyl)
Garlic

Phosphorus, tellurium, arsenic, organic phosphorus compounds, selenium, thallium, dimethyl sulfoxide (DMSO)
Hay
Phosgene
Mothballs
Naphthalene, *p* -dichlorobenzene, camphor
Pepper
0 -chlorobenzylidene malonitrile
Rope (burnt)
Marijuana, opium
Shoe polish
Nitrobenzene
Tobacco
Nicotine
Vinegar
Acetic acid
Vinyl
Ethchlorvynol (Placidyl)
Violets
Turpentine (metabolites excreted in urine)
Wintergreen
Methyl salicylate

Characteristic Odor Potentially Responsible Xenobiotic

TABLE 21-1. Diagnostic Odors

The most common causes of anosmia and hyposmia are viral infections, trauma, xenobiotics, tumors, and congenital and psychiatric disorders (Table 21-3).[44 , 133 , 139 , 147 , 150] Viral infections may result in olfactory impairment either by obstructing nasal airflow or by causing damage to the olfactory epithelium.[78] Trauma to the head or nose can shear fragile olfactory nerves crossing the cribriform plate. In fact, as many as 5% of patients

with head trauma have subsequent olfactory dysfunction.[150, 169]

Chronic exposures to numerous xenobiotics are associated with olfactory dysfunction (Table 21-3). The most common toxic mechanism related is perceptive olfactory dysfunction. This may be a result of a direct injury or of a structural alteration of the receptor, or its components such as G proteins, adenylate cyclase, or receptor kinase.[76, 77] Anosmia or hyposmia from hydrocarbons, formaldehyde, heavy metals such as cadmium, and antineoplastic agents such as cytarabine result from direct effects on the receptor sites.[48, 77, 82] Local effects on the epithelium and the receptors from antibiotic nose drops may lead to temporary anosmia and hyposmia.[88, 178] Inhaled corticosteroids may have local effects on the epithelium, as well as direct effects on both G proteins and adenylate cyclase.[79] Cocaine insufflation causes direct local effects, as well as effects on receptor functions.[65, 73] Because of local effects of most xenobiotics and the regenerative ability of the olfactory receptor neurons, most xenobiotic-induced olfactory dysfunction is reversible.

Most people with anosmia have congenital anosmia to selected individual molecules, such as hydrogen cyanide, *N* -butyl mercaptan, trimethylamine, and isovaleric acid.[7, 44] Some extreme forms of congenital anosmia are associated with other abnormalities, such as Kallmann syndrome, a hereditary form of anosmia associated with hypogonadotropic hypogonadism. Agenesis of the olfactory bulbs and incomplete development of the hypothalamus causes this form of anosmia.[44, 150]

Dysosmia or parosmia is the distorted perception of smell (Table 21-3). Subclassifications of dysosmia include the perception of foul smell or cacosmia, the sensation of smell without a stimulus or phantosmia, and the sensation of the smell of a burnt or metallic material, torqosmia.[147] The etiologies are classified as peripheral or central. Peripheral etiologies include abnormalities of the nose, sinuses, and upper respiratory tract. Central etiologies

may be related to disorders such as Addison disease, hypothyroidism, temporal lobe epilepsy, and psychosis, or to conditions such as pregnancy.[44, 111, 148] How these conditions actually alter the perception of smell is unclear. A number of xenobiotics with similar effects are listed in Table 21-3. Bromocriptine alters dopaminergic transmission and inhibits adenylate cyclase. Levodopa also affects the dopaminergic transmission and chelates zinc, which is important in the maintenance of normal receptor functions.[77, 79]

Evaluation of Olfactory Impairment

General evaluation of olfactory function should include a detailed history, focusing on types, duration, and progression of symptoms, recent illnesses, head and nose trauma, sinus problems, family history, occupational history, hobbies, medications, and drug history.[39, 68] A complete physical examination and detailed examination

of the nasopharynx and sinuses should be performed to assess the potential for inflammation or structural abnormality. A simple set of olfactory stimulants, such as ground coffee, almond extract, peppermint extract, and musk, should be used to test each nostril individually with the patient's eyes closed.[68, 150] Standardized smell tests such as the UPSIT (University of Pennsylvania Smell Identification Test) and the CCCRC (Connecticut Chemosensory Clinical Research Center) tests are now commercially available; a composite score based on a panel of tests can determine the degree of olfactory dysfunction.[103] Pungent odors or stimulation associated with ammonia, capsaicin, acetone, and menthol are dependent on the trigeminal nerve (CN V) olfactory function, which is mainly

responsible for tactile pressure, pain, and temperature sensation in the mouth and nasal cavity. A patient who has olfactory nerve

damage should be able to detect these substances; conversely, a person with hysteria may deny detection of these substances that should physiologically be recognized.[68 , 150 , 178] If a xenobiotic-mediated mechanism is suspected, the offending agent should be discontinued. A coronal CT of the sinuses and nose or a CT or a MRI of the brain may be required if structural abnormalities are suspected.[150 , 178] Gas chromatographic analysis of the urine may be useful in patients with fish odor syndrome associated with trimethylaminuria.[98 , 156] Complicated cases and patients with significant impairment should be referred to an otolaryngologist or neurologist.

Tube 1
Tube 7
Case history:
A lethargic 28-year-old woman was brought to emergency department with an altered mental status.
Case history:
A 4-year-old boy was brought to the emergency department with a temperature of 103.5Â°F (39.7Â°C), a respiratory rate of 32 breaths/min, and markedly altered mental status. Laboratory tests on admission showed a high-anion-gap metabolic acidosis. The patient smelled like a â€œwintergreen candy.â€•
Odor:
Toxin:
Vinyl smell
Ethchlorvynol
Contents of tube:
Liquid contents of Placidyl capsule
Tube 2

Case history:
A 34-year-old man in cardiopulmonary arrest found in a chemical plant near several gas cylinders.
Odor:

Wintergreen

Toxin:

Methyl salicylate

Odor:

Bitter almond

Contents of tube:

Oil of wintergreen or wintergreen candy

Toxin:

Cyanide

Contents of tube:

Macerated seeds from inside of peach pit or almond extract.

Tube 8

Case history:

A 3-year-old boy was brought to the emergency department in considerable pain. On examination the department in considerable pain. On examination the child exhibited dysphagia and dysphonia, the oral mucosa appeared blistered and erythematous. The child's mother stated that he must have gotten into cleaning supplies.

Tube 3

Case history:

A 27-year-old man was brought to the emergency department with necrotic burns on his oral mucosa after gargling with an unknown liquid germicide.

The patient thought it would help his sore throat. The pH of the germicide was 5.

Odor:

Toxin:

Ammonia

Ammonia

Odor:

White paste (glue)

Contents of tube:
Ammonia (diluted household)
Toxin:
Phenol

Contents of tube:
Phenol (liquefied) (<1% concentration)
Tube 9

Case history:
A 2-year-old girl was brought to the emergency department after vomiting and having what was described as a grand mal seizure. The child had been playing several minutes earlier in a storage closet.
Tube 4

Case history:
A comatose 35-year-old man employed as a sanitary engineer was pulled out of the sewer by a fellow worker. CPR was initiated. When he was brought to the emergency department, the patient smelled like rotten eggs.

Odor:
Toxin:
Moth balls
Camphor
Odor:
Rotten eggs
Contents of tube:
Camphor
Toxin:
Hydrogen sulfide

Contents of tube:

Sulfurated potash or *N* -acetylcysteine

Tube 5

Case history:
A photographer was brought to the emergency department after unintentionally ingesting a chemical used in developing film. On presentation, patient was drooling and grasping his throat in considerable distress. On examination the patient's mouth and throat were erythematous and he smelled â€œlike a salad.â€•

Odor:
Vinegar

Toxin:
Glacial acetic acid

Contents of tube:
Vinegar

Tube 6

Case history:
A crop duster was brought to the emergency department in acute respiratory distress. The patient had hypersalivation, miotic pupils (2 mm), a very unpleasant breath odor, and coarse rhonchi in both lung fields.

Odor:
Garlic

Toxin:
Organic phosphorus insecticide

Contents of tube:
Garlic

Definitions: Anosmia = the loss of smell; Cacosmia = sensation of a foul smell; Dysosmia = a distorted perception of smell; Hyposmia = a decreased perception of smell; Phantosmia = sensation of smell without stimulus.

Hyposmia/Anosmia Dysosmia/Cacosmia/Phantosmia

TABLE 21-3. Differential Diagnosis of Xenobiotics Responsible for Disorders of Smell

Gustation

Anatomy and Physiology

Taste, the sensory interpretation of orally ingested materials, is determined by taste buds on the tongue, palate, throat, and upper third of the esophagus. The cells in the taste buds are constantly renewed, and have a life span of 10 days.[11, 147] The taste buds on the anterior two-thirds of the tongue and the palate are innervated by the facial (CN VII) nerve, those on the posterior one-third of the tongue by the glossopharyngeal (CN IX) nerve, and those on the laryngeal and epiglottal regions by the vagus (CN X) nerve. There are at least 13 known chemical taste receptors responsible for the four primary taste sensations, sweet, sour, bitter, and salty: 2 sodium receptor types; 2 potassium receptor types; 1 chloride receptor; 1 adenosine receptor; two inosine receptor; 2 sweet receptor types; 2 bitter receptor types; 1 glutamate receptor; and 1 hydrogen ion receptor.[70] One substrate will typically activate multiple taste receptors, the combined effects of these stimulated receptors determine the taste of the substance.[57]

The structure of the taste receptors is similar to that of the olfactory receptors, in that they are coupled to G proteins and sodium and calcium channels permitting neural stimulation. The pH of the xenobiotic determines sour or acid taste, whereas sodium or potassium concentrations determine salty taste. Many xenobiotics such as sugars, glycols, aldehydes, ketones, amides, amino acids, inorganic salts of lead, and bretylium, activate the sweet receptors. Bitter taste may be the result of long-chain organic substances containing nitrogen, or alkaloids, including quinine, strychnine, caffeine, and nicotine.[70] Salivary proteins, such as zinc-containing gustin and ebnerin, are important in the regulation of taste sensation.[77, 81, 100, 155] These molecules may serve as binding proteins and growth factors for the regeneration of taste receptors. Taste is also affected significantly by the appreciation of aromas or odors and, to a lesser extent, by visual perception.[148]

Etiology of Gustatory Impairment

Types of gustatory dysfunction include ageusia, the inability to perceive taste; hypogeusia, the diminished sensitivity of taste; and dysgeusia, the distortion of normal taste. There are several variations of dysgeusia, such as cacogeusia, which is a perceived foul, perverted, or metallic taste.[68, 108] Taste impairment is commonly related to direct damage to the taste receptors, adverse effects on their regeneration, or effects on receptor mechanisms.[77] These effects can result from various xenobiotics, diseases, aging, and nutritional disorders (Table 21-4).[63, 70, 138, 165] Any abnormality that interferes with either the direct contact of a xenobiotic with the gustatory cells of the tongue or cranial nerves VII, IX, or X dramatically affects taste.[147] Most common forms of xenobiotic-induced dysgeusia are related to direct effects on the taste receptor site or effects related to receptor mechanisms such as G proteins, adenylate cyclase, and calcium channels.[96] Other forms of dysgeusia may result from direct stimulation of chemical receptors by xenobiotics.[70, 77]

Angiotensin-converting enzyme (ACE) inhibitors commonly cause gustatory impairment, usually hypogeusia and dysgeusia.[19, 65, 110, 180] ACE inhibitors work by inhibiting zinc-dependent ACE, and chelating zinc from taste receptors and salivary proteins resulting in taste dysfunction. Calcium channel blockers act by inhibiting calcium channels of the taste receptor mechanisms.[70] Many diuretics cause zinc depletion by enhancing zinc elimination in the urine.[77] In addition, furosemide and spironolactone may also chelate zinc. Numerous other xenobiotics also cause gustatory dysfunction through variable degrees of zinc chelation, such as amrinone, ethambutol, hydralazine, methyldopa, the nonsteroidal antiinflammatory drugs (NSAIDs), the antithyroid agents, penicillamine, and phenytoin.[70, 77, 181] Metals, such as arsenic, mercury, chromium, and lead, may either chelate zinc or replace zinc in salivary proteins because of a higher level of affinity.

Antineoplastic agents and antimicrotubular agents such as colchicine inhibit cellular division and taste-receptor regeneration.[74] The oral antiseptic agent chlorhexidine directly alters taste-receptor function.[56] Acetazolamide causes cacogeusia when carbonated beverages are consumed. The exact mechanism is unclear, but is

postulated to be a result of the inhibition of carbonic anhydrase causing carbon dioxide accumulation and an increased tissue bicarbonate.[77, 89, 112]

TABLE 21-4. Xenobiotics Responsible for Alterations of Taste

Taste-Aversive Agents and Poison Prevention

Nontoxic taste-aversive agents are frequently added to products such as shampoo, cosmetics, cleaning products, automotive products, and rubbing alcohol to discourage ingestion.[70] Except in the case of rubbing alcohol, this is done primarily to prevent poisoning in children. The most common taste-aversive agents are the denatonium salts, particularly denatonium benzoate (Bitrex, benzyldiethyl[(2,6-xylylcarbamoyl)methyl] ammonium benzoate), one of the most bitter-tasting substances known.[26 , 42] The bitter taste of denatonium benzoate can be detected at 50 parts per billion (ppb). This agent is used in concentrations of 6â€“50 parts per million (ppm), typically 6 ppm in cosmetic products and ethanol and 30â€“50 ppm in methanol and ethylene glycol.[16 , 123]

Only limited data are available on the usefulness of taste-aversive agents for prevention of poisoning. Studies using denatonium benzoate added to liquid detergent and orange juice can decrease the amount ingested by children.[13,160] However, the degree of taste aversion is not universal; in one study, some children were noted to take more than one sip of denatonium benzoate-laced orange juice.[160] Taste aversion is partially a learned response; frequently young children do not find a bitter taste as offensive as do adults.[14] It seems unlikely that taste-aversive agents will eliminate unintentional ingestions in children, because oral ingestion is required for aversive effects to occur. Taste-aversive agents may be most beneficial in the prevention of poisoning by toxic and nonaversive xenobiotics, such as ethylene glycol, methanol, paraquat, certain pesticides, acetonitrile, and bromate-containing cosmetics, where more than one or two sips of the product must be ingested to cause toxicity. In 1995, Oregon became the first state to mandate the addition of an aversive agent to ethylene glycol- or methanol-containing car products (the 1995 Toxic Household Products statute). Analysis on the incidence and severity of ethylene glycol and methanol exposures before and after the mandate could not demonstrate any difference.[119] Taste-aversive agents are not and cannot be substitutes for other poison prevention modalities (Chap. 129).

Hearing

Anatomy and Physiology

Normal hearing begins when sound waves are captured by the external auricle, traverse the external auditory canal, and are conducted to the tympanic membrane, the three auditory ossicles of the middle ear, and through the oval window to the perilymph in the scala vestibuli of the cochlea (Figs. 21-1 and 21-2). The sound wave is then transferred through the Reissner membrane at

the roof of the cochlear duct, to the endolymph and the organ of Corti.[52 , 161] The specialized hair cells of the organ of Corti convert mechanical waves into neurologic signals. The hair cells contain cross-linked stereocilia projections that detect transmitted shear forces, which lead to the influx of potassium from the endolymph through opened potassium channels.[41 , 101] Depolarization of the hair cells result in calcium influx and neurotransmitter release to the cochlear nerve. Neurologic signals from the cochlear nerve are conducted to the cochlear nucleus of the pons; bilateral projections are then sent to the superior olivary nucleus of the midbrain, nuclei of lateral lemnisci, inferior colliculus, medial geniculate body of the thalamus, and then to the auditory cortex of the temporal lobe.[161] Interruption or damage to any part of the hearing mechanism may lead to auditory impairment.

The anatomy and physiology of the cochlea and its importance in the biomechanics of hearing are reviewed to understand the potential for xenobiotic injury. The word *cochlea* is derived from the Greek word *kochlias* , meaning snail, and describes its general structureâ€”a 2.5-turn, spirally wound tube. The cochlea is further divided into 3 inner tubular structures: the upper tube or scala vestibuli, the middle tube or cochlear duct, and the lower tube or scala tympani. The scala vestibuli and the scala tympani contain the perilymph fluid. The cochlear duct contains endolymph fluid, the Reissner membrane at the roof, and the organ of Corti.[161] The cochlear fluids serve multiple functions: to conduct sound waves to the hair cells; to provide nutrients for and remove waste from the cells lining the cochlear duct; to control pressure distribution in the cochlea; and to maintain an electrochemical gradient for the function of the hair cells. The sodium concentration of the perilymph is similar to that of the extracellular fluid, and the potassium concentration of the endolymph is similar to that of the intracellular

fluid.[54] Any significant alterations of the sodium or potassium concentrations will depress the cochlear potential and function. The stria vascularis controls the production of the cochlear fluids and the repolarization of the hair cells, and maintains the electrochemical gradient between the endolymph and the perilymph. The stria vascularis contains a high concentration of the oxidative enzymes, Na^+ -K^+ -adenosine triphosphatase (ATPase), adenylate cyclase, and carbonic anhydrase, which are highly susceptible to xenobiotics.[21 , 82 , 145]

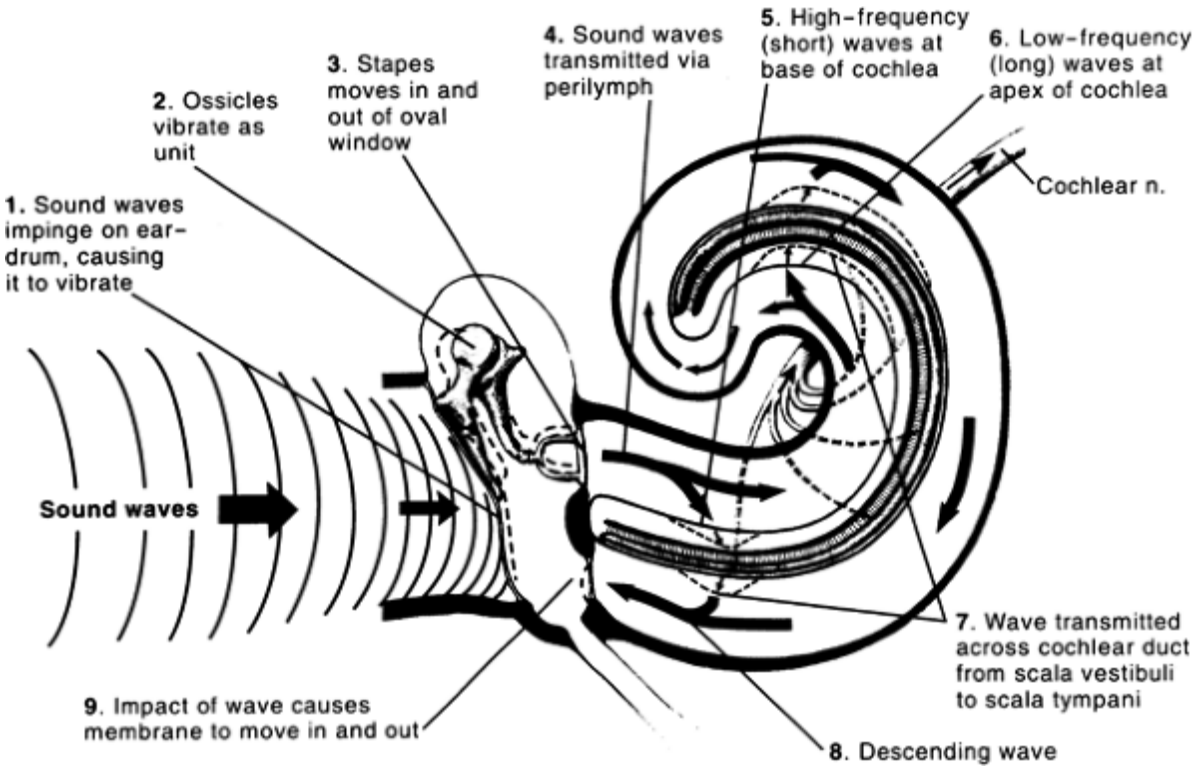

Figure 21-1. Pathways of sound conduction in the ear. *(Reproduced with permission from Silverstein H, Wolfson RJ, Rosenberg S: Diagnosis and management of hearing loss. Clin Symposia 1994;44:3.)*

Although human speech is composed of sounds in the frequency of 250â€“3000 Hz, humans can normally detect sounds in the frequency range of 20â€“20,000 Hz.[121] The cochlea is a

â€œtunedâ€• structure with varying width and stiffness, such that different regions can receive different sound waves. The stiffer and wider base of the cochlea serves as a receptacle for higher-frequency sounds, whereas the apex is responsible for receiving the lower-frequency sounds.[52] Because various regions of the cochlea are susceptible to different forms of injury, appropriate audiologic testing should be tailored specifically to each patient.[29]

Xenobiotic-Induced Ototoxicity

Ototoxicity includes effects on the cochlear and vestibular system. This chapter focuses on cochlear toxicity. Quinine and salicylates were widely recognized in the 1800s and streptomycin in the 1940s as etiologies of ototoxicity.[83,140] Several hundred xenobiotics have been implicated as ototoxins, some of which cause reversible ototoxicity, and others, irreversible toxicity (Table 21-5).[24,87,94,117] Ototoxic agents primarily affect two different sites in the cochlea: the organ of Corti, specifically the outer hair cells and the stria vascularis. Because of the limited regenerative capacity of the

sensory hair cells and other supporting cells, when significant cellular damage occurs, the loss is often permanent.[46,52,83,158] Although cell death of the outer hair cells from inflammation and necrosis is expected when sufficient insults occurred, apoptotic cell death is now postulated to be a major mechanism of ototoxicity from certain xenobiotics such as cisplatin and aminoglycosides.[43,137] Inhibition of caspases and calpain associated with apoptosis of the hair cells is demonstrated to decrease ototoxicity from cisplatin and aminoglycosides in animals.[137,157] Evidence supports the concept that xenobiotic-related injury can be potentiated by loud noises and other ototoxic agents.[21,24,83,87] Although the actual cellular mechanisms for many forms of ototoxicity remain unclear,[177] some of the mechanisms are known.[60] Loop diuretics, such as furosemide, bumetanide, and ethacrynic acid, cause physiologic dysfunction and edema at the stria vascularis, resulting in reversible hearing loss.[83,106] The underlying mechanisms appear to be the inhibition of potassium pumps and G proteins associated with adenyl cyclase.[9] Physiologic studies of loop diuretics demonstrate decreased potassium activity in the endolymph and a decreased endocochlear potential.[142] Permanent hearing loss associated with furosemide and ethacrynic acid is also reported, and may be related to direct interference with oxidative metabolism in the

outer hair cells.[95, 106, 142]

Reversible
Antimicrobials: chloroquine, erythromycin, quinine
Carbon monoxide
Diuretics: acetazolamide, bumetanide, ethacrynic acid, furosemide, mannitol
NSAIDs
Salicylates

Irreversible
Aminoglycosides
Antineoplastics: bleomycin, cisplatin, nitrogen mustard, vincristine, vinblastine
Bromates
Hydrocarbons: styrene, toluene, xylene
Metals: arsenic, lead, mercury

TABLE 21-5. Etiologies of Xenobiotic-Induced Hearing Loss

Salicylates are a well-known cause of ototoxicity. Aspirin (acetylsalicylic acid)-induced hearing impairment was first reported in 1877.[90] Salicylate-induced hearing loss is generally mild to moderate (a 20â€“40 dB loss) and reversible.[18, 85] Animal studies demonstrate immediate hearing impairment with the use of high doses of salicylates.[17, 108, 129] The mechanism of salicylate-induced ototoxicity is unclear, although multiple factors are postulated. Salicylates and other NSAIDs inhibit cyclooxygenase, which converts arachidonic acid to prostaglandin G_2 and prostaglandin H_2. These effects may interfere with Na^+-K^+-ATPase pump function at the stria vascularis, and also decrease cochlear blood flow.[31, 49, 90] A reversible decrease in outer hair cell turgor secondary to membrane permeability changes may

impair otoacoustic emissions.[128, 132] In support of these theories, pretreatment of animals with leukotriene antagonists and Î±-adrenergic receptor antagonists attenuates or prevents salicylate-induced ototoxicity.[90]

NSAIDs and the cinchona alkaloid quinine also cause reversible hearing loss, particularly at the higher frequencies.[33, 83] Occasionally, quinine-induced hearing loss may be permanent.[83, 146] The primary mechanism is related to prostaglandin inhibition.[90] Quinine inhibits phospholipase A_2 enzyme, which converts phospholipids to arachidonic acid. Quinine also inhibits calcium channels that interact with prostaglandins.[90]

Antineoplastic agents, such as cisplatin, vinblastine, and vincristine, can cause permanent ototoxicity.[83] Cisplatin is the most toxic of the group, with clinically apparent hearing loss noted in 30â€“70% of the patients receiving doses of 50â€“100 mg/m^2. Children may be even more susceptible to ototoxicity. These agents typically damage the outer hair cells but may also affect the stria vascularis.[83] The underlying mechanisms may be related to the inhibition of adenyl cyclase in the stria vascularis, the inhibition of protein synthesis, and the formation of oxygen free radicals.[9, 83, 151] The generation of oxygen free radicals and the depletion of antioxidants is a significant mechanism in the irreversible damage to the hair cells.[51] Furthermore, cranial radiation will cause synergistic toxicity if radiation precedes cisplatin therapy. Various antioxidants and free radical scavengers prevent cisplatin-induced ototoxicity in animals.[115, 134, 141, 163, 176] Neurotrophic agents also prevent cisplatin-induced toxicity in animals, perhaps preventing oxidative injury induced apoptosis to hair cells.[137] Amifostine (WR-2721), a precursor to a thiol free radical scavenger, is available to prevent cisplatin-induced nephrotoxicity. However, amifostine does not appear to prevent cisplatin-induced ototoxicity.[144]

The aminoglycosides are the best known group of drugs associated

with irreversible ototoxicity.[127] Aminoglycosides are not concentrated in the cochlea. The endolymph concentration of gentamicin is approximately 10% of that in the serum. Neomycin and kanamycin are the most ototoxic of these antibiotics, although all aminoglycosides are potentially toxic.[95] With the development of newer aminoglycosides and therapeutic drug monitoring, the incidence of aminoglycoside-related ototoxicity appears to be decreasing. The reported rates of ototoxicity for the more commonly used aminoglycosides gentamicin and tobramycin are between 5 and 8%.[105] In China, where aminoglycosides are readily available as nonprescription medications, as much as 66% of deaf-mutism may be directly related to aminoglycoside toxicity.[58 , 102] A genetic predisposition to aminoglycoside-induced ototoxicity has been identified. The genetic transmission appears to be maternal via mitochondrial DNA.[55] Chinese patients with this genetic defect may suffer rapid and severe hearing loss compared to whites with a similar aminoglycoside exposure.[137]

Several mechanisms of ototoxicity have been postulated. Aminoglycosides antagonize calcium channels of the outer hair cells of the cochlea, blocking transduction of the hair cells and resulting in acute, reversible hearing deficits. Aminoglycosides also bind to polyphosphoinositides of cell membranes and alter their functions. Polyphosphoinositides are essential for the generation of the second messengers diacylglycerol and inositol triphosphate and their ultimate cellular function, for the maintenance of lipid membrane structure and permeability, and as a source for arachidonic acid.[171] Aminoglycosides interact with the transition metals iron and copper to generate free radicals, damaging the hair cells. Aminoglycosides also inhibit ornithine decarboxylase. The inhibition of this enzyme, important for cellular recovery following an injury, makes the cell more susceptible to toxicity.[145] It is postulated that toxicity is related to the metabolites of aminoglycosides and not the parent compounds because toxicity can be reproduced in in vivo models, but not in in vitro models.[145]

The outer hair cells of the cochlea are increasingly susceptible to aminoglycosides and damage progresses from the inner row of the outer hair cells to the basal turn of the cochlea, and, ultimately, to the apex.[4,7,95,136]

The risks of ototoxicity are increased with a duration of therapy of greater than 10 days, concomitant use of other ototoxic agents, and the development of elevated serum levels.[7,53,143] There is no evidence that single daily dosing of aminoglycosides alters the risk of ototoxicity.[124,172] Loop diuretics increase aminoglycoside toxicity by increasing aminoglycoside penetration into the endolymph. In animal models, certain free radical scavengers, such as glutathione, amifostine, and deferoxamine, decrease aminoglycoside-induced ototoxicity.[61,146,164,170,173] Fosfomycin, a phosphonic antibiotic, has limited efficacy in reducing aminoglycoside-induced ototoxicity and salicylates are also suggested to reduce ototoxicity.[120,154] Salicylates may act as free radical scavengers in low doses. Leupeptin and Z-DEVD-FNK, a calpain and caspase inhibitor respectively that affects the apoptotic pathway, is demonstrated in animal models to decrease ototoxicity.[157] Further studies are required to determine their applicability to humans.

Other antibiotics are also implicated as causing ototoxicity, particularly erythromycin, vancomycin, and their respective analogs.

There are a number of reports of hearing loss following erythromycin therapy in humans and an animal study supporting the ototoxic potential. Most deficits in humans are transient, although several cases of permanent hearing loss are reported.[22,23] The mechanisms of toxicity remain unclear, although the proposed effects are on the central auditory pathways. Erythromycin-induced hearing loss occurs at both lower and higher frequencies for speech, allowing for recognition in the early stages of ototoxicity.[22] Ototoxicity from the newer macrolide antibiotics

has also been reported.

The evidence for vancomycin-induced ototoxicity is less convincing. Although numerous cases of presumed vancomycin-related ototoxicity are reported, concomitant use of other ototoxic antibiotics was common or audiometric studies were not performed. In limited animal studies, vancomycin alone did not induce ototoxicity, but the agent increased ototoxicity when administered concomitantly with an aminoglycoside. Vancomycin analogs such as teicoplanin and daptomycin probably have similar ototoxic potentials.

Bromates are among the most extensively studied ototoxic agents.[36, 104, 130] Bromates are used in hair neutralizers, bread preservatives, and as fuses in explosive devices.[84, 130, 166] The stria vascularis and hair cells of the organ of Corti can be irreversibly damaged with significant exposure.[130] Bromates may also cause renal failure with substantial exposure, perhaps increasing the ototoxic potential.[84, 130]

It is intriguing that agents such as the bromates and aminoglycosides primarily affect both the cochlea and the kidneys. One possible explanation is that the stria vascularis and the renal tubules have similar functions in maintaining electrochemical gradients.[130, 131] However, renal tubules may regenerate while damage to the hair cells and the stria vascularis of the cochlea is more likely to be permanent.

Other xenobiotics implicated as ototoxins are carbon monoxide, lead, arsenic, mercury, toluene, xylene, and styrene.[80, 159] However, both human and animal data are quite limited. Carbon disulfide, carbon tetrachloride, and trichloroethylene, are also suspected of being ototoxic, but toxicity has not been demonstrated in humans.[80, 159] Because exposures to xenobiotics are frequently occupational, they are of great concern as they may potentiate or be additive to other types of occupational hearing impairments.[92, 135]

High-frequency hearing is most vulnerable, and early or limited impairment may not be noticeable unless audiometry, especially at 8 kHz and above, is performed.[171] These hearing tests can be performed in infants using the measurement of auditory brainstem response.[12]

Noise-Induced Hearing Impairment

Noise-induced hearing impairment was recognized for hundreds of years, but became of great concern and prevalence with the discovery of gunpowder and the industrial revolution.[52] Some of the anatomic changes in the organ of Corti and the audiometric features of noise-induced hearing impairment were well described by 1900.[2,3,109] Unfortunately, few longitudinal studies on noise-induced hearing impairment have been performed.

Although noises of sufficient magnitude may cause hearing impairment with limited exposure, most noise-induced hearing losses result from preventable prolonged cumulative occupational exposure. NIOSH has estimated that up to 1.7 million workers in the United States between 50 and 59 years of age have significant occupation-related hearing loss.[121] Noise can be defined as any unwanted sound, which can be further characterized by duration, time pattern (continuous, intermittent, or impulsive), frequency, and intensity. The intensity is measured in sound pressure levels (SPLs) and expressed in a logarithmic scale in decibels (dB). The intensity of a normal conversation is approximately 65 dB (Table 21-6).[121] The risk of noise-induced hearing loss is related to cumulative duration of exposure, intensity, and individual susceptibility.[118,125,175] Much of the risk assessment of noise-induced hearing loss is inexact. Most authorities agree that sounds with maximal intensity below 75â€“80 dB will not cause hearing impairment, regardless of the duration of exposure.[118] At higher intensity, the risk of hearing impairment increases with increased duration of exposure. Continued occupational exposure at 90â€“94

dB typically causes some high-frequency hearing loss in approximately 10 years.[2,125] Further exposure results in hearing loss in the lower-frequency range. The Occupational Safety and Health Administration (OSHA) established guidelines for permissible occupational noise exposure based on an analysis of the average intensity and duration of exposure (Table 21-7).[2,175]

Sound Decibels

TABLE 21-6. Typical Sound Levels on the Decibel Scale

The pathophysiology of noise-induced hearing impairment is related to an excessive energy impact on the cochlea, but the exact biochemical changes are unclear. Apoptotic death of the hair cells have now been demonstrated and inhibition of apoptosis pathways mitigate noise-induced toxicity in animal models. A limited exposure to excessive noise results in a temporary hearing impairment or temporary threshold shift with a duration of hours to weeks. However, prolonged exposure results in a permanent threshold

shift or hearing impairment.[3, 52, 175] Initially, outer hair cells are lost, but more significant exposures result in damage to both inner and outer hair cells and all supporting structures in the organ of Corti. Cochlear nerve fibers degenerate after hair cell damage.[52, 175] The section of the cochlea most at risk from loud noises is at the 9â€“13 mm region (the total length is 32 mm).[109] This region is responsible for hearing at the 3â€“6 kHz range, corresponding to the typical noise-induced hearing loss pattern.

dBA[a]	Duration of Exposure Per Day in Hours

TABLE 21-7. OSHA Standard for Permissible Noise Exposure

Much of the clinical assessment and monitoring of noise-induced hearing loss is based on pure tone hearing loss, demonstrating an audiometric deficit at 3â€“6 kHz.[121 , 175] This typical pattern occurs in other conditions and becomes less typical with aging.[125] Although human speech is composed mainly of low frequency sounds, the ability to perceive the higher frequency sounds is extremely important in speech recognition. For this reason, the major impairment in patients with noise-induced hearing loss is an inability to discriminate speech, particularly from background noise.[2 , 40] Currently, the science of the investigation of speech discrimination is limited with extensive areas for research.

Blast injury to the ear results from exposure of extremely short duration, but very high-intensity sound waves, usually greater than 140 dB. Military personnel are particularly at risk.[32 , 126 , 171] Hearing loss from blast injury may be related to rupture of the tympanic membrane, disruption of the ossicles, temporary cochlear dysfunction, and permanent cochlear dysfunction from

labyrinthine fistulae and basilar membrane rupture.[30] When a large tympanic membrane rupture or disruption of the ossicles occurs, surgical intervention may be required to treat hearing impairment.[30]

Prevention of any type of noise-induced hearing loss remains the best solution. Various hearing-protection devices are available, if the noise exposure cannot be reduced. Better monitoring and more longitudinal studies are required on noise-induced hearing loss. Exposure to xenobiotics that can impair hearing may have synergistic effects with noise-induced hearing loss.[92, 94] These factors should be considered when noise exposure is evaluated. Furthermore, noise exposure is not limited to the workplace. Significant noise exposure may occur at home or from leisure activities, such as power tools, stereo, and ambient exposure.[15, 37, 71, 125] The impact of noise exposure outside of the workplace has only recently attracted the attention of investigators.

Etiology of Tinnitus

Tinnitus is the sensation of sound not resulting from mechanoacoustic or electric signals. Virtually all humans experience tinnitus during their lives. The exact mechanism or mechanisms resulting in tinnitus are largely unknown.[149] Tinnitus may or may not be associated with hearing loss. Several theories are proposed, but none is completely satisfactory. Tinnitus may result from spontaneous neurologic discharges when the hair cells and/or cochlear nerve are injured. Altered sound perception may result from local or central effects when feedback mechanisms are interrupted.[47, 50, 86, 108] Severing the cochlear nerve terminates tinnitus in less than half of affected patients, suggesting important central mechanisms.[10] Furthermore, certain etiologies of tinnitus, such as migraine headache and temporal lobe seizures, do not affect hearing directly. *N* -methyl-D-aspartate (NMDA) glutamate receptor activation (and enhanced

cochlear signal transmission) has been implicated as a mechanism for tinnitus in animal models; NMDA receptor activation may result from cyclooxygenase inhibition or neurologic injuries. Xenobiotics, including salicylate, may cause hair cell dysfunction and may modify neurotransmission centrally in both the cochlear nucleus and the inferior colliculis.[62, 174] For salicylate and NSAIDs, cyclooxygenase inhibition and resulting NMDA receptor activation is the likely mechanism for tinnitus. Although the probable sites involved in tinnitus may be classified as peripheral (external ear, middle ear, or cochlear [CN VIII]), central, or extraauditory (vascular, nasopharyngeal), some etiologies may affect peripheral and central sites, and many etiologies remain unknown.[35, 50, 108]

Tinnitus may result from trauma or disease or as a manifestation of xenobiotic toxicity. Tinnitus is most commonly related to any mechanism that affects hearing. Excessive cerumen, fluid, or a foreign body in the external canal, perforated tympanic membrane, acoustic trauma resulting from exposure to excessive noise, otosclerosis, acoustic neuroma, and otitis media may produce tinnitus. However, the only otologic problem that always results in tinnitus is MÃ©niÃ¨re disease, a triad of tinnitus, vertigo, and diminished hearing. Other etiologies for tinnitus include diabetes, hypertension, autoimmune disease, hypothyroidism, and arteriovenous aneurysms.[34, 35, 108]
